Summary

Photosynthetic bacteria have relatively simple photosystems, and they are therefore attractive models for the study of the absorption of light, and the transfer and trapping of excitation energy. This simplicity extends to the organization and expression of genetic information, and it would be a missed opportunity if molecular genetics were not used to examine the assembly, organization and function of light harvesting complexes. Furthermore, directed mutagenesis of genes encoding structural subunits of the antenna, in combination with various forms of spectroscopy, provides a means of testing structural models for these complexes, and of enhancing our understanding of existing crystallographic data.

The potential of using genetic techniques to provide partial photosystems was realized over thirty years ago

by, among others, Clayton and Sistrom, and indeed the carotenoidless, LH2- deficient mutant R26 isolated by Clayton in 1961 is still used today. The availability of mutants lacking either the peripheral LH2 complex or the core LH1 complex provides a means of simplifying spectroscopic studies that would otherwise be complicated by overlapping signals, as well as a way of rapidly and efficiently obtaining a given complex using detergent-based isolation procedures. This chapter provides an account of the way in which various antenna mutants have been used for such purposes, concentrating on the bacteria for which an array of molecular genetic tools have been developed, *Rhodobacter (Rb.) capsulatus* and *Rb. sphaeroides*. The latter part of the chapter concentrates on more recent developments in which protein engineering has been used to modify the assembly and the spectroscopic properties of LH1 and LH2, by altering various aminoacids singly, or in groups. Further progress in this rapidly moving field is aided by new developments in spectroscopy, as well as by the application of combinatorial mutagenesis and the heterologous expression of LH genes. It is expected that molecular genetics will play an increasingly important role in the study of light harvesting complexes.

I. Introduction

A. Early Examples of Valuable Mutants

The use of genetic techniques to study bacterial light harvesting complexes has a long history, and the early work of Clayton and Sistrom contains several examples of using a genetic approach to advance the study of photosynthesis. This chapter will briefly survey this early work before moving on to the possibilities recently opened up by the application of molecular genetic and cloning techniques. Such a survey is particularly appropriate, since the forerunner of this volume was *The Photosynthetic Bacteria*, edited by Clayton and Sistrom in 1978.

The use of bacterial mutations has had a profound impact on biochemistry in general, and mutational analysis of *Escherichia coli*, for example, has established the order of many biochemical pathways and has facilitated the eventual identification of hundreds of genes. The small genome size of *E. coli* and the availability of gene transfer techniques lend themselves to this kind of genetic analysis, and so it would be surprising, and a missed opportunity, if similar approaches could not be used to analyze the most important and fundamental process on Earth, photosynthesis. The existence of bacteria that can photosynthesize would seem to offer almost limitless possibilities to explore the molecular biology of this

Abbreviations: B800, 850, 875 – bacteriochlorophyll absorbance in vivo at 800, 850 and 875 nm; *E.* – *Escherichia*; FP – fluorescence polarisation; I – reaction center pheophytin acceptor; LDAO – lauryl dimethyl amine oxide; LDS, SDS – lithium, sodium dodecyl sulfate; LH – light harvesting; P – reaction center primary donor; PCR – polymerase chain reaction; Q – the reaction center quinone, Q_A; *Rb.* – *Rhodobacter*; RC – reaction center; *Rc.* – *Rhodocyclus*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*; WT – wild-type

process. This is certainly the case now for the study of light harvesting complexes. However, thirty years ago, there were restrictions imposed by the lack of molecular cloning techniques. Despite this, several elegant experiments were performed that turned out to have lasting significance.

The earliest example of the production of mutant antennas was in 1956, when Griffiths and Stanier isolated around 50 mutants of *Rhodobacter (Rb.)* (then *Rhodopseudomonas (Rp.)*) (Griffiths and Stanier, 1956; Sistrom et al., 1956). They noticed that some of these, such as UV-33, had alterations in carotenoid content, and that this was reflected in the absorbance spectrum in the near infrared arising from the light harvesting bacteriochlorophylls. In particular, the major absorbance peaks at 800 and 850 nm, attributable to the peripheral LH2 complex, were absent; this arose from a blue-green strain with the major peak at approximately 870 nm, which we now know to be the light harvesting LH1 complex. Interestingly, a minor peak of 800 nm could be seen which arises from the monomeric BCh1800 molecules within the reaction center, so this was an early sighting of reaction center absorbance.

At the time, the concept of a reaction center, first advanced by Duysens in 1952, was a relatively recent one. His studies involved *Rhodospirillum (Rs.) rubrum*, which can be thought of as a naturally occurring LH2⁻ strain. Indeed, the contribution of LH2⁻ strains was to have a crucial bearing on subsequent progress toward the isolation of the reaction center (Reed 1969; Clayton and Wang, 1971; Feher, 1971), and the eventual elucidation of the structure by X-ray crystallography (Deisenhofer et al., 1985; Allen et al., 1987; Chang et al., 1991). In each case the purification of the reaction center was facilitated either by the use of another naturally-

occurring LH2⁻ strain, *Rp. viridis* or by the LH2⁻ mutant R26, because the absence of LH2 eliminates the need to remove this complex in a purification protocol. R26 has occupied an important role in bacterial photosynthesis for these reasons, although it was originally isolated as strain CC1R26 in a study of photooxidative killing in *Rb. sphaeroides* (Clayton and Smith, 1961).

The work of Siström and Clayton in 1963 produced a number of other interesting mutations in the bacterial photosynthetic apparatus; the mutant PM-8 was shown to lack the photochemical activity of the reaction center and contained diminished levels of the LH1 light harvesting complex. This study of PM-8 provided important evidence for the role of the reaction center 'P870' in photosynthesis (Siström and Clayton, 1963). As part of this study a derivative of PM-8, PM-8:bg58, was obtained which also lacked reaction center activity as well as the major absorbance peaks of 800 and 850 nm attributable to the major light harvesting complex, LH2. Thus PM8:bg58 was the first LH1-only mutant. Subsequently, Clayton and Haselkorn (1972) demonstrated that PM8 lacked the H, M and L subunits of the reaction center. PM8, or at least a more pigmented variant called PM8dp, was to find further use as the source of membranes for reconstitution in vitro with purified reaction centers. It was already known that addition of reaction centers to membranes from the bacteriochlorophyll-deficient mutant 01 resulted in restoration of cyclic light-driven electron flow (Hunter and Jones, 1979); the performance of the system could be improved by adding either the purified light harvesting LH2 complex to the reconstitution, or by using membranes from PM8dp; this demonstrated that the reaction centers can insert into the PM8dp membrane and receive excitation energy from the endogenous antenna (Hunter et al., 1979b).

At this stage, the genetics of *Rb. sphaeroides* were much less well understood than for *Rb. capsulatus* and although various kinds of gene transfer had been successfully carried out with *Rb. sphaeroides* (for example, Siström, 1977; Miller and Kaplan, 1978; Pemberton and Bowen, 1981) the availability of the gene transfer agent which is specific for *Rb. capsulatus* (Yen et al., 1979) facilitated genetic mapping of a region of the chromosome known to contain most of the information for photosynthesis (Yen and Marrs., 1976). Thus, light harvesting mutants, lacking either LH2 or LH1 complexes were reported for *Rb. capsulatus* quite early on (for example, Feick and

Drews, 1978), well before further advances in genetics enabled gene-specific deletions and site directed mutagenesis to be undertaken.

B. A Brief Summary of the Molecular Genetics Underlying the Production of Mutant Antennas

A detailed consideration of the molecular genetics of the purple bacteria is outside the scope of this chapter, and for this information the reader should refer to Chapters 57, 58 and 59 by Beatty, Bauer and Klug in this volume. It is intended to be a quick summary for those whose main interest is in antenna function, rather than gene regulation. Thus, it will suffice to say that the genes for the major objects of study, LH1 and LH2, have been cloned, mapped and sequenced. This includes the LH2 genes of *Rb. sphaeroides* (Ashby et al., 1987; Kiley and Kaplan, 1987) and of *Rb. capsulatus* (Youvan and Ismail, 1985). LH1 genes were sequenced by Kiley et al., (1987) for *Rb. sphaeroides*, by Youvan et al. (1984) for *Rb. capsulatus*, and by Bérard et al. (1986) for *Rs. rubrum*. In the case of LH1, the genes (*pufBA*) lie upstream of the *pufLM* genes encoding two of the bacterial reaction center subunits and these *puf* genes form part of a single transcriptional unit (Zhu et al., 1986; Belasco et al., 1985; Bélanger and Gingras, 1988). In both *Rb. capsulatus* and *Rb. sphaeroides* the LH1-RC genes lie at one end of the photosynthesis gene cluster, the other end of which is conveniently defined by *puhA* encoding the reaction center H subunit (Zsebo and Hearst, 1984, Coomber and Hunter, 1989). The LH2 genes (*pucBA*) are situated approximately 18 kb from *puhA* in *Rb. sphaeroides* (Suwanto and Kaplan, 1989) but lie over 1000 kb away on the other side of the chromosome in *Rb. capsulatus* (Fonstein and Haselkorn, 1993).

Many spectroscopic studies on antenna mutants in the last ten years have been conducted on point mutants where the mutation was known to reside within a given gene, although the precise location of the alteration was unknown. This situation has now improved somewhat, so that genetically defined deletions or site directed alterations can be studied. Moreover, protein engineering studies on light harvesting (or reaction center) complexes require a well-defined genetic background: the altered genes are expressed on plasmids, that is independently of the chromosome, and the native copies of the gene have been excised from the chromosome and have been replaced by a selectable marker which confers

resistance to a particular antibiotic. This is an important point, since the spectral effects arising from alterations in the plasmid-borne copy of the gene should not be superimposed on those from the normal version of the gene. A point mutation which merely inactivates the chromosomal copy of the gene but leaves it in place will not suffice, because it still leaves potential sites for recombination with the plasmid-borne altered copy since the sequences are still likely to be more than 99% homologous. Such events in the purple bacteria have been documented and cannot be ruled out since recombination-deficient strains are not widely available. Recombination between an inactive chromosomal copy containing a point mutation, and a plasmid-borne copy of a gene with a site-directed alteration could in theory produce a normal copy.

Youvan and co-workers were the first to construct deletion strains lacking either LH2 genes, or LH1-RC genes (Youvan et al., 1985) and they went on to use the LH1-RC deletion-complementation system to great effect, by producing a series of fascinating and important site-directed mutants in the reaction center complex, reviewed by Coleman and Youvan (1990). The LH2 genes (*pucBA*) of *Rb. sphaeroides* were deleted by Burgess et al., (1989) who replaced *pucBA* with a kanamycin resistance cassette, to produce strain DBC1. Subsequently, DBC Ω was constructed by using a streptomycin resistance cassette instead (Jones et al., 1992a). In each case the strain is LH2⁻ LH1⁺ RC⁺. Conversely, the LH1-RC genes of *Rb. sphaeroides* (*pufBALMX*) have been deleted and replaced with a kanamycin resistance gene to produce strain DPF2, which is therefore LH2⁺ LH1⁻ RC⁻. Finally, a combination of the DBC Ω and DPF2 deletions produced strain DD13 which is LH2⁻ LH1⁻ RC⁻ (Jones et al., 1992a). A summary of these deletions, which in principle also applies to *Rb. capsulatus*, appears in Fig. 1. Despite its outwardly featureless and uninteresting phenotype, DD13 is valuable since it acts as a null background for the expression of LH2, LH1 or RC genes either singly or in any combination. In addition, three different carotenoid variants of DD13 are possible in which phytoene, neurosporene or spheroidenone are the major pigments. Thus many different phenotypes are available for the examination of site directed alterations in photosynthetic complexes (Jones et al., 1992a). Some of these possibilities are represented in Fig. 2. A comparable degree of flexibility exists for *Rb. capsulatus*, particularly since a double deletion

strain has recently been constructed (unpublished; referred to in Goldman and Youvan, 1992). The main reason for constructing these various deletion strains is to provide a 'clean' background for the expression of mutated genes, although it is worth noting that they are interesting in their own right because they provide 'partial' photosystems for study, as will be mentioned later on.

The plasmids that are used to express mutated genes are generally based on derivatives of the broad host range plasmid RK2; the significance of the host range is that the plasmid will replicate equally well in either *E. coli* or, for example, *Rb. sphaeroides*. RK2 is a large (~54 kb) plasmid and so relatively small derivatives have been constructed, such as RK415 which is 10.5 kb in size (Keen et al., 1988). This plasmid confers tetracycline resistance on the recipient and contains several useful cloning sites. Once the gene(s) of interest is cloned into such a vector, it would normally be desirable to perform several rounds of directed mutagenesis in order to introduce a series of unique restriction sites flanking each individual gene so that each one can be removed, mutated and sequenced independently of the others (Jones et al., 1992a). The gene can be mutated by standard procedures such as that described by Kunkel (1985), reintroduced into the expression plasmid, and then transferred, usually by conjugation, into the recipient deletion strain.

It should be mentioned that as a result of expressing a given gene chromosomally or extrachromosomally there are now two different ways to obtain, for example, an LH2-only strain: either the LH1-RC genes could be deleted from the chromosome, leaving the LH2 genes, or an LH2-only expression plasmid could be introduced into a double deletion (LH2⁻ LH1⁻ RC⁻) background. The only difference would be that the latter strain would probably express the LH2 complex to higher levels since the number of plasmids per cell will typically be 4–6 for pRK415 derivatives (Davis et al., 1988), compared to the copy number of one for the single, chromosomal copy of the LH2 genes. In a direct comparison of the levels of antenna in two such strains, LH1-only in this case, the cellular level of LH1 was 2–3-fold higher for the plasmid-expressed genes than for strain M2192 containing a single genomic copy (Hunter et al., 1991). It is not unlikely that at this level of abundance the membrane could run into 'capacity constraints' when faced with such high levels of antenna. However, plasmid-based expression is still a useful way of

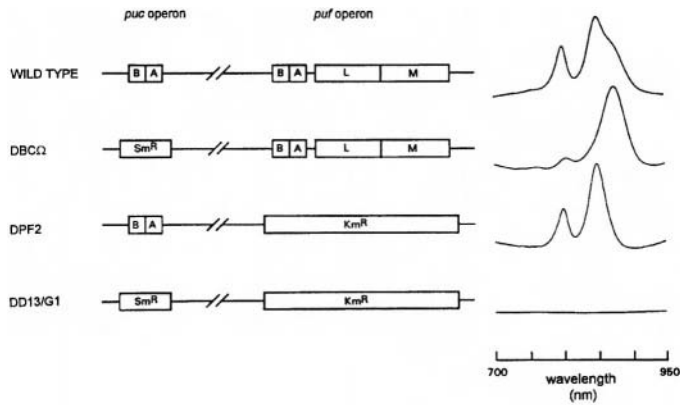

Fig. 1. A scheme showing deletions of the *puc* (LH2) and *puf* (LH1-RC) operons and the attendant affects on absorbance spectra.

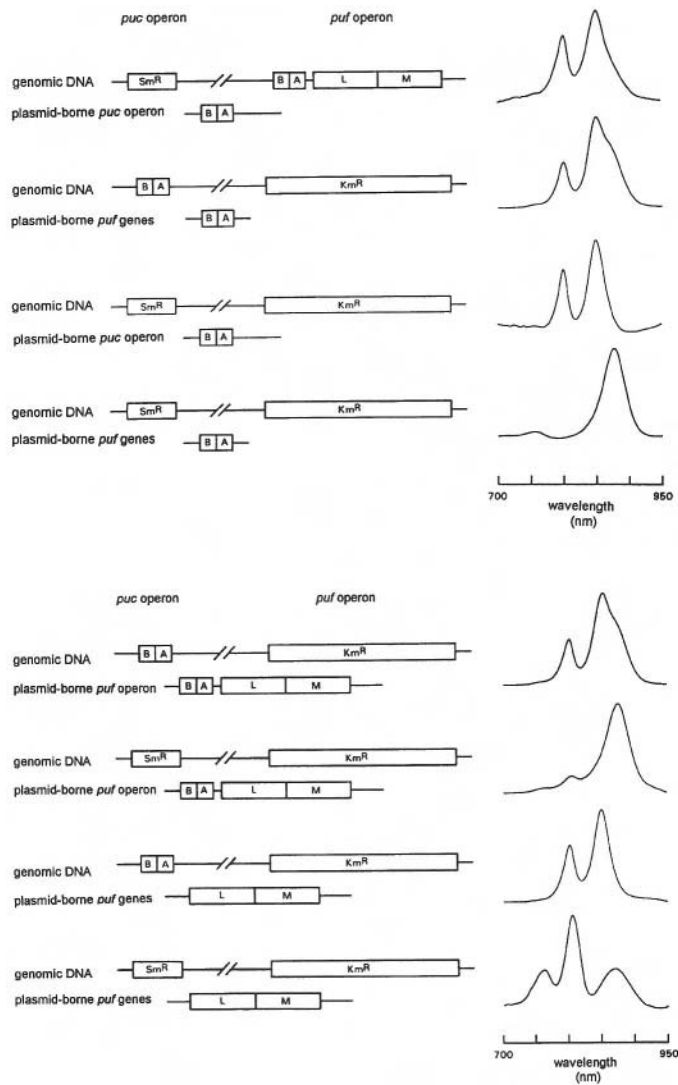

Fig. 2. A scheme showing the complementation of deletion strains deficient in LH2 and LH1-RC complexes, by plasmid-borne genes. The restoration of the appropriate complex can be seen by inspection of the absorbance spectra.

increasing the levels of complex, for example, crystallization trials (see section IIIA).

II. The Effect of Genetic Alteration of Antennas on the Morphology of Intracytoplasmic Membranes

Alteration of the normal composition of the photosynthetic unit, notably by abolishing the synthesis of the LH2 complex, has a radical effect on the morphology of the intracytoplasmic membranes. A more detailed discussion of the organization of cellular membranes appears in Chapter 12 by Drews and Golecki in this volume; for the purposes of discussing mutated antennas it is sufficient to note that the normal membrane morphology can vary widely between different genera. In *Rb. sphaeroides* and *Rb. capsulatus* a fully pigmented cell contains hundreds of spherical or near-spherical invaginations. The loss of the LH1-RC core appears to have little effect on the presence of these invaginations, as judged by electron microscopy of strain NF57, for example (Hunter et al., 1988). However, the loss of the LH2 complex can produce gross distortions resulting in flattened lamellae or tubular membranes that can sometimes spiral round the cytoplasm (Kiley et al., 1988.; Hunter et al., 1988). These observations were made earlier by Lommen and Takemoto (1978), who showed that the carotenoidless LH2⁻ strain R26 also displays lamellar membrane morphology. In apparent contradiction of the observations on carotenoid containing LH2⁻ strains such as the point mutant M21, Oelze and co-workers found a normal spherical morphology (Golecki et al., 1991) in the LH2⁻ strain 19. More recent work by Gibson et al. (1992) employed deletion and insertion mutagenesis of the LH2 structural genes *pucBA* (encoding the β and α subunits of LH2, respectively), as well as *pucC* which lies downstream of *pucBA*, and is essential for LH2 synthesis. The morphology of intracytoplasmic membranes was disrupted under conditions where the *pucBAC* operon is disrupted, but no clear correlation was observed between morphology and the position of the mutation. Whereas it is true to say that loss of LH2 can markedly affect membrane morphology, this is not always the case and it will be necessary to construct further mutations in order to define the relationship between LH2 biosynthesis and membrane morphology.

Finally, it should be mentioned that although LH2 could exert some effect on membrane morphology in some species of photosynthetic bacteria, the naturally LH2-deficient species *Rs. rubrum* still contains spherical invaginations (Drews and Oelze., 1981), so it might not be possible to draw any far-reaching conclusions on membrane morphology from a study of *Rhodobacter*.

III. The Use of LH1-Only and LH1-RC Mutants to Facilitate Biochemical and Structural Studies

This is an area of research that is to some extent under-exploited. In theory, the availability of mutants capable of synthesizing only one of the three possible pigment-protein complexes should be an invaluable aid for the purification of antenna and reaction center complexes. In practice, however, biochemical techniques are able to overcome these problems by physically separating the complexes by, for example, column chromatography or by electrophoretic techniques. In addition, some detergents can selectively destabilize a particular unwanted complex, which removes one purification problem from the protocol. This is illustrated by the observation that some of the most commonly used detergents such as lauryldimethylamine oxide (LDAO) destabilize the LH1 complex, leaving only LH2 and the RC, which can be easily separated and purified. Thus the RC and LH2 complexes of *Rb. sphaeroides* were purified relatively early on (Clayton and Wang, 1971; and Clayton and Clayton, 1972) whereas another eight years elapsed before a relatively mild procedure was found for the purification of LH1 from the wild-type, using lithium dodecyl sulphate-polyacrylamide gel electrophoresis in the dark at 4 °C (Broglie et al., 1980). It has already been mentioned in section I how the LH2⁻ LH1⁺ RC⁺ carotenoidless mutant R26 was able to provide pure reaction centers relatively easily, because once LDAO had destroyed LH1, RCs are the only complex present. In subsequent work, Sauer and Austin (1978) were able to turn R26 to further advantage by purifying the carotenoidless LH1 complex. Other LH2⁻ LH1⁺ RC⁺ mutants have been reported subsequently. For example, Kaufmann et al. (1984) used transposon Tn5 mutagenesis to disrupt LH2 biosynthesis and produce an LH1⁺ RC⁺ strain, NK3. Bachmann et al. (1983) used *Rb.*

sphaeroides strain 19, which contains RCs and LH1 as well as carotenoids, as a means of purifying the LH1 complex, and presented an amino acid analysis of the LH1 subunits. The LH1 complex was characterised further by Sebban et al. (1985) who used a mutant strain 3P17 of *Rb. sphaeroides* as a source of material. This mutant, although non-photosynthetic, contained reaction centers and very small amounts of LH2 in addition to the major complex, LH1. Treatment of membranes from this mutant by lauryldimethylamine oxide (LDAO) followed by column chromatography yielded an LH1 complex, and the lack of other absorbance peaks demonstrated the value of using a mutant as the source of LH1.

A. Structural Studies

Conventional biochemical techniques have been able to yield pure LH2 (and RCs) for many years, and therefore it would be surprising if X-ray crystallographic studies, which are notorious for consuming vast quantities of pure protein, did not progress first with these two complexes. Thus, Cogdell and co-workers have reported the crystallization of the B800–850 and B800–820 LH2 complexes of *Rp. acidophila* (Papiz et al., 1989; Guthrie et al., 1992) and Michel has reported diffracting crystals of the LH2 complex from *Rs. molischianum* (Michel, 1991). The *Rb. capsulatus* LH2 has also been crystallized (Welte et al., 1985). Clearly, the construction of an LH1-only strain could be of real benefit to structural studies of the LH1 complex, as long as suitably mild detergents are employed, and the LH1-only *Rb. sphaeroides* mutant M2192 has been used to provide large quantities of LH1 for X-ray crystallography, using β -octyl glucoside as the detergent (Nunn et al., 1992). In addition, *Rs. rubrum* has furnished LH1 for 2-dimensional crystallisation work on the LH1 complex (Ghosh et al., 1993; Karrasch et al., 1995).

At this point, strain M2192 will be briefly described, since it has been extremely useful for biochemical and spectroscopic studies (see also section V). The parental strain for M2192 is the mutant M21 which contains a point mutation at some undefined position in the *puc* operon; transconjugants of M21 containing this operon exhibit a normal phenotype (Ashby et al., 1987). Transposon Tn5 mutagenesis of the *Rb. sphaeroides* wild type had already identified several constructs which would selectively disrupt the *pufLM*

gene pair encoding reaction center subunits (Hunter, 1988). One of these was introduced into strain M21, a manipulation which therefore produced an LH1-only strain, named M2192 (Hunter et al., 1989).

Mutant M2192 has been used as a source of LH1 for several purposes. For example, a recent electron microscopy study of the structure and aggregation behavior of LH1 (and LH2) used M2192 (Boonstra et al., 1993). In this work the LH2 complexes have a molecular mass of 150 kDa, and the particles corresponded to a ring-shaped structure consistent with 4–6 $\alpha\beta$ heterodimers. The LH1 complexes were isolated as 360 kDa dimeric particles and each particle was 5.2 nm in diameter and 6.2 nm in height, similar to the LH2 particle. Image analysis suggested a three or six-fold symmetry and an $\alpha_6\beta_6$ configuration. The crystallographic studies on LH complexes mentioned above are often held back by the lack of isomorphous heavy atom derivatives necessary to solve the phase problem. Again, the application of molecular genetics is able to make a contribution, this time by using the plasmid-encoded expression system mentioned earlier in section IA, in which LH genes are expressed in an LH2⁻ LH1⁻ RC⁻ genetic background (Jones et al., 1992a). Creation of potential heavy atom binding sites, through the introduction of cysteine residues for example, can provide a possible way forward. Moreover, this approach can be coupled with the heterologous expression of the other antenna complexes in *Rb. sphaeroides* for example, to facilitate the introduction of heavy atom binding sites in LH2 complexes from *Rp. acidophila* and *Rc. gelatinosus* (G.J.S. Fowler, S.J. Barrett, R.C. Mackenzie, R.J. Cogdell and C.N. Hunter, unpublished; see also section VI). Recently, the structure of the LH2 complex from *Rp. acidophila* has been determined by X-ray crystallography (McDermott et al., 1995) using a conventional approach for obtaining heavy atom derivatives. However, molecular genetics may still prove to be invaluable for other structural work.

B. The Production of α and β Subunits to Study the *in vitro* Assembly of the LH1 Complex

The study of bacterial antenna complexes in general and LH1 complexes in particular was advanced considerably by the isolation of the B820 particle (see Chapter 21 by Loach and Parkes-Loach). In this respect, LH1 appears to be more stable to such a

fractionation process and little equivalent progress has been made with the LH2 complex. In most cases so far, the starting material has been an LH2-deficient background; in fact it is possible to generate the B820 particle using membranes as the starting material even if reaction centers are also present. Thus, the LH2⁻LH1⁺RC⁺ species *Rs. rubrum* proved to be the ideal starting point for this work and Miller et al. (1987) published a characterization of the subunits of the core antenna of *Rs. rubrum*, following on from the first report of this approach by Loach et al., (1985). They showed that dissociation of the complex from its normal oligomeric ($\alpha\beta$)₁₂ state (for example) resulted in a reversible shift of the absorption maximum from 873 nm to 820 nm after addition of 0.8% N-octyl- β -D-glucopyranoside (β OG). At even higher detergent concentrations, a second reversible blue shift to 777 nm is observed (Parkes-Loach et al., 1988). It appears to be important to remove carotenoids prior to detergent treatment, although the use of N-octyl-rac 2, 3, dipropylsulfoxide can circumvent this problem (Visschers et al., 1992). This approach has been extended to the LH2⁻ mutants MW442 of *Rb. capsulatus*, and puc705BA of *Rb. sphaeroides*. (Heller and Loach, 1991; Chang et al., 1990a). Ghosh et al., (1988) have suggested that this B820 subunit form is an ($\alpha\beta$)₂ particle, and its relatively small size provides a good model system for various kinds of spectroscopy. Thus it has been shown that in spectroscopic terms at least, B820 behaves as an excitonically coupled $\alpha\beta$ dimer; measurements of low-temperature polarisation, CD and triplet-singlet spectroscopy are in good agreement with a dimer model in which a pair of excitonically coupled BChl *a* molecules are bound to the $\alpha\beta$ subunits (Chang et al., 1990b; van Mourik et al., 1991; Visschers et al., 1991, 1993a). The recent application of resonance Raman spectroscopy to the B820 species demonstrates that dissociation of the LH1 complex correlates with the replacement of internal hydrogen bonds by bonding to the detergent (Visschers et al., 1993b).

These results all show that the LH1 complexes studied so far are possibly built up as oligomers of an $\alpha\beta$ dimer, and apart from using molecular genetics to provide LH1-only strains for this kind of approach, it might be possible in the future to couple dissociation experiments with the production of site-specific alterations in LH complexes, in order to improve the spectroscopic characterisation of LH1 mutants.

IV. The Use of Antenna Mutants to Simplify Spectroscopic Studies of Antenna Complexes in a Membrane Environment

Despite the kind of advance made possible by the use of detergents to break down the oligomeric state of antenna complexes in order to simplify spectroscopic studies, summarised above, it is clear that there may be attendant effects of detergents which complicate spectroscopic work. This would arise from the creation of unwanted aggregation or dissociation states, or by altering or shifting absorbance peaks. At the same time, 'mixed' antenna systems containing both LH1 and LH2 are difficult to investigate because of overlapping signals. The availability of mutants deficient in one or two pigment proteins have made a valuable contribution to both problems, since the antenna is present in a spectroscopically pure state in its native lipid environment. This section will summarize the results of work undertaken on such mutants.

A. LH2-Only Mutants

This section will include some early work on both LH2-only and LH1-only mutants of *Rb. capsulatus* before moving on to summarize more recent work on a *Rb. sphaeroides* LH2- only mutant.

Several mutants of *Rb. capsulatus* provided valuable experimental material for spectroscopic studies, in particular the LH2-only mutants Y5 and the LH1-RC strain Ala⁺ both of which were used as the starting point for the purification of the respective antenna complexes (Feick and Drews, 1978; Tadros et al., 1982). They demonstrated that the LH2 complex in this species has three subunits of 8, 10 and 14kDa, the latter having no involvement in pigment binding. The amino acid composition was also determined for the subunits. In the case of LH1 the carotenoidless nature of Ala⁺ may have contributed to the lability of the detergent-solubilized complex. The fluorescence emission properties of the same mutants were reported by Feick et al., (1980). Subsequently, Y5 and Ala⁺ were studied using circular and linear dichroism, and Bolt et al. (1981a) were able to use these mutants to resolve the spectroscopic properties of the separate antennae into two classes. In particular, a strong CD signal reflecting exciton interactions was found in Y5 but was attenuated more than ten-fold in Ala⁺; they concluded that these two LH complexes have

significantly different chromophore arrangements or local environments. The same two mutants were used to provide a pure source of antenna for determination of the primary sequences of LH2 and LH1 subunits (Tadros et al., 1983; 1984).

The LH2-only mutant Y5 of *Rb. capsulatus* was used as a source of B800–850 complex in a study of the temperature-dependence of energy transfer in the range 4–300K (van Grondelle et al., 1982). This work, which also included LH2 complexes purified from *Rb. sphaeroides* strains with different carotenoid contents, concluded that the energy transfer efficiencies from carotenoid to B800 and B850 are greater than 90% at all temperatures, and at 4K carotenoids transfer energy preferentially to B850. The yield of emission from B800 at 4K was used to calculate the B800–850 dipole-dipole distance as $\leq 21\text{\AA}$, a figure which was subsequently used in the model of Kramer et al. (1984a).

Thus, these *Rb. capsulatus* mutants were useful in ascribing basic properties to the antenna chlorophylls in LH complexes. Scolnik et al., (1980) provided an elegant example of how LH1 and LH2-only mutants could be used to examine the spectral properties of the carotenoids in these complexes. It was already known that the ‘natural’ carotenoid spheroidenone was unsuitable for conducting such a study due to its broad and relatively featureless absorption in the visible region, so the gene transfer agent was used to introduce a *crtD* mutation, producing neurosporene plus its methoxy and hydroxy derivatives. Thus the original LH2-only strain Y142 became BY 1424 and the LH1+RC strain MW442 became MW4422. The study of these mutants demonstrated that carotenoids bound to LH1 are relatively blue-shifted, that those in LH2 are red-shifted and that only the LH2 carotenoids undergo a bandshift. However, the energy transfer efficiency from carotenoid to BChl was similar in each complex.

Another way to disrupt the synthesis of the LH1-RC core is to mutate the gene for the reaction center H subunit, *puhA* (Youvan et al., 1983; Hunter and van Grondelle, 1988; Sockett et al., 1989), although the reasons for the effect on the LH1 complex at least are not understood. Mutant NF57 of *Rb. sphaeroides* is a point mutant, which is complemented by a 1.4 kb *Bam*HI fragment encoding *puhA*, although the precise location of the mutation has never been determined. The preferable approach of constructing a defined deletion was carried out by Sockett et al., (1989) and

mutant PUHA1 also lacked both the LH1 and RC complexes. The interesting mechanisms of gene expression and complex assembly that accompany these observations are discussed more fully in Sockett et al., (1989). Recently, a chromosomal deletion has been described in which only sequences internal to *puhA* are removed, which also produces an LH1-phenotype. Thus the loss of LH1 can be assigned to the deletion of *puhA* (J.T. Beatty, personal communication). The LH2 complex of mutant NF57 was analyzed by a variety of spectroscopic and biochemical techniques since it provided a membrane-bound form of this antenna. Low-temperature absorbance, fluorescence emission and polarised light spectroscopy (van Dorssen et al., 1988) showed that in many respects the LH2 of NF57 was as expected from earlier results on the LDAO-solubilised complex (Kramer et al., 1984a), except that the ‘B850’ absorbance band was broader due to the presence of a minor pool of red-shifted bacteriochlorophylls. There was no indication of a residual LH1 complex to explain this broadening, especially at the levels of red-shifted absorbance seen of approximately 15% of the B850 band. It was significant that a linear combination of the NF57 (LH2) and M21 (LH1+RC) spectra could be fitted to the wild type profile in a satisfactory manner, but that a combination of the respective detergent-solubilized complexes could not (van Dorssen et al., 1988). The analysis of singlet-singlet annihilation in mutant NF57 demonstrated that at room temperature it contains domains of more than 370 B850 BChls connected for energy transfer, a figure which is reduced to 30 B850 BChls at 4K when thermal barriers to energy transfer help to ‘resolve’ the domains into smaller structures (Vos et al., 1988); see Fig. 3. Since NF57 consists of domains of approximately 30 B850 BChls at 4K, this corresponds to ~ 45 (B800 + and B850) pigments, and an oligomeric state of $(\alpha\beta)_{15}$. This is in good agreement with the size of one of the detergent-solubilised species of LH2 measured as $(\alpha\beta)_{14}$ by electrophoretic mobility in LDS-PAGE (Hunter et al., 1988); a direct comparison of the aggregation state of LDS- solubilized and membrane-bound LH2 is discussed in Hunter and van Grondelle (1988). Thus it appeared that approximately 30 BChl 850 + 15 BChl 800 is a fundamental unit of LH2 structure, although this is 18 BChl 850 + 9 BChl 800, at least for the detergent-solubilized LH2 complex from *Rp. acidophila* (McDermott et al., 1995). It is worthwhile

Fig. 3. Models for the in vivo functional sizes of light harvesting complexes (domains) from wild-type and mutant strains of *Rb. sphaeroides*, using the data of Vos et al. (1988), Hunter and van Grondelle (1988) and Hunter et al. (1989). These models depict the domains estimated from singlet-singlet annihilation data, but do not attempt to predict the two-dimensional arrangements of the complexes. Mutant M21 is LH2⁻, NF57 is LH1⁻RC⁻ and M2192, LH2⁻RC⁻. The figures after each mutant represent the domain sizes at room temperature and 4K, respectively; the 4K domains are indicated by dashed lines. The individual circles represent: ● RC; ⊙ LH2 - 6BChl850, 3BChl800; ○ LH1 - 6BChl875; ⊖ LH1 - 6BChl896, using a two-pool approximation of spectroscopic behavior at temperatures $\geq 77\text{K}$.

to mention that although the singlet-singlet annihilation technique does not necessarily produce an accurate number at all times, the domain size for the water-soluble BChl *a* complex of *Prosthecochloris aestuarii* was determined to be 24 ± 4 BChl *a* (van Grondelle et al., 1983); the size determined by X-ray crystallography is 21 BChl *a* (Fenna and Matthews, 1975).

NF57 was put to further use, to obtain in situ extinction coefficients for LH2 BChls, which were determined to be 226 ± 10 and $170 \pm 5 \text{ mM}^{-1} \text{ cm}^{-1}$ respectively for BChl 800 and BChl 850 (Sturgis et al., 1988). Also, picosecond absorption spectroscopy was used to investigate energy transfer dynamics within the membrane-bound LH2. The inhomogeneity within the B850 absorbance band was again

noted and the transfer of energy to what at 77K appears as a red-shifted pool was determined to be $39 \pm 9 \text{ ps}$ (Hunter et al., 1990). It should be pointed out that this two-pool model has been re-evaluated in terms of an inhomogeneously broadened band, at least for the LH1 complex at 4K (van Mourik et al., 1992a). The use of NF57 has been discontinued since the availability of a defined LH2⁻ only deletion strain, DPF2, (Jones et al., 1992a). However, Reddy et al. (1992) used NF57 as part of a wider study of the application of spectral hole burning to the study of several antenna complexes.

More recently, the alternative method of generating LH2-only mutants, by introducing plasmid-borne LH2 genes into an LH2⁻ LH1⁻ RC⁻ background, has produced a great deal of new information when

coupled with Fourier transform resonance Raman spectroscopy and ultrafast time-resolved absorption spectroscopy. However, since this work was carried out as part of a site directed mutagenesis program, it will be summarized in section V C1.

B. LH1-Only and LH1-RC Mutants

The availability of LH1-only mutants is a great advantage, because the purification of this complex from wild-type membranes is hampered by the presence of other complexes. As noted earlier in section IIIA, biochemically-based studies such as X-ray crystallographic and reconstitution projects benefit greatly from the availability of large amounts of LH1. Spectroscopic projects are less demanding to an extent, since there is no particular necessity to remove LH1 from the membrane and so one can examine the complex in situ unless the manipulation of the aggregation state is of particular interest.

The LH1-only mutant M2192 of *Rb. sphaeroides* has been mentioned already in section IIIA. It has been used for a variety of spectroscopic studies for investigating the aggregation state of LH1, and the energy transfer dynamics within this antenna. A comparison of the M2192 absorbance spectrum with the LH1 complex purified by LDS-PAGE reveals some broadening and a slight blue shift of the long wavelength absorbance maximum for the mutant (Hunter et al., 1989). A comparison with the LH1-RC parental strain M21 showed a striking difference in fluorescence polarization (FP) in the 880–920 nm region: the FP of M2192 hardly increases over the wavelength region where the FP of M21 reaches a maximum value of 0.45. This work suggested a model in which the absence of reaction centers causes the LH1 complexes to adopt an altered conformation so that the depolarization resulting from energy transfer between red-shifted pools of pigment, which is normally prevented by the presence of reaction centers, can now take place. This would suggest that the red-shifted pools were located near to the reaction center. It is interesting to note that the rise in FP seen in both the LH1-RC mutant M21 and in the wild type is qualitatively similar to that seen for the LDS-solubilized LH1 complex; in this latter case the complex is sufficiently small that red-shifted pools of pigment cannot transfer energy among similar units. Vos et al. (1988) measured the annihilation behavior of M21 and M2192 to investigate the aggregation state of the LH1 antenna, with and

without reaction centers. It was concluded that M21 contained rather larger domains than did M2192 (≥ 330 and 150 BChl *a* respectively), and that although the domains of M21 were resolved into units of around 100 BChl *a* at 4K the number for M2192 barely changed, to 125 (Fig. 3) This demonstrates two things: firstly that the LH1-RC 'core' in vivo probably contains a functional unit of up to 150 LH1 BChl *a* associated with 2, 3 or even 4 reaction centers; second, that the absence of reaction centers exerts an effect on the ability of the core antenna to aggregate, a phenomenon probably connected with the FP results summarised above. This large LH1 domain that constitutes the core antenna is made up of smaller fundamental units, which have been investigated by spectroscopic and biochemical techniques. The results of van Grondelle et al., (1983) suggest 6–8 BChl *a* as the likely size of the LDS-solubilised complex, which would correspond to $(\alpha\beta)_3$ or $(\alpha\beta)_4$. This figure is also predicted from the electrophoretic mobility studies of Hunter et al. (1988), which indicated two species of 54.6 ± 4.4 and 48.0 ± 3.0 kilodaltons corresponding also to $(\alpha\beta)_4$ and $(\alpha\beta)_3$ respectively.

As was the case for mutant NF57, strain M21 was useful for determining the extinction coefficient for the relevant antenna which was found to be $118 \pm 5 \text{ mM}^{-1} \text{ cm}^{-1}$ for the B875 absorbance band (Sturgis et al., 1988).

The energy transfer dynamics within LH1 have been studied intensively and a complete survey of this topic appears in Chapter 17 by Sundström and van Grondelle. For the reasons mentioned already, the naturally occurring LH1-RC species *Rs. rubrum* is extensively used for such work, since it provides a relatively simple system for study. Thus, Borisov et al. (1982) had proposed early on that there may be an energetically low-lying component in the LH1 antenna, which would correspond to the B896 component identified in FP measurements (Bolt et al., 1981b; Kramer et al., 1984b), and by the fluorescence lifetime measurements performed on the reaction center-less mutant C71 (Sebban et al., 1984). The presence of what at 77K can be described as a small pool of energetically low-lying pigments does not appear to depend on the presence of the reaction center, since it can be seen in both the purified LH1 complex, as well as in mutant M2192 (Kramer et al., 1984b; Hunter et al., 1989).

The single wavelength picosecond absorption recovery measurements of Hunter et al., (1990)

showed that at 77K mutant M21 behaves similarly to *Rs. rubrum*, and that excitation energy is transferred to the red-shifted pool with a time constant of about 22 ps. The lifetime of the excited state measured from the terminally emitting pigments in the red wing of the LH1 absorbance band was approximately 168, 335 and 670 ps for M21, M2192 and the LDS-B875 complex respectively, which could reflect differences in the aggregation state of the red-shifted pool caused by either the lack of reaction centers (in M2192) or the lack of reaction centers in combination with separation into smaller units in the LDS-B875 complex, as noted in Hunter et al., (1989). It is interesting to note the differences in time-resolved anisotropy, which reflect depolarization of excited states arising from relatively slow energy transfer in the red-shifted pool, and which provide a complementary approach to the FP measurements in Hunter et al., (1989). In M2192, the anisotropy is time dependent which could reflect energy transfer among similarly red-shifted pigments, whereas in the LDS-solubilised small units this parameter is high, and time-independent (Bergström et al., 1988).

A study of the temperature dependence of energy transfer from the red-shifted pool to the reaction center was carried out between 77 and 177K (Visscher et al., 1989). In this case, the reaction center traps were kept open. It was shown that for both the *Rb. sphaeroides* wild type and the M21 mutant the absorption changes were virtually independent of temperature in the range studied. A calculation was made of the activation energy for the final transfer step to the reaction center, which was 30 cm^{-1} or less; the transfer time would correspond to a distance of 26–31 Å between the donor LH1 BChl and the special pair within the RC.

Although the 'two-pool' model of LH1 explains many experimental observations at 77K quite satisfactorily (van Grondelle et al., 1988), it was insufficient to explain the results of Timpmann et al. (1991) who measured time-resolved fluorescence at 4K (discussed in Valkunas et al., 1992). The decay of fluorescence contained several components, the relative contributions of which depended on the wavelength of detection. The two-pool (B875/B896) model was analyzed further by van Mourik et al., (1992) who used site-selected fluorescence emission spectroscopy at 4K on the LH1 complex purified from mutant M2192 to demonstrate that the wavelength of maximum emission depends on the wavelength of excitation. This would not be the case

if all the pigments present were strongly coupled so that all emission took place from a single red-shifted pool; thus the absorption spectrum is now proposed to arise from the inhomogeneous broadening of the 'B875' absorption band. At 4K, each part of the total absorbance band contains a contribution from a series of weakly coupled clusters of pigments; the most significant parameter determining the wavelength of the maximum emission is the number of interacting pigments within a cluster. Thus, this measurement contains information on the number of connected pigments within such a cluster, which was calculated to be composed of 8 closely interacting BChl *a* dimers (van Mourik et al., 1992). This would correspond to two of the 6–8 BChl entities reported from biochemical and annihilation experiments (Hunter et al., 1988., van Grondelle et al., 1983). More recent data shows that, as expected, the emission maximum is only weakly dependent on excitation wavelength in intact membranes of M2192 at 4.2K, which suggests strongly-coupled clusters of larger size. At temperatures higher than 4K, such as 77K, energy transfer between clusters will become more feasible, so that the concept of a 'terminal emitter' from the absorbance band as a whole can be introduced; thus the two-pool model will still suffice at 77K. It appears likely that recent progress in crystallography, spectroscopy and molecular genetics will provide further information on this topic in the next few years. As an example of the two latter techniques, the combination of ultrafast (~40 fs) spectroscopy and molecular genetics has resulted in the first demonstration of coherent nuclear motion and exciton state relaxation in light harvesting complexes from *Rb. sphaeroides* (Chachisvilis et al., 1994; Pullerits et al., 1994).

C. R26 and R26.1

The carotenoidless mutant R26 of *Rb. sphaeroides* has already been mentioned in section 1 A, as has its value as a source of pure reaction centers. Davidson and Cogdell (1981) noticed that an alteration to the absorbance spectrum had occurred at some time since the isolation of the mutant in 1961, in which the 870 nm maximum shifted down to 855–860 nm. They demonstrated that this blue-shifted strain, designated R26.1, contained not only LH1 but also an altered LH2 complex, in which the B800 peak is absent. This explained earlier spectroscopic observations that R26.1 contains two types of antenna

complex (for example, Rijgersberg et al., 1980) and this was confirmed by subsequent work (Robert et al., 1984). Theiler et al. (1985) determined the amino acid sequence of the LH1 polypeptides from R26.1 and a comparison with the wild type LH1 revealed a β Leu29 \rightarrow Pro change, which was proposed to weaken the $\alpha\beta$ heterodimer. In addition an α Val24 \rightarrow Phe alteration in LH2 was observed (Theiler et al., 1984; Theiler and Zuber 1984). The accumulation of these mutations might be considered to be of no importance and indeed a reason to discard R26.1 as a source of antenna complexes, but R26.1 has been used several times as a model system, and the α Val24 \rightarrow Phe mutation is interesting in its own right.

Braun and Scherz (1991) fractionated the 'B850' complex of R26.1 using SDS gel electrophoresis, and obtained several bands which were examined by absorption spectroscopy and by circular dichroism. Models of the organization of LH polypeptides were presented based on these data in which the basic unit is a $(\alpha\beta)_2$ tetramer. They proposed that three tetramers form a dodecamer having C_3 symmetry, and that larger hexagonal assemblies could assemble from these dodecamers.

Recently, the α Val24 \rightarrow Phe change has been introduced into LH2 by site-directed mutagenesis, as part of an attempt to explain the reversion of R26 to R26.1 (G.J.S. Fowler and C.N. Hunter, unpublished). When expressed in a phytoene background the level of LH2 complex in the membrane is consistently higher when the α Val24 \rightarrow Phe mutation is present and ultrastructural analysis of the transconjugant strains shows an enhanced ability to form intracytoplasmic membranes. A speculative sequence of events could be firstly that the lack of carotenoid destabilizes the BChl800 binding site and the LH2 complex as a whole and that the LH2 polypeptides are unfavorable in some way for the viability of the cell. Pressure for suppression mutations arises from the need to provide additional light harvesting capacity; the α Val24 \rightarrow Phe mutation might improve matters by fostering additional interactions to counterbalance the loss of stability resulting from the lack of carotenoid and B800.

D. Mutants Containing LH2 and RCs, with No LH1

It is possible to generate LH1⁻ mutants, either by random chemical mutagenesis or by a more deliberate process of deleting LH1 genes. Examples of both

methods exist, and these will be summarized below. The absence of LH1 raises some fascinating questions about the 'uniqueness' of LH1 as a donor of energy to the reaction center, and the structural similarity between LH1 and LH2.

The first report of such a mutant was in 1985, when Meinhardt et al. published a spectral characterization of the *Rb. sphaeroides* mutant RS103. They measured the relative efficiency of energy transfer from LH2 to the reaction center and concluded that RS103 exhibited only 24% of the efficiency of the wild type, even though the photosynthetic unit was larger than normal. In a subsequent paper Kiley et al. (1988) demonstrated that RS103 contains approximately 25% of the normal complement of the LH1 α polypeptide; the amount of the β polypeptide was not determined. It was clear that in this mutant the lack of intact LH1 complex did not inhibit the assembly or function of the reaction centers, in contrast to the situation found in the LH1 mutant PAS 108 of *Rb. capsulatus* (Jackson et al., 1986, 1987) where reaction centers are apparently assembled but do not receive excitation energy from the LH2 complex. In this mutant LH1 polypeptides could form but they were turned over relatively rapidly; indeed it is possible that low levels of the LH1 complex are present at all times in PAS108 (Jackson et al., 1986). It was concluded that in the absence of LH1, reaction centers of *Rb. capsulatus* assemble but are not capable of useful work. A direct comparison of *Rb. sphaeroides* RS103 and *Rb. capsulatus* PAS108 concluded that the two species must differ in their requirements for the correct insertion of reaction centers, and that in this respect LH1 is essential in *Rb. capsulatus* but not in *Rb. sphaeroides* (Jackson et al., 1987). However, later work on site-directed LH1 mutants of *Rb. capsulatus* (see also section IVB) produced some LH1⁻ RC⁺ phenotypes in a U43 background, which is LH2⁻ by virtue of a point mutation in *pucC* downstream of structural genes for the LH2 complex. (Tichy et al., 1989; 1991). Thus Bylina et al. (1988), Dorge et al. (1990), Richter et al. (1991, 1992) and Garcia et al. (1991) have all reported *Rb. capsulatus* strains which were LH2⁻ LH1⁻ RC⁺, and which would appear to contradict the results of Jackson et al. (1987). Finally, though, it should be mentioned that Babst et al. (1991) report some site-directed alterations to LH1 which do affect RC assembly.

The availability of defined deletion strains in *Rb. sphaeroides* enabled Jones et al. (1992a) to construct

a mutant similar to RS103 of Meinhardt et al. (1985), but with the LH1 genes deleted. This was accomplished by introducing a plasmid containing only the *pufQLM* (and *X*) genes encoding reaction center subunits and from which the LH1 genes had been deleted, into strain DPF2 which contains a genomic copy of the LH2 genes and a deletion of *pufBALMX*. The resulting strain, DPF2 (pRKEH2) grows relatively slowly at low light intensity with a doubling time of 8 hours, compared with 4 hours for the wild type. However, it grows more rapidly than a strain which is completely devoid of antenna complexes, DD13/G1 (pRKEH2), which contains only reaction centers and which has a doubling time of 12 hours. This simple experiment shows firstly that reaction centers do assemble in the absence of the LH1 complex as first demonstrated by Meinhardt et al. (1985), and that there must be at least some productive energy transfer from LH2 to the RC. Recently the kinetics of energy transfer and trapping in DPF2 (pRKEH2) were examined by time-resolved absorption and fluorescence methods (Hess et al., 1993). Following excitation at 840 nm, the recovery of ground-state bleaching was monitored at 880 nm, which had a time constant of 55 ± 5 ps. A long-lived bleaching was observed which is characteristic of the charge separated states P^+I^-Q/P^+IQ^- . This demonstrates that trapping and charge separation in DPF2 in (pRKEH2) occur with a time constant of 55 ± 5 ps at room temperature; in the same experiment the results for the wild type were 60 ± 5 ps. Time-resolved fluorescence measurements demonstrated that the decay of antenna fluorescence with open reaction centers in DPF2 (pRKEH2) is largely (>80%) dominated by a 52 ± 5 ps decay component, in good agreement with the absorption measurements. Similar results were obtained for the wild type. These results demonstrate directly that LH2 can transfer energy efficiently and rapidly to reaction centers in this LH1-deficient mutant.

It is remarkable that the trapping of excitation energy by the reaction center appears to be unaffected by the removal of the LH1 core antenna. It would be reasonable to assume an optimized design of LH1-reaction center contacts and interchromophore distances, which could not be easily reproduced for the peripheral LH2 antenna. The fact that the rate of trapping is virtually the same in DPF2 (pRKEH2) and the wild type therefore suggests that the part of the core antenna surrounding the reaction center is not highly specialized, with finely tuned antenna-

reaction center distances and a number of antenna pigments dedicated to energy transfer to each reaction center. Rather, it appears that when antenna polypeptides pack around the reaction center a suitable organization is formed more or less spontaneously; the exact organization of the antenna polypeptides around the reaction center is not known. It could also be the case that the architecture and organization of LH1 and LH2 may be similar, a point which is being addressed by progress on the crystallography of these complexes (McDermott et al., 1995; Karrasch et al., 1995).

The LH2-RC mutant DPF2 (pRKEH2) provides other opportunities, such as the study of fast energy transfer within LH2, without the complications of LH1 being present (Hess et al., 1993). This follows on from an earlier characterisation of membrane-bound LH2 only systems such as NF57 (Hunter et al., 1990). The measurements on DPF2 (pRKEH2) in this instance were conducted with reaction centers closed in the state $P870^+$, which are normally relatively efficient quenchers of antenna excitations, although this mechanism is poorly understood. Substitution of the LH1 core antenna by the LH2 complex provided an opportunity to gain new insight into the mechanism of antenna quenching by $P870^+$. The 330 ± 30 ps time constants of LH2 absorption decay at 860 nm contrasts with the 200 ps lifetime observed for the wild type under similar conditions. The ΔA spectrum for reaction center charge separation (P^+IQ^- minus PIQ) shows that $P870^+$ develops an absorption band at wavelengths greater than 900 nm, where $P870$ has very little absorption initially. This absorption has very good spectral overlap with the fluorescence from LH1, but less overlap with LH2 fluorescence. This directly demonstrates that there are possibilities for energy transfer from the LH1 antenna to $P870^+$, which probably dissipates the energy as heat through a radiationless process. The smaller spectral overlap for $LH2 \rightarrow P870^+$ energy transfer also explains why the LH2 antenna within DPF2 (pRKEH2) with closed reaction centers has a considerably longer excited state lifetime than the wild type. The broad $P870^+$ absorption band is consistent with the observation that the quenching time with closed reaction centers is virtually temperature independent in the species of purple bacteria studied so far.

The degree of spectral inhomogeneity within the B850 absorption band of DPF2 (pRKEH2) was assessed by exciting the antenna with a picosecond pulse at 835–845 nm at 77K with closed reaction

centers and by monitoring the absorption changes in the 835–880 nm range. The kinetics at the different probe wavelengths were well described by two lifetime distributions centered at ~10 ps and 350 ps, the first of which corresponds to fast (1–5 ps) hopping of the excitation energy between small clusters of BChl molecules from the blue-absorbing to red-absorbing pigments within LH2. Anisotropy measurements show that very fast depolarizing energy transfer occurs on a subpicosecond timescale. Very recently these processes have been resolved through the application of 80 fs pulses (Hess et al., 1994).

E. Reaction Center-Only Mutants

Reaction center structure and function is an extremely large subject, and is outside the scope of this chapter. It is relevant to mention, though, that the correct series of deletions in light harvesting genes will result in a strain containing only reaction centers. This has been found many times for *Rb. capsulatus*, on occasions where mutations inactivating LH1 assembly are expressed in a U43 (LH2⁻) background (Bylina et al., 1988; Garcia et al., 1991). Expression of reaction centers is then occurring in a background where small but unstable quantities of both LH1 and LH2 polypeptides can be incorporated into the membrane (Tichy et al., 1989), but a more recent modification of this approach by Jones et al., (1992a) relied on the expression of a plasmid bearing RC (*puf* *LMX*) genes in an LH2⁻ LH1⁻ RC⁻ background. The resulting strain, RCO1, has been characterised (Jones et al., 1992b), and is an ideal vehicle for the study of various mutations on reaction center structure and function in its native membrane environment.

F. PufX

The *pufX* gene is located at the 3' end of the *puf* operon, and is mentioned briefly here, since its function, at least in part, appears to concern the association of the LH1 complex with the reaction center in some way. Farchaus and Oesterhelt (1989) constructed a strain of *Rb. sphaeroides* lacking *pufL*, *M*, and *X* and complemented it with a plasmid containing only *pufB*, *A*, *L* and *M*, a manipulation which effectively produces a *pufX*⁻ strain. Although all of the photosynthetic complexes are still present, the transconjugant strain is non-photosynthetic (Farchaus et al., 1990). Lilburn et al., (1992) have demonstrated that in a *Rb. capsulatus* *pufX*⁻ strain,

electron transfer from the RC to the cytochrome *bc*₁ complex is impaired. In addition, Westerhuis et al. (1993) suggest that the *pufX* gene product may limit the aggregation state of the LH1 complex. However, it appears that the PufX protein does not directly facilitate electron transfer between the RC and the cytochrome *bc*₁ complex, because there is no requirement for PufX for photosynthetic growth in an RC-only strain (McGlynn et al., 1994). Recently, the fascinating observation has been made that intergenic suppressors can restore photosynthetic growth to strains lacking *PufX* and that many of the revertants sequenced so far contained a modification of α Trp43 in the LH1 α subunit where a stop codon was introduced instead (Barz and Oesterhelt, 1994). Thus, truncation of this LH1 subunit compensates in some unknown way for the loss of *PufX*, which adds another level of complexity to the study of LH1-reaction center interactions.

V. Site-Directed Mutagenesis of Bacterial Light Harvesting Complexes

A. The Rationale for the Design of Site-Directed Mutations in Bacterial Light Harvesting Complexes

It is important to introduce some element of choice into the construction of site-directed mutants, unless this element is abolished and a highly discriminatory screening step is applied, as in random mutagenesis methods (see section V C4). The availability of a number of polypeptide sequences has provided important clues as to the conformation of the antenna polypeptides, and for a detailed account of the conclusions that can be drawn from these alignments, the reader is referred to Brunisholz and Zuber (1992) and Chapter 16 by Zuber and Cogdell in this volume. The generally accepted model, where a central membrane-spanning α helical region is flanked by polar N- and C-terminal domains, has been verified by X-ray crystallographic analysis (McDermott et al., 1995). For convenience, the $\alpha\beta$ polypeptide pairs of *Rb. sphaeroides* LH2, LH1 and *Rb. capsulatus* LH1 have been represented in this form to facilitate the discussion of the site directed mutants in sections V B and C.

An inspection of aligned sequences in Fig. 4 reveals several interesting similarities and differences; it is immediately apparent that the α polypeptides of

Fig. 4. Alignments of sequences of bacterial light harvesting complexes, using the data of Brunisholz and Zuber (1992). The boxes indicate those features which have been explored by site-directed mutagenesis techniques, and which are reviewed in sections V B and C.

LH1 and LH2 are rather similar, as are the β polypeptides. In the α polypeptides, the KIW motif is a possible membrane anchor, and the highly conserved proline is a likely location for a turn (see McDermott et al., 1995). In the membrane spanning region, the histidine is a ligand to a bacteriochlorophyll molecule and in the C-terminal region there is a cluster of conserved aromatic residues. Mutagenesis of these regions of the LH1 α subunit will be summarized in section V B.

In the β polypeptide alignment in Fig. 4 there is a conserved histidine, which participates in the binding site of BChl 800 within LH2; however it is also present in LH1 which has no such pigment. In the LH2 sequences an arginine at position 29 in *Rb. sphaeroides*, *Rb. capsulatus*, *Rp. palustris* and *Rp. acidophila* is also involved in B800 binding and it is absent in all LH1 sequences. Again, there is a histidine in the membrane-spanning domain which is a likely ligand to BChl *a* and on the C-terminal (periplasmic) side there is a totally conserved proline-tryptophan

pair. Mutagenesis of the first mentioned histidine, as well as the arginine in the transmembrane region will be summarized in the next section.

B. The LH1 Antenna Complex

A simple model of the LH1 complex is presented in Fig. 5; since most of this section deals with *Rb. capsulatus* it is this complex which is depicted in Fig. 5. Much of the information contained therein shows the locations of the site-directed mutations summarized below. The first report of the site-directed mutagenesis of any bacterial light harvesting complex was published by Youvan's group (Bylina et al., 1988), working on *Rb. capsulatus*. The object of study was the putative bacteriochlorophyll binding sequence Ala-X-X-His (see above and Chapter 16 by Zuber and Cogdell); α His32 was changed to Asn, Asp, Gln, Thr, Arg, and Pro, and α Ala28 was changed to Gly, Ser, Cys, Val, Asp, Glu, Phe and His. They concluded that no other residue in this list would

substitute for histidine and that residues with side chains smaller than valine can substitute for alanine, but larger ones cannot.

In the last few years, there have been a series of studies which have mainly concentrated on those residues which have some bearing on the process of the integration and assembly of the LH1 polypeptides. It has been known for several years that intrinsic membrane proteins conform to the 'positive-inside' rule (von Heijne, 1986) in which the balance of charge on periplasmically and cytoplasmically exposed domains is with the positive residues in greater number on the cytoplasmic face. Indeed, it has been possible to reverse the orientation of leader peptidase by reversing the charge balance (von Heijne, 1989; Nilsson and von Heijne., 1990). Another

determinant of membrane protein stability appears to be the location of aromatic groups at the membrane interface (Schiffer, 1992). A series of publications from Drews' group have addressed these and other aspects of LH1 assembly (Fig. 5). Dorge et al. (1990) examined the role of charged amino acids in the N-terminal regions of the α and β subunits. The changes Lys \rightarrow Glu at positions $\alpha 3$ and $\alpha 6$ or β Asp2, β Asp5 \rightarrow Lys, Arg had little effect on LH1 assembly, but the additional exchange of α Arg14, α Arg15 \rightarrow Glu, Asp and/or β Asp13, β Glu14 \rightarrow Arg, Arg had a strongly inhibitory effect. Stiehle et al. (1990) examined these mutations constructed in the α or β subunits separately and found that the positively charged residues of the N-terminus of α and the negatively charged residues of the N-terminus of β influence LH1 assembly

differently. For example the α mutations (Lys3, Lys6, α Arg14, α Arg15 \rightarrow Glu, Glu, Glu, Asp) resulted in a transient insertion of LH1 polypeptides whereas the β mutations (β Asp2, β Asp5, β Asp13, β Glu14 \rightarrow Lys, Arg, Arg, Arg) resulted in a much slower degradation of LH1 polypeptides. This second series therefore permits the accumulation of small amounts of the LH1 complex.

Richter and Drews (1991) examined the stability of LH1 α in the absence of β , and vice-versa, by deleting either *pufB* or *A*, followed by expression in a U43 background. In neither case did an LH1 complex assemble, so pulse chase experiments were used to find transient levels of LH1 subunits. In the 'wild type' control LH1 β was found to appear in membranes before LH1 α ; moreover the β subunit could insert transiently in the absence of α but the reverse was not observed. These experiments were complicated by the presence of transiently expressed LH2 subunits in the U43 strain, as well as another labelled polypeptide in the background, but nevertheless it appears that LH1 α and β are not inserted simultaneously.

The studies of Babst et al., (1991) targeted several residues, and the effects seen among the eighteen mutations varied widely, even at a single position. The three tryptophan exchanges at position α 8, for example, resulted in either the absence of a core complex, that is, the abolition of LH1 and RC assembly (α Trp8 \rightarrow Leu), the absence of the core antenna (α Trp8 \rightarrow Ala) or a reduction in the carotenoid content (α Trp8 \rightarrow Tyr). Richter et al. (1991) also noted that α Trp8 is important for the insertion of LH1 α into the membrane: α Trp8 \rightarrow Ala abolished LH1 assembly, in agreement with Babst et al. (1991). However, substitution of α Trp8 by Phe or Tyr appeared to have little effect on assembly or on carotenoid content, in contrast with Babst et al. (1991); the introduction of α Trp8 \rightarrow His yielded a less stable LH1 complex. Several other alterations produced an elevated amount of bacteriochlorophyll in LH1, such as α Phe23 \rightarrow Ala and β Gly10 \rightarrow Val which produced a 1.3-fold higher level: this was attributed to the presence of additional BChl molecules not attached at the normal co-ordination sites. The change β Arg45 \rightarrow Asp destabilized the LH1 antenna considerably, but surprisingly β Arg45 \rightarrow Glu did not. Several of the changes studied produced a small blue shift in the absorbance maximum which is normally at 878 nm, notably those at α Trp43 \rightarrow Tyr (867 nm), Ala (868 nm) and

Leu (870 nm). The authors suggested that this residue interacts with BChl *a* and that it modulates the absorbance behavior of this pigment. It is interesting to note that α Trp43 is conserved in all LH1 antennae, and that in *Rb. sphaeroides* it is the site of the intergenic suppressor mutation provoked by the reversion of *pufX* mutants to photosynthetic growth (Barz and Oesterhelt, 1994). Moreover, Fourier transform resonance Raman spectroscopy of α Trp43 mutants of *Rb. sphaeroides* demonstrates that this residue is hydrogen bonded to the 2 acetyl carbonyl of one of the BChl *a* molecules in LH1 (Olsen et al., 1994). The bond is abolished in an α Trp43 \rightarrow Phe mutant, but strengthened in an α Trp43 \rightarrow Tyr mutant; thus, at least one mechanism underlying these spectral shifts in vivo is likely to be by hydrogen bonding to the BChl. One interesting consequence arising from the demonstration of this hydrogen bond is that there must be a turn towards the N-terminal end of LH1 α ; this is consistent with the presence of a conserved proline residue in this region in both *Rb. capsulatus* and *Rb. sphaeroides*.

Richter et al. (1992) further examined the role of the LH1 α N-terminus in the insertion and stability of the LH1 complex by deleting amino acids 6–8, 9–11, 12 and 13, or 14 and 15. In addition the hydrophobic stretch of amino acids 7–11 was lengthened by the addition of hydrophobic or hydrophilic amino acids. All of these mutations abolished the formation of LH1; however, a photosynthetic revertant of Δ Leu9-Val10-Phe11 contained an intragenic suppression mutation which arose from an in-frame duplication of an existing sequence, Lys6, Ile7, Trp8. In summary, the wild-type sequence is: Met-Ser-Lys-Phe-Tyr-Lys-Ile-Trp-Leu-Val-Phe-Asp. The revertant was Met-Ser-Lys-Phe-Tyr-(Lys-Ile-Trp)₂-Asp. The revertant strain had double the normal carotenoid content of an LH1 complex with respect to BChl, and an increase in the size of the photosynthetic unit. This interesting experiment supports the notion that α Trp8 in particular could be part of a carotenoid binding motif, as well as a determinant of LH1 stability. Preliminary work on the mutagenesis of α Trp8 in *Rb. sphaeroides* supports this: mutation of α Trp8 \rightarrow His and Tyr had no effect on LH1 assembly, but α Trp8 \rightarrow Leu, Arg and Ala did (McMaster et al., 1992). In contrast with the observation of Babst et al. (1991) that α Trp8 \rightarrow Ala abolished reaction center assembly, no effect was observed, and it seems likely that different factors govern the stability of LH1-RC

cores in *Rb. capsulatus* and *Rb. sphaeroides*, as noted earlier by Jackson et al. (1987). The flexibility of the genetic system of Jones et al. (1992a) facilitates the examination of a given antenna mutation in three different carotenoid backgrounds and therefore the possibility that α Trp8 and carotenoids interact in some way could be examined. For example, it was observed that the insertion and assembly of LH1 took place in the α Trp8 \rightarrow Leu mutant in a neurosporene background, but not when phytoene was the major carotenoid.

C. The LH2 Antenna Complex

At the time of writing rather fewer residues of the LH2 complex have been altered by mutagenesis, compared to LH1. This is partly because until recently there was no LH2⁻ LH1⁻ RC⁻ (Δpuc , Δpuf) double deletion strain of *Rb. capsulatus*, although a single

deletion LH2⁻ (Δpuc) strain has been available since 1985 (Youvan et al., 1985). Another reason is that the work on *Rb. sphaeroides* has been conducted with the aim of presenting a thorough spectral characterisation for each mutant which lengthens the turnover time of the whole process. Fig. 6 shows a simple model of the *Rb. sphaeroides* complex in the style of Fig. 5 which indicates the locations of the site-directed changes made.

1. Blue-Shifted Complexes Produced by Mutagenesis of α Tyr44 and Tyr45

The first example of the mutagenesis of an LH2 complex was in 1992 when Fowler et al. reported the effects of altering α Tyr44, Tyr45 firstly to Phe, Tyr then Phe, Leu. The rationale for this was that the mechanisms underlying the red-shifts of bacteriochlorophylls in vivo are poorly understood, although

Fig. 6. Representation of the $\alpha\beta$ dimer of the *Rb. sphaeroides* LH2 complex showing the positions of the site-directed mutations reviewed in section VC. The original references can be found as follows: (1) Fowler et al., 1992; (2) Fowler et al., 1993; (3) Crielaard et al., 1994; (4) Vischers et al., 1994; (5) Hunter et al., 1993. The His residues are represented by hatched circles; some residues are hidden by the BChl molecules and the sequences flanking these regions are: α -ASVVIHAAVLT; β -MALIAHFLAAA.

it is clear that aggregation effects such as those examined *in vitro* are important (Visschers et al., 1991). The B800–820 LH2 α subunit from *Rp. acidophila* strain 7050 has a Phe, Leu pair where the *Rb. sphaeroides* B800–850 LH2 pair is Tyr, Tyr. This suggests a simple mutagenesis experiment, in which Tyr, Tyr is changed first to Phe, Tyr then to Phe, Leu, to see if this modulates the absorbance behavior of the complex. The altered genes were expressed in both single deletion (LH2 $^-$, Δpuc) and double deletion (LH2 $^-$, LH1 $^-$, RC $^-$ (Δpuc , Δpuf)) backgrounds. In the latter case, an unequivocal account of the effects on LH2 could be obtained: at 77K the absorbance maximum of the 850 nm band is shifted by 11 nm to 839 nm (Phe, Tyr) whereas in the Phe, Leu mutant there was a further shift to 826 nm. The intensity of this band decreased to the point where the absorbance spectrum of the Phe, Leu mutant did indeed resemble that of the *Rp. acidophila* B800–820 complex (Fig. 7). Excitation spectra demonstrated that in these mutants BChl800 was fully able to transfer energy to, and elicit fluorescence from the 850, 839 or 826 nm component. Expression of the altered genes in an LH1 $^+$ RC $^+$ background resulted in a 'pseudo' wild type, in which the altered LH2 was completely efficient in energy transfer to the native core. Circular dichroism in the near infrared, which is a sensitive indicator of perturbations to the relative geometry of the pigments, showed the same, strong conservative signal in each core albeit a progressively blue-shifted one. Thus the absorbance behavior of these BChls is modulated by the protein framework of the antenna, by the use of the Tyr, Tyr motif in this case. The mechanism underlying this effect was examined by further mutations to Tyr, Phe, and Tyr, Leu (Hunter et al., 1993) and in summary the main shift arises from a Tyr \rightarrow Phe change. Therefore, interactions between π - π^* orbitals of aromatic residues and the bchl macrocycles probably do not cause blue shifts, but rather it is hydrogen bonding between Tyr and the BChl (Hunter et al., 1993). A resonance Raman study of these mutants is in support of this, and demonstrates the disruption of at least one hydrogen bond to the C2 acetyl carbonyl of one of the B850 BChls in the mutants (Fowler et al., 1994). The X-ray crystallographic structure for the *Rp. acidophila* LH2 complex is consistent with the proposed hydrogen bonding arrangement (McDermott et al., 1995). This work runs parallel with the Raman assignment of LH1 α Trp43 mutants (Olsen et al., 1994). As in the case of LH1, this bond in LH2 necessitates a turn

near the predicted membrane interface, at the sequence Thr-Trp-Leu-Pro-Ala (Fig. 6). More recent work shows that there are several ways to produce the same blue-shifted phenotype: for example, alteration of $\beta\text{Lys22} \rightarrow \text{Gln}$ (wrongly numbered as βLys22 in Fowler et al., 1993) produces a B800–837 complex, in this case possibly by affecting the relative disposition of the α and β subunits, and therefore the pigments as well. The mechanism underlying this change has not yet been determined.

The availability of LH2 complexes with progressively blue-shifted absorbance bands prompted an investigation of energy transfer dynamics within LH2 by spectral hole-burning (van der Laan et al., 1993). These measurements were performed on the BChl800 band at very low temperature (1.6–4K) and the measured hole-widths were related to the rate of B800 \rightarrow B850 energy transfer. For wild-type LH2 complexes, good agreement was found with the B800* lifetimes obtained by time-resolved absorption techniques at 77K (Hess et al., 1994), with both techniques giving approximately 2.4 ps. The rates determined by hole-burning experiments on the mutants did not follow a clearly increasing trend, unlike the time-resolved study which produced rates of approximately 1.6 and 0.8 ps for the B800–839, 800–826 mutants, respectively. Thus, the time-resolved measurements at 77K correlated with the Förster description of the energy transfer rate whereas the hole-burning measurements at 4K did not. A discussion of the causes of this discrepancy is beyond the scope of this chapter, but these results emphasise the value of spectrally modified LH complexes to the study of energy transfer dynamics in antenna systems.

2. Alteration of the Absorbance Properties of the B800 Bacteriochlorophyll

LH2 contains an extra absorbance band (B800), when compared to LH1 and it is already known that this band is relatively labile in the presence of the detergent lithium dodecyl sulfate, for example, (Clayton and Clayton, 1981; Kramer et al., 1984). This band presents an attractive target for mutagenesis, and this then offers the prospect of being able to re-examine the conclusions of Kramer et al. (1984), who proposed a model of LH2 based on experiments conducted on a modified LH2 complex of *Rb. sphaeroides* lacking B800.

The residues chosen for this study were βHis21 and βArg29 (Visschers et al., 1994). In the former

case, this histidine was an attractive site for the study of BChl binding, notwithstanding the fact that BChl800 is absent from LH1 which possesses a histidine residue at the analogous position. In addition, resonance Raman spectroscopy found no evidence for histidine coordination of BChl800 (Robert and Lutz, 1985). βArg29 was chosen because it is conserved in most LH2 complexes, and is not found at the analogous position in LH1 (see fig 4). Both mutations ($\beta\text{His21} \rightarrow \text{Ser}$; $\beta\text{Arg29} \rightarrow \text{Glu}$) lead to severe changes in the spectroscopic characteristics of the BChl800 pigment. The $\beta\text{His21} \rightarrow \text{Ser}$ mutant has a greatly attenuated BChl800 absorbance band, and membranes of the mutated strain have only a B850 absorbance peak which is shifted to the red by 2–3 nm. The $\beta\text{Arg29} \rightarrow \text{Glu}$ mutant results in a blue shift to 787 nm and a broadening of the absorbance band, suggesting that this residue also plays a role in determining the absorbance properties of BChl800. Circular dichroism reveals no perturbations of the BChl850 binding sites in either mutant. The residual BChl800 pigment in these mutants is still fully efficient for energy transfer to BChl850, and when expressed in an LH1-RC background energy transfer from the modified LH2 complexes to LH1 is still efficient. Linear dichroism of the Q_x region shows that the Q_x transitions of the B800 pigments are in the plane of the membrane, in good agreement with Kramer et al. (1984).

The conclusion from this work is that both βHis21 and βArg29 have some influence on the properties of BChl800, although results from studying whole cells are instructive, in that rather more BChl800 absorbance is preserved. Preparation of membranes results in some loss of BChl800, which demonstrates that site-directed mutants can be labile even at this stage; one would expect that even more spectral losses and modifications would occur if a detergent purification protocol was added. Nonetheless, it is interesting that a modification such as the loss of BChl800 is specific and does not prevent the assembly and function of the LH2 complex. The conclusions drawn from the study of these mutants is consistent with the crystallographic data, which show that these residues are in close proximity to the BChl 800 pigment (McDermott et al., 1995).

3. Alteration of the Binding, Function and Electrochromic Behavior of the Carotenoids

The same changes specified above, $\beta\text{His21} \rightarrow \text{Ser}$

and $\beta\text{Arg29} \rightarrow \text{Glu}$, had pronounced effects on the carotenoids in the LH2 complex (Crielaard et al., 1994). The altered LH2 genes were expressed in a double deletion (LH2- LH1- RC⁻) background which carries a mutation in the *crtD* locus leading to the synthesis of neurosporene and its methoxy-and-hydroxy derivatives (Coomber et al., 1990). The distinct spectral features of carotenoids in the green LH2 antenna are preferable to the rather featureless spectrum of spheroidenone in the wild-type. Difference spectra in the visible region (LH2-WT vs. $\beta\text{His21} \rightarrow \text{Ser}$ and LH2-WT vs. $\beta\text{Arg29} \rightarrow \text{Glu}$) clearly showed that the loss of the histidine residue results in a broadening and a blue shift of 3 nm in all carotenoid peaks. A similar blue-shift of 1 nm was seen in the βArg29 mutant although no broadening was observed. In neither case was there any indication of a lower carotenoid binding capacity, despite the attenuation or loss of BChl800. Fluorescence excitation spectra at 77K showed that no disturbance of energy transfer to BChl had occurred, so that energy was being transferred directly to B850. Linear dichroism in the visible region indicated that no rearrangement of carotenoids had occurred in the mutants. With regard the model of Kramer et al., (1984a) these results show that an energy transfer pathway from carotenoid \rightarrow BChl800 is not obligatory, at least in the mutants, which is not consistent with earlier data (Trautmann et al., 1990; Crielaard et al., 1992). More data is required on site-directed mutants to examine this point further.

Diffusion potentials were applied to membranes from the LH2-WT, $\beta\text{Arg29} \rightarrow \text{Glu}$ and $\beta\text{His21} \rightarrow \text{Ser}$ strains; all 3 contained electrochromically active carotenoids, but in the βHis21 mutant the difference spectrum was shifted 6 nm to the blue; a similar, smaller shift of 3.5 nm was observed for the βArg29 mutant. Finally, the relationship between the carotenoid absorption change and the membrane potential was examined. Each time a linear relationship was observed, demonstrating that a local field is still present, but in both mutants, particularly $\beta\text{Arg29} \rightarrow \text{Glu}$, there was a severely reduced response. In all cases, an inverse potential reversed the sign of the absorption changes. The hypothesis that there is a large permanent field in the vicinity of the reactive carotenoids is strengthened by the observation that changing the positively charged βArg29 to glutamate has a major effect on the response to an applied membrane potential, indicating a change in the permanent field near the carotenoid. From the

structural data of McDermott et al. (1995), it appears that βArg29 exerts an effect on the carotenoid despite the intervening presence of BChl 800; the creation of new mutations at this position should clarify the nature of the side chain-BChl-carotenoid interactions involved.

4. A Combinatorial Library of Localized Point Mutations

A careful inspection of the sequence alignments in Fig. 4 reveals a large number of potential point mutations which would yield interesting structural information, provided that the spectroscopy brought to bear on these mutants is sufficiently thorough. Nonetheless, even this 'rational' approach might represent potentially 20^{20} mutations, a number which would deter any spectroscopist. The second point to make is that there will be interesting mutations that are not readily suggested from sequence comparisons, and there is no way of predicting in advance what these will be. Douglas Youvan and co-workers have developed a different approach to mutagenesis, which involves a means of applying random, or semi-random mutagenesis to a target sequence which generates a large number of potential mutants (Goldman and Youvan, 1992; also see Chapter 61 by Goldman and Youvan). A typical library of mutants could consist of several thousand colonies, and then the pressure falls upon the speed and discrimination of screening, which in this case is facilitated by digital imaging spectroscopy. The spectral resolution of this technique is sufficient to allow the classification of 3 major classes of mutants in the case of LH2 : pseudo wild-type absorbing at 800 and 860 nm; pseudo LH1 showing reduced absorbance at 800 nm and a maximum near 875 nm, and finally mutants with no appreciable absorbance in the near infra-red. There are several ways to generate the mutations, for example by using error-based PCR of a whole subunit (McMaster and Hunter, unpublished), by combinatorial cassette mutagenesis which uses all 20 amino acids at each position, or by the aforementioned target set mutagenesis (Goldman and Youvan, 1992). In the latter case various parameters such as sequence alignments or structural considerations are used to limit the possible number of options; this has demonstrable benefits for the screening stage later on. The other limitation is the width of the target 'window' which was 15 residues in Goldman and Youvan (1992), sufficient to encompass almost half

the length of a LH subunit. In this case, the window was located with the BChl-binding β His-39 at the center. The DNA sequence is determined following the screening procedure, instead of beforehand as in conventional site-directed mutagenesis.

More recently Delagrave et al., (1993) described recursive ensemble mutagenesis, which is the application of successive rounds of combinatorial cassette mutagenesis (Goldman and Youvan, 1992), so that a list is compiled of 'acceptable' amino acids at each mutated position. This list allows another cassette to be designed which can increase the frequency of 'positive' mutants 30-fold, when compared to combinatorial cassette mutagenesis and 30,000-fold compared to random mutagenesis.

It is clear that the application of random and semi-random techniques will produce mutants which could not be designed or predicted merely from a study of aligned sequences, and therefore it is likely that this approach will make a valuable contribution to the study of antenna complexes in the future.

VI. Heterologous Expression of LH Genes in *Rhodobacter sphaeroides*

It is clear from the sequence alignments in Fig. 4 that nature has provided a large number of natural variants in light harvesting sequences among different species. Not many of these interesting bacteria can be examined by a full array of molecular genetic techniques, however. This difficulty can be overcome by expressing foreign LH genes in *Rb. sphaeroides*, for example. In Fig. 8 the absorbance spectrum of the *Rp. acidophila* LH2 antenna complex is shown, in an LH2-LH1-RC⁻ *Rb. sphaeroides* background. Transcription is driven by the *Rb. sphaeroides puc* promoter (McGlynn and Hunter 1992) on a broad host range plasmid designed for expression of *Rb. sphaeroides* genes. There are several benefits from this approach: it is possible to observe and measure the absorbance of a *Rp. acidophila* LH2 complex for the first time in isolation and in a membrane environment. Second, *Rp. acidophila* has a family of many LH2 genes and this technique has allowed us to examine the complexes that result from previously 'silent' gene pairs. Third, the fact that the expressed complex appears to accommodate the host's carotenoid, neurosporene, in place of the normal pigment rhodopin poses interesting questions about the specificity of carotenoid binding in these antenna.

Fig. 8. Absorbance spectrum of *pucBA* gene pairs from (a) *Rp. acidophila* and (b) *Rc. gelatinosus* expressed in a LH2-LH1-RC⁻ *Rb. sphaeroides* background (G. J. S. Fowler, A. T. Gardiner, R. C. Mackenzie, S. J. Barratt, A. E. Simmons, R. J. Cogdell and C. N. Hunter, unpublished).

Finally, when expressed in an LH1⁺RC⁺ *Rb. sphaeroides* background a mixed photosynthetic unit is obtained which raises new possibilities for productive contacts between membrane proteins.

All of the above can just as easily be applied to complexes from *Rc. gelatinosus* (see Fig. 8) and this approach of heterologous expression could in principle be extended further to examine other spectroscopically interesting antennae.

VII. Concluding Remarks

The objective of this review was to establish the value of genetic alterations to the study of bacterial antennas, firstly as a means of generating 'partial' systems, secondly for site-directed mutagenesis and finally for the study of antenna complexes for genetically poorly characterised bacteria. It is undoubtedly true that altered antenna systems muddy the waters a little. To echo the sentiments expressed in Marrs (1978): 'Why do you study crippled strains? It's hard enough to figure out how the normal ones work'. However, a thorough and patient spectroscopic examination of genetically altered complexes will, in combination with structural studies, reveal many of the molecular details of these complexes within the next few years. By the time this chapter is published, the structure of the *Rp. acidophila* LH2

complex will have been determined by X-ray crystallography (McDermott et al., 1995). With this new information, we look forward to using mutagenesis techniques to examine the role of various amino acid residues in determining the properties of this antenna.

Summary

Photosynthetic reaction centers from purple bacteria are the best known membrane protein complexes. In this review, X-ray crystal structures of the reaction centers from *Rhodospseudomonas (Rp.) viridis* and *Rhodobacter (Rb.) sphaeroides* are compared on the basis of data quality and quantity, maximum resolution limits, and structural features. In contrast to earlier comparisons and on the basis of the most recent, best defined *Rb. sphaeroides* structure, a number of the reported differences between the two species cannot be confirmed. Not only the overall architecture of the reaction centers and the relative positions and orientations of the cofactors, but also specific structural features are well conserved. For example, the hydrogen-bonding pattern between the protein and the monomeric bacteriochlorophylls, the bacteriopheophytins, and the primary quinone, Q_A , are identical. Therefore, the asymmetry between the A- and B- branch is maintained. However, there are small conformational differences which might provide a basis for the explanation of observed spectral and functional discrepancies between the two species.

A particular focus in this review is on the binding site of the secondary quinone (Q_B), where electron transfer is coupled to the uptake of protons from the cytoplasm. For the description of the Q_B -binding site, an improved coordinate set for the *Rp. viridis* reaction center has been included. In particular, a new understanding of the role of Ser L223 in the Q_B -binding site has become apparent. In addition, chains of ordered water molecules are found leading from the cytoplasm to the Q_B site in the best defined structures of both *Rp. viridis* and *Rb.*

sphaeroides reaction centers. New insights concerning the binding of triazine-type electron transfer inhibitors to the *Rp. viridis* Q_B site include the identification of additional hydrogen bonds and of two tightly bound water molecules. Finally, recent developments regarding the structures of mutant reaction centers are discussed.

I. Introduction

The first steps of photosynthetic light-energy conversion take place in the photosynthetic membranes from various bacteria or organelles. Light is absorbed first by light-harvesting antenna complexes (see Chapters 15–22 of this volume for reviews). Upon transfer of the energy from the light-harvesting antenna to the photosynthetic reaction center, or direct excitation by light of the reaction center itself, an excited singlet state of the 'primary electron donor' is created. This event leads to the primary charge separation and a subsequent vectorial electron transfer in the photosynthetic reaction center across the photosynthetic membrane. The photosynthetic reaction centers are complexes containing several integral membrane proteins and a number of pigment molecules. Best characterized are those from the purple bacteria (for earlier reviews, see Okamura and Feher, 1992; Breton and Vermeiglio, 1992; Deisenhofer and Norris, 1993). In general, they consist of three protein subunits, which are called H (heavy), M (medium) and L (light) according to their apparent molecular weights as determined by sodium dodecylsulfate polyacrylamide gel electrophoresis. The H subunit can frequently be removed without impairing the primary photochemistry (see e.g. Debus et al., 1985). The L and M subunits bind the photosynthetic pigments (cofactors) which are one carotenoid molecule, 2 bacteriochlorophylls (a or b), one ubiquinone (or menaquinone) as a primary electron acceptor Q_A , one non-heme iron, and another ubiquinone as the secondary electron acceptor Q_B . The L and M subunits possess a sequence homology of about 25–35% (Youvan et al., 1984; Williams et al., 1984; Michel et al., 1986a; Williams et al., 1986). The reaction centers from most purple bacteria contain a fourth protein subunit, a cytochrome *c* with four covalently bound heme groups. Among these is the reaction center from *Rhodospseudomonas* (*Rp.*) *viridis*, which possesses bacteriochlorophylls and bacteriopheophytins of the *b* type, and menaquinone-9 as Q_A . The carotenoid is 1,2-dihydroneurosporene

(Sinning, 1988). The reaction center from *Rhodobacter* (*Rb.*) *sphaeroides* contains bacteriochlorophylls and bacteriopheophytins of the *a* type, ubiquinone-10 as Q_A , and spheroidene as the carotenoid. It does not possess a tightly bound cytochrome subunit.

The isolated photosynthetic reaction center from the filamentous green aerobic bacterium *Chloroflexus* (*Cf.*) *aurantiacus*, consists of an L and M subunit which show sequence similarities to the reaction centers from purple bacteria (Ovchinnikov et al., 1988a, 1988b, Shiozawa et al., 1989). There is no evidence for the presence of an H subunit. However, *in vivo* a four-heme containing cytochrome subunit, similar to that from *Rp. viridis*, is present (Dracheva et al., 1991). Much of what will be said about the three-dimensional structure of the photosynthetic reaction center core from purple bacteria will also be valid for the reaction center from *Cf. aurantiacus*. The known amino acid sequences of reaction center subunits from purple bacteria have been compiled and compared with those from *Cf. aurantiacus* recently (Nagashima et al., 1993, 1994). The photosynthetic reaction centers from the anaerobic green sulphur bacteria are completely different (see Chapter 30 by Feiler and Hauska).

The photosynthetic reaction centers from purple bacteria are the best known membrane protein complexes: The crystal structures of the reaction centers from the purple bacteria *Rp. viridis* and *Rb. sphaeroides* have been determined as the first membrane protein complexes. Initially, the structure of the reaction center from *Rp. viridis* was solved by the multiple isomorphous replacement method (Deisenhofer et al., 1984, 1985) and refined to a crystallographic R-factor of 19.3% up to a resolution of 2.3 Å (Deisenhofer and Michel, 1989, Deisenhofer et al., 1995). The structure of the reaction center from *Rb. sphaeroides* was then determined by three different groups using a partially refined coordinate set of the *Rp. viridis* reaction center by the molecular replacement method. All three groups used an orthorhombic crystal form with slightly different cell dimensions for structure determination (Allen et al., 1986, Chang et al., 1986, Arnoux et al., 1989). The structures were refined at a resolution around 3

Å with crystallographic R-factors between 20 and 22%.

Although the overall structure of the *Rb. sphaeroides* reaction center was published to be very similar to that from *Rp. viridis*, a number of substantial differences in cofactor binding have been reported (Yeates et al., 1988, Allen et al., 1988) However, there are also differences between the published structures of the *Rb. sphaeroides* reaction centers (El-Kabbani et al., 1991). Recently, a trigonal crystal form has been obtained which diffracts X-rays to a resolution of at least 2.65 Å (Buchanan et al., 1993). Structure determination using this crystal form and the refinement to a crystallographic R-factor of 18.6% has now been completed (Ermler et al., 1994). The Protein Data Bank ID code for this structure is 1PCR. Due to the improved resolution, more and better data and the lower R-factor, the new structural model of the *Rb. sphaeroides* reaction center is considerably better defined. The average coordinate error is now reduced to 0.3 Å compared to 0.4 Å or 0.5 Å for the previously published structures whereas it is 0.26 Å for the *Rp. viridis* reaction center (cf. Table 1). In addition, as for the *Rp. viridis* reaction center, more than 160 firmly bound water molecules could be identified and added to the atomic model. For the description of the Q_B -binding site we will also use an improved coordinate set for the *Rp. viridis* reaction center which was obtained after reconstitution of Q_B with ubiquinone-2, data collection, and refinement (Lancaster and Michel, to be published). The Q_B site in the *Rp. viridis* reaction center crystals is normally only 30% occupied, resulting in a 'mixed' structure around Q_B .

Table 1 lists the coordinate sets, which are available either from the Brookhaven Protein Data Bank (Bernstein et al., 1977; Peitsch et al., 1995) or from the authors upon request. The publications from one group originally describing the *Rb. sphaeroides* reaction center structure (Allen et al., 1987; Yeates et al., 1988, Allen et al., 1988; Komiya et al., 1988) are based on a coordinate set (1RCR) which has now been replaced by 4RCR without an updated publication. Also, very recently, another set of coordinates named 1PSS for the *Rb. sphaeroides* reaction center from wild type strain WS 231, has been deposited (Chirino et al., 1994). Due to the higher accuracy we will mainly use the coordinate set obtained with the new trigonal crystal form of *Rb. sphaeroides* reaction center in the following comparison of the reaction center from both species.

II. Structural and Functional Overview

Figure 1 shows an overview of the photosynthetic reaction center from *Rp. viridis* similar to that published by Deisenhofer et al. (1985). In such a representation the reaction center from *Rb. sphaeroides* would look nearly identical with the exception that the cytochrome subunit shown at the top (green) would be missing. The protein subunits are shown in the form of a smoothed ribbon diagram, the cofactors as atomic models with yellow carbon atoms, blue nitrogen and red oxygen atoms. The reaction center from *Rp. viridis* has an overall length of 130 Å. This is in the direction perpendicular to the membrane. Parallel to the membrane, the maximum width is about 70 Å. The central core of the reaction center is formed by the L subunit (shown in brown) and the M subunit (shown in blue) which possess five membrane spanning helices each. Both subunits are closely associated and bind the bacteriochlorophylls, the bacteriopheophytins, the quinones, the non-heme iron, and the carotenoid. With the exception of the carotenoid, the cofactors and the L and M subunits show a high degree of local twofold symmetry with the symmetry axis perpendicular to the membrane. On the external (periplasmic) and internal (cytoplasmic) side this central core forms flat surfaces. The cytochrome subunit with its four covalently bound heme groups is attached to this core on the periplasmic side, the H subunit on the cytoplasmic side. In addition the H subunit is anchored to the membrane by a single membrane spanning helix. The cytochrome subunit also possesses a membrane anchor. This membrane anchor is made up by two C_{18} -fatty acids which are covalently bound to the N-terminal Cys-residue via a glycerol moiety (Weyer et al., 1987a). It is not visible in the electron density map. Most likely it is disordered in the detergent micelle which surrounds the hydrophobic trans-membrane helices, as indicated by neutron crystallography (Roth et al., 1989).

The pigments form two branches (see also Fig. 2) each consisting of two bacteriochlorophylls, one bacteriopheophytin and one quinone, which both cross the membrane starting from a 'special pair' of two closely associated bacteriochlorophylls (one of which belongs to each branch) near the periplasmic side, followed by the 'accessory' bacteriochlorophyll, one bacteriopheophytin and a quinone. Only the branch more closely associated with L subunit is used in the light-driven electron transfer. According

Table 1. Reaction Center Structures^a

^a Structures 1PRC, 2RCR, 4RCR, 1PSS and 1PCR are named according to their four-character entry code in the Brookhaven Protein Data Bank (PDB). Names Q282 and DGM are unofficial and refer to the quinone-reconstituted complex and the triazine inhibitor complex, respectively.

^b These values were calculated for the number of reflections actually used in refinement and may differ from those given in the appropriate references.

^c n_{obs} = number of observed unique reflections (only the reflections used for refinement are considered)

n_{par} = number of parameters necessary to define the model. This includes 3 parameters (x,y,z coordinates) per non-zero-occupancy atom plus one (isotropic atomic B-factor) where applicable (the 2RCR structure is reported without atomic B-factors), plus additional parameters (occupancy) for alternate conformations.

^d estimate of the upper limit of the mean coordinate error from a Luzzati (1952) plot.

to the nomenclature proposed by Hoff (1988) it is called the A (active)-branch, the inactive one the B-branch. The active branch ends with Q_A , the inactive one with Q_B . Halfway between both quinones a non-heme iron atom is located. The carotenoid is associated with the second bacteriochlorophyll of the inactive branch. Which branch is used in electron transfer, could be decided by optical spectroscopy with polarized light on single crystals (Zinth et al., 1983) in combination with the structural data (Michel and Deisenhofer, 1986) keeping in mind that the bacteriopheophytin involved in electron transfer absorbs light at longer wavelengths than the other (Vermeglio and Paillotin, 1982). The final electron transfer from Q_A to Q_B occurs parallel to the membrane. After or during a second electron transfer Q_B becomes doubly protonated. This reaction is discussed in Chapter 26 by Okamura and Feher.

III. Arrangement of the Cofactors

Figure 2 shows the arrangement of the cofactors for the *Rp. viridis* (green) and the *Rb. sphaeroides* reaction centers (red). The two pigment branches A and B can clearly be seen, starting with the bacteriochlorophylls D_A and D_B constituting the

primary electron donor ('special pair'), then the accessory bacteriochlorophylls B_A and B_B , the bacteriopheophytins ϕ_A and ϕ_B , the primary electron acceptor Q_A (menaquinone is *Rp. viridis*, ubiquinone in *Rb. sphaeroides*), the secondary electron acceptor Q_B (ubiquinone in both species) and the non-heme iron halfway between Q_A and Q_B . The carotenoid is in van der Waals contact with B_B and disrupts the twofold symmetry. The linear row of the four heme groups in the *Rp. viridis* reaction center is seen at the top.

The arrangement of the cofactors is very similar in both reaction centers. The head groups of the cofactors are in nearly identical positions except for Q_B which is discussed below. The small differences of the cofactor arrangement are difficult to discuss because they depend on the coordinate errors and the way of superposition. Both reaction centers were superimposed with the program O (Jones et al., 1991) using only $C\alpha$ atoms of the L, M, and H subunits. The relative centers of mass of the ring systems of the cofactors relative to the polypeptide chain are displaced by less than 1 Å.

The arrangement of the bacteriochlorophyll monomers D_A and D_B may be slightly different in both reaction centers (Ermler et al., 1994). In projection, the overlapping area of the two pyrrole

Fig. 1. (See Color Plate 7A) The photosynthetic reaction center from *Rp. viridis*. The protein subunits are depicted in form of a smoothed ribbon diagram with the C subunit in green, the L subunit in brown, the M subunit in blue, and the H subunit in purple. The cofactors are represented as atomic models with carbon atoms in yellow, nitrogen atoms in blue, oxygen atoms in red, and magnesium and iron atoms in grey. Figs. 1, 2, 10, and 11 were generated with the computer program package O (Jones et al., 1991).

rings I of D_A and D_B is slightly larger in the reaction center from *Rp. viridis* than in that from *Rb. sphaeroides*. Furthermore, the distance between the pyrrole rings I of D_A and D_B is 3.4 Å in *Rb. sphaeroides* and 3.2 Å in *Rp. viridis*.

The accessory bacteriochlorophyll molecule B_B of the B-branch in the *Rb. sphaeroides* reaction center seems to be located closer to the periplasmic side than in the *Rp. viridis* reaction center. Consequently,

Fig. 2. (See Color Plate 7B) Superposition of the reaction center cofactors from *Rp. viridis* (green) and *Rb. sphaeroides* (red). The phytol side chains of the bacteriochlorophyll and bacteriopheophytin molecules have been omitted for the sake of clarity.

in the *Rb. sphaeroides* reaction center the distance between the centers of D_B and B_B is 0.6 Å shorter, between the centers of B_B and ϕ_B 0.5 Å larger. The Q_B position is shifted substantially and is located about 3.5 Å further away from Q_A when compared to the reaction center from *Rp. viridis* and the older *Rb. sphaeroides* reaction center structures.

A nearly perfect agreement between both reaction centers is obtained when the deviation angles from the twofold axis for the cofactors of the A- and B-branch are compared (Michel and Deisenhofer, 1989; Ermler et al., 1994). An optimal superposition of D_A and D_B is obtained by a rotation of 179.7° in the *Rp. viridis* reaction center and 177.9° in the *Rb. sphaeroides* reaction center, of B_A and B_B by a rotation of -175.8° and -176.8°, respectively, and of ϕ_A and ϕ_B by a rotation of -173.2° and -171.9°, respectively.

Large conformational differences between both reaction centers are found for the phytol side chains of the cofactors, particularly along the B branch. The arrangements of the phytol side chains in the A and B branches deviate from the local twofold symmetry. This might be partially due to the carotenoid molecule

attached to the B branch. In both species the crystallographic temperature factors, which are a measure for the rigidity of the structure, are considerably higher along the B branch than along the A branch.

IV. The Structure of the Protein Subunits

A. The L Subunit

The structures of the L subunits of the reaction centers from *Rp. viridis* and *Rb. sphaeroides* are shown in Fig. 3 in the form of $C\alpha$ -traces. The dominant features are the five long membrane-spanning helices (A-E). They possess a length of 21 (helix A), 24 (helices C and E) or 28 (helices B and D) residues. The segments connecting the transmembrane helices and the C-terminus are also partly helical. On the periplasmic side, the connection of transmembrane helices C and D contains a helix with eleven residues, and the C-terminal stretch one of 9 residues. On the cytoplasmic side, the connection of transmembrane helices D and E contains a helix of 12 residues which partly intrudes into the membrane. This region of the structure forms the binding site of the secondary

electron acceptor Q_B , which is also shown. On the cytoplasmic side, the L and M subunits are tightly interwoven. In projection, viewed from the top of the membrane, the transmembrane helices A-E form a half circle, in the order A,B,C,E and D. Polar interactions between transmembrane helices seem to be weak, there are only up to two hydrogen bonds per pair of helices. The cytoplasmic ends of the transmembrane helices frequently contain charged residues. Transmembrane helix A is an exception which starts with a Phe-Phe pair already in the hydrophobic part of the membrane. Transmembrane helices A, B and D are straight, helix E is smoothly curved, and helix C possesses a kink of more than 30° which is due to a Pro residue. However, helix C contains another Pro which does not lead to such a kink, but to only minor distortions from the regular helix geometry. On the periplasmic side there is an excess of negatively charged residues, on the cytoplasmic side of positively charged residues, leading to a permanent electric dipole moment across the membrane. When the L subunits from *Rp. viridis* and *Rb. sphaeroides* are compared, an additional 8 amino acids are found at the C-terminus in *Rb. sphaeroides*.

Fig. 3. Stereo pair of the $C\alpha$ -traces of the *Rp. viridis* (thin black line) and the *Rb. sphaeroides* (thick grey line) L subunits and the Q_B molecules of *Rp. viridis* (black) and *Rb. sphaeroides* (grey). The letters 'A' to 'E' designate the five transmembrane helices. Figures 3 to 9 and Fig. 12 were made with the computer program MOLSCRIPT (Kraulis, 1991).

Fig. 4. Stereo pair of the C α -traces of the *Rp. viridis* (thin black line) and the *Rb. sphaeroides* (thick grey line) M subunits and the Q_A molecules of *Rp. viridis* (black) and *Rb. sphaeroides* (grey). The labels refer to *Rp. viridis* residues.

B. The M Subunit

In a similar way the peptide chains of the M subunits of the reaction centers from *Rp. viridis* and *Rb. sphaeroides* are displayed in Fig. 4. As indicated already by the sequence identity of around 30% between the L and M subunits the overall protein fold is very similar. In *Rp. viridis* the five transmembrane helices of the M subunit possess a length of 24 (C), 25 (A, E), 26 (D) or 27 (B) residues. The short helices in the connections of transmembrane helices C and D (12 residues) near the C-terminus (7 residues) on the periplasmic side, and in the connection of the helices D and E (14 residues), forming part of the Q_A-binding site, are also present. Accompanied by an insertion of seven amino acids (compared to the L subunits) each, short additional helices are formed in the connections of transmembrane helices A and B (7 residues) on the periplasmic side, and of transmembrane helices D and E (6 residues) on the cytoplasmic side. Much of what has been said for the L subunit is also valid for the M subunit: Transmembrane helices A, B and D are straight, E is curved and C contains a kink due to a Pro-residue. Negatively charged side chains dominate on the periplasmic side, positively charged ones on the cytoplasmic side. When the L and M subunits are compared the N-termini of the M subunits

are 26 (*Rp. viridis*) or 25 (*Rb. sphaeroides*) residues longer than the N-termini of the L subunits. At the C-terminus the M subunit from *Rb. sphaeroides* is 9 amino acids shorter than the L subunit. The C-terminus of the M subunit from *Rp. viridis* possesses an additional 18 amino acids, which interact with the cytochrome subunit (see also Fig. 1). The M subunit from *Rb. sphaeroides* compared to that from *Rp. viridis* contains an insertion of one residue after amino acid M38, and another one after residue M104 (*Rp. viridis* numbering), so that the equivalent residue between residues M38 and M104 (*Rp. viridis* numbering) differ by one number and beyond M104 by two numbers (see Michel et al., 1986a).

C. The H Subunit

The H subunits from *Rp. viridis* and *Rb. sphaeroides* possess a sequence identity of 39% only with several insertions and deletions (Williams et al., 1986). Nevertheless, the protein fold is very similar with the exception of several loop regions as can be seen in Fig. 5. The N-terminus is located on the periplasmic side of the membrane. Residues H12 to H35 form a membrane-spanning helix, which is an α -helix at its beginning but a π -helix at its very end. Around the C-terminus of the helix a cluster of seven charged residues is found in *Rp. viridis* (residues H33-H39),

Fig. 5. Stereo pair of the Ca-traces of the *Rp. viridis* (thin black line) and the *Rb. sphaeroides* (thick grey line) H subunits. The labels refer to *Rp. viridis* residues. Residues H47 to H53 of the *Rp. viridis* H subunit are not observed in the electron density and no statement regarding their position is made. This region on the right of the figure is nevertheless included in order to facilitate chain tracing.

but of only three in *Rb. sphaeroides* (residues H34, H37, H38). The next 70 residues are preferentially in contact with the LM complex. A globular region follows that contains an extended system of antiparallel and parallel β -sheets, and an α -helix close to the C-terminus. The β -sheets form a pocket which is lined with hydrophobic amino acid residues. The significance of this pocket is unclear.

The function of the H subunit is not well defined at present. It is not involved in pigment binding. Its cytoplasmic domain helps to shield the Q_A -binding site from contact with the cytoplasm. Several glutamic acid residues of the H subunit line up the channel of bound water molecules that leads to the Q_B -binding site (see below). There is also some evidence that the H subunit is involved in the assembly of the reaction center (Chory et al., 1984). It may form a matrix for the sequential assembly of the reaction center components. However, there is no evidence for the presence of an H subunit in the green aerobic bacterium *Cf. aurantiacus*.

D. The Cytochrome Subunit

As mentioned in the introduction the reaction centers from most purple bacteria do possess a bound cytochrome subunit containing four covalently bound heme groups (see Chapter 36 by Nitschke and Dracheva). This is not the case for the reaction

centers from the most frequently studied species *Rb. sphaeroides*, *Rb. capsulatus*, and *Rhodospirillum (Rs.) rubrum*, which also can grow very well under aerobic conditions. The amino acid sequences are known for the cytochrome subunits from *Rp. viridis* (Weyer et al., 1987b), from *Rhodocyclus (Rc.) gelatinosus*, now called *Rubrivivax gelatinosus* (Nagashima et al., 1993, 1994), and from the green aerobic bacterium *Cf. aurantiacus* (Dracheva et al., 1991). Only in *Rp. viridis* the cytochrome subunit is so firmly bound to the reaction center, that it is also present in the isolated reaction center. A recognition site for the covalent attachment of a diglyceride and removal of the signal peptide by signal peptidase II is present in *Rp. viridis* and *Rc. gelatinosus*, but not in *Cf. aurantiacus*.

The structure of the cytochrome subunit from the *Rp. viridis* reaction center has been described in detail (Deisenhofer et al., 1995). It consists of five segments. The N-terminal segment (residues C1-C66) from the Cys-residue with the attached diglyceride, to the beginning of the first heme binding segment (at the top of the reaction center) with the binding sites for heme 1 and heme 2 (see Figs. 1,2,6). This first segment contains two strands of antiparallel β -sheet parallel to the membrane surface followed by an α -helix (residues C25-C34) and irregular secondary structure. The first heme binding segment (residues C67-C142) with the binding sites for heme

Fig. 6. The C subunit of the *Rp. viridis* reaction center. The protein backbone is shown in a smoothed ribbon diagram, the cofactor heme groups are displayed as atomic models.

1 and heme 2 is followed by a connecting segment (residues C143-C225) with little regular secondary structure. This connecting segment comprises around 60% of the contact surface with the M subunit. Then the second heme binding segment with the binding sites for heme 3 and heme 4 (residues C226-C315), and the C-terminal segment (residues C316-C336) follow. The heme binding segments and their attached heme groups are related by local twofold symmetry.

The hemes and the heme-binding segments make up the core of the cytochrome subunit. Each heme-binding site consists of an α -helix that runs parallel to the heme plane, a loop and the heme attachment site with the sequence Cys-X-Y-Cys-His. The Cys-residues form thioether bonds with the heme groups, the His is the fifth ligand to the heme iron. The Met residues C74, C110 and C233 in the parallel helices are the sixth ligands to hemes 1, 2 and 3, the sixth ligand to heme 4 is His C124, which is located in the loop region of the heme 2 binding site.

The redox midpoint potentials of the four heme groups follow the order low, high, high, low in the sequence, or high, low, high, low if the hemes are ordered with increasing distance (see Fig. 2) from the primary electron donor (Shopes et al., 1987; Alegria and Dutton, 1987; Dracheva et al., 1988; Fritsch et al., 1989; Vermeglio et al., 1989; Shinkarev et al., 1990). Heme 3, closest to the primary electron donor has the highest redox potential (370 mV), heme 4 has 10 mV, heme 2 has 300 mV, and heme 1, the most distant one, has -60 mV. A recent theoretical investigation (Gunner and Honig, 1991) taking into account the different solvent exposures of the heme groups, the electrostatic effects of the protein environment and the heme arrangement reproduced the experimentally determined redox potentials with reasonable accuracy. The function of the alternate spatial order of high and low potential heme groups is unknown. Under physiological conditions of cyclic electron flow, only the high potential hemes are

reduced. It is most likely heme 2, the second from the top (see Fig. 2), which is reduced by a water soluble cytochrome c_2 . It transfers its electron to heme 3, from where the photooxidized primary electron donor is re-reduced.

V. Cofactor Conformation and Protein-Cofactor Interactions

A. The Primary Electron Donor

The primary electron donor ('special pair') is located at the interface of the L and M subunits near the periplasmic side (see Figs. 1 and 7). It interacts with residues of the C, D and E transmembrane helices and the connections of the C and D helices. The special pair bacteriochlorophylls D_A and D_B in both species are held in their position by specific interactions with the protein matrix (Fig. 7). The N ϵ atoms of His L173 and His M200 (M202 in *Rb. sphaeroides*) bind strongly to the central Mg atoms with distances of 1.9–2.3 Å in both species. The ring I acetyl group of D_A is hydrogen bonded to His L168 in the *Rb. sphaeroides* (3.2 Å) as well as in the *Rp. viridis* reaction center (2.8 Å), in contrast to an earlier publication (Yeates et al., 1988). The symmetry-related amino acid residue near D_B is Phe M197 in *Rb. sphaeroides*. Thus, no hydrogen bond can be formed. In *Rp. viridis* it is Tyr M195 forming a hydrogen bond (3.0 Å) with the acetyl carbonyl oxygen of ring I. Thr L248 forms a hydrogen bond (2.6 Å) with the ring V keto carbonyl of D_A in *Rp. viridis*. It is absent in *Rb. sphaeroides*. Neither the ester nor the keto carbonyl oxygens of ring V from D_B undergo polar interactions with the polypeptide chain in the *Rb. sphaeroides* reaction center, in contrast to published results (El Kabbani et al., 1991).

Substantial conformational differences between both reaction centers are found around rings V of D_A and D_B . In *Rp. viridis* ring V is bent towards Thr L248 (Fig. 7), whereas it is oriented into the opposite direction in *Rb. sphaeroides*. This difference is presumably due to the presence of bulky side chains on opposite sides of D_A in *Rp. viridis* and in *Rb. sphaeroides* (Ermler et al., 1994). Met L127 in *Rp. viridis* corresponds to a smaller Ala in *Rb. sphaeroides* on one side. *Vice versa* Gly L247 and Thr L248 in *Rp. viridis* are replaced by the larger Cys L247 and Met L248 in *Rb. sphaeroides* on the other side. Similar but less pronounced conformational differences are also seen at ring V of D_B .

B. The Accessory Bacteriochlorophylls

The accessory bacteriochlorophylls B_A and B_B are located between D_A and D_B and the bacterio-*pheophytins* ϕ_A and ϕ_B respectively and are in van der Waals contacts with both. Although the intermediate position and the favorable redox properties of B_A suggest a direct role as very first electron acceptor (Zinth and Kaiser, 1993) its role is still under discussion (Kirmaier and Holten, 1993; also see Chapter 24 by Woodbury and Allen in this volume).

Significant conformational differences between the reaction centers from *Rp. viridis* and *Rb. sphaeroides* are only found at the ethyl groups of ring II (see Fig. 7) caused by the structural difference between the ethyl group of bacteriochlorophyll *a* and the ethylidene group of bacteriochlorophyll *b*. The polar interactions with the protein matrix are symmetric and identical in both reaction centers. The N ϵ atoms of His L153 (distance 2.2 Å in *Rp. viridis*, 2.3 Å in *Rb. sphaeroides*) and His M180 (182) (2.1 Å in *Rp. viridis*, 2.2 Å in *Rb. sphaeroides*) are the ligands to the central Mg atoms. The N δ atom of His L153 is hydrogen bonded to the peptide carbonyl oxygens of Gly L149 and Ile L150. This kind of interaction between the Mg²⁺ and His L153 was not observed in one of the published *Rb. sphaeroides* reaction center structures (Yeates et al., 1988). In both reaction centers the ring V carbonyl oxygen atoms are hydrogen bonded via a water molecule to His L173 and His M200(M202) respectively. In contrast to earlier studies on the orthorhombic crystal forms of the *Rb. sphaeroides* reaction center (Yeates et al., 1988; El-Kabbani et al., 1991) the hydroxyl group of Ser L178 is at 4.3 Å too far away from the ester carbonyl oxygen to form a hydrogen bond.

The carotenoid molecule makes van der Waals contacts with B_B and with hydrophobic residues of the helices A, B, C and the connection of helices C and D. The carotenoid molecule possesses a kinked conformation with its conjugated π -system parallel to the membrane. The kink can be caused by a *cis* bond in position 13 or 15. A definite assignment has to await refinement at higher resolution. A 13 *cis* bond would contradict the results obtained by Raman spectroscopy (Arnoux et al., 1989; deGroot et al., 1992) which indicates a *cis* bond at position 15.

The carotenoid protects the reaction center against photooxidation by quenching triplet states of the primary electron donor. Its proximity to B_B suggests that the energy transfer from the triplet state of the primary electron donor occurs via B_B as proposed

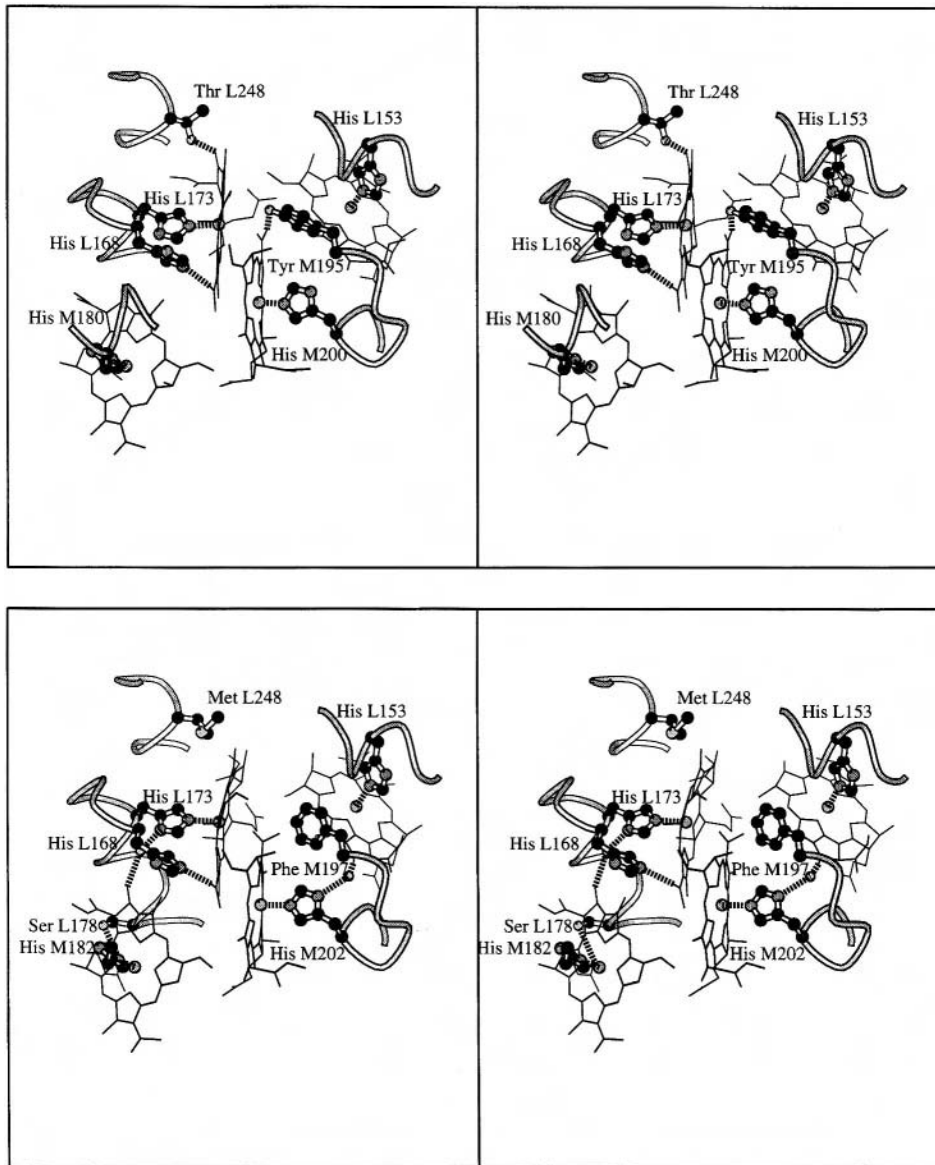

Fig. 7. Stereo pairs of the regions of the special pair and the accessory bacteriochlorophyll molecules of *Rp. viridis* (top) and *Rb. sphaeroides* (bottom). Hydrogen bonds and ligand binding Mg-His are indicated by thick dashed lines.

from spectroscopic measurements (Schenck et al., 1984).

C. The Bacteriopheophytins

Figure 8 shows for both reaction centers the location of the bacteriopheophytin ϕ_A between B_A and Q_A . At the top Tyr M208(M210) seems to be of importance since it is in van der Waals contact with D_B , D_A and B_A . The conformations of ϕ_A and ϕ_B are identical in both reaction centers except at the side chains of

pyrrole rings II due to the chemical difference of the ethyl and ethylidene side chains. The pattern of hydrogen bonds formed by ϕ_A and ϕ_B with the protein matrix is identical in both species. Trp L100 and TrpM127 (129) respectively form a hydrogen bond with the ester carbonyls of ring V of ϕ_A (3.0 Å in *Rp. viridis*, 2.8 Å in *Rb. sphaeroides*) and ϕ_B (2.7 Å in *Rp. viridis*, 2.8 Å in *Rb. sphaeroides*) respectively (Michel et al., 1986b, Ermler et al., 1994). The carboxyl group of Glu L104 is probably in the protonated state and forms a short hydrogen bond (2.7 Å) to the ring

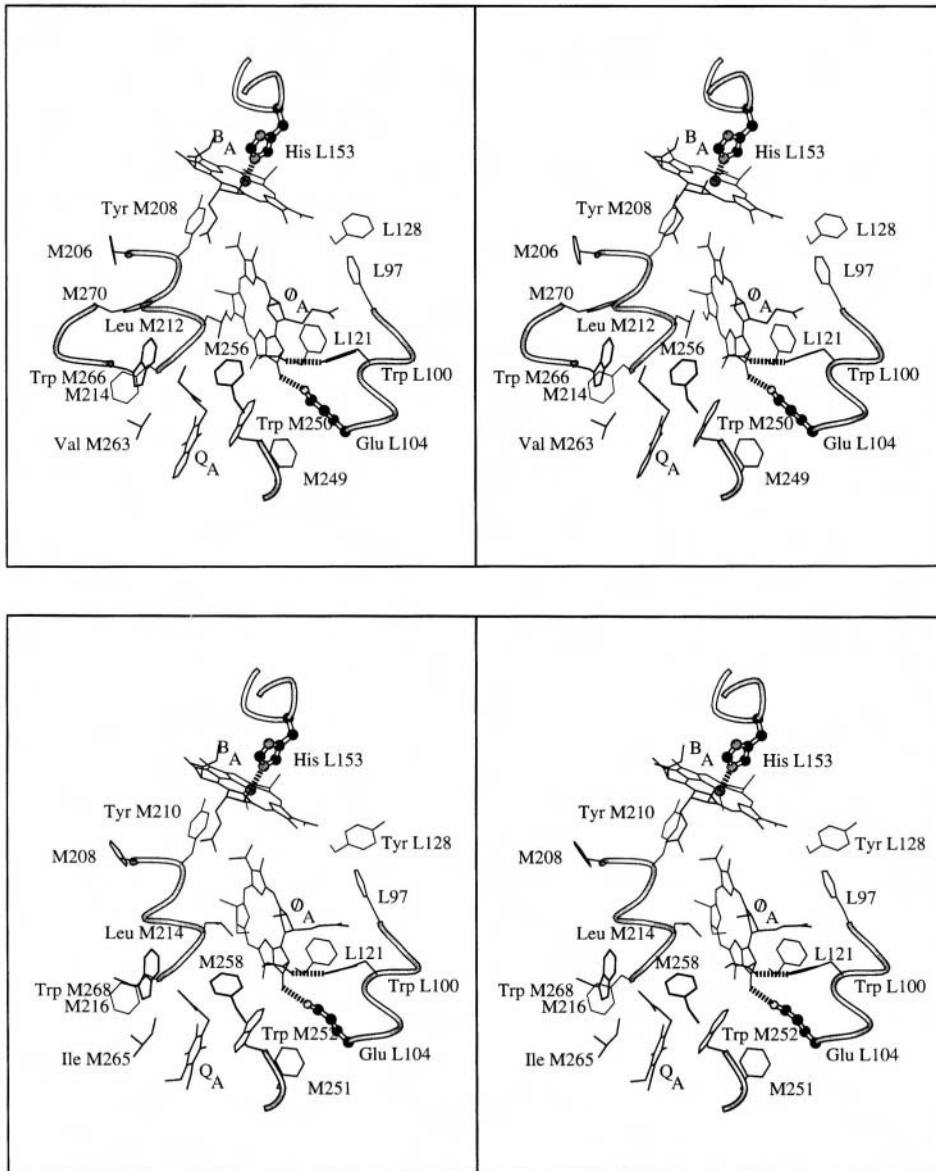

Fig. 8. Stereo pairs of the regions of the bacteriopheophytin molecules ϕ_A of *Rp. viridis* (top) and *Rb. sphaeroides* (bottom), respectively. Hydrogen bonds and ligand binding Mg-His are indicated by thick dashed lines. Not all of the phenylalanine residues in these regions are displayed for reasons of clarity. The phenylalanine residues are labeled by chain designator and residue number only.

V keto carbonyl in both reaction centers. No such hydrogen bond is found for ϕ_B . Replacement of Glu L104 by neutral amino acids in *Rb. capsulatus*, which is closely related to *Rb. sphaeroides*, influences the spectral properties of the reaction center, but only scarcely the dynamics and directionality of the electron transfer (Bylina et al., 1988). In the M subunit of the *Rb. sphaeroides* reaction center the residue corresponding to Glu L104 is Thr M131. In

contrast to the results from the orthorhombic crystal forms (Yeates et al., 1988; El-Kabbani et al., 1991) the hydroxyl group of Thr M131 is at 3.9 Å too far away from the ring V carbonyl group to form a hydrogen bond. The bacteriopheophytin ϕ_A is surrounded by an astonishing number of phenylalanine residues (see Fig. 8). These bulky residues may contribute to the rigidity of the structure in the environment of ϕ_A . Around ϕ_B they are replaced to a

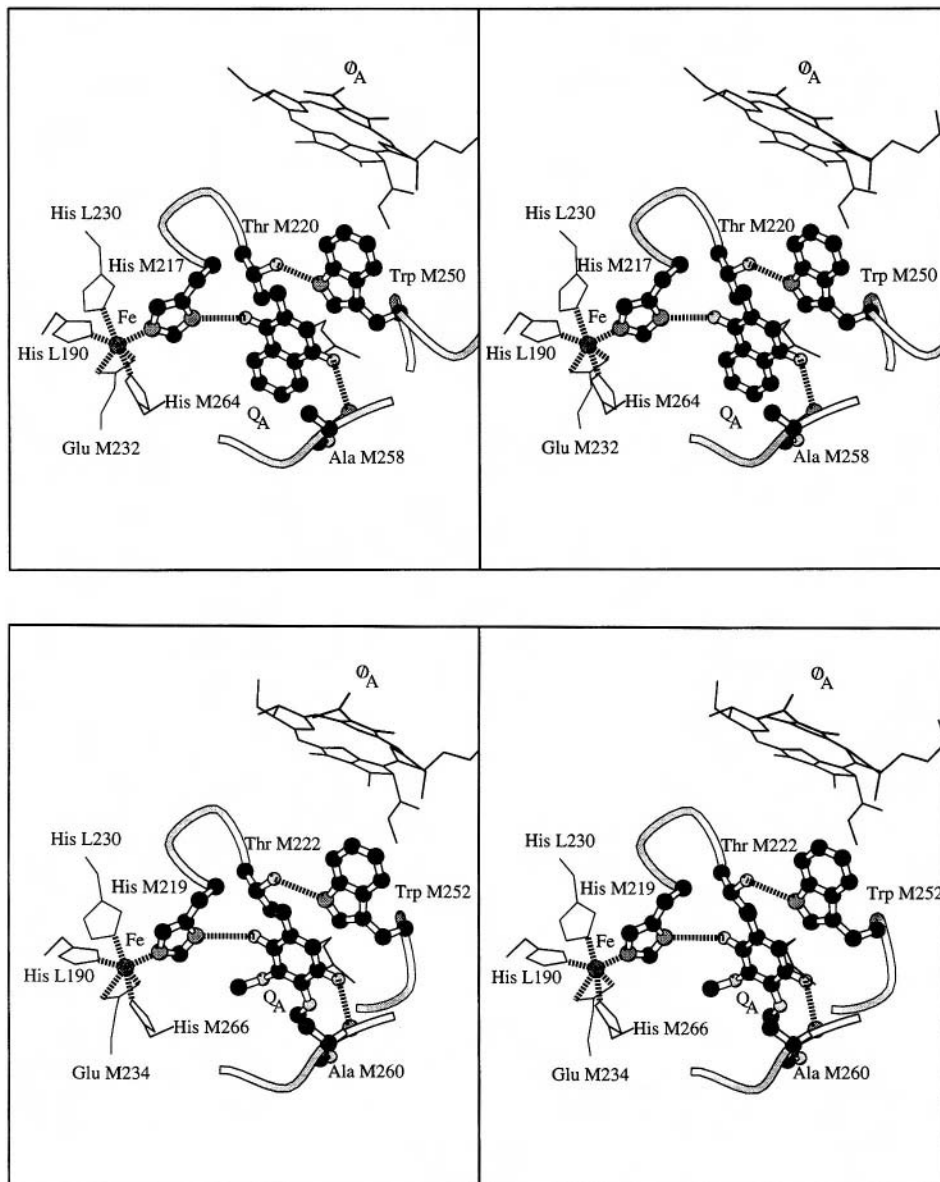

Fig. 9. Stereo pairs of the regions of the Q_A molecules and non-heme iron atoms of *Rp. viridis* (top) and *Rb. sphaeroides* (bottom), respectively.

large extend by smaller amino acid residues. As seen in Figs. 8 and 9 Trp M250(M252) with its large aromatic side chain bridges the gap between ϕ_A and Q_A in both reaction centers. In the symmetry-related position a phenylalanine is found. This observation implies a role for Trp M250(M252) in the electron transfer from ϕ_A to Q_A . A 'superexchange mechanism' has been postulated for the electron transfer from ϕ_A to Q_B with Trp M250(M252) as superexchange mediator (Plato et al., 1989).

D. The Primary Electron Acceptor Q_A and the Non-Heme Iron

Figure 9 shows the binding site of the first quinone Q_A for both reaction centers. Q_A is located on the A side where the L subunit dominates, but the quinone ring system exclusively interacts with residues of the M subunit. The Q_A -binding site clearly is more hydrophobic than the Q_B -binding site. A major part of the Q_A -binding site is made up by Trp M250-

(M252). The ring systems of the tryptophan and Q_A are parallel. Trp M250(M252) forms a hydrogen bond with Thr M220(M222). The structural difference between the menaquinone as Q_A in *Rp. viridis* and the ubiquinone as Q_A in *Rb. sphaeroides* causes only minor rearrangements of the Q_A -binding site, which are not shown in Fig. 9 for clarity.

In both species Q_A interacts with the protein surrounding in the same way. The first quinone oxygen atom is hydrogen bonded to the side chain of His M217(M219) (distance 3.1 Å in *Rp. viridis* and 3.2 Å in *Rb. sphaeroides*), the second one to the peptide nitrogen of the M258(M260) (distance 3.1 Å in *Rp. viridis* and 2.8 Å in *Rb. sphaeroides*). A shorter bond length for one hydrogen bond would be consistent with the finding that one carbonyl group is dominant for Q_A binding (Warncke and Dutton, 1993). Earlier studies on the orthorhombic crystal form (Allen et al., 1988, El-Kabbani et al., 1991) of the *Rb. sphaeroides* reaction center indicated a hydrogen bond between the first quinone oxygen and Thr M222. This result is excluded on the basis of the analysis of the trigonal crystal form.

His M217(M219) is one of four histidine ligands to the non-heme iron (Fig. 9), His M264(M266), His L190 and His L230 are the other three. Glu M232(M234) is a bidentate ligand to the non-heme iron. Both oxygen atoms are in contact with the iron. As a result the ligands to the non-heme iron form a distorted octahedron in both reaction centers. In the region around the iron both reaction centers can be superimposed with an rms deviation of better than 0.5 Å. Despite this hint about the importance of the non-heme iron, its role remains an enigma.

E. The Secondary Electron Acceptor Q_B

The binding site of the secondary acceptor quinone Q_B is formed exclusively by residues of the L subunit. In particular, it involves residues of the transmembrane helices D (L189, L190, L193) and E (L226, L229, L232), of the connecting helix DE (L212, L213, L216) and of the loop region connecting the latter two helices (L222–L225). The profile of the pocket is conserved in all characterized reaction center structures. Q_B in the *Rb. sphaeroides* model based on the trigonal crystal form (1PCR) is displaced by approximately 5 Å from the other Q_B models (cf. Fig. 10) and displays high isotropic temperature factors (Ermler et al., 1994). It is mostly omitted from the following comparative discussion, because

it seems likely that this Q_B site contains the quinol and not the quinone. Since it combines the requirements of high quinone occupancy and a sufficiently high $n_{\text{obs}}/n_{\text{par}}$ ratio (cf. Table 1), the structure of the ubiquinone-2-reconstituted *Rp. viridis* reaction center complex (Q282) will be used as a guideline for the following discussion of the Q_B site.

The proximal carbonyl oxygen of Q_B , i.e. the one closer to the non-heme iron, accepts a hydrogen bond from the N δ atom of His L190, whereas the distal carbonyl oxygen accepts two hydrogen bonds from the peptide nitrogens of Ile L224 and Gly L225. The side chain O γ of Ser L223 is also within hydrogen-bonding distance of the distal carbonyl oxygen and was originally inferred to donate a hydrogen bond to the quinone carbonyl (Deisenhofer and Michel, 1989). However, in the refined quinone-reconstituted structure, the O γ of Ser L223 donates a hydrogen bond to the side chain O δ of Asn L213 (cf. Fig. 10). In the absence of a hydrogen bond, the presence of the Ser L223 O γ so close to the distal carbonyl oxygen is electrostatically unfavorable for quinone binding. This finding explains the observed 9-fold increase in quinone affinity for the *Rp. viridis* mutant T1, where one of the mutations is Ser L223 \rightarrow Ala (Sinning et al., 1989). While not favorable for quinone binding, the close association of the two oxygen atoms is compatible with the importance of Ser L223 in stabilizing the reduced quinone and for efficient proton donation to Q_B as demonstrated for the *Rp. viridis* reaction center by Leibl et al. (1993) and for the *Rb. sphaeroides* reaction center by Paddock et al. (1990). Apart from this new insight regarding the role of Ser L223, the hydrogen-bonding pattern is similar in the structures 1PCR, 4RCR, and 1PSS (cf. Fig. 10 and Table 2), although in the latter structure the hydrogen bond between Gly L225 N and the distal carbonyl oxygen is lost. The displacement of the Q_B model in the 1PCR structure has already been discussed. In the 2RCR structure, the quinone ring plane is oriented nearly perpendicular (65°–80°) to the other Q_B rings.

As Trp M250 (M252 in the *Rb. sphaeroides* reaction center) for Q_A , Phe L216 forms a significant part of the Q_B -binding pocket. In the ubiquinone-2-reconstituted structure Q282, the ring planes of Phe L216 and Q_B are approximately parallel, with an angle between the two planes of only 5.6° (cf. Table 3). The distance between the two planes is approximately 3.5 Å. However, as the rings are displaced in the planes (cf. Fig. 10), the centroid-to-centroid distance

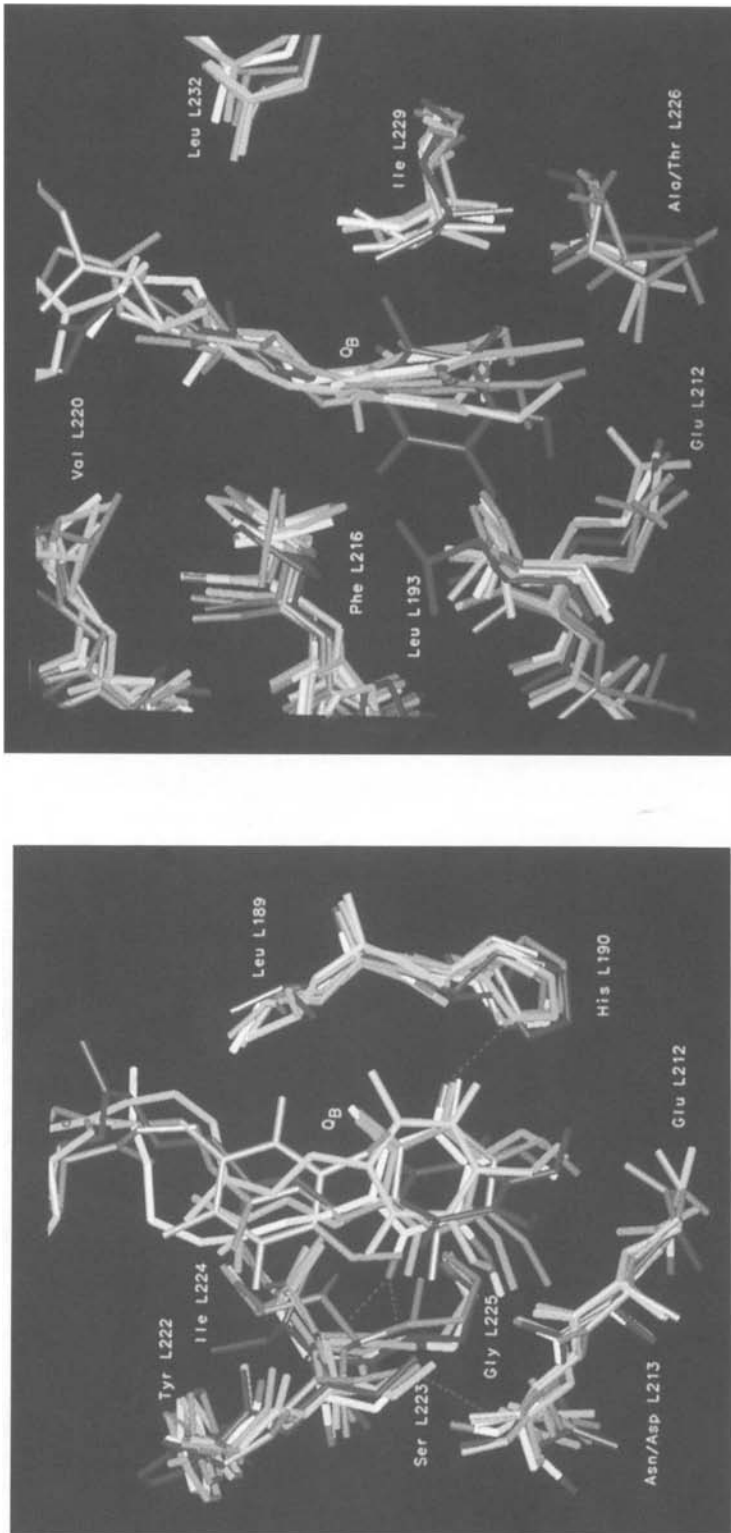

Fig. 10. (See Color Plate 8) Orthogonal views of the Q_B site: Six different structures are superimposed. The color coding is as follows: Q_{B282} (multi-colored: carbon atoms are yellow; nitrogen atoms are blue, oxygen atoms are red), $1PCR$ (green), $2RCR$ (dark blue), $4RCR$ (brown), $1PSS$ (light blue) and $1PCR$ (purple). The dashed red lines indicate hydrogen bonds in the Q_{B282} structure.

Table 2. Distances Between Prospective H-Bonding Donors and Acceptors in the Q_B-site

Donor	Acceptor	Structure				
		<i>Rp. viridis</i>		<i>Rb. sphaeroides</i>		
		Q282	1PRC	2RCR	4RCR	1PSS
His L190 δN	Q _B O2*	2.7	2.7	2.9	2.6	2.8
His L190 δN	Q _B O3*	3.3	3.0	(4.0)	3.4	(4.3)
Ser L223 γO	Q _B O5*	2.9	2.7	3.0	2.7	3.4
Ile L224 N	Q _B O5*	3.1	3.2	(5.2)	3.3	3.0
Gly L225 N	Q _B O5*	3.0	2.7	(5.5)	3.3	(5.5)

* O2 = proximal carbonyl oxygen; O3 = proximal methoxy oxygen; O5 = distal carbonyl oxygen

Distances in parentheses are too long for hydrogen-bonding interactions

Table 3. Angles Between Phe L216 and Q_B ring planes

Structure	Q282	1PRC	2RCR	4RCR	1PSS
Angle between planes	5.6°	12.9°	68.4°	78.7°	22.1°

of 5.3 Å is significantly larger. The importance of Phe L216 for quinone binding is illustrated by a reduced affinity for quinone in a PheL216 →Ser *Rp. viridis* mutant. (Sinning et al., 1989). The most striking discrepancy concerning the Phe L216 residues of the other structures (cf. Fig. 10) is the 60°–70° plane deviation in the 4RCR structure.

A major difference between the binding sites of Q_A and Q_B is the presence of protonable residues at the Q_B site. Some evidence has been provided for the residues Glu L212, Asp L213 (in *Rb. sphaeroides*, Asp M43 in *Rp. viridis*), and Ser L223 to be involved in the transfer of protons to Q_B (Paddock et al., 1990; Takahashi and Wraight, 1992; Leibl et al., 1993; Rongey et al., 1993). Glu L212 forms a large part of the bottom of the Q_B site. A major difference in the orientation of the Glu L212 side chain is observed between the fully occupied quinone-reconstituted structure (Q282) and the original structure with 30% Q_B occupancy (1PRC). In this region, the latter structure is similar to a quinone-depleted structure (Lancaster and Michel, unpublished), in which one of the water molecules replacing the quinone is hydrogen-bonded to Glu L212. This seems to indicate that the 70% Q_B-depleted reaction centers in the 1PRC crystals dominate this part of the structure.

The side chain of Tyr L222 has an indirect effect on Q_B binding, as is illustrated by the reduced Q_B affinity of a Tyr L222 →Phe *Rp. viridis* mutant (Sinning et al., 1989). The nature of this indirect effect and the structural consequences of the mutation are discussed below (cf. Section VI).

The residues Leu L189, Leu L193, Val L220, Ala/

Thr L226, Ile L229, and Leu L232 form a large part of the Q_B-binding pocket (cf. Fig. 10). The importance of some of these residues for Q_B binding has been demonstrated by the characteristics of the following mutants. A Val L220 →Leu mutation in *Rp. viridis* (with a second-site mutation ArgL217 →His) reduces the affinity for Q_B by a factor of eight (Ewald, 1992). A mutation of Thr L226 →Ala in *Rb. capsulatus* (i.e. from the residue also present in *Rb. sphaeroides* to the one present in the *Rp. viridis* reaction center) leads to a threefold increase in the affinity for Q_B (Baciou et al., 1993). An Ile L229 →Ser mutant of *Rb. capsulatus* (Baciou et al., 1993) and an Ile L229 →Met mutant of *Rb. sphaeroides* (Paddock et al., 1988) both display a reduced affinity for Q_B. The only major discrepancy among the different structures regarding these residues is observed for the side chain of Leu L193 (cf. Fig. 10) in the 2RCR structure. This is a consequence of the large deviation of the Q_B molecule in this structure compared to the others.

In summary, the improved model of the *Rp. viridis* Q_B site displays only small but important differences to the original (1PRC) model. In particular, this applies to the hydrogen bonding of the quinone and the role of Ser L223. The discrepancies between the four *Rb. sphaeroides* Q_B sites are substantially greater than those between the two *Rp. viridis* Q_B site models. The 1PCR Q_B is most likely reduced, but the discrepancies among the other *Rb. sphaeroides* structures underline the requirement for more and higher resolution data in order to resolve ambiguities. These could be resolved by additional measurements on the new trigonal crystal form. Considering the

conservation of the overall profile of the Q_B site between *Rp. viridis* and *Rb. sphaeroides*, it may well turn out that the Q_B sites are more similar than can presently be discussed.

F. The 'Water Chain' to the Q_B Site

The Q_B site is deeply buried within the reaction center complex. For the protonation of Q_B associated with its reduction to quinol, protons must therefore be transferred from the cytoplasm through the protein to the Q_B site. This is likely to involve protonatable residues together with water molecules. The protons may move along a chain of proton donors and acceptors connected by hydrogen bonds. In both *Rp. viridis* reaction center structures considered (1PRC and Q282) and the *Rb. sphaeroides* reaction center structure based on the trigonal crystal form (1PCR), chains of water molecules from the cytoplasmic surface to the Q_B site are found. Most of them are in hydrogen bonding distance to one another (Fig. 11). Surprisingly, more water molecules can be observed in the case of the *Rb. sphaeroides* structure than for the *Rp. viridis* structures, even though the latter are based on higher resolution data. The water molecules are in extensive contact with mainly protonatable amino acid residues. Only in the *Rb. sphaeroides* structure is the row of water molecules uninterrupted over a length of 23 Å from the cytoplasmic surface to the Q_B molecule. In the *Rp. viridis* structures, 'detours' via protonatable amino acid residues must be taken in order to establish an uninterrupted chain.

At least some of the protonatable residues lining the 'water chain' have been shown to be functionally relevant for the proton transfer process. Based on the spectroscopic analysis of site-specific mutants (reviewed by Okamura and Feher, 1992; chapter in this volume) it was suggested that the first proton to Q_B is transferred in the reaction center of *Rb. sphaeroides* via Asp L213 and Ser L223, the second via Asp L213 and Glu L212. In *Rp. viridis*, residue L213 is an asparagine. However, its role can apparently be complemented (Rongey et al., 1993) by Asp M43 (which is Asn M44 in *Rb. sphaeroides*). In the *Rp. viridis* structures, Asp M43 and Glu L212 are within hydrogen-bonding distance to members of the 'water chain', whereas in the *Rb. sphaeroides* this is the case for Glu L212, but not for Asp L213. Another residue shown to be functionally relevant to the proton transfer process is Arg M231 (M233 in *Rb. sphaeroides*), as observed in the case of

photocompetent revertants of mutants incapable of proton transfer. Exchanging Arg M233 to cysteine in *Rb. sphaeroides* (Okamura et al., 1992) and Arg M231 to leucine in *Rb. capsulatus* (Hanson et al., 1993) restores the photosynthetic activity to a level similar to that of the wild type. In *Rp. viridis*, Arg M231 forms salt bridges to Asp H125 and Glu H235, in *Rb. sphaeroides*, Arg M233 interacts with the corresponding residues Glu H122 and Glu H230. In the *Rb. sphaeroides* reaction center, Glu H122 directly interacts with water molecules of the water chain. In the *Rp. viridis* reaction center, this applies to both Asp H125 and Arg M231 itself. On the other hand other residues, such as Glu H173 (Takahashi unpubl., cited by Shinkarev and Wraight, 1993) and Asp L210 (Paddock et al., 1992) in *Rb. sphaeroides*, corresponding to Glu H177 and Glu L210 in *Rp. viridis*, are possibly nonobligatory participants in the proton transfer pathways.

The many fixed water molecules observed in the 'water chain' may, however, solely be a consequence of the increased local polarity caused by a large number of charged residues. At present, there is no evidence for the use of this 'water chain' in proton transfer. It will be interesting to see whether an interruption of the 'water chain' is possible by site-directed mutagenesis and what effect this might have on the protonation of Q_B .

G. The Binding of Triazine Inhibitors to the Reaction Center

The Q_B site is also a well-established site of action of electron transfer inhibitors. Of particular interest in this respect are herbicides. Over 50% of commercially available herbicides function by inhibition of higher plants at the Q_B site on the D1 polypeptide of the photosystem II (PS II) reaction center (Percival and Baker, 1991). Many of them are triazines. The probably best available model to date in this reaction center is based on the X-ray structure of the reaction center from *Rp. viridis* (Michel and Deisenhofer, 1988). Although the triazine binding site has been localized by X-ray crystallographic analysis of the reaction center-terbutryn complex at 2.9 Å resolution (Michel et al., 1986b), description of the exact nature of the mode of binding and the effect of binding on the structure of the protein has to await the refinement of high resolution structures. The refined structure at 2.3 Å resolution of a *Rp. viridis* reaction center complex with the chiral atrazine derivative DG-

Fig. 11. (See also Color Plate 9) The 'water chain' from the cytoplasm to the Q_B site in the reaction centers of *Rp. viridis* (left) and *Rb. sphaeroides* (right), respectively. The protein backbones of the subunits are displayed in green, the water molecules and the protonatable amino acid residues lining the 'water chain'.

420314 (Lancaster and Michel, unpublished), has yielded a highly reliable model of triazine inhibitor binding based on over 100,000 unique reflections (cf. Table 1). Novel general principles of triazine class inhibitor binding include a tightly-bound water molecule involved in accepting a hydrogen bond from the N δ atom of His L190 and donating a second hydrogen bond to a nitrogen of the triazine ring (cf. Fig. 12). A second tightly-bound water molecule is involved in completing the hydrogen-bonding web with hydrogen bonds to the first water molecule and to the O ϵ of Glu L212. In addition, a subtle change is observed in the conformation of the loop region (L220–L226) connecting helices DE and E, bringing the backbone carbonyl oxygen of tyrosine L222 within hydrogen bonding distance of the triazine. Also shown in Fig. 12 are the two hydrogen bonds observed previously (Michel et al., 1986b) between the backbone N of Ile L224 and the N5 of the triazine ring and between the aminoethyl N and Ser L223 O γ , respectively. This means that the triazine molecule forms three hydrogen bonds with the protein on the distal side of the molecule and is only indirectly bound via water molecules on the proximal side. Finally, compared to the quinone-reconstituted complex of the reaction center, the aromatic ring of Phe L216 is reoriented by 18.2° to be aligned approximately parallel (with an angle between planes of 2.4°) to the plane of triazine ring, which is tilted by 14.5° compared to the quinone ring plane (Fig. 12).

VI. The Structure of Mutant Reaction Centers

Considering the importance of the photosynthetic reaction center it is not amazing that several groups have tried to establish systems for site-directed mutagenesis of photosynthetic reaction centers. Reviews of this recently developed field are already available (Coleman and Youvan, 1990; Diner et al., 1991). Work started with the photosynthetic reaction center from *Rb. capsulatus*, which is genetically very well characterized, and able to grow non-photosynthetically under aerobic conditions, as well as under anaerobic conditions using e.g. dimethylsulfoxide as electron acceptors. Most importantly, under these latter conditions the photosynthetic apparatus is fully induced. Unfortunately, the reaction center from *Rb. capsulatus* could not be crystallized, so that proper inspection for structural changes cannot

be performed on *Rb. capsulatus* reaction centers. The closely related *Rb. sphaeroides* can be grown under similar non-photosynthetic conditions, so that site-directed mutagenesis is also straightforward. Also, structural changes in mutant reaction centers can be investigated by X-ray crystallography (Chirino et al., 1994) even more now with the availability of the new, better ordered trigonal crystal form. Site-directed mutagenesis of the structurally best characterized reaction center from *Rp. viridis* is now also possible (Laußermair and Oesterhelt, 1992). However, *Rp. viridis* can grow only under photosynthetic and, very slowly, under microaerophilic conditions. Under microaerophilic conditions the photosynthetic apparatus is not induced. Photosynthetic growth conditions exert a selection pressure for revertants and suppressor mutants if the reaction centers are functionally impaired. However, very interesting herbicide-resistant mutants were obtained by classical selection procedures, with mutations some of which would not have been made by site-directed mutagenesis (Sinning et al., 1989; Ewald et al., 1990; Sinning, 1992).

Many amino acids which were considered to be of importance for pigment binding or electron transfer (Michel et al., 1986b) were changed in *Rb. sphaeroides* reaction centers, and characterized by spectroscopic methods. Most outstanding is the mutation Tyr M210 \rightarrow Phe. In the mutant reaction center the rate of the initial electron transfer is slowed down by a factor of 4–6 (Finkle et al., 1990; Nagarajan et al. 1990). The X-ray crystallographic analysis (Chirino et al., 1994) did not reveal any significant structural changes except for the absence of the O atom, so that the decrease of the electron transfer rate can be ascribed to removal of the oxygen atom. Other mutations such as GluL212 \rightarrow Gln, AspL213 \rightarrow Asn, with the protonatable residues presumably involved in protonation of Q_B (see Chapter 26 by Okamura and Feher) and HisM219 \rightarrow Cys, removing a ligand to the non-heme iron, also do not lead to detectable structural changes. (Chirino et al., 1994). However, the resolution of the latter data set was limited to 4 Å. When the residues His L173 and His M202 liganded to the special pair bacteriochlorophylls D_A and D_B are replaced by Leu residues, bacteriopheophytins are incorporated as D_A and D_B respectively. *Vice versa*, in the LeuM214 \rightarrow His mutant, a bacteriochlorophyll is incorporated as ϕ_A instead of a bacteriopheophytin. Using the new trigonal crystal form, the reaction center mutants Trp

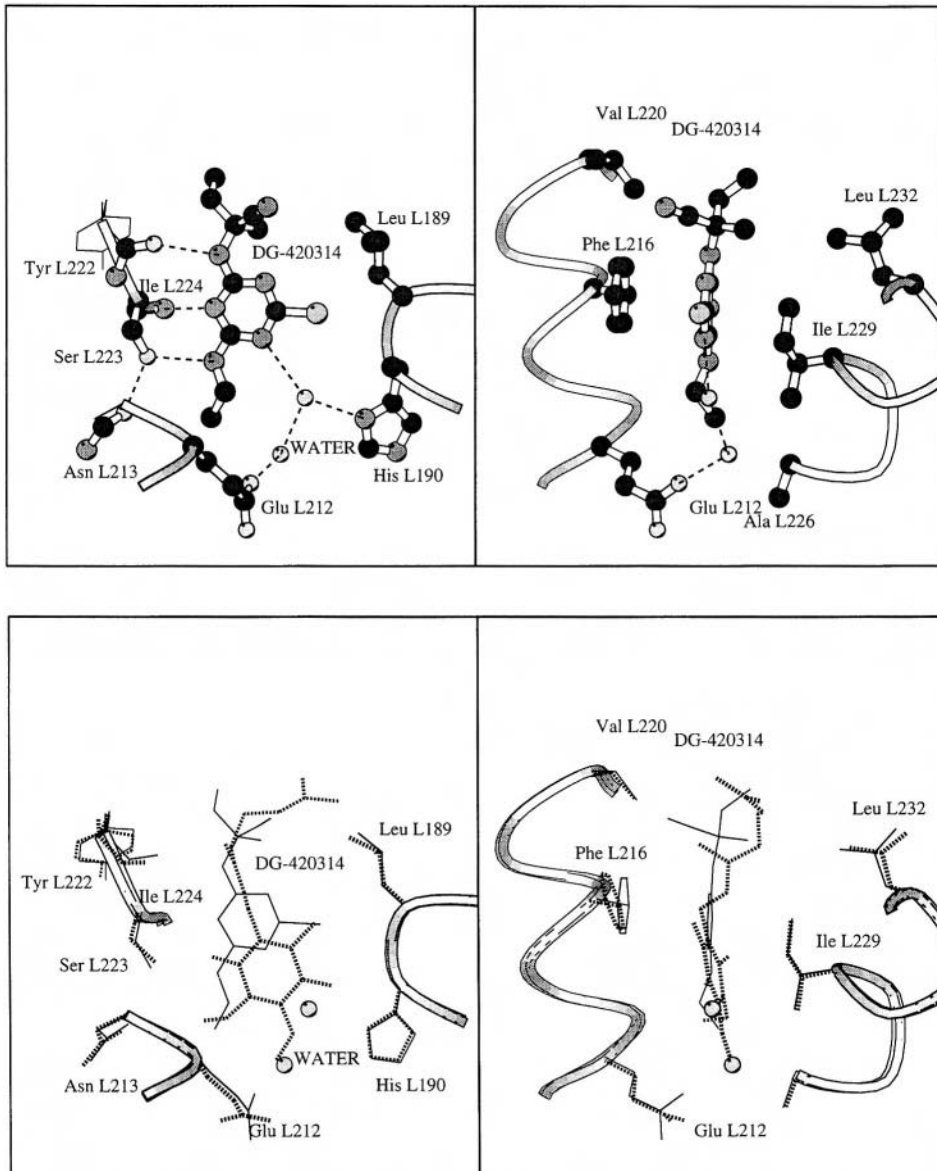

Fig. 12. Orthogonal views of triazine inhibitor binding to the Q_B site in the *Rp. viridis* reaction center (top) and in comparison to ubiquinone-2 binding (quinone complex in dashed lines, bottom).

M252 (see Figs. 8 and 9) \rightarrow Phe, Trp M252 \rightarrow Tyr, and Thr M222 \rightarrow Val (Stilz et al., 1990) have been analyzed. In these mutants the electron transfer from ϕ_A to Q_A has been slowed down by a factor of three. The structural analysis (Merckel M, Ermler U, Fritsch G, Michel H, Stilz U and Oesterhelt D, manuscript in preparation) indicates some structural changes in the Trp M252 \rightarrow Tyr mutant due to the fact that tyrosine is longer than the original tryptophan which forms a hydrogen bond to Thr M222. This

hydrogen bond cannot be formed by tyrosine for steric reasons. The tyrosine evades towards Q_A , pushing back also Q_A . On the other side, Phe M151 is pulled in the same direction by the newly created tyrosine, so that the van der Waals and aromatic interactions are maintained. The mutations Trp M252 \rightarrow Phe and Thr 222 \rightarrow Val do not lead to detectable structural changes.

Some of the herbicide resistant mutants of the reaction center from *Rp. viridis* have also been

analyzed by X-ray crystallography (Sinning et al., 1990; Sinning, 1992; Lancaster et al., unpublished). The double mutant (ArgL217 → His, SerL223 → Ala) shows some structural changes: The side chain of AsnL213 which is hydrogen-bonded to Ser L223 in the wild type is rotated towards the cavity which is created by the replacement of Arg L217 by the smaller His. At the same time, Q_B becomes more firmly bound (Sinning et al., 1989), as discussed above. The mutation TyrL222 → Phe unexpectedly leads to resistance against the herbicide terbutryn. In the wild type, TyrL222 forms a hydrogen bond with the peptide carbonyl oxygen of AspM43. Since this hydrogen bond is now missing, a stretch of the M subunit (M25–50) moves into a new position. The side chain of PheL222 rotates by 90° into the herbicide binding site (see above) thereby preventing the binding of terbutryn by steric hindrance. The Q_B binding pocket becomes slightly wider. Work on other mutants is in progress.

VII. Conclusions

As the result of the structure determination of the reaction centers from purple bacteria and sequence comparisons it could be concluded that the core of the reaction center from photosystem II is made up of the D1 and D2 subunits (Michel and Deisenhofer, 1986; Trebst, 1986; Michel and Deisenhofer, 1988). This proposal could be verified (Nanba and Satoh, 1987). In addition, the availability of a structural model of the photosynthetic reaction centers from two purple bacteria has led to a much better understanding of the primary charge separation and the electron transfer across the membrane. Physicists and theoreticians now have a solid basis for their experimental and theoretical investigations. Geneticists and biochemists start to understand the role of individual amino acids. As a result of the combined efforts one may have a satisfactory understanding of the first steps in photosynthetic electron transfer in the near future.

Summary

The light driven electron transfer reactions of photosynthesis are best characterized in the reaction centers of purple nonsulfur bacteria such as *Rhodobacter sphaeroides*. These reactions are extraordinarily fast: the first of them taking place within a few picoseconds. Because photosynthetic electron transfer is initiated by light, and the redox active cofactors have distinct spectral signatures, both the kinetics and thermodynamics of the reaction can be studied on the timescale of the actual reactions. This, in combination with the availability of detailed structural information, has made the electron transfer reactions of purple nonsulfur bacteria some of the most completely characterized electron transfer reactions in biological systems. In addition to the spectroscopic tools which have been used to characterize the electron transfer reactions, the reaction center has also been the subject of mutagenesis studies. The ease with which genetic engineering can be performed in these bacteria, coupled with the structurally robust nature of the reaction center, has resulted in many mutations which affect the early electron transfer reactions. Critical protein-cofactor interactions have now been identified and analyzed which affect the metal content, redox potentials, electronic structure and intermolecular coupling of the bacteriochlorophylls and bacteriopheophytins of the reaction center. In combination, these studies have suggested various possible mechanisms for early electron transfer which involve both the electronic states of the cofactors as well as nuclear conformational changes in the surrounding protein.

I. Introduction

Light absorption by the photosynthetic apparatus of purple nonsulfur bacteria results in the formation of the lowest excited singlet state of bacteriochlorophyll (BChl). Subsequently, this energy is transferred from one BChl-complex to another in the photosynthetic membrane until it arrives at the reaction center, a special BChl containing protein-cofactor complex which is the site of the initial photosynthetic electron transfer reactions. One of the most important constraints on these early electron transfer reactions is the brief lifetime of the BChl excited singlet state. In organic solvents, the lifetime of the excited singlet state of BChl is about 3 nanoseconds (Seely and Connolly, 1986). Thus, the initial electron transfer reactions in the bacterial photosynthetic reaction center must take place on a timescale much shorter than this in order to achieve a high quantum yield. The requirement for ultrafast electron transfer in the reaction center is made even more imperative by the competition between forward electron transfer and backward energy transfer to the antenna, a process which is usually thermodynamically favorable due

to the large number of antenna pigments per reaction center (Dawkins et al., 1988; Woodbury and Parson, 1986).

The initial electron transfer reactions of photosynthesis have been best studied in the reaction centers of the purple nonsulfur bacteria (Kirmaier and Holten, 1987, 1993; Feher et al., 1989; Parson, 1991; Martin and Vos, 1992). Though many of the mechanistic details of this process remain unclear, the overall kinetics are well known. The initial charge separation takes place within a few picoseconds and is followed by two subsequent electron transfer reactions that take place on the hundred picosecond and hundred microsecond timescales, respectively. The state formed at each step is progressively more stable, starting with the excited singlet state, which has an intrinsic lifetime that is probably less than a nanosecond (see below) and resulting in a final charge-separated state with a lifetime of roughly a second and a quantum yield of nearly 100%. Of course, there is a price to be paid for this stability and reaction specificity; the final charge-separated state of the purple bacterial reaction center conserves only about one third of the standard free energy available in the initial excited singlet state, relative to the ground state.

The success of studying photosynthetic electron transfer in the purple nonsulfur bacteria comes from the many technical advantages of working with the reaction centers from these organisms. The reaction centers of several species are readily isolated in high

Abbreviations: B_A – A-side BChl monomer. yield and in most cases are stable for days in the dark at room temperature or indefinitely when frozen (Feher and Okamura, 1978; Prince and Youvan, 1987; Snozzi and Bachofen, 1979). They have a small, well defined number of absorbing cofactors and, importantly, the electron transfer function of the reaction center can be cleanly separated from the energy gathering function of the antenna, making the performance and interpretation of optical spectroscopy much simpler than it is in systems where the antenna and the reaction center have not or cannot be separated. Finally, genetic manipulation of the reaction center genes has become routine in recent years, and the reaction center of purple nonsulfur bacteria has proven to be a surprisingly robust system for directed mutagenesis studies (Coleman and Youvan, 1990; Bylina and Youvan, 1991).

This chapter is devoted to a brief, and necessarily incomplete, summary of what has been learned, primarily during the past 10 years, about the pathway, kinetics and thermodynamics of early electron transfer in the reaction centers of purple nonsulfur bacteria and their mutants. The chapter starts with a discussion of the structural aspects of the reaction center that are known to affect the early electron transfer reactions and a brief description of some of the mutations that have been constructed and characterized. This leads to a description of reaction center spectroscopy and then to a discussion of possible mechanisms of electron transfer, particularly for the initial charge separation reaction. While there is at present no consensus on the mechanism of initial electron transfer, an attempt is made to distinguish between possible mechanisms and to point out the complex aspects of the experimental observations that have proven difficult to unambiguously explain using simple kinetic models.

II. The Reaction Center of *Rhodobacter sphaeroides*

Spectroscopically, the best characterized of the purple bacterial reaction centers is the complex isolated from *Rhodobacter (Rb.) sphaeroides*. The three dimensional structures of both this reaction center and the reaction center from *Rhodospseudomonas (Rp.) viridis* have been determined by X-ray diffraction studies as described in detail in Chapter 23 by Lancaster et al. Briefly, the structure of the reaction center of *Rb. sphaeroides* has two symmetry

related subunits, L and M, that each have five transmembrane helices, and a third subunit, H, that has one transmembrane helix and a large globular domain (Fig. 1A; Allen et al., 1987; Chang et al., 1991; Chirino et al., 1994; Ermeler et al., 1994). The reaction center BChls, bacteriopheophytins (BPhes) and quinones are divided into two branches, labeled A and B, that are related by the same C_2 symmetry axis as the L and M subunits (Fig. 1A). Apparent in the structure is a closely interacting dimer of BChls that serves as the primary electron donor (P). Symmetrically placed with respect to P are two BChl monomers (B_A and B_B), two BPhes (H_A and H_B), and two quinones (Q_A and Q_B). Between the two quinones is a non-heme iron atom that appears to serve a structural role in stabilizing the complex. In carotenoid containing strains of *Rb. sphaeroides*, there is also a symmetry breaking carotenoid molecule situated near B_B .

The two BChls which make up P overlap at the ring I position with a separation of approximately 3 Å (Fig. 1A,B). The twofold symmetry of the dimer is broken by molecular interactions involving the protein. Some distances involving symmetry related residues are not equivalent. For example, the distances between each of the magnesiums of the initial electron donor BChls and the ligating Nε of histidines L173 and M202 in *Rb. sphaeroides* are different, respectively 2.1 Å and 2.6 Å (Chirino et al., 1994). Also, different side chains are found at some symmetry related positions. For example, the symmetry related residue of His L168, that forms a hydrogen bond with the acetyl group of ring I of the A-side BChl of the dimer, is Phe M197 which cannot form such a bond. The asymmetry in the protein interactions has led to the suggestion that these structural differences should establish the asymmetry in electron transfer (Plato et al., 1988; Scherer and Fischer, 1989; Parson et al., 1990; Thompson et al., 1991).

Electron transfer proceeds from the excited state of the primary donor, P^* , to H_A in approximately 3.5 ps. The closest distance between P and H_A is approximately 7 Å. To explain the fast rate of electron transfer over this distance, bridging intermediates have been suggested, most commonly B_A located between P and H_A (see Fig. 1A). Near H_A is the primary quinone (Q_A) that receives the electron in approximately 200 ps. The electron is subsequently transferred to the secondary quinone (Q_B) in about 200 μs.

Fig. 1. (A) The structure of the cofactors (left side of panel) and a ribbon diagram of the L, M and H protein subunits (right side of panel) in reaction centers from *Rb. sphaeroides* R-26 reaction centers (Brookhaven Data Base, file 4RCR). The two BChls that make up the closely interacting pair of BChls (P) at the top of the cofactor structure are labeled P_A and P_B. The two monomer BChls are labeled B_A and B_B. The two Bphes are labeled H_A and H_B. The two quinones are labeled Q_A and Q_B. An approximate C₂ rotational axis runs from the center of P to the nonheme iron atom at the bottom of the figure. The subunit ribbon diagram is shown in the same orientation as the cofactors, and the C₂ symmetry extends to the positions of the helices between the L (right side of the ribbon diagram) and M (left side of the ribbon diagram) subunits. In vivo, the reaction center is embedded in the photosynthetic membrane such that the C₂ axis is perpendicular to the plane of the membrane. The two possible transmembrane electron transfer pathways, comprised of the A-side and B-side cofactors, respectively, utilize exactly the same cofactors with very similar spatial positions and orientations, yet electron transfer appears to occur nearly exclusively along the A-side branch. (B) A stereo view of the BChl dimer, P, and some of the amino acids which interact closely with it. This is the view obtained by looking from the top of panel A along the C₂ axis. Mutations have been made at all of these sites as discussed in the text. (C) A stereo view of the two Bphes, H_A and H_B, and two closely associated amino acids which have been the target of mutagenesis studies (see text).

III. Reaction Center Mutants

A number of mutations have been constructed involving residues near the dimer and monomer BChls in *Rb. sphaeroides* and a closely related bacterium, *Rb. capsulatus* (Fig 1B). These mutations fall into 4 general classes: 1) mutations of the histidines that provide ligands for the Mg of the BChls, 2) mutations of the aromatic residues, 3) alterations of hydrogen bonds to the dimer, and 4) large scale symmetry changes of the M subunit to corresponding regions of the L subunit and vice versa. In addition, two mutations have been constructed near one of the BPhe's, H_A, (Fig. 1C) that: 1) introduce a potential Mg ligand and 2) break an existing hydrogen bond donor to the 9-keto group of ring V. The general characteristics of these mutations are described briefly below.

A. Heterodimer Mutants

Histidines L173 and M202 (or M200 in *Rb. capsulatus*) that provide ligands for P have been altered in both *Rb. sphaeroides* and *Rb. capsulatus* (Bylina and Youvan, 1988; Kirmaier et al., 1988; McDowell et al., 1991a,b). Changing either of these histidines to leucine results in the formation of a BChl-BPhe heterodimer in place of the normal BChl-BChl homodimer. Based upon the higher midpoint potential of the BPhe, the unpaired electron would be expected to be localized primarily on the BChl side of the pair forming BChl⁺ BPhe⁻. In both of the heterodimer mutants the yield of electron transfer is decreased by roughly a factor of two. The measured decay rates of the excited state are 42 ps, 18 ps and 14 ps for the L173 and M202 mutants in *Rb. sphaeroides*, and the M200 mutant in *Rb. capsulatus*, respectively. The rate and yield of transfer from H_A⁻ to the primary quinone is essentially unchanged. The M202 and L173 heterodimer mutants of *Rb. sphaeroides* have been characterized by X-ray diffraction to resolutions of 3.0 Å and 4.0 Å, respectively (Chirino et al., 1994). The structure of the M202 mutant has been refined and shows that the BPhe is substituted into a position similar to that normally occupied by the BChl. Displacements and rotations of amino acid residues, including Phe L181 and Phe M197, are observed as well as an apparent loss of a nearby water molecule. The limited resolution of the L173 data prevented refinement of the structure although features similar to that of the M202 mutant were

observed in difference electron density maps.

B. Mutation of Aromatic Residues

Two symmetry related aromatic residues Phe L181 and Tyr M210 (M208 in *Rb. capsulatus*) are located near the dimer, BChl monomer, and BPhe on the A and B sides, respectively. These residues have been altered to a variety of other residues in various combinations by several groups in both *Rb. capsulatus* and *Rb. sphaeroides* (Nagarajan et al., 1990, 1993; Finkele et al., 1990; Chan et al., 1991a; Jia et al., 1993). The replacement of Tyr M210 by a Phe resulted in an electron transfer rate to H_A approximately five-fold slower than wild type. Replacement of the symmetrically related residue, Phe L181, with a Tyr resulted in a roughly two-fold increase in the P* decay rate. The mutations result in only small changes in the reaction center structure as measured by resonance Raman, linear dichroism, and X-ray diffraction (Mattioli et al., 1991a; Gray et al., 1990; Chirino et al., 1994). Theoretical calculations have suggested that the observed changes in rates for the mutants principally arise from altered energy levels of the charge-separated states due to changes in the electrostatic field (Parson et al., 1990; Nagarajan et al., 1993).

C. Hydrogen Bond Mutants

The BChl dimer has carbonyl groups in the conjugated system of rings I and V of both BChls. In wild type *Rb. sphaeroides* reaction centers, only one of these carbonyl groups forms a hydrogen bond to a nearby amino acid (His L168). Residues near the other three carbonyl groups, Leu L131, Leu M160, and Phe M197 have all been mutated to His in *Rb. sphaeroides* (Williams et al., 1992a,b,c) and Phe M195 in *Rb. capsulatus*, which corresponds to M197 in *Rb. sphaeroides*, has also been changed to His (Stocker et al., 1992). In addition, the one hydrogen bond present in the wild type has been removed by the mutation of the His at L168 to a Phe (Murchison et al., 1993). In each case that a histidine was inserted near a ring I or ring V carbonyl group, a new hydrogen bond resulted (Mattioli et al., 1994, 1995; Nabedryk et al., 1993). The addition of each hydrogen bond to the BChl dimer resulted in an increase of 50–120 mV in the midpoint potential of P in *Rb. sphaeroides* (Williams et al., 1992b; Murchison et al., 1993; Lin et al., 1994) and at least 100 mV in the Phe^{M195} → His

mutant of *Rb. capsulatus* (Stocker et al., 1992). Associated with the decrease in the P^*/P^+H^- free energy difference for each mutant is a decrease in the rate of P^* decay ranging from 1.5 to 4-fold at 295 K (Williams et al., 1992b; Murchison et al., 1993). The loss of the existing hydrogen bond in the $\text{His}^{\text{L168}} \rightarrow \text{Phe}$ mutant resulted in a corresponding decrease in the P/P^+ midpoint potential of 80 mV but the rate of electron transfer was essentially unchanged at 295 K (Murchison et al., 1993).

D. Large-Scale Symmetry Mutants

Large scale symmetry changes have been made by exchanging regions of the L subunit with the corresponding region of the M subunit, and vice versa, in *Rb. capsulatus* (Robles et al., 1990; Taguchi et al., 1992). Replacing residues M192 to M217 that form the D-helix of the M subunit with the corresponding residues of the L subunit, L165 to L190, results in a reaction center that is not capable of electron transfer due to the loss of H_A (the 'D_{LL} mutant', Robles et al., 1990). The corresponding replacement of the D-helix of the L subunit with M subunit sequences has also been constructed as has the complete D-helix swap between the L and M subunits (Robles et al., 1990). In the D_{LL} mutant, the excited state of P, P^* , has a lifetime of 190 ps, allowing a detailed spectroscopic characterization of this state (Breton et al., 1990). Another symmetry mutant, *sym1*, was constructed by replacing residues M187 to M203 of the M subunit with the corresponding residues of the L subunit, L160 to L176. This mutant has a decreased quantum yield of electron transfer (65–70%), a three-fold decrease in the rate of P^* decay, and an increase in midpoint potential of at least 100 mV (Stocker et al., 1992; Taguchi et al., 1992). Many of these functional changes were attributed to the specific change of Phe to His at M197 that results in the introduction of a hydrogen bond to the dimer (see above). None of the large scale symmetry mutants, nor any of the single site mutants that have been characterized to date, result in clearly demonstrable electron transfer involving the inactive (B-side) cofactors of the reaction center.

E. Mutations Near H_A

The introduction of a potential Mg ligand at M214 in *Rb. sphaeroides* by the mutation Leu to His results in a mutant with a BChl replacing H_A (the ' β ' mutant;

Kirmaier et al., 1991). The decay rate of the stimulated emission from P^* in this mutant is 6.4 ps and the electron transfer rate from the β cofactor to the primary quinone occurs in approximately 350 ps with a 60% quantum yield of $P^+Q_A^-$ (Kirmaier et al., 1991). The standard free energy difference between P^* and $P^+H_A^-$ (see below) was 85 mV less negative in the mutant than the value determined for wild type reaction centers.

A second mutation near H_A involves the loss of a hydrogen bond between Glu L104 and the ring V keto group of the BPhe. This mutation, $\text{Glu}^{\text{L104}} \rightarrow \text{Leu}$, resulted in a 12 nm shift of the Q_x band of BPhe_A and a slightly slower rate of 4.8 ps for the decay of P^* with no change in yield compared to wild type (Bylina et al., 1988).

IV. The Ground State Optical Spectrum of Reaction Centers

The ground state optical spectrum of reaction centers isolated from *Rb. sphaeroides* strain 2.4.1 is shown in Fig. 2 at 295 K and at 20 K. The small number of bacteriochlorins (4 BChls and 2 BPhe) makes the isolated reaction center much simpler to study by optical spectroscopy than the intact photosynthetic membrane, and essentially all of the direct measurements of electron transfer discussed in this chapter have been performed on isolated complexes.

A great deal of experimental and theoretical investigation has been directed towards the assignments of the different reaction center spectral bands. Though the spectral features are complex (Fig. 2), and it is very likely that there is substantial mixing between the electronic transitions of the different cofactors affecting both the energy and oscillator strengths of the individual transitions, the transitions seen at 865, 802, 760, 590, and 540 nm in the 295 K spectrum of *Rb. sphaeroides* (960, 830, 790, 600, and 540 nm in *Rp. viridis*) can be largely assigned to specific cofactors or types of cofactors (Zinth et al., 1985; Parson, 1987, 1991; Breton, 1988; Breton et al., 1989; Feher et al., 1989). It is clear that the 865 nm band seen in the 295 K spectrum of *Rb. sphaeroides* is predominantly the Q_y transition of the pair of BChls, P. The band at 802 nm in the 295 K spectrum of Fig. 2 is thought to be largely due to the Q_y transitions of the monomer BChls. At 20 K, this band resolves into at least two transitions (the 802 nm transition becomes asymmetric, Fig. 2) at 802 and

Fig. 2. The ground state absorption spectrum of reaction centers isolated from a strain of *Rb. sphaeroides* containing wild type reaction center subunit genes. The spectrum is shown both at 295 K and 20 K. The low temperature spectrum is identical to that published by Williams et al., 1992b.

810 nm, possibly representing the two monomer BChls in distinct environments (Beese et al., 1988; Williams et al., 1992b), though contributions from other transitions in this region are possible as well (Breton, 1988; Breton et al., 1989). The band at 760 nm in the 295 K spectrum of Fig. 2 is predominantly due to the Q_V transition of the BPhes. At low temperature, this band becomes more asymmetric in *Rb. sphaeroides*, due, at least in part, to the two different environments of the BPhes as shown by specific reduction of the individual BPhes by photopumping methods (Robert et al., 1985). This is more easily seen in reaction centers from *Rp. viridis* where the two BPhes Q_V bands are well resolved at low temperature (Tiede et al., 1987; Kellogg et al., 1989). The band near 600 nm in Fig. 2 is due to the overlapping Q_X transitions of all of the reaction center BChls. The band near 540 nm at room temperature in Fig. 2 is the combined Q_X transitions of the BPhes. The Q_X bands of the BPhes resolve quite cleanly into two transitions at low temperature. The BPhes which is predominantly involved in the electron transfer gives rise to the narrower 546 nm peak at 20 K while the broader 533 nm transition shows much less photobleaching activity (Fig. 3 and Bylina et al., 1988). Linear dichroism studies of single crystals (Zinth et al., 1985) and specific mutagenesis near H_A affecting its spectral properties (Bylina et al., 1988) have shown that the red absorbing BPhes is H_A . Mutagenesis studies have indicated that the spectral shift between the BPhes is largely due to

Fig. 3. The upper curve represents the 510 to 560 nm region of the ground-state absorption spectrum of reaction centers from the carotenoidless strain of *Rb. sphaeroides*, R-26, at 20 K. The lower curve shows the difference absorption spectrum of the charge-separated species formed during a 15 ps time range transient absorption measurement at 20 K. This difference spectrum was determined as the constant term in a global exponential fit of the transient absorption changes occurring over that time period at 40 wavelengths. In this case the fit was to an exponential term and a constant: $A_1(\lambda)\exp(-kt) + A_2(\lambda)$ where λ is the wavelength, $A_i(\lambda)$ are amplitudes allowed to vary freely at each wavelength during the fit and k is a rate constant which is wavelength independent. The lower curve in the figure is $A_2(\lambda)$. (This type of analysis and the apparatus used is described by Woodbury et al., 1994). The reaction centers were excited with a roughly 200 fs duration pulse with a 10 nm spectral band width centered at 880 nm. Note that the transient absorption spectrum was offset such that there was a zero absorbance change on average between 510 and 520 nm. There was a small (roughly 0.01) positive absorption in this region before the adjustment. Barring accidental absorption change cancellations, the amount of bleaching seen in the transient absorption spectrum due to the 533 nm H_B spectral transition in the ground state spectrum is less than 5% for reaction centers isolated from this strain. These results are similar to those published previously for R-26 reaction centers (Kirmaier et al., 1985a; Lockhart et al., 1990).

a glutamic acid in the L-subunit which hydrogen bonds to H_A (Bylina et al., 1988), though further mutagenesis in this region and at the symmetrically located site in the M subunit has suggested that other factors in the protein environment of the BPhes may significantly affect these transition energies as well (Williams and Allen, unpublished results).

V. The Spectral and Kinetic Properties of P^*

The only known photochemically active excited singlet state of the reaction center is the lowest excited singlet state of the initial electron donor, P^* .

This is also the state that is produced upon energy transfer from the antenna, and direct excitation into any of the other BChls or BPhes in the reaction center rapidly results in energy transfer to P again forming P* (Breton et al, 1986; Breton et al., 1988; Du et al., 1992; Xiao et al., 1994).

A. Spontaneous Emission from P*

Though in wild type reaction centers the quenching of the excited singlet state of P is predominantly via charge separation, P* can also decay by other nonradiative pathways (see below) or by emitting a photon. The emission spectrum for P* is shown in Fig. 4B. The natural radiative rate constant of P* is estimated to be about $8 \times 10^7 \text{ s}^{-1}$ (Woodbury and Parson, 1984). Characterizing the decay of the spontaneous emission from P* is a useful method for determining its population as a function of time. Several laboratories have used picosecond and subpicosecond resolution transient spectroscopy to study the kinetics of the spontaneous emission from P*. The kinetic behavior of P* decay determined by these measurements is complex. It does not show single exponential kinetic behavior as one would expect for a simple irreversible, first order reaction. Fig. 5a shows the multiexponential decay of the spontaneous emission on the picosecond timescale in *Rb. sphaeroides* reaction centers (Du et al., 1992; Muller et al., 1992; Hamm et al., 1993). Fig. 5b shows that emission is also observed on timescales as long as nanoseconds, when forward electron transfer to the quinone is blocked (Schenck et al., 1982; Sebban and Moya, 1983; Woodbury and Parson, 1984; Peloquin et al., 1994; Ogrodnik et al., 1994). When fit as a series of exponential decay terms, at least three time constants are required to accurately describe the P* decay in reaction centers with unreduced quinones. At least five rate constants are probably required to describe the decay of P* in reaction centers with reduced or removed quinones.

B. Stimulated Emission and Absorption Changes Associated with P*

It is also possible to follow the decay of P* by observing the transient absorption spectrum of reaction centers as a function of time. One of the features of the transient difference spectrum of P* often used to follow the decay of this state is the stimulated emission in the 915 nm region (Woodbury

Fig. 4. (A) The 295 K spectrum of the transient absorption changes believed to be due to stimulated emission from the excited singlet state of P, P*. The data shown was taken using reaction centers of *Rb. sphaeroides*, strain R-26. The curve in panel A is the amplitude spectrum, $A_1(\lambda)$, determined from global exponential decay analysis of the absorption changes at 50 wavelengths between 860 and 960 nm on a 15 ps timescale. The data was fit to one exponential decay term and a constant (using the fitting equation in the legend to Fig. 3) following excitation with an 840 nm, 200 fs pulse. The amplitude spectrum shown is that of the absorption change signal which is decaying on the 3.5 ps timescale in this spectral region. Most of the rapidly changing signal in this wavelength region is believed to be due to stimulated emission, as described in the text. Similar spectra have been published previously (Nagarajan et al., 1993; Taguchi et al., 1992; Williams et al., 1992a). (B) The 295 K spectrum of the spontaneous emission from quinone-reduced R-26 reaction centers. This was measured as the integrated emission during the first 2 ns after excitation using a time-correlated single photon counting apparatus. Data taken from Woodbury and Parson (1984).

et al., 1985; Martin et al., 1986; Kirmaier and Holten, 1987, 1988b; Fleming et al., 1988; Holzappel et al., 1989). Fig. 4 compares the spectrum of the steady-state spontaneous emission (Fig. 4B) with the spectrum of the stimulated emission (Fig. 4A) from *Rb. sphaeroides* reaction centers as determined by exponential decay analysis of multiwavelength ultrafast transient absorption measurements in the

Fig. 5. (A) Spontaneous emission decay of P* on the picosecond timescale in reaction centers from *Rb. sphaeroides* strain R-26 at 295 K. Excitation was at 850 nm with a 160 fs duration pulse and emission was detected at 940 nm by gating the emission with a second pulse at a particular time relative to excitation using nonlinear two-photon mixing of the emission photon and the gating photon in a LiIO₃ crystal (so called 'up-conversion'). The points represent experimental results for different relative delays of the gating pulse. The solid line represents the best fit to two exponentials, $A_1 \exp(-k_1 t) + A_2 \exp(-k_2 t)$, where t is time, A_i are the preexponential amplitudes used as free parameters in the fit and k_i are the rate constants which are also free parameters in the fitting routine. For this fit, $A_1 = 0.808$, $A_2 = 0.192$ ($A_1 + A_2$ has been normalized to 1.0), $k_1 = 1/(2.7 \text{ ps})$, and $k_2 = 1/(12.1 \text{ ps})$. This figure was reproduced from Du et al. (1992). (B) Spontaneous emission decay of P* on the tens of picosecond to nanosecond timescale in R-26 reaction centers measured by time-correlated single photon counting. Decay components are present on the 100 ps, 800 ps, and several nanosecond timescales in the curves at each temperature. Note that the abscissa has a logarithmic gauge, while the ordinate is linear. (C) Same as panel B except for the Leu^{L131}→His mutant of *Rb. sphaeroides*. The data of panels B and C were taken from Peloquin et al. (1994) and the experimental details are described there.

900 nm region. One disadvantage in measuring the decay kinetics of P* by following the stimulated emission instead of the spontaneous emission is that sensitivity to small stimulated emission signals is poor in comparison to that obtainable by following the spontaneous emission. This is because a low level of stimulated emission is indistinguishable from small absorption changes which underlie the stimulated emission band in the difference absorption spectrum. Despite these difficulties, multiexponential decay of the stimulated emission has been observed which closely matches that of the spontaneous emission from P* over the first 20 ps (Vos et al., 1992; Woodbury et al., 1994).

The state P* also has other characteristic features

in the time-dependent difference absorption spectrum recorded on subpicosecond timescales by fast transient absorption spectroscopy (Kirmaier and Holten, 1987; Kirmaier and Molten, 1993). The time evolution of the absorption change spectrum in the 700–860 nm region is shown in Fig. 6A at room temperature. Fig. 6B shows a single difference spectrum at 0.4 ps that represents primarily the state P*. There is a broad absorption throughout the 700–820 nm region with small, but distinct, features in the 800 nm region (Fig. 6B). There is also a large bleaching of the Q_y band of P as would be expected for the excited state of this cofactor. This can be seen most clearly in Fig. 6C which shows the difference absorption spectra as a function of time over a broader

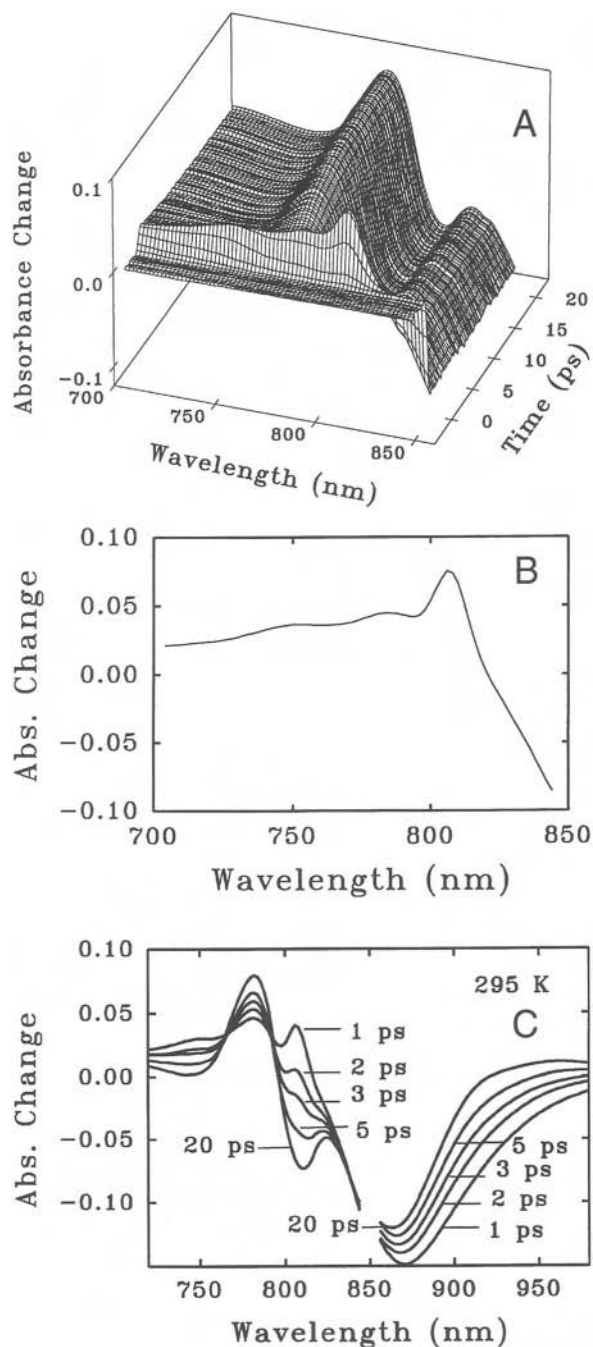

Fig. 6. (A) An absorption change vs. time and wavelength surface taken using reaction centers from *Rb. sphaeroides* strain R-26 at 295 K. Data points were taken every 200 fs over a 20 ps time range and every 2 nm between 705 and 845 nm. Excitation was with a roughly 200 fs pulse at 860 nm. (B) A single spectral slice through the surface of part A at 0.4 ps after excitation. This is thought to represent the absorption changes associated with the initial excited singlet state, P*. (C) 295 K transient absorption difference spectra of R-26 reaction centers as a function of time taken over a larger wavelength range. Excitation was with a roughly 200 fs pulse at 850 nm.

spectral range. The bleaching at early times in the 870 to 940 nm region is the superposition of the stimulated emission discussed above on the bleaching of the ground state Q_Y band of P.

C. The Intrinsic Lifetime and Electronic Characteristics of P*

Much of what is known about the electronic properties of P* comes from studies of the transition between the ground state and P*. For example, electric field effects on the energy of the P to P* transition provide information about the magnitude and direction of the difference dipole moment between P and P*. Low temperature hole-burning experiments provide insights into the mechanism of broadening of the Q_Y absorption band of P and about the degree of inhomogeneity and the vibronic structure of the excited singlet state. These issues have been considered in detail in recent reviews (Boxer, 1993; Reddy et al., 1992).

There is also complimentary information available about the inherent properties of P* from fast transient absorption measurements of both wild type and mutant reaction centers. One very important property of P* from a kinetic standpoint is its intrinsic lifetime in the absence of electron transfer. One can easily assign a minimum value to this number simply by considering the yield of initial electron transfer. The quantum yield of stable photooxidation of P has been measured to be at least 98% (Wraight and Clayton, 1973). If the observed lifetime of P* is about 3 ps at room temperature (just using the single exponential decay lifetime), this means that the intrinsic lifetime of P* must be at least 150 ps. Without a more precise measurement of the quantum yield of the first electron transfer step, it is difficult to do more than put a lower limit on the intrinsic lifetime in the wild type reaction centers. However, this value is much better known in several mutants with quantum yields of the initial electron transfer reaction that are low enough to accurately measure. The simplest example of such a mutant is the D_{LL} mutant (Robles et al., 1990) which does not undergo electron transfer at all. P* decays in about 190 ps in the D_{LL} mutant, consistent with the minimum value estimated above (Breton et al., 1990). This in itself is an interesting result, because monomeric BChl in solution typically decays on a timescale more than ten times this long (Seely and Connolly, 1986). Further information about the mechanism behind the rapid decay of P* comes from

measurements of other mutants that perturb the symmetry of this state. The best studied of these are the heterodimer mutants (Bylina and Youvan, 1988; Kirmaier et al., 1988; McDowell et al., 1991a,b). In both heterodimer mutants the yield of electron transfer drops dramatically due to both a decrease in the rate of initial electron transfer and to a decrease in the intrinsic lifetime of P^* (McDowell et al., 1991a; Kirmaier et al., 1988). For example, when the histidine at M200 is replaced by leucine in the *Rb. capsulatus* reaction center, the intrinsic lifetime of P^* , as calculated from the yield and the observed lifetime of P^* , is about 30 ps (Kirmaier et al., 1988). This has been rationalized in terms of the stabilization of the charge transfer state of the heterodimer, $BChl^+BPhe^-$, relative to the homodimer charge transfer state, $BChl^+BChl^-$, in the wild type. Model studies have indicated that when the excited state of a dimer has a large charge transfer character, nonradiative decay of the excited singlet state is more rapid (e.g. Bilsel et al., 1990). The results from these mutants have led to the suggestion that P^* in wild type reaction centers has an intrinsic lifetime much shorter than monomeric BChl in solution, possibly due to contributions to P^* from the charge transfer state. However, it is noteworthy that in one mutation ($Tyr^{M210} \rightarrow Phe$ in *Rb. sphaeroides*) the intrinsic lifetime of P^* is thought to be more than 300 ps at room temperature and in the nanosecond range at low temperature (Nagarajan et al., 1990). The variability of the intrinsic lifetime of P^* among different mutants makes an accurate estimate of this important number in wild type reaction centers difficult.

D. Coherence Dephasing and Vibrational Relaxation of P^*

It has recently been possible to directly observe an oscillatory time dependence of both absorption changes (Vos et al., 1991, 1993, 1994a, 1994b, 1994c) and emission decay profiles (Stanley and Boxer, 1994) shortly after P^* formation. These are apparently temporal manifestations of the vibrational modes that have been observed by resonance Raman and photochemical hole-burning techniques (Shreve et al., 1991; Reddy et al., 1992; Cherepy et al., 1994). The Fourier transform of the oscillatory parts of these decays reveals two broad frequency regions. In wild type reaction centers, one of the modes strongly coupled to the P to P^* transition is centered near 120 cm^{-1} at 10 K or 140 cm^{-1} at 295 K, the other is in the

15 to 30 cm^{-1} range (Vos et al., 1994a,b,c; Stanley and Boxer, 1994). The frequency of the lower energy mode is rather uncertain due to the fact that the oscillation is on the same timescale as the electron transfer in wild type (Stanley and Boxer, 1994). Fig. 7 shows the oscillatory behavior of the stimulated emission in the D_{LL} reaction center mutant of *Rb. capsulatus*. Here, the P^* decay time is much longer than the period of the lower frequency mode, making the determination of the mode frequency by Fourier transform analysis more certain. In all studies performed on this phenomenon in reaction centers, coherence dephasing occurs on the 1–2 ps timescale (Vos et al., 1991, 1993, 1994a, 1994b, 1994c; Stanley and Boxer, 1994).

There is presently no direct measurement of the timescale of the vibrational relaxation of P^* . The observation of vibrational coherence indicates that at least some of the modes coupled to P^* are not well coupled to the bath on timescales comparable to the overall rate of initial electron transfer. In addition, results from hole-burning measurements of reaction centers suggest that thermal equilibration with the bath is not instantaneous (Middendorf et al., 1991), and in vitro measurements of monomer and dimer porphyrins have indicated that vibrational relaxation of porphyrin excited states can occur on a timescale of picoseconds to tens of picoseconds (Rodriguez and Holten, 1989; Rodriguez et al., 1991). There are also changes in the transient absorption difference spectrum on the subpicosecond timescale which could be interpreted as a change in the state P^* (Vos et al., 1992). Recently, Vos et al. (1994c) have shown that the spectral features of the stimulated emission evolve dramatically during the first few hundred femtoseconds after light absorption. One would expect that dipolar relaxation of the protein around the excited state would give rise to a dynamic Stokes shift (Pierce and Boxer, 1992). The spectral changes seen in the stimulated emission from P^* do imply an overall displacement of the excited state potential surface relative to the ground state potential surface (Vos et al., 1994c), though the excited state evolution observed appears to be a coherent movement and may not represent the complete vibrational relaxation process (Vos et al., 1994b). There is also recent evidence that in a reaction center mutant ($Tyr^{M210} \rightarrow Phe$) with a somewhat longer P^* lifetime than that observed in wild type there is a shift of the stimulated emission spectrum to higher energies as a function of time (Nagarajan et al., 1993). This has been

Fig. 7. Coherent oscillations in the stimulated emission from D_{LL} mutant reaction centers in antennaless membrane preparations from *Rb. capsulatus*. The results of observation at several different probe wavelengths are shown. The traces are normalized to the average amplitude of the overall signal. The oscillatory part at each probe wavelength is obtained by taking the residuals of a fit to a step function convoluted with the instrument response function. Discrete Fourier transformation describes the input signal $I(t)$ by its amplitudes A and phases ϕ as a function of the frequency ν as

$$\sum_n \text{Re}(A_n e^{i(2\pi\nu_n t - \phi_n)})$$

(Re: real part) and was taken, for all probe wavelengths, over a 2.13 ps data interval (64 points), yielding a spectral resolution of 15 cm^{-1} . The Fourier transform (FT) window was started at $t=0.10$ ps, excluding the pump-probe overlap time interval. The 80 fs pump pulse duration determines the vibrational bandwidth of the experiment at about 70 cm^{-1} . The spectral region above about 200 cm^{-1} represents the noise level of the data. The FT amplitudes of the oscillatory parts all peak at 15 cm^{-1} and 77 cm^{-1} ; the inset shows the FT amplitude for probe wavelength = 945 nm. Upper left: control experiment at 10 K (probe wavelength = 930 nm) using the same cuvette containing only the buffer/glycerol mixture. The arrow indicates $t = 0$. The trace is plotted on the same amplitude scale as the protein sample (930 nm trace). This figure is reproduced from Vos et al. (1993), and this reference should be consulted for further details.

interpreted as a relaxation of P^* possibly involving changes in underlying absorption transitions of the excited state or changes in the oscillator strength of the stimulated emission.

VI. The State P^+

A. The Spectral Properties of P^+

The oxidized state P^+ can be formed as a stable state either by freezing reaction centers in the presence of light (forming $P^+Q_B^-$) or by addition of an oxidant such as ferricyanide (forming P^+). One can also cause nearly complete conversion to the state $P^+Q_B^-$ by steady-state illumination of reaction centers at room temperature. The P/P^+ difference absorption spectrum in the near infrared is dominated by a bleaching of the Q_Y band of P (865 nm in *Rb. sphaeroides*, Fig. 2) and a shift to higher energy of

the 802 nm transition, presumably due to an electrochromic shift of one or both of the monomer BChls in this region. These features also dominate the $P^+Q_A^-$ and $P^+H_A^-$ spectra (see below). In addition, at 1250 nm in *Rb. sphaeroides* there is a small absorption band which appears upon P^+ formation, and at 2600 cm^{-1} an additional P^+ transition has been detected by Fourier transform infrared spectroscopy (Breton et al., 1992).

The stability of P^+ produced either chemically or photochemically has allowed it to be characterized by electron paramagnetic resonance (EPR) and electron nuclear double resonance (ENDOR) (reviewed in Lubitz, 1991). The initial modeling of the electron donor as a BChl dimer was based on the EPR and ENDOR spectra of P^+ in *Rb. sphaeroides* (Feher et al., 1975; Morris et al., 1975). In these models, the delocalization of the unpaired electron over a symmetrical dimer reduces the width of the EPR spectrum by a factor of $\sqrt{2}$ and reduces the

hyperfine coupling constants of the ENDOR spectra by a factor of 2 compared to the spectra of BChl⁺ in organic solvents. More refined models for the distribution of the electron spin density of P⁺ have been developed using molecular orbital calculations based upon the three dimensional structure of the reaction center (reviewed in Plato et al., 1991). Analyses of these data indicate an unequal distribution of the electron spin density over the dimer halves, favoring P_A by approximately 2:1 in both *Rb. sphaeroides* and *Rp. viridis* (Lendzian et al., 1988, 1993). Essentially identical ENDOR spectra have been reported for P⁺ in chromatophores of *Rb. sphaeroides*, *Rb. capsulatus*, *Rhodospirillum (Rs.) centenum* and *Rs. rubrum* (Rautter et al., 1994). While reaction centers isolated from *Rb. sphaeroides* and *Rs. rubrum* showed ENDOR spectra similar to those observed in chromatophores, reaction centers isolated from *Rb. capsulatus* and *Rs. centenum* had significantly altered ENDOR spectra that indicate a 5:1 ratio of spin density favoring P_A rather than the 2:1 ratio observed in chromatophores (Rautter et al., 1994). In addition, the availability of reaction center crystals has allowed determination of the anisotropic components of the hyperfine coupling constants and consequently a significant improvement in accuracy of the calculated spin density of P⁺ for reaction centers from *Rb. sphaeroides* (Lendzian et al., 1993).

Changes in the spin density due to altered interactions with the protein can be measured by EPR, ENDOR and FT Raman. The heterodimer mutants show large changes in the EPR and ENDOR signals due to the predominant localization of the unpaired electron on the BChl side of the dimer (Huber et al., 1990; Bylina et al., 1990). The *symI* mutant also shows a broadened EPR signal indicating a more localized cation state than wild type (Stocker et al., 1992). Analyses of ENDOR experiments on the hydrogen bond mutants of *Rb. sphaeroides* have enabled the quantitative determination of the relative spin densities on the two BChls of the dimer. The addition of each hydrogen bond causes a significant redistribution of spin density yielding a series of mutants with P_A/P_B spin density ratios ranging from 0.3 to 5.0 (Rautter et al., 1992, 1995). These spin density changes have been modeled in terms of preferential stabilization of P_A⁺ or P_B⁺ due to the introduction of each hydrogen bond. The magnitude of the oxidation induced upshift of one of the dimer carbonyl Raman bands is also an indicator of the localization of the electron spin density (Mattioli et

al., 1991a). This upshift provides estimates that are consistent with the ENDOR values (Mattioli et al., 1994, 1995)

B. The P/P⁺ Midpoint Potential

The P/P⁺ midpoint potential can be measured in reaction centers by monitoring the amplitude of the Q_y dimer band while titrating the sample either by chemical oxidants and reductants or by electrochemical titration. In wild type reaction centers from *Rb. sphaeroides*, the measured midpoint potential is approximately 500 mV (Williams et al., 1992b; Nagarajan et al., 1993). A number of mutations near the dimer have been characterized that alter the P/P⁺ midpoint potential by 10 to 50 mV (Du et al., 1992; Nagarajan et al., 1993). Two types of reaction center mutations have been found that result in significantly larger midpoint potential changes. First, due to the altered cofactor composition, the *Rb. sphaeroides* heterodimer, His^{M202} → Leu, has a P/P⁺ midpoint potential that is 160 mV above that of wild type (Davis et al., 1992). Second, addition or removal of hydrogen bonds between P and the surrounding protein results in large midpoint potential changes. The loss of the hydrogen bond between the ring I acetyl group and His L168 in *Rb. sphaeroides* reaction centers results in an 80 mV decrease in potential (Murchison et al., 1993). The gain of a hydrogen bond between a histidine and the other acetyl group or one of the keto groups of the dimer results in an increase of 55 mV to 125 mV (Williams et al., 1992a,b,c; Stocker et al., 1992). The combination of hydrogen bonds is additive (Lin et al., 1994) and correlated with the total change in hydrogen bonding energy (Mattioli et al., 1995). The combination of mutations yielding hydrogen bonds to histidine at all four keto and acetyl groups of P results in a net increase in the P/P⁺ midpoint potential of 260 mV compared to wild type (Lin et al., 1994). The formation of a hydrogen bond between a Tyr and the acetyl group of ring I results in a smaller increase in the potential (30 mV, Wachtveitl et al., 1994). This suggests that the large increase in potential due to the formation of hydrogen bonds with histidines is due either to the formation of a strong hydrogen bond or to another specific property of the histidine, such as electrostatic interaction (Williams et al., 1992b; Mattioli et al., 1994, 1995).

VII. The Product of Initial Charge Separation

A. The Formation and Spectral Properties of the State $P^+H_A^-$

As one might expect from the complexity of the decay of the initial electron donor excited singlet state, the kinetics of formation of the first fully populated charge-separated state are complex as well (Holzapfel et al., 1989; Dressier et al., 1991; Kirmaier and Holten, 1990; Kirmaier and Holten, 1991; Chan et al., 1991b). Time constants between 0.9 and 4 ps have been reported at room temperature, depending on the wavelength measured and the method of analysis (single exponential vs. multiexponential). Complex kinetics are also obtained at low temperature, with lifetimes determined by exponential decay analysis on the 0.6 to 2.5 ps timescale as well as on the roughly 15 ps timescale (Kirmaier and Holten, 1990; Lauterwasser et al., 1991; Woodbury et al., 1994). Possible explanations for the complex spectral and kinetic behavior during the first 10–15 ps are discussed later in this chapter along with a consideration of several mechanistic models involving intermediate states. Here, we will consider the spectral properties of the charge-separated state present on the 15–20 ps timescale.

Though there is considerable disagreement about the mechanism of formation of the state present 15 ps after light absorption, there is general agreement about the spectral properties of the state that is formed. Examples of difference absorption spectra as a function of time for *Rb. sphaeroides* reaction centers are shown in Fig. 6A and 6C at room temperature and in Fig. 8A at 20 K. The difference spectrum on subpicosecond timescales is mostly that of P^* (Fig. 6B). This then evolves with time to form the state shown at 20 ps in Fig. 6C. The absorption decreases in the 760 nm (Fig. 6C) and 546 nm (Fig. 3) bands of the reaction center at this time have been used to argue that the state present is predominantly a charge-separated state made up of the cation of P and the anion of the A-side BPh_e (H_A^- ; see below for a discussion of the relative yields of charge separation along the A and B cofactors), though the absorption changes near 800 nm complicate this assignment (Kirmaier and Holten, 1987). The extent of the 760 and 800 nm absorption changes associated with formation of the anion can be seen most easily when the contribution of the absorption changes due to P^+ have been subtracted.

Fig. 8. (A) Transient absorption change spectra at 20 K from R-26 reaction centers (*Rb. sphaeroides*). Excitation was with a roughly 200 fs pulse at 880 nm. The difference spectra shown are representative spectral slices through a 20 K absorption change vs. time and wavelength surface similar to that shown in Fig. 6A at 295 K. (B) The 20 K ground state spectrum of R-26 reaction centers over the same wavelength region as in panel A.

Since the quinone does not absorb significantly in the near infrared, the $P^+Q_A^-$ difference spectrum is usually taken to represent absorption changes due to P^+ . Fig. 9A compares the $P^+H_A^-$ absorbance change spectrum (15 ps) and the $P^+Q_A^-$ absorbance change spectrum (660 ps). Fig. 9B shows the result of subtracting the $P^+Q_A^-$ spectrum from the $P^+H_A^-$ spectrum. In the resulting difference spectrum there is a large bleaching not only at 760 nm presumably corresponding to H_A^- , but also a large bleaching near 800 nm. The concept that this state might be an equilibrium mixture of two states, $P^+H_A^-$ and $P^+B_A^-$, was proposed (Shuvalov and Parson, 1981) but later thought improbable due to the fact that the relative absorption changes between the 760 and 800 nm regions were not very temperature dependent (Kirmaier and Holten, 1987). Since BPh_e has a less negative midpoint potential, it seemed reasonable that, at least at low temperature where thermal population of two states with different enthalpies is unlikely, $P^+H_A^-$ would predominantly remain. As will be discussed below, however, the energetics of initial charge separation is still a matter of debate and its temperature dependence is not entirely understood.

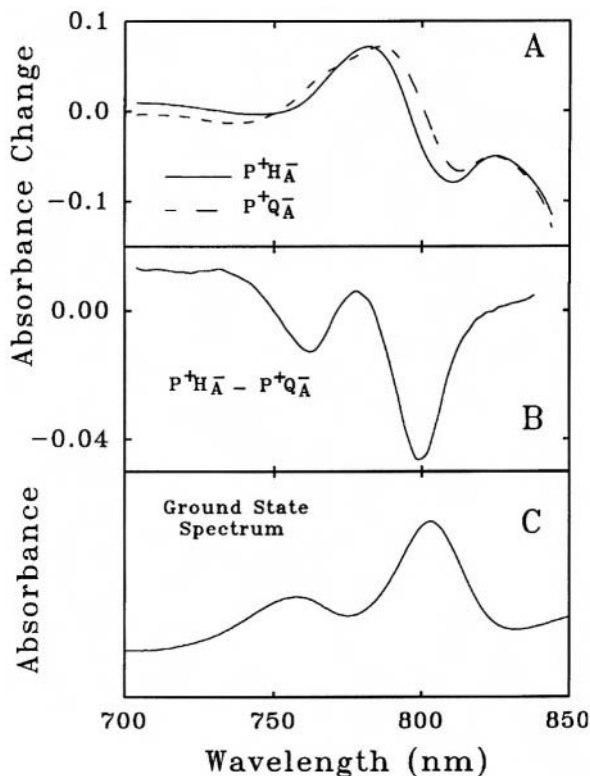

Fig. 9. (A) 295 K transient absorption change difference spectra of reaction centers from *Rb. sphaeroides* strain R-26 at 20 ps (solid line) and 660 ps (dashed line) thought to correspond to the states $P^+H_A^-$ and $P^+Q_A^-$, respectively. Spectra taken as described in Fig. 6. (B) The difference between the two spectra in panel A thought to represent the contribution from H_A^- . (C) The ground state spectrum of R-26 reaction centers in the same wavelength region as the difference spectra in panels A and B.

Mutagenesis has also helped in understanding the charge-separated state. In the β mutant, the spectral characteristics of the state present after initial electron transfer are dramatically altered (Fig. 10), again implying that H_A is probably playing a predominant role in the formation of the 15 ps charge-separated state in the wild type (Kirmaier et al., 1991). This evidence coupled with detailed kinetic and photodichroism studies of a transient absorption increase near 650 nm thought to represent the anion of the charge-separated state (Fig. 10; Kirmaier et al., 1985a; Kirmaier and Holten, 1991) has led to the general acceptance of the assignment of the state present 15 ps after light absorption as being predominantly $P^+H_A^-$ (Kirmaier and Holten, 1987).

Fig. 10. Absorption difference spectra for (A) wild type reaction centers from *Rb. sphaeroides* at 0.4 ps and 15 ps and (B) $Leu^{L214} \rightarrow His$ mutant reaction centers (the β mutant) at 0.4 ps and 30 ps. The absorption change spectra at 0.4 ps are thought to represent the initial excited state, P^* . The longer time spectra shown are thought to represent the charge separated state $P^+H_A^-$ in the case of wild type and $P^+\beta_A^-$ in the case of the β mutant. Note that there are no absorbance changes observed in the 530 to 550 nm region in the β mutant, in sharp contrast to the wild type. This figure was reproduced from Kirmaier et al. (1991), and further details can be found in that publication.

B. Charge Recombination in the State $P^+H_A^-$

It is possible to measure the intrinsic decay time of the state $P^+H_A^-$ in reaction centers where the subsequent transfer of an electron to Q_A has been blocked by reduction or removal of the quinones. At room temperature, the lifetimes reported for this state vary from 10 to 20 ns, depending on the sample conditions and the state of the quinone (reduced or removed, Schenck et al., 1982; Ogrodnik et al., 1982; Chidsey et al., 1984). There are three pathways for decay of $P^+H_A^-$ (Scheme (1)). First, it is possible to have recombination reforming the excited singlet state which then decays by mechanisms discussed above to the ground state. This probably has very little role in the decay of $P^+H_A^-$ in wild type reaction centers, since the free energy of the state $P^+H_A^-$ is substantially below that of P^* on the nanosecond timescale (see below). It does appear to play a role in

the decay of $P^+H_A^-$ in some mutants in which the midpoint potential of the special pair has been greatly increased, resulting in a much smaller free energy gap between P^* and $P^+H_A^-$ (Taguchi et al., 1992; Peloquin et al., 1994).

The second possible decay route for $P^+H_A^-$ is direct recombination to the ground state. This occurs with a time constant of roughly 10 ns in *Rb. sphaeroides* reaction centers where electron transfer to the quinone is blocked by reduction (Schenck et al., 1982). This is the dominant decay path in wild type reaction centers at room temperature; nearly 90% of the decay follows this route (Parson et al., 1975). This reaction is interesting in its own right, since it represents electron transfer between H_A and P, much as does the forward reaction, except that different molecular orbitals of P and H_A are involved.

The final decay path for $P^+H_A^-$ involves triplet formation. After charge separation, the coupling between the electron spins of the radical pair is small enough so that over a period of nanoseconds the spins can dephase resulting in the formation of radical pair states with triplet character (Parson et al., 1975). Charge recombination then results in the formation of triplet P, 3P , with a yield of 5–10% at 295 K. At 77 K, the recombination reaction in the singlet state slows down and 3P formation becomes the dominant decay product of $P^+H_A^-$ when electron transfer to the quinone is blocked.

VIII. Electron Transfer to the Primary Quinone

A. The Absorption Changes Associated with Electron Transfer to Q_A

As described above, most investigators believe that the state present 15 ps after excitation of the reaction center is predominantly $P^+H_A^-$. During the subsequent several hundred picoseconds, this state decays to form the state $P^+Q_A^-$. This process can be followed by

observing the absorption changes at 546 or 760 nm due to recovery of the ground state absorption of the BPhe as the electron is transferred to the quinone or by observing the change in the absorption near 650 nm where the anion of BPhe absorbs (Kirmaier and Holten, 1987). As was the case with the initial electron transfer reaction, the rate at which these absorption changes occur depends on the wavelength of measurement (Kirmaier et al., 1985b; Kirmaier and Holten, 1990). Single exponential fits of the absorption changes yield time constants ranging from 80 ps to 320 ps in *Rb. sphaeroides* reaction centers. There are various possible ways of explaining the complex kinetics, but because there are no obvious intermediate charge-separated states between the BPhe and the primary quinone, it has been suggested that multiple conformational states of the reaction center, either as a static distribution or a dynamic progression, give rise to the kinetic and spectral complexity observed. Like the kinetics of the initial electron transfer reaction, the rate of electron transfer to Q_A is only weakly temperature dependent, increasing by about a factor of two as the temperature is lowered from 295 K to 4 K (Kirmaier et al., 1985b).

B. $P^+Q_A^-$ Charge Recombination

If electron transfer to the secondary quinone is blocked, $P^+Q_A^-$ decays to the ground state in about 100 ms at room temperature in *Rb. sphaeroides* reaction centers. Charge recombination in this state is faster at low temperature, occurring in about 30 ms at 77 K (Parson, 1987). There is a substantial body of literature that considers the mechanism of this recombination reaction. Much of this work has utilized conditions, mutations or quinone substitutions that change the midpoint potential of Q_A or P, followed by measurement of the effects of those changes on the charge recombination kinetics (Gunner et al., 1982; Gopher et al., 1985; Popovic et al., 1986a,b; Woodbury et al., 1986; Lösche et al., 1987; Franzen et al., 1990, 1993; Williams et al., 1992c; Franzen and Boxer, 1993; Lin et al., 1994). The thermodynamics of this state and the effect of changing the redox chemistry of the quinone on charge recombination will be considered in a later section of this chapter. However, measurements in *Rb. sphaeroides* reaction centers point to the concept that with ubiquinone in the Q_A pocket at room temperature, most of the recombination occurs

utilizing $P^+H_A^-$ as a virtual intermediate in a superexchange mechanism (Franzen et al., 1993). When quinones with more negative redox potentials are substituted for ubiquinone, an activated route, probably also involving $P^+H_A^-$ as a thermally accessible intermediate, becomes dominant (Woodbury et al., 1986; Gunner et al., 1982). The thermally activated path is also observed in native reaction centers of *Rp. viridis* (Shopes and Wraight, 1987).

IX. Electron Transfer from the Primary to Secondary Quinone

In many respects, the most complex reaction that occurs in the reaction center is electron transfer between the two quinones. Unlike the other electron transfer reactions that occur between one-electron carriers in a nearly solid-state configuration, Q_B is a two electron carrier and electron transfer is linked both to proton uptake and binding of quinone to the Q_B site. The details of this reaction are the subject of Chapter 26 by Okamura and Feher.

X. The Thermodynamics of Reaction Center Electron Transfer

A. The Standard Free Energy Difference Between P^* and $P^+H_A^-$

Two primary techniques have been used to measure the standard free energy difference between P^* and early charge-separated states. One of these involves monitoring the yield and decay of 3P . The predominant path to 3P formation in the reaction center is intersystem crossing in the state $P^+H_A^-$ followed by charge recombination (Scheme (1)); Parson et al., 1975). The yield of formation and the rate of decay of the triplet state are sensitive to the free energy difference between $P^+H_A^-$ and 3P (Chidsey et al., 1985). Combined with the known energies of 3P and P^* relative to the ground state, the free energy gap between P^* and $P^+H_A^-$ has been estimated as about 0.26 eV in *Rb. sphaeroides* reaction centers (Takiff and Boxer, 1988; Goldstein et al., 1988; Ogrodnik et al., 1988). The limitation of this technique is that it can only be used to determine the free energy gap tens of nanoseconds or microseconds after electron transfer has occurred.

The other common method for estimating the free

energy gap between P^* and the early charge-separated states is to monitor the fluorescence of P^* as a function of time after excitation and to compare the initial fluorescence amplitude of P^* (the initial concentration of P^*) to the amplitude of the fluorescence due to back electron transfer from early charge-separated states (Schenck et al., 1982). This method has the advantage of giving information about electron transfer energetics on the timescale of electron transfer. However, the analysis is model dependent, requiring the assumption that the small amplitude fluorescence components are due to thermal repopulation of P^* from $P^+H_A^-$. Though this interpretation is largely accepted on the nanosecond timescale, there are alternative, kinetically consistent, interpretations of the very early time complexities of P^* decay that involve an intrinsic static heterogeneity in the reaction center population giving rise to several different rates of P^* decay (discussed below; see also Ogrodnik et al., 1994).

If one accepts the model that the complex kinetic decay of the excited singlet state is due to thermal repopulation of P^* from a series of charge-separated states with different energies (this model for the decay kinetics of P^* is discussed in more detail below), then this leads to the conclusion that the standard free energy gap between P^* and the early charge-separated state(s) depends strongly on the timescale of the measurement. On the nanosecond timescale, in reaction centers in which electron transfer past $P^+H_A^-$ is blocked by reduction of the quinones, the standard free energy gap between P^* and $P^+H_A^-$ calculated from the long-lived fluorescence amplitude is nearly 0.20 eV (Woodbury and Parson, 1984; Schenck et al., 1982; Woodbury et al., 1986), approaching that determined by the longer timescale triplet P technique. However, on the timescale of a few tens of picoseconds, the free energy gap estimated from the P^* fluorescence decay is only about 0.12 eV (Williams et al., 1992b). If one interprets the multiexponential decay of P^* on the picosecond timescale in terms of equilibration with a charge-separated state, then the free energy gap calculated is a few tens of meV or less, depending on the temperature (Woodbury et al., 1994). Obviously, the issue of the driving force for electron transfer at early times is not completely understood, and the estimates one obtains for this number are dependent on the model one uses to describe the kinetics of electron transfer.

One of the most confusing and controversial aspects

of the thermodynamics of electron transfer is its temperature dependence. If one estimates the standard free energy change between P^* and $P^+H_A^-$ on microsecond timescales by monitoring the 3P state, one finds that the free energy determined is nearly temperature independent (Takiff and Boxer, 1988; Ogrodnik et al., 1988). This implies that the driving force for electron transfer is largely enthalpic. However, if one estimates the free energy change between P^* and $P^+H_A^-$ from the fluorescence decay as described above, then one finds that the standard free energy change calculated is very temperature dependent, decreasing from approximately 120 meV on the ten picosecond timescale at 295 K to less than 10 meV on the same timescale at 20 K (Peloquin et al., 1994). A plot of the time evolution of the standard free energy difference between P^* and the early product(s) of charge separation as a function of temperature, calculated from the fluorescence decay, is shown in Fig. 11 for one of the high potential hydrogen bond mutants ($\text{Leu}^{\text{L131}} \rightarrow \text{His}$). Similar results are obtained for R-26 reaction centers, though the level of the long-lived fluorescence is lower (see below). According to this analysis, the free energy becomes very small as one approaches zero time and

zero temperature. A naive analysis of the temperature effect on the free energy gap might imply that the driving force for electron transfer was largely entropic, contrary to the experiments performed on longer timescales. However, a more careful consideration of the temperature dependence of the P^* decay shows that the relationship between free energy and temperature is not linear over a very large temperature region as would be expected for a purely entropic process (Woodbury and Parson, 1984; Peloquin et al., 1994). Instead, the slope of the temperature dependence varies dramatically, particularly near 200 K and 100 K. This, coupled with the fact that the free energy appears to be smaller at early times, has led to the suggestion that the free energy of the system is strongly affected by movements of the cofactors and their protein environment, and that these movements are frozen out at low enough temperature or simply have not had time to occur at early times (Peloquin et al., 1994; Woodbury et al., 1994). Another possibility is that the time and temperature dependence of the fluorescence decay results from a broad distribution of charge-separated state free energies which is static on the time scale of

Fig. 11. The time and temperature dependence of the standard free energy difference between P^* and $P^+H_A^-$ for $\text{Leu}^{\text{L131}} \rightarrow \text{His}$ mutant reaction centers. The free energy gap was calculated as described in Peloquin et al. (1994). The figure is reproduced from Peloquin et al. (1994).

these experiments (Ogrodnik et al., 1994).

One further way of exploring the thermodynamics of the early electron transfer reactions is to consider the effects of mutations known to change the steady-state P/P^+ midpoint potential. For the hydrogen bond mutants that change the P/P^+ reduction potential over a nearly 400 mV range (Williams et al., 1992a,b; Murchison et al., 1993; Lin et al., 1994), one finds that as the P/P^+ midpoint potential is increased, more long-lived fluorescence due to back electron transfer is observed. This is consistent with the idea that much of the long-lived fluorescence is due to back electron transfer reforming P^* , since one would expect an increase in the P/P^+ midpoint potential to be correlated with a decrease in the free energy gap between $P^+H_A^-$ and P^* making thermal repopulation of P^* more favorable.

B. The Relative Standard Free Energy of $P^+B_A^-$

Little experimental evidence exists on the free energy of $P^+B_A^-$. However, there is one recent paper which addresses this question within the model of an initial charge separation reaction forming a true $P^+B_A^-$ state followed by a faster reaction forming $P^+H_A^-$ (see below). In this work, Schmidt et al. (1994) used a transient absorbance increase near 1050 nm as a indication of the population of B_A^- . By performing a replacement of H_A with pheophytin (instead of bacteriopheophytin) they were able to increase the relative free energy of $P^+H_A^-$. This resulted in thermal repopulation of $P^+B_A^-$ and P^* from $P^+H_A^-$ which allowed them to estimate energies for these states. From the level of the apparent anion absorbance near 1050 nm under these conditions they calculated a standard free energy difference of about 50 meV between $P^+B_A^-$ and P^* . It is important to note that, like the fluorescence methods discussed above, the use of thermal repopulation to calculate the free energy of $P^+B_A^-$ in this system depends explicitly on the model employed.

C. The Relative Standard Free Energy of $P^+Q_A^-$

The decay of the much weaker long-lived (millisecond) fluorescence from P^* in thermal equilibrium with $P^+Q_A^-$ has given rise to estimates for the standard free energy of this state as well. $P^+Q_A^-$ is estimated to be about 0.86 eV below P^* in free energy or about 0.52 eV above the ground state in *Rb. sphaeroides* (Arata and Parson, 1981). The latter value very nearly

matches what one obtains by using the measured midpoint potentials of P and Q_A . Similar measurements have placed $P^+Q_B^-$ about 60 meV below $P^+Q_A^-$ at neutral pH (Arata and Parson, 1981). A similar value is also obtained by a consideration of the decay kinetics of these two states (Kleinfeld et al., 1984; Maróti and Wraight, 1988). A much larger free energy difference between $P^+Q_A^-$ and $P^+Q_B^-$ is observed in reaction centers of *Rp. viridis* (Gao et al., 1991).

Similar estimates of the standard free energy difference between P^* and $P^+Q_A^-$ have been made on a series of reaction centers in which Q_A has been removed and replaced by a quinone other than ubiquinone (Woodbury et al., 1986). As with the series of mutations described above that alter the P/P^+ midpoint potential, one would expect that substitution with quinones of higher reduction potential than ubiquinone would result in a $P^+Q_A^-$ state that is closer to P^* in energy and thus would give rise to more thermal reformation of P^* during the lifetime of $P^+Q_A^-$. A clear correlation is observed between the amplitude of the long-lived (millisecond) fluorescence decay and the reduction potential of the quinone used, supporting the validity of the estimates of the relative free energy of $P^+Q_A^-$ using the fluorescence measurements.

A summary of the energetics of the excited and charge-separated states of *Rb. sphaeroides* reaction centers is given in Fig. 12.

XI. Reaction Center Symmetry and the Direction of Electron Transfer

One of the most striking features of the reaction center crystal structure is the approximate 2-fold rotational symmetry which encompasses both the cofactors and the two core protein subunits, L and M (Fig. 1A; Deisenhofer et al., 1984; Allen et al., 1987; Chang et al., 1991). As alluded to above, however, the predominant cofactors involved in the initial electron transfer events appear to be those on the A-side of the reaction center. The exact ratio of A vs. B side electron transfer is not agreed upon. Values have been published ranging from about 3.6:1 favoring the A-side to 200:1 (Horber et al., 1986a,b; Tiede et al., 1987; Kellogg et al., 1989; Michel-Beyerle et al., 1988; Kirmaier et al., 1985a; Breton et al., 1986; Bylina et al., 1988; Lockhart et al., 1990). The evidence for electron transfer directionality comes primarily from monitoring the absorption

Fig. 12. Free energy diagram of the states P^* , $P^+H_A^-$, $P^+Q_A^-$ and $P^+Q_B^-$ relative to the ground state (set at zero on the diagram) at 295 K. The energy of P^* relative to the ground state was determined for the estimated zero-zero transition energy (Woodbury and Parson, 1984). The standard free energy difference between P^* and $P^+H_A^-$ was determined from the long-lived fluorescence amplitude on the roughly 20 ps timescale (Peloquin et al., 1994; Williams et al., 1992a; Woodbury and Parson, 1984; Schenck et al., 1982). The standard free energy differences between P^* and $P^+Q_A^-$ and between P^* and $P^+Q_B^-$ were determined from the amplitude of the millisecond fluorescence (Arata and Parson, 1981).

changes due to reduction of the two BPhes which can be distinguished spectrally at low temperature (Fig. 3). Steady state photopumping experiments have been performed in which the rate or yield of H_B reduction is measured and compared to that of H_A reduction (Tiede et al., 1987; Kellogg et al., 1989). Also, direct measurements of absorption changes in the H_B spectral bands have been performed on the picosecond timescale (Fig. 3; Kirmaier et al., 1985a,b; Breton et al., 1986; Bylina et al., 1988; Lockhart et al., 1990). All of these have shown electron transfer strongly favoring formation of H_A^- though the magnitude and interpretation of the small spectral changes in the H_B absorption bands varies between different reports and using different samples and conditions.

It is clear from the photopumping measurements that it is possible to form the state $P^+H_B^-$, implying that this state does not lie very far above P^* in energy. However, it is not clear at this point whether the major determining factor in the directionality of electron transfer is the kinetics or the thermodynamics

of the process. Because the mechanistic reasons underlying the predominant A-side electron transfer are not known and the formation of $P^+H_B^-$ is clearly at least possible under certain conditions, it is difficult to extrapolate accurately between measurements at cryogenic temperatures (where the BPh spectral bands are well resolved) in isolated reaction centers and the actual working of the photosynthetic apparatus at physiological temperatures in an energized biological membrane. However, the indication from the available spectroscopic data is that electron transfer in vivo predominantly involves A-side cofactors.

Several attempts have been made to alter the symmetry of the reaction center by mutagenesis. The first, and perhaps most relevant of these to our present understanding of the importance of symmetry in electron transfer, are the two heterodimer mutants. One might think that the symmetry-breaking aspect of the reaction center that is important for the observed asymmetry in electron transfer would be the environment around the special pair itself. Since there is no unambiguous evidence for B-side electron transfer on any timescale, it makes sense to suggest that the asymmetry of importance exists in the very initial state of the system, P^* . It also seems reasonable to suppose that changing one of the BChl molecules of the special pair to a BPh would skew the electron density in this state to one side (as it does in the state P^+ ; Huber et al., 1990; Bylina et al., 1990), therefore predisposing the system to undergo electron transfer along one of the branches. However, neither heterodimer mutant significantly affects the directionality of electron transfer (McDowell et al., 1991b).

Further evidence that the environment of the special pair does not play a predominant role in determining the direction of initial electron transfer comes from the *Rb. capsulatus* mutant, *sym I*, which symmetrizes a large fraction of the amino acids in the vicinity of P (Taguchi et al., 1992; Stocker et al., 1992). Though a small fraction of the B-side BPh Q_X band appears to bleach in this mutant at 20 K, the effect is no larger than that observed in wild type grown and isolated under the same conditions (Woodbury et al., unpublished results). Apparently, the symmetry of the electron distribution of the special pair is not the only determining factor in the direction of electron flow.

This points to the environment of cofactors further along the chain as potentially important in

determining the electron transfer asymmetry. Several different mutations have been made that alter the environment of one or the other monomer BChl in the reaction center. One of the amino acids predicted to significantly affect the energy of B_A is the tyrosine at M210 in *Rb. sphaeroides* (Parson et al., 1990). Changing this to a phenylalanine, the identity of the symmetrically related amino acid at L181, increases the lifetime of the excited singlet state of P, but does not appear to affect the direction of electron flow (Nagarajan et al., 1990; Finkle et al., 1990). Similarly, changing the phenylalanine at L181 to a tyrosine or preparing the double mutant in which the tyrosine and phenylalanine are exchanged between the two subunits affects the lifetime of P^* , but does not appear to dramatically alter the direction of electron transfer (Chan et al., 1991b).

One other mutation that speaks to this issue is the β mutant that changes the A-side BPhe to a BChl (Kirmaier et al., 1991). This mutation cleanly removes any bleaching due to H_A in the BPhe Q_x region of the spectrum, and by perturbing the energy of the A-side electron acceptor, it could potentially force the electron transfer down the other branch, particularly if the determining factor in the electron transfer asymmetry was the thermodynamics of the charge-separated state (Kirmaier et al., 1991). Despite these changes, however, there is no significant bleaching in the Q_x absorption band of H_b in this mutant (Fig. 10; Kirmaier et al., 1991).

Finally, large scale mutations were prepared in which a number of amino acids in the D-helix near the monomer BChls and the BPhes have been either made the same between the L and M subunits or have been exchanged (Robles et al., 1990). These mutations do have large effects on electron transfer, but no evidence has been obtained for B-side electron transfer. Of particular note in this regard is the D_{LL} mutant that appears to completely lack the A-side BPhe. There is no evidence, even with the A-side completely nonfunctional, for significant electron transfer along the B-side (Vos et al., 1991).

XII. The Pathway and Mechanism of Initial Electron Transfer

The pathway and mechanism of the initial electron transfer reaction has been the source of considerable controversy (Holzapfel et al., 1989, 1990; reviewed by Kirmaier and Holtén, 1993; Chan et al., 1991a;

Martin and Vos, 1992) and as yet no consensus has been reached. As described above, the kinetics of both P^* decay and of the formation of subsequent charge-separated states is complex. P^* decay occurs on many timescales with multiple kinetic components as determined by exponential decay analysis of the spontaneous emission. The absorption changes associated with charge separation are also complex, involving multiple exponential decay components and wavelength dependent kinetics, at least at physiological temperatures. Since P^* can be monitored by following the emission from this state, its population can be detected even at very low levels, and therefore, its decay kinetics have been characterized over longer timescales than charge-separated state formation. Thus, models to describe the decay of the excited state will be considered first.

A. Kinetic Models for P^* Decay

There are two general types of models that have been suggested to explain the multiexponential decay of the excited singlet state. One is that the different kinetic components of the P^* decay represent different subpopulations of reaction centers with different rate constants for electron transfer (Kirmaier and Holtén, 1990; Müller et al., 1992). This could explain the complexity of the P^* decay on the picosecond to hundred picosecond timescales if one assumed a very broad distribution of electron transfer rate constants within the reaction center population. However, it is unlikely that this could be used to account for P^* decay times longer than a few hundred picoseconds because the intrinsic lifetime of P^* in the absence of electron transfer is thought to be only 100–300 ps in the wild type (see above) and even shorter in some mutants that still show substantial levels of long-time fluorescence (Williams et al., 1992a; Peloquin et al., 1994). At least on the longer timescales, one needs to invoke the participation of substantial back electron transfer reforming P^* from the charge-separated state(s).

The concept of reversible electron transfer brings up the second class of possible explanations. The complex kinetics of P^* could be generated by reversible reactions between P^* and several different charge-separated states or multiple nuclear configurations of the same charge-separated state. This could manifest itself as several possible parallel products of P^* decay (Müller et al., 1992; Hamm et al., 1993) or as a linear sequence of product states

(Kirmaier et al., 1985b; Du et al., 1992; Woodbury et al., 1994). The latter model has been used for the estimation of free energy gaps from fluorescence decay data (discussed above in the section on thermodynamics; Schenck et al., 1982; Woodbury and Parson, 1984; Peloquin et al., 1994). The one requirement of any model involving substantial backwards electron transfer is that the states involved must be close enough in free energy so that significant thermal repopulation of the initial state is possible. This last point has important implications. A linear series of charge-separated states in a homogeneous reaction center population can only give rise to the complex P^* decay observed if significant back electron transfer occurs, reforming P^* from the charge-separated state(s). A spectral analysis of the reaction center absorption changes that are concurrent with the various decay components of P^* is consistent with the notion that a series of protein conformational changes altering the free energy of the state $P^+H_A^-$ occurs as a function of time (Woodbury et al., 1994). A similar model also explains the temperature dependence of the long-lived fluorescence from reaction centers (Peloquin et al., 1994). However, since the decay of P^* is complex even at low temperature, this model requires that the free energy difference between P^* and the form of $P^+H_A^-$ present shortly after electron transfer is very small, a few meV at 20 K (discussed above; see also Peloquin et al., 1994; Woodbury et al., 1994).

None of the simple models described above to explain the complex P^* decay are wholly satisfactory. It is not clear either how electron transfer at low temperature could occur with driving forces of a few meV or why there would be a distribution of productive electron transfer reaction rates within the reaction center population spanning two to three orders of magnitude. Before considering mechanistic issues further, the experimental evidence from transient absorption studies for the involvement of intermediate states in this reaction will be considered.

B. The Role of B_A in Initial Electron Transfer

The absorption changes associated with the early charge separation reaction involve both multiple exponential decay components and wavelength-dependent kinetics, at least at room temperature. Perhaps the simplest way to explain a wavelength-dependent reaction timecourse is to introduce an intermediate state with a significantly different

spectrum from the initial or final states. Due to the position of the A-side monomer BChl in the reaction center structure (Fig. 1 A), the state $P^+B_A^-$ is an obvious possibility for such a state as illustrated in the following kinetic scheme:

where the time constants shown are for fits performed at 295 K of the data in Fig. 6A. Absorption change kinetics at some key wavelengths that have been used as evidence for a $P^+B_A^-$ intermediate are shown in Fig. 13. As shown in Fig. 14A, multiexponential fits of this transient absorption data over a broad wavelength range result in a fast (0.9 ps) change in these regions followed by a slower (3.1 ps) kinetic component. It is particularly striking that in some spectral regions these two changes are actually in opposite directions (see 788 nm in Fig. 13). This has been taken as strong evidence that there are more

Fig. 13. The kinetics of absorption changes at several representative wavelengths between 760 and 840 nm using reaction centers from *Rb. sphaeroides* strain R-26 at 295 K. These curves represent temporal slices through the absorption change surface of Fig. 6A.

than two spectrally independent components involved in the reaction.

The involvement of anion states of bacteriochlorophyll has also been inferred from transient absorbance measurements in the 1000 to 1100 nm region where the anion of bacteriochlorophyll is expected to absorb. Zinth and coworkers have observed a short-lived absorbance increase in this region which they have assigned to the low steady-state population of $P^+B_A^-$ using a model similar to kinetic Scheme (2) above (Arlt et al., 1993; Schmidt et al., 1994).

Note that in Scheme (2) the initial reaction is slower than the second reaction (i.e., $k_1 < k_2$). This is because the spectral evidence for the intermediate state involves relatively small absorption changes compared to those expected from the state $P^+B_A^-$. Fig. 14A shows the amplitude spectra of the absorption changes associated with the 0.9 ps, 3.1 ps and constant terms which result from an exponential fit of the absorption change surface in Fig. 6A.

Using the global exponential decay analysis of Fig. 14A, one can take a specific kinetic scheme, such as Scheme (2), and calculate the difference spectra for the proposed intermediate states. The results of such an analysis for Scheme (2) at 295 K are shown in Fig. 14B. Similar analyses have been performed by Holzzapfel et al. (1990) on a series of kinetic traces with less spectral resolution. The calculated spectrum of the $P^+B_A^-$ intermediate state in this model does show substantial bleaching near 800 nm, as one might expect for a BChl anion. However, the spectra derived from this model are complex, and both $P^+B_A^-$ and $P^+H_A^-$ have significant absorption changes in all of the Q_y spectral transitions of the reaction center. Thus, identification of the two spectra predicted by this model as $P^+B_A^-$ and $P^+H_A^-$ is not unambiguous. In any case, an irreversible scheme, such as Scheme (2), could not be entirely correct because it predicts a single exponential decay of P^* , contrary to what is observed.

At low temperature (20 K), the complex kinetics of electron transfer still remain (Lauterwasser et al., 1991; Woodbury et al., 1994), but the wavelength dependence of the kinetics is much less pronounced (Kirmaier and Holten, 1990) and isobestic points are maintained throughout the initial electron transfer reaction (Kirmaier and Holten, 1988a). Singular value decomposition analysis (which is model independent) demonstrates that at 20 K there are only two spectrally distinct states required to describe the early electron

transfer reactions of R-26 reaction centers (Fig. 15 and Woodbury et al., 1994). This argues against the concept that there is a distinct $P^+B_A^-$ intermediate at 20 K since one would expect this state to have a spectrum different from either P^* or a pure $P^+H_A^-$ state. It is possible that the electron transfer pathway is different at low and high temperatures (Chan et al., 1991b). However, the fact that the complex kinetics are present at both temperatures suggests that there may be an explanation other than a significantly populated $P^+B_A^-$ intermediate for the multiexponential kinetics of the absorption changes associated with early charge separation.

C. Other Possible Reaction Intermediates

Because the kinetic model in Scheme (2) is not unequivocally supported at 295 K and appears not to hold at 20 K, several other possible explanations for the complex absorbance change kinetics at early times have been considered. First, one could assume that the 0.9 ps component (using the 295 K kinetics) represents the first reaction and the 3.1 ps component the second reaction as shown in Scheme (3).

Here, due to the small size of the absorption changes associated with the fast kinetic component, one possible intermediate state in this model could be an altered form of P^* (Holzapfel et al., 1989). A spectral analysis of the same kinetic decays used for Scheme (2) is also shown in Fig. 14C for Scheme (3). Here one can see that the proposed intermediate state indeed looks similar to the initial P^* in spectral features, though there are changes in the magnitude of the relative extinction coefficient as a function of wavelength. Evidence for changes in the state P^* during the first few hundred femtoseconds after light absorption has been presented by Vos et al. (1991, 1994a,c). This model could explain some of the early time complexity in the decay kinetics of the fluorescence from P^* assuming that P_2^* was also able to fluoresce. Of course, it does not explain the components of the fluorescence decay on the several picosecond to hundreds of picosecond timescale (see above).

D. Reaction Center Heterogeneity

The fact that at low temperature, the wavelength

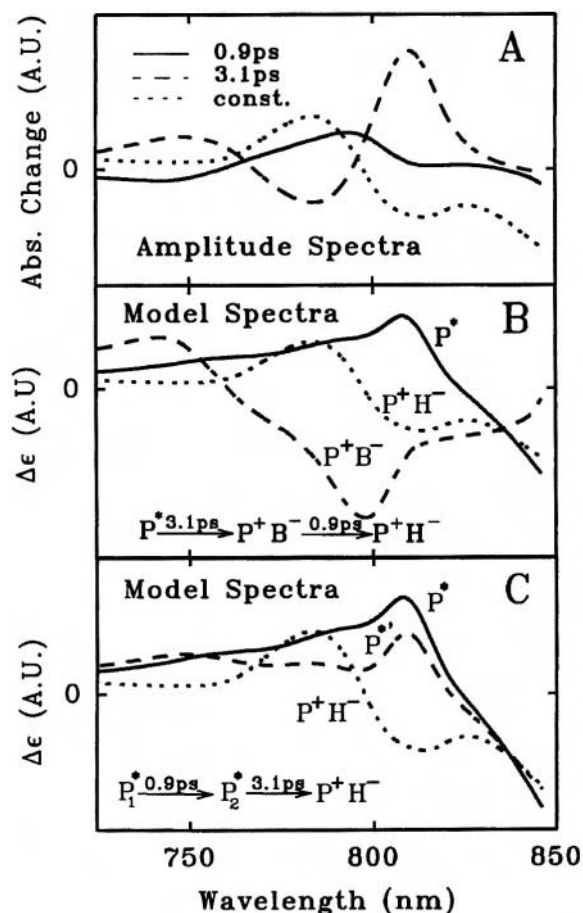

Fig. 14. (A) Preexponential amplitude spectra determined by fitting a time vs. wavelength absorbance change surface of Fig. 6A to a sum of two exponential terms and a constant, $A_1(\lambda)\exp(-k_1t) + A_2(\lambda)\exp(-k_2t) + A_3(\lambda)$, where λ is the wavelength, t is time, $A_i(\lambda)$ are the wavelength dependent preexponential amplitudes resulting from the fit and k_i are first order exponential decay rate constants. In this fit, k_1 was $1/(0.9\text{ ps})$ and its associated preexponential amplitude spectrum, $A_1(\lambda)$, is represented by the solid line, k_2 was $1/(3.1\text{ ps})$ and its preexponential amplitude spectrum, $A_2(\lambda)$, is given by the line with long dashes, and the amplitude spectrum of the constant term, $A_3(\lambda)$, is given by the line with short dashes. Seventy wavelengths were included in each fit over the wavelength region indicated. One hundred time points separated by 150 fs were collected at each wavelength. (B) The wavelength dependence of the model dependent relative difference extinction coefficient ($\Delta\epsilon$) spectra were calculated (see Woodbury et al., 1994) from the amplitude spectra of panel A for each of the states (A, B and C) in a three state irreversible electron transfer model with the first step being slower than the second as described by Holzzapfel et al. (1990). Holzzapfel et al. (1990) have assigned the state A to P^* , the state B to P^+B^- and the state C to P^+H^- . (C) As in panel B except that the model used involves a fast (0.9 ps) irreversible reaction followed by a slower (3.1 ps) one.

Fig. 15. Singular value decomposition analysis of the time vs. wavelength absorption change surface associated with electron transfer in reaction centers from *Rb. sphaeroides* strain R-26 at 20 K. The singular value decomposition was performed using the algorithms of Press et al. (1992). Panel A represents spectral slices through the portion of the time vs. wavelength absorption change surface which is described by matrix multiplication of the column vector representing the first spectral component of the singular value decomposition and the row vector representing the first temporal component weighted by the first diagonal element of the weighting matrix (see Press et al., 1992). Similarly, panels B and C are spectral slices through the surfaces defined by matrix multiplication of spectral and temporal vectors of the second (B) and third (C) components of the decomposition, respectively. It is important to note that the absorption change scale shown in these panels corresponds to the true absorption change associated with each singular value decomposition component. The sum of the surfaces represented by panels A, B and C is exactly equal to the original time vs. wavelength surface represented by the data which was used for this analysis, minus a small contribution from the fourth and higher singular value decomposition components. Panel D is the row vector associated with the third temporal singular value decomposition component. The abscissa of this panel has been scaled so that the timecourse is representative of absorption changes occurring in the 820 nm region. The size of absorption changes in the 790–810 nm region that are associated with this singular value decomposition component are even smaller. The data for this were taken from Woodbury et al. (1994) and this publication should be consulted for further details.

dependence of the kinetics essentially disappears and one finds only two spectrally distinct states involved in the initial electron transfer reaction, presumably P^* and $P^+H_A^-$ (Kirmaier and Holten, 1988a; Kirmaier and Holten, 1990; Woodbury et al., 1994), has suggested that the complex spectral changes in the first few picoseconds may be due to a reaction center population heterogeneity that is either static or dynamic (Kirmaier et al., 1985b; Kirmaier and Holten, 1990; Muller et al., 1992; Small et al., 1992; Jia et al., 1993; Wang et al., 1993; Ogronik et al., 1994; Woodbury et al., 1994; Bixon et al., 1995). There could be either a static heterogeneity in the rate of initial electron transfer or a dynamic heterogeneity due to a series of $P^+H_A^-$ states formed sequentially each with a different free energy relative to P^* , as described above to explain the complex P^* decay. For example, the data of Figs. 6 and 13 could be explained in terms of a model in which there are two distinct reaction center subpopulations each undergoing electron transfer with a different rate. In this model, one needs to assume that the two subpopulations undergo electron transfer at different rates and that the states formed are significantly different in their spectral properties in the 800 nm region at 295 K but not at 20 K (Kirmaier and Holten, 1990; Woodbury et al., 1994). Alternatively, a model in which the free energy difference between P^* and $P^+H_A^-$ is small and time dependent can be used, accounting for the complex absorption change kinetics on the picosecond timescale and for the complex emission decay kinetics on timescales from picoseconds to nanoseconds. However, this model requires a very small free energy difference between P^* and $P^+H_A^-$, particularly at low temperature (Woodbury and Parson, 1984; Peloquin et al., 1994; Woodbury et al., 1994; see also sections above on P^* decay and the thermodynamics of charge separation).

E. Pathway and Mechanism

As described above, there are several possible ways to describe the complex kinetic features associated with the initial electron transfer reaction, and no single mechanism for this reaction has yet been widely accepted. From the present understanding of electron transfer theory in these systems, it is clear that all three bacteriochlorins that comprise the A-side electron transfer chain must play some role in the early electron transfer pathway. Those who support the notion that the kinetic complexity during the first

few picoseconds can be explained by the formation of $P^+B_A^-$ think of this state as a true populated intermediate between P^* and $P^+H_A^-$ (Holzapfel et al., 1989; Arlt et al., 1993; Schmidt et al., 1994). On the other hand, those who use other mechanisms to explain the complexity of the transient absorption data usually assign the role of $P^+B_A^-$ as that of a virtual state, modifying the coupling between P^* and $P^+H_A^-$ but never itself being populated (Kirmaier and Holten, 1991). Alternatively, it is possible that the excited and charge-separated states involved in electron transfer are close in energy and strongly coupled and that none of these states exist in pure form at any time during the course of the reaction (Woodbury et al., 1994; Small et al., 1995), though present theoretical estimates of the electronic coupling between the states involved in electron transfer argue against this concept (Plato et al., 1988; Scherer and Fischer, 1989).

XIII. The Role of the Reaction Center Protein in Electron Transfer

The discussion above has concentrated on the kinetics, thermodynamics and pathway of electron transfer in terms of the reaction center BChls, BPhes and quinones. Because the visible and near infrared spectroscopy of the reaction center is determined by the electronic structure of these cofactors, the cofactors have occupied center stage in electron transfer models. However, there is growing evidence that the protein may play an extremely important role in driving the reaction forward and preventing side reactions which might otherwise occur.

There are a number of studies which have supported the concept that there are changes in nuclear structure during the charge separation (as suggested above), and that the result of these movements either stabilizes the charge-separated state or prevents recombination to form the ground state. For example, the $P^+Q_A^-$ to $P^+Q_B^-$ electron transfer reaction will not occur at cryogenic temperatures if the sample is cooled in the dark. However, cooling the sample in the light results in a significant population of reaction centers apparently frozen in a conformation that allows this reaction to proceed (Kleinfeld et al., 1984). As described above, the multiexponential decay kinetics of P^* can be explained in terms of protein motions progressively stabilizing the charge-separated state (Woodbury and Parson, 1984; Peloquin et al., 1994;

Woodbury et al., 1994). Similarly, some of the complex absorption changes observed during electron transfer to Q_A have been suggested to be due to nuclear motion (Kirmaier and Holten, 1990).

Recently, concerted protein motion has been used to explain the oscillatory behavior of the picosecond and subpicosecond absorption signals in the stimulated emission region of the spectrum (Vos et al., 1993, 1994a,c), opening up the possibility for a direct role of protein motion (or at least direct involvement of protein vibrational modes) in the electron transfer event. Finally, there have been indications from FTIR and resonance Raman measurements of changes in protein-protein or protein-cofactor interactions upon formation of P^+ or Q^- (Breton et al., 1991; Nabedryk et al., 1990a,b; Mattioli et al., 1991b). Ultrafast absorption changes in the infrared spectral region hold promise for further direct observation of protein motion during the early electron transfer reactions (Maiti et al., 1993).

Acknowledgments

The authors would like to acknowledge Drs. A. Taguchi and J. Williams for critical reading of the manuscript and Drs. S. Lin, J. Peloquin, R. Alden, W. Parson, R. Blankenship, C. Kirmaier, D. Holten and S. Boxer for helpful discussions. Some of the data presented here has not been published elsewhere and funding for this work came from grants DMB89-17729 and DMB91-58251 from the National Science Foundation and grants GM41300 and GM45902 from the National Institutes of Health. Instrumentation was purchased with funds from NSF grant DIR-8804992 and Department of Energy grants DE-FG-05-88-ER75443 and DE-FG-05-87-ER75361. This is publication No. 215 from the Arizona State University Center for the Study of Early Events in Photosynthesis.

Summary

Photosynthetic bacterial reaction centers provide a rich territory for exploring the nature of biological electron-transfer reactions. The crystal structures of reaction centers from two species of bacteria are known, and the structures can be modified by site-directed mutagenesis or by substituting other pigments for the natural bacteriochlorophylls, bacteriopheophytins or quinones. Femtosecond laser excitation pulses of various wavelengths can be used to prepare the initial excited state in a variety of conditions, and the kinetics of the subsequent charge separation and recombination reactions can be measured with extremely high time resolution. Measurements can be made under an extraordinarily wide range of conditions, including low temperatures and the presence of external electrical or magnetic fields. Further, there are many intriguing observations to explain. Several of the reactions occur extremely rapidly and become even faster with decreasing temperature; electron transfer along the active 'L' branch of the pigments is much faster than that along the 'M' branch; and seemingly drastic changes in the structure sometimes have little effect on the directionality or rates of the reactions. What is it, then, that determines the speed and temperature dependence of an intermolecular electron-transfer reaction in a protein?

This chapter discusses electron-transfer reactions from a theoretical perspective. Beginning with the picture provided by simple time-dependent perturbation theory, we first set down general expressions that relate electron-transfer rate constants to the energies of the vibrational states of the reactants and products. We then

consider some of the phenomenological expressions that can be used to describe electron transfer under various simplifying assumptions. These expressions range from the classical Marcus equation to the quantum mechanical equation of Kubo and Toyozawa. Many of the expressions have been applied in discussions of reaction centers and have been used to fit experimental data on rate constants as functions of temperature or of the overall free energy change in the reaction. We then turn to microscopic calculations of electron-transfer parameters on the basis of the actual structure of the protein. We show how molecular-dynamics simulations using potential energy functions allow one to calculate free-energy changes and reorganization energies and to evaluate the vibrational modes that are coupled to a reaction. These parameters can be used in several types of dynamic simulations of electron transfer, including fully quantum mechanical density-matrix treatments that incorporate vibrational relaxations of intermediate or product electronic states. The chapter ends with a brief survey of microscopic calculations of electronic coupling factors.

I. Introduction

Imagine a system consisting of an electron donor (D) and acceptor (A) that are very far apart. Let's designate by α the state of the system in which D is reduced and A oxidized, and by β the state in which D is oxidized and A reduced. We'll neglect electronic spins, which give rise to singlet and triplet substates of β , and for the moment we'll also neglect vibrational substates of α and β as well as the interactions of the molecules with their surroundings. We can represent states α and β by wavefunctions ψ_α and ψ_β , with $\psi_\alpha = \psi_D \psi_A$ and $\psi_\beta = \psi_D^+ \psi_A^-$. As long as A and D are too far apart to interact, transitions between states α and β do not occur. In this case, ψ_α and ψ_β are eigenfunctions of the Hamiltonian operator, H_0 , and either wavefunction satisfies the Schrödinger equation, $H_0 \psi = i\hbar \partial \psi / \partial t$.

Now suppose we bring D and A closer together so that the electrical fields from electrons on each molecule begin to contribute to the potential energies of the electrons on the other. These interactions introduce a new term to the Hamiltonian, $H_{\alpha\beta}$, which makes our original solutions to the Schrödinger equation no longer satisfactory. ψ_α and ψ_β now are *adiabatic* states that do not diagonalize the complete Hamiltonian. However, if the interactions between D and A are still relatively weak, reasonably satisfactory wavefunctions can be written in the form of linear combinations of ψ_α and ψ_β , with coefficients (C_α and C_β) that reflect the extent to which the state of the system resembles α or β :

$$\psi = C_\alpha \psi_\alpha + C_\beta \psi_\beta \quad (1)$$

When this expression for ψ is inserted in Schrödinger equation along with the full Hamiltonian $H_0 + H_{\alpha\beta}$ (see, e.g., Merzbacher, 1970; Atkins, 1983), the coefficients C_α and C_β are found to oscillate with time. The frequency of the oscillation depends on the *interaction matrix element* or *electronic coupling factor*, $H_{\beta\alpha}$, which is the integral

$$H_{\beta\alpha} = \langle \psi_\beta | H_{\alpha\beta} | \psi_\alpha \rangle \quad (2)$$

The nomenclature $\langle b | O | a \rangle$ here means that operator O operates on function a , the result is multiplied by the complex conjugate of function b , and the product is integrated over all space. The amplitude of the oscillations of C_α and C_β depends on both $H_{\beta\alpha}$ and the magnitude of the energy difference $\Delta E_{\beta\alpha}$ between states α and β , and it peaks sharply when $\Delta E_{\beta\alpha}$ goes to zero. If we start out with molecule D reduced ($C_\alpha = 1$ and $C_\beta = 0$), the probability of finding that an electron has moved to A ($C_\beta^* C_\beta$, or $|C_\beta|^2$) will begin to grow with time according to the expression

$$|C_\beta(t)|^2 = 2 |H_{\beta\alpha}|^2 \frac{1 - \cos[\Delta E_{\beta\alpha} t / \hbar]}{(\Delta E_{\beta\alpha})^2} \quad (\text{for } t \approx 0) \quad (3)$$

The initial rate of the transition is obtained by differentiating Eq. (3) with respect to time:

$$\frac{\partial}{\partial t} |C_\beta(t)|^2 = (2 / \hbar) |H_{\beta\alpha}|^2 \frac{\sin[\Delta E_{\beta\alpha} t / \hbar]}{\Delta E_{\beta\alpha}} \quad (\text{for } t \approx 0) \quad (4)$$

Abbreviations: B_L and B_M – accessory bacteriochlorophylls on the L (photochemically active) and M (inactive) sides of the purple bacterial reaction center; H_L and Q_A – bacteriopheophytin and quinone that act as the initial electron acceptors; P – bacteriochlorophyll dimer that serves as the primary electron donor; *Rb.* – *Rhodobacter*; *Rp.* – *Rhodospseudomonas*

In general, an electron-transfer reaction involves a variety of nuclear vibrational and rotational substates of the product electronic state β , so $\Delta E_{\beta\alpha}$ can take on different values. Interactions with the surroundings broaden the distribution of energies by causing the initial product to decay into more stable forms. To obtain an expression for the electron-transfer rate constant (k_{et}), we therefore must integrate Eq. (4) over a range of energies. However, the term $\sin[\Delta E_{\beta\alpha}t/\hbar]/\Delta E_{\beta\alpha}$ drops off very rapidly as $\Delta E_{\beta\alpha}$ departs from zero.

The contributions of transitions to various nuclear substates can be assessed by writing the time-dependent wavefunction of the system as a sum of products of the electronic wavefunctions (ψ_α and ψ_β) and nuclear wavefunctions (χ_i and χ_f):

$$\Psi = \sum_i C_{i(\alpha)} \psi_\alpha \chi_i + \sum_f C_{f(\beta)} \psi_\beta \chi_f \quad (5)$$

The matrix elements for the individual vibronic transitions then are given by

$$H_{f(\beta)i(\alpha)} = \langle \psi_\beta \chi_f | H_{\alpha\beta} | \psi_\alpha \chi_i \rangle \approx \langle \chi_f | \chi_i \rangle H_{\beta\alpha} \quad (6)$$

The square of the overlap integral of a pair of nuclear wavefunctions, $|\langle \chi_f | \chi_i \rangle|^2$, is termed a *Franck-Condon factor*. If the reacting system is in thermal equilibrium with its surroundings, summing up the contributions of all the possible vibrational transitions and integrating Eq. (4) over the widths of the vibrational energy levels gives

$$k_e = (2\pi/\hbar) |H_{\beta\alpha}|^2 \sum_i \frac{e^{-E_i/k_B T}}{Z} \sum_f |\langle \chi_f | \chi_i \rangle|^2 \delta_{E_f, E_i} \quad (7)$$

$$\text{where } Z = \sum_i e^{-E_i/k_B T}$$

and k_B is the Boltzmann constant. The factor $e^{-E_i/k_B T}/Z$ weights the contribution from vibrational level i of α according to the population of this level at temperature T . The delta function δ_{E_f, E_i} is 1 if the energy of level f of β (E_f) is the same as that of α 's level i (E_i), and zero otherwise.

Electron transfer thus can occur at an appreciable rate only if the reactants have a thermally accessible nuclear state whose energy is the same as that of a nuclear state of the products, and if the Franck-Condon factor for this combination of states is not zero. The semiclassical statement of these conditions

is that electron transfer occurs at points where the potential-energy surfaces of the reactants and products intersect (Fig. 1). It is only at these intersections that the system can move from the reactant to the product surface while conserving both energy and momentum. The electron-transfer rate depends on the frequency at which random structural fluctuations of the reactants and their surroundings bring the system to such crossing points, and on the strength of the coupling factor that then can induce transitions to the product state. If $H_{\beta\alpha}$ is relatively small, so that the

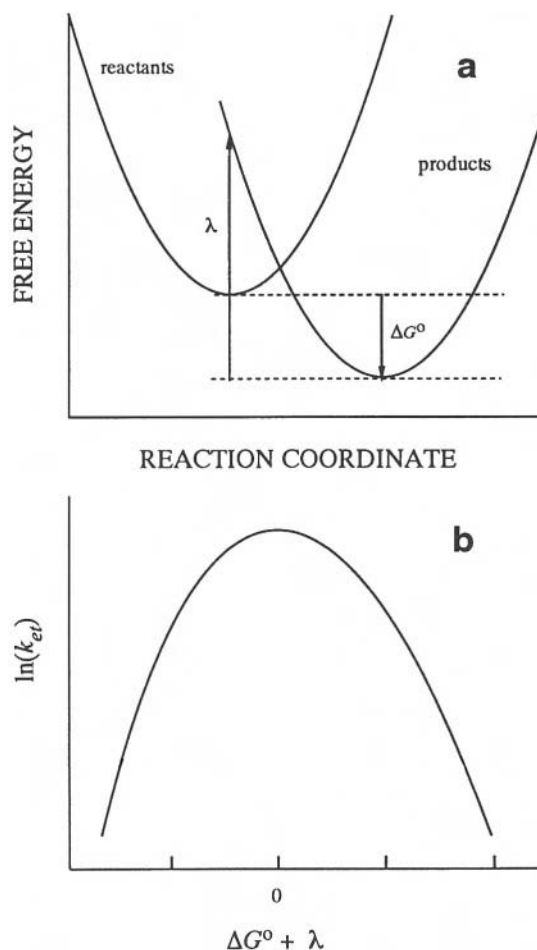

Fig. 1. (a) A schematic depiction of the free-energy surfaces for the reactant and product states in an electron-transfer reaction. The abscissa is the reaction coordinate (x). Electron transfer can occur when structural fluctuations bring the system to a region where the reactant and product surfaces intersect. The free energy change (ΔG°) and the reorganization energy of the reaction (λ) are indicated. (b) According to the Marcus Eq. (9), the rate of an electron-transfer reaction is maximal when $\Delta G^\circ = -\lambda$. The two free-energy surfaces then intersect at the bottom of the reactant surface.

system usually passes through the crossing point without evolving into the products, the reaction is said to be *nonadiabatic*. Most of the electron-transfer steps in photosynthetic reaction centers probably are nonadiabatic, with the possible exception of the initial reduction of bacteriopheophytin H_L . If $H_{\beta\alpha}$ is large enough so that a transition to the product state occurs virtually every time the system reaches a crossing point, the reaction is termed *adiabatic*. In this case, the approximations inherent in the analysis outlined above become severe, and the problem usually is better treated by starting with wavefunctions that diagonalize the full Hamiltonian (see Warshel and Hwang, 1986).

The electronic coupling factor $H_{\beta\alpha}$ depends on the overlap of the molecular orbitals of the electron donor and acceptor, and so falls off approximately exponentially with the distance between the two molecules (Moser et al., 1992). It can be increased by *superexchange* coupling through virtual intermediate states. In superexchange, the virtual intermediate state (γ) connects the initial and final states (α and β) by mixing quantum mechanically with both of them. The strength of this mixing depends, in part, on the energy difference $\Delta E_{\gamma\alpha}$ between γ and α (or β) at the point where $\Delta E_{\beta\alpha} = 0$. If $\Delta E_{\gamma\alpha}$ is large relative to the interaction matrix elements $H_{\gamma\alpha}$ and $H_{\gamma\beta}$, then

$$H_{\beta\alpha} \approx 2H_{\gamma\alpha}H_{\gamma\beta}/\Delta E_{\gamma\alpha} \quad (8)$$

II. Phenomenological Descriptions of Electron-Transfer Reactions

Attempts to apply Eq. (7) to an actual system such as the reaction center encounter both conceptual and practical problems. For one thing, we have assumed that the reactants are in thermal equilibrium with their surroundings, and that the various vibrational modes of the system are excited stochastically, i.e., with random phases. Studies with femtosecond excitation flashes indicate that such an equilibrium may not be attained during the short lifetime of P^* in the reaction center (Vos et al., 1993). Second, we have neglected the matter of what happens to the product state β after it forms. This amounts to assuming that the vibrational substates of β that are populated in the reaction relax by transferring energy to the surroundings rapidly enough so that back-reactions to α are insignificant, but not so rapidly as to give a large uncertainty-broadening of their

energies. Perhaps most importantly, Eq. (7) leaves us with the practical problem of finding the energies and Franck-Condon factors for all the vibrational modes of the system. This is not yet feasible for a system as large as the reaction center, or indeed for any protein. Let us therefore consider some possible simplifications of the problem.

In a classic series of papers, Marcus (1956, 1965; reviewed by Marcus and Sutin, 1985) showed that the electron-transfer rate constant often can be related to the overall free energy change in the reaction, ΔG^0 , and a phenomenological parameter termed the *reorganization energy*. The reorganization energy (λ) is the change in free energy associated with distorting the system from the mean nuclear configuration of the reactants to that of the products, or (equivalently, if the curvatures of the reactant and product free-energy surfaces are the same) from the mean nuclear configuration of the products back to that of the reactants. Marcus assumed that the free energies of the reactants and products were harmonic (quadratic) functions of the displacement of the system along the reaction coordinate (see Fig. 1a). The relationship between the reaction coordinate and the actual nuclear coordinates of the system was not clearly defined initially, but such a definition was not necessary at this level of the theory. (More precise definitions of the reaction coordinate and the free energy surfaces are given in Section III.) The assumption of classical, harmonic free-energy surfaces led to the expression

$$k_{et} = \frac{2\pi}{\hbar} \frac{|H_{\beta\alpha}|^2}{\sqrt{4\pi\lambda k_B T}} \exp\left\{-\frac{(\Delta G^0 + \lambda)^2}{4\lambda k_B T}\right\} \quad (9)$$

Here as in Fig. 1, λ is defined to be a positive quantity, and $\Delta G^0 = G^0_{\text{products}} - G^0_{\text{reactants}}$; many authors use the reverse convention with regard to ΔG^0 .

Equation (9) has several important implications. First, in order for k_{et} to be greater than zero λ must be nonzero, except possibly in the event that ΔG^0 also is zero. This means that there must be a difference in nuclear geometry between the equilibrium structures of the reactants and products. Second, the activation free energy for the reaction, ΔG^\ddagger , is given by $(\Delta G^0 + \lambda)^2/4\lambda$, and thus depends quadratically on $(\Delta G^0 + \lambda)$. If $\Delta G^0 = -\lambda$, ΔG^\ddagger should be zero and the rate should be essentially independent of temperature. Further, a plot of $\ln(k)$ vs ΔG^0 should go through a maximum when $\Delta G^0 = -\lambda$ (Fig. 1b). Making the

reaction more exothermic should speed up the reaction in the region where $\Delta G^\circ > -\lambda$, but (perhaps more surprisingly) should slow down the reaction in the 'inverted region' where $\Delta G^\circ < -\lambda$. Marcus' prediction concerning the inverted region lacked experimental support for many years, but the qualitative trend eventually was observed in studies of covalently linked donor-acceptor pairs (Miller et al., 1984; Wasielewski et al., 1985; Closs and Miller, 1988).

In the reaction center, ΔG° for the reactions $P^*H_L \rightarrow P^+H_L^-$ and $P^+Q_A^- \rightarrow PQ_A$ has been varied by substituting other quinones for ubiquinone as Q_A (Gunner et al., 1986; Gunner and Dutton, 1989), by external electrical fields (Popovic et al., 1986; Feher et al., 1988; Boxer et al., 1989; Franzen et al., 1990; Franzen and Boxer, 1993), and by genetic modifications (Finkele et al., 1990; Nagarajan et al., 1990, 1993; Chan et al., 1991; Williams et al., 1992a, 1992b). Phenomenological fits of the rate constant to the Marcus equation have been used to extract values of λ and $|H_{\beta\alpha}|$. The notion that $\Delta G^\circ \approx -\lambda$ has been invoked to account for the observation that the activation energies for these reactions are zero. (Both reactions actually speed up somewhat with decreasing temperature.) However, this analysis fails to explain why the $P^+Q_A^- \rightarrow PQ_A$ reaction still speeds up with decreasing temperature even if ΔG° is altered substantially (Gunner et al., 1986; Gunner and Dutton, 1989; Nagarajan et al., 1993). Also, although the $P^+Q_A^- \rightarrow PQ_A$ reaction does slow down when ΔG° is made more negative in the inverted region, the decrease is not as pronounced as Eq. (9) predicts. As we will discuss below, this discrepancy probably reflects the fact that the classical Marcus equation neglects quantum mechanical nuclear tunnelling (Warshel et al., 1989a,b).

Several authors have developed expressions that incorporate quantum mechanical effects and thus should be better suited than Eq. (9) for treating reactions at low temperatures. Probably the most general expression is due originally to Lax (1952) and Kubo and Toyozawa (1955), who showed that the thermally-weighted Franck-Condon factors in Eq. (7) can be expressed analytically if the vibrational modes are assumed to be harmonic and to have the same frequencies in the reactants and products. With these assumptions (and with the same assumptions made above concerning thermal equilibrium and irreversibility), the rate constant takes the form of a Fourier transform:

$$k_{et} = |H_{\beta\alpha}/\hbar|^2 \int_{-\infty}^{\infty} \exp\{(i/\hbar)\langle\Delta E_{\beta\alpha}\rangle_\alpha t + \gamma_Q(t)\} dt \quad (10)$$

with

$$\gamma_Q(t) = \frac{1}{2} \sum_j \Delta_j^2 [(\bar{n}_j + 1)e^{i\omega_j t} + \bar{n}_j e^{-i\omega_j t} - (2\bar{n}_j + 1)]$$

Here $\langle\Delta E_{\beta\alpha}\rangle_\alpha$ is the mean value of $\Delta E_{\beta\alpha}$ when the system is in the reactant state α , ω_j is the frequency of vibrational mode j ; and $\bar{n}_j = 1/[\exp(\hbar\omega_j/k_B T) - 1]$. Δ_j is the difference between the mean nuclear coordinates for mode j in states α and β , which is defined to be dimensionless by setting $\Delta_j^2 = 2\lambda_j/\hbar\omega_j$. The problem of choosing appropriate values of the ω_j and Δ_j for an actual system such as the reaction center may appear to be intractable because the total number of vibrational modes available to a protein of this size can exceed 10^5 . However, the assumption of harmonic vibrational modes simplifies this task significantly. We will return to this point below.

In the multimode model of Kubo and Toyozawa, the overall reorganization energy is

$$\lambda = \frac{1}{2} \sum_j \Delta_j^2 \hbar\omega_j \quad (11)$$

A particular vibrational mode contributes to λ , and to the rate constant, only if Δ for that mode is nonzero. Vibrational modes that meet this test are *coupled* to the reaction. The dimensionless factor $\Delta_j^2/2$ is sometimes referred to as the Huang-Rhys factor. Motions along coordinates for which Δ is zero affect the potential energies of both the reactant and the product states equally, without helping to bring the system to a crossing point.

The quantum mechanical Franck-Condon factors in Eq. (10) allow nuclear transitions that are forbidden classically. Such nuclear tunnelling to excited vibrational levels of the product electronic state becomes particularly important when $\langle\Delta E_{\beta\alpha}\rangle_\alpha$ is more negative than λ , and this makes electron transfer in the inverted region faster than predicted by the classical Eq. (9) (Warshel et al., 1989a,b).

Alden et al. (1992) have derived an expression that gives a good approximation to Eq. (10) but avoids the need to evaluate the Fourier transform. A possible further simplification is to treat the high-frequency vibrational modes (e.g., those with $\hbar\omega_j \gtrsim 50 \text{ cm}^{-1}$) quantum mechanically, and the lower-frequency modes classically. In principle, this should be satisfactory as long as $k_B T \gg \hbar\omega$ for the low-

frequency modes. Another simplification is to treat all of the vibrational modes (or all the high-frequency modes) as a single mode with effective values of ω , Δ and \bar{n} . Following this approach, Levich (1966), Jortner (1976, 1980), Kestner et al. (1974) and Efrima and Bixon (1976) obtained expressions of the form

$$k_{et} = (2\pi |H_{\beta\alpha}|^2 / \omega \hbar^2) \exp[-\Delta^2(\bar{n} + 1/2)] \times I_p \{ \Delta^2 [\bar{n}(\bar{n} + 1)]^{1/2} \} [(\bar{n} + 1)/\bar{n}]^{p/2} \quad (12)$$

where

$$p = | \langle \Delta E_{\beta\alpha} \rangle_{\alpha} | / \hbar \omega$$

and

$$I_p \{ y \} = (y/2)^p \sum_{q=0}^{\infty} (y^2/4)^q / q!(p+q)!$$

Equation (12) reduces to the classical Eq. (9) in the high-temperature limit, as does Eq. (10). Kakitani and Kakitani (1981) have considered the case that the effective frequency ω differs in the reactants and products. The result in this case is formally the same as Eq. (12) except that a temperature-dependent free energy change (ΔG^0) replaces the energy gap $\langle \Delta E_{\beta\alpha} \rangle_{\alpha}$. Sarai (1979, 1980) presented a treatment that retained a small number of discrete modes instead of just one effective mode.

Small et al. (1992) have developed expressions that collect the vibrational modes into one or two effective modes but consider a heterogeneous sample with a Gaussian distribution of energy differences between the reactant and product states. If the mean energy gap is $\langle \Delta E_{\beta\alpha} \rangle_{\alpha}$ as before, and the width of distribution of $\Delta E_{\beta\alpha}$ is $2D$,

$$k_{et} = \frac{2\pi |H_{\beta\alpha}|^2}{\hbar [2\pi(D^2 + \lambda W)]^{1/2}} \exp \left\{ - \frac{(\langle \Delta E_{\beta\alpha} \rangle_{\alpha} + \lambda)^2}{2(D^2 + \lambda W)} \right\} \quad (13)$$

where $W = \hbar \omega \coth(\hbar \omega / 2k_B T)$. Besides including an energy distribution, this expression differs from the Marcus Eq. (9) primarily in the substitution of $\hbar \omega \coth(\hbar \omega / 2k_B T)$ for $k_B T$, which incorporates the main quantum mechanical effect of the zero-point vibrational energy (Hopfield, 1974). For the initial electron-transfer step in reaction centers, Small et al. (1992) argue that D^2 is not large enough relative to

λW to have much effect on the kinetics.

As mentioned above, Eqs. (7) through (13) all assume that the reacting species are in thermal equilibrium with their surroundings. Marcus (1988), Almeida and Marcus (1990) and Marcus and Almeida (1990) have considered the case of a reaction that proceeds through a very short-lived intermediate state, which reacts in a second step before it has much opportunity to relax. They refer to such a process as a 'nonsuperexchange coherent' mechanism, and derive phenomenological expressions that take into account vibrational coherence between the intermediate and final states. Kitzing and Kuhn (1990) have derived expressions for an electron-transfer reaction that is adiabatic in nature but is limited by the rate of thermal relaxation.

III. Microscopic Calculations of Electron-Transfer Parameters

Although the phenomenological expressions discussed in the previous section provide a great deal of insight into the nature of electron-transfer reactions, the significance of fitting experimental kinetic results to any of these equations is questionable because such fits rarely determine the parameters uniquely. Equivalent fits usually can be obtained by choosing various combinations of ΔG^0 and λ or various vibrational frequencies, or by making some of the parameters temperature dependent. Further, these expressions do not tell us how to *predict* the rate of a reaction for a given molecular system, because they do not specify how to calculate the values for any of the parameters on the basis of the system's microscopic structure. However, new computational approaches and advances in computer power are making such calculations possible for increasingly large and complex systems. In the following sections, we will describe microscopic calculations of free energy changes, reorganization energies, and the frequencies and displacements of vibrational modes that are coupled to electron-transfer processes in photosynthetic reaction centers. We also will indicate how the same computational approaches allow one to simulate electron-transfer dynamics using either semiclassical or quantum mechanical formalisms. For more detailed reviews that also discuss electron-transfer reactions in solution, see Warshel and Parson (1991) and Parson and Warshel (1993).

A. Electrostatic Energies and the Importance of a Complete Description of the Micro-environment

As an illustration of a microscopic calculation of ΔG^0 for an electron-transfer reaction, consider the energy of $P^+B_L^-$ in the reaction center of *Rhodospseudomonas (Rp.) viridis*. Attempts to detect $P^+B_L^-$ experimentally have given controversial results, and it presently is unclear whether this state is a real intermediate in electron transfer from P^* to H_L , or whether it simply mediates the electronic coupling of P^* and H_L by superexchange. Accurate calculations of the energy of $P^+B_L^-$ should help to resolve this issue.

The free energy change associated with moving an electron from P to B_L is:

$$\Delta G^0 = \Delta E^\ddagger + \Delta\Delta G_{\text{sol}}(P^+B^-)^{\text{pro}} \quad (14)$$

where ΔE^\ddagger is the energy of forming the $P^+B_L^-$ ion pair in the gas phase and $\Delta\Delta G_{\text{sol}}(P^+B^-)^{\text{pro}}$ represents the difference between the solvation free energies of P^+B^- and PB by their surroundings in the protein [$\Delta\Delta G_{\text{sol}}(P^+B^-)^{\text{pro}} = \Delta G_{\text{sol}}(P^+B^-)^{\text{pro}} - \Delta G_{\text{sol}}(PB)^{\text{pro}}$].

The evaluation of the gas-phase energy ΔE^\ddagger is immediately problematic. In principle, ΔE^\ddagger could be obtained by gas-phase quantum mechanical calculations, and this approach has been taken by Scherer and Fischer (1989a,b), Thompson and Zerner (1991) and Marchi et al. (1993). However, such calculations are not yet able to give accurate results for the ionization energies and electron affinities of such large molecular systems as P and B. At present, it seems more reliable to use a thermodynamic cycle that incorporates experimental information on the midpoint redox potentials of P and B_L in the protein, or where necessary, of bacteriochlorophyll in solution (Creighton et al., 1988; Parson et al., 1990). This can be done by writing:

$$\Delta E^\ddagger = \Delta E^{\text{vac}} + \Delta V_{\text{QQ}} \quad (15a)$$

$$\Delta E^{\text{vac}} = -\mathcal{F}[E_m^B - E_m^P] - \Delta\Delta G_{\text{sol}}(P^+ + B^-)^{\text{ref}} \quad (15b)$$

Here ΔE^{vac} is the energy of forming $P^+B_L^-$ with P and B_L separated to infinite distance in a vacuum, ΔV_{QQ} is the calculated change in electrostatic interaction

between P and B_L at their actual positions in the reaction center (still without any dielectric shielding by the protein or the surroundings), \mathcal{F} is the Faraday constant, E_m^B and E_m^P are the redox potentials of the reactants, and $\Delta\Delta G_{\text{sol}}(P^+ + B^-)^{\text{ref}}$ is the calculated change in solvation energy for forming the individual ions under the reference conditions of the redox measurements [$\Delta\Delta G_{\text{sol}}(P^+ + B^-)^{\text{ref}} = \Delta G_{\text{sol}}(P^+ + B^-)^{\text{ref}} - \Delta G_{\text{sol}}(P + B)^{\text{ref}}$]. The thermodynamic cycle composed of these steps is shown in Fig. 2.

Combining (14) and (15) gives

$$\Delta G^0 = -\mathcal{F}[E_m^B - E_m^P] + \Delta V_{\text{QQ}} + \Delta\Delta G_{\text{sol}}(P^+B^-)^{\text{pro}} - \Delta\Delta G_{\text{sol}}(P^+ + B^-)^{\text{ref}} \quad (16)$$

This expression circumvents the problem of calculating quantum mechanical gas-phase energies

Fig. 2. The free energy change for electron transfer from P to B_L in the reaction center (ΔG^0) can be obtained from a thermodynamic cycle that includes a combination of experimentally measured midpoint redox potentials of P and B_L (E_m values), calculated solvation energies (ΔG_{sol}), and the calculated direct Coulombic interaction between P^+ and B_L^- (ΔV_{QQ}). Superscript *pro* refers to the environment in the reaction center protein; *vac*, to a vacuum; *ref*, to the reference conditions of the redox titrations. Using the redox potentials allows one to bypass quantum calculations of gas-phase energy differences (ΔE^\ddagger or ΔE^{vac}); in addition, the final result depends on differences between the solvation energies for the protein and the reference conditions, rather than the absolute energies. In practice, because the E_m of B_L has not been measured experimentally, it is necessary to use the E_m and ΔG_{sol} for monomeric bacteriochlorophyll in solution (see Parson et al., 1990).

directly. Calculations of solvation energies, though subject to difficulties we will discuss below, are presently more reliable and are necessary anyway for evaluation of the term $\Delta\Delta G_{\text{sol}}(\text{P}^+\text{B}^-)^{\text{pro}}$ in Eq. (14). In addition, Eq. (16) reduces the problem largely to a calculation of the *difference* between the solvation energy of P^+B_L^- and the sum of the solvation energies for P^+ and B_L^- . This is helpful because some types of errors tend to cancel out in the result.

Given the molecular structure and rudimentary descriptions of the molecular orbitals of P and B_L^- , ΔV_{QQ} can be obtained straightforwardly by summing the interactions of the partial charges on the atoms of the two molecules, using a dielectric constant of 1. Evaluating the solvation energies requires more discussion. One approach here would be to use a macroscopic reaction-field treatment. The solvation energy of P^+B_L^- , for example, could be expressed in the form:

$$\Delta\Delta G_{\text{sol}}(\text{P}^+\text{B}^-)^{\text{pro}} = -C \frac{|\mu|^2}{b^3} (\epsilon - 1)/(2\epsilon + 1) \quad (17)$$

where $|\mu|$ is the dipole moment of the P^+B_L^- dipole, b is the effective radius of the protein cavity around the dipole, ϵ is the effective dielectric constant of the protein, and $C = 332 \text{ kcal mol}^{-1} \text{ \AA}^3$ (electronic charge)⁻². However, it is not clear what value of ϵ to use inside the protein (Warshel and Åqvist, 1991), nor how to choose the appropriate value of b (Luzhkov and Warshel, 1991). Since $\Delta\Delta G_{\text{sol}}(\text{P}^+\text{B}^-)^{\text{pro}}$ is proportional to b^{-3} , Eq. (17) cannot be used to obtain a reliable value for ΔG^{p} . In addition, resort to such a macroscopic treatment would dash any hopes of exploring how microscopic structural features give rise to differences in electron-transfer rates on the L and M sides of the reaction center.

The three main options are molecular-dynamics simulations with an all-atom model (Warshel et al., 1986; King and Warshel, 1989; Beveridge and DiCapua, 1989), the protein-dipole-Langevin-dipole (PDL) model (Warshel and Russell, 1984; Lee et al., 1993) and the discretized-continuum model (Sharp and Honig, 1990). In the PDL model, the solvation energy is broken into a sum of terms for the changes in (i) direct electrostatic interactions of P and B with the protein ($\Delta V_{\text{O}\mu}$), (ii) interactions with induced dipoles in the protein (ΔV_{ind}), (iii) interactions with mobile water ($\Delta V_{\text{H}_2\text{O}}$) and/or phospholipid side chains (ΔV_{memb}), (iv) interactions with solvent ions

(ΔV_{ions}), and (v) interactions with solvent outside the sphere of protein that is treated microscopically (ΔV_{Born}):

$$\begin{aligned} \Delta\Delta G_{\text{sol}}(\text{P}^+\text{B}^-)^{\text{pro}} = & \Delta V_{\text{O}\mu} + \Delta V_{\text{ind}} + \Delta V_{\text{H}_2\text{O}} + \Delta V_{\text{memb}} \\ & + \Delta V_{\text{ions}} + \Delta V_{\text{Born}} \end{aligned} \quad (18)$$

The direct interactions ($\Delta V_{\text{O}\mu}$) are evaluated using a dielectric constant of 1; ΔV_{ind} , $\Delta V_{\text{H}_2\text{O}}$, ΔV_{memb} and ΔV_{ions} are evaluated by iterative procedures that seek self-consistent solutions for the potentials, charges and induced dipoles at all atoms of the pigments and protein and on a grid of points surrounding the protein. ΔV_{Born} is treated with macroscopic expressions due to Born and Onsager. The term $\Delta\Delta G_{\text{sol}}(\text{P}^+\text{B}^-)^{\text{ref}}$ in Eqs. (15b) and (16), which pertains to the redox measurements, includes additional reorganization energies that are obtained as described in the following section.

Calculations of electrostatic energies in proteins can easily go astray as a result of the use of improper boundary conditions or the omission of the solvent or other key components of the system (Warshel and Åqvist, 1991). A particularly important concern is the assignment of charges to ionizable amino acid residues. Calculations that take all the ionizable residues to be in their charged forms, but neglect the effects of mobile solvent molecules in and around the protein (Marchi et al., 1993; Treutlein et al., 1992), lead to a much higher energy for P^+B_L^- than calculations that treat the ionizable groups as neutral or well solvated (Creighton et al., 1988; Parson et al., 1990). In the former treatment, the results also are very sensitive to the size of the system that is included in the analysis. Since most of the ionizable residues are near the surface of the protein including larger fractions of the reaction center brings more of these residues into the system. If the charged groups are not completely solvated, the calculated electrostatic energies will continue to fluctuate until the system contains essentially the entire protein. In our experience, this is an artifact of using an insufficiently complete model. Experimentally, observed interactions between charged groups in proteins usually are relatively weak because the charged atoms are well shielded by solvent or by induced dipoles of the

protein (Warshel et al., 1986; Warshel and Åqvist, 1991). Conversely, ionizable groups that are not well solvated by the solution or by other groups in the protein are unlikely to be charged.

The reaction center ordinarily is embedded in a phospholipid bilayer or a belt of detergent molecules (Roth et al., 1989). Yet there may also be many water molecules around the protein. Although some water molecules are seen in the crystal structure, others probably are too mobile to be resolved. In the regions of B_L and B_M , the surface of the protein has grooves that could contain water because they fall well inside the cavity defined by placing straight phospholipid chains around the protein. Including a polarizable solvent in this region lowers the calculated free energy of $P^+B_L^-$ substantially with respect to $P^+H_L^-$. It therefore seems essential to consider the polarizability of the solvent in any discussion of electrostatic energies in the reaction center, and to use methods with proper boundary conditions (e.g., Lee et al., 1993) that give accurate calculations of absolute pK_a values and related properties of other proteins.

B. Free Energy Surfaces and Reorganization Energies

Microscopic calculations of reorganization energies require evaluating the free energy surfaces of the reactant and product states in terms of the actual structure of the system. This can be done by using semiempirical potential-energy functions of the atomic coordinates ($V(r)$) to treat the vibrations, rotations, and van der Waals and electrostatic interactions of all the atoms within a sphere surrounding the electron carriers. As the microscopic reaction coordinate (X), it is advantageous to choose the energy difference $\Delta V_{\beta\alpha}$ between states α and β ($\Delta V_{\beta\alpha} = V_\beta - V_\alpha$) (Warshel, 1982; Warshel and Parson, 1991). Free energy functions then can be defined as

$$\Delta g_\alpha(X) = -k_b T \ln[P(X)_\alpha] \quad (19)$$

where $P(X)_\alpha$ is the probability that a system in state α has a value of $\Delta V_{\beta\alpha}$ equal to X . $P(X)_\alpha$ can be obtained by keeping track of $\Delta V_{\beta\alpha}$ as a function of time during a molecular-dynamics simulation (Fig. 3). In such simulations, the atoms in the computer model are initially assigned random kinetic energies corresponding to a selected temperature. The structure then is allowed to fluctuate a series of small time

steps according to the classical Newtonian equations of motion (Jorgensen, 1989; Beveridge and DiCapua, 1989; Kollman and Merz, 1990; Warshel, 1991; van Gunsteren and Berendsen, 1990; Straatsma and McCammon, 1992).

A molecular-dynamics trajectory on the potential-energy surface of the initial state (V_α) is unlikely to yield reliable information about the activation energy of a reaction if ΔG^\ddagger is much larger than $k_b T$, because the probability that the trajectory will reach the crossing point between V_α and V_β ($X=0$) then is very small. However, this problem can be overcome by free-energy-perturbation and umbrella-sampling procedures (Warshel, 1982; Hwang and Warshel, 1987; Kuharski *et al.*, 1988; King and Warshel, 1990). The idea is to force the system to move through regions of configuration space near $X=0$. This is accomplished by running trajectories on hybrid potential surfaces of the form

$$V_m = (1-m)V_\alpha + mV_\beta \quad (0 \leq m \leq 1) \quad (20)$$

From the values of $\Delta V_{\beta\alpha}$ obtained from simulations with different values of m , one can determine Δg_α and Δg_β for each value of X (Warshel, 1982; Hwang and Warshel, 1987; King and Warshel, 1990; Kuharski *et al.*, 1988). The free-energy functions $\Delta g_\alpha(X)$ and $\Delta g_\beta(X)$ are the microscopic equivalents of the Marcus parabolas shown in Fig. 1a, and the reorganization energy (λ) can be obtained directly from the Δg functions (Warshel, 1982; Hwang and Warshel, 1987). This approach has been used to obtain $\Delta g_\alpha(X)$, $\Delta g_\beta(X)$ and λ for the formation of $P^+B_L^-$ and $P^+H_L^-$ in mutant and wild-type reaction centers (Creighton et al., 1988; Parson et al., 1991).

Although they are expressed as functions of a single reaction coordinate whose choice may seem odd ($X = \Delta V_{\beta\alpha}$), Δg_α and Δg_β reflect the multi-dimensional, anharmonic fluctuations of the actual structure, at least to the extent that the starting crystal structure and the semiempirical potential energy functions V_α and V_β are reliable. It is important to note that, as in the calculations of ΔG^\ddagger discussed above, the potential energy functions are not chosen specifically to fit data for a particular electron-transfer reaction of interest; they are parametrized on the basis of a large body of spectroscopic and thermodynamic data for many different systems including both macromolecules and small molecules. Of course, calculations on reaction centers are subject

Fig. 3. The relationship between the time-dependent energy gap and the free energy functions for an electron-transfer reaction. (A) A typical history of the potential energies V_α (solid line) and V_β (dashed line) during a molecular-dynamics trajectory on V_α . V_α and V_β fluctuate as a result of the motions of the pigments, protein and solvent. Vertical arrows indicate values of $\Delta V_{\beta\alpha}$ at various points of the trajectory. The number function $n_\alpha(X)$ is obtained by counting the number of times that $\Delta V_{\beta\alpha} = X$ for each value of X . In this example, $n_\alpha(-5) = 3$, $n_\alpha(0) = 6$ and $n_\alpha(3) = 4$. (B) A plot of $n_\alpha(X)$. (C) The free energy function $\Delta g_\alpha(X)$ is obtained from $n_\alpha(X)$ by Eq. (19). $\Delta g_\beta(X)$ can be obtained in the same manner from a trajectory on V_β . (Reprinted from Warshel and Parson (1991).)

to the same uncertainties discussed in the previous section concerning the charges on ionizable residues and the effects of the surrounding solvent.

C. Semiclassical-Trajectory Simulations

Molecular-dynamics trajectories can provide the information needed for several types of dynamic simulations of electron-transfer reactions. In a *semiclassical-trajectory* or *surface-hopping* simulation (Tully and Preston, 1971; Miller and George, 1972; Warshel, 1982; Warshel and Hwang, 1986), a transition from the reactant to the product state can occur whenever the trajectory reaches an intersection

of V_α and V_β . The probability that a system starting in α will be in β at time t is given by $|C_\beta(t)|^2$, with

$$C_\beta(t) = \int_0^t (-i/\hbar) C_\alpha(\tau) H_{\beta\alpha} \times \exp\left\{(-i/\hbar) \int_0^\tau \Delta V_{\beta\alpha}(\tau') d\tau'\right\} d\tau \quad (21)$$

(Warshel, 1982). As in Eqs. (3)–(13) above, $C_\alpha(t)$ is assumed to be ≈ 1 , and conversions to the product state are considered to be effectively irreversible. If

$H_{\beta\alpha}$ is small, the average rate constant is

$$k_{et} \approx \lim_{t \rightarrow \infty} \langle (1/t) \langle |C_{\beta}(t)|^2 \rangle_{\alpha} \rangle \quad (22)$$

where $\langle \rangle_{\alpha}$ means an average over many trajectories on V_{α} . The exponent in Eq. (21) is a rapidly oscillating function that contributes to the rate constant only when $\Delta V_{\beta\alpha} \approx 0$. Thus k_{et} can be obtained by running a single long trajectory and collecting the transition probability every time V_{α} and V_{β} intersect (Warshel, 1982; Warshel and Hwang, 1986). For harmonic potential surfaces, the high-temperature limit of Eqs. (21) and (22) is identical to the high-temperature limit of the exact quantum mechanical expression (Eq. 10) (Warshel and Hwang, 1986):

$$k_{et} \approx |H_{\beta\alpha} / \hbar|^2 (\pi \hbar^2 / k_B T \lambda)^{1/2} \exp[-\Delta V^{\ddagger} / k_B T] \quad (23)$$

$$\Delta V^{\ddagger} = (\Delta V_{\beta\alpha}^0 + \lambda)^2 / 4\lambda$$

Here $\Delta V_{\beta\alpha}^0$ is the difference between the average potential energies of states β and α ($\Delta V_{\beta\alpha}^0 = \langle V_{\alpha} \rangle_{\beta} - \langle V_{\alpha} \rangle_{\alpha}$), and the reorganization energy λ is $\langle \Delta V_{\beta\alpha} \rangle_{\alpha} - \Delta V_{\beta\alpha}^0$. Equation (23) can be viewed as the product of the probability that the system has the energy required in the transition state ($\exp[-\Delta V^{\ddagger} / k_B T]$), and the average rate of crossing from the reactant to the product surface in this state. If potential energies are replaced by free energies, Eq. (23) is identical to the Marcus Eq. (9).

Equations (21) and (22) provide more than an alternative derivation of Eq. (9) because they also can be used in the high-temperature limit for *anharmonic* systems. For an anharmonic system, the activation energy ΔV^{\ddagger} in Eq. (23) is replaced by the activation free energy Δg^{\ddagger} obtained from the Δg_{α} and Δg_{β} functions, so that the factor $\exp[-\Delta g^{\ddagger} / k_B T]$ reflects the actual probability of reaching the transition state. This application is important because we presently have no analytical recipe for quantization of a multidimensional, anharmonic system such as a protein.

Creighton et al. (1988) have described semiclassical-trajectory simulations of *Rhodobacter (Rb.) sphaeroides* reaction centers. Transitions from \mathbf{P}^* to $\mathbf{P}^+\mathbf{B}_{\text{L}}^-$ and from $\mathbf{P}^+\mathbf{B}_{\text{L}}^-$ to $\mathbf{P}^+\mathbf{H}_{\text{L}}^-$ were evaluated in separate trajectories by means of Eq. (21), and were incorporated into coupled differential equations for the concentrations of \mathbf{P}^* , $\mathbf{P}^+\mathbf{B}_{\text{L}}^-$ and $\mathbf{P}^+\mathbf{H}_{\text{L}}^-$. The results

agreed reasonably well with the experimental measurements. $\mathbf{P}^+\mathbf{H}_{\text{L}}^-$ rose with a time constant of about 3.5 ps, with the build-up of a small amount of $\mathbf{P}^+\mathbf{B}_{\text{L}}^-$ during the first 1 ps. Figures 4 a and b show the results of a similar simulation (Warshel and Parson, 1991). The autocorrelation function of the energy gap between \mathbf{P}^* and $\mathbf{P}^+\mathbf{B}_{\text{L}}^-$ is shown in Fig. 4c.

Molecular-dynamics simulations of the *Rp. viridis* reaction center have been described by Treutlein et al. (1992) and Marchi et al. (1993). Treutlein et al. focused on the structural reorganization that follows the simulated formation of $\mathbf{P}^+\mathbf{H}_{\text{L}}^-$ from \mathbf{P}^* . They found that most of the relaxation occurred within 0.2 ps, which is consistent with the rapid decay of the autocorrelation function shown in Fig. 4c. Similar rapid relaxations have been obtained in other simulations of charge-transfer processes in solutions (Warshel and Hwang, 1986; Hwang et al., 1988) and proteins (Churg and Warshel, 1985; Warshel et al., 1988b). Marchi et al. (1993) note that the relaxations of $\mathbf{P}^+\mathbf{H}_{\text{L}}^-$ also appear to include a much slower component.

D. Quantum Mechanical Simulations and Vibrational Relaxations

Semiclassical-trajectory simulations neglect the contributions to electron-transfer processes from the nuclear tunnelling that can occur even when the energy of the system is not sufficient to reach the transition state. A practical way to examine these classically forbidden transitions is provided by the 'dispersed polaron' model (Warshel and Hwang, 1986; Warshel *et al.*, 1989a,b). This model is based formally on the exact quantum mechanical expression for electron transfer in a multi-dimensional harmonic system (Eq. 10). The fluctuations of the time-dependent energy gap $\Delta V_{\alpha\beta}(t)$ during a molecular-dynamics simulation can be related to the fluctuations that would occur in a multidimensional harmonic system by equating the Fourier transforms of $\Delta V_{\alpha\beta}(t)$. In the Fourier transform of the harmonic model, each vibrational mode contributes a peak at its characteristic frequency (ω_j), with an amplitude proportional to the corresponding displacement (Δ_j). The time-dependent energy gap for the actual system thus provides all the necessary input for Eq. (10) except for $H_{\beta\alpha}$. If the dependence of $H_{\beta\alpha}$ on the fluctuations of the system is known, or is assumed to be negligible, a molecular-dynamics simulation for a single temperature yields all the information needed to

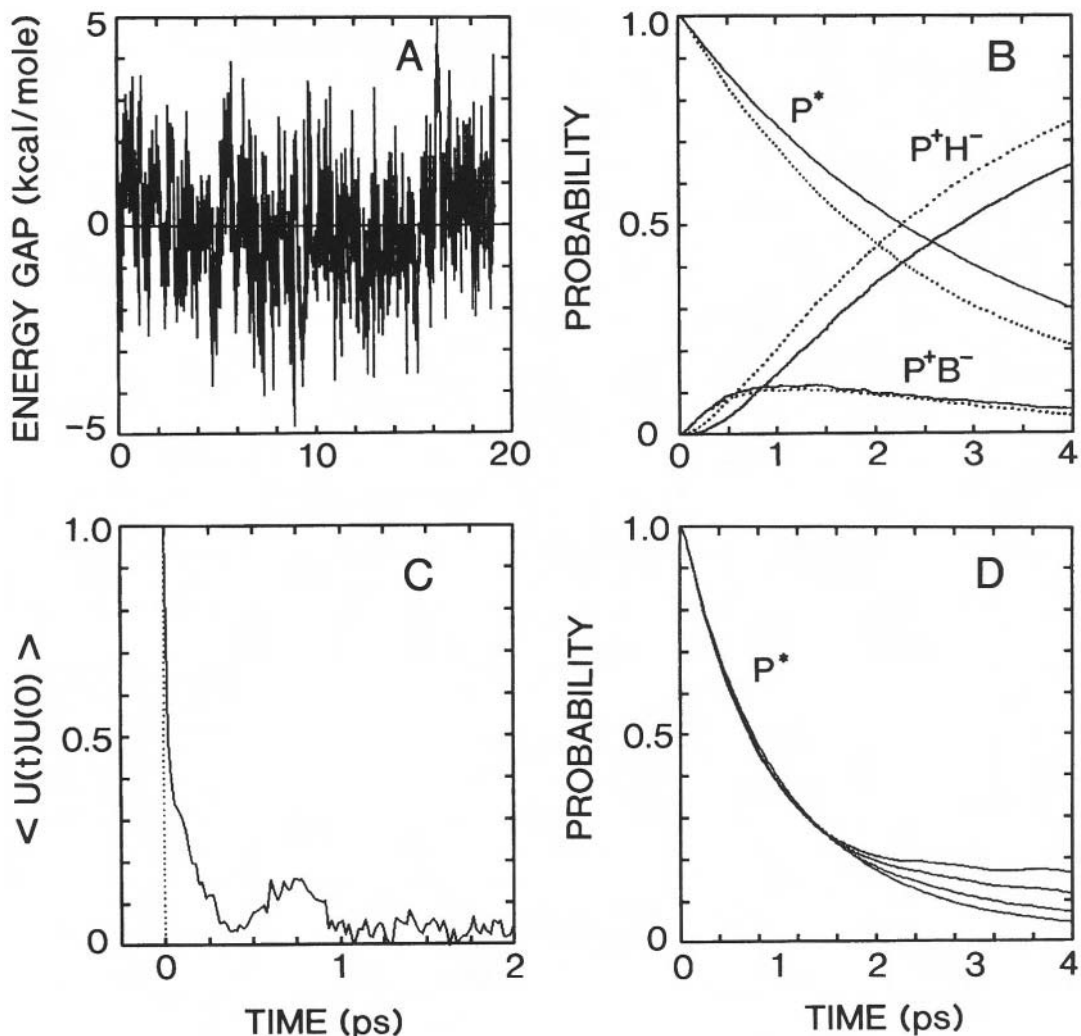

Fig. 4. (A) The time-dependent energy gap between P^* and $P^+B_L^-$ in *Rb. sphaeroides* reaction centers, calculated during a molecular-dynamics simulation similar to that described by Creighton *et al.* (1988). (B) A semiclassical-trajectory simulation of the reaction $P^* \rightarrow P^+H_L^-$, using the energy gap of (A) for $P^* \rightarrow P^+B_L^-$ and a similar energy gap from a trajectory on $P^+B_L^-$ for $P^+B_L^- \rightarrow P^+H_L^-$. The electronic couplings were 25 cm^{-1} between P^* and $P^+B_L^-$ and 80 cm^{-1} between $P^+B_L^-$ and $P^+H_L^-$. The smooth curves are obtained by concatenating the 20-ps record for each energy gap to make a repeating waveform, and averaging 200 simulations with the fluctuations of each of the energy gaps starting at random times in the two waveforms. The simulation shown with solid curves considered only the pathway through $P^+B_L^-$ as a real intermediate; that shown with dotted curves also included superexchange. Shifting the average energy of $P^+B_L^-$ or $P^+H_L^-$ by $\pm 2.5 \text{ kcal/mole}$ can change the calculated rate considerably. (C) The autocorrelation function

$$\langle U(t)U(0) \rangle = \int_0^{\infty} U(\tau+t)U(\tau) d\tau / \int_0^{\infty} U(\tau)U(\tau) d\tau, \text{ where } U(\tau) = \Delta V_{\beta\alpha}(\tau) - \langle \Delta V_{\beta\alpha}(\tau) \rangle_{\alpha}$$

reflects the dynamics of nuclear relaxations on the classical potential energy surface of state α . (A, B and C: reprinted from Warshel and Parson, 1991.) (D) A density-matrix simulation of the reaction $P^* \rightarrow P^+B_L^- \rightarrow P^+H_L^-$ at 50 K. The Franck-Condon factors were obtained from a dispersed-polaron analysis. (The low-frequency region of the Fourier transform of the energy gap shown in (A) was divided among vibrational modes of 20, 40, 60, 80 and 100 cm^{-1} with $\Delta = 0.97, 0.57, 0.73, 0.75$ and 0.86 , respectively. The same modes were used for both electron-transfer steps.) The electronic couplings were 20 cm^{-1} between P^* and $P^+B_L^-$ and 80 cm^{-1} between $P^+B_L^-$ and $P^+H_L^-$. ΔG° was set $\approx \lambda$ for each step. A total of 288 vibronic levels were included. The four curves show the disappearance of P^* (initially populated with thermally equilibrated vibrational levels for this simulation), as calculated with a time constant (T_1) of (from top to bottom) 2.0, 1.0, 0.5 or 0.2 ps for vibrational equilibration within each of the three electronic states. The time constant for pure dephasing (T_2^*) was 20 ps. Superexchange is included automatically in the density-matrix formulation. (Reprinted from Parson and Warshel, 1993.)

describe the kinetics of electron transfer at any other temperature, including the effects of nuclear tunneling. The temperature dependence of the rate constant enters Eq. (10) naturally through the \bar{n}_j . Schulten and Tesch (1991), Treutlein et al. (1992) and Marchi et al. (1993) recently have adopted a simulation strategy they term a 'spin boson' treatment, which is essentially identical to the dispersed polaron treatment.

The dispersed polaron model has been used to examine the reaction in which an electron moves from H_L^- to the first quinone (Q_A) in the reaction center, and also the much slower back-reaction between Q_A^- and P^+ (Warshel *et al.*, 1989a,b). The calculated rate of electron transfer from H_L^- to Q_A was essentially independent of temperature, in agreement with the experimental observations on *Rp. viridis*. By reducing the value of $\langle \Delta V_{\alpha\beta} \rangle_\alpha$, the reaction could be made to speed up with decreasing temperature, as is seen experimentally in *Rb. sphaeroides* (Kirmaier et al., 1985). The back-reaction was found to be relatively insensitive to the free energy difference between $P^+Q_A^-$ and the ground state, in agreement with studies in which the free energy of $P^+Q_A^-$ was changed experimentally (Gunner *et al.*, 1986; Gunner and Dutton, 1989). As was discussed above, the classical Eq. (9) predicts that the rate constant would decrease more abruptly when $\Delta G^0 \ll -\lambda$.

The information on vibrational frequencies and displacements provided by the dispersed-polaron model also can be incorporated directly into fully quantum mechanical simulations. The idea here is to write the time-dependent wavefunction of the system as a sum of products of electronic and vibrational wavefunctions as in Eq. (5). This expression can be expanded to include an arbitrary number of electronic states. The nuclear overlap integrals that enter into the transition matrix elements between the various vibronic levels (Eq. 6) can be calculated straightforwardly if the vibrational energies and displacements are known.

The best way to treat the relaxation processes that result from interactions of the system with its surroundings probably is to construct the density matrix from the time-dependent coefficients. The elements of the reduced density matrix of the system, ρ , are defined by $\rho_{mn} = C_m^* C_n$. Diagonal terms of ρ represent the time-dependent probabilities of finding the system in particular vibronic states, while off-diagonal terms can convey information about coherent electronic or vibrational oscillations of an

ensemble of many molecules (Redfield, 1965; Silbey, 1989; Hu and Mukamel, 1989; Jean et al., 1992). The initial values of the coefficients can be chosen to model a variety of situations, such as a thermally equilibrated excited state or a nonequilibrated state created by a femtosecond excitation flash with a given spectrum of wavelengths. The subsequent evolution of the system then is described by the set of simultaneous differential equations

$$\frac{\partial}{\partial t} \rho_{mn} = (-i/\hbar) \sum_k (H_{mk} \rho_{kn} - \rho_{mk} H_{kn}) + \sum_j \sum_k \Gamma_{mn;jk} \rho_{jk} \quad (24)$$

Here Γ , the relaxation matrix, includes both the stochastic thermal equilibration of vibrational levels within each electronic state and the 'pure dephasing' processes due to fluctuations of the energies of the vibronic states. The density-matrix treatment is particularly appropriate for the two-step reaction pathway from P^* to $P^+H_L^-$ through P^+B^- because it provides a way of dealing with the relaxation of the intermediate state.

The simultaneous equations for the ρ_{mn} can be solved either by Runge-Kutta integration or by unfolding the $N \times N$ matrix of derivatives to a vector of N^2 elements and diagonalizing the corresponding $N^2 \times N^2$ matrix (Silbey, 1989; Sugawara et al., 1990). However, procedures for calculating the terms of Γ on the basis of microscopic simulations have not yet been developed for systems as complicated as proteins. The best that can be done at present probably is to treat the relaxation terms as phenomenological time constants (T_1 and T_2^*) that are related to an autocorrelation function such as that shown in Fig. 4c.

An early density-matrix treatment that considered intramolecular vibrational modes of the pigments was described by Friesner and Wertheimer (1982) before the Franck-Condon factors for the protein were available. Recently, Sugawara et al. (1990) and Alden et al. (1992) also have used a density-matrix treatment based on the vibrational modes of the pigments. In their formulation of the problem, transitions between different electronic states are included in the relaxation matrix Γ , rather than in H . The density-matrix approach can be extended to include the vibrational modes of the protein by using the dispersed-polaron treatment to obtain the

vibrational frequencies and displacements (Warshel and Parson, 1991; Parson and Warshel, 1993).

Figure 4d shows a density-matrix simulation of the initial electron-transfer step in the *Rp. viridis* reaction center. The simulated behavior is similar to that obtained with the surface-hopping model (Fig. 4b). The small oscillatory components reflect coherent electronic oscillations that are incompletely damped by the relaxation terms. Their magnitude decreases if one shortens the phenomenological time constants for thermal equilibration (T_1) or pure dephasing (T_2^*) in Γ . The oscillations also become less distinct with increases in the number of vibrational levels that are included, and they would be attenuated if the vibronic energies were broadened by a distribution function. Oscillations have been seen experimentally in the absorption and stimulated-emission signals from excited reaction centers, particularly in a mutant strain that is missing the initial electron acceptor, H_L (Vos et al., 1993). However, these appear to represent coherent vibrational motions, rather than the electronic oscillations depicted in Fig. 4d.

E. Electronic Coupling Factors

Microscopic calculations of electronic coupling factors for intermolecular electron transfer reactions are still in early stages of development. To a reasonable approximation, $H_{\alpha\beta}$ decreases exponentially with the edge-to-edge distance between the donor and acceptor (Moser et al., 1992). Yet, within a series of closely related donor-acceptor pairs, the observed coupling factor can depart from this simple relationship by several orders of magnitude, depending apparently on the details of the individual molecular structures (Beratan et al., 1991, 1992). For widely separated donors and acceptors, the relative magnitude of $H_{\alpha\beta}$ can be calculated remarkably well by considering the network of possible connecting pathways through covalently bonded atoms and placing a penalty on jumps through space (Beratan et al., 1991, 1992). In this picture, the overall coupling factor for a particular pathway is a product of superexchange matrix elements for a series of microscopic steps. Attempts to include the molecular orbitals of the intervening amino acids explicitly in a supermolecular quantum mechanical description of the donor-acceptor complex also have met with some success (Broo and Larsson, 1989).

Several efforts have been made to calculate the coupling factors for electron transfer from P^* to B_L

or from B_L^- to H_L in bacterial reaction centers (Parson et al., 1987; Warshel et al., 1988; Plato et al., 1988; Scherer and Fischer, 1989; Thompson and Zerner, 1991). Here, the electron donors and acceptors seem close enough together for electrons to jump directly from one carrier to the other without extensively involving the surrounding protein. The central difficulty is that $H_{\alpha\beta}$ depends on the overlap of the molecular orbitals of the donor and acceptor in the intermolecular region where the orbital amplitudes are small and not reliably characterized. In addition, the calculated coupling factors could be sensitive to small errors in the crystal structures. Whereas calculations using the *Rp. viridis* crystal structure have given results of the right order of magnitude to account for the observed rate of electron transfer, those calculated with the *Rb. sphaeroides* structures are considerably smaller. However, it seems clear for both species that B_L must play a role in mediating electron transfer from P^* to H_L because the coupling factor calculated for a direct reaction without the aid of B_L is too small by many orders of magnitude.

Acknowledgments

Summary

The reaction center from purple bacteria mediates the initial steps of a light driven proton pump, coupling light induced electron transfer to proton uptake. The key steps in this reaction involve the two electron reduction of the secondary quinone Q_B with the concomitant uptake of 2 protons:

Recent advances in studies of reaction centers from purple bacteria have provided insight into the pathway of proton transfer into the RC and the mechanism of coupling proton and electron transfer reactions. Studies using site directed mutagenesis have identified 3 residues near Q_B that are important for proton transfer in RCs from *Rb. sphaeroides*. The mutation of Ser L223 and Asp L213 to Ala and Asn, respectively, block proton transfer and the second electron transfer involved in Q_B reduction. Mutation of Glu L212 to Gln blocks proton transfer associated with Q_B reduction but 2 electron reduction of Q_B still occurs. The model explaining these results is that Ser L223 and Asp L213 are involved in the proton transfer pathway for uptake of the first proton which is bound prior to the second electron transfer, whereas Glu L212 is involved in the pathway for the second proton which is bound after the second electron transfer. These results clearly show that specific residues play important roles in proton transfer. However other functionally active mutant RCs have been obtained in which either Asp L213, Ser L223 or Glu L212 were absent indicating that the pathways for proton transfer are not

unique. The structure of the RC near the Q_B site suggests the involvement of water molecules in addition to protein residues in the proton transfer chain to Q_B . In addition, negatively charged residues near Q_B increase the proton coupled electron transfer rate by stabilizing a proton in the interior of the RC.

I. Introduction

In photosynthetic bacteria light energy is transformed into chemical energy by the action of a light driven proton pump coupled to electron transfer (see Fig. 1). The bacterial reaction center (RC) plays a key role in this process by performing the initial light-activated electron transfer reactions and the initial proton uptake reactions of the proton pump (Feher et al., 1989; Breton and Vermeglio, 1992). The key reaction required in purple bacteria for coupling proton transfer with electron transfer involves the two electron reduction and concomitant binding of two protons by the secondary quinone Q_B on the RC:

The two electrons in this reaction arise from successive photoionizations of the primary electron donor, a bacteriochlorophyll dimer, D which transfers the electron to Q_B through a series of electron acceptors (bacteriopheophytin and Q_A) (see Chapter 24 by Woodbury and Allen). The two protons in this reaction originate from the aqueous solution of the cytoplasm and are transferred to Q_B through a chain

Fig. 1. Schematic representation of electron and proton transfer in bacterial photosynthesis. Electron transfer steps are indicated by solid lines; proton transfer steps by dashed lines; and diffusion steps by dotted lines. Proton transfer is coupled to electron transfer via the proton coupled electron transfer reaction of Q_B (From Paddock et al., 1989).

of proton acceptor/donor groups which include several protonatable residues. The exact sequence of the proton and electron transfer steps remains to be determined. After the two electron reduction, the doubly reduced quinone subsequently dissociates from the RC and is reoxidized by the cytochrome bc_1 complex releasing protons on the periplasmic side of the membrane (Fig. 1). The net result of these reactions is the vectorial transport of protons across the membrane driven by electron transfer, as proposed by Mitchell, 1961. This proton transport is used to drive ATP synthesis (reviewed in Crofts and Wraight, 1983; Cramer and Knaff, 1990).

Recently, the molecular basis for proton and electron transfer have begun to be elucidated as the result of two major developments in RC research. The first was the determination of the X-ray crystal structure of the RCs from *Rhodospseudomonas (Rp.) viridis* by Deisenhofer et al. (1984) and *Rhodobacter (Rb.) sphaeroides* by Allen et al. (1986) and Chang et al. (1986) (see Chapter 23 by Lancaster et al.). The second was the use of molecular biology in studying RCs by site directed mutagenesis (Bylina et al., 1989; Paddock et al., 1989; Takahashi and Wraight, 1990). The X-ray crystal structure revealed that Q_B is located in the interior of the protein, out of contact with the aqueous solution and suggested the possibility that protonatable amino acid side chains from the protein were responsible for proton transport to Q_B . Site-directed mutagenesis of several of these residues to non-protonatable groups resulted in loss of proton transport to Q_B and conclusively demonstrated that the protein plays an important role in proton transport and coupling between electron and proton transfer. Proton transfer to Q_B in bacterial RCs has been recently reviewed by several authors (Takahashi et al., 1992; Okamura and Feher, 1992; Feher et al., 1992; Takahashi and Wraight, 1994). In this review, we will focus on the coupling between electron and proton transfer reactions of Q_B in bacterial RCs, emphasizing the results from site-directed mutagenesis. Earlier reviews of quinones in bacterial RCs have been published (Parson, 1978; Okamura et al., 1982; Wraight, 1982; Morisson et al., 1982).

Fig. 2. Stereo view of the structure of the RC from *Rb. sphaeroides* near Q_B showing the residues affecting proton coupled electron transfer to Q_B (Allen et al., 1988). The free circles represent the predicted positions of internal water molecules (Beroza et al., 1992).

II. Structure of the Bacterial Reaction Center Near the Q_B Site

The structure of the RC from *Rb. sphaeroides* in the region near Q_B is shown in Fig. 2 (Allen et al., 1988). The Q_B binding site consists of a loop of amino acid residues spanning the region between the D and E transmembrane helices of the L subunit. One carbonyl oxygen of Q_B is hydrogen bonded to His L190 which is liganded to the Fe^{2+} . The other carbonyl oxygen is hydrogen bonded to Ser L223. The quinone ring is near the hydrophobic amino acid residues Ile L229, Val L220, and Phe L216. Also nearby are the acidic residues Glu L212, Asp L213, Asp L210 and the basic residue Arg L217. These acidic and basic residues could serve to modify the electrostatic potential at Q_B and/or serve as proton donor groups in a proton transfer pathway to Q_B .

Several residues which have been implicated in Q_B function are shown in Fig. 2. The residues Asp L213 (Takahashi and Wraight, 1990; Paddock et al., 1993), Ser L223 (Paddock et al., 1990a) and Glu L212 (Paddock et al., 1989; Takahashi and Wraight, 1992) have been shown by site-directed mutagenesis to be involved in proton transfer to Q_B . Near Q_B is the hydrophilic residue Asn M44. This residue is homologous to the Asp M43 in RCs from *Rp. viridis* (Deisenhofer and Michel, 1989) and several other photosynthetic bacteria that contain an Asn (instead of Asp) at position L213. The Asp at L213 could serve the same function as the Asp at M43 as suggested by recent experiments (Hanson et al., 1992b; Rongey et al., 1993). In the region below Q_B

that defines an interface between the H subunit and the LM core of the RC are found numerous acidic and basic residues from the M and H subunits. Among these residues is Arg M233. The mutation of Arg M233¹ to Cys has been shown to partially restore the proton and electron transfer rates in deficient mutants containing the Asp L213 → Asn mutation (Okamura et al., 1992). A similar mutation of the homologous Arg M231 → Leu was shown to confer photosynthetic competence to deficient RCs from *Rb. capsulatus* containing the mutations Asp L213 → Ala and Glu L212 → Ala (Hanson et al., 1992a).

The X-ray crystal structure of *Rp. viridis* shows many internal water molecules including several in the region near Q_B that may be involved in proton transfer (Deisenhofer and Michel, 1989). The lower resolution structure of the RC from *Rb. sphaeroides* does not show the position of water molecules. However, the void spaces in the structure suggest the presence of water molecules. A computational approach to predict water in the *Rb. sphaeroides* structure was used by Beroza et al. (1992). They used the algorithm of Rashin et al. (1986) based on finding sites at positions capable of providing hydrogen bond interactions to stabilize water molecules in the interior of the RC. Interestingly, a considerable number of water molecules are predicted to be near Q_B in the *Rb. sphaeroides* RC. A high density of water is located near the methoxy groups below the quinone in a region called the 'methoxy pocket.'

¹ This mutation was inadvertently mislabeled Arg M223 by Okamura et al. (1992).

Fig. 3. The quinone reduction cycle. Light induced electron transfer to Q_A (steps 1 and 3) are followed by electron transfer to Q_B (steps 2 and 4) coupled to proton uptake (see squares) (steps 4 and 5). Two possible mechanisms are indicated for step 4. In the upper, electron transfer precedes protonation, in the lower proton transfer precedes electron transfer. The final step is quinone exchange (step 6). All steps are reversible. The cycling time in native RCs is ~ 1 ms.

These water molecules may play a role in proton transfer to Q_B as well as in stabilizing the charge on the reduced quinone. Recently, a chain of 14 water molecules extending 23 Å from Q_B to the cytoplasmic surface of the RC was reported in the structure of RCs from *Rb. sphaeroides* determined from X-ray diffraction studies at 2.65 Å resolution (Ermler et al., 1994).

III. The Quinone Reduction Cycle

The light-induced electron and proton transfer reactions that couple electron transfer to the uptake of protons in the RC are represented by the quinone reduction cycle shown in Fig. 3. This cycle summarizes the results of electron transfer (Vermeglio, 1977; Wraight, 1977; Wraight, 1979), and proton transfer (Wraight, 1979) as well as site-directed

mutagenesis (Paddock et al., 1990a; Takahashi and Wraight, 1992). Two electrons are transferred and two protons are bound to Q_B as a result of two separate photochemical events resulting in the oxidation of two cytochrome molecules.

The cycle starts with the RC in the initial state DQ_AQ_B . The sequence of steps shown in Fig. 2 are as follows:

1) *First Light-Induced Q_A Reduction.* The first step in the cycle involves the transfer of an electron to Q_A and concomitant cytochrome oxidation. This involves 3 rapid successive electron transfer steps not explicitly shown in Fig. 3. These are: (a) Electron transfer from the primary donor to the bacteriopheophytin molecule. (b) Electron transfer from bacteriopheophytin to Q_A . (c) Electron transfer from a cytochrome c_2 molecule to D^+ .

2) *First Electron Transfer to Q_B , $k_{AB}^{(1)}$* . The second reaction in the cycle involves the transfer of the first electron from Q_A^- to Q_B . This reaction is reversible and gives rise to an equilibrium between the states $Q_A^-Q_B$ and $Q_A Q_B^-$. In *Rb. sphaeroides* RCs $k_{AB}^{(1)} \approx 10^4 \text{ s}^{-1}$ (Vermeglio, 1977; Wraight, 1979; Kleinfeld et al., 1984).

3) *Second Light-Induced Q_A Reduction*. The third step is a repeat of step 1), a light induced electron transfer that gives rise to the diradical state $DQ_A^-Q_B^-$.

4) *Second Electron Transfer to Q_B , $k_{AB}^{(2)}$* . The fourth reaction is an electron transfer coupled to proton uptake that gives rise to the singly protonated doubly reduced state $DQ_A(Q_BH)^-$. This reaction could proceed through two possible paths: Proton uptake followed by electron transfer or electron transfer followed by proton uptake. These two mechanisms are shown as parallel paths in step 4 in Fig. 4. In *Rb. sphaeroides* RCs $k_{AB}^{(2)} \approx 10^3 \text{ s}^{-1}$ (Wraight, 1979; Kleinfeld et al., 1985).

5) *Second Proton Uptake*. Following the formation of the $DQ_A(Q_BH)^-$ -state, Q_B takes up the second proton in reaction 5 to form the dihydroquinone $DQ_AQ_BH_2$. The rates for the individual steps in reactions 4 and 5 have not been resolved, but the overall time for reaction 4 and reaction 5 is about 1 ms (pH 7.5) (Wraight, 1979, Kleinfeld et al., 1985). Results from site-directed mutagenesis suggest that the two protons $H^+(1)$ and $H^+(2)$ are taken up via 2 separate pathways (Paddock et al., 1990b; Takahashi and Wraight, 1992).

6) *Quinone Exchange*. After reduction, the dihydroquinone dissociates from the RC and is replaced by an oxidized quinone (McPherson et al., 1990), thereby completing the cycle. The exchange times for the quinone depend on the nature of the quinone and detergent composition, but are generally in the ms range.

The electron transfer rate of the cycle, which is the turnover rate for cytochrome photo-oxidation by RCs under saturating light intensity in the presence of excess cytochrome and quinone, is about 10^3 s^{-1} . The values of the rates for electron and proton transfer reactions for RCs from different bacteria and mutants are shown in Table 1.

IV. Properties of the Quinones

Despite the roughly 2-fold symmetry of the RC about an axis bisecting the two quinones (Allen et al., 1988) the electron transfer functions of the quinones Q_A and Q_B are quite different. The primary quinone Q_A undergoes a rapid one electron reduction, taking an electron rapidly from the reduced bacterio- pheophytin acceptor with a rate of 10^{10} s^{-1} (for a discussion see Chapter 24 by Woodbury and Allen). On the otherhand, Q_B undergoes a slower two electron reduction by electron transfer from Q_A in two one-electron steps with rates of 10^3 – 10^4 s^{-1} with a concomitant uptake of 2 protons. Some properties of the quinones in RCs are summarized below.

The one-electron redox potential for Q_A/Q_A^- was found to be pH dependent with a value of –65 to –80 mV for *Rb. sphaeroides* at pH 8 (Prince and Dutton, 1978). The redox potentials for the Q_B/Q_B^- and Q_B^-/Q_B^{2-} couples (40 and –40 mV respectively at pH 8) (Rutherford and Evans, 1980) for *Rb. sphaeroides* are somewhat higher, favoring the electron transfer from Q_A^- to Q_B . A convenient assay for the free energy difference between the $Q_A^-Q_B \rightleftharpoons Q_A Q_B^-$ states is the recombination rate k_{BD} for electron transfer from Q_B^- to D^+ which has been shown to proceed in *Rb. sphaeroides* RCs through the reaction $D^+Q_AQ_B^- \rightleftharpoons D^+Q_A^-Q_B \rightarrow DQ_AQ_B$ (Kleinfeld et al., 1984). Thus, a small k_{BD} indicates a stabilization of Q_B^- . Values of k_{BD} for RCs from different mutants are shown in Table 1. The structural basis for the difference in redox potentials between the two quinones must lie in the protein structure, since both quinones are ubiquinone. Interestingly, the electron transfer equilibrium favors Q_B^- over Q_A^- despite the preponderance of negatively charged residues near Q_B . Possible reasons for the stabilization of Q_B^- may be the effect of helix dipoles (Gunner, 1993) or internal water molecules (Beroza et al., 1992).

The semiquinone states Q_A^- and Q_B^- have been shown to be unprotonated by a number of spectroscopic techniques, i.e. optical (Vermeglio, 1977; Wraight, 1977), EPR (Hales and Case, 1981), ENDOR (Lubitz et al., 1985; Feher et al., 1985) and IR spectroscopy (Breton et al., 1991b, 1991a). The transient protonation of the semiquinone may play a role in the mechanism of proton coupled electron transfer.

Proton uptake accompanying the reactions $Q_A \rightarrow Q_A^-$ and $Q_B \rightarrow Q_B^-$ exhibits a proton uptake stoichi-

ometry of $< 1H^+ / e^-$. (Wraight, 1979; Maróti and Wraight, 1988; McPherson et al., 1988). This proton uptake has been attributed to proton binding by acidic residues whose pK_a s have been shifted due to interactions with the negative charge on the quinone. Recent IR studies have shown that Glu L212 near Q_B is involved in proton uptake upon Q_B^- formation (Hienerwadel et al., 1992). Proton uptake measurements on the $Q_B \rightarrow Q_BH_2$ reaction have shown the binding of $2 H^+ / 2e^-$ (Wraight, 1979; Maróti and Wraight, 1988; McPherson et al., 1993). However, a decrease in proton binding at $pH > 8.5$ has been observed. This decrease has been attributed to the ionization of bound Q_BH_2 or nearby protein residues (McPherson et al., 1993).

V. Effects of Site-Directed Mutagenesis on Electron and Proton Transfer Rates

The study of mutants with changes of amino acid residues near Q_B has served to elucidate the mechanisms of proton and electron transfer to Q_B . The results of replacing proton donor residues with non-proton donor residues were used to identify amino acid residues involved in the pathway for proton transfer to Q_B . The effect of modifying the environment of Q_B helped establish the role of the electrostatic potential in the mechanism of electron and proton transfer to Q_B . Mutations to residues affecting proton coupled electron transfer were obtained by 1) site-directed mutagenesis in *Rb. sphaeroides* (Paddock et al., 1989, 1990b; Takahashi and Wraight, 1992) 2) selection of second site mutations that compensated for detrimental effects of initial mutations (Hanson et al., 1992b; Okamura et al., 1992; Bylina and Wong, 1992) 3) Herbicide resistance mutants (Leibl et al., 1993). RCs containing the altered residues were isolated and characterized by measuring the cytochrome turnover rate (i.e. the rate of cytochrome oxidation during continuous illumination in the presence of excess cytochrome *c* and quinone), as well as by measuring electron transfer rates ($k_{AB}^{(1)}$, $k_{AB}^{(2)}$ and k_{BD}) and proton uptake (k_H). The characteristics of several RC mutants are described below.

A. Mutations Affecting Proton Transfer

1. Glu L212

Mutation of Glu L212, located near the Q_B binding

Fig. 4. Cytochrome photo-oxidation rates in native and mutant RCs. Native RCs showed a rapid turnover. Mutant RCs showed slow rates of turnover indicating a block in the quinone reduction cycle after oxidation of 2 or 3 cytochromes for the Ser L223 \rightarrow Ala and Glu L212 \rightarrow Gln mutants, respectively (from Okamura and Feher, 1992).

site (see Fig. 2) to Gln in RCs from *Rb. sphaeroides* reduced the cytochrome turnover rate by a factor of ≈ 70 following the fast oxidation of 3 cytochromes (Paddock et al., 1989) (see Fig. 4).

This result was explained by a reduction in the rate of transfer of the second proton $H^+(2)$ (see step 5 in Fig. 3) which slows down the turnover of the quinone reduction cycle. Since this block occurs after electron transfer of the second electron to Q_B , the RC can absorb a third photon to form the fully reduced quinone complex $Q_A(Q_BH)^-$ resulting in the oxidation of 3 cytochrome molecules. This hypothesis was verified by direct measurements of the electron and proton transfer rates, which showed that both the electron transfer rates $k_{AB}^{(1)}$, $k_{AB}^{(2)}$ were not appreciably changed, whereas the proton transfer rate was. When RCs were illuminated with a multi-turnover flash, biphasic proton uptake was observed with fast uptake of about one proton and slow uptake of a second proton (see Fig. 5) (Feher et al., 1990; McPherson et al., 1994).

The proton uptake rate k_H , measured using a pH sensitive dye, was biphasic with the slow phase reduced by a factor of about 200 to a rate of $6 s^{-1}$ ($pH 7.5$). This slow proton uptake rate accounted for the slow cytochrome turnover $12 s^{-1}$ (2 cytochromes/turnover). Control experiments in which Glu L212 was changed to Asp gave RCs with high turnover rates (Paddock et al., 1989, 1990a). The Glu L212 \rightarrow Gln mutant was also studied by Takahashi and Wraight, (1992) who found a biphasic rate of electron transfer $k_{AB}^{(2)}$ after two flashes at pH above 7. The slow

Fig. 5. Proton uptake measurements in Native (left) and mutant (right). RCs in the presence of excess cytochrome *c* after a strong saturating light pulse ($t \approx 1$ ms). The slow proton uptake step in the Glu L212 \rightarrow Gln mutant indicates a bottleneck in a proton transfer step (from Okamura and Feher, 1992).

phase $k \approx 0.3$ s $^{-1}$ (pH 7.5) was attributed to a slow proton uptake by the Glu L212 \rightarrow Gln mutant. The difference between the rate observed by Takahashi and Wraight, (1992) and that measured by Feher et al., (1990) is at least partly due to the reduction of Q_A to Q_A^- under multi turnover conditions. The RCs containing Q_A^- exhibit a faster rate of protonation than those containing Q_A (McPherson et al., 1994). Shinkarev et al., (1993) used flash induced electrogenicity measurements on chromatophores from the Glu L212 \rightarrow Gln mutant to show that the doubly reduced Q_B remains bound to the RC and inaccessible to the cytochrome *bc*₁ complex on the ms time scale. This shows that proton uptake is required before the release of $Q_B H_2$.

The change of Glu L212 \rightarrow Gln is structurally conservative since the size and shape of the two residues are approximately the same. Preliminary X-ray crystallography measurements have indicated that no large changes (<0.5 Å) in the structure of the Glu L212 mutant are observed (Chirino et al., 1994). The pH dependence of the rates $k_{AB}^{(1)}$ and k_{BD} was eliminated in the mutant. Native RCs show a pH dependence with inflection points near pH 9.5 (Paddock et al., 1989; Takahashi and Wraight, 1992). This was explained by an apparent pK_a of 9.5 for Glu L212. However, recent results from IR spectroscopy indicate that Glu L212 is at least partially unprotonated at pH 7, indicating that a more

complicated model for protonation must be invoked (Hiernerwadel et al., 1992). Two models based on electrostatic calculations have been proposed to explain the results. In one model presented by Gunner and Honig, (1992), Glu L212 is fully ionized over the whole pH range when Q_B is oxidized. Formation of Q_B^- results in full proton uptake by Glu L212. Compensating proton release by other interacting residues account for the small value for the net proton uptake. In another model, (Beroza et al., 1995) Glu L212 is partially ionized from pH 7 to 9 and becomes fully ionized at higher pH. Formation of Q_B^- results in the fractional proton uptake by Glu L212, which increases with increasing pH. Further work is required to resolve the protonation state of Glu L212 and other interacting residues.

2. Ser L223

Ser L223, which provides a hydrogen bond to Q_B , was changed to Ala in RCs from *Rb. sphaeroides* (Paddock et al., 1990b). The cytochrome turnover rate slowed by a factor of 60 after an initial fast oxidation of 2 cytochromes (see Fig. 4). This was explained by a reduced rate for the transfer of the first proton, $H^+(1)$, in the quinone reduction cycle (step 4 – Fig. 3). A block in the uptake of this proton would reduce the rate of the second electron transfer and lead to the accumulation of the state $Q_A^- Q_B$ after

oxidation of only 2 cytochromes. This interpretation was supported by the result that both proton uptake and electron transfer rates, $k_{AB}^{(2)}$, were found to be decreased by a factor of 400 (pH 7.5) (Table I). The change of Ser L223 \rightarrow Ala does not lead to large structural changes as indicated by the lack of change in the electron transfer rates for the first electron $k_{AB}^{(1)}$ and the recombination k_{BD} and by an unchanged EPR spectrum of $Q_B^-Fe^{2+}$ (Paddock et al., 1990b). Control experiments in which Ser L223 was changed to the protonatable residues Thr and Asp gave RCs with normal turnover rates while substitution with Asn resulted in slow turnover (see Table 1). A second-site mutation of Tyr L222 \rightarrow Cys was found to compensate for the Ser L223 \rightarrow Ala change, restoring photosynthetic competence in *Rb. sphaeroides* (S. H. Rongey, unpublished).

The importance of Ser L223 was also shown by mutant RCs from *Rp. viridis* selected for herbicide resistance. Leibl et al., (1993) found that a mutation of Ser L223 \rightarrow Ala was accompanied by a large reduction in the second electron transfer rate similar to that associated with this mutation in RCs from *Rb. sphaeroides*. The *Rp. viridis* RCs contained both the Ser L223 \rightarrow Ala change and a change of Arg L217 \rightarrow His. Evidence that the slow second electron transfer rate was due to the Ser L223 change and not the Arg L217 change came from a second double mutant containing the Arg L217 \rightarrow His mutation along with a Val L220 \rightarrow Leu change in which the second electron transfer rate was close to the native rate. In RCs from *Rb. capsulatus*, Bylina et al., (1992) found that the Ser L223 \rightarrow Ala mutation resulted in a loss of photosynthetic competence, consistent with the slow rates of electron and proton transfer measured in RCs from *Rb. sphaeroides* and *Rp. viridis*. However, mutations of Ser L223 to Thr, Glu, Gly in *Rb. capsulatus* resulted in photosynthetically competent strains (Bylina et al., 1992). The Ser \rightarrow Gly mutant is interesting since it lacks a proton donor group to replace the OH group in Ser. This mutation in RCs from *Rb. sphaeroides* did not decrease the proton coupled electron transfer rate $k_{AB}^{(2)}$ (Paddock et al., 1995). The X-ray crystal structure of the Ser L223 \rightarrow Gly mutant RC showed that there were no changes in conformation (Axelrod et al., 1995). These results were interpreted in terms of a water molecule replacing the Ser side chain as the proton donor to Q_B .

Several Photosystem II RC herbicide resistant mutants have been obtained with alterations at Ser

L264 on the D1 protein, homologous to Ser L223 in bacterial RCs (Oettmeier, 1992). These include Ser \rightarrow Gly (Hirschberg and McIntosh, 1983), Ser \rightarrow Ala (Erickson et al., 1984), Ser \rightarrow Thr (Sato et al., 1988) and Ser \rightarrow Asn (Pay et al., 1988). Interestingly, a Photosystem II mutant from *Amaranthus hybridus* containing the Ser \rightarrow Gly at position 264 on the D1 subunit homologous to the Ser L223 site in purple bacteria, was also found to be photosynthetically competent and displayed normal electron transfer kinetics (Taoka and Crofts, 1990).

3. Asp L213

The Asp L213 residue located near Q_B was changed to Asn in RCs of *Rb. sphaeroides* (Takahashi and Wraight, 1990, 1992; Paddock et al., 1990b, 1994). The cytochrome turnover rate was decreased by a factor of 250 after a fast oxidation of 2 cytochromes similar to the effect of the Ser L223 \rightarrow Ala mutation indicating a block in proton and electron transfer associated with the second electron. The electron transfer rate $k_{AB}^{(2)}$ coupled to proton transfer was found to be reduced by a factor of 1500 to $\approx 0.3 \text{ s}^{-1}$ at pH 7.5. The change of Asp L213 \rightarrow Asn produced significant changes in other rates besides $k_{AB}^{(2)}$. Both the first electron transfer rate $k_{AB}^{(1)}$ and recombination rate k_{BD} were decreased by a factor of ≈ 10 at pH 7.5 (see Table 1). These changes in rate are likely due to electrostatic effects associated with the loss of a negative charge on Asp L213 whose pK_a is estimated to be below 7. In addition, a double mutant with the changes Asp L213 \rightarrow Asn and Glu L212 \rightarrow Gln was constructed (Takahashi and Wraight, 1992; Takahashi et al., 1992). RCs from this mutant exhibited slow rates of cytochrome turnover and electron and proton transfer associated with the second electron $k_{AB}^{(2)}$, similar to the Asp L213 \rightarrow Asn mutant. However, the rate of the first electron transfer $k_{AB}^{(1)}$ was fast and pH independent, similar to the Glu L212 \rightarrow Gln mutant.

The reductions in proton and electron transfer rates described above can be explained if Asp 213 is involved in proton transfer of the first proton $H^+(1)$ that is necessary for the second electron transfer (see Fig. 3 step 4). Evidence for a proton donor role for Asp L213 comes from the finding that its replacement by Ser, Thr, Leu as well as Asn gives slow rates for $k_{AB}^{(2)}$ $\approx k_H \approx 0.5 \text{ s}^{-1}$. However, replacement with the proton donor Glu gives a faster rate $k_{AB}^{(2)} \approx 15 \text{ s}^{-1}$ (Paddock et al., 1994). This rate is slower than the rate observed in native RCs $k_{AB}^{(2)} \approx 10^3 \text{ s}^{-1}$, which is attributed to an

electrostatic effect, as indicated by a slow k_{BD} (Table 1). Evidence that the reduction in proton uptake and electron transfer rates in the Asp L213 \rightarrow Asn mutant are due to a proton transfer bottleneck comes from the observation by Takahashi and Wraight (1991) that these rates are increased by addition of azide and other weak acids. Paddock et al. (1994) found that azide also increases the recombination rate k_{BD} in Asp L213 \rightarrow Asn RCs, indicating a destabilization of Q_B^- . This finding suggests a model in which binding of the azide anion near the Q_B site provides a negative charge which facilitates proton transfer. A similar increase in proton transfer rate was observed by addition of azide to proton transfer mutants of bacteriorhodopsin (Tittor et al., 1989; Otto et al., 1989).

The Asp L213 residue is the closest proton donor residue to Glu L212. It has, therefore, been suggested that it is involved in proton transfer to Glu L212 (McPherson et al., 1991; Takahashi and Wraight, 1992; Shinkarev et al., 1993). Supporting evidence of the involvement of Asp L213 in the proton transfer pathway to Glu L212 comes from experiments on the Asp L213 \rightarrow Asn mutant in which the rate $k_{AB}^{(1)}$ for the reaction $Q_A^- Q_B^- \rightarrow Q_A Q_B^-$ is slower than in native RCs (see Table 1) (McPherson et al., 1991; Takahashi and Wraight, 1992). One explanation for the slower rate postulates a rate limiting proton transfer to ionized Glu L212 as a process that is required for electron transfer to Q_B . The slower rate in the mutant RCs lacking Asp L213 suggests that Asp L213 is involved in the proton transfer to Glu L212 (McPherson et al., 1991). Shinkarev et al. (1993) have presented a model for the pH dependence of $k_{AB}^{(1)}$ which accounts for the results from native RCs and the Glu L212 \rightarrow Gln mutant but not the Asp L213 \rightarrow Asn mutant. The failure of this model to account for the electron transfer rate in the Asp L213 \rightarrow Asn mutant was attributed to a slow protonation rate in the Asp L213 \rightarrow Asn mutant. This result was interpreted to indicate the central role of Asp L213 in proton transfer to residues near Q_B .

4. Glu H173

Recent work has implicated a residue on the H subunit in proton coupled electron transfer. The mutation of Glu H173 \rightarrow Gln in RCs from *Rb. sphaeroides* has been found to decrease $k_{AB}^{(2)}$ by 20–50 (pH 7.5) indicating a possible role in proton coupled electron transfer (Takahashi and Wraight,

1995; Rongey et al., 1995). However, in contrast to the Asp L213 \rightarrow Asn mutant, the back reaction rate k_{BD} was increased, indicating a destabilization of Q_B^- . These results could, in principle, be attributed to a slower rate limiting proton transfer in mutant RCs. However, measurements of the effects of substituting low potential quinones in the Q_A site on $k_{AB}^{(2)}$ showed that electron transfer, not proton transfer, was the rate limiting step. Thus, the mutation of Glu H173 \rightarrow Gln slows down the rate of electron transfer or decreases the stability of the protonated semiquinone (M. S. Graige et al., 1995; and unpublished results).

B. Second-Site Mutants Compensating for Asp L213 (Asn M44, Arg M233, Gly L225)

Several second-site mutations which compensate for the loss of Asp L213 in *Rb. sphaeroides* and Asp L213 and Glu L212 in *Rb. capsulatus* have been obtained. These mutations give important information about the factors responsible for fast proton and electron transfer rates.

An interesting second-site mutation involves the Asn M44 \rightarrow Asp change in *Rb. sphaeroides* (Rongey et al., 1993) and the homologous Asn M43 \rightarrow Asp change in *Rb. capsulatus* (Hanson et al., 1992b, 1993; Maróti et al., 1994). These changes restore photosynthetic competence to the non-photosynthetic parent strains lacking Asp L213. The rates of the electron transfer reactions $k_{AB}^{(1)}$, $k_{AB}^{(2)}$ and k_{BD} for the double mutant in *Rb. sphaeroides* were found by Rongey et al., (1993) to be very similar to those in native RCs (see Table 1). The compensatory Asn M43 \rightarrow Asp change in RCs from *Rb. capsulatus* containing the double mutation Asp L213 \rightarrow Asn and Glu L212 \rightarrow Ala increased $k_{AB}^{(2)}$ and proton transfer by about 10-fold compared to the low rates in the double mutant; however, these rates were considerably less (by $\approx 10^2$) than in native RCs (see Table 1; Maróti et al., 1994). The observation that either Asp L213 or Asp M44 can serve the same function in proton transfer explains the puzzling fact that Asp L213 is not conserved in different strains of photosynthetic bacteria. An Asp at either L213 or M44² is found in all photosynthetic bacteria in which RCs have been sequenced. RCs from *Rb. sphaeroides* (Williams et al., 1983, 1984), *Rb. capsulatus* (Youvan et al., 1984), and *Erythrobacter* OCH114 (Liebetanz et al., 1991) contain Asp at position L213 and an Asn at position

² Or the homologous residues, eg. M43 or M231 in *Rb. capsulatus*

M44, while RCs from *Rp. viridis* (Michel et al., 1986), *Rhodospirillum rubrum* (Belanger et al., 1988) and *Chloroflexus aurantiacus* (Ovchinnikov et al., 1988a,b) contain Asn at position L213 and Asp at position M44².

Another interesting second-site mutation involves the change of Arg M233 \rightarrow Cys in *Rb. sphaeroides*¹ (Okamura et al., 1992) and the homologous change of Arg M231 \rightarrow Leu in *Rb. capsulatus* (Hanson et al., 1992a). These changes confer photosynthetic competence to the parent strain lacking Asp L213. The mutant showed an increase in the recombination rate k_{BD} which is indicative of a negative charge near Q_B . The value of $k_{AB}^{(2)}$ in the second site mutant RCs from *Rb. sphaeroides* is larger than in RCs lacking Asp L213 but still slower than in native RCs (see Table 1). The unusual feature of the M233 site is its large distance to Q_B (≈ 15 Å) (see Fig. 2). The question, therefore, arises how a change at the M233² position can restore the rapid proton coupled electron transfer rate to Q_B . Possible explanations proposed involve the effect of altered electrostatics on a cluster of charged residues spanning the region between M233 and Q_B and the role of water molecules as proton donors (Hanson et al., 1992a; Okamura et al., 1992).

Other second-site mutations that restore photosynthetic competence to RCs from *Rb. capsulatus* lacking Asp L213 and Glu L212 are the changes of Gly L225 \rightarrow Asp (Schiffer et al., 1993), Arg L217 \rightarrow Cys and Asn M5 \rightarrow Aso (Hanson et al., 1995). An important feature of this mutation as in all other second-site mutations that restore activity to RCs lacking Asp L213 is the increase in negative charge. These mutations show the importance of electrostatic effects on proton-coupled electron transfer.

C. Mutations Not Affecting Proton Transfer (Arg L217, Asp L210, His L190)

Mutations that did not produce large changes in the proton transfer rate include several conservative replacements that preserved the proton donating ability (see Table 1) eg. Glu L212 \rightarrow Asp (Paddock et al., 1990), and Ser L223 \rightarrow Thr (Paddock et al., 1990a). Several other mutations that did not result in a significant loss of activity were Arg L217 \rightarrow Gln (M. L. Paddock unpublished) and Asp L210 \rightarrow Asn (M. L. Paddock unpublished). Preliminary results on a mutant in which the residue His L190, which provides the second H bond to Q_B , was changed to

Gln showed a near normal cytochrome turnover rate (J. Williams, unpublished). The role of H-bonded protons Q_B^- was studied by ENDOR measurement of their rates of exchange with deuterium (Paddock et al., 1995b). One of the protons, assigned to the H-bond from His L190, exchanged slowly ($\tau \approx 20$ s) with a rate that was independent of quinone turnover. The result was interpreted as indicating that this proton is not part of the proton transfer chain.

VI. Mechanism of Proton Coupled Electron Transfer

The coupling between electron transfer and proton uptake occurs in the second electron transfer to Q_B . The proposed mechanism for this step involves the uptake of two protons $H^+(1)$ and $H^+(2)$. The first proton uptake could occur either before or after electron transfer as shown in the upper and lower paths of Eq. (1) (Maróti and Wraight, 1990; Takahashi and Wraight, 1992; Paddock et al., 1994).

A difficulty in deciding between the two paths is that both $Q_A Q_B H$ and $Q_A Q_B^{2-}$ are high energy intermediates that are not formed in sufficient quantity to be observed. The upper path (proton transfer before electron transfer) would be expected to dominate if $Q_A^- Q_B H$ is lower in energy than $Q_A Q_B^{2-}$. The energy of these two states depends on the environment of the quinone. The reduced Q_B^- and Q_B^{2-} states may be stabilized with respect to their protonated state, for instance, by hydrogen bonding. This could permit the electron transfer to proceed before protonation. It is also possible that proton transfer and electron transfer are highly cooperative and tightly coupled. In this case, electron transfer and proton transfer may proceed simultaneously. Experimentally, the individual steps have not yet been resolved kinetically, except for the case of the mutant (eg. Glu L212 \rightarrow Gln) in which the second proton transfer is slow.

The mechanism involving the protonated semi-

quinone (upper path) can explain the observed values for $k_{AB}^{(2)}$ as follows (Paddock et al., 1994; Takahashi and Wraight, 1992). If the proton transfer rate $k_H^{(1)}$ is fast, $k_H^{(1)} \gg k_{AB}^{(2)} \approx 10^3 \text{ s}^{-1}$, the observed rate would be given by $k_{AB}^{(2)} = k_{et}^{(2)} F(Q_B H)$ where $k_{et}^{(2)}$ is the rate of electron transfer to the protonated semiquinone shown in Eq. (2), and $F(Q_B H)$ is the fraction of protonated semiquinone.³ We estimate $k_{et}^{(2)}$ to be $\approx 10^4 \text{ s}^{-1}$, approximately the same as $k_{AB}^{(1)}$. This assumes that similar free energy changes are associated with $k_{et}^{(2)}$ and $k_{AB}^{(1)}$ (see Eq. (3) below). For this value of $k_{et}^{(2)}$ and a $pK_a \approx 4$ for the protonated semiquinone the pH dependence $k_{AB}^{(2)}$ would approach an asymptotic limit of $\approx 10^4 \text{ s}^{-1}$ near pH 4, in agreement with the observed value. Various estimates for the pK_a of the protonated semiquinone $Q_B H$ have been made. The pK_a for protonated ubisemiquinone in aqueous solution has been found to be near 5–6 (Swallow, 1982). The pK_a of the protonated semiquinone state $Q_A Q_B H$ in *Rb. sphaeroides* RCs was estimated to be < 7.4 (Kleinfeld et al., 1984; Takahashi and Wraight, 1992). Although the expected values for the pK_a of the protonated semiquinone is in reasonable agreement with those required by the mechanism of the upper path in Eq. (1), further evidence for the protonated semiquinone is needed to support the mechanism. The protonated semiquinone state $Q_A Q_B H$ has not been observed even at relatively low pH (≈ 5) (P. McPherson, unpublished results). Alternatively, a mechanism through the upper path could involve a rate limiting proton transfer $k_H^{(1)} < k_{et}^{(2)}$ at pH > 5 . This would account for the pH dependence of $k_{AB}^{(2)}$ approaching the maximum value of $k_{et}^{(2)}$ at low pH. The mechanisms through the upper path can also explain the slow rate for $k_{AB}^{(2)}$ seen in the Asp L213 \rightarrow Glu mutant by either a pK_a shift of the proton donor Glu L213 or by a reduction in the population of the protonated semiquinone (Paddock et al., 1994).

The mechanism involving the doubly reduced Q_B^{2-} state (lower path) cannot be excluded at present. However, estimates of the magnitude of the rate discussed below suggest that it may be less likely. The electron transfer rate $k_{et}^{(2)}$ for the reaction $Q_A Q_B^{2-} \rightarrow Q_A Q_B^{2-}$ involving the unprotonated semiquinone, depends on the free energy change of the reaction, $\Delta G_{et}^{o'}$. The dependence of $k_{et}^{(2)}$ on $\Delta G_{et}^{o'}$ can be obtained

³ For simple titrations $F(Q_B H) = 0.5$ at $pH = pK_a$. However, the functional form of $F(Q_B H)$ in the RC may be more complicated due to interactions between interacting residues (see Paddock et al., 1994).

from the Marcus equation (Marcus and Sutin, 1985) which gives the rate of electron transfer as a function of an intrinsic rate k_0 and a reorganization energy λ :

$$k_{et} = k_0 e^{-(\Delta G^o - \lambda)^2 / 4 \lambda k_B T} \quad (3)$$

where k_B is the Boltzmann constant and T the absolute temperature. The value for k_0 depends on the electron transfer pathway between the donor and acceptor. The value of λ depends on the change in energy due to structural changes associated with electron transfer. We assume that the values of k_0 and λ are the same for the first and second electron transfer between Q_A and Q_B . Furthermore, under the conditions that $\lambda \gg |\Delta G|$ we can obtain the electron transfer rate $k_{et}^{(2)}$ involving the unprotonated semiquinone by comparing it with $k_{AB}^{(1)}$ and correcting for the difference in free energy using Eq. (4) (Paddock et al., 1991).

$$k_{et}^{(2)} = k_{AB}^{(1)} e^{-\delta G / 2 k_B T} \quad (3)$$

where $\delta G = \Delta G_{et}^{o'(2)} - \Delta G_{AB}^{o'(1)}$ is equal to the difference in free energies of the two reactions involving the second and first electrons, respectively. ($\Delta G_{AB}^{o'(1)} \approx -100 \text{ meV}$, $k_{AB}^{(1)} \approx 10^4 \text{ s}^{-1}$).

One estimate of the limiting value for $\Delta G_{et}^{o'(2)}$ comes from the equilibrium constant of the reaction $Q_A Q_B^- \rightleftharpoons Q_A Q_B^{2-}$ in RCs (where the protonation state of Q_B^{2-} is not known). At high pH (> 10.5) the equilibrium constant for this reaction approaches a value of ≈ 0.02 . Assuming that the quinol is unprotonated above pH 10.5, the value of $K_{et}^{(2)} \approx 0.02$ and $\Delta G_{et}^{o'(2)} \approx 100 \text{ meV}$ (Kleinfeld et al., 1984; Takahashi and Wraight, 1992; McPherson et al., 1993, 1994). However, the $pK_a \approx 10.5$ for the ionization of the second proton from $Q_B H_2$ is much lower than observed for fully reduced ubiquinone in solution which has a pK_a for the first proton near 13 (Swallow, 1982; Morrison et al., 1982). The second proton would have an even higher pK_a . A smaller value ($< 2 \times 10^{-4}$) for the equilibrium constant $K_{et}^{(2)}$ involving the unprotonated Q_B^{2-} was estimated by Paddock et al., (1994). This gave a lower limit of $\Delta G_{et}^{o'} > 220 \text{ meV}$. The $k_{et}^{(2)}$ values calculated from Eq. (4) using these estimated free energies were respectively ~ 1 and 2 orders of magnitude smaller than the observed values of $k_{AB}^{(2)} \approx 10^3 \text{ s}^{-1}$ at pH 7.5. This suggests that the mechanism does not involve the unprotonated Q_B^{2-} state. Another observation (Paddock et al., unpublished) which argues against the Q_B^{2-} mechanism is that use of quinone analogues with substitution of Br

for the ring proton in Q_o decreases the value of $k_{AB}^{(2)}$. Bromine-substituted quinones are expected to stabilize Q_B^{2-} , which would result in an increase of $k_{AB}^{(2)}$ of the lower path. This is in disagreement with the observation and therefore argues in favor of the upper path. (See note added in proof.)

VII. Pathways for Proton Transfer

A model for the proton transfer pathways in RCs from *Rb. sphaeroides* based on site directed mutagenesis studies is shown in Fig. 6 (Okamura and Feher, 1992; Paddock et al., 1990b; Takahashi and Wraight, 1994). In this model two protons $H^+(1)$ and $H^+(2)$ are transferred from solution to Q_B along two pathways. The first proton $H^+(1)$ is transferred along a pathway involving Ser L223 and Asp L213. The second proton is transferred along a pathway involving Glu L212 and Asp L213. Inspection of the X-ray crystal structure shows that protons from solution have access to the region near Asp L213 with Asp L210 or Arg L217 possibly acting as intermediates, although evidence for the direct involvement of these residues is lacking. In addition, a void in the protein structure large enough to hold 5–6 water molecules is seen in the X-ray crystal structure in a region bordered by the methoxy groups of Q_B , Asp L213 and Glu L212 (Beroza et al., 1992).

This pocket is likely to contain water molecules which could play an important role in the proton transfer to Q_B .

The pathway shown in Fig. 6 is based on the assumption that the large changes in proton transfer rate due to mutations of Glu L212, Ser L223 and Asp L213 result from the properties of the mutated residue and not from conformational changes. In addition, the model makes the assumption that the loss of activity due to mutation of a protonatable residue indicates its role as a proton donor in a proton transfer chain. Other interpretations of the results from site-directed mutagenesis are possible. These include: a) short range steric effects or long range conformational effects not related to the role of the mutated residue as a proton donor; b) electrostatic effects on either the rate or the equilibrium of the proton transfer reaction.

Although the mutagenesis results indicate that specific amino acid residues play important roles in facilitating proton transfer, the results from second-site mutations indicate that proton transfer pathways are not unique and that alternate proton transfer pathways are possible. The general requirement for fast proton transfer is the availability of suitably oriented proton donor/acceptor groups with appropriate pK_a s. A likely possibility is that in some cases internal water molecules may be involved in proton transport. In addition, negatively charged groups

Fig. 6. Pathways for Proton Transfer in RCs from *Rb. sphaeroides*. The pathway for the first proton $H^+(1)$, to the quinone carbonyl H-bonded to Ser L223, involves Asp L213 and Ser L223. The pathway for the second proton $H^+(2)$, to the carbonyl H-bonded to His L190 involves Glu L212 and possibly Asp L213. A cavity near the methoxy groups of Q_B presumably containing internal water is likely to play a role in the proton transfer (from Okamura and Feher, 1992).

appear to be necessary to facilitate proton transfer by stabilizing protons in the interior of the protein.

The results obtained in bacterial RCs may also be applicable to RCs in oxygen-evolving species. The RC of Photosystem II in these organisms contains a bound Q_B site with properties similar to those observed in RCs from purple bacteria. In Photosystem II there are no obvious homologies to the Glu L212 and Asp L213 residues. However, a bound bicarbonate (Govindjee and van Rensen, 1993) has been shown to increase the rate of the second electron transfer reaction to Q_B . Diner and Petrouleas (1990) have suggested that the bicarbonate binds to the non-heme Fe in the PS II RC and plays a role in proton transfer similar to the acid groups in the RCs from purple bacteria. Takahashi and Wraight (1991) have suggested that the bicarbonate effect in Photosystem II RCs is similar to the azide effect in purple bacterial mutants deficient in proton transfer. It is interesting that Arg residues 233 and 251 in the D2 protein have been implicated in bicarbonate binding (Cao et al., 1991). These residues may have some homology with the Arg M233 found to affect proton transfer in bacterial RCs (Hanson et al., 1992a; Okamura et al., 1992). In view of the diversity in proton transfer pathways in bacterial RCs and mutants it is not surprising that specific residues responsible for fast proton transfer to Q_B in bacterial RCs are not conserved in the Photosystem II RC. Nevertheless, the Photosystem II RC may utilize the same principles for increasing proton transfer, e.g. the presence of protonatable groups and negative charges near Q_B to facilitate proton transfer.

Note Added in Proof

The mechanism of proton coupled electron transfer for the second electron $k_{AB}^{(2)}$ was studied in native RCs by substituting low potential quinones for Q_{10} in the Q_A site while retaining Q_{10} in the Q_B site (Graige et al., 1995). This should change the rate of electron transfer but not the rate of proton transfer. The values for $k_{AB}^{(2)}$ were found to increase with increasing driving force with a dependence consistent with the Marcus theory, indicating that electron transfer was the rate limiting step. This result, along with those previously discussed, indicates a mechanism in which rate limiting electron transfer follows rapid proton transfer ($Q_A^- Q_B^- + H^+ \rightleftharpoons Q_A^- Q_B H \rightarrow Q_A Q_B H$).

Acknowledgements

We would like to acknowledge M. L. Paddock, P. H. McPherson, S. H. Rongey, P. Beroza for helpful discussions and contributions to our understanding of proton transfer in bacterial reaction centers. The work from our lab was supported by grants from NIH and NSF.

Summary

When electron transfer to the primary quinone is blocked, the radical pair P^+H^- (P: primary donor, H: bacteriopheophytin at the A-branch) recombines on the 10 ns time scale either to the ground state P or, after hyperfine-induced singlet-triplet-mixing, to the triplet state $^3P^*$. An external magnetic field hinders singlet-triplet-mixing, thus reducing the yield of $^3P^*$ and slowing the recombination of P^+H^- . Magnetic field dependent measurements of the recombination dynamics allow the determination of the recombination rates k_s and k_T and the exchange interaction J. From these parameters free energies, electronic matrix elements and reorganization energies relevant for the fast charge separation and slow charge recombination processes in the reaction center can be determined. In many cases, recombination data constitute the sole experimental access to such parameters, which constitute the basis for the theoretical treatment of electron transfer processes.

In this review, results obtained on quinone-depleted reaction centers of *Rhodobacter sphaeroides*, *Rhodobacter capsulatus* and *Chloroflexus aurantiacus* are discussed in the context of (i) the similarity of reaction centers from different organisms, (ii) the mechanism of primary charge separation, (iii) the distinction between structural and energetic effects of genetic alterations of the reaction center, and (iv) the effects of an external electric field, which shifts the energy of the charge separated states. Furthermore, different recombination dynamics observed in transient absorption and delayed fluorescence reveal an inhomogeneous broadening of radical pair energies in the reaction center. This energetic broadening allows us to understand a variety of phenomena: (a) the observed multiphasic electron transfer kinetics, (b) the unexpectedly weak electric field effects on the fluorescence and (c) the discrepancies of energetics determined by delayed fluorescence and transient absorbance measurements. As a consequence, absorption measurements are better suited to determine the average of the energetic distribution of the radical pair P^+H^- .

I. The Magnetic Field Effect

Excitation of reaction centers (RCs) from *Rhodobacter (Rb.) sphaeroides* in which the primary quinone Q at the active A-branch was reduced showed the formation of a state P^F (Parson et al., 1975; Cogdell et al., 1975). This state was identified as the radical pair P^+H^- , P being the primary donor and H the bacteriopheophytin (BPheo) at the active branch. At room temperature, P^F was found to decay on the 10 ns time scale, partly to the ground state and partly to the state P^R , identified as the lowest triplet state $^3P^*$. From its unusual spin polarization (Dutton et al., 1973; Uphaus et al., 1974; Thurnauer et al., 1975)

this triplet state was recognized (Blankenship et al., 1977; Haberkorn and Michel-Beyerle, 1977) to be formed via the magnetic field dependent radical pair mechanism (Michel-Beyerle et al., 1976; Schulten and Schulten, 1977; Werner et al., 1978; Haberkorn and Michel-Beyerle, 1979). In accordance with this mechanism, the yield of $^3P^*$ (Blankenship et al., 1977; Hoff et al., 1977) and the lifetime of P^+H^- (Michel-Beyerle et al., 1979, 1980) were found to be affected by an external magnetic field. Since the early eighties, RCs depleted of the primary quinone were predominantly investigated (Ogrodnik et al., 1982), because the interpretation of the results for Q-reduced RCs suffers from several difficulties: (i) the

complex spin dynamics due to the coupling of the radical electron spin on H to the electron spin on Q (Lang, 1991), which in turn is coupled to the fast relaxing spin on the iron ion (Okamura et al., 1975), (ii) the distortion of the energies of the charge-separated states by the negative charge on Q which affects the electron transfer kinetics (Breton et al., 1986) and (iii) the destabilization of the Q binding site by reduction of Q (Scheidel, 1989). For earlier reviews see (Hoff, 1981, 1986; Boxer et al., 1983).

A. Hyperfine Induced Singlet-Triplet-Mixing

After formation of P⁺H⁻ from the singlet state ¹P* on the ps timescale (Kaufmann et al., 1975; Rockley et al., 1975; Woodbury et al., 1985; Martin et al., 1986; Fleming et al., 1988; Holzapfel et al., 1989), the radical electron spins on P and H are in a singlet configuration. In RCs in which the electron transfer from H to Q is blocked the radical pair P⁺H⁻ recombines with a lifetime on the 10 ns timescale (Parson and Cogdell, 1975; Ogrodnik et al., 1982; Schenck et al., 1982; Chidsey et al., 1984; Ogrodnik et al., 1988). During this time the spins of the radical electrons on P and H undergo singlet-triplet-mixing (S-T-mixing). S-T-mixing is due to the hyperfine interaction (HFI) of the radical electron spins with their respective nuclear spin environments. In a simplified picture it can be viewed as a precession of the electron spins around the effective magnetic fields originating from the nuclear spins. Since the two electrons have different nuclear environments, in general the precession frequencies of the two electron spins will be different, resulting in a coherent oscillation between the original singlet and the triplet spin configuration.

B. Reaction Scheme of Radical Pair Recombination

The complete scheme for the recombination of P⁺H⁻ is shown in Fig. 1. In addition to recombination to the

Fig. 1. Kinetic scheme for the recombination of P⁺H⁻ in Q-depleted or Q-reduced RCs. The energetic splitting of ¹(P⁺H⁻) and ³(P⁺H⁻) due to exchange interaction (*J*) and Zeeman interaction ($\pm g\beta B$) are shown considerably enlarged.

singlet ground state P, HFI induced S-T-mixing opens a second recombination channel from the triplet radical pair state to ³P*. Also shown are the exchange interaction *J*, i.e. the energy splitting of ¹(P⁺H⁻) and ³(P⁺H⁻) ($\approx 10\text{G} \approx 10^{-7}\text{eV}$),¹ and the Zeeman splitting of the triplet states in an external magnetic field *B*. The dipole interaction between the two radical electron spins, causing additional splitting of the triplet radical pair energies, is small ($D = 5.5\text{G}$) due to their large distance (17Å, as deduced from the X-ray structure (Deisenhofer et al., 1984; Chang et al., 1986; Allen et al., 1987)) and can be neglected for the discussion of radical pair recombination (Ogrodnik et al., 1985).²

The isoenergetic S-T-mixing is hindered by an energetic splitting of the singlet and triplet radical pair levels. For a magnetic field $B_{\text{max}} = J$ one of the triplet states is isoenergetic to the singlet state, thus one expects the maximum triplet yield (ϕ_{T}) for this field. The width ΔB of the magnetic field dependence of ϕ_{T} around resonance is determined by inhomogeneous broadening due to hyperfine interaction and homogeneous broadening reflecting the lifetime of singlet and triplet levels, with the lifetime broadening constituting the dominant contribution in RCs (Haberkorn and Michel-Beyerle, 1977, 1979; Werner et al., 1978).

Abbreviations: B – BChl monomer at the active branch; BChl – bacteriochlorophyll; BPheo – bacteriopheophytin; Car – carotenoid; Cf. – *Chloroflexus*; H – BPheo at the active branch; HFI – hyperfine interaction; MARY – MAgnetic field dependence of the Reaction Yield; P – primary donor (BChl dimer); PVA – polyvinyl alcohol; Q – quinone at the active branch; Rb. – *Rhodobacter*; RC – reaction center; Rp. – *Rhodospseudomonas*; RYDMR – Reaction Yield Detected Magnetic Resonance; S-T-mixing – singlet-triplet-mixing

¹ In this article, *J* is given in units of G, corresponding to the value of $J/g\beta$, with *g* the *g*-factor and β Bohr's magneton.

² In this reference a factor of 0.5 was erroneously dropped, thus the correct value of *D* is 5.5G.

In general, the rates for recombination via the two channels are different. For Q-reduced and Q-depleted RCs of *Rb. sphaeroides* it was found that the rate k_s for recombination via the singlet channel is smaller than the rate k_t for recombination via the triplet channel (Michel-Beyerle et al., 1980; Norris et al., 1982; Ogrodnik et al., 1982; Wasielewski et al., 1983a,b, 1984; Chidsey et al., 1984; Ogrodnik et al., 1988). This conclusion immediately follows from the observed increase of the lifetime τ_{RP} of P^+H^- upon application of a magnetic field which increases the yield of recombination via the slow singlet channel. Also, from the lifetime broadening of the radical pair levels, as measured by the width ΔB , the sum of the rates k_s and k_t can be estimated to be on the order of 1 ns^{-1} . Since τ_{RP} is on the order of 10 ns, the larger rate has to be k_t , with S-T-mixing constituting the bottleneck for the recombination via the fast triplet channel. The value of ΔB , therefore, is a convenient measure for the triplet recombination rate k_t .

C. Methods: MARY and RYDMR

The measurement of the magnetic field dependence of the yield ϕ_T of $^3P^*$ has been given the name MARY- (MAGnetic field dependence of the Reaction Yield)-spectroscopy (Lersch et al., 1982). As will be shown in the next section, from MARY spectra the parameters k_t and J can be determined, while the measurement of the radical pair lifetime allows the determination of k_s .

In addition to the static magnetic field a microwave field can be applied. If the frequency ω_{MW} of this field is in resonance with the Zeeman splitting of the triplet states of P^+H^- , it couples these states, thus modulating the triplet recombination yield (RYDMR—Reaction Yield Detected Magnetic Resonance) (Frankevich et al., 1977). The method has been applied to RCs by Bowman et al. in 1981. The modulation of ϕ_T depends on the external magnetic field B_0 as well as on the strength B_1 of the microwave field. As in MARY spectroscopy, a quantitative analysis of the experimental results allows the determination of k_t and J . The determination of J even is possible in a range of values which is not accessible to MARY spectroscopy (Lersch, 1987). However, this extended range for the determination of J is relatively small and, in contrast to MARY spectroscopy, RYDMR spectroscopy shows a significant selectivity in the case of sample inhomogeneity (see section II.D.2.c). For a recent

review see (Lersch and Michel-Beyerle, 1989).

II. Temperature Dependent Recombination Dynamics of P^+H^- in Native RCs of Various Photosynthetic Bacteria

The parameters directly accessible to transient absorbance measurements are the radical pair lifetime τ_{RP} , the triplet and singlet recombination yields ϕ_T and ϕ_S and their magnetic field dependence, ϕ_S is the portion of RCs recombining to the ground state P and can best be determined by monitoring the nanosecond-recovery of the ground state absorbance band at 865 nm, normalized to the initial bleaching directly after the formation of P^+H^- . The remaining bleaching of this band after recombination is completely finished is due to $^3P^*$, thus being a measure for ϕ_T .

A. Previous Measurements

Table 1 summarizes previously reported results for the radical pair lifetime τ_{RP} and the triplet yield ϕ_T in Q-reduced and Q-depleted RCs. Most of these results refer to RCs of *Rb. sphaeroides* R26. As mentioned before, the application of an external magnetic field leads to a decrease of ϕ_T and an increase of τ_{RP} . Upon lowering the temperature, both ϕ_T and τ_{RP} increase. Also given are results for the magnetic field $B_{1/2}$ at which half of the maximum magnetic field effect on ϕ_T is found in the MARY spectrum, which is a measure for k_t , and values of k_s , k_t and J obtained from MARY- and RYDMR-measurements.

Additional information has been obtained for Q-depleted RCs of *Rb. sphaeroides* at room temperature from measurements in high magnetic fields, which cause an increase of the triplet yield (accompanied by a decrease of τ_{RP}) because of the enhanced S-T-mixing due to the different g-factors of the radical electrons (Δg -effect) (Chidsey et al., 1980; Boxer et al., 1982a,b,c). At 50 kG values of $\phi_T = 0.4$ and $\tau_{RP} = 9 \text{ ns}$ were measured (Chidsey et al., 1984). Above 120 kG saturation at a triplet yield of 0.5 was observed (Goldstein et al., 1988). At such high magnetic fields a radical pair lifetime of 5 ns was extracted from fluorescence measurements (Goldstein and Boxer, 1989a).

The Δg -induced S-T-mixing in high magnetic fields was found to be pronouncedly anisotropic. In principle, conclusions on the RC structure can be

τ_{RP} radical pair lifetime; ϕ_T triplet yield; $B_{1/2}$ magnetic field at which half of the magnetic field modulation of ϕ_T is observed in the MARY spectrum; k_S , k_T singlet and triplet recombination rate; J exchange interaction of P⁺H⁻. If not stated otherwise, results refer to RCs of *Rb. sphaeroides* R26 (RT: room temperature).

drawn from this anisotropy of the Δg tensor (Boxer et al., 1983). In contrast, the HFI-induced S-T-mixing in low fields shows only a small anisotropy due to the small anisotropy of HFI and dipole interaction (Boxer et al., 1982a,c; Ogrodnik et al., 1985).

High pressure was found to have only small effects on the recombination dynamics of P⁺H⁻ in Q-reduced RCs at room temperature, reducing its lifetime from 12 ns to approx. 8 ns at 345 MPa (Windsor and Menzel, 1989).

B. Measurements with High Accuracy on Quinone-Depleted RCs of Rhodobacter sphaeroides R26, Rhodobacter capsulatus and Chloroflexus aurantiacus

In the following we summarize the results of highly precise measurements on Q-depleted RCs of the purple bacteria *Rb. sphaeroides* R26 (Table 2) and *Rb. capsulatus* (Table 4) and of the green bacterium *Chloroflexus (Cf.) aurantiacus* (Table 3), all recently obtained in our lab. The results for the RC of *Rb.*

Table 2. Results of (a) MARY- and (b) RYDMR-measurements on Q-depleted native RCs of *Rb. sphaeroides* R26 and Q-depleted mutagenetically altered RC of *Rb. sphaeroides* GA (Tyr^{M210} → Phe).

τ_{RP} lifetime of P⁺H⁻ (measured in the Q_y-absorbance band of P around 870 nm or in the Q_y-absorbance band of H around 750 nm) (± 1 ns); ϕ_T recombination yield of ³P* (± 0.01); $B_{1/2}$ magnetic field at which half of the maximum magnetic field modulation of ϕ_T is observed (± 1 G); ΔB halfwidth of the MARY spectrum (hwhm) (± 1 G); τ_3 lifetime of ³P* (± 2 μ s); k_S singlet recombination rate ($\pm 0.2 \times 10^7$ s⁻¹); k_T triplet recombination rate ($\pm 0.1 \times 10^9$ s⁻¹); ΔG_T free energy gap between P⁺H⁻ and ³P* (± 8 meV); J exchange interaction of P⁺H⁻ (± 2 G). MARY-results were determined with two set-ups using an optical and an electronic delay between exciting and probing laser pulse, see text.

sphaeroides given here are the first set of all parameters of interest obtained on the same sample for a wide range of temperatures. They will be compared to the results obtained for the very similar RC of *Rb. capsulatus* (Prince and Youvan, 1987) and for the RC of *Cf. aurantiacus*, which has a different pigment content (BPheo at the position of the bacteriochlorophyll (BChl) at the inactive B-branch) (Blankenship et al., 1983; Pierson and Thornber, 1983) and, in spite of a high overall homology of the primary structure, contains different amino acid residues at various significant positions (Ovchinnikov et al., 1988a,b; Shiozawa et al., 1989).

The lifetime and MARY data in Tables 2a, 3a and 4a were obtained in spectrometers for time-resolved

measurement of absorbance changes using either an optical delay line with a maximum delay of 92 ns (*Rb. sphaeroides*, *Rb. capsulatus*) or an electronic delay (*Rb. sphaeroides*, *Cf. aurantiacus*). The spectrometers have been described in Ogrodnik et al. (1988) and Volk et al. (1992), respectively. The electronic delay makes delay times in the nano- to millisecond range accessible, thus allowing the simultaneous measurement of radical pair recombination, the lifetime τ_3 of ³P* and of the residual fraction of RCs containing Q (Volk et al., 1992), see Fig. 2. The RYDMR data in Tables 2b, 3b and 4b were measured as described in Lersch et al. (1989).

For *Rb. sphaeroides* and *Cf. aurantiacus* the radical pair lifetime τ_{RP} was determined from a mono-

τ_{RP} lifetime of P⁺H⁻ (measured in the Q_y-absorbance band of H around 750 nm) (± 2 ns); ϕ_{T} recombination yield of ³P* (± 0.03); $B_{1/2}$ magnetic field at which half of the maximum magnetic field modulation of ϕ_{T} is observed (± 2 G); ΔB halfwidth of the MARY spectrum (hwhm) (± 2 G); k_{S} singlet recombination rate ($\pm 0.3 \times 10^7 \text{ s}^{-1}$); k_{T} triplet recombination rate ($\pm 0.05 \times 10^9 \text{ s}^{-1}$); J exchange interaction of P⁺H⁻ (± 2 G).

Fig. 2. Time-dependent P absorbance bleaching at 888 nm in Q-depleted RCs of *Rb. sphaeroides* at 90 K, 0 G and 700 G. (—) monoexponential fits in the range 5–200 ns and 1–500 μ s, respectively.

exponential fit of the time dependent recovery of the P absorbance in the maximum of the Q_y -band, as shown in Fig. 2 for the case of *Rb. sphaeroides* at 90K. For *Rb. sphaeroides* also the recovery of the Q_y -band of H around 750 nm was measured, yielding slightly different time constants, see Table 2a. The observed small deviations from monoexponentiality (compare the residuals for the monoexponential fits of radical pair recombination and decay of ${}^3P^*$ in Fig. 2) and the wavelength dependence of τ_{rp} can be interpreted in a quantitative way, as will be discussed in Section II.C. The triplet recombination yield ϕ_T was determined from the bleaching of P after radical pair recombination is complete, normalized to the initial amplitude at 0 ns. Both the radical pair lifetime and the triplet yield have similar values in *Rb. sphaeroides* and *Cf. aurantiacus* (Tables 2a and 3a).

The MARY spectra were obtained by measuring the bleaching of the Q_y -absorbance of P at 92 ns and 200 ns in the spectrometer with optical and electronic delay, respectively. Figure 3 shows some of the spectra obtained for *Cf. aurantiacus* at different temperatures. Above 230K a pronounced resonance structure was observed, allowing the direct determination of the exchange interaction J . At lower temperatures no such resonance can be resolved due to the increasing width of the MARY spectrum. For RCs of *Rb.*

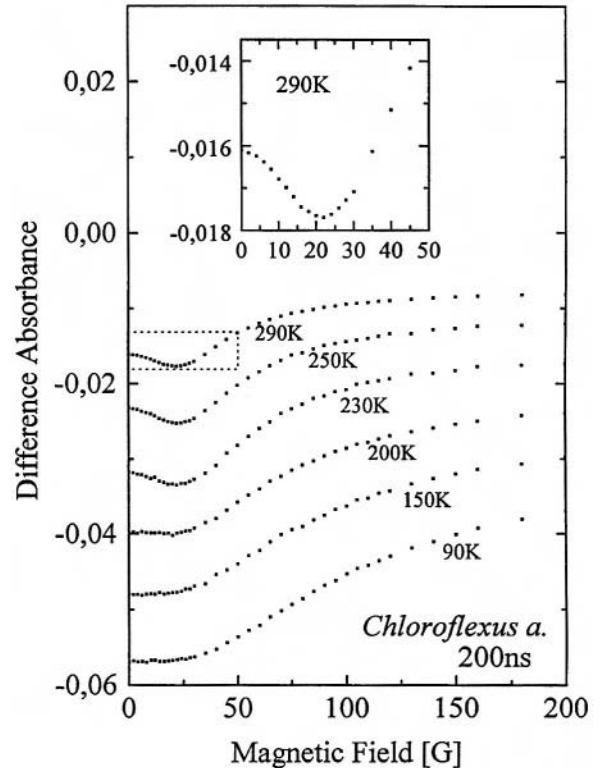

Fig. 3. Magnetic field dependence of the Q_y -absorbance bleaching of P in Q-depleted RCs of *Chloroflexus aurantiacus* at different temperatures, 200 ns after excitation (MARY spectrum). Inset: enlargement of MARY spectrum at 290 K.

sphaeroides we observed a weakly resolved resonance structure (with a maximum triplet yield near 10G) only at 230K. For the cases without resonance structure the halfwidth ΔB of the MARY spectra was determined by subtracting the value of J (10G for *Rb. sphaeroides*, 21G for *Cf. aurantiacus*, Section II.D.3, both essentially temperature independent), where resonance is expected to occur, from the value $B_{1/2}$ of the magnetic field at which half of the maximum magnetic field modulation of ϕ_T is observed. ΔB is almost temperature independent with values between 28G and 45G in the case of *Rb. sphaeroides*, while it increases from 34G at 290K to 94G at 90K in the case of *Cf. aurantiacus*.

The measurements on RCs of *Rb. capsulatus* are handicapped by the presence of carotenoids (Car). As in carotenoid containing RCs of *Rb. sphaeroides* (Schenck et al., 1984), fast energy transfer (within approx. 100 ns) from ${}^3P^*$ to ${}^3Car^*$ could be observed here. Since the decay of ${}^3P^*$ proceeds on a similar time scale as radical pair recombination, τ_{rp} was

determined from the recovery of the bleaching of the H absorbance band at 750 nm, where neither $^3\text{P}^* \rightarrow \text{P}$ nor $\text{Car} \rightarrow ^3\text{Car}^*$ cause substantial absorbance changes. The magnetic field dependence of ϕ_T was measured indirectly by monitoring $^3\text{Car}^*$ in its strong absorbance band at 560 nm. No resonance was found in the MARY spectra at 80K and 280K, $\Delta\mathbf{B}$ again was determined by subtracting the value of J (10G, from RYDMR measurements) from $B_{1/2}$. Due to the uncertainties of the $^3\text{Car}^*$ extinction coefficients, the absolute value of ϕ_T could not be determined directly, but was concluded upon from the magnetic field dependence of τ_{RP} and the magnetic field modulation of ϕ_T with the use of Eq. (1). All observed parameters have very similar values as the ones for *Rb. sphaeroides* (because of the inherent wavelength dependence of the observed time constants, (see Section II.C), only the values of τ_{RP} determined at corresponding wavelengths should be compared).

The values for k_T and J determined from RYDMR measurements on reaction centers of *Rb. sphaeroides*, *Cf. aurantiacus* and *Rb. capsulatus* (Lersch et al., 1990; Lang et al., 1990) are given in Tables 2b, 3b and 4b (see section II.D.2.b. for a more detailed description of the theoretical treatment of RYDMR data).

C. Inherent Inhomogeneity of the Singlet-Triplet-Mixing

The recombination of P⁺H⁻ shows small, but significant deviations from monoexponentiality (Fig. 2), which were observed for all RCs investigated. Also, the observed time constants were found to depend on the probing wavelength (Table 2a). Such effects can be ascribed to structural or energetic heterogeneities. Here, however, they mostly arise from an inherent ‘physical’ inhomogeneity of the effective hyperfine coupling due to the random orientation of nuclear spins (Feick et al., 1990). This inhomogeneity of the HFI leads to a distribution of the frequency of S-T-mixing (Schulten and Wolynes, 1978; Goldstein and Boxer, 1987). Since RCs with strong S-T-mixing preferentially recombine via the fast triplet channel, while RCs with weak S-T-mixing recombine via the slower singlet channel, the inhomogeneous HFI leads to a distribution of radical pair lifetimes. Indeed, the observed deviations from monoexponentiality are more pronounced for RCs of bacteria with high triplet recombination yield, that is with considerable recombination via the triplet

channel which introduces the inhomogeneity.

The distribution of τ_{RP} ranges from $\tau_{\text{RP}} \approx 2/(k_S + k_T)$ for the case of fast S-T-mixing (leading to a quasi-equilibration of singlet and triplet levels) to $\tau_{\text{RP}} = 1/k_S$ for the case of zero S-T-mixing. This is a rather broad distribution, ranging from 3 ns to 60 ns in RCs of *Rb. sphaeroides* at 90K. It can be approximated in an analytical form (Volk, 1991) using the one-proton model (Haberkorn and Michel-Beyerle, 1979) and assuming a Gaussian distribution of the effective HFI constant (Schulten and Wolynes, 1978; Goldstein and Boxer, 1987), Fig. 4.

The inhomogeneity of radical pair recombination observed at a particular wavelength, and consequently the average time constant measured at this wavelength, depend on the spin state of the recombination products which are monitored at that wavelength. For example, simulations of the radical pair recombination using the stochastic Liouville-Equation, Eq. (3), and the Hamiltonian, Eq. (4), for $k_S = 2 \times 10^7 \text{ s}^{-1}$ and $k_T = 1 \times 10^9 \text{ s}^{-1}$ (similar to the values for RCs of *Rb. sphaeroides* at 90K) yield average time constants of 22.0 ns, 14.4 ns and 16.8 ns for the recovery of the singlet ground state, the formation of $^3\text{P}^*$ and the overall radical pair decay, respectively. In measurements of the recovery of the

Fig. 4. Distribution of the radical pair lifetime τ_{RP} due to the inherent inhomogeneity of S-T-mixing, simulated with the one-proton model assuming a Gaussian distribution of the effective HFI constant (Volk, 1991). The parameters used for the simulation (indicated in the figure) are similar to those for RCs of *Rb. sphaeroides* at 90 K.

P ground state absorbance at 887 nm, the formation of $^3P^*$ absorbance at the isosbestic point of the P^+H^- difference spectrum at 552 nm and the recovery of the H absorbance at 762 nm we could determine these time constants experimentally, yielding values of 22.7 ns, 18.2 ns and 18.5 ns for RCs of *Rb. sphaeroides* at 90K (M. Volk, unpublished). The difference between the values at different wavelengths is significant, but not as pronounced as expected from the simulations. As shown recently (Ogrodnik et al., 1994), the energy of P^+H^- is inhomogeneously broadened, probably due to different conformational substates of the protein (section V.C.). This leads to an inhomogeneity of the recombination rates k_T and k_S which also contributes to the observed deviations from monoexponentiality and was shown to partially cancel the effect of the inherent inhomogeneity of the S-T-mixing on the wavelength dependence of τ_{RP} (Aumeier, 1993).

Due to the deviations from monoexponentiality and the wavelength dependence of the observed time constants, an unambiguous determination of the average radical pair lifetime is not straightforward. Simulated radical pair recombination data, obtained with the stochastic Liouville equation, were employed to find the best procedure (Volk, 1991). They show that monoexponential fits of the recovery of the P ground state absorbance indeed yield time constants close to the average radical pair lifetime for the typical parameters observed in bacterial RCs. For the recombination parameters found in D1D2Cytb-559-RCs of Photosystem II, however, the distribution of the radical pair lifetimes is much broader because of the unusually small value of k_S and complicates the determination of the average radical pair lifetime from the experimental data (Volk et al., 1993).

A more comprehensive discussion of the inherent inhomogeneity of S-T-mixing and its effects on the recombination dynamics of P^+H^- will be given elsewhere (M. Volk et al., unpublished).

D. Determination of the Recombination Rates and the Exchange Interaction

For RCs of *Rb. sphaeroides* at room temperature ϕ_T was found to be smaller than (i) any value compatible with the reaction scheme, Fig. 1 (Chidsey et al., 1984; Goldstein and Boxer, 1989b) and (ii) the value expected from simulations of the radical pair recombination using the stochastic Liouville

equation, Eq. (3), (Volk, 1991). These discrepancies can be explained self-consistently by equilibration between $^3P^*$ and the triplet state of the BChl monomer in the inactive branch on the time-scale of P^+H^- recombination or faster. The triplet state of this BChl is expected to have an energy higher than $^3P^*$ by about 0.02–0.03 eV (Shuvalov and Parson, 1981; Schenck et al., 1984) and was shown to be an intermediate for the triplet energy transfer to the carotenoid in Car-containing RCs (Frank and Violette, 1989). With this extension of the reaction scheme, at higher temperatures the observable concentration of $^3P^*$ after completion of P^+H^- recombination will be smaller than the overall portion of RCs recombining via the triplet channel. In agreement with this scheme, no discrepancies are observed for RCs of *Rb. sphaeroides* at low temperatures and for RCs of *Cf. aurantiacus* even at high temperatures, since here the BChl at the inactive branch is replaced by a BPh (Ovchinnikov et al., 1988a,b; Shiozawa et al., 1989). The conclusions described below are not affected by neglecting this extension to the reaction scheme, since only relative triplet yields will be considered.

This extension contrasts to the previously proposed reaction scheme (Goldstein and Boxer, 1989b), which assumed fast recombination of P^+H^- preceding nuclear relaxations on the time scale of a few nanoseconds. Such an explanation does not hold, however, since in measurements of the recombination dynamics of P^+H^- with ps-time resolution (Chidsey et al., 1984) no corresponding recovery of the Q_y -absorbance of P in the first nanoseconds was observed.

1. The Singlet Recombination Rate k_S

The average radical pair lifetime is given (Haberhorn and Michel-Beyerle, 1979) by

$$\tau_{RP} = \frac{1 - \phi_T}{k_S} + \frac{\phi_T}{k_T} \quad (1)$$

The determination of τ_{RP} and ϕ_T at zero magnetic field and at a magnetic field B of several hundred G allows the determination of k_S from Eq. (1):

$$k_S = \frac{\phi_T(0) / \phi_T(B) - 1}{\tau_{RP}(B) \phi_T(0) / \phi_T(B) - \tau_{RP}(0)} \quad (2)$$

The values of k_s obtained with Eq. (2) are included in Tables 2a, 3a and 4a. Within the error of measurement the singlet recombination rate is identical in RCs of *Rb. sphaeroides* and *Rb. capsulatus*, decreasing from $4 \times 10^7 \text{s}^{-1}$ to $1.5 \times 10^7 \text{s}^{-1}$ upon lowering the temperature from 290 K to 90 K. This is in agreement with previously published data (Norris et al., 1982; Ogrodnik et al., 1982, 1988; Chidsey et al., 1984; Budil et al., 1987). The values for k_s in RCs of *Cf. aurantiacus* are only slightly larger and are independent of the temperature below 200K.

In principle, the singlet recombination rate has a contribution from recombination via $^1\text{P}^*$ which is thermally activated. The absence of a significant activation of k_s for bacterial RCs shows that even at room temperature this recombination path is negligible (Ogrodnik et al., 1988).

2. The Triplet Recombination Rate k_T

a. Approximate Determination from the Width of the MARY Spectrum

A direct determination of k_T from τ_{RP} and ϕ_T , comparable to the determination of k_s , Eq. (2), as has been attempted in (Chidsey et al., 1984), is not possible, since the second term in Eq. (1) is much smaller than the first and, therefore, k_T has no significant direct contribution to the value of τ_{RP} . As described above, the width ΔB of the MARY spectrum is a measure for the triplet recombination rate k_T . However, there are other factors contributing to the width of the MARY spectrum like the HFI interaction. For a quantitative determination of k_T the measured MARY and RYDMR spectra have to be fitted to theoretical ones as described below. These fits indeed yield results for k_T which are very similar to the ones obtained directly from ΔB . Therefore, ΔB indeed is a good measure for k_T and will be used for the discussion of the temperature dependence of k_T , see Fig. 5.

b. Determination from Numerical Simulations

The dependence of the triplet yield on static magnetic fields and/or microwaves can theoretically be calculated by the solution of the stochastic Liouville equation for the density matrix ρ (Werner et al., 1978; Haberkorn and Michel-Beyerle, 1979; Lersch and Michel-Beyerle, 1983)

$$\frac{d}{dt}\rho = -\frac{i}{\hbar}[\mathbf{H}, \rho] - \frac{k_S}{2}(\mathbf{P}^S \rho + \rho \mathbf{P}^S) - \frac{k_T}{2}(\mathbf{P}^T \rho + \rho \mathbf{P}^T) \quad (3)$$

for the appropriate Hamilton operator

$$\mathbf{H} = \sum_n^P \mathbf{I}_n^P \mathbf{A}_n^P \mathbf{S}^P + \sum_n^H \mathbf{I}_n^H \mathbf{A}_n^H \mathbf{S}^H + g_P \beta (B_0 + B_1(t)) \mathbf{S}^P + g_H \beta (B_0 + B_1(t)) \mathbf{S}^H - J \mathbf{P}^S \quad (4)$$

Here \mathbf{P}^S and \mathbf{P}^T represent the projection operators on the singlet and the triplet subspaces, respectively, \mathbf{I}_n^P and \mathbf{I}_n^H the n th nuclear spin of P or H with the respective HFI tensor \mathbf{A}_n^P or \mathbf{A}_n^H , \mathbf{S}^P and \mathbf{S}^H the spin of the radical electron on P or H with g -factors g_P and g_H , β Bohr's magneton, B_0 the static magnetic field, $B_1(t)$ the magnetic field of the applied microwaves and J the exchange interaction. Due to their large distance, the dipole interaction between the two radical electron spins can be neglected for the calculation of ϕ_T (Ogrodnik et al., 1985). Similarly, the anisotropy of the HFI tensors is neglected because of the small observed anisotropy of the HFI induced triplet yield (Boxer et al., 1982a,c).

Because of the large number of nuclear spins contributing to the HFI an exact solution of the Liouville equation is not feasible. In the one-proton model the manifold of nuclear spins is replaced by only one representative spin with a suitably chosen HFI constant, giving analytical expressions for ϕ_T (Haberkorn and Michel-Beyerle, 1979). However, this model does not account for the effects from the random orientation of nuclear spins. In a semiclassical model the sum of the nuclear spins, weighted with their hyperfine constants, is replaced by a classical magnetic field. The strength of this field can be modeled by a Gaussian distribution due to the large number of nuclear spins with random orientation (Schulten and Wolynes, 1978).

Using the semiclassical model, the measured MARY and RYDMR spectra³ can be fitted with k_T and J as free parameters, inserting the values for k_s given above. The width of the distribution of the magnetic field modelling the HFI corresponds to the HFI-induced width of the EPR spectrum of the

³ In view of the discrepancies with respect to the absolute triplet yield ϕ_T (Section II.D), only relative MARY and RYDMR spectra (i.e. the shape of these spectra) were considered here.

respective radical. These were determined to be 9.5G for P^+ in *Rb. sphaeroides* (McElroy et al., 1972), 9.8G for P^+ in *Cf. aurantiacus* (Bruce et al., 1982) and 13.0G for H^- (Okamura et al., 1979). For the magnetic fields employed here, the difference of the g -factors ($g_H - g_P \approx 0.001$ (McElroy et al., 1972; Okamura et al., 1979)) as well as their anisotropy (van der Est et al., 1993) can be neglected.

Fits of the MARY spectra yield values of 0.8–0.95 ns^{-1} for k_T in the case of *Rb. sphaeroides*, independent of the temperature. In the case of *Cf. aurantiacus* a value of 0.9–1 ns^{-1} was obtained at 290 K, increasing to 2–2.5 ns^{-1} upon lowering the temperature to 90 K. No fits of the MARY data for *Rb. capsulatus* were performed so far; however, due to the close similarity of the data obtained for RCs of *Rb. capsulatus* and *Rb. sphaeroides*, almost identical results are expected for k_T in the RCs of these bacteria.

These values are almost the same as those calculated from the MARY-width ΔB under the assumption of ΔB being the purely homogeneous width due to k_T (Fig. 5). The latter values are slightly larger due to the neglect of other contributions to ΔB , the largest of which is expected to be HFI with values of 9.5 G for P^+ and 13 G for H^- .

Values for k_T resulting from fits of the RYDMR spectra are given in Tables 2b, 3b and 4b. For *Rb. sphaeroides* the value is approx. 0.5 ns^{-1} , independent of the temperature. A somewhat smaller value is obtained for *Rb. capsulatus* at 277K. For RCs of *Cf. aurantiacus* a pronounced increase of k_T by a factor of 2 upon lowering the temperature from 280K to 170K was deduced from RYDMR data; the value of k_T obtained from the fits, however, depended on the microwave power. The cause of this discrepancy and of the different values obtained by the different methods will be discussed in the following section.

c. Inconsistency of the Values Obtained by Different Methods

The values of k_T determined in MARY and RYDMR measurements differ by a factor of up to 2. Similarly, RYDMR measurements on RCs of *Cf. aurantiacus* at different microwave powers could not be simulated with the same value of k_T (Table 3b).

As discussed in section V.C., from the measurement of the magnetic field dependent recombination dynamics of P^+H^- in delayed fluorescence one can conclude that there is an inhomogeneous distribution of the energy of P^+H^- . This yields a distribution of the recombination rates k_S and k_T , explaining the

inconsistency of the values for k_T determined with the different techniques. It can be shown that the amplitude of the RYDMR spectra decreases rapidly with increasing k_T , particularly at low microwave powers (Lersch, 1987). Therefore, the overall signal from a sample inhomogeneous with respect to k_T will not be sensitive to contributions from RCs with large k_T .

Another method for the determination of the value of k_T is the measurement of τ_{RP} in very high magnetic fields (>100 kG). At these magnetic fields S-T-mixing is predominantly caused by the different g factors of P and H and ultimately leads to an equilibration of singlet and triplet levels, implying

$$\tau_{RP} = \frac{2}{k_S + k_T} \quad (5)$$

A value of $k_T = 0.4 ns^{-1}$ was determined with this method for RCs of *Rb. sphaeroides* at room temperature from time resolved fluorescence measurements (Goldstein and Boxer, 1989a). This corresponds well with the value determined from RYDMR spectra (0.46 ns^{-1}), but is in disagreement with the MARY spectra, yielding $k_T \approx 0.8–0.95 ns^{-1}$. However, again the method is not sensitive to RCs with large rates of k_T , because large values of k_T yield lifetimes that could not have been resolved, particularly in view of the fast fluorescence components that are present even at low magnetic fields.

Therefore, the observed discrepancies can be resolved and even confirm the inhomogeneity of the RCs with respect to k_T . In fact, simulations of the MARY spectrum for *Rb. sphaeroides* at 290 K under the assumption of two populations of RCs with values of k_T of 0.4 ns^{-1} (70%) and 2.5 ns^{-1} (30%) reproduce the measured spectrum significantly better than under the assumption of only one value of k_T (Volk, 1991).

3. The Exchange Interaction J

As can be seen in Fig. 1, one of the triplet levels of P^+H^- is isoenergetic with the singlet level for an external magnetic field of $B_{res} = J$. S-T-mixing is most efficient for this magnetic field. The observation of a pronounced resonance structure in the MARY spectrum, therefore, allows the determination of the exchange interaction J . If the width of the MARY-spectrum is much larger than J , however, no resonance is observed. If only a weak resonance is found, the

maximum triplet yield is not observed at $B = J$, since S-T-mixing to the complementary triplet level distorts the shape of the resonance. In this case, the value of J has to be obtained from a numerical fit. For *Cf. aurantiacus* the MARY spectra yield a value for J of 21 G at 310 K increasing to 25 G at 230 K. For the other RCs no resonance is found and the MARY spectra only allow the determination of an upper limit for the value of J .

For these cases a determination of J is possible from the fit of the RYDMR spectra. An almost temperature independent value of $J = 10$ G was found for *Rb. sphaeroides* (Table 2b) and *Rb. capsulatus* (Table 4b). For *Cf. aurantiacus* the best fits were obtained for values of J between 20 G and 25 G (Table 3b), in agreement with the MARY results.

In the literature, a value of $J = (14 \pm 1)$ G has been reported for *Rb. sphaeroides* at temperatures between 296 K and 222 K from the magnetic field dependent measurement of τ_{RP} with less resolution than the one employed here (Norris et al., 1987a). From the anisotropic electron spin polarization of Q⁻ in Q-reduced RCs of *Rhodospirillum rubrum*, which are very similar to RCs of *Rb. sphaeroides*, a value of J of 10 G was determined (Hore et al., 1993).

E. Determination of the Free Energies of P⁺H⁻ and P⁺B⁻

From the parameters of the P⁺H⁻ recombination dynamics and the magnetic field dependent lifetime of ³P^{*}, the free energy difference between ³P^{*} and P⁺H⁻ can be deduced (Chidsey et al., 1985; Goldstein et al., 1988; Ogrodnik et al., 1988). At low temperatures the triplet state ³P^{*} decays on the 100 μs time scale to the singlet ground state P via intersystem crossing with the rate k_{isc} . At higher temperatures the lifetime decreases and becomes magnetic field dependent. This magnetic field dependence has been shown to be parallel to that of the triplet recombination yield, implying a decay mechanism that involves thermal repopulation of ³(P⁺H⁻) from ³P^{*} with the rate k_{-T} followed by triplet-singlet-mixing and subsequent recombination to the ground state. A thorough treatment yields the following equation for the effective decay rate of ³P^{*} (Chidsey et al., 1985):

$$1/\tau_3(B) = k_{OBS}(B) = k_{isc} + \frac{1}{3} \frac{k_s}{k_T} \phi_T(B) k_{-T} \quad (6)$$

The magnetic field dependence of k_{OBS} allows the separation of the two contributions and the determination of k_{-T} . From the ratio of k_T and k_{-T} the free energy difference ΔG_T between ³P^{*} and P⁺H⁻ can be obtained. Measurements on Q-depleted RCs of *Rb. sphaeroides* at room temperature yielded values of (0.173 ± 0.004) eV (Goldstein et al., 1988) and (0.165 ± 0.008) eV (Ogrodnik et al., 1988).

The apparatus with electronic delay allows the simultaneous determination of the lifetime τ_3 of ³P^{*} and of the recombination parameters. The values of τ_3 and ΔG_T obtained for RCs of *Rb. sphaeroides* (Ogrodnik et al., 1988) and *Cf. aurantiacus* (Volk, 1991) are included in Table 2a and 3 a, see also Fig. 8. The value of ΔG_T for RCs of *Cf. aurantiacus* is significantly larger (0.20 eV compared to 0.16 eV in *Rb. sphaeroides* at room temperature). Such a difference has been predicted from electrostatic calculations (Michel-Beyerle et al., 1988b; Parson et al., 1990a) due to the exchange of the polar (protonated) glutamic acid at position L 104 in *Rb. sphaeroides* to the unpolar glutamine in *Cf. aurantiacus*.

The value of ΔG_T shows only a weak temperature dependence. A linear fit of the data yields values for the enthalpy difference $\Delta H_T = (0.10 \pm 0.03)$ eV and the entropy difference $\Delta S_T = -(2 \pm 1) \times 10^{-4}$ eV/K for *Rb. sphaeroides* and $\Delta H_T = (0.13 \pm 0.05)$ eV and $\Delta S_T = -(2.5 \pm 1) \times 10^{-4}$ eV/K for *Cf. aurantiacus*. The value of ΔH_T for *Rb. sphaeroides* determined here is more precise than the value determined in (Goldstein et al., 1988) from the temperature dependence of τ_3 , where the temperature dependence of ϕ_T and k_s was not available.

For *Rb. sphaeroides* a value of $\Delta H(^1P^* - ^3P^*) = 0.41$ eV was obtained from fluorescence and phosphorescence spectra (Takiff and Boxer, 1988) and from the temperature dependence of microsecond delayed fluorescence (Shuvalov and Parson, 1981). Because the entropy difference between ¹P^{*} and ³P^{*} should be negligible, $\Delta G(^1P^* - ^3P^*) = \Delta H(^1P^* - ^3P^*)$, thus with $\Delta G_T = \Delta G(P^+H^- - ^3P^*) = 0.16$ eV a free energy gap for charge separation to P⁺H⁻ of $\Delta G(^1P^* - P^+H^-) = 0.25$ eV can be calculated. At room temperature this value agrees with the one obtained from delayed fluorescence data (Hörber et al., 1986).⁴ Fluorescence measurements with better time

⁴ This result also can be derived from the data in (Woodbury et al., 1986), if referring to the slowest fluorescence component (Ogrodnik, 1990).

resolution yield a somewhat lower value of 0.21 eV (Ogrodnik et al., 1994). However, due to the energetic inhomogeneity of P^+H^- , the apparent value of $\Delta G(^1P^* - P^+H^-)$, as determined from fluorescence, strongly decreases upon lowering the temperature, see Section V.C.

In the carotenoid-containing RCs of *Rb. capsulatus*, energy is transferred from $^3P^*$ to the triplet state of the carotenoid on the 100 ns timescale; therefore, ΔG_T cannot be determined directly. From the close similarity of the temperature dependence of k_T in RCs of *Rb. capsulatus* to that in RCs of *Rb. sphaeroides*, however, one can conclude that the energy of P^+H^- is similar in both RCs, see Section II.F.5.

The recombination dynamics of P^+H^- also gives access to the free energy difference ΔG_{23} between P^+H^- and P^+B^- (B: BChl monomer at the active branch). Fast hopping between P^+H^- and P^+B^- affects various observables of the recombination dynamics (Haberkorn et al., 1979; Bixon et al., 1987; Ogrodnik et al., 1982, 1988; Michel-Beyerle and Ogrodnik, 1990; Ogrodnik, 1990). In this context the additional triplet recombination channel via $^3(P^+B^-)$, leading to an effective recombination rate

$$k_T = k_T^H + k_T^B e^{-\frac{\Delta G_{23}}{k_B T}} \quad (7)$$

gives the best access to ΔG_{23} . Here, k_T^H and k_T^B denote the rate of recombination to $^3P^*$ from $^3(P^+H^-)$ and $^3(P^+B^-)$, respectively. From the experimentally found inverted temperature dependence of k_T , Fig. 5, the activated second term in Eq. (7) can be estimated to contribute less than 20% even at room temperature in RCs of *Cf. aurantiacus* and of *Rb. sphaeroides*, corresponding to less than 0.2 ns⁻¹.

The electronic coupling between $^3(P^+B^-)$ and $^3P^*$ is similar to the coupling between $^1(P^+B^-)$ and $^1P^*$, which was estimated from the activationless rate of primary charge separation to be ≈ 20 cm⁻¹ in RCs of *Rb. sphaeroides* (Bixon et al., 1988, 1989). This is larger than the electronic coupling between $^3(P^+H^-)$ and $^3P^*$ by a factor of 20, see section II.F.4. The free energy of P^+B^- is above that of P^+H^- and the triplet recombination from P^+H^- is near the activationless case, thus k_T^B is in the inverted region, but close to the activationless case as long as P^+B^- does not have a very large free energy. Therefore, the Franck-Condon-

factor for k_T^B is expected to be similar to that of k_T^H , a decrease by at most a factor of 2 will be assumed here. It can be concluded that $k_T^B \geq (20)^2/2k_T^H \approx 200$ ns⁻¹.

With these values, a lower limit for ΔG_{23} of 0.17 eV can be estimated for *Rb. sphaeroides*. Due to the slightly slower primary charge separation in RCs of *Cf. aurantiacus*, the corresponding calculation yields $\Delta G_{23} > 0.16$ eV in this case.

As a consequence, the free energy gap $\Delta G_1 = \Delta G(^1P^* - P^+B^-)$ for charge separation to P^+B^- can be estimated to be smaller than 0.05 eV in *Cf. aurantiacus* and smaller than 0.08 eV in *Rb. sphaeroides*.

In a recent investigation (Schmidt et al., 1994) effort has been made to determine ΔG_1 in RCs of *Rb. sphaeroides* with the bacteriopheophytin exchanged with pheophytin. In this case, ΔG_{23} becomes so small that the electron transfer step $P^+B^- \rightarrow P^+H^-$ slows down to $k_2 \approx 1/300$ ps. This should give rise to delayed fluorescence from P^+B^- . From the amplitude of the experimental fluorescence component with a lifetime corresponding to that of P^+B^- , $\Delta G_1 \approx 450$ cm⁻¹ = 0.06 eV has been derived. However, (1) contributions to this fluorescence component not originating from recombination of P^+B^- and (2) an inhomogeneity of ΔG_1 (see Eq. (18)) would lead to an underestimation of the true average value of ΔG_1 . Together with the limit derived above, ΔG_1 can thus be confined to 0.06 eV < ΔG_1 < 0.08 eV. We include this result in Fig. 8.

F. Conclusions

The recombination of P^+H^- cannot compete with forward electron transfer to Q, which in native RCs occurs with a quantum yield close to unity (Wraight and Clayton, 1973; Volk et al., 1991). This high quantum yield only is possible because the recombination to the ground state is slow due to the large energy gap and the fast recombination via the triplet channel is hindered by the ‘bottleneck’ of HFI-induced S-T-mixing. On the other hand, the parameters obtained from the measurement of the recombination dynamics, i.e. k_g , k_T and J , can be discussed in relation to the charge separation steps from $^1P^*$ to P^+H^- and allow the determination of free energies, as was shown in the previous section, as well as electronic matrix elements and reorganization energies.

1. Nonadiabatic Electron Transfer Theory

In the framework of nonadiabatic electron transfer theory, the simplest expression for the electron transfer rate (considering only protein vibronic modes with $\hbar\omega \ll kT$) is given by the electronic coupling matrix element V , the free energy ΔG of the reaction and the reorganization energy λ (Jortner, 1980a,b; Marcus and Sutin, 1985; see Chapter 25 by Parson and Warshel):

$$k_{\text{ET}} = \frac{2\pi}{\hbar} \frac{V^2}{\sqrt{4\pi\lambda kT}} e^{-\frac{(\Delta G + \lambda)^2}{4\lambda kT}} \quad (8)$$

The matrix element relevant for the recombination of P⁺H is expected to be dominated by superexchange coupling via P⁺B⁻ (Michel-Beyerle et al., 1988a; Bixon et al., 1991):

$$V = \frac{V_{\text{PB}} V_{\text{BH}}}{\delta E(\text{P}^+\text{B}^- - \text{P}^+\text{H}^-)} \quad (9)$$

with V_{PB} denoting the coupling between P and P⁺B⁻, V_{BH} the coupling between P⁺B⁻ and P⁺H⁻ and $\delta E(\text{P}^+\text{B}^- - \text{P}^+\text{H}^-)$ the vertical energy separation between P⁺B⁻ and P⁺H⁻ at the nuclear coordinates where the transition takes place. In Section V.C. experimental evidence for the predominance of the superexchange coupling mechanism for the recombination of P⁺H⁻ is described.

2. k_s — A Rate in the Marcus Inverted Region

From the energies given in Section II.E., together with the known energy of ¹P*, the free energy ΔG_s for the singlet recombination process can be estimated to be $\approx 8000 \text{ cm}^{-1}$. The reorganization energy λ_s is expected to be similar to the one for the triplet recombination process, which will be shown below to be 1000–1500 cm^{-1} . Therefore, k_s is a rate deep in the Marcus inverted region ($-\Delta G \gg \lambda$). For this case, a reduction of the rate by many orders of magnitude is expected upon lowering the temperature from 290 K to 90 K according to Eq. (8). In all three bacterial RCs discussed here, however, the singlet recombination rate k_s shows only a weak temperature dependence, decreasing by a factor of less than 3 upon decreasing the temperature from room temperature to 90 K. This can be reconciled with

Fig. 5. Temperature dependence of the MARY halfwidth ΔB (left ordinate) for Q-depleted RCs of *Rb. sphaeroides* and *Chloroflexus aurantiacus*. On the right ordinate ΔB is converted to the triplet recombination rate k_T under the assumption of the lifetime broadening δE due to k_T being the only contribution to ΔB ($k_T = 2\pi/\hbar \delta E = 2\pi/\hbar 2g\beta\Delta B$). (.....) and (—): simulations of k_T with Eq. (8), using the values of ΔH_T and ΔS_T for *Rb. sphaeroides* and *Chloroflexus aurantiacus* given in Section II.E., values of λ_T given in the figure (in [cm^{-1}]), values of V_T chosen to scale the curves to the same value at high temperatures.

electron transfer theory by including the coupling of high energy vibronic modes to the recombination process, as has been discussed in (Bixon and Jortner, 1991). Such couplings strongly influence electron transfer rates in the inverted region and can diminish their temperature dependence to a large extent.

3. Determination of the Reorganization Energy λ_T

Figure 5 shows the temperature dependence of the MARY halfwidth ΔB for *Rb. sphaeroides* and *Cf. aurantiacus*. On the right hand ordinate of Fig. 5, ΔB is converted into the triplet recombination rate k_T . It shows an inverted temperature dependence, which according to Eq. (8) only is possible for an (pseudo)activationless (Bixon and Jortner, 1989) process, i.e. $-\Delta G_T \approx \lambda_T$. This discussion neglects possible thermal contraction effects altering the value of V_T upon changing the temperature. However, in the light of the small changes of the radical pair lifetime observed under extremely high pressure (Windsor and Menzel, 1989), such effects are expected to be small.

The curves in Fig. 5 are simulations of the temperature dependence of k_T with Eq. (8) (scaled to k_T at room temperature) for various values of λ_T with the values of $\Delta G_T(T) = \Delta H_T - T\Delta S_T$ as determined in Section II.E. It can be seen that for both species the measured temperature dependence of k_T is well reproduced by the simulations for a value of λ_T of 1000–1200 cm^{-1} . For *Cf. aurantiacus* these simulations indicate an activationless rate k_T ($-\Delta G_T = \lambda_T$) around 100 K and a small activation at higher temperatures, while in *Rb. sphaeroides* the activationless case is expected at the higher temperatures due to the different value of ΔH_T . Taking into account the uncertainty of the temperature dependent values of ΔG_T , the value of λ_T can be concluded to be in the range 1000–1500 cm^{-1} .

4. Determination of the Electronic Coupling V_T

With the values of k_T , ΔG_T and λ_T as determined above, the matrix element V_T for the triplet recombination process can be determined from Eq. (8). Taking into account the uncertainties of ΔG_T , λ_T and k_T , values of $V_T = (0.85 \pm 0.2) \text{ cm}^{-1}$ and $V_T = (1.0 \pm 0.2) \text{ cm}^{-1}$ are obtained for RCs of *Rb. sphaeroides* and *Cf. aurantiacus*, respectively.

5. Similarity of the Recombination Dynamics of P^+H^- in the Different RCs

The recombination dynamics of P^+H^- in the RC of *Rb. sphaeroides* and *Rb. capsulatus* is almost identical, while the RC of *Cf. aurantiacus* shows a somewhat different behavior. The triplet recombination rate k_T is similar in all RCs at room temperature, but, in contrast to *Rb. sphaeroides*, shows a pronounced increase to lower temperatures in *Cf. aurantiacus*. In addition, the value of the exchange interaction J in RCs of *Cf. aurantiacus* is more than twice as large as compared to *Rb. sphaeroides*. This is directly seen from the resonance structure of the MARY spectra, Fig. 3.

As discussed in Section II.F.3, the different temperature dependence of k_T in RCs of *Rb. sphaeroides* and *Cf. aurantiacus* is due to the different free energy gap ΔG_T (Fig. 5). In *Cf. aurantiacus* $-\Delta G_T$ is close to λ_T at 100K, resulting in an activationless electron transfer rate k_T , while in *Rb. sphaeroides* $-\Delta G_T$ is smaller than λ_T by several 100 cm^{-1} , resulting in a small activation energy.

Upon increasing the temperature, k_T becomes slightly activated in *Cf. aurantiacus*, while it approaches the activationless case in *Rb. sphaeroides*, which explains the different temperature dependence of k_T in the two RCs. No further assumptions, such as different values of λ_T or effects of thermal contractions have to be made.

In RCs of *Rb. capsulatus*, on the other hand, the temperature dependence of k_T is almost identical to that in RCs of *Rb. sphaeroides*, as can be concluded from the temperature dependence of ΔB , Table 2a and Table 4a. Therefore, in reversal of the foregoing discussion, one expects ΔG_T to be very similar in *Rb. sphaeroides* and *Rb. capsulatus*.

From the absolute values of k_T , the electronic coupling V_T was estimated to be slightly larger in *Cf. aurantiacus* than in *Rb. sphaeroides*.⁵ Indeed, if the electronic coupling for recombination is dominated by superexchange coupling via P^+B^- , one expects it to be larger in *Cf. aurantiacus* than in *Rb. sphaeroides*, due to the higher free energy of P^+H^- . The vertical energy separation $\delta E(\text{P}^+\text{B}^- - \text{P}^+\text{H}^-)$ can be estimated from the sum of $\Delta G(\text{P}^+\text{B}^- - \text{P}^+\text{H}^-)$ and the reorganization energy λ_2 for $\text{P}^+\text{B}^- \rightarrow \text{P}^+\text{H}^-$ to have a value of approx. 3000 cm^{-1} (here a value of approx. 1000 cm^{-1} was assumed for λ_2 , close to the value determined for λ_T). The different free energy of P^+H^- , as determined in Section II.E, leads to a correspondingly different value of $\delta E(\text{P}^+\text{B}^- - \text{P}^+\text{H}^-)$. An electronic coupling that is 10% larger in *Cf. aurantiacus* than in *Rb. sphaeroides*, indeed, is expected from Eq. (9).

The different free energy of P^+H^- also can explain the larger value of J in RCs of *Cf. aurantiacus* compared to the value found in RCs of *Rb. sphaeroides*. This notion is based on several arguments. (i) The stronger electronic coupling in the case of *Cf. aurantiacus* results in a larger value of J . (ii) The shift J_s of $^1(\text{P}^+\text{H}^-)$ due to its interaction with $^1\text{P}^*$ (Eq. 10b) has an energy denominator which is smaller in the case of *Cf. aurantiacus* than in *Rb. sphaeroides*. (iii) The absolute value of ΔG_T is slightly smaller than λ_T in *Rb. sphaeroides*, therefore the energy of $^3\text{P}^*$ at the equilibrium nuclear coordinate of P^+H^- is higher than that of P^+H^- . The interaction of the two states results in a shift of $^3(\text{P}^+\text{H}^-)$ to lower energies, parallel to the energetic shift of $^1(\text{P}^+\text{H}^-)$,

⁵ Within the uncertainty given in Section II.F.4, V_T is the same in both RCs. However, this uncertainty of the absolute value of V_T mostly arises from the uncertainty of λ_T . If one assumes the same value for λ_T for both RCs, V_T can be shown to be different in the two RCs by approx. 10%.

leading to a partial compensation of the two shifts. In *Cf. aurantiacus*, on the other hand, $|\Delta G_T|$ is larger than λ_T , so that $^3(\text{P}^+\text{H}^-)$ is shifted to higher energies and the two shifts add.

From this argument, the sign of J can be concluded to be positive in RCs of *Cf. aurantiacus*, which means that $^3(\text{P}^+\text{H}^-)$ is higher in energy than $^1(\text{P}^+\text{H}^-)$. A similar conclusion for *Rb. sphaeroides* is not possible, because it is not clear whether the singlet or the triplet contribution, both shifting P⁺H⁻ to lower energies, predominates.

Summarizing, the differences in the recombination dynamics of *Rb. sphaeroides* and *Cf. aurantiacus* result from the different energy of P⁺H⁻ presumably caused mostly by the exchange of the polar (protonated) glutamic acid at position L 104 in *Rb. sphaeroides* to glutamine in *Cf. aurantiacus* (Michel-Beyerle et al., 1988b; Parson et al., 1990a). All other parameters seem to be very similar in the two RCs.

III. The Effect of Genetic Mutations on the Recombination Dynamics of P⁺H⁻

A. Mutagenesis of Tryptophan^{M250}

The amino acid residue tryptophan^{M250} (Trp^{M250}, in *Rhodospseudomonas (Rp.) viridis* Trp^{M252}), located between H and Q in RCs of *Rp. viridis* (Deisenhofer et al., 1984) and *Rb. sphaeroides* (Chang et al., 1986; Allen et al., 1987), is conserved in all bacterial RCs sequenced so far as well as in Photosystem II (Komiya et al., 1988). It is essential for the binding of Q (Coleman et al., 1990a,b) and has been suspected to enhance the electronic coupling for the electron transfer P⁺H⁻ → P⁺Q⁻ with the rate k_q via the superexchange mechanism (Plato et al., 1989). Indeed, the mutagenic replacement of Trp^{M250} by amino acid residues with high lying energy levels, as leucine or phenylalanine in RCs of *Rb. capsulatus* (Coleman et al., 1990a,b) or tyrosine or phenylalanine in RCs of *Rb. sphaeroides* (Stilz et al., 1990), leads to a significant decrease of k_q due to a reduction of the electronic coupling. However, this reduction could be due to structural changes affecting H and/or Q and/or changed energetics of the amino acid in its role as superexchange mediator.

To investigate possible structural changes of the H site, the recombination dynamics of P⁺H⁻ were measured in Q-depleted RCs of *Rb. capsulatus* in

which Trp^{M250} had been replaced by leucine (Leu), glutamic acid (Glu) or phenylalanine (Phe) (Coleman et al., 1990a; Lang et al., 1990; Lersch et al., 1990; Volk, 1991). Lifetime and MARY data as well as RYDMR data are almost unaffected by the mutation, Table 4. In all mutant RCs k_T increases slightly upon decreasing the temperature, similar to the native RCs of *Rb. capsulatus* and *Rb. sphaeroides*. This observation shows that ΔG_T is essentially unaffected by the mutation. The similarity of the values of k_s , k_T and J in the mutant and native RCs leads to the conclusion that mutation induced structural effects at the sites of P and H are small.

Conclusions on the specific role of Trp^{M250} as a superexchange mediator could not be drawn, since structural changes at the Q binding site might be predominant. This view is supported by (i) a decreased Q binding affinity after the mutation (Coleman et al., 1990a,b; Stilz et al., 1990) and (ii) the fact, that the aromatic Phe has a similar effect on k_q as the aliphatic Leu.

B. Mutagenesis of Tyrosine^{M210}

The amino acid residue tyrosine^{M210} (Tyr^{M210}, in *Rp. viridis* Tyr^{M208}) is in van-der-Waals-distance to P, B and H on the active branch in RCs of *Rp. viridis* (Deisenhofer et al., 1984) and *Rb. sphaeroides* (Chang et al., 1986; Allen et al., 1987). It is conserved in all purple bacterial RCs sequenced so far. Electrostatic calculations (Parson et al., 1990a) predict an increase of the free energy of P⁺B⁻ by 1000–1300 cm⁻¹ and a smaller increase of the free energy of P⁺H⁻ upon replacement of Tyr^{M210} by phenylalanine (Phe). Such energetic shifts are expected to cause significant effects on the rate of primary charge separation. Indeed, the mutagenic replacement of Tyr^{M210} by Phe, tryptophan, isoleucine or leucine in RCs of *Rb. sphaeroides* slows primary charge separation considerably (Finkele et al., 1990; Parson et al., 1990b; Nagarajan et al., 1993). This could be due to effects of the mutation on the energies of the states involved in primary charge separation and/or mutation-induced structural changes affecting the electronic couplings. Measurements of the recombination dynamics of P⁺H⁻ on Q-depleted RCs of *Rb. sphaeroides* GA (Tyr^{M210} → Phe) were performed to distinguish between these two possibilities (Volk et al., 1993a).

Neither the radical pair lifetime τ_{RP} nor the

magnetic field dependence of the triplet yield were found to be strongly affected by the mutation, Table 2a (because of the inherent wavelength dependence of the observed time constants (Section II.C.), only the values of τ_{RP} determined at the same wavelengths should be compared)⁶. The magnetic field $B_{1/2}$, at which half of the maximum modulation of ϕ_T is observed, was found to be larger in the mutant at 90K, but smaller at 290K. Since the genetic modification had been constructed in strain GA of *Rb. sphaeroides*, energy transfer from ${}^3P^*$ to ${}^3Car^*$ was found to occur on the 100 ns timescale between 90K and 290K. Consequently, the determination of the free energy gap between ${}^3P^*$ and P^+H^- from the lifetime of ${}^3P^*$ (Section II.E) was not possible.

However, the temperature dependence of the triplet recombination rate k_T (estimated from $B_{1/2}$) in the Tyr^{M210} → Phe mutant, increasing by a factor of almost 2 upon lowering the temperature from 290K to 90K mirrors the temperature dependence of k_T found in RCs of *Cf. aurantiacus*, see Fig. 5. In analogy to the discussion in Section II.F.5, this allows the conclusion that the mutation causes an increase of the free energy of P^+H^- to a value similar to that in *Cf. aurantiacus*, which was found to be shifted by 0.04 eV compared to *Rb. sphaeroides*, see Section II.E. A similar increase of the free energy of P^+H^- by 0.046 eV due to Tyr^{M210} → Phe was concluded upon from the amplitude of delayed fluorescence (Nagarajan et al., 1993). However, the conclusions on the energetics of P^+H^- from fluorescence measurements suffer from uncertainties with respect to the energetic inhomogeneity of P^+H^- (Section V.C.). The major contribution to the altered energetics of P^+H^- seems to arise from the altered redox potential of P/P^+ , which is increased by 30 mV (Nagarajan et al., 1993).

From the difference of the absolute values of k_T between the native and the mutated RCs, it can be estimated that the replacement of Tyr^{M210} by Phe results in a decrease of the electronic coupling V_T by 10%. Such a reduction of the electronic couplings also is supported by results from RYDMR measurements (Lang, 1991) revealing reduced values of k_T and J .

⁶In (Nagarajan et al., 1993) an increase of τ_{RP} at 295K is reported due to the replacement of Tyr^{M210} by Phe. However, these results do not allow conclusions on the majority of RCs, since they originate from delayed fluorescence measurements which might be dominated by a minority of RCs (Section V). Furthermore, they refer to Q-reduced RCs.

The singlet recombination rate k_S was determined from Eq. (2) to be $1.1 \times 10^7 \text{ s}^{-1}$ at 90 K and $3.0 \times 10^7 \text{ s}^{-1}$ at 290 K, which is 30% smaller than in native RCs of *Rb. sphaeroides* R26. The temperature dependence of k_S is unaffected by the mutation. This is to be expected for a rate in the Marcus inverted region strongly coupled to high energy modes, which is insensitive to small variations of the free energy gap. The smaller value of k_S in the modified RCs, consequently, indicates that there has been a decrease of the electronic coupling V_S by a factor of 0.85.

The major contribution to the electronic couplings V_S and V_T for the recombination of P^+H^- is expected to arise from superexchange via P^+B^- , Eq. (9). The vertical energy separation $\delta E(P^+B^- - P^+H^-)$ was estimated above to have a value of approx. 3000 cm^{-1} . From this, it can be calculated that the predicted increase of the energy of P^+B^- by 1000 cm^{-1} , together with the predicted and indeed observed increase of the energy of P^+H^- by 400 cm^{-1} , should lead to a reduction of the superexchange couplings by a factor of approx. 0.85. This is in full agreement with the effect actually observed.

Summarizing, the effects of the replacement of Tyr^{M210} by Phe on the recombination dynamics of P^+H^- can be understood with the predicted shifts of the free energies of P^+B^- and P^+H^- (Section VI.B), without assuming any mutation-induced structural changes.

IV. Recombination Dynamics of P^+H^- in an External Electric Field

External electric fields are a powerful tool for experimentally altering the energies of charge separated states due to their large dipole moments (Popovic et al., 1986; Feher et al., 1988; Lockhart et al., 1990; Ogrodnik and Michel-Beyerle, 1992; Ogrodnik, 1993). The ion radical pair P^+H^- has a considerable electric dipole moment which can be calculated from the X-ray structure of the RC (Deisenhofer et al., 1984; Chang et al., 1986; Allen et al., 1987) to be 82 D. The interaction of this dipole moment with the external electric field leads to a shift of the energy of P^+H^- . Depending on the orientation of the dipole moment in the electric field, this shift can adopt a value of up to 800 cm^{-1} in a field of $6 \times 10^5 \text{ V/cm}$. Recently, the recombination dynamics of P^+H^- in an external electric field was measured (Volk et al., 1993b). The results necessitated

the development of an extended theoretical treatment for the exchange interaction J .

A. Results

Nanosecond time-resolved absorbance measurements in an external electric field (6×10^5 V/cm) were performed on quinone-depleted RCs of *Rb. sphaeroides* in PVA at 90 K and 210 K (Volk et al., 1993b). Within the experimental uncertainty, τ_{RP} was essentially unaffected by the electric field. Similarly, the shape of the MARY-spectra were hardly altered ($B_{1/2}$ was reduced from 52 G to 51 G at 90 K and from 55 G to 48 G at 210 K in the electric field).

However, significant effects of the electric field were observed on the P absorbance bleaching. At a delay time of 0 ns (± 1 ns) a reduction of this bleaching by approximately 8% was found both at 90 K and at 210 K. This effect, evolving on the picosecond time scale (Ogrodnik et al., 1992), reflects the reduction of the quantum yield of P⁺H⁻ formation in the electric field. On the 10 ns time scale the relative electric field effect on the bleaching of P changes, mirroring an electric field effect on the triplet yield ϕ_T . At 90 K an electric-field-induced reduction of ϕ_T by 6% is observed at 0 G and at 700 G, while at 210 K there is a slight increase of ϕ_T in the electric field by 3% at 0 G and almost no effect at 700 G.

The electric-field-induced reduction of the overall yield of ³P* at 90 K, described in Volk et al. (1993b), agrees with that reported by Boxer and coworkers (Franzen et al., 1992; Boxer et al., 1992) at 80 K. In contrast to the above findings, Boxer and coworkers, however, did not obtain a difference between the electric field effects on P⁺H⁻ and ³P*, implying no effect on the recombination process yielding ϕ_T . Taking into account the increase of the relative field effect with a time constant of approximately 10 ns, due to the limited time resolution (excitation pulse width 8 ns) of the setup used by Boxer and coworkers caused them to fail to observe this difference.

B. The Effect of the Electric Field on the Recombination Rates

An energetic shift of P⁺H⁻ alters the free energy differences ΔG_S and ΔG_T for the charge recombination rates k_S and k_T . The triplet recombination rate k_T , being almost activationless, is expected to decrease upon any changes of ΔG_T . Indeed, the slight reduction

of $B_{1/2}$ at 210 K might reflect this decrease of k_T . The lack of such effects at 90 K suggests that the decrease of k_T in some RCs is compensated by the increase in other RCs, which is expected if $-\Delta G_T$ is not exactly equal to λ_T , as it is the case in *Rb. sphaeroides* at 90 K. The singlet recombination rate k_S , on the other hand, is a rate in the Marcus inverted region strongly coupled to high energy vibronic modes, which is expected to depend only weakly on the free energy (Bixon and Jortner, 1991). In summary, the observed small electric field effects on $B_{1/2}$ and τ_{RP} can be understood in terms of the energetic shift of P⁺H⁻ by the electric field.

C. The Effect of the Electric Field on the Exchange Interaction—Extended Theoretical Treatment of J

1. Effects Expected from a Perturbation Theoretical Treatment of J

In a perturbation theoretical approach, the energy separation between the singlet and the triplet phased radical pair ¹(P⁺H⁻) and ³(P⁺H⁻) arises from the different energetic shifts J_S of ¹(P⁺H⁻) and J_T of ³(P⁺H⁻) due to their interaction with the manifolds of other singlet and triplet states:

$$J = J_T - J_S \quad (10)$$

The dominant contributions to J_S and J_T result from the interaction with ¹P* and ³P*:

$$J_T = V_T^2 / \delta E_T^0 \quad (11a)$$

$$J_S = V_S^2 / \delta E_S^0 \quad (11b)$$

with $V_{T,S}$ denoting the electronic coupling and $\delta E_{T,S}^0$ the vertical energy separation (at the equilibrium nuclear coordinates of P⁺H⁻) between ³P* and ³(P⁺H⁻), and ¹P* and ¹(P⁺H⁻), respectively. The activationless nature of k_T implies that $|\delta E_T^0|$ is smaller than ≈ 400 cm⁻¹ (Michel-Beyerle et al., 1988a; Bixon et al., 1988, 1989). The singlet vertical energy separation δE_S^0 , on the other hand, can be estimated to be approx. 3000 cm⁻¹ from the sum of the free energy difference $\Delta G(\text{¹P*} - \text{P⁺H⁻}) \approx 2000$ cm⁻¹ and the reorganization energy $\lambda_S = \lambda(\text{¹P*} - \text{P⁺H⁻})$ which, in turn, is expected to be similar to $\lambda_T \approx 1000$ cm⁻¹. Due to these differences in the vertical energy separation, energetic shifts of P⁺H⁻ by the electric field on the

order of up to 800 cm^{-1} should strongly affect J_T , while they do not alter J_S considerably.

For the sake of clarity, in the following it will be assumed that $J_S \ll J_T$. For similar singlet and triplet electronic couplings, this is reasonable, because the triplet vertical energy separation is much smaller. However, the conclusions described here are valid also for $J_S \approx J_T$. With $|\delta E_T^0| \leq 400 \text{ cm}^{-1}$ in zero electric field, an electric field of $6 \times 10^5 \text{ V/cm}$ causes a shift of $|\delta E_T^0|$ to values under 200 cm^{-1} in 25% of the isotropically oriented RCs (Volk et al., 1993b). With $V_T \approx 1 \text{ cm}^{-1}$ the absolute value of J_T in these RCs is larger than $5 \times 10^{-3} \text{ cm}^{-1}$ according to Eq. (11a). This is more than the width of the MARY spectrum ($\Delta B \approx 45 \text{ G} \approx 4 \times 10^{-3} \text{ cm}^{-1}$) and, therefore, S-T-mixing to all three triplet levels should be effectively inhibited. On the other hand, in RCs with orientations leading to a reduction of J in the electric field, no significant enhancement of S-T-mixing occurs, because the value of J at zero electric field ($1 \times 10^{-3} \text{ cm}^{-1}$) already is small. Therefore, after averaging over all orientations, the electric field is expected to lead to a significant reduction (of at least 25%) of the overall triplet yield.

These expected large electric field effects on the triplet yield were not observed. In the electric field ϕ_T was found to be reduced by less than 10% at 90 K and even to increase at 210 K. In addition to the effects on the triplet yield, the wide distribution of J in an isotropic sample of RCs in an external electric field as expected from Eq. (10) should have resulted in pronounced effects on the shape of the MARY spectrum which were not observed. In principle, the inhibition of S-T-mixing in 25% of the RCs could be compensated by an increase of ϕ_T due to electric field effects on the recombination rates k_s and k_r in the remaining RCs. This can be ruled out on the basis of the small electric field effects on MARY spectrum, radical pair lifetime and monoexponentiality of radical pair recombination (Volk et al., 1993b).

In conclusion, the observed electric field effects on the recombination dynamics of P^+H^- are much smaller than expected from the simple perturbation theoretical treatment of J , Eq. (11). In the next section we will describe an extension to this theory that reconciles theory and experiment.

2. Extended Theoretical Treatment of J

The shift J_T of $^3(\text{P}^+\text{H}^-)$ arising from the interaction with $^3\text{P}^*$ is very sensitive to the vertical energy

separation δE_T between P^+H^- and $^3\text{P}^*$, which for Eq. (11a) is taken at the equilibrium position of P^+H^- . However, the nuclear coordinates are not fixed at this position, but oscillate around it. These oscillations lead to pronounced fluctuations of the vertical energy separation, especially in the domain of small δE_T^0 .

Assuming displaced harmonic potentials for P^+H^- and $^3\text{P}^*$ with the same vibrational frequency ω , the vertical energy separation δE_T at the (generalized) nuclear coordinate q can be calculated:

$$\delta E_T(q) = \delta E_T^0 - \sqrt{2\lambda_T \hbar \omega} q \quad (12)$$

Here $q = 0$ denotes the equilibrium position of P^+H^- . In the Born-Oppenheimer approximation, the energetic shift of $^3(\text{P}^+\text{H}^-)$ due to its interaction with $^3\text{P}^*$ can be calculated at each nuclear coordinate q from Eq. (11a). The effective triplet shift then is given by averaging over all values of q . With the wavefunction $\psi(q)$ for the harmonic oscillation (Davydov, 1965) in the nuclear vibronic ground state of P^+H^- this averaging yields

$$J_T = \int \frac{V_T^2}{\delta E_T(q)} |\psi(q)|^2 dq \quad (13)$$

For $T > 0$, the same average over q can be calculated for all excited nuclear vibronic states of P^+H^- and the value of J_T then is obtained by thermal averaging over these values.

For the sake of simplicity, the Born-Oppenheimer approximation also is used near the intersection of the two potential energy surfaces, although this may not well be justified in general. However, the results obtained here are in agreement with those of a thorough quantum mechanical treatment (Bixon et al., 1993).

The typical oscillation of the nuclear coordinates ($q \approx 1$) in an harmonic oscillator lead to fluctuations of the vertical energy separation δE_T between P^+H^- and $^3\text{P}^*$ around δE_T^0 of the order of $\sqrt{2\lambda_T \hbar \omega}$, which for typical parameters ($\lambda_T = 1000 \text{ cm}^{-1}$, $\hbar \omega = 100 \text{ cm}^{-1}$) has a value of $\approx 500 \text{ cm}^{-1}$. If the energy separation δE_T^0 at the equilibrium position of P^+H^- is smaller than those fluctuations, a partial cancellation of negative and positive contributions to J_T is expected. For the case $\delta E_T^0 = 0$, the negative and positive contributions to J_T should cancel completely in this approximation.

Fig. 6. Triplet shift J_T : (—) calculated from Eq. (13) for $T = 0$ K, $\lambda_T = 1300$ cm⁻¹ and $\hbar\omega = 50$ cm⁻¹, 100 cm⁻¹, 200 cm⁻¹, 500 cm⁻¹; (---) calculated from Eq. (11a); $V_T = 1$ cm⁻¹ in all cases. From (Volk et al., 1993b).

Figure 6 shows the dependence of J_T on δE_T^0 calculated with Eq. (13) for typical values of $\hbar\omega$ and λ_T . For comparison, the result obtained with Eq. (11a) also is given. For values of $|\delta E_T^0|$ smaller than 500–1000 cm⁻¹, the results of the extended theory indeed deviate considerably from Eq. (11a). At higher values, both approaches yield very similar results. As expected, for $\delta E_T^0 = 0$ a value of J_T of 0 is obtained with Eq. (12). Thus the inclusion of nuclear oscillations removes the unrealistic discontinuity of $J_T(\delta E_T^0)$ found with Eq. (11a) at this point.

With the extended treatment the discrepancies between predicted and observed electric field effects on the triplet yield and the shape of the MARY spectrum are removed. No matter to which values δE_T^0 is shifted by the electric field, $|J_T|$ calculated with Eq. (13) does not take values larger than $3\text{--}5 \times 10^{-3}$ cm⁻¹ ($\approx 30\text{--}50$ G) (for $V_T = 1$ cm⁻¹), comparable to the width of the MARY-spectrum. In addition, the small values of $|J_T|$ calculated with the extended treatment also allow to rationalize the small value of the experimentally determined exchange interaction, being smaller than 25 G ($\approx 2.3 \times 10^{-3}$ cm⁻¹) in all RCs investigated so far, in spite of considerable differences in the energy of P⁺H⁻.

V. Observation of the Recombination Dynamics of P⁺H⁻ in Delayed Fluorescence: Evidence for an Energetic Inhomogeneity of P⁺H⁻

A nonuniform RC population with an energetic inhomogeneity with respect to P⁺H⁻ can be revealed by comparing the recombination kinetics monitored by transient absorbance and by delayed fluorescence (due to repopulation of ¹P* from P⁺H⁻). While transient absorbance measurements are sensitive to all RCs, the fluorescence signal will be dominated by RCs with an energetically higher-lying radical pair. From the observed different magnetic field dependence of delayed fluorescence and transient absorbance in RCs of *Rb. sphaeroides* it was concluded that the free energy of P⁺H⁻ is inhomogeneously broadened (Ogrodnik et al., 1994).

A. Expected Magnetic Field Dependence of the Delayed Fluorescence

The delayed fluorescence due to thermal repopulation of ¹P* mirrors the concentration of the singlet radical pair ¹(P⁺H⁻). Therefore, it monitors the lifetime τ_{S-RP} of ¹(P⁺H⁻) defined as

$$\tau_{S-RP}(B) = \int_0^{\infty} [P^+H^-](t, B) dt \quad (14)$$

with $[^1(P^+H^-)]$ denoting the concentration of the singlet radical pair (normalized to 1 at $t = 0$) and B the magnetic field. Note, that τ_{S-RP} is not the same as the overall radical pair lifetime τ_{RP} (see Section II.C).

Equation (14) allows us to relate the delayed fluorescence to transient absorbance measurements, because the yield of recombination to the singlet ground state of P ($\phi_S = 1 - \phi_T$) is given by the product of the singlet recombination rate k_S with the same integral (Haberkmorn and Michel-Beyerle, 1979):

$$\phi_S(B) = k_S \int_0^{\infty} [P^+H^-](t, B) dt = k_S \tau_{S-RP}(B) \quad (15)$$

Therefore, the magnetic field dependence of τ_{S-RP} , as monitored by delayed fluorescence, and of the singlet or triplet recombination yield, as monitored by the transient absorbance at delay times sufficiently

longer than τ_{RP} , are expected to have the same lineshape.

B. Results

A multiexponential decay of the time resolved fluorescence is observed at all temperatures for Q-depleted RCs of *Rb. sphaeroides*. Being in agreement with previous observations (Woodbury et al., 1986; Goldstein and Boxer, 1989a), further components could be revealed with higher time resolution (Ogrodnik et al., 1994). For example, at 275 K the fit yields a fast initial decay (within the temporal resolution of the set-up) followed by components with 135 ps, 550 ps, 2.6 ns and 11 ns lifetime with continuously decreasing amplitudes. The time constant of 11 ns compares fairly well with the lifetime τ_{RP} of P^+H^- (see Table 2a), therefore this component certainly relates to delayed fluorescence arising from thermal repopulation of $^1\text{P}^*$ from $^1(\text{P}^+\text{H}^-)$. Only this component is expected to be affected by the application of an external magnetic field, while all other lifetimes and all amplitudes are necessarily independent of the magnetic field. This is indeed confirmed by measurements of the fluorescence in an external magnetic field of 600 G.

Due to the multiple decay components it is difficult to isolate the lifetime $\tau_{\text{s-RP}}(B)$ in a fitting procedure with sufficient resolution to obtain its magnetic field dependence. A more precise determination of $\tau_{\text{s-RP}}$, Eq. (14), can be obtained by integrating over the decay of the delayed fluorescence signal $F_d(t, B)$ (normalized to 1 at $t = 0$):

$$\tau_{\text{s-RP}}(B) = \int_0^{\infty} F_d(t, B) dt \quad (16)$$

Because contributions from the other fluorescence components (summarized as $F_0(t)$) in the experimentally accessible total fluorescence $F(t, B) = F_0(t) + F_d(t, B)$ are independent of the magnetic field, the magnetic field dependence of $\tau_{\text{s-RP}}$ can be obtained from:

$$\begin{aligned} \frac{\int_0^{\infty} F(t, B) dt - \int_0^{\infty} F(t, B=0) dt}{\int_0^{\infty} F(t, B=0) dt} &= \alpha \frac{\tau_{\text{s-RP}}(B) - \tau_{\text{s-RP}}(B=0)}{\tau_{\text{s-RP}}(B=0)} \\ &= \alpha \frac{\phi_s(B) - \phi_s(B=0)}{\phi_s(B=0)} \end{aligned}$$

$$\text{with } \alpha = \int_0^{\infty} F_d(t, B=0) dt / \int_0^{\infty} F(t, B=0) dt \quad (17)$$

The magnetic field dependence of the integrated fluorescence at different temperatures is shown in Fig. 7 and compared with the MARY spectra of the singlet yield $\phi_s (= 1 - \phi_T)$ obtained from transient absorption measurements. There are significant differences in the linewidths of the curves, particularly at low temperatures. While in transient absorbance measurements $B_{1/2}$ is almost temperature independent, increasing from 38 G to 55 G upon lowering the temperature from 290 K to 90 K (Table 2a), $B_{1/2}$ as measured in fluorescence increases from 65 G to 130 G in the same temperature range. Apparently, RCs with different recombination dynamics are monitored in fluorescence and absorbance measurements. Because $B_{1/2}$ is a measure for k_T , one can conclude that those RCs predominantly detected in fluorescence have larger rates k_T than the RCs that are detected in absorption.

Simulations of the recombination dynamics and its magnetic field dependence using the stochastic Liouville equation, Eq. (3), were carried out to search for the best match to the magnetic field dependence of ϕ_s and $\tau_{\text{s-RP}}$, respectively. At low temperatures a perfect match to the fluorescence data could be obtained, at high temperatures slight deviations had to be accepted. The values for k_T obtained from the simulations of the fluorescence data were significantly larger than the values obtained from the best fits of the absorption data (3.8 ns⁻¹ compared to 1.0 ns⁻¹ at 90 K, 1.8 ns⁻¹ compared to 0.8 ns⁻¹ at 290 K). Simulations of the time dependence of the overall concentration of P^+H^- were matched to the absorption recovery at 760 nm and simulations of the concentration of $^1(\text{P}^+\text{H}^-)$ were matched to the delayed fluorescence decay to obtain values for k_s . Again the k_s values obtained from the fluorescence data are significantly larger than those from the absorption data (5.5 × 10⁷ s⁻¹ compared to 1.5 × 10⁷ s⁻¹ at 90 K, 6.5 × 10⁷ s⁻¹ and 3.5 × 10⁷ s⁻¹ at 290 K).

C. Energetic Inhomogeneity of P^+H^-

The delayed fluorescence signal is proportional to the singlet radical pair concentration weighted by the Boltzmann factor for repopulation of $^1\text{P}^*$ and thus has a preferential selectivity to radical pairs energetically close to $^1\text{P}^*$, while the absorption signal is related directly to the radical pair concentration.

Fig. 7. Comparison of MARY spectra detected in absorption (Δ) and emission (\blacksquare) in Q-depleted RCs of *Rb. sphaeroides*. (Δ) relative increase of the singlet recombination yield $\phi_S = 1 - \phi_T$ by a magnetic field, determined from the transient absorbance measurements in the Q_y -band of P described in Section II.B. (\blacksquare) relative increase of τ_{S-RP} by a magnetic field (Eq. 17), scaled to the same modulation as the increase of ϕ_S . The ordinate on the left refers to 85 K, the ordinate on the right to 180 K and 275 K. From (Ogrodnik et al., 1994).

Therefore, the experimental finding that fluorescence and absorbance measurements probe different RCs implies an energetic inhomogeneity of the free energy gap between $^1P^*$ and P^+H^- . In contrast to transient absorbance that monitors the majority of RCs, most of the delayed fluorescence can result from a small minority of RCs. At lower temperatures, the delayed fluorescence selects radical pairs even closer to $^1P^*$ than those selected at higher temperatures.

A significant energetic inhomogeneity of the state $^1P^*$ should lead to excitation wavelength dependent rates of primary charge separation. In photochemical hole-burning spectra in the Q_y -absorbance band of P, however, no dependence of the lifetime of $^1P^*$ on the burn frequency was found (Lyle et al., 1993). Furthermore, an energetic inhomogeneity of $^1P^*$ is not expected to have significant effects on the recombination of P^+H^- to the ground state. Therefore, the inhomogeneity of $\Delta G(^1P^* - P^+H^-)$ observed here has to arise from an energetic inhomogeneity of P^+H^- .

Differences in fluorescence and absorbance measurements will result from an energetic inhomogeneity of P^+H^- only, if at least one of the relevant recombination parameters changes with the free energy of P^+H^- . The k_T value of the majority of RCs was concluded to be near the activationless limit. Shifting the radical pair energy to higher values should result only in a small increase of the Franck-Condon factor when reaching this limit and a

subsequent decrease upon a further shift. The difference in the apparent values of k_T measured at low temperatures in fluorescence and absorption, however, is distinctly larger, suggesting that not only the Franck-Condon factor, but also the electronic coupling V_T is changed with energy. The notion of a significant dependence of the recombination matrix element on the energy of P^+H^- is confirmed by the inhomogeneity of k_S which is found to parallel that of k_T . The Franck-Condon factor of this rate is expected to depend only weakly on the free energy, because the reaction is deep in the Marcus inverted region. Thus, a dependence of V_S on the free energy of P^+H^- corresponding to that of V_T can be deduced.

Indeed, the energetic inhomogeneity of P^+H^- is expected to affect V_S and V_T , if the superexchange mechanism prevails for these couplings, see Eq. (9). The expected dominance of superexchange coupling for the recombination rates k_S and k_T (Michel-Beyerle et al., 1988a; Bixon et al., 1991), thus, can be supported from experimental results.

From the temperature dependence of the delayed fluorescence, the width of the energetic distribution of P^+H^- can be estimated (Ogrodnik et al., 1994). When neglecting the energetic inhomogeneity, the activation barrier for the recombination process from P^+H^- to $^1P^*$ can be calculated from the ratio of the amplitudes of the prompt and the 10 ns-delayed fluorescence components to be 0.2 eV at 290 K and 0.08 eV at 90 K. However, due to the energetic

inhomogeneity of P^+H^- , the delayed fluorescence amplitude is proportional to the average of the Boltzmann factor for recombination of P^+H^- to ${}^1P^*$ over the distribution of the free energy of P^+H^- . The apparent value ΔG_{app} as determined from the observed fluorescence amplitude will be smaller than the average value of $\Delta G(P^+H^- \rightarrow {}^1P^*)$, because energetically higher radical pairs are weighted more strongly by the Boltzmann factor. Assuming the energy of P^+H^- to have a Gaussian distribution of width 2σ around a maximum value ΔG_0 , a simple approximate expression was derived for ΔG_{app} , which holds as long as σ is small compared to ΔG_0 :

$$\Delta G_{app} = \Delta G_0 - \frac{\sigma^2}{2kT} \quad (18)$$

With the values of 0.2 eV and 0.08 eV for ΔG_{app} at 290 K and 90 K, respectively, the width σ of the energetic distribution of P^+H^- is calculated to be approx. 0.05 eV. The maximum of the distribution is at $\Delta G_0 = 0.25$ eV, in full agreement with the value obtained from transient absorbance measurements.

VI. Recombination Dynamics as a Unique Diagnostic Tool: Conclusions

The unique merits of the elucidation of the recombination dynamics in absorption and emission experiments refer to two issues: (i) the demonstration of inhomogeneous broadening of radical pair energies and (ii) the determination of radical pair energetics for the majority of RCs, Fig. 8. Due to the specificity of delayed fluorescence experiments to energetically high lying radical pair states, as discussed in Section V, they may not yield information on the bulk of the RCs, unless suitable extrapolation from high temperature data is made. Thus, information derived from MARY absorption data constitutes in many cases the only direct access to parameters basic for the treatment of rates in the framework of electron transfer theories.

A. Implications of the Energetic Inhomogeneity of P^+H^-

Until recently, electron transfer dynamics in photosynthetic reaction centers were assumed to be single-exponential. Considering the complexity of the system with the numberless degrees of freedom of the protein, it was not surprising when growing

evidence for deviations from homogeneous kinetics appeared with increasing experimental precision. Bi- and multiphasic kinetics were observed for the recombination of $P^+Q_A^-$ (Kleinfeld et al., 1984; Parot et al., 1987; Sebban and Wraight, 1989; Franzen et al., 1990) and $P^+Q_B^-$ (Gao et al., 1990), for the primary charge separation (Feick et al., 1990; Becker et al., 1991; Vos et al., 1991, 1992; Du et al., 1992; Hamm et al., 1993) and for delayed fluorescence (Sebban and Barbet, 1984; Woodbury and Parson, 1984; Woodbury et al., 1986; Hörber et al., 1986). Indications for inhomogeneity were also derived from kinetics that were found to depend on the probing wavelength (Kirmaier and Holten, 1990). The described inhomogeneities referred to phenomenological nonuniformities of the measured dynamics or to spectral information, but could not directly address the origin of these inhomogeneous features, so that various assumptions have been made on this issue (Woodbury and Parson, 1984; Goldstein and Boxer, 1989b; Feick et al., 1990; Hamm et al., 1993).

As discussed in Section V.C, the different magnetic field dependence of the recombination dynamics observed in delayed fluorescence and in transient absorbance measurements proves an energetic inhomogeneity of the radical pair P^+H^- . It is reasonable to suspect that this energetic inhomogeneity originates from differences of the interaction of the charged cofactors with their protein surroundings in different configurational states (Frauenfelder et al., 1988). If the protein matrix is thus responsible for the proven energetic inhomogeneity of P^+H^- , the assumption of a similar inhomogeneity for P^+B^- or any other radical pair seems justified.

Primary charge separation is discussed to form either P^+H^- or P^+B^- in the first electron transfer step. The energetic inhomogeneity of these radical pairs yields the physical basis for interpreting the multiphasic kinetics detected in the charge separation process (Wang et al., 1993; Ogrodnik et al., 1994). Due to the influence of the energy on the electron transfer rate via the Franck-Condon factor, a continuous distribution of the lifetime of the primary donor state ${}^1P^*$ is expected, which should become broader at lower temperatures. We propose that the multiphasic decay of ${}^1P^*$ detected experimentally in stimulated emission or fluorescence upconversion results from this inhomogeneity. This multiphasic decay extends with continuously decreasing amplitudes to considerably longer times, which have been detected in photon counting experiments. These prompt fluorescence lifetimes are limited by the

internal conversion rate of ¹P^{*}, which was determined to be faster than 1 ns (Eberl et al., 1992). Thus, we are inclined to assign the fluorescence components up to about 1 ns to very slow charge separation processes.

The influence of an external electric field on the fluorescence has been studied with the intention to clarify the mechanism of primary charge separation, in particular to assign the identity of the primary radical pair state to either P⁺H⁻ or P⁺B⁻ (Lockhart et al., 1988; Ogrodnik et al., 1991; Ogrodnik and Michel-Beyerle, 1992; Ogrodnik, 1993). Compared to theoretical expectations (Bixon et al., 1989), the observations yielded a weak dependence of the fluorescence on the electric field, both in steady-state and time resolved measurements. These weak effects now can be understood by taking into account the energetic inhomogeneity of the state P⁺B⁻ and/or P⁺H⁻. Due to the interaction of the dipole moments of the radical pairs P⁺H⁻ and P⁺B⁻ with the electric field, these states will be shifted by a value in the order of 0.1 eV in the electric fields employed. Because the shift depends on the orientation of the dipole in the electric field, and isotropic RC samples were used, a continuous distribution of the radical pair energies around the levels at zero field will be induced by the field. If the radical pairs have a well-defined energy at zero field, this will result in a significant spread of the charge separation rate, leading to a significant increase of the average ¹P^{*} lifetime and thus of the prompt fluorescence quantum yield. However, if the energy levels of P⁺B⁻ and/or P⁺H⁻ already are broadened in absence of the field, the electric field mainly causes a redistribution of the energy levels and only results in an additional broadening. In this case, it is not surprising to find the field induced changes of the prompt or delayed fluorescence partially masked by the initial inhomogeneity.

Another important consequence of the energetic inhomogeneity of P⁺H⁻ is the impossibility of measuring the energetics in the majority of RCs by delayed fluorescence directly. Since those RCs with a higher energy of P⁺H⁻ will contribute predominantly, delayed fluorescence will yield an apparent energy gap between ¹P^{*} and P⁺H⁻ which is smaller than the mean value, see Eq. (18). This effect is stronger at lower temperatures, therefore it is not surprising that a significant decrease of ΔG(¹P^{*}–P⁺H⁻) with decreasing temperature was derived from delayed fluorescence measurements. In contrast to delayed fluorescence, transient absorbance measurements are not expected to be affected by the energetic inhomogeneity of P⁺H⁻ and indeed do not show the

strong temperature dependence of ΔG, Table 2a. On the other hand, the temperature dependence of the apparent free energy difference determined from the delayed fluorescence allows one to estimate the width of the energetic distribution of P⁺H⁻, as described in Section V.C, and to extrapolate to the mean energy of the majority of RCs.

Summarizing, the energetic inhomogeneity of radical pair states, which was proven by the comparison of P⁺H⁻ recombination dynamics measurements in delayed fluorescence and transient absorbance, allows us to understand the multiphasic kinetics observed for electron transfer processes in the RC. It also explains the unexpectedly weak dependence of prompt and delayed fluorescence on an external electric field and discrepancies in the energetics of P⁺H⁻ determined by delayed fluorescence and transient absorbance measurements.

B. Energetics and Mechanism of Primary Charge Separation

After excitation of a RC of *Rb. sphaeroides*, an electron is transferred from the primary donor P to H within 3–4 ps (Woodbury et al., 1985; Martin et al., 1986; Fleming et al., 1988; Holzzapfel et al., 1989). The detailed mechanism of this primary charge separation, especially the role of the accessory BChl monomer B, is still discussed controversially (Holzapfel et al., 1989; Kirmaier and Holten, 1990; Lauterwasser et al., 1991; Chan et al., 1991). Under debate are models, in which electron transfer either occurs in two steps via B or directly to H with B enhancing the electronic interaction between P and H via the superexchange mechanism (See Chapter 24 by Woodbury and Allen and Chapter 25 by Parson and Warshel).

In principle, both mechanisms will contribute in parallel to the primary charge separation. The relative contribution of each mechanism is determined mostly by the free energy gap ΔG₁ between ¹P^{*} and P⁺B⁻. At physiological temperatures the two-step-mechanism is expected to dominate as long as the free energy of P⁺B⁻ is not above that of ¹P^{*} (Bixon et al., 1991), while at 100 K the two-step-mechanism still should prevail, if P⁺B⁻ is more than 300 cm⁻¹ under ¹P^{*}. This is just the upper limit of ΔG₁ derived from the recombination dynamics of P⁺H⁻ in RCs of *Rb. sphaeroides*, Fig. 8A. Therefore, the energetic results from the recombination dynamics are fully compatible with both superexchange and two-step charge separation even at 100 K. In the case of *Cf.*

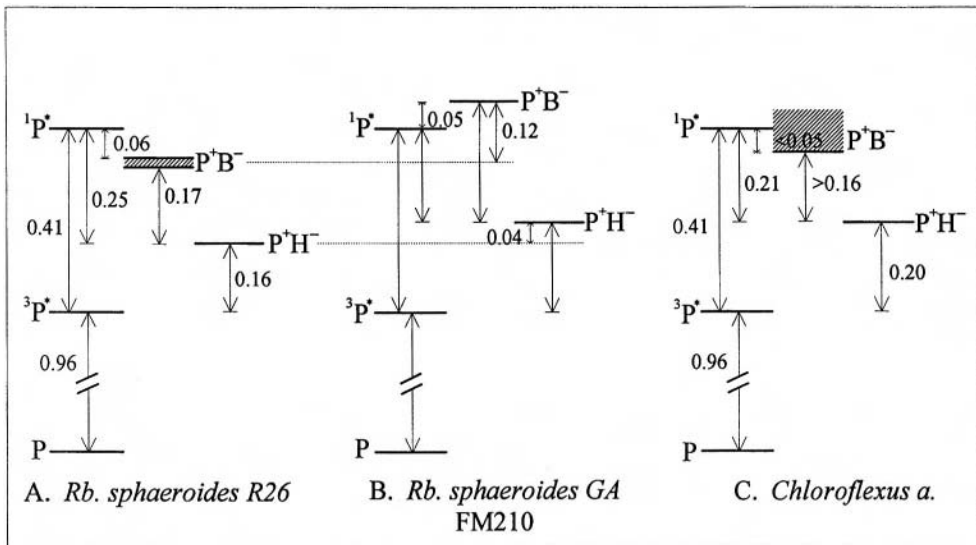

Fig. 8. Comparative energetics for Q-depleted RCs of (A) *Rb. sphaeroides* R26, (B) the Tyr^{M210} → Phe mutant of *Rb. sphaeroides* GA, and (C) *Chloroflexus aurantiacus*, as determined in Section II.E. and Section III.B.

aurantiacus, the upper limit of ΔG_1 is 150 cm^{-1} (Fig. 8C), again compatible with both mechanisms of charge separation, at least at physiological temperatures (however, the analysis by Bixon et al. (1991) strictly only refers to *Rb. sphaeroides*, because it is based on various assumptions and parameters taken from *Rb. sphaeroides*).

Besides picosecond time resolved spectroscopy and hole burning experiments (Reddy et al., 1992), both yielding information about the rate of charge separation, also the exchange interaction J of P^+H^- has been used to draw conclusions on the mechanism of primary charge separation (Marcus 1987, 1988; Michel-Beyerle et al., 1988a; Bixon et al., 1988, 1989, 1991). Even before the X-ray crystal structure of the RC revealed the location of B between P and H (Deisenhofer et al., 1984; Chang et al., 1986; Allen et al., 1987), the observed small value of J led to the proposal of two-step charge separation (Haberkorn et al., 1979). This was necessary to reconcile the small value of J with the strong electronic interaction concluded from fast electron transfer.

From the activationless rate of primary charge separation the relevant matrix element could be estimated to be approx. 20 cm^{-1} . Under the assumption of one-step (superexchange) charge separation, this is the electronic coupling between $^1\text{P}^*$ and P^+H^- . This coupling is also relevant for the calculation of the singlet shift J_s of P^+H^- due to its interaction with $^1\text{P}^*$. The value of J_s estimated this way is on the order of

several 100 G, much larger than the experimentally observed value of J . Still, two possibilities resolving this discrepancy were discussed so that one step charge separation could not be ruled out solely on the basis of recombination data (Bixon et al., 1988, 1989; Michel-Beyerle et al., 1988a). (i) A fortuitous compensation of J_s by an equivalently large shift J_T of $^3(\text{P}^+\text{H}^-)$ in the same direction. However, the maximum values of J_T calculated with the extended treatment including nuclear motion, Eq. (13), are not large enough to compensate the expected large values of J_s . (ii) A fast decrease of the coupling between P and H due to some configurational relaxation after charge separation.

In a two-step model, the strong electronic interaction derived from the primary charge separation rate refers to the coupling between $^1\text{P}^*$ and P^+B^- . Theoretical calculations based on the known structure predict that the coupling between P^+B^- and P^+H^- is larger than that between $^1\text{P}^*$ and P^+B^- by a factor of 6 (Plato et al., 1988). Together with an estimate of the vertical energy gap between P^+H^- and P^+B^- ($\delta E(\text{P}^+\text{B}^- - \text{P}^+\text{H}^-) \approx 3000 \text{ cm}^{-1}$, see Section II.F.5), the superexchange coupling between $^1\text{P}^*$ and P^+H^- can be calculated⁷ to be on the order of 1 cm^{-1} , in accordance with the value determined for the coupling V_T between $^3\text{P}^*$ and P^+H^- (Section II.F.4). This coupling

⁷ Even in the case of two-step charge separation, charge recombination is a one-step process dominated by superexchange coupling, Eq. (9), see Section II.F.1.

yields a value of J_s of several G, which is very compatible with the observed value of J .

Summarizing, the results obtained from the recombination dynamics of P^+H^- in native RCs of *Rb. sphaeroides* and *Cf. aurantiacus* can only be reconciled with the superexchange mechanism of charge separation, if configurational relaxation leads to a substantial decrease of the electronic coupling between P and H after charge separation. The energetics of P^+B^- as determined from the recombination dynamics of P^+H^- are compatible with both mechanisms. It has to be stressed that the conclusions described are based on energetics derived from transient absorbance measurements. Therefore, they refer to the average values of the majority of RCs and are not distorted by the energetic inhomogeneity of the radical pair states discussed in Section V.C.

In the context of the investigation of mutagenic or chemical modifications of the RC, the measurement of the magnetic field dependent recombination dynamics of P^+H^- yields important information. In particular, conclusions about the effects on the energies of the charge-separated states can be derived, see Section III. In contrast to other investigations referring only to mutationally induced changes of the oxidation potential of P, information derived from recombination data includes energetic changes of H^- as well. The altered energies have to be taken into account for the discussion of the effects of any modification of the RC on the rate and mechanism of primary charge separation.

Acknowledgments

The biochemical basis of our work with respect to native bacterial reaction centers and their manipulation has developed in a long-standing cooperation with R. Feick (Max-Planck-Institut für Biochemie, Martinsried), to whom we are especially grateful. Mutagenetically altered reaction centers were designed by and investigated with two different biochemical laboratories: mutants of *Rb. capsulatus* with D.C. Youvan and W.W. Coleman (MIT, Cambridge), mutants of *Rb. sphaeroides* with D. Oesterhelt and K.A. Gray (Max-Planck-Institut für Biochemie, Martinsried).

The theoretical understanding of spin dynamics in radical pairs, esp. its manifestations in RYDMR spectroscopy, has been developed by W. Lersch. The interpretation of exchange interaction and electron

transfer phenomena has been worked out in close collaboration and stimulating discussions with M. Bixon and J. Jortner (Tel Aviv University).

Finally, we want to thank all the people in the lab involved in recombination studies referred to in this review: R. Letterer, G. Aumeier, T. Langenbacher, T. Häberle, W. Neumann, E. Lang, G. Rousseau.

Since we were summing up over a central part of our studies within the last decade, it is a special pleasure to thank at this occasion E. W. Schlag (Institut für Physikalische Chemie, TU München) for his continuous interest and scientific support.

The totality of this work has been funded by the Deutsche Forschungsgemeinschaft in the framework of the Sonderforschungsbereich 143 ('Elementarprozesse der Photosynthese').

Summary

In the past 10 years infrared Spectroscopy has become a valuable tool for the analysis of the primary processes in reaction centers. Because it analyzes vibrational properties of the entire molecule, it can yield information on the protein which is otherwise difficult to obtain. In this chapter, the basic concepts of IR spectroscopy for macromolecules and the reaction-induced difference techniques using Fourier transform and single-wavelength techniques are briefly reviewed. The strategies used for the assignment of vibrational modes are described. Light-induced Fourier transform difference spectra monitoring charge-separated states and electrochemically-induced spectra monitoring the redox transitions of individual cofactors are reported. A major section deals with the vibrational spectra of the quinones in the RC, and information on the modes of the quinones in situ and of their protein sites is discussed. Finally, time-resolved IR experiments at individual wavelengths showing quinone reduction and concomitant protonation processes are reviewed.

I. Introduction: What Can We Learn About Reaction Centers From Infrared Spectroscopy?

Infrared spectroscopy analyzes vibrational properties of a molecule and can thus address other properties of reaction centers (RC) than those monitored by optical spectroscopy in the UV, visible, and near-infrared region. The vibrational spectrum of the RC is composed of individual and coupled modes of the numerous bonds of the protein, the pigments, the quinones, lipids, and water constituting the entire molecule, and thus contains abundant information on structural details and functional properties. In this chapter we shall deal with the information that can be drawn from this 'messy' overlap of multiple IR bands. This subject is also covered by recent reviews by Hoff (1992) and Mäntele (1993b).

In infrared spectroscopy, photons with energies that match those of vibrational sublevels of the molecule (typically 0.5–0.05 eV) are directly absorbed. These low-energy photons do not cause photochemistry and thus can be used at high intensities. A large variety of techniques in infrared spectroscopy have emerged in recent years, and most of them can be applied to obtain useful information on structural and functional properties of the RC.

Infrared spectroscopy probes vibrational modes of the pigments, the quinones, the polypeptide backbone and amino acid side chains without any selectivity and may thus be used to address questions on pigment and quinone in situ properties and interactions, on the role of the protein mediating electron transfer and coupling proton transfer to electron transfer. This is complementary to Raman spectroscopy, where resonance enhancement can yield spectra of individual pigments even in a complex photosynthetic membrane. A problem of the non-selectivity of IR spectroscopy is the background absorption of the bulk part of the RC, of lipids, water, and buffer, which necessitates difference techniques. Since the size of the RC protein does not allow 'classical' difference spectroscopies where two different samples are compared, 'reaction-induced' IR difference techniques on a single sample have to be used. The result are highly structured difference spectra which represent the sum of all molecular

changes associated with the induced reaction.

IR spectroscopy relies on physical processes with short intrinsic lifetimes and thus allows very high time resolution for the study of intermediate states in electron transfer as well as of the dynamic processes in the protein. The past few years have seen developments especially in time-resolved IR spectroscopy which have given access to all steps of electron transfer, from picoseconds to several seconds. To date, quite a few processes in RCs have been detected in real-time in this entire time range which are functionally related to the electron transfer and proton transfer phenomena, but kinetically uncoupled from these. Vibrational spectroscopy can thus provide us with a detailed molecular view of the role of the protein in mediating electron transfer.

II. Technical Aspects of Infrared Spectroscopy of Reaction Centers

The above-mentioned non-selectivity of IR spectroscopy necessitates difference techniques on a single sample, rather than subtracting the IR absorbance spectra obtained from two different samples. The basic concept of this reaction-induced IR difference spectroscopy for the study of protein function and reaction mechanisms has been recently discussed (Mäntele, 1993). The technical developments of the past 20 years have increased the sensitivity of IR spectroscopy to a level where the contributions of individual bonds in the RC to its total IR spectrum are detectable. These include the practical applicability, availability, and 'affordability' of Fourier transform infrared techniques which have been predominantly applied to RCs. Further developments include sensitive semiconductor quantum detectors and tunable IR laser sources for CW and pulsed applications. Although the main purpose of this chapter is to review the molecular information obtained from vibrational spectroscopy, we shall briefly 'dive' into the technical aspects.

A. Steady-State FTIR Spectroscopy

FTIR spectroscopy of stationary states in the RC has become the easiest and most widespread technique and relies on commercially available FTIR instruments. An FTIR spectrophotometer makes use of an interferometer, rather than scanning the individual wavelength elements dispersed by a prism or a grating.

Abbreviations: *Cm.* – *Chromatium*; FTIR – Fourier transform infrared; IR – infrared; *Rb.* – *Rhodobacter*; RC – reaction center; *Rc.* – *Rhodocyclus*; *Rp.* – *Rhodospseudomonas*; *Rs.* – *Rhodospirillum*

The detector intensity as a function of the interferometer position is called the interferogram; its Fourier transform yields the IR spectrum. The theory, basic principles, and applications of FTIR spectroscopy to the study of proteins and biological membranes has been described in some recent reviews (Griffiths and DeHaseth, 1986; Susi and Byler, 1986; Braiman and Rothschild, 1988; Arrondo et al., 1993; Rothschild, 1993; Mäntele, 1993). FTIR spectroscopy results in a number of advantages over dispersive spectroscopy, like *Jacquinot's* advantage (the high energy throughput because of the lack of resolution-determining slits), and *Conne's* advantage (the high wavelength accuracy because of the laser reference interferometer). The major improvement, however, is the simultaneous recording of all spectral elements (*Felgett's* advantage), which takes less than a second even for a simple FTIR spectrophotometer and only a few milliseconds for sophisticated 'rapid scan' interferometers. *Felgett's* advantage can be either used toward a gain in sensitivity by accumulating many interferometer scans before performing the Fourier transform, or toward time-resolved studies using a series of single interferometer scans.

A steady-state FTIR experiment on RCs consists of recording a single beam IR spectrum of the RC in an initial state, inducing a triggering reaction, and recording a single beam IR spectrum of the final state. The resulting difference spectra should arise from the particular structural changes induced by the triggering reaction, with the absorption from the bulk of the protein being removed, and is selective for the functionally important part rather than for the global structure. The 'trigger' should provide a minimum disturbance of the sample, but specifically and quantitatively start the desired reaction.

In RC, mostly the intrinsic photoreactions have been applied to create a reaction-induced ('light-induced') IR difference spectrum. The photo-stationary state of an RC sample in the FTIR spectrophotometer beam can be easily modified by additional bleaching light, which does not perturb the measurement, since the spectral regions (VIS/NIR for excitation, mid-IR for detection) are well-separated. Light-induced FTIR difference spectra reflecting charge-separation between P and Q_A or Q_B are easily obtained at moderate bleaching intensity. These spectra reflect the differences for the $PQ_{A,B} \rightarrow P^+Q_{A,B}$ transition and are termed $P^+Q_A^-/PQ_A$ or $P^+Q_B^-/PQ_B$ difference spectra, with the understanding that the bands of the disappearing state, $PQ_{A,B}$, are

negative, and those of the appearing state, $P^+Q_{A,B}$ are positive. However, care needs to be taken with higher intensities of the bleaching light, and correct filtering is recommended, since even minor heating of the sample results in changes of hydration, leading to unspecific signals which can be much larger than those caused by light-induced charge separation. In general, it is advantageous to add a number of light-dark difference cycles rather than to accumulate a high number of scans for the dark-adapted or the light-adapted state. Efficient thermostating of the samples is a prerequisite for high-quality spectra.

Light-induced difference spectroscopy combined with the use of exogenous donors can be used to obtain difference spectra between further states of the RC. Rapid rereduction of P^+ at low redox potential conditions leads to formation of H^+ , a procedure which has been used for *Rhodospseudomonas (Rp.) viridis* RC and *Chromatium (Cm.) vinosum* membrane particles, and, recently, for *Rhodobacter (Rb.) sphaeroides* RC. At moderately reducing conditions, but in the presence of a redox mediator to shuttle electrons rapidly to the photooxidized P^+ , reduction of Q_A or Q_B has been achieved without oxidizing a detectable fraction of P^+ . In RCs with bound cytochromes, adjusting the redox potential for the IR samples has led to light-induced FTIR difference spectra where charge separation between the hemes and the quinone acceptors can be observed.

All steady-state FTIR difference spectra that have been obtained by use of the intrinsic photochemical reactions, however, present signals from a mixture of states such as of P, P^+ , Q, and Q^- in spectra reflecting charge separation. Difference spectra in which an exogenous donor has been used seem to change only one cofactor's redox state. However, the difference spectra due to the redox reaction of the exogenous donor adds to that of the respective RC cofactor, although convincing evidence comes from control experiments that the difference bands of the exogenous donor are broad and featureless or simply in a different spectral region.

This limitation has been successfully overcome with the development of ultra-thin-layer electrochemical cells that allow redox reactions in the RC to be triggered at a transparent electrode in combination with UV-VIS-NIR and FTIR spectroscopy. Electron transfer at an electrode is more specific than light as a trigger, and different cofactors of the RC could be selected by the choice of the appropriate potential ('dial-a-cofactor'). These 'redox-induced' difference

spectra are as detailed and sensitive as are light-induced difference spectra; moreover, individual bands can be titrated and thus assigned to a specific redox transition. It should be mentioned that both, redox-induced and light-induced difference techniques, can be combined on one RC sample to start photochemical reactions from a well-defined redox clamp.

B. Time-Resolved FTIR Spectroscopy

Time-resolved FTIR studies can be carried out by three different techniques. In *rapid-scan* FTIR spectroscopy (Braiman et al., 1987), the interferometer mirror is moved as fast as possible (and as fast as digitization of the detector signal allows) to successively record and store interferograms (which may be transformed afterwards) in the course of a reaction. For RCs, IR spectra spaced some tens of milliseconds can be recorded after flash excitation. With the *stroboscope technique* (Braiman et al., 1991), a series of interferograms is collected, each with a different delay time with respect to the triggering event. This set of interferograms is then used to construct a set of time-resolved spectra in the microsecond-to millisecond time domain, with (partial) loss of the multiplex advantage. The *'step-scan'* technique (Uhmann et al., 1991) uses a stepwise (instead of continuously) moving interferometer to record the time dependence at fixed mirror positions and reconstructs time-dependent IR spectra from them, without a loss of the multiplex advantage.

C. Single Wavelength Techniques, Diode Lasers, PS Techniques

As an alternative to FTIR, time-resolved IR studies are possible by single-wavelength techniques, either using thermal IR sources with a monochromator (Siebert et al., 1980; Iwata and Hamaguchi, 1990) or tunable lead salt IR diode lasers (Mäntele et al., 1990a). The latter can be continuously tuned over 100–400 cm^{-1} in the 2000–1000 cm^{-1} range and provide sufficient power (up to a few mW) to allow sensitive detection of transient changes of band intensities. Investigations of dynamic processes in the RC in the ns to ms time domain by this technique will be discussed below. CO lasers, a principal alternative IR source of abundant power, have not yet been used for time-resolved studies at longer (ms to ns) time scales because of their limited amplitude stability and tunability. Recently, several laboratories

have applied picosecond techniques for ultrashort IR studies on RC. The first approach (mainly from the Hochstrasser group) used a CO laser for the generation of IR probing light, with 'upconversion' techniques to detect the transient ps IR signal in the visible spectral range (Diller et al., 1992). The second approach (from the Zinth group) used the generation of an ultrashort IR pulse from visible light by mixing techniques with detection in the IR. The latter authors elegantly used the spectral width of their IR pulse ($\sim 60 \text{ cm}^{-1}$) for multiwavelength detection with an IR multichannel analyzer (Hamm et al., 1995)

D. Reaction Center Samples for Infrared Spectroscopy

The IR range accessible with most FTIR spectrophotometers spans from > 4000 to $< 600 \text{ cm}^{-1}$. However, most difference spectroscopic studies are confined to the 2000–1000 cm^{-1} range, where the majority of bands with diagnostic relevance are located. The strong water H-O-H bending mode centered around 1650 cm^{-1} with an extinction coefficient of ca. 20 $\text{l mol}^{-1} \text{ cm}^{-1}$ necessitates thin layers for aqueous samples, because the absorbance from water at this frequency is around 1 for a pathlength of 10 μm . As an additional problem, the extinction coefficients for most of the protein modes (at most 1000 $\text{l mol}^{-1} \text{ cm}^{-1}$) are one or two orders of magnitude smaller than the electronic transition moments of pigments, quinones, or hemes. RC IR samples thus need to be of much higher concentration than samples used for optical transmission spectroscopies.

IR windows used for studies on RC are almost always from CaF_2 , a compromise between transmission (from 190 nm to 10 μm), stability against aqueous solutions, and price. IR cells with CaF_2 windows allow spectroscopic investigations of the same samples from the UV to the mid-IR, or excitation in the VIS/NIR range and detection in the mid-IR. The considerably differing extinction coefficients for the pigments in the NIR (for example for the monomeric BChls) and for the RC protein (the amide I band) lead to comparable absorbance at 800 nm and at approx. 1650 cm^{-1} , a fact which facilitates excitation coaxially with the IR beam, or simultaneous VIS/NIR and mid-IR spectroscopic investigations such as described in a recent review (Mäntele, 1993b).

Two major types of samples have been used for FTIR and kinetic IR investigations. The first type are thin, semihydrated films dried on CaF_2 windows

from solutions or suspensions of RCs in detergent, RCs reconstituted in lipid vesicles, or from membranous particles containing RC. Salt, buffer, and detergent concentrations in the suspensions need to be reduced considerably to avoid excessively high salt concentrations or detergent enrichment in the films upon drying, and controlled hydration of the films is essential to maintain full activity. Correct buffering and ionic strength are almost impossible to maintain, and there has been a continuous concern that these films at reduced water content might not correspond to RCs in dilute solutions. In addition, the RCs become oriented upon drying, leading to polarization effects even for samples perpendicular to the IR beam. Careful control of the structural and functional integrity by measurement of the electron transfer rates is recommended, and has provided evidence that the electron transfer activity of the RC at high hydration (for example at equilibrium with 98% relative humidity) is indistinguishable from that in dilute solution.

The second type of IR samples used are concentrated solutions or suspensions. Detergent-solubilized RCs can be concentrated to 1–2 mM in ultrafiltration cells and transferred to demountable IR microcells with pathlengths as low as 5–10 μm . Ionic strength can be easily controlled this way, and orientation does not occur, however, the pH may be offset toward the isoelectric point of the RC if the concentration of the buffer is too low with respect to that of the RC. This type of sample has been routinely used for electrochemical investigations, where diffusibility of the RC is a prerequisite.

Finally, the amounts of protein needed for either sample type have frequently been overestimated, a misjudgment from the 'old days' of IR spectroscopy. Quantities of ca. 2–5 μL of a 0.5–1 mM solution are sufficient for a film or concentrated suspension IR sample, and correspond to what is conveniently used at higher dilution for UV and VIS spectroscopy.

III. From Bands to Bonds: Strategies for Band Assignments

Ideally, the bands in an IR spectrum are assigned to the vibrational modes of the molecule by performing a normal mode calculation and matching the force field parameters by replacing all atoms with stable isotopes, a procedure far out of reach for the RC. Even without the limitation of computer capacity, a

force field yielding consistent modes would be difficult to obtain. In the case of the RC, the concept of group frequencies, i.e. of vibrational modes uncoupled from others, has proven to be very useful. This concept assumes the vibrational spectrum of the RC to be composed of modes from the backbone, from amino acid side chain groups, from cofactors, lipids, detergent and buffer molecules, and water. Coupling of such modes is possible, but will only result in small shifts depending on the interactions. For each of these group frequencies, an empirical assignment then becomes possible by isotopic labeling and comparison of the observed with the calculated frequency shifts.

The most simple isotope labeling experiment is substitution of $^1\text{H}_2\text{O}$ by $^2\text{H}_2\text{O}$, easily done by resuspending concentrated RC or membrane suspensions in a $^2\text{H}_2\text{O}$ buffer and equilibrating. The resulting exchange of accessible N-, O-, or S-bound protons leads to distinct shifts in the spectrum, some of which will be discussed below. The probability for a given group to exchange depends on the global accessibility for water to the protein domain, on the local environment, and on the pK of the group. The extent of exchange can be monitored at the relative intensities of the amide II and the amide II' (the corresponding mode of the amide I group in $^2\text{H}_2\text{O}$) modes.

Other mass labels, like ^{13}C , ^{15}N , or ^{18}O , can be introduced biosynthetically, but will not be incorporated specifically. Isotope-labeled amino acids, introduced into the RC via the nutrient, in combination with site-directed mutations, present the tedious yet clear tool to identify and to assign specific vibrational modes of the protein. In general, the remarkable potential of site-directed mutagenesis of RCs is a tempting tool for IR assignments. However, any mutant resulting in severe blocking of the function renders reaction-induced IR difference spectroscopy useless. A further problem of site-directed mutagenesis, in the case of charged residues, is the perturbation of entire charge patterns, for which IR difference spectroscopy (which monitors the changes of dipole moments) is a very sensitive technique. The balance seems to require generation of mutants with sufficiently small perturbations, but with retained general functional properties. In this line, natural variants can be considered to be of a similar relevance.

In RCs, the exchange of cofactors has long been limited to the secondary and the primary quinone acceptor, and only recently exchange of the

monomeric bacteriochlorophylls and the bacteriopheophytins by analogs has been reported (see Chapter by Scheer and Hartwich). Nevertheless, the comparison of light- or redox-induced FTIR difference spectra with the spectra of the isolated cofactors, i.e. bacteriochlorophylls, bacteriopheophytins, and quinones and numerous analogs, all in their neutral and relevant ion radical, dianion, or protonated forms, has created a basic data set of vibrational modes. Table 1 summarizes the IR frequencies that can be expected in reaction induced difference spectra of the RC in the 2000 cm^{-1} to 1000 cm^{-1} range.

IV. Light-Induced Difference Spectroscopy of Charge Separation in Reaction Centers

Steady-state light-induced FTIR difference spectra reflecting the difference between the neutral PQ and the charge-separated P^+Q^- state have been the first and most widespread data used to analyze the molecular processes occurring upon charge separation. Mostly RCs from *Rb. sphaeroides*, but also RC, membrane particles and chromatophores from *Rp. viridis*, *Rb. capsulatus*, *Cm. vinosum*, *Rhodospirillum (Rs.) rubrum*, *Rhodocyclus (Rc.) gelatinosus*, and *Rp. palustris* were investigated (Mäntele et al., 1985a; Hayashi et al., 1986, 1990; Nabedryk et al., 1986, 1987, 1990; Gerwert et al., 1988; Buchanan et al., 1990a,b, 1992).

The light-induced difference spectra consist of sharp difference bands, indicating that predominantly intramolecular processes are observed. The maximum size of the difference bands is small, only about 0.5 – 1 % of the total absorbance at the strongest band of the amide I mode at around 1650 cm^{-1} . A first and general conclusion from all authors was that no major protein conformational change occurred upon charge separation and stabilization. Even though the signal amplitude in these difference spectra is small, the sensitivity of FTIR difference spectroscopy shows that even minor and subtle band structures are highly reproducible in amplitude and in frequency. All signals arise from primary charge separation and present a key to the molecular processes around the pigments and the quinone(s).

The highest-frequency band in these difference spectra is a positive band (we use the notation that positive bands correspond to the light-induced P^+Q^- state, while negative bands correspond to the

quiescent PQ state) at approx. 1750 cm^{-1} . In the absence of model compounds, and, later, using IR spectra of isolated pigments, this band was assigned to the 13^2 ester C=O group of the primary donor BChls (Mäntele et al., 1985a, 1988b). A differential signal at 1712(+)/1683(–) cm^{-1} was assigned to the 13^1 -keto C=O group. In the region from 1660 cm^{-1} to 1600 cm^{-1} , several small bands were candidates for the 3 acetyl C=O group.

The clear assignment of the rich band structures in these spectra awaited numerous models studies. The cation-minus-neutral difference spectra of isolated BChls generated electrochemically in a variety of solvents clearly reproduce the band structures of the light-induced FTIR difference spectra of RCs in the carbonyl region (Leonhard et al., 1989a,b). However, the exact band positions depend on the solvation of the pigments and may thus be used for the mapping of the in vivo interaction of the pigments. The electrochemically-generated BChl a^+ /BChl a FTIR difference spectra insufficiently describe the light-induced FTIR difference spectra in the 1600–1400 cm^{-1} region. Nevertheless, the assignment of a band doublet at 1566 cm^{-1} and at 1546 cm^{-1} to C=C/C-C modes appears justified, although these bands are shifted with respect to model compound spectra (Mäntele et al., 1990c).

Clearly, the comparison of light-induced FTIR difference spectra with model spectra of monomeric pigments is not very satisfying, and it would be highly desirable to either analyze the vibrational modes of the light-induced spectra in comparison with a model dimer or to extract pigments and reconstitute with isotopically labeled or structurally different analogs. A dimeric model suitable as a maquette for IR spectroscopy would have to be precisely defined, not only for its neutral state, but also for the cation radical form. Besides, it should be very difficult to mimic the heterogeneous environment of the pigments in the RC. As for the second point, exchange of pigments has actually only been possible for the monomers and the pheophytin (Struck and Scheer, 1990; Struck et al., 1990). FTIR spectra of RC with modified monomers have been obtained (Leonhard, 1991), and revealed only minor effects on the primary donor cation vibrational spectrum.

The quinone contribution in light-induced P^+Q^- /PQ difference spectra could not be separated easily, mainly because the strong modes of the pigments mask the weaker quinone modes. We shall discuss the approaches to generate 'pure' Q^-/Q difference

Table 1. Vibrational modes from the RC constituents in the 2000–1000 cm^{-1} range

Component	Assigned bond(s) and vibrational modes	Frequency [cm^{-1}]
Polypeptide backbone		
amide I	mainly C=O stretching	1620–1690
amide II	C=O stretching, N-H bending	ca. 1550
amide III	C-N stretching, N-H bending	ca. 1300
Amino acid side chains		
ASP, GLU	COOH carboxyl C=O stretching	1750–1710
	COO ⁻ antisymmetric stretching	1620–1570
	COO ⁻ symmetric stretching	1450–1350
ASN, GLN	C=O stretching	ca. 1680
	NH ₂ deformation	ca. 1620
	NH ₃ ⁺ deformation	ca. 1470
ARG	CN ₃ H ₅ ⁺ antisymmetric stretching	1680–1670
	CN ₃ H ₅ ⁺ symmetric stretching	1630–1640
LYS	NH ₃ ⁺ antisymmetric deformation	1640–1610
TYR	NH ₃ ⁺ symmetric deformation	ca. 1525
	TYR-O-H ring stretching	ca. 1600
	TYR-O-H ring stretching	1520–1510
	C-O-H stretching	ca. 1270
	TYR-O ⁻ ring stretching	ca. 1600
	TYR-O ⁻ ring stretching	ca. 1500
HIS	TYR-O ⁻ C-O ⁻ stretching	ca. 1270
	NH ₂ ⁺ deformation	ca. 1660
PHE	ring stretching	ca. 1600
	ring stretching	ca. 1495
TRP	ring stretching	1550–1530
Bacteriochlorophyll and Bacteriopheophytin		
	10a-, 7c- ester C=O stretching	1750–1720
	9a-keto C=O stretching	1710–1670
	2a-acetyl C=O stretching	1650–1620
	skeletal C-C, C-N	ca. 1600
	skeletal C-C, C-N	ca. 1560
	skeletal	ca. 1520
Quinone	CH ₃ C-H bending	ca. 1375, 1340
	quinone C=O stretching	1660–1650
	quinone C=C stretching	1610–1600
	semiquinone anion C-O stretching	ca. 1490–1470
Water	semiquinone anion C-C stretching	ca. 1490–1460
	H-O-H bending	ca. 1660–1640

spectra in a separate section.

The availability of site-directed mutants in the primary donor environment was recently used to probe binding and interaction of the primary donor BChls (Nabedryk et al., 1992a-c). For the 'heterodimer' mutants His M200 → Leu and His L173 → Leu, the most prominent differences were found in the 1200–1600 cm^{-1} region, with strong bands missing, thus supporting the previous view based on comparison of light-induced difference spectra with monomeric BChl that bands in this range are characteristic for a dimeric BChl. The comparison of RCs with mutations near the primary donor like Leu

M160 → His, Leu L131 → His, and His L168 → Phe, which add one or more hydrogen bonds to the primary donor, had a large effect in the keto C=O region. For a detailed discussion of the effect of mutations around the primary electron donor, the reader is referred to a previous review by Hoff (1992).

While the spectra discussed above were obtained in steady-state upon continuous illumination, Thibodeau et al. (1990a,b) have recorded rapid-scan FTIR spectra to follow the decay after a pulse of light to create a charge-separated state. The bands of P⁺ (and those of Q⁻) decayed in a concerted manner, and no long-term molecular changes could be observed.

Recently, Burie et al. (1993) have used the *step-scan* technique to record light-induced spectra in the microsecond time domain. The spectral features characteristic for P^+ formation could already be detected 10 μs after flash excitation and were quite comparable to those found in steady-state spectra. The same authors used RCs with a chemically prerduced primary quinone acceptor to generate the triplet state of the primary electron donor. This triplet state, which gives rise to characteristic IR absorbance changes decaying with half-times of 130 μs , compares well with the triplet difference spectrum ($^3P/P$) obtained from the same group by steady-state FTIR spectroscopy at low temperature (Breton and Navedryk, 1993a,b). In the steady triplet spectrum, bands at 1648 cm^{-1} and 1619 cm^{-1} were assigned to the free and H-bonded 3 acetyl C=O groups of the primary electron donor, respectively. Peaks at 1749 and at 1740 cm^{-1} were assigned to the ester (13^2) C=O groups, and peaks at 1695 and at 1682 cm^{-1} to the 13^1 -keto C=O group. It was noted that all these bands were downshifted by 3P formation. The major conclusion given by the authors was that the triplet state is mostly delocalized over the two bacteriochlorophyll molecules.

Ultrafast time-resolved measurements of charge separation in RC have recently been performed by the Hochstrasser group (Hochstrasser et al., 1992; Cowen et al., 1993; Maiti et al., 1993) and by the Zinth group (Hamm et al., 1995). IR difference spectra at 70 ps and at 600 ps (Hochstrasser et al., 1992; Cowen et al., 1993) showed mainly band features which can be constructed from the static P^+ , H^- , and Q_A^- spectra, with some additional bands not observed in static spectra. At present, it is unclear whether the spectral features observed at shorter time intervals can be interpreted in terms of a transient reduction of the monomeric BChl. Hamm et al. (1995) have recorded the full spectral range from 1800 to 1000 cm^{-1} in the time domain from 200 fs to 1000 ps, and constructed spectra at $t=1$ ps (mainly P^+/P), 10 ps (mainly P^+H^-/PH) and 1000 ps ($P^+Q_A^-/PQ_A^-$). The 1 ps spectrum exhibits a shift of a band at 1684 cm^{-1} to 1666 cm^{-1} (attributed to a shift of the keto C=O group to lower frequencies) and several strong positive bands at 1532 cm^{-1} , 1458 cm^{-1} , and between 1300 and 100 cm^{-1} . However, no effect of P^+ formation on the ester C=O modes was noted.

V. Electrochemically-Induced FTIR Difference Spectra

Unlike light-induced FTIR difference spectra, which always involve a donor/acceptor couple, electrochemically-induced FTIR difference spectra offer the opportunity to investigate single cofactors and their redox transitions, in equilibrium with a potential applied via an electrode (Moss et al., 1990). The electrochemically-induced FTIR difference spectrum of the primary donor of *Rb. sphaeroides* and *Rp. viridis* RC was analyzed by Leonhard and Mäntele (1993). A difference spectrum (P^+/P) of *Rb. sphaeroides* RCs is reproduced in Fig. 1 (courtesy of Dr. M. Leonhard). It should be emphasized that this vibrational difference spectrum exclusively represents the primary donor reactions. This can be shown by titration of the IR difference spectrum, which yields the correct midpoint potential for all bands.

The difference spectrum obtained by electrochemical titration was extremely similar to the light-induced spectrum, a result which gives confidence to the previous assignments of the bands in the 1750 cm^{-1} to 1660 cm^{-1} region to the C=O modes of the primary electron donor. The sharp band at 1748 cm^{-1} can be assigned to the 13^2 ester C=O mode in the P^+ state. The apparent lack of a negative band for the P state was proposed to be explained by assuming strong hydrogen bonding in this state, resulting in extreme broadening. The bands at 1682 cm^{-1} and at 1702 cm^{-1} have been assigned to the 13^1 keto C=O modes of the primary electron donor in the P and P^+ states, respectively. Both the negative and the positive

Fig. 1. Electrochemically-induced FTIR difference spectrum of the primary electron donor in *Rb. sphaeroides*.

bands have some high-frequency shoulder.

Equilibration of the RC in $^2\text{H}_2\text{O}$ did not change the signals above approx. 1680 cm^{-1} . This allowed to exclude contributions from protonation/deprotonation of carboxylic groups at neutral pH, where these experiments were performed. However, effects of $^2\text{H}_2\text{O}$ were observed below 1680 cm^{-1} : a broad signal between 1680 cm^{-1} and 1600 cm^{-1} is removed in $^2\text{H}_2\text{O}$, hand in hand with appearing signals centered around 1450 and 1200 cm^{-1} . The authors explained this by the disappearance of an $^1\text{H-O-}^1\text{H}$ mode and the appearance of corresponding $^1\text{H-O-}^2\text{H}$ and $^2\text{H-O-}^2\text{H}$. This effect, however, was only observed in *Rb. sphaeroides* RCs.

The direct accessibility of the vibrational difference spectra for the BChls in situ by these electrochemical techniques probably presents the most direct access to the impact of the protein on the primary donor pigments, since it yields spectra free from contributions of other cofactors. For further work, this approach should be of use in combination with RCs from site-directed mutants, with RC containing isotopically labeled amino acids, and with RCs with pigments removed and exchanged by chemically-modified pigments.

VI. Vibrational Modes of the Quinones and Their Host Sites

Infrared difference spectra of the quinones in RCs ($\text{Q}_\text{A}^-/\text{Q}_\text{A}$ or $\text{Q}_\text{B}^-/\text{Q}_\text{B}$) without contributions from other cofactors have been obtained by various techniques:

(1) Electrochemically, by direct electrochemical reduction of the primary electron acceptor quinone Q_A by protein electrochemistry in a thin-layer cell (Mäntele et al., 1990b,d; Bauscher, 1991; Bauscher et al., 1993a,b). Selective reduction of Q_B in reaction centers containing a full Q_B complement has not been possible, mainly because Q_B in part became doubly reduced, but also because of equilibration of Q_B^- with Q_A .

(2) Photochemically/electrochemically, by subtraction of an electrochemically generated P^+/P difference spectrum from a light-induced $\text{P}^+\text{Q}_\text{A}^-/\text{PQ}_\text{A}$ or $\text{P}^+\text{Q}_\text{B}^-/\text{PQ}_\text{B}$ difference spectrum, both obtained from the same sample under identical conditions (Mäntele et al., 1990b; Bauscher, 1991; Bauscher et al., 1993a,b).

(3) Photochemically, by illumination of an RC sample in the presence of a strong electron donor and a mediator to rapidly rereduce P^+ , resulting in $\text{Q}_\text{A}^-/\text{Q}_\text{A}$ difference spectra for RC with the Q_B site blocked by a herbicide or in $\text{Q}_\text{B}^-/\text{Q}_\text{B}$ difference spectra with RC containing a full Q_B complement at much weaker illumination. Principally, these spectra contain contributions from the electron donor which becomes partly oxidized and undergoes chemical reactions through this procedure, however, convincing evidence could be presented that these signals were either broad (arising from a reaction in aqueous solution) or negligible in the spectral region under consideration (Breton et al., 1991a,b).

(4) Photochemically/ electrochemically, by flash-induced formation of $\text{P}^+\text{Q}_\text{A}^-/\text{PQ}_\text{A}$ or $\text{P}^+\text{Q}_\text{B}^-/\text{PQ}_\text{B}$ (whichever functioned as the terminal electron acceptor in the RC), rapid rereduction of P^+ by cytochrome (Cyt) c_2 present in the sample, and rereduction of the oxidized Cyt c_2 by protein electrochemistry, resulting in net $\text{Q}_\text{A}^-/\text{Q}_\text{A}$ or $\text{Q}_\text{B}^-/\text{Q}_\text{B}$ difference spectra (Bauscher, 1991; Bauscher et al., 1993a,b, 1994).

In addition to these 'single' $\text{Q}_\text{A}^-/\text{Q}_\text{A}$ or $\text{Q}_\text{B}^-/\text{Q}_\text{B}$ difference spectra, double difference spectra $\text{Q}_\text{A}^-/\text{Q}_\text{B}^-$ were obtained by various techniques:

(5) By illumination of an RC sample at different cryogenic temperatures to obtain $\text{P}^+\text{Q}_\text{A}^-/\text{PQ}_\text{A}$ difference spectra (at approx. 100 K) or $\text{P}^+\text{Q}_\text{B}^-/\text{PQ}_\text{B}$ difference spectra (at ~ 260 K) (Nabedryk et al., 1990; Bagley et al., 1990).

(6) By time-resolved FTIR spectroscopy making use of the rapid-scan technique and the different reaction half times of approx. 60 ms for charge recombination from Q_A and approx. one second for recombination from Q_B (Thibodeau et al., 1990a,b). In this case, FTIR spectra recorded immediately (within 100 ms) after charge separation by a light pulse yielded difference spectra from all charge-separated states ($\text{P}^+\text{Q}_\text{A}^-/\text{PQ}_\text{A}$ and $\text{P}^+\text{Q}_\text{B}^-/\text{PQ}_\text{B}$) in RCs containing an intermediate (ideally 50%) Q_B complement, and spectra recorded at extended time intervals (> 500 ms) yielded spectra reflecting predominantly the $\text{P}^+\text{Q}_\text{B}^-/\text{PQ}_\text{B}$ state. Double difference spectra (late minus early) were obtained using a normalization

procedure to make P and P⁺ bands disappear.

(7) By recording light-induced $P^+Q_A^-/PQ_A$ and $P^+Q_B^-/PQ_B$ difference spectra from two different samples (one with a full Q_B complement, the other with the Q_B site empty or blocked with a herbicide) and using a similar normalization to remove the P and P⁺ contributions (Buchanan et al., 1990, 1992).

(8) A further technique using time-resolved IR spectroscopy in the microsecond time domain (Mäntele et al., 1990) also yields double difference spectra. Here, the transient IR signals after laser flash illumination measured at different IR probing wavelengths provided by tunable IR diode lasers were recorded straightforwardly and analyzed for reaction time constants in the μ s to ms time domain, which can be ascribed to $Q_A \rightarrow Q_B$ electron transfer.

The approaches to generate IR difference spectra which give access to the vibrational modes of Q_A , Q_B , and their respective protein host sites differ considerably, and we should keep in mind that deviations in the band structures can arise from the experimental conditions rather than being due to experimental inaccuracies. For example, the methods (1) to (7) assess the relaxed state of the protein after Q_A or Q_B formation, whereas the approach using microsecond kinetics (8) monitors 'real-time' kinetic processes upon electron transfer to Q_A and from Q_A to Q_B . A second difference is the involvement of charge-separated states in the methods (2), (5), (6), (7) and (8), which may result in contributions from more distant residues because of the formation of transprotein dipoles. Yet, the common feature of all different methods is that the strong vibrational modes of the primary electron donor, which dominate in light-induced difference spectra of charge separation and make the detection of quinone or quinone site modes in the latter difficult (Nabedryk et al., 1990) or impossible, could be suppressed.

As an example for the IR signals obtained upon Q_A or Q_B reduction, figure 2 shows the Q_A^-/Q_A and Q_B^-/Q_B FTIR difference spectra obtained according to method (4) described above, i.e. with cytochrome c as secondary electron donor in a reaction probably closest to native RC electron transfer. These seemingly complicated FTIR difference spectra, at first glimpse, allow a number of conclusions:

(1) The changes in the vibrational spectrum upon

Q_A or Q_B reduction are minute, at most ≈ 0.5 mOD or ca. 5×10^{-4} of the total absorbance, and in general much smaller. This size of absorbance changes is in agreement with the small IR extinction coefficients of, for example, C=O or C=C bonds, and supports the view that the signals in fact correspond to alterations of individual bonds which, however, can be followed reproducibly by the FTIR techniques described.

(2) The spectra obtained for Q_A or Q_B reduction are significantly different, although the same type of quinone (UQ-10) occupies both sites in *Rb. sphaeroides* RCs. It is thus evident that the changes in the vibrational spectrum are largely dominated by the site rather than arising from the quinone molecule itself.

(3) This point (2) is illustrated by comparison of these spectra with the electrogenerated Q^-/Q difference spectrum of UQ-10 in the non-protic solvent tetrahydrofuran (Bauscher and Mäntele, 1992), which is relatively simple and shows the disappearance of the C=O and C=C modes of the neutral quinone at approx. 1650 cm^{-1} and 1610 cm^{-1} , respectively, as well as the appearance of C-O and C-C modes from the semiquinone anion in a broad band around 1488 cm^{-1} . The difference spectra shown in figure 2 contain a substantial number of bands in excess of those that have been found in these model spectra.

Thus, the message is that Q_A or Q_B reduction has a considerable impact on their respective protein sites, and possibly even on more distant residues. This impact seems to be much higher at the quinone side than at the donor side (see above), a fact which may arise from the spatial density of the excess negative charge on the acceptor side, which is considerably higher than that of the 'hole' on the donor side. We may hypothesize that the changes in the vibrational spectrum reflect the solvation of the negative charge.

The signal amplitudes in Q_A^-/Q_A or Q_B^-/Q_B difference spectra are small, at least a factor of five smaller for the strongest bands as compared to the strongest bands of the difference spectra obtained from the donor side. This may explain why the quinone signals have proven elusive in earlier light-induced difference spectra.

Model spectra of quinones have been an essential tool for the 'fishing' of assignments in these quinone

spectra, especially since FTIR difference spectra between neutral quinones and their electrochemically generated anions (as well as dianions and quinols) became available for a number of relevant quinones and their analogs which can be incorporated in the Q_A or Q_B sites (Bauscher and Mäntele, 1988, 1992; Bauscher et al., 1989, 1990a,b, 1991; Bauscher, 1991). Most of these model difference spectra are remarkably simple in comparison with the highly structured and complex Q_A^-/Q_A or Q_B^-/Q_B difference spectra. For the further discussion, the complicated spectra with numerous protein modes necessitate to distinguish between Q_A , Q_A^- , Q_B , and Q_B^- as the respective quinone 'species' or as quinone-protein 'states'.

A. Genuine and Non-Genuine Quinone Vibrational Modes

Most Q_A^-/Q_A and Q_B^-/Q_B difference spectra have been analyzed in the 1800–1000 cm^{-1} region, though band structures also appear above and below this range. We can discern four major frequency regions where sharp and structured bands appear. The strongest signals are found in the 1700–1600 cm^{-1} region, where the quinone C=O and C=C modes, but also peptide C=O modes and modes from some amino acid side chain residues are expected. This region is rather complex and contains at least 6–8 signals, the strongest at 1684 (–), 1666 (–), 1647 (–), 1627 (–) cm^{-1} in Q_A^-/Q_A difference spectra and at 1684 (–), 1661 (–), 1650 (+), 1638 (–) and 1616 cm^{-1} (–) in Q_B^-/Q_B difference spectra, (we follow here the convention that negative bands are counted to the Q_A (Q_B) state, and positive bands to the state of the corresponding semiquinone anion radicals). According to model quinone spectra (Bauscher and Mäntele, 1988, 1992; Bauscher, 1991, Bauscher et al. 1989, 1990a,b, 1991), the C=O and the C=C modes of the neutral species should appear as negative bands in this region between approx. 1670 and 1630 cm^{-1} (C=O) and at approx. 1610–1600 cm^{-1} (C=C). Although one is tempted to ascribe one of the strong negative bands in the Q_A^-/Q_A or Q_B^-/Q_B difference spectra to the quinone C=O or C=C mode, detailed analysis using RCs with isotopically-labeled quinones or structurally different quinones has shown that the majority of the bands in this range arises from the quinone site rather than from the quinone itself.

In the 1600 cm^{-1} – 1500 cm^{-1} region, mainly signals from aromatic amino acid side chain residues (ring

stretching modes, see Table 1) are expected. A second possible origin of signals is the amide II mode (coupled C=O stretching and N-H bending). Difference bands arising from the amide II mode should show some correlation with signals from the amide I mode, i.e. whenever an amide I mode is perturbed resulting in a signal in the 1600 cm^{-1} to 1700 cm^{-1} range, a corresponding amide II signal should appear.

The spectral region below 1500 cm^{-1} is governed by the C-O and C-C modes of Q^- between approx. 1500 cm^{-1} and 1460 cm^{-1} and thus can be used to probe the in situ binding and interaction of the semiquinone anion.

The 1700 cm^{-1} – 1750 cm^{-1} range is potentially the most interesting one, since it contains the COOH modes of protonated Asp and Glu residues and should provide a means of following protonation/deprotonation of amino acid side chain residues in response to electron transfer. A positive signal in this range would correspond to protonation ($\text{COO}^- + \text{H}^+ \rightarrow \text{COOH}$), a negative signal to deprotonation ($\text{COOH} \rightarrow \text{COO}^- + \text{H}^+$). The location of the C=O group in this range depends on solvation: a noninteracting group would be located at the upper end of the scale; H-bonding and polar environment would lower the C=O frequency to as low as approx. 1700 cm^{-1} . In addition, the location and width of the band contain information on the degree of conformational flexibility and accessibility. Apart from protonation and deprotonation, difference signals in this range could also be generated by changes of environment without changing the degree of protonation. In addition to signals from Asp and Glu side chains, there is a chance that quinone reduction might affect neighboring pigments (the bacteriopheophytin on the L or M branch) by electrostatic effects and cause signals from their ester or keto C=O groups.

B. Assignment of Genuine and Non-Genuine Quinone Modes

Assignments for bands arising from the modes of the quinone molecule itself have been proposed on the basis of quinone extraction and reconstitution with either isotopically labeled (Bagley et al., 1990; Thibodeau et al., 1990; Breton et al., 1994) or structurally different quinones (Breton et al., 1991a,b, 1992b; Bauscher et al., 1993a,b).

In a first paper by Bagley et al., $P^+Q_A^-/PQ_A$ and $P^+Q_B^-/PQ_B$ difference spectra were compared for

Rb. sphaeroides RC containing native and ^{13}C or ^{18}O labeled UQ-10. It was noted that a strong band in Q_A^-/Q_A difference spectra at 1649 cm^{-1} did not shift upon isotope substitution, thus excluding a vibration from Q_A itself. Small effects were seen at around 1625 cm^{-1} and 1618 cm^{-1} for ^{13}C and ^{18}O labeling. Thus, a C=O stretching mode could not be detected unambiguously. However, a band at 1604 cm^{-1} in native RCs still present for ^{18}O -UQ-10 RCs, but absent for ^{13}C -UQ-10 RCs was tentatively assigned to the quinone C=C mode for Q_A . In a second study, Thibodeau et al. (1990) used time-resolved FTIR spectroscopy to construct $Q_A^-Q_B^-/Q_A^-Q_B^-$ double difference spectra according to method (6) described above. Bands at 1670 cm^{-1} and at 1652 cm^{-1} in these spectra remained at the same position when Q_A and Q_B were replaced by ^{13}C UQ-10 and thus could be excluded as candidates for *genuine* quinone modes. However, a complex negative band at $1493\text{--}1480\text{ cm}^{-1}$ for the native UQ-10 shifted to 1434 cm^{-1} and was thus attributed to the C-C modes of the semiquinone anions, without excluding the possibility of C-O contributions.

A more thorough analysis using isotopes was recently carried out by Breton et al. (1994), giving final hints for the identification of the C=O and C=C mode(s) on the basis of constructed double-difference spectra from pairs of Q_A^-/Q_A spectra obtained from RC reconstituted with $^{18}\text{O}/^{16}\text{O}$ UQ-6 and UQ-1, $^{13}\text{C}/^{12}\text{C}$ UQ-8, and $^{13}\text{C}^{18}\text{O}/^{12}\text{C}^{16}\text{O}$ UQ-8. The double difference spectra revealed two C=O bands at 1660 cm^{-1} and at 1628 cm^{-1} and one C=C band at 1601 cm^{-1} for the neutral quinone. The inequivalence of the two C=O bands was explained by the asymmetrical bonding properties of the site as already proposed from X-ray crystallography and quinone exchange experiments. In particular, the isotopic shifts observed for the various quinone C=O and C=C bands indicated that the mixing of C=O and C=C modes is affected by the site, and that the 1628 cm^{-1} and the 1601 cm^{-1} bands of UQ-6 *in vivo* are highly mixed. Since no splitting of the C-O mode after photoreduction was observed, it was concluded that more symmetrical bonding was prevalent after photoreduction.

Replacement of the native UQ-10 at the Q_A site of *Rb. sphaeroides* RC by naphthoquinone analogs (Breton et al., 1992b) and by duroquinone, anthraquinone and 2-Cl-anthraquinone (Bauscher et al., 1993b) has also been used for tentative Q_A C=O and C=C assignments, which were in agreement with the isotope replacement studies discussed above.

In general, these replacements result in minor perturbations of the spectra in the 1700 cm^{-1} to 1600 cm^{-1} range, but show substantial differences with respect to the native quinone in the range between 1500 and 1400 cm^{-1} , where the C-C and C-O bands of the semiquinone anion appear. Interestingly, the Q_A^-/Q_A spectra of *Rb. sphaeroides* RC reconstituted with vitamin K_1 are very similar in this range to Q_A^-/Q_A spectra of *Rp. viridis* RCs (Breton et al., 1992b). It is important to note that the alterations of the quinone site by bulkier quinones or quinones with Cl substituents, whenever they are functioning as electron acceptors, do not affect strongly the conformationally-sensitive $1700\text{--}1600\text{ cm}^{-1}$ range. Moreover, the spectral range above 1700 cm^{-1} , which reflects signals from protonated Asp and Glu side chain groups, is not altered at all. This range will be described in more detail below.

An analysis of the *non-genuine* quinone modes, i.e. of those arising from the amino acids lining the binding site(s) and from more distant groups is still in its beginning. Clearly, this task needs isotopically-modified amino acids entered biosynthetically and a multitude of site-directed mutations for a complete analysis, and appears to be a Sisyphean task, even if shared among many research groups¹.

The first assignment of a protein signal associated with quinone reduction was made by Nabedryk et al. (1990). A signal at 1650 cm^{-1} present in $P^+Q_A^-/PQ_A$ difference spectra and not in the $P^+Q_B^-/PQ_B$ difference spectra from *Rb. sphaeroides* RCs, but in both spectra for *Rp. viridis* RCs, was interpreted in terms of a conformational change of the protein backbone near Q_A and tentatively assigned to the peptide C=O of a conserved alanine residue in the Q_A pocket.

Further possible tentative assignments of bands to protein modes were proposed by Bauscher et al. (1993a) on the basis of the proximity of amino acids to the primary and secondary quinone, and confirmed or rejected by analyzing the effect of $^1\text{H}_2\text{O} \rightarrow ^2\text{H}_2\text{O}$ substitution (Bauscher et al., 1994). A small shift of a differential signal at $1552(-)/1560(+)$ to $1548(-)/1556(-)\text{ cm}^{-1}$ upon $^1\text{H} \rightarrow ^2\text{H}$ exchange was used for assignment to the aromatic stretching mode of a Trp residue, and Trp M252 in van-der-Waals contact

¹ This reminds me of an FTIR paper which we had submitted some time ago, and which contained some highly structured difference spectra. It returned with the following reviewers comments: '... I have counted approx. 50 bands in your spectra, of which you have assigned only five. Please resubmit the paper when you have assigned the rest of the peaks ...'

with Q_A was proposed as a candidate. Several bands between 1600 cm^{-1} and 1700 cm^{-1} could tentatively be assigned to amide I modes, since they experience only small shifts or none for $^1\text{H} \rightarrow ^2\text{H}$ exchange. The positive band at 1538 cm^{-1} in Q_B^-/Q_B difference spectra only present in $^1\text{H}_2\text{O}$, was assigned to an amide II mode. Overall, these tentative assignments present reasonable hints and may help to select and to reduce the number of site-directed mutations needed for a conclusive picture of the microstructural changes at the Q_A and Q_B site.

C. Protonation/Deprotonation of Amino Acid Side Chains upon Quinone Reduction in the Reaction Centers

The bands in FTIR difference spectra between 1700 cm^{-1} and 1780 cm^{-1} are not affected by the substitution of quinones by (even exotic) analogs, provided that these function as electron acceptors. However, band positions and intensities are changed by $^1\text{H} \rightarrow ^2\text{H}$ exchange (Bauscher et al., 1994). The fact that model quinones do not show any mode in this range has led to the assumption that the appearance and disappearance of C=O modes of Asp and Glu side chains is predominantly responsible for spectral changes in this range, thus making it an ideal spectral region for probing protonation/deprotonation reactions in the RC. The major difference signals for Q_A^-/Q_A FTIR difference spectra are a negative peak at 1732 cm^{-1} and positive peaks at 1724 and 1712 cm^{-1} , respectively. In Q_B^-/Q_B difference spectra, a negative signal at 1738 cm^{-1} and a positive signal at 1725 cm^{-1} are observed (the numbers refer to the spectra shown in Fig. 2; peak intensities and positions may vary slightly for other spectra reported). As a simple working hypothesis, one could assume that the reduction of Q_A results in partial deprotonation of a group absorbing at 1732 cm^{-1} and partial protonation of groups absorbing at 1724 and 1712 cm^{-1} . Consequently, reduction of Q_B results in deprotonation of a group absorbing at 1738 cm^{-1} and protonation of a group absorbing at 1725 cm^{-1} . In the case of Q_B reduction, the residues involved could be the ones lining the binding sites; for Q_A , however, one would have to assume rather distant residues (the closest Asp or Glu residues are at least $8\text{--}10\text{ \AA}$ away).

In addition to these steady-state FTIR spectra which clearly reflect the relaxed state of the protein upon reduction of Q_A and Q_B , time-resolved IR spectroscopy using tunable diode lasers has provided

Fig. 2. FTIR difference spectra (Q_A^-/Q_A and Q_B^-/Q_B) of the reduction of the primary and secondary electron acceptor quinone in *Rb. sphaeroides* RCs (courtesy of Dr. M. Bauscher):

insight into the dynamic nature of these protonation/deprotonation processes. Hienerwadel et al. (1992) have reported IR signals with microsecond time resolution at various frequencies between 1700 and 1450 cm^{-1} which show the disappearance and appearance of modes in real-time. In addition to signals rising/decaying immediately, which were attributed to primary charge separation $PQ_A \rightarrow P^+Q_A^-$, signals with half-times of $60\text{--}100\text{ ms}$ and approximately 1 sec , which were attributed to charge recombination from Q_A and Q_B , respectively, and signals with half-times of approx. $100\text{ }\mu\text{s}$ which were attributed to modes changing upon $Q_A \rightarrow Q_B$ electron transfer, it was noted that transient IR signals in the 1700 to 1750 cm^{-1} range exhibit half times of approx.

1 ms. These signals were proposed to arise from Asp or Glu side chain protonation/deprotonation reactions.

Recently, Hienerwadel et al. (1995) have reported a detailed analysis of the temporal and spectral distribution of these signals in the 1700 cm^{-1} to 1760 cm^{-1} range. Figure 3a shows the major signal at 1725 cm^{-1} . The fast rising component originates from primary charge separation $\text{PQ}_A \rightarrow \text{P}^+\text{Q}_A^-$ and was suppressed for the display of the three-dimensional representation of the transient signals shown in Fig. 3b. Adopting the above working hypothesis, namely that the absorbance changes in this range predominantly represent protonation/deprotonation reactions at Asp or Glu residues, this representation corresponds to a *real-time video* of proton movements in the RC upon $\text{Q}_A^-\text{Q}_B \rightarrow \text{Q}_A\text{Q}_B^-$ electron transfer.

A total of two negative signals (1698 cm^{-1} and 1716 cm^{-1} , respectively) and three positive signals (1706 cm^{-1} , 1725 cm^{-1} , and 1732 cm^{-1} , respectively) is seen. Global fit analysis of these signals showed that they can be described by two kinetic processes with approximately 1 ms and approx. $180\text{ }\mu\text{s}$ half time at wavelength-dependent amplitude proportions. Both kinetic components depend strictly on electron transfer between Q_A and Q_B and are thus absent in terbutryn-treated RC (see Fig. 3a). The only evidence for transient signals in the absence of Q_B is around $1730\text{--}1740\text{ cm}^{-1}$, where weak components in the μs domain were detected (Hienerwadel et al., 1995). The attribution of the major signal at 1725 cm^{-1} to an Asp or Glu COOH group is further confirmed by the absence of the signal at this frequency for the COO^2H group of RCs equilibrated in $^2\text{H}_2\text{O}$. Analysis of the signal for RCs from site-directed mutants, where a Glu L212 Gln mutant showed a complete absence of the signal, while it was little affected in an Asp L213 Asn mutant (Hienerwadel et al., 1995). This provided the final clue to identify the residue involved as Glu L212. It was further concluded from the sign and amplitude of the signal that Glu L212 takes up approx. 0.3 to 0.6 H^+ upon formation of Q_B^- . This calculation of the stoichiometry was based upon an the (integrated) extinction coefficient of Glu side chain residues in model compounds, which may not be a good approximation for a Glu residue embedded in the protein. The proton uptake was found to show little variation with pH, in disagreement with a Henderson-Hasselbalch titration curve expected for a single titrating residue, and thus taken as evidence for the titration of Glu L212 in a cluster of strongly interacting ionizable groups (Hienerwadel et al., 1995).

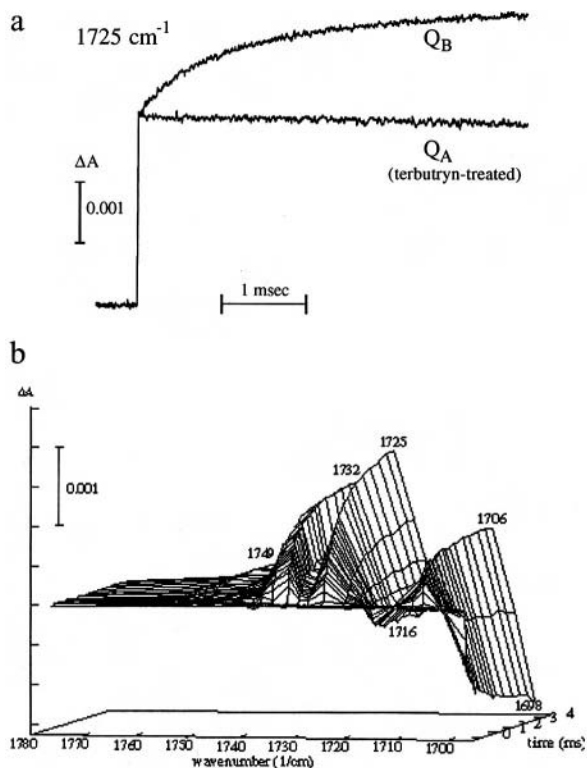

Fig. 3. a) kinetic IR signal at 1725 cm^{-1} . b) 3D representation of the kinetic IR signals between 1690 cm^{-1} and 1760 cm^{-1} . (Courtesy of Dr. R. Hienerwadel.)

The appearance of a COOH mode from Glu L212 should be strictly correlated with the disappearance of the antisymmetric and symmetric COO^- modes. Hienerwadel et al. (1992b) have proposed that a negative transient signal at 1617 cm^{-1} which closely matches the kinetics of the 1725 cm^{-1} signal and is also absent in RC lacking Q_B , could arise from the disappearing COO^- mode.

One might be tempted to attribute the entire set of transient IR signals between 1700 cm^{-1} and 1760 cm^{-1} to deprotonation and protonation processes at specific Asp/Glu residues or to shifts of the C=O modes of protonated Asp/Glu residues upon Q_B^- formation. This may be oversimplified, since the signals can be partly explained assuming IR absorbance changes upon reduction of Q_A which then decay upon $\text{Q}_A \rightarrow \text{Q}_B$ electron transfer. In fact, the transient IR difference spectrum between 1760 cm^{-1} and 1690 cm^{-1} can be modeled by the sum of a Q_B^-/Q_B and of an inverted Q_A^-/Q_A FTIR difference spectrum. As already discussed above, an alternative but less likely interpretation of signals in this range is that shifts of ester and keto C=O modes from the

pigments lead to additional signals.

Further kinetic IR and steady-state FTIR studies on RC from site-directed mutants have indicated that a another group involved in the cluster of ionizable residues is Asp L210, presumably associated with the smaller positive IR signal at 1706 cm^{-1} (see Fig. 3b.). In ongoing experiments, a complete pH dependency of the transient IR signals for several mutant RCs is recorded for each mutant RC, since the removal of the ionizable group may affect the pK values of other groups in the cluster.

The question is whether a conclusive interpretation can be given for the signals in the 1700 cm^{-1} to 1600 cm^{-1} range. The comparison with quinone model compounds has indicated that only a small fraction is due to modes from the quinone itself, and the majority presumably arises from peptide carbonyl groups. One possible explanation is that reduction of Q_A or Q_B strongly polarizes or depolarizes the peptide $C=O$ bonds of neighboring groups, depending on their orientation relative to the charge density on the respective quinone. Gunner (personal communication) has pointed out the role of the backbone carbonyl groups in stabilizing buried charges in the protein, and it may well be that the signals discussed here are a manifestation of this process.

D. Can IR Spectroscopy Provide a Model for H^+ Transfer to Q_B ?

The data presently available from steady-state FTIR difference spectroscopy and time-resolved IR spectroscopy on the molecular processes at the Q_B site upon Q_B^- formation suggest a role of the site in maintaining a favorable electrostatic situation. The movements of protons in the site and the net proton uptake of the RC upon Q_B^- formation may represent a rearrangement of charges to form local countercharges for the negative charge on the quinone (Q_B^-), which is predominantly localized on the quinone $C=O$ oxygens. On the basis of the present data, which have identified Glu L212 (and tentatively also Asp L210) as groups that increase protonation, the following scenario summarized in Fig. 4 is proposed.

In this scenario, we assume Q_B to be surrounded by a cluster of several ionizable residues, which interact strongly and form a pattern of charges around Q_B . Note that the arrangement and the distances of the three residues with respect to Q_B shown in Fig. 4 are purely schematic. This cluster may include Glu L212, Asp L213, and Asp L 210, as well as other residues identified by X-ray structural analysis to be

Fig. 4. Schematic representation of Q_B surrounded by a cluster of ionizable residues forming a delocalized countercharge.

close to Q_B . Positively charged amino acid residues may also be part of the cluster; however, they are omitted in this simplified scheme.

In this scenario, the residues located closest to the quinone carbonyls are proposed to be partly or fully ionized for neutral Q_B . Upon formation of Q_B^- , excess negative charge resides on either quinone carbonyl oxygen. It is now conceivable that this excess charge induces pK shifts on the neighboring carboxyl group residues. These shifts of pK may lead to internal reequilibration of protons in the cluster as well as to a net proton uptake. Hiernerwadel et al. (1995) have hypothesized that the fast kinetic components that correspond to those of the electron transfer (approx. $100\text{ }\mu\text{s}$) could be due to movements of protons directly correlated to electron transfer, and the slow kinetic components (approx. 1 ms) could be due to net proton uptake.

In order to provide details of this scenario, the rates of electron transfer, proton transfer, and proton uptake need to be determined separately. Hiernerwadel (1993) has analyzed the rate of reduction of Q_B by following the rate of appearance of its semiquinone $C-O$ mode at 1478 cm^{-1} . This rate was found to be much higher than the shift of the pheophytin signal at $750\text{--}760\text{ nm}$, which is the 'classical' monitor for $Q_A \rightarrow Q_B$ electron transfer. The half-time found (approx. $150\text{ }\mu\text{s}$ at 6°C) was much shorter than that of the protonation of Glu L212 (approx. 1 ms at 6°C) and was almost temperature-independent. The protonation of Glu L212 and the shift of the pheophytin signal, however, match perfectly in their kinetic parameters and their temperature dependence. Consequently, Hiernerwadel et al. assumed that the pheophytin absorbance responds to changes of

protonation rather than to the charge of the quinone.

It may be difficult to fully separate protonation and electron transfer events, since any movement of charges in the RC will probably result in a concerted electrostatic reaction. In this line, we could hypothesize that the transient IR signals seen in the absence of Q_B represent alterations in the empty Q_B site caused by formation of Q_A^- . One could imagine these alterations as a means of 'preparing' a favorable electrostatic situation for $Q_A \rightarrow Q_B$ electron transfer.

For the first turnover of the RC and Q_B^- formation, the protonation and deprotonation processes seen by kinetic IR and FTIR spectroscopy seem to reflect the response of an *electrostatic reaction field* which account for local electroneutrality. The groups forming this cluster may also be involved in supplying the protons for protonation of Q_B upon transfer of the second electron to form the quinol. Kinetic IR experiments are in progress to follow the fate of the Glu L212 for the second turnover; however, they are complicated by the fact that a rapid secondary donor to the RC is involved which can contribute to the difference spectra, and that quinone/quinol exchange at the Q_B site has to proceed before the system can be repetitively excited by double flashes. Nevertheless, we may be confident that within the next years kinetic IR and FTIR spectroscopy will bring some light into the pathway of protons to Q_B .

VII. RC-Associated Cytochromes

In the cytochrome subunits of RC from *Rp. viridis*, *Chloroflexus (Cf.) aurantiacus*, *Rc. gelatinosus* and others, c-type hemes are bound and given a wide range (almost 0.5V) of redox potentials (see Chapter 36 by Nitschke and Dracheva). This presents an example of how a protein can modulate the spectral and redox properties of a cofactor by varying charged residues near the hemes, placing water molecules into the heme pocket, and playing with the ionization state of the heme propionates. Gunner and Honig (1990, 1991) have calculated the electrostatic potential in the cytochrome subunit of the *Rp. viridis* RC and pointed out the weight of the factors determining the midpoint potential.

IR spectroscopy has been used to seek for experimental evidence for the nature of the heme-protein interactions and for the role of the protein in stabilizing a heme redox state. Nabedryk et al. (1991)

have obtained light-induced $\text{Cyt}_{\text{ox}}Q^-/\text{Cyt}_{\text{red}}/Q$ FTIR difference spectra and subtracted the Q^-/Q contributions by normalizing to bands previously assigned to quinone reduction. They obtained reduced-minus-oxidized difference spectra of the two high-potential hemes (c-559 and c-556) as well as of one low-potential heme (c-552). Fritz (1995) has used electrochemically-induced FTIR spectroscopy to directly generate the reduced-minus-oxidized difference spectra of all four hemes of the *Rp. viridis* reaction center and of the isolated tetraheme subunit from *Cf. aurantiacus* reaction centers. The difference spectra obtained from the *Rp. viridis* cytochrome by either method agree in their main band features. The differences observed for smaller peaks may be the result of the different states of the RC used: the first approach involves charge-separated states, while in the second approach the hemes are in thermodynamic equilibrium with the applied potential.

In general, the band amplitudes in the reduced-minus-oxidized IR difference spectra are about 5 times smaller than those observed for primary donor oxidation on comparable samples, and on the order of the signals observed for the quinones. Again, we may conclude that no major rearrangement occurs in the protein structure as a result of the redox transitions. The difference spectra have a common signature in the conformationally-sensitive 1700 cm^{-1} to 1600 cm^{-1} spectral region: two negative bands at 1658 cm^{-1} and at 1686 cm^{-1} and two positive bands at 1634 cm^{-1} and at 1676 cm^{-1} are observed. Further deviations among the different hemes were observed in the amide II region, where the c-559 high-potential heme exhibits a negative band doublet at 1558 and 1540 cm^{-1} .

In the difference spectra, fairly strong signals appear between 1680 and 1710 cm^{-1} , a region characteristic for the heme propionates. Signals in this region were also observed in reduced-minus-oxidized FTIR difference spectra of different cytochromes *c* (Moss et al., 1990) and of cytochromes c_2 from *Rp. viridis*, *Rb. sphaeroides*, and *Rs rubrum* (Baymann, 1991). and tentatively assigned to the heme propionate C=O. This immediately implies that one or both propionate groups are at least partially protonated at neutral pH, where these experiments were performed. Furthermore, a differential signal would imply that the protonation state changes upon the redox transition. At present, the problem seems unresolved for the *Rp. viridis* RC, where electrostatic calculations (Gunner and Honig, 1990, 1991 and

Gunner, personal communication) rather favor ionized heme propionates, while the FTIR spectra provide some evidence for propionate C=O signals.

In contrast to *Rp. viridis* RC, the cytochrome subunit of *Cf. aurantiacus* can be removed from the RC and investigated separately. Fritz (1995) has analyzed the FTIR difference spectra of the isolated subunit obtained by electrochemical oxidation/reduction. In this case, the IR difference bands could be titrated and thus assigned to the individual hemes. As in the case of the *Rp. viridis* cytochrome, each heme exhibits a characteristic set of IR signals, including difference bands which can be tentatively attributed to the propionate C=O group.

In the case of the isolated tetraheme cytochrome subunit of *Cf. aurantiacus*, the titration of the IR difference signals offered an interesting additional application. In this tetraheme subunit, all hemes exhibit α -bands at the same wavelength, which makes an optical titration of all four hemes almost impossible. Fritz (1995) has thus used the titration of IR difference signals to determine the redox midpoint potentials of the four hemes. In the IR difference spectra, bands common to all four hemes, to three or two hemes only, but also characteristic for individual hemes were detected, thus allowing very precise titrations.

We currently see the studies of the cytochrome subunits at an early stage, and particularly weak on the assignments of vibrational modes. Nevertheless, it appears that the heme protein interactions and the stabilization of redox states translate to the vibrational difference spectra and make this a worthwhile approach.

VIII. Conclusions

The past decade has seen vibrational IR spectroscopy of RCs developed as a new technique which had earlier gained interest only for the probing of CO binding in heme proteins and for retinal proteins. The major outcome seems to be that IR spectroscopy can be used to probe the relaxation of the protein in electron transfer processes (not only in photosynthetic RCs). Even within these ten years, the progress from easy-to-obtain light-induced FTIR difference spectra to the more sophisticated IR difference spectra of single cofactors or to transient spectra showing slow or even ultrafast electron transfer steps in real-time was breathtaking (at least for me).

Among the lessons learned from IR spectroscopy, the one that no large conformational changes occur with electron transfer was the first one. It taught us to look closer and search for microconformational changes in the vicinity of cofactors, which are clearly present and most pronounced (and best characterized) for the quinones. Although the scenario shown in Fig. 4 may not fully correspond to reality, it may illustrate why the protein is sometimes called an 'optimized solvent,' and I find it very helpful for the understanding of the role of the protein pocket of a cofactor.

The deficit of IR spectroscopy of RCs is certainly the question of the band assignment (here I agree with a reviewer's opinion mentioned in the footnote in section VI.B). It is clear that further progress will have to include more experiments using site-directed mutagenesis and isotope labeling, but I doubt that we shall ever be able to fully explore the wealth of information contained in an IR difference spectrum. Yet, focusing on 'hot' spectral regions like the carboxyl group ranged between 1700 cm^{-1} and 1750 cm^{-1} is most promising, and I am optimistic that a full mapping of this range is within reach.

Ultrafast IR spectroscopy of RC is just at its beginnings: The present data range from several hundred femtoseconds to nanoseconds and open the possibility to follow the role of the protein in the primary steps. Soon these experiments will have evolved from mostly being technical highlights, and the search for protein signals in primary charge separation will be a rewarding task. Altogether, the use of IR spectroscopy on the RC over a wide wavelength range and, even more important, over more than twelve orders of magnitude in the time domain, will help us to understand the role of the protein matrix in charge separation, stabilization and photosynthetic energy conversion.

Acknowledgments

I would like to thank my coworkers involved in the work summarized here and the many colleagues in the field for valuable discussion and for providing information on unpublished work and on work in press. Our own work in this field has only been possible because of continuous financial support from the Deutsche Forschungsgemeinschaft through several grants and a Heisenberg fellowship.

Summary

Bacteriochlorophylls at sites $B_{A,B}$ and bacteriopheophytins at sites $H_{A,B}$ can be exchanged against modified pigments in reaction centers of purple bacteria. The exchange can be carried out at both branches simultaneously (exchange of B_A and B_B , of H_A and H_B), or selectively at either the A- or B-branch. Pigment modifications include both the peripheral substituents of the tetrapyrroles and the central metal. The structural requirements for all four binding sites are discussed, as well as the stabilization of the reaction centers by the cofactors. The modified reaction centers were used to assign overlapping absorption bands, as well as to study pigment-protein- and pigment-pigment-interactions, singlet and triplet energy transfer, and light-induced electron transfer.

I. Introduction

Cofactor modifications complement site-directed mutagenesis in evaluating the structural and functional determinants of reaction centers (RC); the two techniques can be used separately or in combination. For the preparation of RCs with modified tetrapyrrolic pigments, there exist currently three different routes: 1) Exchange of chromophores into native or partly denatured RCs by chemical or enzymatic means. 2) Modification of binding sites to incorporate different chromophores, e.g. by mutagenesis. 3) Mutagenic modifications of the pigments' biosynthetic pathways. Alternative routes which have been applied to other photosynthetic pigment-protein complexes, involving the chemical or enzymatic modification of chromophores within the RC¹ or the complete reassembly from the components (apoproteins and cofactors) have as yet been unsuccessful. This chapter deals with recent results obtained by a method of type (1) which was developed several years ago in our laboratory (Struck, 1990; Scheer and Struck, 1993). It allows us to introduce, singly or in combination, modified pigments into the sites B_A and B_B of the monomeric bacteriochlorophylls (BChl) or the sites H_A or H_B of the bacteriopheophytins (BPhe). A first example of method (3) has been reported recently², and method (2) is discussed in the Chapter 24 by Woodbury and Allen.

II. Selectivity of the Exchange

The structural modifications to BChl and BPhe are summarized in Fig. 1. Most of the pigments used for

exchange experiments have been modified only at a single position, however, metalation and hydroxylation at C-13² have frequently been combined with other structural changes. Preparative procedures for most of the pigments have been summarized by Scheer and Struck (1993).

A. Influence of Central Metal

Chlorophylls (Chl) and BChls contain Mg as the central metal. Although formally four coordinate, it is coordinatively unsaturated and is normally five or six coordinate by binding of extraneous ligands above or below the tetrapyrrole plane. This affinity is so high, that in dry, nonpolar solvents, it is a major driving force for (B)Chl aggregation via ligation to peripheral C=O or OH groups of neighboring molecules (Katz et al., 1978). A fifth ligand has also been identified in all (B)Chl protein complexes whose structures are known with sufficient resolution. A variety of such ligands have been characterized: Histidine³ is the common one in RC, but it can be replaced by site-directed mutagenesis with glutamine, asparagine, serine and threonine without loss of the BChl in the assembled RC (Coleman and Youvan, 1990; Bylina et al., 1991; Scheer and Struck, 1993). In the water-soluble Fenna-Matthews-Olson (FMO)-protein from *Prosthecochloris aestuarii*, which is involved in energy transfer from the chlorosome to the RC (Olson, 1978), five of the seven BChls are also ligated to histidines, one to a backbone peptide carbonyl, and one to water (Fenna et al., 1977) (see Chapter 20 by Blankenship et al.).

Yet another motif has recently been characterized in the LHCII antenna from green plants (Kühlbrandt et al., 1993). Here, at least two of the chlorophylls

¹ See Struck et al., 1991 for the discussion of an attempt along this line. It should also be mentioned that under the exchange conditions used by us (Scheer and Struck, 1993), small amounts of BChl *a'* (the 13²-epimer of BChl *a*) and of 13²-hydroxy-BChl *a* are extracted from treated reaction centers. Since these pigments are not extracted from untreated samples, they should be formed within the reaction centers during the treatment. However, they are present in non-stoichiometric amounts and their binding sites are not specified, so this method is presently not useful for preparative work.

² First examples of pigment modification by manipulating the biosynthesis have recently been achieved (C. Bauer, private communication, 1993). By systematically inactivating the genes of the BChl biosynthesis cluster, they obtained mutants containing BChl *a*_{gg} (through inhibition of the geranyl-geraniol dehydrogenase) and [8-vinyl]-BChl *a*_p (through inhibition of the 8-vinyl-hydrogenase). Pigments of the latter type have also been found naturally in prochlorophytes (Goerckle, 1990; Goerckle and Repeta, 1992; Chisholm et al., 1992). Aside from interesting biogenetic implications, the mutants had no functional phenotype, and reaction centers isolated from the second mutant had the same kinetics as the wild type ones (J. Allen, private communication, 1993).

³ The early notion of too long histidine-N-to-Mg distances at the P-sites in *Rb. sphaeroides* (Allen et al., 1987) has been corrected by newer structures with higher resolution (Chang et al., 1991; Ermler et al., 1994).

Fig. 1. Modifications in (bacterio) chlorins that are accepted in the binding sites of *Rb. sphaeroides*. Left: BChl-derivatives that exchange into B_A and/or B_B. Right: (B)Phe-derivates that exchange into H_{A,B} (normal print) or selectively into H_A (*italic print*). The substituents R present in native BChl *a* (M = Mg) and BPhe *a* (M = 2H) are underlined. Stereochemistry at C-13² is generally undefined, unless mentioned in the text.

(Chl *a* or *b*) have an aspartate ligand, which in turn is bound to an arginine. Interestingly, this motif has a precedence in the biliproteins, where it does not bind to the central metal of a cyclic tetrapyrrole, but rather to two nitrogens located in the 'inner' rings (B,C) of a linear tetrapyrrole (Schirmer et al., 1987; Düring et al., 1990,1991). The two rings (pyrrole and pyrrolenine), are in a Z,s-syn-geometry, and the latter is believed to be protonated (Scharnagl and Schneider, 1989,1991), this partial structure thus constitutes one half of the dication of a cyclic tetrapyrrole. The similar binding then would support the similarity between metal complexes and dications of tetrapyrroles.

Bacterial RCs of type II⁴ possess binding sites for BChl (= Mg-complexes) and BPhe (= free bases). A major distinction between these two types of sites is the presence of a histidine in a favorable position to bind to the central Mg as a fifth ligand in the BChl binding sites P_{A,B} and B_{A,B}, and an isoleucine in the respective position of the BPhe binding sites H_{A,B}. This distinction holds also for the RC from *Chloroflexus* (*Cf.*) *aurantiacus*, in which histidine

M180 in the B_B-pocket is replaced by isoleucine, and the normally bound BChl *a* is replaced by BPhe, and for a variety of site-directed mutants of several bacteria. Polar residues capable of ligation result in the binding of BChl, and large, nonpolar residues in the binding of BPhe. A complementary distinction has been found for the pigments during exchange experiments: Bacteriochlorophylls are always exchanged into the BChl pockets B_{A,B}, irrespective of the substituents at the periphery, and (bacterio)-pheophytins lacking the central Mg are always exchanged into the BPhe pockets H_{A,B}.

The peripheries of the binding pockets seem to play a lesser role in the distinction between BChl and BPhe, if judged from the ready change of pigment upon change of the 'central' amino acid; the exchange experiments with modified pigments indicate that this is also true for at least part of the periphery of the pigments (see below). The aforementioned interaction between the central metal and the ligand provides a ready explanation for the selection of BChls: the N-Mg binding energy is large enough to select for the Mg-complexes only. The positive selection of BPhe

Abbreviations: B_{AB} – binding sites for the monomeric BChls; BChl – bacteriochlorophyll; BPhe – bacteriopheophytin; *Cf.* – *Chloroflexus*; Chl – chlorophyll; H_{AB} – binding sites for the BPhe, in each case the subscripts A and B refer to the 'active' and 'inactive branch', respectively; P_{AB} – binding sites for the primary donor BChls; Phe – pheophytin; RC – reaction center; *Rb.* – *Rhodobacter*; *Rp.* – *Rhodospseudomonas*; *Rs.* – *Rhodospirillum*

⁴Type I and II refers to reaction centers which are structurally related to RC from Photosystem (PS) I (like those from heliobacteria and Chlorobiaceae) and to RC from PS II (like those from purple bacteria and Chloroflexaceae), respectively.

and rejection of BChls in the $H_{A,B}$ pockets is more difficult to understand. Probably, it does not simply require the absence of an appropriately placed ligating amino-acid, but also the absence of sufficient space to introduce an extraneous ligand, like e.g. water. There are two lines of evidence for this: Firstly, the FMO-protein provides already an example that water can act as ligand in a BChl protein; if this could be introduced into $H_{A,B}$ in RCs, binding of BChl may be expected. Secondly, there is recent direct evidence for this concept from site-directed mutagenesis of the D1 protein of the PS II-RC (B. Diner and P. Nixon, private communication, 1993). Replacement of His^{D1-168} (which is a presumed ligand to Chl *a* in the P-site) with alanine yields functioning RCs in which neither the content of Phe *a* is increased, nor the content of Chl *a* is decreased. On the other hand, the mutation His^{D1-168} → Ile (the equivalent of which produces a heterodimer in bacterial RC (Coleman and Youvan, 1990)) has a PS⁻ phenotype. The small size of the alanine in the former mutant may allow the introduction of a molecule of water as a fifth ligand to Mg, while this is not possible in the latter. Histidine-to-alanine mutations have been done with bacterial RCs and support, at least in part, this selection mechanism (S. Boxer, personal communication, C. Schenck, personal communication).

B. Replacement of Central Magnesium

Replacement of Mg with other metals allows in porphyrins a systematic variation of the redox potentials (Fuhrhop et al., 1974; Watanabe and Kobayashi, 1991). A series of metallo-bacteriochlorophylls (which more precisely should be termed metallo-bacteriopheophytins) has been recently prepared by us (Hartwich et al., 1995b; see Tables 1 and 2 for their spectroscopic properties and redox potentials). Several pigments in which the central Mg has been replaced by other metals are exchangeable to a high degree of selectivity into the $B_{A,B}$ pockets. These include [Zn]- and [Ni]-BChl *a* (Hartwich, 1994). Zn complexes of porphyrins have been classified by Buchler (1975) as square-pyramidal (=5 coordinate), Ni-porphyrins as square planar (=4 coordinate). In view of the above discussion, an exchange of [Ni]-BChl into both the $B_{A,B}$ and the $H_{A,B}$ sites might be expected. The selective exchange into $B_{A,B}$ and the failure of exchange into $H_{A,B}$ is then surprising and may indicate the operation of additional

steric, electronic or other factors besides ligation. It should also be mentioned, that the coordination of Ni is quite variable, and EXAFS studies have indicated that [Ni]-BChl *a* is five coordinated both in solvents of intermediate polarity and in the RC (Chen et al., 1995). Paulsen et al. (1990, 1991) studied the reconstitution of the LHCII antenna complex from plants with several [metallo]-Chls. Their results also indicate that pigments with central metals other than Mg can replace at least part of the 13–14 molecules of Chl *a* and *b* present. No data on the site of replacement, the type of pigment replaced, or metal coordination states in these reconstituted LHCII complexes are yet available.

The biosynthetic origin of (B)Phe in type-II RCs is unknown. All (B)Phe derive from Mg-porphyrins, which must then be demetalated. Mg-complexes of bacteriochlorins and, even more so of chlorins, are labile, they are readily demetalated by acid. There are also several reports on dechelatase activities (Ziegler et al., 1988; Owens and Falkowski, 1982), but the postulated enzymes have not been purified, no information on their active sites is available, and it is not clear if their function is to provide a pool of (B)Phe which is utilized for supplying the RC, or if they are involved in (B)Chl breakdown⁵. Principally, an alternative mechanism is possible for (B)Phe insertion: BChl (e.g. the Mg-complex) is first bound to all six tetrapyrrole binding pockets, and the pigments at $H_{A,B}$ are subsequently demetalated. None of the exchange experiments support such a mechanism, but it could also mean that once a BPhe is bound, it is no longer exchangeable with BChl. However, other available evidence also points against an in situ demetalation. Walter et al. (1979) identified different esterifying alcohols in BPhe *a* and BChl *a* from *Rhodospirillum (Rs.) rubrum* RCs. Since exchange experiments with these RCs did not strongly discriminate between pigments bearing the two alcohols, viz. phytol or geranylgeraniol (Beese, 1989; Struck et al., 1990; Struck, 1990), this indicates a dedicated synthesis (and possibly even delivery) of the BPhe. The mutagenesis experiments (see e.g. Table 1 in Scheer and Struck, 1993) point in the same direction, unless the exchange of the amino acid next

⁵ Several degradation products of Chl *a* (Engel et al., 1991; Iturraspe et al., 1991; Kräutler et al., 1992; Mühlecker and Kräutler, 1993) and Chl *b* (Iturraspe et al., 1994) have been recently reported, but it is not yet clear if the ring-opening reaction involves the Mg-complexes as substrates, or if a previous demetalation is required.

Table 1. Midpoint-potentials of metallobacteriochlorophylls in THF (in [V] versus Ag/AgCl-electrode)¹

C. Peripheral Substituents

The influence of modified peripheral substituents on the exchange of (B)Chl or (B)Phe capacity can give new insights to the interaction between amino-acids of the protein with the pigments. However, being a purely operational criterion, only positive results are meaningful. A previous overview of all modifications tested until the end of 1992, has been given (Scheer and Stuck, 1993). Briefly, pigments modified at C-3, or C-17⁴, or hydroxylated at C-13², alone or in combination, exchange into both the B_A and the B_B pockets of carotenoid-less *Rhodobacter (Rb.) sphaeroides* RCs, and into B_A only in wild-type RCs. Also, the exchange into B_B is faster than into B_A (see below).

Tinkering with the isocyclic ring other than hydroxylation at C-13², inhibited an exchange. This includes removal of the 13²-COOCH₃-substituent, as well as enlargement or an opening of the ring. Even the hydroxylation is highly stereospecific: 13²(S)-hydroxy-BChl *a*, which has the same orientation of the COOCH₃-substituent as BChl *a*⁶, exchanges and is functionally competent, whereas the 13²(R)-epimer does not exchange (F. Storch, H. Scheer, unpublished, 1993). This discrimination is so strong, that only the traces of the S-in preparations of the R-epimer are taken up during exchange experiments, rather than the main product with the 'wrong' orientation of the COOCH₃ group. A similar selectivity also applies to 13²-hydroxy-BPhe *a* (see below). Interestingly, 13²(S)-BChl *a*, the epimer of the native 13²(R)-BChl *a* can be found in all 'blank' samples of RCs subjected to the exchange conditions in the absence of extraneous pigments. It is not clear at which site it is bound, but the tight binding and its absence in untreated RCs using the same extraction conditions indicates that it is indeed incorporated into the RC and not merely adsorbed. If the stereoselectivity of the B_{A,B} sites found for 13²-hydroxy-BChl *a* holds

also for BChl *a*, the epimer might then be bound at the P_{A,B} site. It should be mentioned in this context, that both the chlorophyll synthetase (Helfrich et al., 1994) and chlorophyllase (Fiedor et al. 1992; Y. Nishiyama, M. Kitamura, S. Tamura, T. Watanabe, unpublished, 1993) are also highly stereospecific with regard to the 13²-position.

The bacteriochlorin conjugated system appears to be essential for an exchange into the B_{A,B}-sites, since neither Chl *a* nor [3-acetyl]-Chl *a* have been found exchangeable. The latter differs from BChl *a* 'only' by the removal of the two 'extra' hydrogens at C-7 and C-8. Inspection of the crystal structure (Chang et al., 1991) does not indicate an obvious reason for the failure to incorporate chlorins instead of bacteriochlorins, but it may be due to a changed flexibility of the macrocycle (Scheer and Katz, 1975; Senge et al., 1993). The H_{A,B}-sites are much more tolerant in this respect. Phe *a*, Phe *b* and [7-hydroxymethyl]-Phe *a* are exchangeable, they differ from BPhe *a* not only in ring B being unsaturated, but also in the nature of the C-7 substituent. It is hydrophobic in Phe *a*, an H-bond acceptor in Phe *b*, and both acceptor or donor in [7-hydroxymethyl]-Phe *a* (Shkurupatov and Shuvalov, 1993; Meyer, 1992; Scheer et al., 1992; Meyer and Scheer, 1995; A. Y. Shkurupatov, M. Meyer, H. Scheer and V. A. Shuvalov, unpublished).

D. Asymmetric Exchanges

B_A and the symmetry-related site B_B do not strongly discriminate between the pigments tested up to now. There is, however, a kinetic discrimination: The first molecule is exchanged considerably faster than the second one, and there are several lines of evidence for the assignment of the faster exchanging site as B_B. One comes from kinetic analysis of the electron transfer in a partially exchanged sample: After exchange of ≈80% of BChl at sites B_{A,B} with [3-vinyl]-BChl *a*, there were about 40% RC left in which the kinetics of the primary charge separation were unchanged, viz. which contained BChl *a* at site B_A. Even considering the error limits of the analysis, which are in the range of ±10%, this would indicate a larger exchange in B_B than in B_A.

Selective exchange into B_A is possible in wild-type reaction centers. Here, the carotenoid located close to B_B inhibits an exchange into the latter (Hartwich, 1994). This assignment of the exchange site was originally tentative, but it has recently been

⁶ Due to the Cahn-Ingold-Prelog nomenclature rules, the configuration of C-13² changes by replacing the H-substituent present in BChl *a* with the OH-substituent present in 13²-hydroxy-BChl *a*, even though the arrangement of all other substituents remains unchanged.

confirmed by optical-electron-double resonance experiments (see below). The selective exchange into the B_B -site has been accomplished in a more roundabout sequence exemplified here for [3-Vinyl]-13²-hydroxy-BChl *a* (G. Hartwich, 1994). First, both B-sites have been exchanged with [3-Vinyl]-13²-hydroxy-BChl *a* in RC from *Rb. sphaeroides* R26. This is followed by a reconstitution with spheroiden(on)e to protect the B_B -site, and in the subsequent step the B_A site only is brought back 'to normal' by a second exchange with the native pigment, BChl *a*.

The discrimination between the A- and B-sites is much stronger for $H_{A,B}$. 13²-OH- and 13²-demethoxy-carbonyl-bacteriopheophytins do only exchange for one BPhe. There is even a strong discrimination for the alcohol: BPhe α_{gg} (the subscript denoting geranylgeraniol rather than phytol as the esterifying alcohol), exchanges only into one site. There is presently only circumstantial evidence as to which of the sites is affected by the exchange, and whether it is the same in all cases, because the spectra of the aforementioned pigments are very similar and allow no distinction in the Q_x -region. Our working hypothesis is that it is H_B , because there is also a distinctly more rapid exchange at this position (as compared to H_A) with pigments having sufficiently different spectra that the exchange can be followed spectroscopically. There is a selective interaction of glutamine L104 with the 13¹-CO of the pigment in H_A (Allen et al., 1987; Chang et al., 1991; El-Kabbani et al., 1991; Michel and Deisenhofer, 1988; Lutz and Mäntele, 1991) leading to a red-shift of the Q_x -band of this pigment. This interaction may also account for the failure to exchange pigments bearing a 13²-OH- or lacking the 13²-COOCH₃-substituent. In these pigments, enolization of the β -ketoester system at ring V is inhibited, and enolization (Bocian et al., 1987) or at least strong H-bonding between the 13¹-keto-group of BPhe *a* and the neighboring glutamate (see Lubitz, 1991) in H_A has been suggested as the reason for the spectral shift. Because the enolizable β -ketoester system is found in all tetrapyrroles known to participate in electron transfer in RCs, there may be a functional and structural significance at least in this site (as contrasted from $B_{A,B}$, see above). However, it should be noted that Glu^{L104} \rightarrow Gln mutagenesis abolished the shift, but does neither inhibit the binding of BPhe *a* nor the function of these RCs (Coleman and Youvan, 1990).

III. Static Spectroscopy of Reaction Centers with Modified Pigments

All pigments introduced into reaction centers are subject to spectral modifications (absorption shifts, hyperchromism, induced circular dichroism). The origin of these can formally be separated in two components: those induced by the protein moiety, and those induced by pigment-pigment interaction. Both have been discussed by Struck and Scheer (1993) and are summarized here only briefly:

After self exchange experiments, i.e. incubation under exchange conditions with native pigments added exogenously, RCs show that the protein subunit is unaltered as judged by UV/VIS absorption, CD, linear dichroism, magnetic resonance (ENDOR) and vibrational spectroscopy, and by light-induced bleaching of the P-absorption at 870 nm. Accordingly, the treatment leaves the RC largely unchanged.

The absorption spectra (e.g. in diethylether) of many of the pigments used for exchange differ from those of the native pigments (see Scheer, 1988 and Table 2). If the spectra of a series of such pigments in monomeric solution are compared with the spectra of the same pigments incorporated in the RC, a surprisingly constant environment-induced red shift (EIRS) was found: it amounts to $\approx 500 \text{ cm}^{-1}$ (Q_y) and $\approx 700 \text{ cm}^{-1}$ (Q_x) for the sites $B_{A,B}$ and to $\approx 150 \text{ cm}^{-1}$ (Q_y) and $\approx 450 \text{ cm}^{-1}$ (Q_x) for the sites $H_{A,B}$ (Scheer and Struck, 1993; Scheer et al., 1993). In view of the short distances among all pigments in the RC the problem of EIRS has received considerable attention and it is not clear whether this is a result of protein-chromophore or chromophore-chromophore interaction, or both (Scherz et al. 1991; Scherer and Fischer, 1991). Unchanged EIRS in chromophore-exchanged RCs argue against specific protein-chromophore interactions, at least as far as the modified groups are concerned. However, they are compatible with more global changes, e.g. distortions of the macrocyclic system from planarity.

Introduction of spectrally different pigments also leads to negligible changes of the absorption spectral features assigned to P⁷. This indicates that none of the chromophore substituents modified hitherto is strongly involved in pigment-pigment interactions with this site. This is further supported by CD-spectroscopy which is very sensitive to pigment

⁷ The position of this band is considerably affected by the other environmental conditions like detergent, temperature, etc.

interaction and geometry. Besides shifts of the spectral position due to band shifts of the modified pigments, only minor variations of the non-exchanged pigments are observed. ENDOR shows that there is also little to no interaction between the primary donor in its doublet state (P^{+}) and any of the other pigments (Struck, 1990). The situation is more complex and not yet well explored for interactions among the $H_{A,B}$ and $B_{A,B}$ sites. Here, small but distinct shifts are always observed if a neighboring pigment is exchanged, which is most obvious if the newly introduced pigment does not absorb in the same spectral region. Based on kinetic studies with RC in which BPhe *a* has been replaced by Phe *a*, Shkurupatov and Shuvalov (1993) have recently proposed a considerable contribution of the pigments in $B_{A,B}$ to the ≈ 540 nm band assigned generally to BPhe at the $H_{A,B}$ sites.

The differential absorptions in the Q_x -region of BPhe *a* t H_A and H_B was essential in defining and exploring the asymmetry of electron transfer. The former absorbs at longer wavelengths (≈ 545 nm) than the latter (≈ 535 nm) (Clayton and Yamamoto, 1976; Vermeglio et al., 1978; Breton 1985; Kirmaier et al., 1985; Kellog et al., 1989). The two bands overlap at room temperature but can be deconvoluted; at low temperatures they are well resolved. This differentiation has been observed, too, for all replacement pigments in the H-sites, and can be used to establish asymmetric exchanges. No similar differentiation existed for the B-sites. Static spectroscopy after site-selective, asymmetric exchanges at B_A and/or B_B then allowed the spectral assignment and differentiation of the B-sites. Taking advantage of the partial and asymmetric triplet energy transfer from the carotenoid to B_B , BChl at this site could be tagged (see also below). This was explored by low-temperature absorption, ADMR and MIA spectroscopy (Hartwich, 1994; Hartwich et al., 1995c) in RCs, in which B_A and/or B_B were exchanged with [3-vinyl]-13²-OH-BChl *a*, a BChl *a*-derivative where the Q_x and the Q_y transitions in solution as well as in the RCs shifted to the blue. This allowed the following assignments: BChl *a* at B_A absorbs at 803 (Q_y) and 595 nm (Q_x), whereas BChl *a*- B_B absorbs at 812 and 600 nm, respectively. There is furthermore additional evidence from these experiments for locating the upper exciton Q_y -band of the primary donor (P_+) at 808 nm (see also section E), and the Q_x absorption of P at 603 nm.

A. Triplet Energy Transfer

The main previous evidence for specific interaction of the primary donor in its triplet state ($^3P^*$ or P^T) with pigments in $B_{A,B}$ was derived from microwave-induced absorption difference spectra (MIA, often also referred to as singlet-triplet difference, Lous and Hoff, 1987) of RCs, in which the BChl at both sites $B_{A,B}$ was replaced by pigments with progressively blue-shifted absorptions: there is one band in the MIA spectrum which shifts like the absorption band of the exchanged pigments in $B_{A,B}$ from ~ 800 to ~ 770 nm.

Selective exchange experiments of the type mentioned above also allowed a detailed study of the triplet energy transfer within the RC (Hartwich et al., 1995c). The B_B -exchanged sample showed almost the same $^3P^*$ -MIA spectra as the $B_{A,B}$ -exchanged sample, indicating that there is no strong interaction between $^3P^*$ and B_A . The B_A -exchanged sample, however, shows not only the expected features around 815 nm identical to native RCs, but also the 776 nm band indicative of the modified substituent at B_A . This contrasts with the suggestion that $^3P^*$ interacts selectively with B_B , and rather indicates that there is an interaction of the primary donor triplet with both B-sites, at least at liquid He temperatures.

In wild-type RCs, B_B is close to the carotenoid (Car) site, which breaks the high symmetry of the RC. It has a protective function, and the otherwise long-lived $^3P^*$ (≈ 30 μ s), is quenched by fast energy transfer (≈ 30 ns) to Car (Frank, 1993). The latter triplet lies energetically below 1O_2 and is hence photochemically safe, and it furthermore relaxes quickly to the singlet ground state (Parson and Monger, 1977). It is then suggestive, that the partial triplet energy transfer from $^3P^*$ monitored by MIA, is related to the fast and complete transfer to Car, and hence to the protection of RC under conditions where the acceptor Q_A is reduced. This has been supported by two lines of experiments:

In the first one (Hartwich et al., 1995c), MIA spectra of the carotenoid triplet (3Car) from wild-type RC from *Rb. sphaeroides* have been investigated. Besides the signal at 550 nm characteristic for 3Car , they show an additional signal in the long-wavelength region (812 nm) characteristic for BChl at B_B . This has been confirmed by using RCs where B_B has been selectively exchanged with [3-vinyl]-13²-OH-BChl, where this signal is shifted to 775 nm. Modification of BChl at the B_A -site has no effect on the MIA of

^3Car . Thus only the pigment at B_B experiences interaction with ^3Car , indicating this pigment as a mediator or even an intermediate in energy transfer from $^3\text{P}^*$ to ^3Car . These experiments allowed at the same time an unequivocal assignment of the two exchange sites (see above).

A second experiment (Frank et al., 1993) was based on the suggestion that the triplet transfer via B_B is an activated process, and that specifically the activation barrier is determined by the energy difference of ^3P and 3B_B . The origin of this suggestion is the temperature dependence of the triplet transfer, which stops in wild-type RC from *Rb. sphaeroides* at $\approx 35\text{K}$ (Schenk et al., 1984). The onset of triplet transfer has now been measured in RCs derived from the R26 mutant, in which first BChl *a* in both B_A and B_B had been exchanged against modified pigments, and which have then been (re)constituted with Car. The onset of triplet transfer to Car in these RCs, followed the estimated increase in the triplet energy of the modified BChls, thus confirming the activation hypothesis, and furthermore suggesting B_B as a real intermediate.

It can be concluded that unidirectionality of triplet energy transfer is conditioned by interaction of $^3\text{P}^*$ with $B_{A,B}$ and selective interaction of ^3Car with B_B , and that this transfer is an activated process. This asymmetry of triplet energy transfer to the B-branch may be compared to the well known and still not understood asymmetry of electron transfer to the A-branch.

B. Singlet Excitation Energy Transfer

Reaction centers where BChl *a* in (B_A or) $B_{A,B}$ is replaced by [Ni]-BChl *a* seem to be a powerful tool in explaining the role of the accessory BChls. They are capable of charge separation, but with a lower quantum yield, which is furthermore dependent on the excitation wavelength. The preliminary analysis indicates that both energy and electron transfer in these RCs are strongly impaired (Hartwich, 1994).

Energy transfer was studied by fluorescence spectroscopy. The excitation spectrum for the emission of $^1\text{P}^*$ (Fig. 2) shows a much decreased quantum yield ($<30\%$) for all spectral regions where the Ni-BChl or the BPhe are excited, as compared to direct excitation of P. It is concluded, that i) [Ni]-BChl in $B_{A,B}$ is a trap for excitation energy and that ii) after excitation of BPhe in $H_{A,B}$ energy is transported, at least partly, via the accessory BChls to the primary

Fig. 2. Simultaneously recorded absorption (—) and excitation (---) spectra of *Rb. sphaeroides* R26 RC (upper panel) and of RC with 13^2-OH-Ni-BChl in $B_{A,B}$ (bottom panel) at $T = 85\text{K}$. Fluorescence is detected at 930nm and normalized to the primary donor absorption.

donor (Hartwich et al., 1995a). Further measurements (e. g. transient absorption etc.) will be necessary to elucidate the effect of [Ni]-BChl in B_A and/or B_B on the dynamics and unidirectionality of charge separation. The energy trapping of [Ni]-BChl can be explained by the electronic structure of the pigment. In solution, excitation energy in the S_1 -state of the π -system is transferred within $<1\text{ps}$ to a d-orbital of the Ni, and then to the S_0 ground-state within less than 30ps (Kobayashi et al., 1979). By using an upper limit for the excitation transfer in RC of $\sim 100\text{fs}$ (Breton et al., 1986), the S_1 -to- S_0 relaxation must be faster than 50fs to explain the decreased fluorescence yield. Fluorescence is the competition to charge separation, which is believed to take place only along the active branch (A-branch)⁸. This can be taken as for additional support that exchange of

⁸ Strictly speaking, this is true only of charge separation to Q, whereas transient charge separation to B_B as a 'parking process' has been discussed (see Zinth and Kaiser, 1993).

bacteriochlorophylls in wild-type RCs from *Rb. sphaeroides* is restricted to the B_A -site. These RCs show the same reduction of fluorescence quantum yield as the $B_{A,B}$ -exchanged sample. Even if an additional charge separation in the $B_{A,B}$ -exchanged sample via the B-branch is assumed, one would expect a higher fluorescence quantum yield in the B_A -exchanged sample or for a nonselective exchange in wild-type RCs, detectable within a limit of error of 10%.

IV. Stabilization

Self-organization of (B)Chl is a widely studied process (Katz et al., 1978, 1991, Scherz et al., 1991), and it has been suggested that the pigments also play a role in formation and stabilization of the native pigment-protein complexes. Experimental evidence to this comes also from reconstitution studies with antenna complexes from green plants (Plumley and Schmidt, 1987, Paulsen et al., 1990, 1991) and purple bacteria (Parkes-Loach et al., 1988, 1990; Ghosh et al., 1988; see chapter by Loach and Parkes-Loach). Several lines of evidence indicate a structural role of the bound tetrapyrroles for the integral reaction center complex. The first comes from temperature studies carried out in order to optimize the exchange reaction. In the presence of an excess of exogenous pigment(s), the RC can be heated 3–5 degrees higher than in their absence. This can be rationalized in terms of an equilibrium between RCs with open and occupied binding sites, which is shifted towards the former, more stable ones by the mass action of exogenous pigment(s). Further evidence comes from recent attempts to remove the quinones from modified RCs: the procedure of Okamura et al. (1975) gives much lower yields with such RCs. Interestingly, there is also a stabilizing effect of the quinone(s). If they are removed prior to the exchange of BPhe or BChl, then the yield of the subsequent exchange procedure is much reduced (M. Meyer, G. Hartwich and H. Scheer unpublished results). There is, furthermore, a distinct difference among wild-type reaction centers from *Rb. sphaeroides* 2.4.1 and the carotenoidless mutant R26: the latter tolerates only a 3 degree lower temperature for exchange, viz. it is considerably less stable due to the loss of the carotenoid, 15,15'-*cis*-spheroidenone. The stabilization of reaction centers by their various cofactors, therefore, is clearly a cumulative effect. Only a single exchange has hitherto

been done with RCs modified by site-directed mutagenesis ($\text{Tyr}^{\text{M208}} \rightarrow \text{Phe}$, Göbel, 1993). The stability of wild-type RCs (*Rb. sphaeroides* 2.4.1) under the reaction conditions was comparable to that of non-mutated RCs from the carotenoidless mutant R26.1.

V. Time-Resolved Spectroscopy

RC are energy transducers, they convert excitation into electrochemical energy. Modifications of pigments may help to clarify the assignment of kinetic processes to the different molecular events which are currently discussed controversially (Kirmaier and Holton, 1993; Zinth and Kaiser, 1993; Shuvalov, 1993; Martin and Vos, 1992; DiMagno and Norris, 1993; see Chapter 24 by Woodbury and Allen). If judged from the light-induced bleaching, all reaction centers mentioned in the previous sections are competent for light-induced electron transfer. The quantum yield and recovery of P870 in these samples shows some variations, but none of the recombination times are strongly affected.

The first kinetic experiments of the forward reaction have been done with 'blank' samples which had been subjected to the exchange conditions in the absence of extraneous pigment (Finkele et al., 1992). Spectra and kinetics of these RCs were identical to those of native ones, indicating no significant damage to those RCs which are isolated from the exchange mixture (see above). Only few pigment modifications have hitherto been characterized kinetically. RCs containing $13^2(\text{S})$ -hydroxy-BChl *a* at sites B_{AB} have within the limits of error identical kinetics to native ones (Finkele et al., 1992). Hence, this modification is 'neutral' as far as the charge separation is concerned. At the same time, it supports again that structural changes due to the exchange procedure are negligible. RCs containing [3-vinyl]- 13^2 -hydroxy-BChl *a* at sites B_{AB} gave heterogeneous kinetics (Finkele et al., 1992). At all wavelengths studied, the kinetics could be fit by four components, viz. 0.9, 3.5, 30 and 200 ps. Native reaction centers lack the 30 ps component. The amplitude of this component varied considerably in the 700–800 nm spectral range and showed an inverse relationship to the 3.5 ps one: The former was highest upon excitation at 776 nm, which is the absorption maximum of [3-vinyl]- 13^2 -hydroxy-BChl *a*, while the latter is maximum in the absorption region of BChl *a* at sites $B_{A,B}$, around 800

nm. The most straight-forward explanation is a heterogeneity of the preparation due to only partial exchange at the B_A site: One fraction consisted of (kinetically) native RCs (0.9, 3.5 and 200 ps), the other of modified RCs, in which the 3.5 ps component was replaced by a 30 ps one⁹. If one assumes that the 13²-OH substituent alone has no influence on the kinetics (see above), then the tenfold decrease of the intermediate rate is the result of a replacement of the 3-acetyl- by a vinyl-substituent. In solution, the redox potential of the modified pigment is estimated to be 150 mV more negative (Watanabe and Kobayashi, 1991), one would then expect that the step leading to B_A -reduction becomes slower. However, such an effect would also be expected for a superexchange mechanism. A more direct evidence for a stepwise mechanism is that in exchanged RCs there is no fast component with a high amplitude: if this fast component (0.9 ps in native RC) were to precede the slow component, its amplitude should increase, whereas it is expected to decrease if this step is subsequent to the intermediate one. Since it is no longer observable in regions where the exchanged RC dominate the spectrum, this result is consistent with a stepwise electron transfer (Holzapfel et al., 1989; Finkle et al., 1990). There is some evidence for a kinetic component with $\tau \approx 4$ ps in the modified reaction centers, but this needs further work (Finkle, 1992).

The third detailed characterization has been done with RC in which BPhe *a* has been replaced by Phe *a* (Shkurupatov and Shuvalov, 1993; Arlt et al., 1993). Although its redox potential in solution is ≈ 160 mV more positive (Watanabe and Kobayashi, 1991), the kinetics are not much changed: The most significant difference is the increase of the 200 ps component to ≈ 270 ps, this time relates to the transfer of the electron from H_A to Q_A , and might reflect the changed redox potential. However, the changed redox potential has yet another, more profound, effect of raising the energy of the state P^+H^- to a value close to that of P^+B^- . Because the kinetics of interconversion of these states are much faster than the decay of the former, this allows for thermal equilibration and a cumulative decay of the states. This equilibration does even extend to P^* : it stays populated to $\approx 5\%$ during the lifetime of P^+H^- , thus allowing an estimate

of the energetic separation between P^* and P^+H^- as ≈ 400 cm⁻¹. Taken together, it appears that modification of pigments at the B-site(s) affect the kinetics of electron transfer much more profoundly than those at the H-site(s).

VI. Open Problems and Outlook

Although the method of pigment exchange has so far been tested only with a limited number of pigment modifications and RC species, it seems to be a valuable complement to site-directed mutagenesis, because it allows a direct manipulation of the pigments. Realizing the limited knowledge of bacteriochlorophyll chemistry, a major effort of future work will have to go into the synthesis and the collection of basic data of the modified pigments, not only in situ, but also in solution. (Hartwich, 1994; Hartwich et al., 1994; Feiler et al., 1994; Käss et al., 1994; Teuchner et al., 1994; and unpublished results referred to in the text). Only then can the effects in the native environment be fully evaluated. A potential which is hitherto hardly explored, is selective (isotope) labeling for magnetic resonance or vibrational spectroscopic work.

The exchange method is restricted so far to the monomeric BChl and BPhe, and it appears currently unclear if the principle can be extended to the primary donor as well. There is hope, however, that the recent advances in the folding of previously unwieldy proteins, will render this site accessible, too, in the foreseeable future. A further challenge will be the extension to other RC, in particular those from PS II, but also to the variety of other (B)Chl protein complexes.

Appendix: Updated Procedure for Pigment Exchange

The exchange procedure has been summarized by Struck and Scheer (1993). This is an update for asymmetric exchanges and exchanges with metallo-bacteriochlorophylls.

For replacement of bacteriochlorophylls in the $B_{A,B}$ sites, RC from *Rb. sphaeroides* R26 in TL-buffer (10 mM tris, 0.1% LDAO, pH = 8) are incubated under Ar with a 10-fold molar excess of exogenous pigment in MeOH at 43 °C for 90 min. Recovery of RCs with exchanged chromophores is

⁹ This heterogeneity was supported by pigment analysis and the relatively high intensity at the 800 nm band, indicating the presence of >20% of BChl *a* at site B_A .

30–50%. The concentration of MeOH should not exceed 10% of the volume of the reaction mixture. Under these reaction conditions, which are close to the melting point of the RCs, internal motions become larger and allow for equilibration between the external, modified pigments and the original ones bound to the protein.

A selective substitution at the B_A -site is possible when RC from the carotenoid-containing wild-type strain 2.4.1 of *Rb. sphaeroides* are used, and the temperature is raised to 47 °C in order to account for the increased stability of these RCs. The selectivity is due to the spheroiden(on)e, which is located asymmetrically and adjacent to the B_B -pocket. This pigment probably is responsible for the increased thermal stability of the RC, and seems to block the B_B site from exchange of the chromophore.

For an exchange at the B_B -site only, the starting material are RCs from the carotenoid-less R26 mutant. First BChl *a* is replaced symmetrically at the sites B_A and B_B with exogenous pigment under the standard exchange conditions. After purification, carotenoid (re)constitution was done with spheroidene dissolved to maximal concentration in diethylether and diluted with 3 parts (v/v) methanol. This solution was added to the RC ($OD = 1 \text{ cm}^{-1}$ at 865 nm) to a concentration of the organic solvent of 10% (v/v), and the mixture incubated for 50 min at 43 °C under Ar. By this (re)constitution, the B_B -pocket becomes blocked, and native BChl *a* can finally be re-exchanged into the B_A -pocket under the conditions described above for the wild-type strain 2.4.1.

For the exchange with some metallo-bacteriochlorophylls (e. g. [Ni]-BChl_a) as well as for the replacement of (bacterio-)pheophytins into R26 RC, the reaction conditions were similar, but acetone was used instead of methanol, because of poorer solubility and/or pigment aggregation effects in the latter, and the reaction time was 1 h at 43.5 °C.

Protein and pigment analyses of modified RCs were done as detailed in Struck and Scheer (1993). Extraction of pigments is done on DEAE-columns with methanol as denaturant of the protein moiety and CHCl_3 as eluant for the pigments. Exhaustive extraction has to be ensured for quantitative pigment analysis.

Summary

Green sulfur bacterial reaction centers have been usually cited as counterparts of Photosystem I. However, they have remained poorly characterized for a long time, since the main interest was directed towards understanding the unique antenna system of green bacteria, the so-called chlorosomes. Many exciting developments in green sulfur bacterial reaction center research have occurred during the years 1990 to 1995. Important similarities between the reaction centers of green sulfur bacteria, heliobacteria, and Photosystem I have been discovered, such as the presence of the same set of electron acceptors and a similar polypeptide composition. Furthermore, similarities to the purple bacterial-type reaction centers have been described. These include the presence of a bacteriochlorophyll dimer as the primary donor and a reaction-center-associated cytochrome subunit as electron donor to P840. Most surprising, however, has been the discovery of only one gene coding for the dimeric, large reaction center subunits. This feature is in contrast, not only to Photosystem I, but also, to purple bacterial-type reaction centers, and it has raised interesting evolutionary questions which are discussed in this chapter. It has been shown that both types of reaction centers, i.e. purple bacterial- and Photosystem I -type reaction centers share common features, such as the charge separation processes, those pigments involved and a similar organization of the main polypeptides. All this led to the speculation that the different kinds of photosynthetic reaction centers have a common evolutionary origin. In this review we summarize the current state of knowledge about the green sulfur bacterial reaction center structure and function and compare these with those of other Photosystem I-type and purple bacterial reaction centers.

I. Introduction

The observation of a photosynthetic reaction center (RC) in green sulfur bacteria dates back to 1963, when Sybesma and Vredenberg reported photobleaching at 840 nm due to a photooxidizable primary donor, P840, for *Chloropseudomonas ethylicum* 2K. This 'organism' has since been identified as a syntrophic mixture of the sulfur-photooxidizing green sulfur bacterium *Prosthecochloris (Pc.) aestuarii* and the sulfur-respiring bacterium *Desulfovibrio* (Olson, 1978a). P840-photobleaching has subsequently been described for *Chlorobium (Cb.) limicola* (Olson et al., 1973), and other green sulfur bacteria, in pure culture.

The early work on green sulfur bacteria, however, was focused on two other components of their peculiar photosynthetic apparatus—the chlorosomes, which are huge antennae complexes (Cohen-Bazire et al., 1964; see Chapter 13 by Oelze and Golecki and 20 by Blankenship et al.), and a bacteriochlorophyll

(BChl) *a*-protein (FMO-protein), which was the first chlorophyll protein structure to be resolved by X-ray crystallography (Mathews et al., 1979). Therefore little was known about the RC proper of green sulfur bacteria in the pertinent chapters of the comprehensive account on photosynthetic bacteria from 1978 (Gingras, 1978, Olson 1978b, Pierson and Castenholz, 1978). Two years later, Olson (1980) summarized the notion of the photosynthetic apparatus in green sulfur bacteria in more detail, and put forward a structural model for the participating BChl-proteins, which includes the studies by Swarthoff and Ames (1979), and by Staehelin et al. (1980). Its essentials were: 1) The photosynthetic unit contains 900–4500 BChl *c*, *d*, or *e* molecules in the chlorosome, and 80–250 BChl *a* molecules per RC. 2) The BChl *a* molecules are bound in groups of seven on to 42 kDa-polypeptides, which build trimers, most of which form a baseplate between the chlorosome and the RC in the cytoplasmic membrane. 3) Each RC is attached to two BChl *a*-protein trimers. 4) The RC was speculated to be built of 5 BChl-proteins similar to the known 42 kDa BChl *a*-protein, and a core holding P840 and carotenoids.

Another central interest in the RC of green sulfur bacteria is its similarity to the RC of Photosystem (PS) I, which goes back to the finding that green sulfur bacteria are capable of pyridine nucleotide photoreduction without further energy requirement

Abbreviations: ADMR – absorption detected magnetic resonance; BChl – bacteriochlorophyll; BPh – bacteriopheophytin; *Cb.* – *Chlorobium*; Chl – chlorophyll; FeS – iron-sulfur; FMO – Fenna-Mathews-Olson; FT – Fourier transform; HPLC – high performance liquid chromatography; Li/SDS – lithium/sodium dodecyl sulphate; P700 – primary donor of Photosystem I; P800 – primary donor of heliobacterial reaction centers; P840 – primary donor of green sulfur bacterial reaction centers; *Pc.* – *Prosthecochloris*; PS – Photosystem; RC – reaction center

(Buchanan and Evans, 1969), which was substantiated by the identification of iron-sulfur (FeS)-centers as early electron acceptors (Knaff and Malkin, 1976; Jennings and Evans, 1977). After the stimulus that research on PS II obtained from the similarity to the well characterized RCs in purple photosynthetic bacteria (see Chapter 23 by Lancaster et al.), the prospect of elucidating PS I structure and function from its bacterial counterparts grew, inspiring intensive investigations (see below). The recent discovery that the RC of heliobacteria also resembles PS I adds to the value of this comparison (Nitschke et al., 1990b; Liebl et al., 1993; for recent reviews see Mathis, 1990; Nitschke and Rutherford, 1991; Nitschke and Lockau, 1993). Moreover, both green sulfur bacteria (Büttner et al., 1992a, Okkels et al., 1992, Xie et al., 1993) and heliobacteria (Liebl et al., 1993) recently became accessible to molecular biology. In the following we will attempt to compile these new developments, and to update our concept of the RC in green sulfur bacteria. For the similar RC of heliobacteria this will be done by J. Amesz in Chapter 31.

II. Composition of the Reaction Center

A. Different Reaction Center Preparations

The first attempts to purify the RC of Chlorobiaceae consisted in the mechanical separation of the chlorosomes from the cytoplasmic membranes, using the French press and sucrose density gradient centrifugation (Fowler et al., 1971; Olson et al., 1973; Schmidt, 1980). This is equivalent to the separation of the BChl *c*-, *d*- or *e*- from BChl *a*-containing fractions. The latter consisted of a photoactive BChl *a* RC and the 42 kDa BChl *a*-antenna protein. By treatment of such a preparation from *Cb. limicola* with guanidine-HCl, followed by gel filtration on Sepharose, the BChl *a*-protein could be removed, but photoactivity was diminished (Olson et al., 1976a). The residual RC fraction retained about half the BChl *a* and carotenoid, together with photooxidizable cytochrome *c* and photoreducible cytochrome *b*.

A more defined RC particle was subsequently obtained from *Pc. aestuarii* by means of Triton X-100 treatment and sucrose density gradient separation (Swarthoff and Amesz, 1979). It closely resembled the cytoplasmic membrane vesicles mentioned above,

in pigment composition (about 75 BChl *a* molecules per RC) and photoactivity, and its size corresponded to about 600 kDa. Again by treatment with guanidine-HCl, keeping the incubation time short, a sub-particle of about 350 kDa and 35 BChl *a* /RC was prepared, which retained primary charge separation, however with a lower yield. A smaller sub-particle, of about 200 kDa, called the 'core complex' was later described, which had all the BChl *a*-antenna protein removed by treatment with lithium dodecyl sulphate (LiDS), but had lost its photochemical activity (Vasmel et al., 1983). The authors estimated the removal of about two 42 kDa BChl *a*-proteins (14 BChl *a*-molecules), about 20 BChl *a*-molecules remaining in the core complex.

Another extensively purified RC preparation from *Cb. limicola f thiosulphatophilum*, strain Tassajara was obtained with the combination of octylglucoside/cholate for solubilization (Hurt and Hauska, 1984). The BChl *a*-antenna, as well as cytochrome *b* were removed from this preparation. Photooxidation of P840 and of cytochrome *c* were still observable, but were unstable.

More recently, a procedure yielding more stable RC preparations from *Cb. limicola* and from *Cb. phaeobacteroides* was described, using dodecyl-maltoside treatment, and avoiding ammonium sulphate precipitation (Feiler et al., 1992). These preparations retained part of the BChl *a*-antenna protein, and showed light-induced reduction of FeS-centers F_A and F_B as measured by EPR (see III.B.3.). Following this method, the RC has also been purified from *Cb. vibrioforme* (Okkels et al., 1992), with emphasis on the characterization of an electron donating cytochrome *c*-551 (see III.C.).

Meanwhile two more photoactive RC preparations which reveal photoreduction of FeS-centers have been reported, one from *Cb. limicola f thiosulphatophilum*, strain Larsen, using octylglucoside/cholate in the presence of cysteine (Oh-oka et al., 1993), and one from *Cb. tepidum* using Triton X-100 in the presence of dithiothreitol (Kusumoto et al., 1994). Furthermore, the presence of photoreducible FeS centers in the RC preparation of *Cb. vibrioforme* (Okkels et al., 1992) has been observed (Kjaer et al., 1994).

B. Polypeptide Composition

The isolation procedure of Hurt and Hauska (1984) was optimized for obtaining an RC complex with the

minimum polypeptide composition necessary for primary charge separation. Three polypeptides of 65, 32 and 24 kDa M_{app} 's in SDS-PAGE, together with a small amount of residual BChl *a*-antenna protein of 42 kDa were present. Actually the BChl *a*-antenna protein is partially resolved from the other polypeptides on sucrose density gradients, and fractions totally devoid of it can be obtained (Büttner et al. (1992a), demonstrating that it is not required for the primary charge separation. Nevertheless, the 42 kDa BChl *a*-antenna-protein seems to stabilize the RC, and is present in excess in the more stable, photoactive preparations (Feiler et al. 1992; Okkels et al., 1992; Oh-oka et al., 1993). Following the more detailed picture of Olson (1980) we would state, that in the membrane the RC is attached to two trimers of the 42 kDa BChl *a*-protein ($2 \times 3 \times 7 = 42$ BChl *a* molecules), which can be removed by guanidine-HCl (Swarthoff and Amesz, 1979), plus two additional BChl *a* proteins ($2 \times 7 = 14$ BChl *a* molecules), which can be removed by LiDS (Vasmel et al., 1983), or by octylglucoside/cholate (Hurt and Hauska, 1984) treatment.

The 65 kDa polypeptide (Hurt and Hauska, 1984), observed already in the above-mentioned 'core complex' (Vasmel et al., 1983), in the more recent RC preparations is seen at 50 kDa (Feiler et al., 1992), 68 kDa (Oh-oka et al., 1993) or 80 kDa (Okkels et al., 1992). This variation may be caused by different SDS-PAGE conditions. In all cases this polypeptide migrated as a diffuse band, characteristic of hydrophobic proteins, at a similar R_f -value to that of the large subunits of PS I (see Golbeck and Bryant, 1991). For the 65 kDa polypeptide, it was additionally shown that it retained BChl during LiDS-PAGE (Hurt and Hauska, 1984), further, it was not fully unfolded in SDS-PAGE, yielding a green band at about 110 kDa and was easily aggregated by boiling in SDS sample buffer (Hurt and Hauska, unpublished). All this is similar to what is observed for the PS I large subunits. The resemblance of the diffuse 65 kDa band to the large subunits of PS I, binding the primary donor and the early acceptors, has been confirmed by comparison of the genes (see IV.A.).

A heme-staining polypeptide was observed in most of the described RC preparations. The 24 kDa polypeptide (Hurt and Hauska, 1984) represents the photooxidizable cytochrome *c*-550.5, and corresponds to the 21 kDa polypeptide of Oh-oka et al. (1993). Probably, both resemble the 18 kDa

cytochrome *c* in the preparation from *Cb. vibrioforme*, which has been characterized via the gene sequence (Okkels et al., 1992). A cytochrome *c*-553 has been separated from the RC in the purification procedure of Hurt and Hauska (1984). In contrast, the preparation by Feiler et al. (1992) keeps the 32 kDa cytochrome *c*-553 bound and removes the 24 kDa cytochrome *c*-550.5. In a recent study on the isolated 32 kDa cytochrome *c*-553 it was shown that it is a multihemic cytochrome (D. Albouy, W. Nitschke, B. Robert and U. Feiler, unpublished). A cytochrome *c*-553 was already described as the immediate electron donor to P840 in *Chloropseudomonas* by Fowler et al. (1971), and in *Chlorobium* by Prince and Olson (1976). Thus the cytochrome *c*-553 seems to be the electron donor and as to EPR studies on membranes it is possible that it corresponds to a tetraheme cytochrome (Feiler et al., 1989; see Section III.C. and Chapter 36 by Nitschke and Dracheva).

A subunit of about 32 kDa, formerly ascribed to the Rieske protein (Hurt and Hauska, 1984), has recently been identified by immunoblotting as the protein carrying the FeS centers F_A and F_B (Illinger et al., 1993). Therefore, all the RC preparations exhibiting photoreduction of the terminal acceptors, the FeS center F_A and F_B (see III.B.3.), should contain a respective subunit. A 32 kDa polypeptide is indeed present in the preparation described by Okkels et al. (1992) and Oh-oka et al. (1993), but in substoichiometric amounts. The heme-positive 32 kDa band on SDS-PAGE of the preparation of Feiler et al. (1992) might, then, either represent two proteins, cytochrome *c*-553 and the F_A/F_B binding protein or the F_A/F_B binding protein is migrating on SDS-PAGE at different apparent molecular weight.

Minor heme-negative polypeptides of 22, 15 and 12 kDa, or of 15, 9 and 6 kDa are present in the preparations of Feiler et al. (1992) and Okkels et al. (1992), respectively. The preparation by Oh-oka et al. (1993) contains only one small polypeptide of about 12 kDa, together with a number of larger polypeptides, which probably represent contaminations. The possible role of the small polypeptides remains to be established.

The minimal number of subunits in a stable and photoactive *Cb. limicola* RC preparation included the P840 protein (pscA), the 42 kDa BChl *a* antenna protein (FMO), the FeS protein (pscB) and a fourth subunit of 17 kDa (pscD). The presence of PscC, the cytochrome *c*-551, was not required. The gene for PscD was sequenced and codes for a polar, basic

16.5 kDa protein, which showed no sequence homologies, but could still functionally resemble PsaD of PSI (C. Hager-Braun, D.-L. Xie, U. Jarosch, E. Herold, M. Büttner, R. Zimmermann, G. Hauska and N. Nelson, unpublished).

C. Pigment Composition

All green sulfur bacteria contain BChl *a* in their RC complex. Characteristic absorption bands of BChl *a* are the Q_y transition band at ca. 810 nm, the Q_x transition band at ca. 610 nm and the Soret band at ca. 370 nm (in vivo; Olson, 1980). In the case of the primary donor, which is most likely a BChl *a* dimer (see III.A.), the Q_y transition band is shifted to ca. 840 nm.

Figure 1 shows the absorption spectrum of the RC complex of *Cb. limicola f thiosulphatophilum* isolated following the procedure of Feiler et al. (1992). We can estimate the pigment content of the RC complex from this spectrum: At 340, 370, 603 and 810 nm, the characteristic absorption bands of BChl *a* and, additionally, the shoulder at 838 nm indicating the primary donor, are seen. The ratio of BChl *a* to P840 was about 40:1 in this preparation. Considering the model of Olson (1980) discussed above, this ratio might be interpreted as implying two BChl *a*-antenna proteins are attached to the RC complex, while the remaining BChl *a*'s are bound to the RC core.

In Fig. 1, the insert shows part of the absorption spectrum of a preparation enriched in the RC core which contained only about 25 BChl *a* per P840 (Vasmel et al., 1983; Hurt and Hauska, 1984). Characteristic for a RC core complex, from which the BChl *a*-antenna protein is separated, is the shift of the absorption maximum of the Q_y and Q_x transitions of BChl *a*. The absorption maximum of the Q_y transition is now at 814 nm and the shoulder arising from P840 is more pronounced. Additionally, the absorption maximum of the Q_x transition is at 597 nm and shows, like the Q_y transition, an asymmetry possibly reflecting the presence of a heterogeneous population of BChl *a*. The Q_y transition of BChl *a* shown in Fig. 1 are similar to those reported for *Pc. aestuarii* (Swarthoff and Ames, 1979; Vasmel et al., 1983).

Low-temperature absorption spectra of purified membrane particles resolved several BChl *a* Q_y bands arising from exciton interactions within BChl *a* aggregates. Peaks at 805, 816 and 823–824 nm were present in RC containing preparations as well as in

Fig. 1. Room temperature absorption spectrum of the photoactive reaction center complex of *Chlorobium limicola f thiosulphatophilum*. The isolation procedure of Feiler et al. (1992) was used. The insert shows the reaction center core-complex isolated following the procedure of Hurt and Hauska (1984).

the BChl *a*-antenna protein, while 1 or 2 peaks between 833 and 836 nm, due to the primary donor were additionally present in the former only (Swarthoff and Ames, 1979; Olson, 1980; Miller et al., 1994). Likewise, the CD spectra of the same samples were comparable in both band sign and band position. From these similarities in absorption and CD spectra of the two BChl *a*-containing proteins, it was concluded that the exciton interactions and thus, presumably, the organization of the BChl *a*'s, present in the BChl *a*-antenna protein and in the RC-containing membranes, are similar (Olson, 1980).

The absorption band at 672 nm (see Fig. 1) arises, at least partially, from the primary acceptor pigment, called BChl-663, which is a Chl *a*-molecule (van de Meent et al., 1992; Feiler et al., 1994; see III.B.1.). No BChl *c* or bacteriopheophytin (BPh) *c* contributions could be detected by means of resonance Raman spectroscopy in the preparation of Feiler et al. (1992, 1994). However, in earlier RC preparations of *Chlorobium* and *Prosthecochloris* (see II. A.) both BChl *c* and BPh *c* contributed to absorption bands at 670 nm. As detected by low-temperature absorption and CD spectroscopy (Olson, 1980), these contributions are most likely due to residual BChl *c* and BPh *c* presumably formed from chlorosomal BChl *c*.

Absorption bands in the wavelength range from 440 to 505 nm arise from the carotenoids' rhodopin and/or hydroxychlorobactene (Braumann et al., 1986). A ratio of ca. 2 carotenoids per P840 can be

calculated for the spectrum in Fig. 1.

In the RC preparations, *c*-type hemes are present associated with membrane-bound cytochrome(s) (Hurt and Hauska, 1984; Feiler et al. 1992, Okkels et al., 1992; Oh-oka et al., 1993; see III.C.). However, the stoichiometry and the exact nature of these cytochromes associated with the RC is not yet clear (see III.C.). The described *b*-type cytochromes in membranes (Fowler, 1974) do not copurify with the RC.

III. Electron Transfer With in the Reaction Center

A. The Primary Electron Donor P840

1. Optical Properties

Photobleaching of BChl *a* at around 840 nm (P840) was first reported in whole cells of *Chloropseudomonas ethylicum* 2K (Sybesma and Vredenberg, 1963), and has since been observed in both membranes and isolated RC preparations of all green sulfur bacteria studied. This photobleaching is accompanied by additional bleachings at ca. 830 nm and, weaker, at ca. 790 nm (Fowler et al., 1971; Olson et al., 1973; Olson et al., 1976b; Swarthoff and Amesz, 1979). The origin of these additional signals is not yet clear. These bleachings have also been observed in chemically-induced oxidized-minus-reduced difference spectra (Fowler et al., 1971; Olson et al., 1973; Feiler et al., 1992; Miller et al., 1992; Oh-oka et al., 1993).

In light-minus-dark CD difference spectra, only the band at ca. 840 nm was visible (Olson et al., 1973). This might be interpreted as evidence that the two additional bleaching bands at 830 and 790 nm, seen in the absorption difference spectra, arise from monomeric pigments which have very little rotational strength.

Two bands at around 830 and 840 nm, were also observed in low-temperature triplet-minus-singlet absorbance difference spectra of RCs from *Pc. aestuarii* (Vasmel et al., 1984). It was concluded from LD-absorbance detected magnetic resonance (ADMR) spectroscopy experiments that these two transitions are approximately parallel. They, thus, cannot arise from an excitonically split transition, as the transition moments of such an exciton pair are mutually perpendicular. These two bands therefore

do not belong to the same molecular species (e.g. a special pair). A possible explanation is, that only one of the bands, presumably the one at 840 nm, reflects the primary donor (the low energy transition of a strongly exciton coupled, CD-active dimer) while the second band at around 830 nm is arising from electrochromic changes that occur in neighbouring, monomeric pigments.

More specifically, this transition at 830 nm may arise from a special pigment, a so-called 'voyeur'-BChl, as found in purple bacterial RCs (for a review see Kirmaier and Holten, 1987). This is supported by observations of chemical-induced absorption difference spectra of *Chlorobium* RC complexes (Feiler et al., 1992; Okkels et al. 1992); no negative band at ca. 790 nm was observed in the purified RCs. The difference spectra in this region could be interpreted as arising from the shift of the transition of a pigment absorbing at ca. 815 nm resulting in a negative band at ca. 830 nm and a positive band at ca. 800 nm. This is reminiscent of the situation in the purple bacterial RC, where oxidation of the primary donor causes an electrochromic shift of the 'voyeur'-BChl absorption band near 800 nm.

An absorption band at 1157 nm, attributed to P840⁺, was observed in both light-induced and chemical-induced absorption difference spectra (Olson et al., 1976b; U. Feiler, T. A. Mattioli and B. Robert, unpublished, respectively). Like in the purple bacterial RC (for a review see Kirmaier and Holten, 1987) the P⁺ band of green sulfur bacterial RC shows a large red-shift when compared to monomeric BChl *a*⁺, which absorbs near 900 nm (Fajer et al., 1975). This suggests that in green sulfur bacteria the primary donor is a dimer of BChl *a*, or more precisely it keeps its dimeric character in the P⁺ state, as in the purple bacterial RCs.

2. Redox Potential

Measurement of the magnitude of light-induced bleaching of P840 as a function of applied redox potential yielded a titration curve well described by a one-electron Nernst curve with a midpoint potential of +240 mV (Fowler et al., 1971; Prince and Olson, 1976). This potential is ca. 150 mV lower than those of the primary donors in either purple bacteria (see Kirmaier and Holten, 1987) or PS I of plants and cyanobacteria (Golbeck and Bryant, 1991). This decrease in the redox potential is also observed in other redox carriers of Chlorobiaceae (Rieske-protein,

Knaff and Malkin, 1976; cytochrome *c*-555, Meyer et al., 1968) and seems to be an adaptation to the reducing conditions in which they live.

3. Structural Studies

Magnetic studies have given valuable insight into the delocalization of unpaired electrons over the π -system of P840⁺ and hence the structure of the primary donor. The EPR lineshape of P840⁺, studied by the second moment method in ¹³C-enriched *Chlorobium*, demonstrated that the unpaired electron is delocalized over two macrocycles (Wasielowski et al., 1982). Furthermore, the 9–10 Gauss EPR linewidth of P840⁺ (Olson et al., 1976b; Swarthoff et al., 1981a; Feiler, 1991) is narrowed compared to that of monomeric BChl *a*⁺ (12.8 Gauss) by a factor of ca. $1/\sqrt{2}$, as in *Rhodobacter sphaeroides* (Norris et al. 1971), and has also been attributed to a delocalization of the unpaired electron over two BChl *a* molecules.

Additionally, the triplet state of P840 has been studied by both EPR and ADMR spectroscopy. The zero field splitting parameters of ¹³P840 (Swarthoff et al., 1981a; Vasmel et al., 1984; Nitschke et al., 1990a) are similar to those of the primary donor triplet signal in purple bacterial RC (Dutton et al., 1971). Moreover, the orientation of the ¹³P840 EPR signal (Nitschke et al., 1990a) is very similar to that found for ³¹P in purple bacterial RCs (Hales and Gupta, 1979; Tiede and Dutton, 1981).

These studies together with the observation of the P840⁺ band at 1157 nm of Olson et al. (1976) (see III. A. 1.) have shown that the primary donor in green sulfur bacterial RCs is most likely a BChl *a* dimer with a similar geometry to that of the purple bacterial RC.

Analysis of the unpaired electron spin distribution of P840⁺ using electron nuclear double resonance (ENDOR) and special TRIPLE spectroscopy was performed by Rigby et al. (1994). A highly symmetrical distribution of the electron spin density between the two BChl *a* molecules of the special pair was shown, indicating a symmetrical protein environment of the special pair. This is consistent with the proposal of a homodimeric photosynthetic RC (see IV).

Recently, near-infrared Fourier transform (FT) Raman spectroscopy (excited at 1064 nm) has been performed on the isolated RC (U. Feiler, T. A. Mattioli and B. Robert, unpublished). The FT resonance Raman spectrum of the *Chlorobium* RC in the P⁺ state exhibits a band at 1707 cm⁻¹ which is

significantly lower than its counterpart in the P⁺ spectrum from BChl *a*-containing purple bacterial RCs (ca. 1717 cm⁻¹). This 1707 cm⁻¹ band arises from the C₉-keto carbonyl stretching mode of the P⁺ species which is upshifted from 1690 cm⁻¹, observed in the P⁰ FT Raman spectrum of ascorbate-reduced *Chlorobium* RCs. This 17 cm⁻¹ upshift of a free keto carbonyl stretching frequency has been interpreted as indicating a nearly complete and symmetric delocalization of the residual unpaired electron over both BChl *a* molecules in the P⁺ state on the timescale of the resonance Raman effect (10⁻¹³s). In the RC of *Rhodobacter sphaeroides* the corresponding upshift is 26 cm⁻¹ which indicates that nearly the full +1 charge is carried by one of the two dimeric BChl *a* molecules (Mattioli et al., 1991). Therefore the delocalization of the +1 charge in the P⁺ state over two BChl *a* molecules in the *Chlorobium* primary donor is markedly different from the situation in purple bacteria, and supports the suggested homodimeric structure of the RC, which was based on the observation of a sole RC gene (see IV).

B. The Electron Acceptors

1. The Primary Electron Acceptor

In light-minus-dark absorbance difference spectra Swarthoff and Amesz (1979) observed a negative band at 660 nm and a positive band at 678 nm which they proposed to be caused by an electrochromic red shift of a pigment absorbing at 670 nm, possibly a BPh *c*. Since, in the two different RC preparations used (see I.A.), this pigment was present in an approximately constant ratio to P840, they suggested that it might be a functional component of the RC complex. Later, flash-induced absorption changes at around 670 nm were attributed to reduction of a primary acceptor molecule, variously identified as BChl *c* or BPh *c* (van Bochove et al., 1984; Nuijs et al., 1985; Shuvalov et al., 1986).

Evidence of BPh *c* as primary acceptor was based on absorption and CD spectrophotometry data (Olson, 1981) and LD spectroscopy data (Vasmel et al., 1983). From comparison of the absorption spectra of both BChl *c* and BPh *c* in organic solvents with absorption spectra of different RC preparations it was concluded that the observed 670 nm pigment is mainly BPh *c*. CD data showed that only some of the BPh *c* molecules were optically active. Furthermore, a correlation between distorted CD and LD signals

of the 670 nm pigment and the loss of photochemical activity of the RC was shown.

Thin layer chromatography showed, besides BChl *a* and carotenoids, small amounts of BPh *c* and an unidentified pigment (named P-665), with an absorption spectrum similar to that of BPh *c*, were present in *Pc. aestuarii* membranes (Swarthoff et al., 1982). Further analysis of the pigment composition of various pigment-protein complexes from the same bacterium by reversed-phase high-performance liquid chromatography (HPLC) (Braumann et al., 1986), demonstrated the presence of a special pigment with absorption maxima at 663 and 433 nm in these complexes. This pigment, labelled BChl-663, was more lipophilic than BChl *c* and had phytol as the esterified alcohol rather than the *trans-trans* farnesol of BChl *c*. A ratio of 10–15 molecules BChl-663 per RC was calculated. Since this pigment absorbs at 670 nm *in vivo*, a wavelength where absorption changes associated with the primary acceptor reduction were observed (see above and III.C.), it was proposed that BChl-663 is the primary acceptor. BPh *c* which may also absorb at 670 nm was absent from the pigment protein complexes studied. This work was extended by van de Meent et al. (1992) who showed, by normal-phase HPLC, that BChl-663 was present, at a ratio of 3–9 molecules/RC, in five species of green sulfur bacteria studied. By using plasma desorption mass spectroscopy, NMR and absorption spectroscopy they concluded that BChl-663 was a Chl *a*-isomer.

More direct evidence for the role of a Chl *a*-like pigment as the primary acceptor *in situ* was provided by a resonance Raman study of isolated, photoactive, RCs (Feiler et al., 1994). This work demonstrated not only the presence of a Chl *a*-like pigment in highly purified RCs but also that this molecule was bound to the RC protein in a manner very similar to the primary acceptors of both purple bacterial RCs and PS II (see V.A.).

Therefore, it appears that the primary acceptor in green sulfur bacterial RCs is a Chl *a*-like pigment, as it is likely in PS I (Golbeck and Bryant, 1991) and in the heliobacteria (see Chapter 31 by Ames). We will, thus, refer to it as A_0 below.

2. The Secondary Electron Acceptor

The first evidence for the presence of a quinone in the RC of green sulfur bacteria was given by Nitschke et al. (1987) where a low-temperature EPR signal in the

Chlorobium RC similar to that of A_1 in PS I (Mansfield et al., 1987; Mansfield and Evans, 1988) was observed. However, a controversy has since arisen as to the origin of the low-temperature EPR signal of A_1 in PS I (Ziegler et al., 1987; Barry et al., 1988; Heathcote et al., 1993). The experimental conditions necessary to induce the triplet EPR-signal, and thus to reduce the secondary acceptor, were similar in *Chlorobium* and PS I. This provides indirect evidence for the secondary acceptor behaving like a quinone in the *Chlorobium* RC (Nitschke et al. 1990a). In a preliminary study of electron spin polarized EPR spectroscopy performed on *Chlorobium* membranes, an emission/absorption signal was observed, resembling the spectra of purple bacterial RCs in which the rate of electron transfer from BPh (H_M) to quinone (Q_A) was reduced. This can be understood in terms of sequential electron transfer in green sulfur bacteria (Snyder and Thurnauer, 1993).

A preliminary study of the lipid composition of *Chlorobium* RCs by thin-layer-chromatography (Feiler and Hauska, unpublished) demonstrated the presence of a quinone-like component, probably 1'-hydroxy-menaquinone-7 which is one of the three menaquinones identified in whole cells (Powls and Redfearn, 1969). Furthermore, in the same study, a quinone component was observed by redox difference spectroscopy.

Although one could expect a quinone participating in the electron transport chain as in PS I (Hauska, 1988), involvement of such a quinone as secondary acceptor in the RC complex remains unclear and thus further experiments are necessary to clarify the identity of the secondary acceptor. In this context it is noteworthy that the electron transport in the RC of heliobacteria is not affected by removal of extractable menaquinone (Kleinherenbrink et al. 1993 and Chapter by 31 Ames).

3. The Iron-Sulfur Centers as Electron Acceptors

Early EPR data on *Chlorobium* membranes suggested that FeS centers are involved in primary electron transfer processes as RC bound acceptors. However, the early results were inconsistent: Jennings and Evans (1977) observed a signal at $g = 1.90$ which was photoinduced at 4 K and its midpoint potential was estimated as -550 mV. They associated this light-induced signal with the low g -value component, previously reported by Knaff and Malkin (1976) who originally attributed it to a Rieske FeS center,

and suggested that the +160 mV midpoint potential, determined by Knaff and Malkin, was artifactual. Re-examination (Knaff et al., 1979) confirmed the original assignment of the $g = 1.90$ signal to a Rieske FeS center with the $E_m = +160$ mV, and challenged the existence of the photoreducible signal.

Swarthoff et al., (1981b) reported the EPR spectrum of an FeS center with g -values of $g_y = 1.94$, $g_x = 1.89$, and determined the midpoint potential to be more positive than -420 mV. They attributed this signal to the terminal acceptor of the RC. A sample poised at -420 mV and frozen during illumination gave rise to an additional FeS center signal at $g_y = 1.94$ and $g_x = 1.88$. This observation is in line with earlier redox titration experiments (Knaff and Malkin, 1976) that described an FeS center with a g -value of $g = 1.94$ and a redox potential of about -550 mV. Swarthoff and co-workers suggested that the latter FeS center was an earlier electron acceptor with an E_m of ca. -560 mV functioning prior to the terminal acceptor of the RC (Swarthoff et al., 1981b).

Nitschke et al. (1987) showed that, at 200 K in the presence of dithionite at high pH an FeS center could be photoreduced. The EPR signal obtained in this study was similar to the photoinduced FeS signal of Swarthoff et al. (1981b). However, it was still not clear how many FeS centers are involved in photoinduced electron transport within the RC.

A clarifying re-examination by EPR spectroscopy of *Chlorobium* membranes (Nitschke et al., 1990a) finally showed the presence of three different photoreduced FeS centers involved in electron transfer processes in the RC of green sulfur bacteria. One FeS center ($g_{z,y,x}$ -values: 2.07, 1.91, 1.86) was stably photoreduced at 4 K and is probably identical with the 1.90 signal reported by Jennings and Evans (1977). At 200 K an additional FeS center was photoaccumulated ($g_{z,y,x}$ -values: 2.05, 1.94, 1.88) whose spectrum resembles that published by Swarthoff et al. (1981b) when the chemically reduced sample was illuminated during freezing. A further signal was obtained after prolonged illumination at 200 K, identified by a $g_x = 1.78$ and assigned to a third FeS center. Based on the similarities of their g -values and orientations to those of the PS I FeS centers they have been designated as F_B , F_A and F_X , respectively. If this assignment is warranted, the order of low temperature photoreduction of the FeS centers in green sulfur bacterial RCs (i.e. first F_B , second F_A) is reversed compared to PS I (first F_A , second F_B) under the same conditions. FeS centers in

RCs of *Cb. limicola f thiosulphatophilum* are not chemically reducible under these conditions (i.e. 20 mM dithionite, 200 mM glycine pH 11) and thus should have lower redox potentials than ca. -600 mV. A recent report, however, indicates that in the thermophilic *Cb. tepidum* the redox potentials of the FeS centers (as well as that of P840) are slightly more positive, rendering them reducible by dithionite at high pH (Kusumoto et al., 1994).

Both the FeS centers F_A and F_B have been shown to be present in an isolated RC complex (Feiler et al., 1992), and since, the presence of photoreducible FeS centers in *Chlorobium* RCs has been confirmed by several groups (Miller et al., 1992; Oh-oka et al., 1993; Kusumoto et al., 1994; Kjaer et al., 1994).

Preliminary data using electron spin polarized EPR spectroscopy at 283 K have been obtained on *Chlorobium* membranes (U Feiler, W Nitschke, D Stehlik and C Bock, unpublished). An emission/absorption spectrum was observed. Based on the similarities of its g -values and emission/absorption characteristics to those in comparable spectra of PS I, it might be arising from the radical pair P^+FeS^- . However, a clear interpretation of these data is not possible yet.

The putative binding elements for the FeS center F_X are conserved in RCs of *Chlorobium*, PS I and heliobacteria (Golbeck and Bryant, 1991; Büttner et al., 1992a; Liebl et al., 1993). A gene related to the *psaC* gene of PS I, which codes for the protein binding the FeS centers F_A and F_B (Büttner et al., 1992a; see IV), as well as the corresponding protein (Illinger et al., 1993; see II.B.), is also found in *Cb. limicola f thiosulphatophilum*

4. Ferredoxin and Ferredoxin-NAD(P)-Reductase

Green sulfur bacteria are capable of direct photoreduction of $NAD(P)^+$ via ferredoxin without additional energy requirement (i.e. an electrochemical proton gradient) (Buchanan and Evans, 1969). The light-induced $NAD(P)^+$ reduction is insensitive to uncoupling chemicals added in order to collapse the proton gradient (Knaff, 1978). Both soluble ferredoxin and the flavoprotein ferredoxin-NAD(P)-reductase (FNR) have been isolated (Rao et al., 1969; Buchanan et al., 1969; Kusai and Yamanaka, 1973; Shioi et al., 1976). The amino acid sequence of *Chlorobium* ferredoxin (Tanaka et al., 1974) indicates that it is a protein containing two 4Fe4S-clusters,

which is in contrast to the 2Fe2S ferredoxin in PS I. The *Chlorobium* ferredoxin is proposed to be a link between the ferredoxins of non-photosynthetic bacteria and those of photosynthetic bacteria of the *Chromatium*-type (Buchanan et al., 1969; Rao et al., 1969). The FNR catalyses the reduction of NAD(P)⁺ by photo-reduced ferredoxin (Kusai and Yamanaka, 1973; Shioi et al., 1976). Both proteins were proposed to be involved in transferring electrons from the bound FeS centers to NAD(P)⁺ similar to the respective process in PS I (for a review see Knaff and Hirasawa, 1991).

C. The Electron Donor to P840

As early as 1971, a membrane-bound cytochrome *c* with an α -band at 553 nm was proposed to act as electron donor to the photooxidized primary electron donor P840 (Fowler et al., 1971). This was confirmed by light induced kinetic measurements on membrane fragments showing that P840⁺ is rapidly (biphasically, $\tau < 7 \mu\text{s}$ and $70 \mu\text{s}$) rereduced by cytochrome *c*-553 (Prince and Olson, 1976). In whole cells, the rereduction of P840⁺ by cytochrome *c*-553 is seen to be monophasic with $\tau = 6.9 \mu\text{s}$ (U Feiler and W Nitschke, unpublished).

Recently, however, different RC preparations have been reported which have triggered a controversy as to the nature of the cytochrome serving as immediate electron donor to photooxidized P840. A cytochrome *c* with an α -band at 553 nm and a M_{app} of 32 kDa copurifies with the RC proteins in the RC preparation of Feiler et al. (1992). Based on EPR data on membranes and partially isolated cytochrome (Feiler et al., 1989; Feiler, 1991) this cytochrome *c*-553 was proposed to contain four heme groups like the tetraheme cytochromes associated with the RCs of purple bacteria and *Chloroflexus* (see Chapter 36 by Nitschke and Dracheva). A ratio of 4 hemes per RC was determined in solubilized membranes and the isolated RC complex still showed a stoichiometry of 2 hemes/RC (Feiler et al., 1992). Recently this cytochrome *c*-553 was isolated. Its characterization by EPR spectroscopy showed that this cytochrome is multihemic (D. Albouy, W. Nitschke, B. Robert and U. Feiler, unpublished). By contrast, in a preparation reported by Okkels et al. (1992), a photooxidizable 18 kDa monoheme cytochrome with an α -band at 551 nm was observed to copurify with the RC proteins and was proposed as electron donor to P840⁺. Its

Fig. 2. Room temperature kinetics of electron flow in the reaction center complex of green sulfur bacteria. The electron-transfer rates are given, either as single values or, where discrepancies exist, as a range of values (described further in the text). Although the chain of electron carriers conforms to current thinking on the role of each component, uncertainties concerning the identity and, thus, the role of A₁ exist (described in the text).

primary sequence was determined and no significant homology to known cytochromes was found. This cytochrome might be similar to that observed in the preparation of Hurt and Hauska (1984), where a photooxidizable 24 kDa (M_{app}) cytochrome *c*-550.5 copurified with the large RC subunit. More recently, Oh-oka et al. (1993) proposed a cytochrome *c*-551 as electron donor to P⁺ which exhibited a M_{app} of 21 kDa. However, in purified samples the rereduction of P840⁺ via this cytochrome *c*-551 occurred with rather high time constants (130 μs and 560 μs).

To resolve this controversy, further functional studies of the various cytochromes are needed. Further data on amino acid sequences of the several proposed cytochromes and deletions of their respective genes should be performed to obtain more information.

D. Kinetics of Electron Transfer

Primary charge separation and further electron transfer steps in the RC of green sulfur bacteria have been studied by time-resolved optical spectroscopy. Experiments have been performed on different RC preparations with antenna sizes ranging from ca. 20 to ca. 100 BChl *a* per RC (see II.) at both low and room temperatures. In this paragraph, only the data obtained at room temperature are discussed (see Fig. 2).

The time constant (τ) for the primary charge separation was calculated to be <10 (Shuvalov et al., 1986) and 35 ps (Nuijs et al., 1985). The primary acceptor A_0 was identified by measuring a light-induced bleaching around 670 nm together with the primary donor bleaching. Both showed the same kinetics (Swarthoff and Ames, 1979). In a further investigation by flash-induced optical spectroscopy on various kinds of RC preparations, P840 oxidation at 810–850 and 610 nm together with A_0 bleaching around 670 nm, was observed (Swarthoff et al., 1981c). Recovery of the A_0 neutral state was measured by nanosecond flash-induced spectroscopy (van Bochove et al., 1984). A decay time of 20–35 ns was measured for the $P^+A_0^-$ radical pair, most likely mainly to the triplet state of P840, because the preparation used was impaired in electron transfer between the Chl *a*-like acceptor and the secondary acceptor (Swarthoff et al., 1981c). In picosecond absorption spectroscopy the decay time of the A_0^- signal measured at 670 nm was 550 to 770 ps which was attributed to the electron transfer time to the secondary acceptor present in the more intact membrane systems of these studies (Nuijs et al., 1985 and Shuvalov et al., 1986, respectively). This secondary acceptor might be a quinone (see III.B.2.).

No kinetic data are available for forward transfer reactions from A_1 to the terminal acceptors and on recombination reactions of the secondary acceptors to P840.

A BChl *a*-triplet signal with a life time of 90 μ s was interpreted as being due to the triplet-state of P840 (Swarthoff et al., 1981c).

Recombination between the FeS centers F_A and F_B and photooxidized P840 was measured and a time constant of 10 ms was observed (Miller et al., 1992). After removing the FeS centers F_A and F_B by treatment of the RC samples with chaotropic agents, faster rereduction kinetics ($\tau=70\mu$ s) were introduced which

were suggested by the same authors as resulting from a recombination between the FeS center F_X^- and P840⁺.

The respective kinetic data in PS I occurred in the same order of magnitude (see Golbeck and Bryant, 1991), further supporting the similarities to PS I.

Further, rereduction of the primary donor was measured together with the photooxidation of cytochrome *c*. However, several somewhat inconsistent, results have been presented in the literature. Fast electron transfer kinetics ($\tau = 6.9 \mu$ s) between cytochrome *c* with its α -band at 553 nm and P840⁺ was observed in whole cells (U Feiler and W Nitschke, unpublished; see III.B.5. and chapter by Nitschke and Dracheva in this volume). A similar value ($\tau < 7 \mu$ s) was measured in membrane fractions, however the kinetics showed also a slower phase with a time constant of 70 μ s (Prince and Olson, 1976), which might indicate some damage on the donor side to P840⁺. In an isolated RC complex, similar kinetics (time constants of 10 μ s and 70 μ s) were observed. However, they were due to reaction of a cytochrome *c*-551 with P840⁺ (Okkels et al., 1992). The slow kinetics have also been observed by Swarthoff et al. (1981c) ($\tau = 130 \mu$ s) and Miller et al. (1992) ($\tau = 70$ – 120μ s), however, in both cases due to reduction of P840⁺ by cytochrome *c*-553. Depending on the preparation used an even slower phase ($\tau \approx 40$ ms) was seen, which was due to damage on the donor side during purification (Swarthoff et al. 1981c). A 130 μ s and an additional 560 μ s phase, due to oxidation of cytochrome *c*-551 were described by Oh-oka et al. (1993).

It seems clear that the immediate donor to P840⁺ is a membrane bound cytochrome *c*, however, the exact nature still remains unclear. The 7–10 μ s time constant of oxidation of cytochrome *c* likely indicates that this cytochrome is closely associated if not bound to the native RC and slowing down of the respective donation kinetics may indicate damage of the RC preparations.

IV. Genes Encoding Reaction Center Proteins

A transcription unit coding for two subunits of the RC of *Cb. limicola* has been cloned and sequenced by Büttner et al. (1992a). At about the same time the sequence of the gene and its interpretation for the

electron donating cytochrome *c*-551 in a RC preparation from *Cb. vibrioforme* has been published (Okkels et al., 1992). Furthermore, a gene for the large subunit of the RC from *Heliobacillus mobilis* (Liebl et al. 1993; see Chapter 31 by Ames in this volume) has been obtained. Thus the photosynthetic bacteria with PS I-like RCs have become accessible to molecular biology.

The first gene (*pscA*) in the transcription unit of *Cb. limicola* codes for the P840-protein (PscA) related to the P700-proteins PsaA and PsaB, the second (*pscB*) for the protein related to PsaC, which carries the FeS-centers F_A and F_B . Upstream of the transcription unit promoter and ribosome binding motifs are found, and a transcription terminating stem-loop structure occurs after the second gene. This suggests that the two genes are transcribed together into a bicistronic mRNA. See also Section II.B.

A. The Gene for the P840-Protein

The gene for the P840-protein (*pscA*) codes for 730 amino acids, with a calculated mass of 82.24 kDa. This is almost the same mass as the ones for the PsaA/B-proteins, which are 750 and 742 amino acids long, respectively (Fish et al., 1985; see Golbeck and Bryant, 1991). Several hydrophobic peptides long enough to span the membrane occur along the sequence. The 'positive-inside-rule' (von Heijne, 1986) favors eleven transmembrane helices (Büttner et al. 1992a,b). Eleven spans each have also been postulated for the PsaA/B-proteins (Fish et al., 1985), and have been detected in the gene (*pshA*) for the shorter P800-protein (608 amino acids) from *Heliobacillus mobilis* (Liebl et al., 1993). Most striking and valuable for an alignment of these RC proteins is the occurrence of a highly conserved dodecapeptide close to the hydrophobic span IX, as seen in Fig. 3. Of the 12 amino acids identical between PsaA and PsaB, 9 each are conserved in both the P840- and the P800-protein (Trost et al., 1992), which themselves have 11 in common. The PS I-dodecapeptides contain 2 cysteines each, which are suggested to bind the FeS-center F_x between PsaA and PsaB (see Golbeck and Bryant, 1991). From its position the alignment of the P840-protein with the PsaA/B-proteins was started (Büttner et al., 1992a).

The overall identity of the P840-protein to PsaA/

Fig. 3. Alignment of regions of the amino acid sequences for the P840 protein (RCP840) with the large reaction center subunit of heliobacteria (RCP800) and the two large subunits of PS I from maize (PS IAMz/PS IBMz). Identical residues are indicated by dots. The Roman numerals mark three of the putative membrane spanning helices, which are underscored. The putative binding sites of the primary donors (P700, P840, P800) are indicated by arrows, those of the electron acceptors A_0 , A_1 , and F_x are indicated below the alignment. Letter *c* indicates the cytoplasmic side and *p* the periplasmic side of the membrane. The RCP840 sequence is taken from Büttner et al. (1992a), the RCP800 sequence from Liebl et al. (1993) and the PS IA/IBMz sequences from Fish et al. (1985).

B-proteins is only 15 and 14%, respectively. For the P800-protein it is about 17% to both PsaA and B (Liebl et al., 1993). The two large PS I-proteins have 45% of their amino acids in common, indicating that gene duplication occurred later than the separation of green sulfur bacteria and heliobacteria from cyanobacteria. The low overall identity between both P840- and P800-protein to PsaA and -B points to the significant residues, which may be valuable for suggesting site-directed mutations of PS I. These are now possible after successful deletion of the genes for PsaA or-B (Smart et al. 1991; Toelge et al. 1991).

The P840-protein contains only 20 histidines, compared to 42 and 37 in PsaA and -B, respectively. Of these 20 histidines only 7 are found at identical positions in the alignment with PsaA and -B (Büttner et al. 1992a). One of the two histidines conserved in hydrophobic span VI, more likely the one closer to the cytoplasmic surface (Fig. 3), may hold the primary acceptor A_0 (see III.B.1). The one in putative transmembrane helix VIII (Fig. 3) might bind P840, the 'special pair' of BChl *a*'s (see III.A). However, recently, site-directed mutagenesis experiments performed on chloroplast *psaB* gene of *Chlamydomonas reinhardtii* indicated that a conserved histidine in helix X might be the ligand of the primary donor P700 (Cui et al., 1995). Indeed, conserved histidine residues are found for PsaA and PsaB of maize as well as for the reaction center proteins of both *Chlorobium* and *Heliobacillus* (see Fig. 3). The aromatic residues conserved in span IX may contribute to the transmembrane charge separation. Furthermore, the phenylalanine in the conserved dodecapeptide may be involved in the function of A_1 (see III.B.2.).

In the alignment of Büttner et al. (1992a) helices I–III and VI–IX are found at corresponding locations in all RC proteins, while IV and V are not. Possibly helices IV and V are not in the membrane, as considered in a recent folding model (Xie et al. 1992). Indeed, a first structure of the RC of PS I from X-ray crystallography shows only 8 transmembrane helices per PsaA or -B (Krauss et al., 1993).

B. Evidence for a Reaction Center-Homodimer

Only one gene coding for a large, hydrophobic protein is present in the transcription unit as opposed to two genes, mostly in tandem, for PsaA and -B of PS I (Golbeck and Bryant, 1991). A second band in Southern blot analyses with 16 different restriction enzymes, even under low stringency, is not observed (Büttner et al. 1992b), although cross hybridization occurs between the genes for PsaA and PsaB. This again indicates the presence of only one gene, unless the two proteins in the RC are significantly less related than PsaA to PsaB. The most convincing evidence for only one gene, and thus for a homodimeric RC, is that it represents all 7 peptides obtained so far from the large 65 kDa-subunit by proteolytic degradation and amino acid sequencing (Büttner et al., 1992a,b and unpublished). This leaves

a probability of 1/128 for a second protein in the 65 kDa-subunit, if equal accessibility to proteases is assumed. Very similar negative evidence for a respective second gene has been provided for the RC of heliobacteria (Liebl et al. 1993; see Chapter 31 by Amesz).

C. The Gene for the Protein Binding the FeS-Centers F_A and F_B

The second gene (*pscB*) in the transcription unit codes for a protein of 23.87 kDa with 232 amino acids. It contains 8 cysteines in the C-terminal part, which are spaced similar to the smaller PsaC-proteins (8.8 kDa) of PS I (see Golbeck and Bryant, 1991) and probably hold the two 4Fe4S-clusters of centers F_A and F_B . As mentioned above (see II.B.), the gene product has been identified as the 32 kDa-polypeptide (Illinger et al., 1993). The comparatively high apparent mass is probably caused by the positively charged N-terminal extension of 132 amino acids, with a repetitive sequence, which may function in docking the negatively charged ferredoxin (Büttner et al., 1992a), and which may thus substitute for subunit PsaD in PS I (see Golbeck and Bryant, 1991). A similar N-terminal extension is encoded in the gene for cytochrome *b* of *Chlorobium* (Schütz et al., 1994), and a shorter version of it also in the N-terminus of the P840-protein (Büttner et al., 1992a; see Fig. 4).

The redox potentials of FeS centers F_A and F_B are more negative and photoreduction order is turned around in *Chlorobium* RC compared to PS I. An explanation of the latter might be that center F_A in *Chlorobium* is more negative than center F_B (Nitschke et al., 1990a). On the basis of the structural similarities of the PsaC-protein to bacterial 2(4Fe4S) ferredoxins (Adman et al., 1973; Dunn and Gray, 1988; Oh-oka et al., 1988) it was suggested for the PsaC-protein that the first 3 and the last of the 8 cysteines bind one of the two 4Fe4S clusters, while the residual cysteines bind the second cluster. Two positive charges, likely responsible for stabilization of the reduced center F_A , are conserved between the 6th and the 7th cysteines in the PsaC-proteins, but missing from the respective *Chlorobium* sequence. This could explain a shift of the redox potential of F_A to a more negative value in *Chlorobium*. Therefore, center F_A is probably bound to cysteines 4 to 7, while center F_B is bound by the residual four cysteines (Büttner et al., 1992a). This

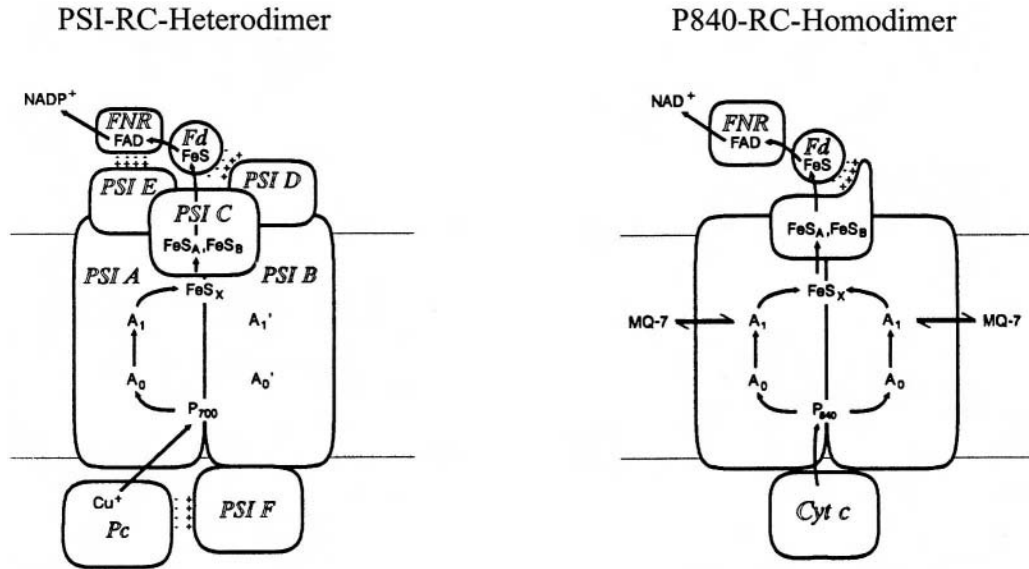

Fig. 4. Comparison of the organization of the heterodimeric reaction center of PS I and the homodimeric reaction center of green sulfur bacteria. Pc stands for plastocyanin, Fd for ferredoxin, FNR for ferredoxin-NAD(P)-oxidoreductase, PsaA-F for the six major subunits of PS I, and MQ-7 for menaquinone-7. The other abbreviations are explained in the text. (Redrawn from Xie et al., 1992)

assignment is in agreement with site directed mutagenesis of *psaC* (Zhao et al., 1992). However, the latter work rose also doubts about correlation of predominant photoreduction and relative redox potentials of F_A and F_B .

D. A Gene for an Electron Donating Cytochrome

Another gene, *pscC* (formerly called *cycA*, Bryant (1994)) was isolated and characterized from *Cb. vibrioforme* by Okkels et al. (1992). The gene codes for the 18 kDa (M_{app}) cytochrome *c*-551 that copurifies with the RC complex and was proposed to function as electron donor to P840. The 621 base pair open reading frame of *pscC* encodes an apoprotein of 22.858 kDa with a single heme binding site. Three N-terminal membrane spanning helices were predicted. Sequence comparison showed no significant similarities to other cytochromes. Northern blot analysis indicated a monocistronic transcript of *pscC* gene and presence of only one *pscC* gene was confirmed by Southern blot analysis. The unique membrane-bound monoheme cytochrome *c*-551 of *Cb. vibrioforme* was assigned to a new class of *c*-type cytochromes. Very recently the sequence of the 24 kDa (M_{app}) cytochrome *c*-550.5, copurifying with the RC proteins in the preparation of Hurt and Hauska (1984), was obtained. It showed a high degree of

identity to the cytochrome *c*-551 sequence (D-L Xie, N Nelson and G Hauska, unpublished). This cytochrome *c*-550.5 was additionally observed to copurify with cytochrome *b*, being separated from the RC (Hurt and Hauska, 1984). Therefore, a function as an equivalent to cytochromes *c₁/f* in a cytochrome *bc*-complex (for review see Hauska (1986) and Chapter 35 by Gray and Daldal) cannot be excluded. This is even more likely since a transcription unit for a cytochrome *bc*-complex of *Cb. limicola* includes the genes for the Rieske FeS-protein and cytochrome *b*, but lacks a gene for cytochrome *c₁/f* (Schütz et al., 1994). Cytochrome *c*-550.5 thus reduced by the cytochrome *bc*-complex could then function as electron donor to either P840 directly, or to a tetraheme cytochrome *c*-553 (see III.C.).

V. Comparison with Other Reaction Centers

All photosynthetic RCs characterized so far can be classified into two types, the 'pheophytin-quinone' RCs of purple bacteria, Chloroflexaceae and PS II, and the 'FeS' RCs of green sulfur bacteria, heliobacteria and PS I (Blankenship, 1992).

The similarity of the Photosystem of green sulfur bacteria to PS I suggested from earlier studies (Buchanan and Evans, 1969) has been substantiated by more recent results on electron transport,

polypeptides and their genes, as detailed in the previous sections. The respective similarities of the heliobacterial PS to PS I have been discovered more recently (Trost et al., 1992; Liebl et al., 1993; see Chapter 31 by Amesz).

Both types of RCs consist of a dimeric core structure containing two hydrophobic subunits, which bind the primary electron donor and the early electron acceptors (see above and Chapter 23 by Lancaster et al.). The primary electron donor is probably a 'special pair' of (bacterio)chlorophylls in all cases (see above), although this is still not clearly shown in PS II (van Mieghem and Rutherford, 1994). The primary electron acceptors are tetrapyrroles, either (bacterio)pheophytins, or Chl *a*-like molecules (see above and Chapters 23, 31 and 32 by Lancaster et al., Amesz, and Feick, respectively, and Golbeck and Bryant, 1991). Quinones universally seem to function as secondary electron acceptors (see above and Chapter 23 by Lancaster et al., however, also see Chapter 31 by Amesz). Furthermore it has been concluded from X-ray crystallography that the distance between the special pair and the Fe at the acceptor side of the 'pheophytin-quinone' RCs is similar to the distance between P700 and FeS center F_x in the PS I RC (Krauss et al., 1993).

The major differences between 'pheophytin-quinone' RCs and 'FeS' RCs are, that the core subunits of the latter are more than twice as large, carrying tens of antenna (bacterio)chlorophylls in the N-terminal part, and that FeS centers of low redox potentials enable the reduction of NAD(P)^+ via ferredoxin (see Golbeck and Bryant, 1991). The two subunits of the 'pheophytin-quinone' RCs with a M_{app} around 30 kDa span the membrane 5 times, while the corresponding subunits of the 'FeS' RCs contain up to 11 hydrophobic spans (Fish et al., 1985; Büttner et al., 1992a,b; Liebl et al., 1993).

Despite these differences, several similarities in the primary structure and the folding models of RC cores have been noted (Robert and Moëne-Loccoz, 1990; Margulies, 1991; Nitschke and Rutherford, 1991; Otsuka et al., 1992). As indicated by the shaded parts in Fig. 6 (see below) it has been suggested that the five transmembrane helices of the 'pheophytin-quinone' RC subunits correspond to the C-terminal part of the two larger 'FeS' RC subunits from transmembrane spans V to IX, based on both conserved residues and folding pattern (Büttner et al., 1992a,b; Liebl et al., 1993). By principal component analysis Otsuka et al. (1992) extended

the structural similarity. According to their results, an additional similarity was proposed between the N-terminal half of the large 'FeS' RC subunits and the 'pheophytin-quinone' RC subunits. This would imply gene duplication and fusion of the small RC core subunits to construct the large RC during evolution.

A. Homodimeric and Heterodimeric Reaction Centers

All RCs exhibit a dimeric core structure which catalyzes transmembrane charge separation. The dimeric structure is apparently necessary for binding the special, electron donating pair of (bacterio)chlorophylls, and also to bind the Fe in the case of the 'pheophytin-quinone' RCs (see Chapter 23 by Lancaster et al.), or the FeS center F_x in the case of the 'FeS' RCs. While the 'pheophytin-quinone' RCs and the PS I RCs are heterodimers, built by two different, although related core subunits, a homodimeric structure is indicated for the RCs of both *Chlorobium* (Büttner et al., 1992a,b) and heliobacteria (Liebl et al., 1993).

The near symmetry of the RCs of purple bacteria not only relates the two subunits L and M, but also the two sets of pigments, one set being strongly favored for charge separation (see Chapters 23 by Lancaster et al. and 24 by Woodbury and Allen). Similar heterodimeric structures are envisaged for the RCs of PS II (Trebst, 1987; Michel et al., 1986) and PS I (see Golbeck and Bryant, 1991). The reasons for the presence of one electron transfer branch, and for the continued existence of the other remains unclear. If the RCs of green sulfur- and heliobacteria are indeed homodimeric, then it is possible their study may aid in the resolution of this question. Furthermore, it is intriguing to consider whether the existence of a homodimeric structure is related to their anaerobic life.

In Fig. 4 schemes for the organization and the electron transfer of the PS I RC heterodimer and of the simpler P840 RC homodimer are compared. It is conceived that the positively charged, N-terminal extension of PscB (equivalent to PsaC) in *Chlorobium* (see IV C.) substitutes for PsaD in binding ferredoxin, and that electron transfer occurs in the two parallel, equally probable, branches of the homodimer. As a consequence, each of the two secondary acceptors A_1 should exchange with the menaquinol pool with equal ease. This might limit the occupancy of the A_1

site and lead to a faster back reaction to $P840^+$ from A_0^- . An increased back reaction rate might raise the vulnerability of this system to oxygen.

Possibly associated with parallel electron transfer in the RCs of green sulfur bacteria is the presence of the charged cluster, which in 'pheophytin-quinone' RCs is C-terminal to transmembrane helix II of subunit L or D1, or C-terminal to helix VI in the PsaA subunit of PS I. The glutamic acid D131 in PS II RC and aspartic acid PsaA414 in PS I have been proposed to bind the respective primary electron acceptors (Robert and Moëne-Loccoz, 1990). From resonance Raman data of *Chlorobium* RCs a single-type of binding site for the primary electron acceptor of *Chlorobium* was proposed (Feiler et al., 1994), supporting the presence of a homodimeric RC core. Additionally, a similar binding force as to those in PS II and purple bacterial RCs was estimated. If PscA is added to the sequence alignment mentioned above (see Fig. 5) it is clear that glutamine PscA397 could be the residue H-bonding the acceptor Chl *a* molecule in each half of the homodimer. Further evidence for the presence of a homodimer comes from ENDOR and special TRIPLE spectroscopy and from FT Raman spectroscopy in the near infrared, which reveals an even distribution of the positive charge in $P840^+$ over the special pair of bacteriochlorophylls in *Chlorobium*, as opposed to purple bacteria (see III.A.3.).

Without a three dimensional structure, it can not be excluded that the two identical core subunits of the P840 RC are rendered asymmetric by binding the protein carrying FeS centers F_A and F_B , as is seen in receptor dimerization by a single, asymmetrically binding growth factor molecule (de Vos et al., 1992). Further, post-translational modification of the polypeptides could lead to an asymmetry. Both possibilities could lead to two unequal electron transfer branches.

B. Evolutionary Aspects

The overall similarities of photosynthetic RCs suggest that all of them originate from one common ancestor (Nitschke and Rutherford, 1991; Blankenship, 1992), and it is rational to assume that the heterodimeric forms of the RC cores evolved from a homodimeric form as depicted in Fig. 6. Based on the parsimony analysis of the RC core subunit sequences at least two independent gene duplications have occurred, giving rise to the L/M and D1/D2 heterodimers, of

Fig. 5. Amino acid sequence comparison of regions of: the B-helix of the L-subunit of *Rhodospseudomonas viridis*; the helix IV of D1 (PS II) and, the helix VI of PsaA (PS I) from spinach; and the helix VI of P840-protein (PscA) from *Cb. limicola*. Conserved amino acids with functional similarities between L, D1, PsaA and/or PscA are indicated by points, or in the case of the amino acids presumed responsible for binding the primary acceptor, marked by lines. The L sequence was taken from Michel et al. (1986), D1 sequence from Zurawski et al. (1982), PsaA sequence from Fish et al. (1985) and PscA sequence from Büttner et al. (1992a).

the RCs of purple bacteria and *Chloroflexus*, and of PS II, respectively (Blankenship, 1992). Thus the divergence of the reaction centers in purple bacteria and those in PS II might have taken place before the gene duplications. Since PsaA and B, in turn, are substantially more closely related to each other, than to the RC subunits in either helio- or green sulfur bacteria (Liebl et al., 1993; Büttner et al., 1992a), gene duplication must have occurred after the divergence of the RC of PS I, and those of green sulfur bacteria and heliobacteria. Earlier, the 'pheophytin-quinone' RCs must have separated from the 'FeS' RCs, but it remains undecided which was first. One may make a case for the 'FeS' RCs, because they occur in strictly anaerobic bacteria, and the early atmosphere was anaerobic. The idea of an iron-sulfur world at early stages of evolution supports this view (Drobner et al., 1990). If the ancestral gene indeed coded for an 'FeS' RC, as shown in Fig. 6, was it small or large? According to the analysis of Otsuka et al. (1992), which suggests the evolution of the large subunits of the recent 'FeS' RCs by yet another gene duplication, a small ancestral gene is more likely. Whether the ancestral photosynthetic RC had a monomeric or dimeric structure remains unclear, although a monomeric form is favored for simplicity (Blankenship, 1992). Finally, recent

Fig. 6. Evolutionary concept of the reaction center dimers. *L* and *M*, and *D1* and *D2* stand for the subunits constituting the heterodimer of the reaction centers in purple bacteria and PS II, respectively, while *psaA* and *psaB* are the denotations of the genes coding for the two large subunits of PS I. Shaded areas of the bars indicate related regions in all reaction centers. (Redrawn from Büttner et al., 1992a)

oxygenic photosynthesis in cyanobacteria and chloroplasts probably evolved by fusion of two bacterial ancestors (Büttner et al., 1992a; Blankenship, 1992) as indicated in Fig. 6, although other alternatives are under discussion (Olson and Pierson, 1989).

VI. Conclusions

Summarizing the present state of our knowledge, it is now certain that the RC complex of green sulfur bacteria is a bacterial counterpart of PS I. This is based on both functional and structural features as well as genetic data. The latter established a convincing level of identity between the sequences of the PS I genes and that of *Chlorobium*. This permits the identification of regions of functional and structural importance in both systems and thus can be used for designing site-directed mutations. Such mutations will lead to a better understanding of the properties of the FeS-type RCs.

Of considerable interest, also, is the nature of the electron donor to P840 since two different candidates (a monoheme- or a tetraheme-containing cytochrome, see III.C. and Chapter 36 by Nitschke and Dracheva) are discussed. In either case, intriguing evolutionary questions should arise.

New and most striking is the possibility of a

homodimeric organization of the green sulfur bacterial RC core, since only one gene coding for the two core subunits has as yet been found. However, it remains unclear whether electron transport occurs symmetrically in the two branches. A three dimensional structure of the RC complex could help answer this question.

Acknowledgments

The authors thank all the people having made essential contributions to the work described in this chapter (some of which was unpublished at this time): M Büttner, C Bock, J Golbeck, N Illinger, W Nitschke, M Schütz, D Stehlik, J Sturgis, M Thurnauer and D-L Xie. We also like to thank D Albouy, RE Blankenship, K Brettel, U Liebl, TA Mattioli, N Nelson, JM Olson, B Robert, AW Rutherford and W Vermaas for many stimulating discussions and TA Mattioli, B Robert and W Nitschke for critical reading of the manuscript. U.F. would like to thank in particular J Sturgis for his patience in translating her 'German' English into 'English' English. U.F. was supported by the EEC (Science program) and G.H. by the Deutsche Forschungsgemeinschaft (SFB43 C2).

Summary

The heliobacteria are a recently discovered group of photosynthetic bacteria that are characterized by the presence of bacteriochlorophyll (BChl) *g* as major pigment. All of the pigments are contained in a single pigment-protein complex, which contains about 35 BChls *g* per reaction center. The primary electron donor, P798, is presumably a dimer of BChl *g* or of its epimer, BChl *g'*; the primary electron acceptor has been identified as hydroxy chlorophyll *a*. There is evidence that iron-sulfur centers act as secondary electron acceptors, while a *c*-type cytochrome, cytochrome *c*-553, acts as secondary electron donor to P798. Energy transfer from the antenna pigments to the reaction center appears to be distinctly faster than in purple bacteria. The major subunit of the antenna reaction center complex is a peptide of 68 kDa, containing 609 amino acid residues, which shows an about 20% homology to the PS I-A and PS I-B reaction center-core peptides of Photosystem I.

The above observations all indicate that the reaction center of heliobacteria, like that of green sulfur bacteria is related to that of Photosystem I of plants and, in fact, the heliobacteria are in many ways excellent material to study the basic processes of Photosystem I-type reaction centers. However, the reaction center is homodimeric, i.e., it contains two identical subunits that bind the antenna pigments and the reaction center components. This indicates that the ancestral lines of Photosystem I and heliobacteria separated before gene duplication occurred in the first one.

I. Introduction

The heliobacteria have been known for only about a decade. The first species, *Heliobacterium (Hb.) chlorum* was discovered by Gest and Favinger (1983) in a soil sample from the Indiana University campus (Gest, 1994), and soon thereafter several species were discovered in rice fields in Asia and Africa (Beer-Romero and Gest, 1987; Beer-Romero et al., 1988; Ormerod et al., 1990). More recently, various strains or species were also found in more natural habitats, like lakeshore muds (A. Hiraishi, personal communication) and even an alkaline hot spring (Starynin and Gorlenko, 1993). It is recognized now that the heliobacteria, at least the species that have been more than summarily investigated, are all very closely related, and it has been proposed to assign them all to one genus (Ormerod et al., 1990), although one species, *Heliobacillus (Hc.) mobilis* (Beer-Romero and Gest, 1987), is still known under a different genus name. In fact, the only three species that have been studied more or less extensively (*Hb. chlorum*, *Hc. mobilis* and *Hb. gestii*) are photosynthetically and spectroscopically virtually indistinguishable, although they are morphologically quite different. 16S rRNA sequence analyses have shown that the heliobacteria are related to the Gram-positive bacteria (Woese et al., 1985; Stackebrandt et al., 1988). All species investigated so far are able to fix nitrogen (Gest and Favinger, 1983; Kimble and Madigan, 1992), which may be of some ecological and economic importance.

For a discussion of the taxonomy and physiology of the heliobacteria refer to Chapter 2 by Madigan and Ormerod in this volume.

II. Pigments and Spectral Properties

The heliobacteria are distinguished from other photosynthetic organisms by the possession of the newly discovered bacteriochlorophyll (BChl) *g* (Brockmann and Lipinski, 1983)(Fig. 1). The pigment resembles BChl *b* with respect to its ethylidene group at C8 (ring II) but has a vinyl group at C3 (ring I), like chlorophyll (Chl) *a*. It is esterified with farnesol (Michalski et al., 1987). The only carotenoid

Fig. 1. Structure and partial carbon numbering of BChl *g* and BChl *g'*.

present in *Hb. chlorum* and *Hc. mobilis* is neurosporene (Gest and Favinger, 1983; Kobayashi et al., 1991a). Ultrastructural studies indicate that these pigments are contained in the cytoplasmic membrane only; heliobacteria have no chlorosomes, and intracytoplasmic membranes, as in purple bacteria, appear to be absent too (Gest and Favinger, 1983; Miller et al., 1986; Starynin and Gorlenko, 1993).

Figure 2 shows the absorption spectrum of BChl *g* in acetone. The Soret transitions of BChl *g* in acetone are located at 364.8 and 404.8 nm., the Q_x and Q_y transitions at 566.4 and 761.6 nm, respectively (Kobayashi et al., 1991a), with a specific extinction

coefficient of $76 \pm 4 \text{ mM}^{-1} \text{ cm}^{-1}$ at 761.6 nm (van de Meent et al., 1991). Cells as well as isolated membranes show bands at 368, 409, 575 and 787 nm (Fig. 3 and Fuller et al., 1985). The amplitude of the Q_y band is higher than in solution, with a specific extinction coefficient of $110 \text{ mM}^{-1} \text{ cm}^{-1}$ (Kleinherenbrink and Amesz, 1993). At low temperature, the Q_y band is resolved into at least three components (Fig. 4), supposedly due to three spectral forms of BChl *g*, BChl 778, BChl 793 and BChl 808 (van Dorssen et al., 1985; Smit et al., 1989). The circular dichroism spectrum shows an approximately conservative signal centered at 793 nm, suggesting that BChl 793 may have a dimeric structure (van Dorssen et al., 1985). Linear dichroism measurements indicate that the Q_y transition of BChl 808 lies more or less in the plane of the membrane, while those of the short-wave forms make a larger angle with the membrane plane (van Dorssen et al., 1985). The Q_x transitions are more perpendicular. The orientation of BChl *g* thus is similar to that of antenna BChl *a* in the membrane of purple bacteria (Breton, 1974).

At room temperature, the fluorescence spectrum of *Hb. chlorum* shows a band at 813 nm. Upon cooling to 4 K, the band intensifies about 20-fold and shifts to 819 nm (van Dorssen et al., 1985) indicating that, at least at low temperature, all of the emission comes from BChl 808. Excitation spectra indicate a nearly 100% efficiency of energy transfer from BChl 778 and BChl 793 to BChl 808, while neurosporene transfers its excitation energy with about 70% efficiency.

III. The Primary Electron Donor and the Antenna-Reaction Center Complex

The primary electron donor of heliobacteria is called P798, after the wavelength of its maximum bleaching in the Q_y -region upon photooxidation (Fuller et al., 1985; Prince et al., 1985). Its redox potential is 225–250 mV and the EPR spectrum of the oxidized radical indicates a dimeric structure (Prince et al., 1985; Brok et al., 1986; Fischer, 1990). A rapid photooxidation of P798 was observed by flash spectroscopy in the ps region, at room temperature as well as at 15 K, confirming the notion that it is the primary electron donor (Nuijs et al., 1985a; van Kan et al., 1989; van Kan, 1991).

At room temperature, the maximum bleaching at 798 nm upon illumination as well as upon chemical

Fig. 3. Absorption spectrum of membranes of *Heliobacterium chlorum*.

Gaussian deconvolution of the 5 K absorption spectrum of membranes of *Heliobacterium chlorum*, showing the estimated contributions by the three spectral species, BChl 778, BChl 793 and BChl 808. Band centers, half-widths and amplitudes are listed in the figure. The band at 763 nm may be a composite of vibrational subbands (Smit et al., 1989).

oxidation is 1/20 to 1/22 of the antenna absorption maximum at 788 nm, both in *Hb. chlorum* and *Hc. mobilis* (Trost and Blankenship, 1989; van de Meent et al., 1990; Kobayashi et al., 1991a). Evidence to be discussed below indicates that the antenna of both species contains about 35 BChls *g* per P798, which means that the differential extinction coefficient of P798/P 798⁺ is considerably higher than the specific extinction coefficient of the antenna (see previous section). In fact, a value of $180 \text{ mM}^{-1} \text{ cm}^{-1}$ has been determined recently (Kleinherenbrink and Amesz, 1993), higher than of any primary electron donor determined to date. An even higher number ($225\text{--}240 \text{ mM}^{-1} \text{ cm}^{-1}$) was reported by Kleinherenbrink et al. (1994a).

The reaction center and the antenna of heliobacteria appear to be bound to a single pigment-protein complex. Antenna-reaction center complexes have

Fig. 5. Absorbance difference spectra caused by photooxidation of P798 obtained upon illumination of (A) membranes of *Heliobacterium chlorum*, (B) the isolated antenna-reaction center complex of *Hb. chlorum* and (C) the antenna-reaction center complex of *Heliobacillus mobilis*. The spectra are normalized to the same antenna absorption (van de Meent et al., 1990).

been obtained by detergent solubilization of membranes of *Hb. chlorum* and *Hc. mobilis* (Trost and Blankenship, 1989; van de Meent et al., 1990) and from *Hb. gestii* (Trost et al., 1992). These complexes have the same spectroscopic properties as isolated membranes and they are fully active in P798 photooxidation (Fig. 5). The fluorescence excitation spectrum showed unimpaired efficiency for energy transfer from short wave absorbing BChls *g* to BChl 808. (van de Meent et al., 1990). These observations indicate that the isolated complexes contain the complete pigment complement of the cells, although some neurosporene may be lost during the isolation (Trost and Blankenship, 1989), and that the structural integrity of the complex is essentially conserved during its isolation.

SDS-PAGE of purified antenna-reaction center preparations showed only one major band on the electrophoresis gel (Trost and Blankenship, 1989; van de Meent et al., 1990). Attempts to sequence the polypeptide were at first hampered by blockage at the N-terminus, but after enzymatic and chemical cleavage, 15 peptide fragments were sequenced from the peptide of *Hc. mobilis* (Trost et al., 1992; Liebl et al., 1993). Subsequent identification and sequencing of the corresponding gene resulted in the amino acid sequence shown in Fig. 6 (Liebl et al., 1992, 1993). Inspection of the sequence reveals a distinct, but limited homology of about 20% with the PS I-A and PS I-B reaction center-core peptides of Photosystem I. Although the molecular mass (68 kDa) and the

Fig. 6 Amino acid sequence of the antenna-reaction center peptide of *Heliobacillus mobilis*. 11 Predicted membrane-spanning helices are underlined (Liebl et al., 1992).

number of amino acid residues (609) are about 20% smaller than of PS I-A and PS I-B, the number of predicted membrane-spanning helices is the same (11). These helices contain 17 histidines as compared to 29 and 24, respectively, on the Photosystem I peptides (Golbeck and Bryant, 1991), in agreement with the notion that the antenna-reaction center complex of heliobacteria contains fewer (B)Chls than does the Photosystem I core. It may be noted, however, that the preliminary results of an X-ray analysis of the reaction center complex of Photosystem I revealed only 8 such helices (Krauss et al., 1993), suggesting that the hydrophathy plots may not be fully reliable. The homology with the PS I-A and B peptides is mainly apparent in the putative reaction center binding areas. A homology of about 50% was found in the extramembranous loop between helices VIII and IX (Fig. 6), that contains two conserved cysteines. These residues are the presumed binding sites for iron in the analogon to F_x , the first iron-sulfur electron acceptor of Photosystem I.

There is no evidence for the existence of a second, related peptide in the antenna-reaction complex of *Hc. mobilis*, and the same applies to the recently sequenced core-complex of green sulfur bacteria, which contains a peptide of 730 amino acid residues and shows a homology pattern similar to that of heliobacteria (Büttner et al., 1992a,b; see also Chapter 30 by Feiler and Hauska). These observations strongly indicate that the reaction centers of heliobacteria and of green sulfur bacteria, in contrast to Photosystem I,

are homodimers. The results clearly support the notion, based on studies of electron transfer (see below), that the three reaction centers are evolutionarily of the same origin, but one has to conclude that the evolutionary tree has branched off before gene duplication occurred in the ancestral line of Photosystem I (Liebl et al., 1992, 1993; Blankenship, 1992; Büttner et al., 1992b). Interestingly, the N-terminal part of the heliobacterial protein, including the first six major hydrophobic regions, shows a significant homology to CP47, suggesting an evolutionary relationship to this antenna protein of Photosystem II (Vermaas, 1994).

A quantitative pigment analysis of isolated antenna-reaction particles as well as membrane fragments and cells of *Hb. chlorum* and *Hc. mobilis* revealed the presence of neurosporene and BChl *g*, but essentially no bacteriopheophytin when material from rapidly growing cells was used (Kobayashi et al., 1991a, van de Meent et al., 1991). In addition, small amounts of the epimer of BChl *g*, BChl *g'* were found. The latter pigment differs from BChl *g* in the configuration of the carboxymethyl group at C13² (ring V), which has the opposite position with respect to the macrocycle (Fig. 1). The absorption spectrum of BChl *g'* in organic solvents resembles that of BChl *g*, but the circular dichroism spectrum is distinctly different (Kobayashi et al., 1991a). Control experiments indicated that BChl *g'* was not produced by epimerization during or after extraction; however, in old cells some artifactual epimerization appeared to occur (Kobayashi et al., 1991a,b).

The epimer of Chl *a*, Chl *a'*, has been implied to constitute the primary electron donor of Photosystem I, P700 (Maeda et al., 1992). By analogy, BChl *g'* might function as primary electron donor in heliobacteria. The amount of BChl *g'* was found to be one molecule per ca. 17 BChl *g* for both species investigated, and it was therefore proposed that P798 would be a dimer of BChl *g'*, giving a BChl *g* to reaction center ratio of ca. 35. It may be noted that such a number would be in fair agreement with the number of histidines in the membrane spanning regions of the reaction center peptides.

IV. The Primary Charge Separation

Measurements of flash-induced absorbance changes in membranes of *Hb. chlorum* at 800 nm (Nuijs et al.,

1985a) showed a transient bleaching, which reversed in some tens of ps, and a 'permanent' one, which did not reverse on the timescale (several ns) of the experiment. When the reaction centers had been closed by a 'preflash', given a few ns before the actual measurement, only the transient bleaching was seen. Thus, the transient bleaching, which will be discussed in more detail in the next section, can be ascribed to excited antenna BChl *g*, whereas the 'permanent' one is caused by the oxidation of P798. A bleaching was also observed near 670 nm. This bleaching again was only observed with 'active' but not with closed reaction centers, indicating that it is caused by the photoreduction of the primary, or at least an early, electron acceptor, which we shall call A_0 . This bleaching decayed in 500–800 ps (Nuijs et al., 1985a; van Kan et al., 1989; Lin et al., 1994a), presumably by electron transfer to the next acceptor, X_1 . Because of energy transfer and absorbance changes occurring in the antenna, an accurate determination of the rate of charge separation has not yet been possible, but it must be faster than 10 ps (van Noort et al., 1992a). In fact, model calculations indicate a time constant of, at most, 1.2 ps for the primary charge separation (Lin et al., 1994a). Measurements at 15 K confirmed the above picture. Photooxidation of P798 could now be observed by the bleaching of a band centered at 793 nm and the reoxidation of A_0^- now occurred in 300 ps, i.e. 2–3 times faster than at room temperature (van Kan et al., 1989; van Kan, 1991). A similar effect has been observed for electron transfer from reduced bacteriopheophytin to the first acceptor quinone in purple bacteria (Kirmaier et al., 1985).

It thus appears that the minor band at 669 nm in the absorption spectrum of heliobacteria (Fig. 3) is, at least in part, due to the primary acceptor. This situation is reminiscent of that in green sulfur bacteria (Nuijs et al., 1985b, Shuvalov et al., 1986; see also Chapter 30 by Feiler and Hauska). Experiments of van Noort et al. (1992a) showed that the bleaching at 670 nm was brought about not only upon excitation at 532 nm, as in the experiments of Nuijs et al., but also upon excitation at 790 nm, excluding the possibility that it would be due to an excited state of the pigment. Supporting evidence came also from measurements of Kleinherenbrink et al. (1991, 1994b), who showed that the lifetime of A_0^- could be extended to 17 ns by applying strongly reducing conditions. The same time constant was now observed in the decay

of $P798^+$, whereas $P798^+$ normally decays in several ms.

The radical pair recombination resulted in the formation of the triplet of $P798$, with a yield of 20–25%. At 6 K, the yield increased slightly, and radical pair recombination slowed down to 55 ns. The lifetimes of the triplet was 35 μs at room temperature and 500 μs at 6 K (Nitschke et al., 1990; Kleinherenbrink et al., 1991). By means of absorption detected magnetic resonance (ADMR) the zero-field splitting parameters (D and E values) of the reaction center triplet, as well as the decay times for the x, y and z sublevels at 1.2 K have been determined (Vrieze et al., 1992). The latter were found to be 270 ± 20 , 360 ± 45 and 1150 ± 60 μs , respectively. Very similar decay times were observed for the triplet of BChl *g* in ethanol. Absorption difference spectra of reaction center triplet formation show a minimum at 794 nm, and have been obtained by flash spectroscopy (Kleinherenbrink et al., 1991) as well as by ADMR (Vrieze et al., 1992). The latter method gives more detailed spectra.

The chemical identity of the primary electron acceptor has recently been determined after purification by HPLC (van de Meent et al., 1991). A pigment was isolated from membranes of *Hb. chlorum* and *Hc. mobilis* which had essentially the same absorption spectrum as Chl *a* from plants, but showed a higher polarity. NMR and mass spectroscopy established its identity as 8^l-OH-Chl *a*, esterified with farnesol. This observation again points to the similarity with the reaction centers of Photosystem I and green sulfur bacteria, where the primary acceptors are Chl *a* (Golbeck and Bryant, 1991) and an isomer of Chl *a* (van de Meent et al., 1992), respectively. The amount of 8^l-OH-Chl *a* was found to be one molecule per 17 BChl *g*, the same as of BChl *g'* (see previous section). With a BChl *g* to reaction center ratio of about 35, this would indicate the presence of two molecules of OH-Chl *a* per reaction center. Since the reaction center is presumably homodimeric, and may be assumed to be inherently symmetrical it is likely that both molecules occupy equivalent positions and that there is no preferred pathway for electron transfer, as in purple bacteria and in Photosystem II. The Q_y transitions of these pigments make a large angle with the plane of the membrane (Francke et al., 1994). It is conceivable that OH-Chl *a* is formed by isomerization and oxidation of BChl *g* at ring II (see also Michalski et al., 1987); some additional OH-

Chl *a* and other oxidation products of BChl *g* are formed in old cells (van de Meent et al., 1991).

V. Transfer and Trapping of Excitation Energy

At room temperature, the fluorescence lifetime of BChl *g* in membranes and isolated antenna-reaction center complexes of *Hc. mobilis* is ca. 25 ps (Trost and Blankenship, 1989), which explains, at least qualitatively, the low fluorescence yield (van Dorssen et al., 1985). Similar results were obtained in time-resolved absorption measurements on membranes of *Hb. chlorum* and *Hc. mobilis*, which showed a bleaching, centered at around 805 nm, which decayed in 20–30 ps (van Noort et al., 1992a; Lin et al., 1992, 1994a). The bleaching developed in less than about 1 ps (Lin et al., 1992, 1994a) indicating a very rapid equilibration of the excitations among the various spectral forms of BChl *g*, BChl 798, 793 and 808 (see section II). Its lifetime was essentially independent of the redox state of $P798$, in agreement with measurements of Deinum et al. (1991), who showed that, at room temperature, $P798$ and $P798^+$ are approximately equally effective in quenching antenna fluorescence. At 6 K, $P798^+$ is almost twice as effective a quencher as $P798$.

The above measurements thus lead to a simple model, where the excitations are equilibrated between BChl 778, BChl 793 and BChl 808 within a very short time, and energy transfer to $P798$ or $P798^+$ effectively takes 20–30 ps (van Noort et al., 1992a), but a model involving more rapid transfer to $P798$ has also been proposed (Lin et al., 1992, 1994a). Energy transfer to the reaction center thus is significantly faster than in purple bacteria (Sundström and van Grondelle, 1992), which may be explained by the binding of $P798$ and antenna pigments to the same protein complex. Because the equilibration is so fast, the results do not permit distinguishing between energy transfer from BChl 793 and BChl 808 to $P798$. The lifetime of excited $P798$ appears to be much shorter than 20 ps, since the bleaching (i.e. reduction) of A_0 was found to occur at the same rate as the disappearance of excited antenna BChl *g* (van Noort et al., 1992a; but see also Lin et al., 1994a).

The fluorescence and absorption kinetics at low temperature cannot be explained by a simple model, however. The action spectrum of $P798$ photooxidation indicates that, at least at low temperature energy

transfer to the reaction center proceeds via BChl 808 (Kleinherenbrink et al., 1992) and steady state fluorescence (van Dorssen et al., 1985) as well as time resolved fluorescence and absorption measurements (van Noort et al., 1992b, 1994; Kleinherenbrink et al., 1993a) indicate very fast energy transfer from the other BChls to BChl 808, presumably within 1 ps. However, the decay of the excitations on BChl 808 shows a complicated pattern, with various time constants, ranging from about 4 to 900 ps. The 4 ps decay appears to reflect energy transfer to the (oxidized) reaction center, while the longer-lived components are associated with BChl 808 species with red-shifted absorption and fluorescence spectra (van Noort et al., 1992b, 1994; Kleinherenbrink et al., 1993a), suggesting the existence of different sites in the antenna which are only weakly coupled to each other and to the reaction center. Energy transfer to the open reaction center was found to occur in about 70 ps (Lin et al., 1994b).

In addition to the reaction center triplet, mentioned in the previous section, antenna triplets are also generated at liquid helium temperature. The overall yield is 1–2%. Most of these appear to be produced by intersystem crossing on long-wavelength forms of BChl 808 (Nitschke et al., 1990; Kleinherenbrink et al., 1991) but a triplet on a BChl *g* species absorbing at 798 nm was also observed (Vrieze et al., 1992). Three different triplets of BChl 808, with somewhat different zero field splitting parameters could be distinguished, confirming the heterogeneity of this antenna component (Vrieze et al., 1992). The lifetimes of the antenna triplets are not much different from those of the reaction center triplet (section IV).

VI. Secondary Electron Transport

There is various evidence, mainly based on low temperature EPR measurements, that iron-sulfur centers act as secondary electron acceptors (Prince et al., 1985; Brok et al., 1986; Smit et al., 1987; Nitschke et al., 1990; Fischer, 1990), as in Photosystem I (Golbeck, 1993). EPR signals with *g*-values of 2.07, 1.93 and 1.89 and of 2.05, 1.95 and 1.90 have been observed which have been attributed to centers which are, except for their relative midpoint potentials, analogous to F_B and F_A in Photosystem I (Nitschke et al., 1990). Since *rates* of reduction of iron sulfur centers are hard to measure, and since the

EPR method cannot be applied at room temperature, direct evidence concerning the role of these iron sulfur centers is not available. Optical evidence for the role of an iron sulfur center analogous to F_x in Photosystem I has recently been reported (Kleinherenbrink et al., 1994a), but no corresponding EPR signal has been observed so far (Trost and Blankenship, 1989). Indirect evidence for the presence of such a center comes from the primary structure analysis (Trost et al., 1992; Liebl et al., 1992, 1993).

The isolated antenna-reaction center complex of *Hc. mobilis* contains about one molecule of menaquinone (vitamin K-2) (Trost and Blankenship, 1989) and 3–4 times larger amounts have been found in isolated membranes of *Hb. chlorum* and *Hc. mobilis*, the main component being menaquinone-9 (Hiraishi, 1989; Trost and Blankenship, 1989; Kleinherenbrink et al., 1993b). Photoaccumulation of reduced quinone was observed by EPR (Brok et al., 1986) and the double reduction of a quinone acceptor was proposed to explain the titration behavior of the recombination kinetics of $P798^+$ (Trost et al., 1992). These observations thus would indicate that menaquinone functions as a first secondary electron acceptor in heliobacteria in an analogous way as phyloquinone (vitamin K-1) does in Photosystem I (Golbeck and Bryant, 1991). However, recent experiments have shed doubt on this hypothesis. It was observed that by extraction with appropriate ether-water mixtures essentially all menaquinone could be removed from membranes while secondary electron transport and charge recombination were not affected (Kleinherenbrink et al., 1993b). In Photosystem I preparations such treatments have a major effect on electron transport (Ikegami et al., 1987). These results do not exclude a function for a very strongly bound quinone, but it should be noted that there is also evidence that at least some of the rates of electron transfer in heliobacteria are about an order of magnitude slower than for Photosystem I, including that of electron transfer from A_0 to the next electron acceptor (see section I and Fig. 7, and also Kleinherenbrink and Amesz, 1993), indicating that there may be rather fundamental differences between the electron acceptor chains of Photosystem I and heliobacteria.

The electron donor to P798 is a *c*-type cytochrome, cytochrome *c*-553. In intact cells of *Hb. chlorum* its oxidation is fairly rapid, with half times of 110 and

Fig. 7. Tentative scheme for electron transfer in membranes of heliobacteria at room temperature (Kleinherenbrink and Amesz, 1993). The existence of three electron acceptors, which may all be iron-sulfur centers, is in part proposed on basis of kinetic evidence. A_0 may represent two identical acceptor molecules acting in parallel (Section IV). Further details are discussed in the text.

700 μ s (Vos et al., 1989), but in isolated membranes a much slower and incomplete photooxidation with a time constant of about 6 ms occurs (Prince et al., 1985; Smit et al., 1987). The cause of this effect is not known; it might be due to a change in binding constant. The cytochrome is removed by detergent treatment to solubilize the antenna-reaction center complex (Trost and Blankenship, 1989; van de Meent et al., 1990), indicating that it is not strongly bound to the reaction center. Recent experiments have shown that the 6 ms time constant is mainly determined by a concomitant back reaction of $P798^+$ with a reduced electron acceptor (Kleinherenbrink and Amesz, 1993). When the back reaction was prevented by the addition of vitamin K-3 (menadione) as an artificial electron acceptor, P798 and cytochrome *c*-553 reacted in stoichiometric amounts with a time constant of approximately 20 ms.

Although outside the scope of this chapter, it may

be mentioned here that the cytoplasmic membrane of heliobacteria contains a cytochrome *bc* complex which may function in cyclic electron transport. The presence of a Rieske iron-sulfur center has been demonstrated (Liebl et al., 1990) and recently the isolation of a cytochrome *bc* complex by detergent solubilization of membranes of *Hc. mobilis* was reported (Nitschke and Liebl, 1992). Interestingly, in various aspects the complex resembles more the Cyt *b₆f*-type complex of oxygenic photosynthesis than the *bc*-type complex of purple bacteria and mitochondria (Liebl, 1992).

VII. Concluding Remarks

Hopefully, the foregoing sections have demonstrated that the heliobacteria, although they may occupy a tiny niche in the ecological spectrum of photosynthetic organisms, are of considerable scientific interest. Even to the reader who is not interested in the heliobacteria *per se* it should be clear that they present a paradigm of the Photosystem I-type reaction center which in many ways is more amenable to investigation than the reaction center of Photosystem I of plants or the related reaction center of green sulfur bacteria. Heliobacteria have a relatively small antenna, and for many experiments the preparation of membrane fragments suffices to obtain material with a higher reaction center to pigment ratio than has the core complex of Photosystem I, which can only be obtained by detergent solubilization and separation of the solubilized pigment protein complexes. A similar comparison applies with respect to the green sulfur bacteria, which have a very large antenna which is difficult to remove entirely. Moreover, the primary electron acceptor, in contrast to Photosystem I of plants, is chemically different from the bulk pigment, and absorbs at a wavelength (670 nm) far removed from the Q_y absorption of the antenna and the primary electron donor, which facilitates optical measurements on charge separation considerably.

Altogether, the heliobacteria provide excellent material for studies of the basic processes of photosynthesis, and although these have been performed in only a few laboratories to date, the heliobacteria are potentially as useful for such studies as the much more extensively investigated purple bacteria.

Summary

The reaction center of the thermophilic green bacterium *Chloroflexus (Cf.) aurantiacus* has a bacteriochlorophyll donor-bacteriopheophytin-quinone acceptor system which is characteristic for purple bacteria and not for Chlorobiaceae reaction centers. It is comprised of 3 BChl *a*-, 3 BPheo *a*-, 1-2 menaquinone molecules and only two protein subunits with almost identical molecular masses of approximately 35,000 Da. The RC complex possesses thermal stability. Despite the absence of the so called H-protein subunit, electron transfer steps are not impaired although the kinetics are somewhat slower than that in the three protein subunit RC of purple bacteria. Hence, the RC of *Cf. aurantiacus* is the smallest functional RC isolated thus far. The two polypeptides possess a moderate identity of 40% each to the L- and M proteins of *Rhodobacter sphaeroides* and *Rhodospseudomonas viridis* RC, respectively. A characteristic feature of the N-terminus of the *Cf. aurantiacus* RC is the extended hydrophilic region at the N-terminus. When compared to purple bacteria RC, a few functionally important amino acids are not conserved; these differences help to explain some of the spectral and kinetic features of the *Cf. aurantiacus* RC.

I. Introduction

Over the last twenty years reaction centers of two members of the Rhodospirillaceae, namely *Rhodobacter (Rb.) sphaeroides* and *Rhodopseudomonas (Rp.) viridis* have emerged as the spectroscopically and biochemically best characterized photoactive pigment-protein complexes for two reasons: the RC of *Rb. sphaeroides* was the first to have been isolated, and the reaction center (RC) of *Rp. viridis* was the first to be crystallized and the first to have its structure elucidated. While RC preparations from other purple bacteria have been described more recently such as that of *Rhodobacter capsulatus*, *Rhodospirillum (Rs.) rubrum* and *Chromatium (Cm.) vinosum*, the reaction center of *Cf. aurantiacus* has emerged over the last decade as perhaps the third best characterized RC. The thermophilic nature of *Cf. aurantiacus* probably contributes to the unusual stability of its RC (Pierson et al., 1983; Nozawa and Madigan, 1991) and makes this RC particularly well suited to spectroscopic analysis. This progress was certainly influenced by some inherent differences between the purple nonsulfur bacteria and the green filamentous bacteria RC.

II. Biochemical Composition of the *Chloroflexus aurantiacus* Reaction Center

A. Cofactors

1. Pigments

Although the preparation of the first *Cf. aurantiacus* RC enriched fraction dates back to 1977 (Fuller and Feick, unpublished), the first isolation procedure yielding RC free of antenna pigment was published by Pierson and Thornber (1983). Purified RC exhibited in the near infrared absorption bands at 865, 813, 756 and a shoulder at around 792 nm in a characteristic ratio of 0.77 : 1 : 0.95 (Fig. 1) which

Fig. 1. Absorption spectra of RC, normalized at 865 nm, from *Cf. aurantiacus* (solid line) and *Rhodobacter sphaeroides* (dashed line). Reprinted from Blankenship et al. (1983) with permission of the publishers.

were attributed to BChl, BChl, BPheo and BChl, respectively (Shiozawa et al., 1987). The light-induced reduced minus oxidized difference spectrum in general resembled that of purple nonsulfur RC with a few minor differences in the 800 nm region.

Based on a spectral comparison to the *Rb. sphaeroides* RC in which the absorbances at 865 nm of both reaction center preparations were normalized, Pierson and Thornber (1983) concluded that the BChl *a* to BPheo *a* stoichiometry is 3:3 in the *Cf. aurantiacus* RC instead of the 4:2 commonly present in purple nonsulfur bacteria RC. No carotenoid was found in the isolated *Cf. aurantiacus* RC despite the fact that this organism contains large amounts of carotenoids. A Gaussian deconvolution of low temperature absorption spectra led Vasmel et al., (1983) to assume a pigment composition of 4 BChl *a* to 3 BPheo *a* molecules per *Cf. aurantiacus* RC. This, however, was subsequently refuted as the following experiments show.

Quantitative pigment extraction experiments (Blankenship et al., 1983) and, in addition, comparative optical and ESR experiments (Blankenship et al., 1984; Mancino et al., 1985) not only confirmed the 3:3 stoichiometry but, furthermore, established extinction coefficients ($135 \text{ mM}^{-1}\text{cm}^{-1}$ at 865 nm and $175 \text{ mM}^{-1}\text{cm}^{-1}$ at 813 nm) and identified the photobleachable primary electron donor as a BChl *a* dimer which absorbs maximally at 865 nm (P865) in analogy to purple nonsulfur bacteria RC.

Abbreviations. B_A – bacteriochlorophyll_L; B_B – bacteriochlorophyll_M; BChl – bacteriochlorophyll; BPheo – bacteriopheophytin; *Cf.* – *Chloroflexus*; *Cm.* – *Chromatium*; H_A – bacteriopheophytin_L; H_B – bacteriopheophytin_M; MQ – menaquinone; P – the special BChl dimer pair; PAGE – polyacrylamide gel electrophoresis; Q_A – primary quinone acceptor; Q_B – secondary quinone acceptor; *Rb.* – *Rhodobacter*; RC – reaction center; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*; SDS – Sodium dodecyl sulfate; UQ – ubiquinone

This pigment composition and spectral characteristics was further supported from theoretical calculations of the *Cf. aurantiacus* RC absorption spectra with the aid of exciton theory (Vasmel et al., 1986; Scherer and Fischer, 1987); however, it was assumed that the pigment geometry was the same as in the structurally known *Rp. viridis* RC.

Initial studies on the primary charge separation in *Cf. aurantiacus* RC clearly established that BPheo is an intermediate electron acceptor of the photochemistry (Kirmaier et al., 1983, 1986; Nuijs et al., 1986; Shuvalov et al., 1986b). Photoselection experiments revealed that the photoreducible BPheo(s) is oriented perpendicular to the special pair P865 transition dipole. The 'third' BChl absorbing at 813 nm possesses roughly the same orientation with an angle of 35–65° with respect to the tetrapyrrole plane of P865 (Kirmaier et al., 1984; Parot et al., 1985).

The midpoint potential for P865 in purified membranes has been determined to be $E_{m,8.2} = +362$ mV, $n = 1$ (Bruce et al., 1982) and in isolated RC to be $E_{m,8.0} = +386$ mV (Shuvalov et al., 1986a) or +420 mV (Venturoli and Zannoni, 1988).

2. Primary and Secondary Electron Acceptors

The primary electron acceptor has been identified through a combination of spectroscopy on isolated RC and by quinone analysis of *Cf. aurantiacus* cells. Time resolved light-induced difference spectroscopy (in the presence of N-methylphenazonium methosulfate) under conditions which prevent the accumulation of oxidized P865 yielded a difference spectrum characteristic of menaquinone (vitamin K_2) anion (Vasmel and Ames, 1983). After isolated *Cf. aurantiacus* RC have been exposed to a 1–5 μ s light pulse, charge recombination (electron transfer back to P865⁺) with a monoexponential decay of = 60 ms occurred (Blankenship et al., 1983; Venturoli et al., 1991). Addition of excess quinone analogues slowed the charge recombination by almost 10-fold (= 550 ms), if Vit K_1 was used (Blankenship et al., 1983) or by a factor of 100 (= 6 s) if UQ₃ was added (Venturoli et al., 1991). This recombination depended to a certain degree on the type of quinone used (Venturoli et al., 1991). If a suitable donor was added to such a quinone-reconstituted RC, so that P865 was maintained in a reduced state, a binary oscillation in semiquinone absorbance was observed which is characteristic of a two electron gate or a two quinone

acceptor system typically observed in purple nonsulfur bacteria RC (Blankenship et al., 1988). Once again o-phenanthroline abolished this spectroscopic behavior while, in contrast to purple nonsulfur bacteria RC, herbicides such as terbutryn and atrazine had no effect (Blankenship, 1984). These experiments clearly showed that the *Cf. aurantiacus* RC has i) a two quinone acceptor system (Q_A , Q_B), ii) the secondary quinone (Q_B) is usually lost during RC isolation, iii) MQ functions both as Q_A and Q_B . Since functional reconstitution of Q_B can be achieved with different quinone types, either UQ or MQ, the identification of Q_B as a MQ rests solely on the quinone analysis of *Cf. aurantiacus* cells (Hale et al., 1983). The absence or noninvolvement of ferredoxin as a primary electron acceptor, commonly found in green sulfur bacteria RC can be indirectly surmised from the amino acid sequence of the *Cf. aurantiacus* RC protein entity.

Redox titrations with membranes yielded a midpoint potential for Q_A of $E_{m,8.1} = -50$ mV (Bruce et al., 1982) or $E_{m,8.0} = -210$ mV (with a pH dependence of 60 mV/pH unit up to pH 9.3 (Venturoli and Zannoni, 1988). Removal of the primary acceptor of *Cf. aurantiacus* RC does not require as harsh of a treatment as for *Rb. sphaeroides* RC. It can be readily removed by a 1% Triton X-100 wash (see below).

B. The Polypeptide Backbone

In contrast to the initial pigment characterization and spectroscopy, the polypeptide composition was at first ambiguous. Using SDS-PAGE as an analytical tool, Pierson et al. (1983) found, in addition to some contaminating polypeptides, two dominant proteins with M_r of 30,000 and 28,000. Feick and Fuller (1984) reported only one major polypeptide with $M_r = 24,000$ –26,000. There was, however, agreement that when the RC preparation was subjected to less harsh denaturation conditions, a photochemically active RC pigment-protein band having $M_r = 52,000$ was observed and was present in relatively high amounts (Blankenship and Fuller, 1986; see also Fig. 2B lane 2).

Complete denaturation and re-electrophoresis of the extracted pigment-protein band (M_r 52,000–55,000) revealed the presence of just two polypeptides with very similar mobilities of approximately M_r of 24,000 (Fig. 2). Subsequently, the isolation of a highly purified *Cf. aurantiacus* reaction center preparation having an A_{280}/A_{813} of 1.3 to 1.4 was

described. After denaturation and electrophoresis on a SDS-PAGE having an optimized composition, only two polypeptides with similar M_r , 24,500 and 24,000, in an 1:1 stoichiometry were observed (Fig. 2, lanes 2–5). These data confirmed that the M_r 30,000 constituent in the Pierson and Thornber (1983) preparation was a proteinaceous contaminant. A third polypeptide corresponding to the H subunit of the purple nonsulfur bacteria reaction center was not found in *Cf. aurantiacus* reaction center preparations. Purified *Cf. aurantiacus* membranes showed no cross reaction with polyclonal antibodies against the H subunit of *Rb. sphaeroides* RC when analyzed by western blot experiments (Shiozawa and Feick, unpublished). Electron transfer and charge recombination kinetics from Q_A and Q_B in isolated and reconstituted *Cf. aurantiacus* RC suggest that a third protein subunit is not present in the reaction center of this bacterial species (Venturoli et al., 1991). Thus, the *Cf. aurantiacus* reaction center is the smallest functional reaction center isolated thus far.

A comparison of the RC constituents from *Cf. aurantiacus*, *Rb. sphaeroides* and *Rp. viridis* is shown in Fig. 3.

III. Structure-Function Relationships of the RC Complex

Protein chemical sequencing of the proteins and nucleotide sequencing of the genes encoding the reaction center polypeptides led to the elucidation of their primary structures (Ovchinnikov et al., 1988a, b, Shiozawa et al., 1989). These studies clearly showed a LM subunit analogy to the purple nonsulfur bacteria reaction center. The M_r 24,000 protein has 40% sequence identity with the L subunit of *Rb. sphaeroides*, is 310 amino acids long and has a M_m of 35,010 Da. The 24,500 polypeptide is 42% identical to the *Rb. sphaeroides* M subunit and possesses a M_m of 34,948 Da. The N-terminal amino acid of the M subunit is modified by a group having a M_m of 60 Da. A characteristic feature of the *Cf. aurantiacus* L subunit is its extended (31 amino acid residues long) hydrophilic (10 of 31 amino acid residues) N-terminus (see Fig. 4). Due to the low degree of sequence identity to the purple nonsulfur bacteria H subunit, it is doubtful that this region could substitute for the missing H subunit. However, it could be involved in stabilizing or anchoring the chlorosome attachment to the cytoplasmic membrane. Also it is not known with certainty whether reaction centers are located exclusively under chlorosomes.

The Kyte and Doolittle hydropathic profiles indicate that each polypeptide has five transmembrane helices. From the overall shape of these profiles, it is assumed that the location of the N- and C-termini correspond to that of purple nonsulfur bacteria reaction centers.

Comparing the primary structure and results of spectroscopic measurements on the *Cf. aurantiacus* RC with that of the two structurally known purple nonsulfur bacteria RC, the arrangement of the cofactors, eg. 3 BChl, 3 BPheo and 2 menaquinones (Q_A and Q_B), should be analogous to that in the *Rb. sphaeroides* and *Rp. viridis* RC where they are arranged in two transmembrane branches. These two branches will be denoted as A (L) and B (M) according to their relative proximity to the corresponding protein subunit (Fig. 5). In the *Cf. aurantiacus* RC, the BChl_B (B_B) is replaced by a BPheo, hence, the B-branch contains two BPheo molecules, H_{1B} and H_{2B} .

Fig. 3. Comparison of constituents of RC from *Cf. aurantiacus*, *Rb. sphaeroides* and *Rp. viridis*

The regions of highest sequence identity between *Cf. aurantiacus* and purple bacteria RC are observed where amino acid residues are known to interact with the special pair BChl (P865 or P) and accessory BChl molecules in the latter RC. A comparison of the functionally important amino acid residues which are involved in pigment binding and electron transfer (Michel et al., 1986; Allen et al., 1988; El-Kabbani et al., 1991) reveals some similarity, though significant differences exist (Fig. 4) and deserve some attention.

His^{M180} which acts as a ligand for the accessory BChl (B_B) in *Rp. viridis* RC is replaced by a Leu in *Cf. aurantiacus* and, hence, might be the reason for the replacement of BChl by the third BPheo in *Cf. aurantiacus* reaction center.

Tyr^{M210} located in the vicinity of P865, BChl_L (B_A) and BPheo_L (H_A) is conserved in all purple nonsulfur bacteria RC and it is proposed to facilitate or influence the primary electron transfer step (Allen et al., 1988) by lowering the energy of the state P⁺B_A⁻ (Parson et al., 1990). A replacement of this residue by Leu could explain the slower photochemical charge separation in *Cf. aurantiacus* RC. The functional role of this amino acid residue could indeed be

L-subunitM-subunit

Fig. 4. A schematic comparison of the primary structures of the L- and M subunits of *Cf. aurantiacus* and *Rhodobacter sphaeroides* RC. The lines are drawn in proportion to their M_n. The boxes represent transmembrane helices as revealed by the three-dimensional structure of *Rp. viridis* RC and of putative transmembrane helices for *Cf. aurantiacus* RC as indicated from hydropathy plots. The degree of identity is given in percent. A complete comparison of amino acid sequences is given in Shiozawa et al. (1989)

confirmed by site-directed mutagenesis of *Rb. sphaeroides* RC where a Tyr^{M210} → Leu change drastically changed the time constant from 3.5 to 22 ps (Gray et al., 1990; Finkele et al., 1990; Nagarajan et al., 1990).

Glu^{L104} is located near BPheo_A (H_A) and is hydrogen bonded with the carbonyl group of ring V of this pigment. This interaction is thought to be responsible for a red shift of the Q_x transition of this BPheo and, hence, allowed a spectroscopic discrimination between BPheo_L (H_A) and BPheo_M (H_B) (Zinth et al., 1983; Zinth et al., 1985). Exchanging this amino acid for Gln, which occurs in *Cf. aurantiacus* RC, significantly diminished this red shift and caused an absorbance in the BPheo Q_x region which is reminiscent of that of *Cf. aurantiacus* RC (Bylina et al., 1988).

Right side: Time constants (τ , 1/e times) for electron transfer steps and approximate midpoint potentials of charge transfer states. * Slightly different values have been reported by Blankenship et al. (1983, 1988)

IV. The Primary Photochemistry

The early events of photochemistry originate from P^* , which is directly formed after absorption of a light quantum by the special pair (P). The initial electron transfer steps which occur well within 1 ns after light excitation have been studied by transient absorption and, more recently, by fluorescence emission spectroscopy with pico- and femtosecond time resolution.

A. The Early Event(s): Before 15 ps —The Formation of $P^+H_A^-$

Initial studies with *Cf. aurantiacus* RC revealed the involvement of BPheo as an intermediate electron acceptor which is reduced within 13 ps. An electron is subsequently transferred within 280–400 ps from the reduced BPheo to Q_A (Kirmaier et al., 1983, 1984, 1986; Nuijs et al., 1986). Despite an improved spectral resolution in the near infrared absorption range compared to purple bacteria RC, the time constants of the kinetics differed somewhat with the detection wavelength. In similar experiments, in which P was directly excited with a 32 ps light pulse, Shuvalov et al. (1986b) interpreted their results as a two step electron transfer, first from P^* to B_A with $\tau =$

10 ps (1/e) and, subsequently, to H_A within 3 ps; these time constants were well within the time resolution of the instrument.

Subpico- and femtosecond absorbance spectroscopy with *Rb. sphaeroides* and *Rp. viridis* RC contradicted this electron transfer sequence (Woodbury et al., 1985; Martin et al., 1986; Breton et al., 1988; Kirmaier and Holten, 1991). No evidence for a state B_A^- was found. According to their data evaluation, charge transfer occurred from P^* directly to H_A within less than 2.2–2.8 ps via a superexchange mechanism (Bixon et al., 1988). See Chapter 24 by Woodbury and Allen for a discussion of this issue.

In contrast, Zinth and coworkers' assessment of their data from femtosecond absorption and fluorescence spectroscopy was fully consistent with a sequential two step electron transfer from P^* to B_A in 3 ps and then to H_A in 0.9 ps (Holzapfel et al., 1990; Hamm et al., 1993; Arlt et al., 1993).

This controversy might be partially related to the mathematical treatment of kinetics (curve fitting) and to the very complex behavior of absorbance changes and their kinetics which are dependent upon i) the temperature, ii) the wavelength of the probing beam and iii) the occurrence of mono- and non-monoexponential decay patterns.

For *Cf. aurantiacus* RC, the quantum yield of

charge separation (to $P^+Q_A^-$) has been initially reported to be 0.6 (Shuvalov et al., 1986a) which is considerably lower than the 1.0 reported for *Rb. sphaeroides* RC (Wraight and Clayton, 1973; Cho et al., 1984). Since such a low yield could be indicative of certain unusual electron transfer characteristics and/or might simply reflect a partial loss of Q_A . This measurement was repeated on a ns time scale, thus making it insensitive to Q -depletion. The value obtained was 1.0 at 280 K (Volk et al., 1991). Furthermore, it was shown that standard *Cf. aurantiacus* RC preparations contained usually 90% Q_A if LDAO, but only 20% Q_A occupancy if Triton X-100 was used as detergent.

Subpicosecond absorption changes associated with the decay of P^* , mirroring the earliest electron transfer step, revealed monoexponential kinetics with a $\tau = 7$ ps at 296 K and $\tau = 9$ ps at 320 K in *Cf. aurantiacus* RC (Becker et al., 1991). At lower temperatures the kinetics became markedly biphasic and could be best fitted with two exponential functions. The time constants for P^* decay were 2 and 24 ps at 10 K and 2 and 12 ps at 240 K with amplitudes of 1:1 at both temperatures (Martin et al., 1990; Feick et al., 1990).

With fluorescence emission studies several (3, 7, 18 ps, Müller et al., 1991) or two (2.7 and 9 ps, Hamm et al., 1993) short lived components could be detected. The 7–9 ps constituent agrees nicely with the $\tau = 7$ ps observed by Becker et al. (1991) and should clearly reflect the formation of P^+ ($P^+B_A^-$ or $P^+H_A^-$). The 2–3 ps kinetics was attributed to energy transfer from the excited B_A to P within the RC (Müller et al., 1991). However, ps absorption measurements with 812 nm excitation failed to confirm this assignment (Hastings et al., 1993). This 2–3 ps energy transfer component could not be the 2 ps component observed by Martin et al. (1990) because P was directly excited in their experiments and uphill energy transfer can be ruled out on such a time scale. The 18 ps fluorescence kinetics was interpreted to originate from charge transfer from P in closed (PQ^-) RC which the authors contributed to a open/closed RC sample heterogeneity. In light of the results of Volk et al. (1991) where standard RC preparations contain about 10% Q -depleted centers, this type of heterogeneity cannot formally be ruled out. Heterogeneous populations of *Cf. aurantiacus* RC which could be caused by differently charged complexes have been reported earlier (Feick et al., 1990). Other interpretations for the origin of the complex decay kinetics of P^* are discussed in detail

by Becker et al. (1991), Müller et al. (1991), Kirmaier and Holten (1991), Hamm et al. (1993), Arlt et al. (1993).

B. Events After 15 ps: Electron Transfer from $P^+H_A^-$ to $P^+Q_A^-$

Regardless of whether the reduction of BPheo (H_A^- within 10 ps) occurs via a one or two step mechanism, the subsequent forward electron transfer from H_A^- results in the formation of the state $P^+Q_A^-$ with $\tau = 320$ ps at 280 K (Kirmaier et al., 1986). The authors observed a dependence of τ on the detection wavelength used. The observed value of τ ranged from 365 ps in the 530–545 nm region to 281 ps at 810 nm. With the knowledge of the *Rb. sphaeroides* and *Rp. viridis* RC crystal structures, a spectroscopic discrimination between the two functionally nonequivalent BPheo-molecules was possible (Zinth et al., 1983, 1985). Subsequently, with the help of a high resolution spectrophotometer, this distinction could also be made on a picosecond time scale (Eberl, 1988; Aumeier, 1990; Aumeier et al., 1990). It was found that, after a 25 ps flash, differential absorption changes at 540 and 533 nm mirrored forward electron transfer from H_A^- or from (if it occurs at all) H_B^- to Q_A . In *Rb. sphaeroides* RC (the equivalent wavelengths were 547 and 530 nm). Since only the 547 nm showed a differential absorption change of $\tau = 200$ ps, the 530 nm feature remained constant over a ms time scale. Thus, it was possible to selectively probe electron transfer along the A- and B-pigment branch. In *Cf. aurantiacus* RC, however, the changes of the 540 nm (due to the disappearance of H_A^-) and 533 nm band with a amplitude ratio of 6:1 disappeared with different kinetics $\tau_{540\text{ nm}} = 320$ ps, $\tau_{533\text{ nm}} = 280\text{--}450$ ps. This behavior was consistent with the interpretation of a significant charge transfer into the B-branch of *Cf. aurantiacus* RC (Eberl, 1988). Later measurements and, also, the high quantum yield of 1.0 were no longer compatible with this notion. Hence, unidirectionality of electron transport, i.e. charge transfer occurs via the A-branch only, also appeared to be a salient feature of *Cf. aurantiacus* RC (Aumeier et al., 1990). However, according to recent picosecond fluorescence measurements under Q_A reduced conditions, a reversible electron transfer into the B-branch, from P^* to H_{1B} , had to be considered as one alternative to explain the observed results (Schweitzer et al., 1992).

C. Electron Transfer from Q_A to Q_B and Charge Recombination

Very few data exist on the forward electron transfer from Q_A to Q_B . This might in part be related due to the fact that isolated *Cf. aurantiacus* RC are Q_B depleted and, hence, require Q-reconstitution prior to measurement. Time constants of 1.3 ms (Blankenship et al., 1988) and 400 μ s (Venturoli and Zannoni, personal communication) for electron transfer from Q_A to Q_B have been determined. The difference could be due to the type of quinone (UQ and MQ analogues) with which the RC have been reconstituted. An even more pronounced quinone dependence has been observed for charge recombination (back electron transfer to the state $PHQ_A Q_B$) which varied from $\tau = 140$ ms in the presence of MQ-6 and $\tau = 5.5$ s in the presence of UQ-3. Further spectroscopic characteristics of Q_A and Q_B have already been addressed above. A summary of the redox potentials and time constants of all photochemical processes occurring in *Cf. aurantiacus* RC are presented in Fig. 5

V. Summary and Conclusions

The photosynthetic apparatus of the thermophilic *Cf. aurantiacus* has many distinctive features which are characteristic for green bacteria. Its RC and photochemical processes are reminiscent of purple nonsulfur bacteria RC. However, significant differences exist: i) a modified pigment composition of 3 BChl:3 BPheo molecules per RC (compared to a 4:2 stoichiometry in purple nonsulfur bacteria RC, ii) it is composed of only two protein subunits with almost identical molecular masses of approximately 35,000 Da and iii) increased thermal stability of the complex. Due to the absence of the so called H-protein subunit, the *Cf. aurantiacus* RC is the smallest functional RC isolated thus far. The two polypeptides possess a moderate identity of 40% each to the L- and M polypeptides of *Rb. sphaeroides*- and *Rp. viridis* RC, respectively. A characteristic feature of the N-terminus of the L-subunit of the *Cf. aurantiacus* RC is the extended hydrophilic region at the N-terminus. This region could be involved in stabilizing or anchoring the chlorosome attachment to the cytoplasmic membrane. A three-dimensional structure is not yet available; all evidence points to a two branch organization of cofactors similar to the two structurally known RC. A few functionally

important amino acids are not conserved and help to explain certain spectroscopic features such as the presence of a BPheo instead of a BChl and slower photochemical reactions. These characteristics and a better resolved absorption spectrum in the near infrared should, in theory, make the *Cf. aurantiacus* RC particularly well suited for ultrafast spectroscopy to complement the existing knowledge of primary photochemical charge separation.

Acknowledgments

We would like to thank Professors M.E. Michel-Beyerle, D. Oesterhelt and H. Scheer for support and Mr. G. Niedermeier for helpful discussions. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 143).

Summary

A variety of cytochromes are present in anoxygenic photosynthetic bacteria including *c*-type, *b*-type and *a*-type. The properties that biosynthetically distinguish these types include: the type of heme group, the nature of the heme linkage to the apoprotein and the topological characteristics within the cell, which are in part determined by the secretion and/or assembly pathway. For example, cytochromes *a* contain heme *a* that is enzymatically modified with formyl and farnesylhydroxymethyl hydrophobic side chains. Although the *b*- and *c*-type cytochromes both have heme *b*, the heme in *c*-type cytochromes is covalently bound through thioether linkages to CysXxxYyyCysHis of the apoprotein. Enzyme(s) must be present in the cell for this ligation reaction. Topologically, the *c*-type cytochromes of Gram-negative bacteria are present in the periplasmic space (or are oriented toward it) and the apocytochromes *c* are synthesized with typical bacterial signal sequences for secretion. In many cases, the *b*- and *a*-type cytochromes are membrane bound and contain numerous transmembrane helices. The topological location of the heme in these cases may vary, thus presenting a further

complication from a biosynthetic standpoint. This chapter discusses the cytochrome assembly pathways and assembly factors that have been discovered in anoxygenic photosynthetic bacteria and their relationship to those in other organisms. Biogenesis pathways of macromolecular membrane complexes like cytochrome bc_1 and the cytochrome aa_3 oxidase are complicated, with some of the assembly rules and potential assembly factors or proteins just beginning to be elucidated. There appears to be at least seven assembly proteins required for the biogenesis of all c -type cytochromes in the anoxygenic photosynthetic bacterium *Rhodobacter capsulatus*. These assembly proteins (called Hel and Ccl) are discussed with respect to their properties and putative roles within a specific cytochrome(s) c biogenesis pathway. The recent discovery of *hel*- and *ccl*-like genes in mitochondrial genomes underscores the idea that related biogenesis pathways may exist in eukaryotes. Their predicted close phylogenetic relationship to the ancestral mitochondrial endosymbiont make *Rhodobacter* and organisms like it ideal systems to study the biogenesis of cytochromes.

I. Introduction: Topological and Biosynthetic Distinctions Among Cytochromes

Cytochromes are heme proteins that function in electron-transfer systems of the cell. The physical and functional properties that distinguish one cytochrome from another include: reduction/oxidation potential, interaction with specific substrates (i.e., electron donors or acceptors), type of heme group and the nature of its binding to the apocytochrome, and the topological location of the cytochrome within the cell. Five types of cytochromes have been classified based on heme characteristics: a , b , c , o and d types (Palmer and Reedijk, 1992). Thus, a - and d -type cytochromes are distinguished by their heme prosthetic group: hemes o and a contain a farnesylhydroxymethyl group, heme a an additional formyl group while cytochromes d contain heme d (also known as heme a_2). Heme d contains two hydroxyl groups on pyrrole ring III. In contrast, both b - and c -type cytochromes contain heme b and are distinguished from each other in that only c -type cytochromes have this heme covalently attached by thioether linkages to Cys XxxYyy Cys His residues of the apocytochrome. Cytochromes c also differ from most b -type cytochromes in their subcellular location; they are either soluble in the periplasm (e.g., cytochrome c_2) or periplasmically orientated if membrane bound (e.g., cytochrome c_1 of the bc_1 complex). (For a detailed discussion of the structure and function of various cytochromes see Chapter 34 by Meyer and Donohue, Chapter 35 by Gray and Daldal and Chapter 36 by Nitschke and

Dracheva, and of the structure and biosynthesis of heme see Chapter 9 by Beale.)

A variety of heme proteins have been reported to be present in anoxygenic photosynthetic bacteria, including a -, b - and c -type cytochromes. In fact, it is not uncommon to find these various types of cytochromes present in a single complex (e.g., cytochrome bc_1 or cytochrome cb oxidases in phototrophic bacteria or as bd oxidases or caa_3 oxidases in other bacteria). Understanding the assembly of these diverse macromolecular complexes is clearly at a very early stage. Nevertheless, it is clear that specific assembly proteins, either transiently or permanently bound to such complexes as the oxidases, may aid in the folding and/or insertion of these polypeptides into the membrane and/or their stability (see IIB below for an example).

Putative assembly factors have been reported for the cytochrome aa_3 oxidase in *Rhodobacter sphaeroides* (Cao et al., 1992; see IIB). Some extragenic (i.e., not apocytochrome structural gene) factors have also been discovered in *Rhodobacter (Rb.) capsulatus* that are specifically required for the synthesis of c -type cytochromes. These factors will be described here and we will evaluate their proposed functions with respect to the assembly of non- c -type cytochromes. Chapter 34 by Meyer and Donohue will address the structural requirements of soluble cytochromes c with respect to heme attachment in *Rb. sphaeroides*. The majority of studies on cytochrome c biogenesis have been conducted in *Rb. capsulatus*. However, the significant homologies observed between many of these *Rb. capsulatus* components and proteins encoded by mitochondrial and chloroplast genes underscores the idea that similar assembly processes may occur in plants and animals. These conservations also reveal the close ancestral

Abbreviations: CCHL – cytochrome c heme lyase; *Rb.* – *Rhodobacter*; TMPD – tetramethyl p -phenylaminediamine; *S.* – *Saccharomyces*; *E.* – *Escherichia*; *B.* – *Bradyrhizobium*; *P.* – *Paracoccus*; *N.* – *Neurospora*

relationship between anoxygenic non-sulfur purple bacterial like *Rb. capsulatus* and mitochondria (Woese, 1987). Clearly, *Rb. capsulatus* and bacteria like it can be used as model systems for the biogenesis of cytochromes in general. A working model for cytochromes *c* biogenesis in *Rb. capsulatus* is presented in Fig. 1 to serve as an aid in understanding the properties and putative functions of these components.

II. Transport of Apocytochromes to the Appropriate Subcellular Locations

A. *c*-Type Cytochromes

The structural genes encoding many *c*-type cytochromes from photosynthetic and non-photosynthetic bacteria have been cloned and sequenced. From these studies, it is clear that these proteins are synthesized with amino-terminal extensions that are not present in the purified (or crystallized) *c*-type cytochrome. These extensions have the properties of typical bacterial signal sequences: 15–30 amino acid

(aa) residues in length with a net positively charged region of 5–8 aa long, followed by a 8–12 aa central hydrophobic core, a predicted 'turn' (e.g., proline) and a polar region of 5–7 aa that terminates in a site for signal cleavage (von Heijne, 1985). In recent years *Escherichia coli* alkaline phosphatase gene (*phoA*) fusions have been used as reporters of secretion since alkaline phosphatase is active only in the periplasm (see Manoil et al., 1990 for review). Gene fusions between *phoA* (without its signal sequence) and the N-termini of specific cytochrome *c* genes have been used to verify the use of these signal sequences in both the photosynthetic bacterium and in the heterologous *E. coli* system (e.g., Varga and Kaplan, 1989). Interestingly, the heterologous secretion of these cytochrome *c*-alkaline phosphatase fusion proteins implies that the general secretory components used in *E. coli* (e.g., SecA, Y, E, D, F) are present in anoxygenic phototrophs. This is supported by the discovery of SecD and SecF homologs in *Rb. capsulatus* (Beckman and Kranz, 1993). Certain indirect evidence (presented in Section IIIA) strongly suggests that the apoproteins and not the holoproteins are secreted across the cytoplasmic

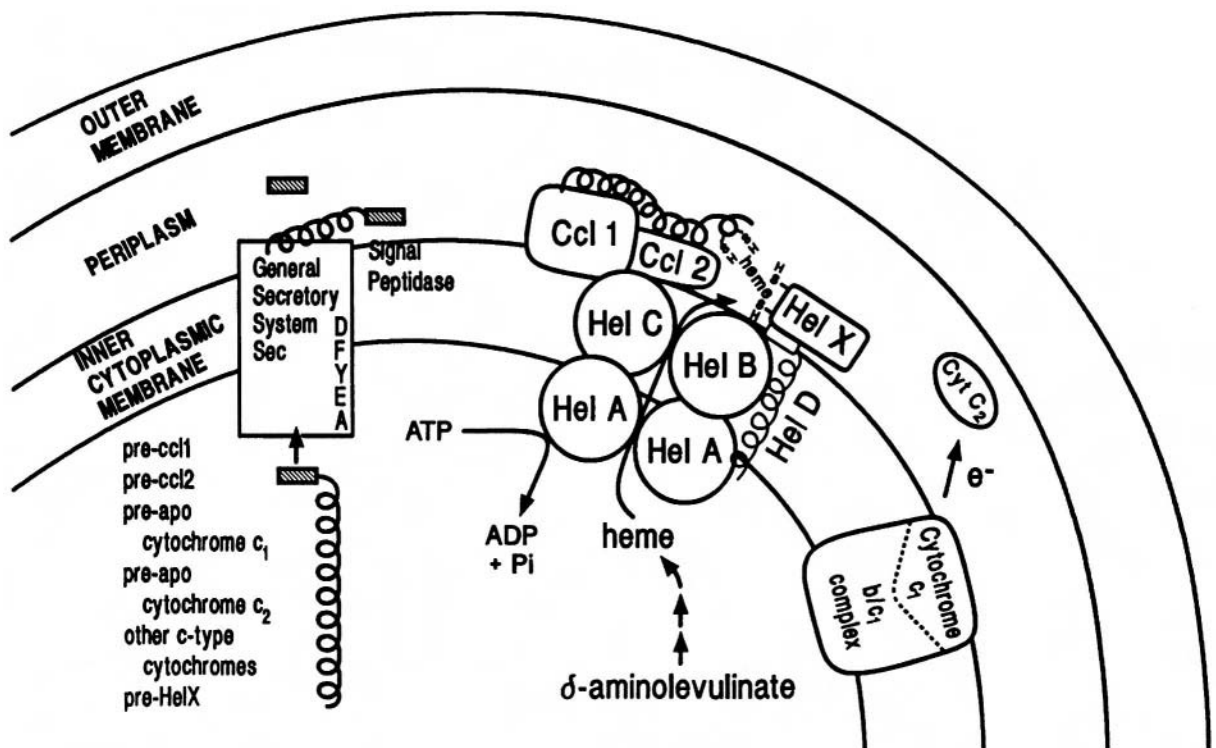

Fig. 1. Working model of cytochromes *c* biogenesis in *Rb. capsulatus* (see text for details).

membrane, probably in an unfolded state. Accordingly, heme and final assembly of the holo-cytochrome occurs in the periplasmic compartment or on the outer leaflet of the cytoplasmic membrane (see III below). This suggestion is consistent with the hypothesis that during signal sequence-dependent transport, a protein must be in the unfolded state for efficient secretion.

B. Other Cytochromes

Specific modification enzymes are needed to form heme *a* or heme *o* for these types of cytochromes (e.g., see review by von Wachenfeldt and Hederstedt, 1992). Although these enzymes or their genes have yet to be discovered in anoxygenic photosynthetic bacteria, they have been characterized in other bacteria (eg. Saiki et al., 1993; Svensson et al., 1993). Undoubtedly, similar enzymes and genes will be discovered in anoxygenic phototrophs.

Topological studies on cytochrome *b* of the cytochrome bc_1 complex in *Rb. sphaeroides* have indicated that some domains are oriented toward the periplasm and others towards the cytoplasm (Yun et al., 1991; see Chapter 35 by Gray and Daldal). A number of important assembly questions remain for the bc_1 complex. Does the *b* apoprotein naturally insert within the membrane via specific hydrophobic rules dictated by the cytochrome *b* primary amino acid sequence? Is heme bound before, during or after this folding pathway? Do other polypeptides within the bc_1 complex play a role in directing this assembly pathway? If heme is oriented towards the periplasm, how does heme get to this location? Are there assembly factors required for this folding pathway?

Putative factors have been proposed for the assembly of specific oxidases (Cao et al., 1992). For example, the *Saccharomyces cerevisiae* COX10 and COX11 mutations result in a block in cytochrome aa_3 oxidase assembly (Nobrega et al., 1990; Tzagoloff et al., 1990). Proteins homologous to COX10 that are encoded by genes adjacent to cytochrome oxidase subunit genes have been discovered in Gram-negative bacteria (e.g., Chepuri et al., 1990) and Gram-positive bacteria (see von Wachenfeldt and Hederstedt, 1992). Very recently, two *Rb. sphaeroides* genes that are linked to cytochrome aa_3 oxidase subunit genes have been shown to be required for proper cytochrome aa_3 oxidase assembly and the proteins encoded by these genes are related to the COX10 and COX11 genes (Cao et al. 1992). These authors (Cao et al., 1992)

note that the high degree of identity between the eukaryotic aa_3 oxidase and that of *Rb. sphaeroides* establish this organism as an excellent model for function, structure and assembly of this important oxidase.

It should be noted that *b*-type cytochromes can be periplasmically located in Gram-negative bacteria. Cytochrome *b*-562, which has a crystal structure surprisingly similar to some soluble *c*-type cytochromes (Lederer et al., 1981), is present in the periplasm of certain *E. coli* strains. Although its function is unknown, cytochrome *b*-562 is synthesized with a typical signal sequence (Nikkila et al., 1991). Accordingly, the question of how heme gets to apocytochrome *b*-562 is particularly pertinent: Could it involve similar mechanisms employed for cytochrome *c* assembly? Some of these generic questions concerning biogenesis of cytochromes will be addressed in this chapter when considering the specific assembly pathway of *c*-type cytochromes (e.g., see IIIA below).

III. Components Required Specifically for Cytochrome *c* Biogenesis

Rb. capsulatus is the only anoxygenic photosynthetic bacterium for which genes involved specifically in the synthesis of *c*-type cytochromes have been characterized. *Rb. capsulatus* contains a *b*-type ubiquinol oxidase in addition to a cytochrome *c* oxidase. Previous studies (La Monica and Marrs, 1976; Hüdig and Drews, 1982) have demonstrated that because either oxidase is sufficient for aerobic growth, it is possible to isolate mutants specifically deficient in *c*-type cytochromes. This property, along with the amenable genetics and gene transfer systems, make *Rb. capsulatus* an excellent model for studying cytochrome *c* biogenesis. A *Rb. capsulatus* mutant that cannot make *c*-type cytochromes will be unable to grow anaerobically since the bc_1 complex is required for photosynthetic growth (Prince and Daldal, 1987; Daldal et al., 1987) and it has been shown that a *c*-type cytochrome may be involved in dark anaerobic growth (Zsebo and Hearst, 1984; Kranz, 1989). In fact, cytochromes *c* biogenesis mutants (Davidson et al., 1987; Kranz, 1989; Biel and Biel, 1990; Beckman et al., 1992; Beckman and Kranz, 1993) have such a phenotype, i.e., they can only grow aerobically. Whether it is possible to isolate null mutants of this pathway in other

anoxygenic photosynthetic bacteria will depend on the particular physiology of the microorganism in that it must have a non *c*-type ubiquinol oxidase or other growth mode that is independent of *c*-type cytochromes.

Analyses of *Rb. capsulatus* mutants and genes have defined seven genes at two loci that are required for cytochromes *c* biogenesis (Kranz, 1989; Biel and Biel, 1990; Beckman et al., 1992; Beckman and Kranz, 1993). Physical maps of these genes are shown in Fig. 2. The *hel* locus contains five genes (*helABCDX*) and the second locus contains two genes (*ccl12*) that are required for cytochromes *c* biogenesis. In addition to the growth phenotype described above, mutants in each of these seven genes have the following properties:

(1) Negative for tetramethyl *P* phenylenediamine (TMPD) oxidase activity.

(2) Complete deficiency of all *c*-type cytochromes, as detected by (a) heme stained polypeptides

separated on sodium dodecyl sulfate gels and (b) spectroscopically.

(3) Wild-type levels of *b*-type cytochromes, except for the cytochrome *b* of the cytochrome bc_1 complex which is spectroscopically and antigenically missing. (It should be noted that mutants lacking cytochrome c_1 have greatly reduced levels of the cytochrome *b* subunit of the bc_1 complex; thus, it is predicted that cytochrome c_1 is required for proper assembly of the bc_1 complex and without cytochrome c_1 , the bc_1 polypeptides are rapidly degraded (Konishi et al., 1991; Davidson et al., 1992; see Chapter 35 by Gray and Daldal).

(4) Secrete extracellular protoporphyrin and coprotoporphyrin. This property appears to be a response to a deficiency in *c*-type cytochromes (or electron transport catalyzed by such) and will be discussed in Chapter 52 by Biel.

(5) All mutants have the ability to synthesize and

Fig. 2. Restriction maps of the *hel* and *ccl* loci of *Rb. capsulatus*, including upstream and downstream regions. At the *hel* locus, *helA*, *helB*, *helC*, *helD*, and *helX* are required for cytochromes *c* biogenesis while 2 genes at the *ccl* locus, *ccl1* and *ccl2*, are required. The predicted gene product of *orf124* exhibits no known homology. Since the predicted gene products of the other ORFs at these loci exhibit significant homology to known proteins, they were thus named accordingly (see Sections IIIA and IIIB).

secrete an apocytochrome c_2 -alkaline phosphatase reporter into the periplasm (Beckman et al., 1992; Beckman and Kranz, 1993 and unpublished). Thus, these mutants still transcribe, translate and transport the apocytochrome c_2 molecule, presumably through the *sec*-dependent pathway. Accordingly, it is probable that each of the proteins encoded by these seven genes plays a role in the biogenesis pathway at a step after the secretion of the apocytochrome molecule to the periplasm.

Following is a discussion of each of the gene products. They will be discussed separately with respect to their properties and putative functions.

A. *HelABC* Proteins: A Putative Heme Exporter that Fits the Paradigm of an ATP-Dependent Transporter

Results with the *Rb. capsulatus* cytochrome c_2 -alkaline phosphatase reporter, as described above, suggest that apocytochrome c_2 is transported either independently of or concurrently with the covalent ligation of heme. Secretion is therefore predicted to occur prior to the assembly of periplasmic *c*-type cytochromes. This is also the conclusion of studies carried out with cytochromes *c* in *Paracoccus denitrificans*; mutants in *P. denitrificans* that do not form the final holocytochromes *c* are still able to synthesize and secrete the apocytochrome to the periplasm (Page and Ferguson, 1989, 1990). Moreover, three separate proteins (i.e., Ccl1, Ccl2, HelX) in *Rb. capsulatus* have been shown to be required for cytochromes *c* biogenesis and present in the periplasm (see below; Beckman et al., 1992; Beckman and Kranz, 1993), a result that is consistent with the post-secretion assembly hypothesis. It is therefore necessary to understand how heme and other assembly factors are transported to the periplasmic compartment.

1. The *hel* Locus in *Rb. capsulatus*

One class of *Rb. capsulatus* mutations and genes involved in cytochromes *c* biogenesis were mapped to a single locus called *hel* (for *heme* for *ligation*). Genetic analyses determined that 5 genes at this locus (called *helABCDX*) are required for cytochromes *c* biogenesis (Kranz, 1989; Beckman et al., 1992; Beckman and Kranz, 1993). Each *hel* gene on the chromosome was inactivated and complemented

with a DNA fragment containing only that *hel* gene. Also present at this locus are genes which are highly homologous to the *E. coli* *secD* and *secF* genes (Gardel et al., 1990); a gene called *orf124* that encodes an open reading frame (ORF) of unknown function that is not required for cytochromes *c* biogenesis; and the *hpt* gene, which is homologous to the human HPRT gene (Beckman and Kranz, 1991a), is also not required for cytochromes *c* biogenesis. Considering transcription at this locus, since the stop of *secF* overlaps the predicted *orf124* translational start site, it is thought that these may comprise a single transcription unit (or a superoperon with multiple promoters). Because it was not possible to inactivate the chromosomal *secD* or *secF* by insertional mutagenesis with growth on minimal media it is assumed that, as in *E. coli*, these genes are required for optimal protein secretion in *Rb. capsulatus*. A mini-*Mu* insertion in the chromosomal *orf124* was obtained, ruling out that *orf124* is required for secretion. Additionally, this insert showed polarity on *hela*, resulting in a cytochromes *c* biogenesis defect. This polarity was confirmed by complementation of this insertion strain using a plasmid with only *hela* and a vector promoter. Similar complementation studies in *helB*, *helC*, *helD* and *helX* indicate that multiple promoters exist, representing a potential *secD* - *secF* - *orf124* - *hela* - *helB* - *helC* - *helD* - *helX* superoperon. It will be interesting to determine if the products of all these genes also interact in a direct fashion to facilitate cytochromes *c* biogenesis (see model in Fig. 1). It should be noted that although the exact functions of SecD and SecF in the *E. coli* secretory pathway are unknown, SecD and SecF are membrane-bound proteins which are oriented towards the periplasm (Gardel et al., 1990). A role at a later stage in the secretory pathway is envisioned.

2. The *Hel ABCD* Proteins

The *hela* gene encodes a product that is a member of a larger class of proteins recently termed ABC transporters (for ATP-binding cassette) or traffic ATPases. Recent reviews on ABC transporters in general, including bacterial and eukaryotic systems, have been published (e.g., Ames, 1992; Higgins, 1992; Reizer et al., 1992). Additionally, a comprehensive review of putative exporters of the ABC protein family, including the *hel* system, has been published (Fath and Kolter, 1993). Substrates for

such exporters include peptides, proteins, polysaccharides and certain antibiotics and anti-tumor agents. An ABC transporter is typically composed of a hydrophilic polypeptide containing a consensus ATP-binding site (i.e., Walker motif; Walker et al., 1982). Additional C-terminal amino acid residues are conserved. In the bacterial systems, the ATP-subunit of the ABC transporter is thought to function either as a homodimer or as a heterodimer of two ATP-binding gene products (see Fig. 1). Members of the ABC transporter family include HisP (for histidine import in *E. coli*), MalK (for maltose import), and HlyA (for hemolysin export in *E. coli*) (see reviews for extended references). Associated with this ATP-binding component of the ABC transporter is one (e.g., hemolysin transporter) or multiple (e.g., histidine transporter) polypeptides containing transmembrane domains. Both HelB and HelC are predicted to have 6 transmembrane helices and they are predicted to associate with a HelA homodimer (see Fig. 1). Accordingly, HelB and HelC are predicted to confer the substrate specificity to this transport system. Recently, it has been demonstrated that the HelA polypeptide is unstable and degraded in *Rb. capsulatus* *helB* and *helC* mutants, results that support the hypothesis that HelABC forms a complex (Goldman and Kranz, unpublished). In contrast, the eukaryotic ABC transporters appear to be composed of a single large polypeptide chain with at least 12 transmembrane helices, 6 each adjoining 2 individual ATP-binding sections. Examples of the eukaryotic ABC transporters include the cystic fibrosis transmembrane conductance regulator protein (chloride transport) and the multidrug-resistance protein (also known as MDR or P-glycoprotein). A notable exception to the eukaryotic 'single polypeptide rule' may be the HelB- and HelC-like proteins observed in mitochondria (see below).

The *helD* gene encodes a 52 aa protein with one potential transmembrane domain in the N-terminus and a highly basic C-terminus. Although this gene has been shown to be essential for cytochrome *c* biogenesis, it is unknown whether it has a role within the ABC transporter model since it does not fit within the current paradigm of ABC transporters. Recent studies indicate that HelD may anchor HelX to the cytoplasmic membrane within the periplasmic space (Beckman and Kranz, unpublished).

The discovery of a specific ABC transporter required for cytochromes *c* biogenesis initially led to a number of theories on its exact function. Substrates

for the Hel transporter included three likely candidates: (1) apocytochromes *c*, (2) heme, or (3) other assembly component(s). An additional possibility was that the *hel* genes encoded an iron importer or exporter. This possibility was rejected as unlikely for a number of reasons. These include the specific nature of the defects, the fact that alternative iron sources do not correct the *hel* defects, the *hel* mutants are as sensitive as wild-type to the iron chelator dipyrindyl, and because the Hel components appear to be well conserved among bacterial and eukaryotic organisms that synthesize *c*-type cytochromes. Iron import systems, on the other hand, are diverse with multiple mechanisms usually operating and available (e.g., Angerer et al., 1992).

That apocytochromes *c* is a substrate of the Hel transporter was ruled out by the previously described apocytochromes *c* - alkaline phosphatase gene fusion studies. Possibility (3) seems unlikely since the currently known periplasmic assembly components (Ccl1, Ccl2 and HelX) all have signal sequences and are presumably exported through a *sec*-dependent pathway. Likewise, Ccl1-, Ccl2- and HelX-PhoA fusion proteins are transported to the periplasm in an *hel*-independent manner. Accordingly, the most likely substrate for the *hel*-encoded transporter is heme. This hypothesis is consistent with the suggestion that assembly takes place within the periplasm. Furthermore, the transport function is corroborated by the discovery of Hel-like components in mitochondria, the site of heme biosynthesis in eukaryotes (see below). Biochemical analysis of heme transport will be required to confirm this hypothesis.

B. Periplasmic Proteins

1. *Ccl1*

A *Rb. capsulatus* mutant in *ccl* was first isolated by Biel and Biel (1990). This mutant, called AJB530, was shown to possess the cytochrome defects previously described for *hel* mutants, yet the DNA fragment that complemented AJB530 was different than the *hel* DNA fragment. Subsequently, Beckman et al., (1992), showed that two genes at this locus were required for cytochrome *c* biogenesis, called *ccl1* and *ccl2* (for cytochrome *c* ligation). Sequence and genetic analysis of this locus indicated that *ccl1* and *ccl2* are located between two other genes not involved in cytochromes *c* biogenesis: *argD* encodes a protein related to *E. coli* acetylornithine

aminotransferase and *fadB1* (Beckman and Kranz, 1991b), encodes a protein related to the mitochondrial enoyl CoA hydratase, an enzyme involved in fatty acid degradation. The *Rb. capsulatus ccl1* gene is predicted to encode a 653 aa protein that has a typical bacterial signal sequence. This observation and the high alkaline phosphatase activity exhibited by a *ccl1-phoA* fusion in *Rb. capsulatus* suggest that Ccl1 is oriented toward the periplasm. However, the Ccl1 protein is also predicted to have as many as 12 potential transmembrane helices, indicating that Ccl1 may be integrally associated with the cytoplasmic membrane. While the defects in *Rb. capsulatus* Ccl1 strains clearly indicate a role in the post-secretory assembly of cytochromes *c*, the exact function can only be speculated. The Ccl1 protein is not homologous to known eukaryotic cytochromes *c* heme lyases (CCHL), the enzyme that ligates heme to apocytochromes *c* in yeast (see below). Moreover, the discovery of mitochondrial ORFs homologous to Ccl1 leads to the premise that the Ccl1 class of proteins have a conserved function that remains to be defined. Possibly, the Ccl1 protein acts as a specific chaperone or scaffold used to concentrate the substrates (i.e., heme and apocytochromes *c*). Curiously, the Ccl1 protein shows limited but significant homology to the HelC protein (in a region called the WWD domain because of the highly conserved tryptophan character of this domain across kingdoms; see Fig. 3). It is conceivable that this WWD domain represents a specific heme and/or apocytochrome *c* binding site for the respective functions of HelC and Ccl1. In fact, a similar tryptophan-rich motif (including WFWD) is conserved in the hemopexin protein from rabbit, rat and human (eg. Morgan et al., 1993). Hemopexin is present in the plasma and carries heme to the liver. Recently, it has been shown using *pho* fusion analysis that the WWD domain of Ccl1 is exposed to the periplasmic space (Beckman and Kranz, unpublished).

2. Ccl2

The *ccl2* gene is located downstream of *ccl1* in a potential *ccl12* operon. *ccl2* is predicted to encode a 149 aa polypeptide with a typical bacterial signal sequence and, with the exception of the hydrophobic domain of its signal sequence and aa residues 105 to 122, is predicted to be hydrophilic in character. Recently, the amino two thirds of Ccl2 (up to residue

105) has been overproduced and purified from the periplasmic fraction in *E. coli*; the signal sequence of this protein has been cleaved off, proving the presence and function of this signal (Monika and Kranz, unpublished). Ccl2 contains a sequence motif within its N-terminus (RCPVCQGEN) that is similar to a motif found in the *S. cerevisiae* CCHL (CPVMQGDN) (Dumont et al., 1987). However, there is no overall similarity between Ccl2 and CCHL. Additionally, the sequence motifs RCVDH and RCPVL have been identified, respectively, as heme-binding motifs in the HAP 1 regulatory protein from *S. cerevisiae* (Creusot et al., 1988; Pfeifer et al., 1989) and erythroid aminolevulinic synthase (Lathrop and Timko, 1993). Ccl 2 may play a role in the heme ligation process itself, although definitive proof awaits biochemical analyses of this aspect of the assembly pathway.

3. HelX, a Thioredoxin-Like Protein

Using deletion mutagenesis, the *Rb. capsulatus helX* gene, downstream of *helD*, was shown to be specifically required for cytochromes *c* biogenesis (Beckman and Kranz 1993). The *helX* gene is predicted to encode a hydrophilic protein of 176 aa residues with a typical N-terminal signal sequence. Using *helX-phoA* as a secretion reporter, it was shown that HelX is a periplasmic protein. HelX shares significant overall homology to *E. coli* thioredoxin (49% similarity and 23% identity) as well as to other thioredoxins (Beckman and Kranz, 1993). Thioredoxins are enzymes involved in reducing protein disulfide bonds and they are characterized by their active site cysteines (WCXPC) that are involved in the redox reactions. The *Rb. capsulatus* HelX protein has this conserved active site. Site-directed mutagenesis of each cysteine residue of HelX, when replaced with a serine residue, results in an inactive protein, unable to complement the *helX* deletion strain (Monika and Kranz, unpublished). This result is taken as evidence that HelX is involved in a red-ox reaction at its active site. It is noteworthy that another class of periplasmic oxido-reductases has recently been characterized. Represented by its first member, the *E. coli* DsbA (Bardwell et al., 1991; Kamitani et al., 1992) protein has been shown to be required for oxidizing cysteine residues of specific secreted proteins (presumably for the latter's proper folding pathway)(Bardwell et al., 1991). The DsbA-class of periplasmic oxido-reductases do not have significant

overall similarity to thioredoxins but do contain the active site cysteine residues. HelX is not homologous to DsbA overall. Moreover, HelX cannot be DsbA since high levels of alkaline phosphatase activities were observed *in vivo* in a Δ helX mutant (Beckman and Kranz, 1993). In contrast, an *E. coli* DsbA mutant strain shows significantly reduced levels of alkaline phosphatase activity because its cysteine residues are not oxidized, consequently altering the folding pathway of this enzyme (Bardwell et al., 1991). Thus, the HelX protein is proposed to be involved not in the oxidation of cysteine, but in maintenance of reduced cysteine residues. Alternatively, HelX may be required for the maintenance of heme in the reduced state. Each hypothesis is consistent with the view that both heme (Nicholson and Neupert, 1989) and apocytochrome cysteine residues (Enosawa and Ohashi, 1987) must be in the reduced state prior to ligation. Many questions remain, including the ultimate need or supply of reducing equivalents for such reactions to occur within the periplasmic compartment. Obviously, some reactions within this compartment are reducing and some are oxidizing; specific rather than general redox mediating enzymes are therefore likely.

C. Other Proteins

It is important to remember that it remains to be determined whether there exists only one generic CCHL (or one for each *c*-type cytochrome in the cell). The phenotype of mutants in all seven *Rb. capsulatus* genes described above (*helABCDX* and *ccl 12*) are clear—they are totally deficient in all *c*-type cytochromes. Thus, if Ccl2 represents a CCHL, then it is probably a CCHL for all *c*-type cytochromes. Nevertheless, it is possible that a CCHL exists for each (or for soluble versus membrane-bound) *c*-type cytochrome. In this respect, it is interesting to note that a recently described mutant from *Bradyrhizobium japonicum* is deficient in soluble cytochrome *c* but not membrane-bound *c*-type cytochromes (Ritz et al. 1993). The gene complementing this mutant, *cycH*, encodes a periplasmically oriented protein that is not homologous to Hel, Ccl, or eukaryotic CCHL proteins. The function of CycH awaits further investigation. Some results seem to imply that bacterial lyase systems are not highly specific. A number of reports have been made that indicate synthesis and heme attachment of certain *c*-type cytochromes can occur in heterologous *E. coli*

expression systems (e.g., Sanbongi et al., 1991; von Wachenfeldt and Hederstedt, 1990).

IV. Synthesis of *c*-Type Cytochromes in Other Bacteria and in Eukaryotes: Analogous Components

A. Other Gram-Negative Bacteria

Genes that are homologous to the *Rb. capsulatus helABCDX* have been reported in the nonphotosynthetic bacterium *B. japonicum* (Ramseier et al., 1991). *B. japonicum* mutants in *cycV* (*helA*-like) *cycW* (*helB*-like) and *cycX* (*helD*-like) were isolated using Tn5. These mutations resulted in strains that are specifically deficient in *c*-type cytochromes. Surprisingly, inactivation of *orf263*, which is located between *cycW* and *cycX* and homologous to *helC*, resulted in the wild-type *B. japonicum* phenotype. Why this gene is not required is unknown. Another gene product in *B. japonicum* called Orf132 is related to the *Rb. capsulatus* HelX. However, in contrast to *helX*, a deletion or insertion in *orf132* could not be constructed and the *orf132* gene product is neither reported to have a signal sequence, nor does its N-terminus show resemblance to HelX. However, recent results indicate that a cosmid containing the *B. japonicum orf132* (provided by Dr. Mark O'Brian, University of New York, Buffalo) complements the *Rb. capsulatus helX* deletion strain to photosynthetic growth (Beckman and Kranz, unpublished). Accordingly, similar functions are envisioned for *B. japonicum* Orf132 and HelX.

Very recently, mutants deficient in cytochrome *c* biogenesis in *Methylobacterium extorquens* AM1 have been reported (Oozeer et al., 1993). DNA fragments complementing these mutants mapped to two locations and the authors speculate that these may be *ccl*- and *hel*-like genes.

Clearly, biogenesis components similar to those of *Rb. capsulatus* are present in non-photosynthetic Gram-negative bacteria.

B. Gram-Positive Bacteria

Because of the different structural limitations placed on the cell envelope compartments within Gram-positive bacteria, *c*-type cytochromes are of necessity bound to the cytoplasmic membrane. Some of the genes encoding *c*-type cytochromes in *Bacillus* have

Fig. 3. Ccl1 homology to other proteins. A. Pairwise alignment of Ccl1 to ORF509 from the mitochondrial genome of *Marchantia polymorpha* (liverwort) (Oda et al., 1992) and to ORF577 from the mitochondrial genome of *Oenothera* (Schuster et al., 1993). Using the Wisconsin GCG version 7.2 BESTFIT analysis (Devereux et al., 1984), Ccl1 shows 38% identity and 64% similarity to ORF509 and 22% identity and 48% similarity to ORF577. Using the BLASTP program (Altschul et al., 1990), overall homologies to Ccl1 which are not shown in this figure include the carrot mitochondrial ORF579 (unpublished; GenBank accession number X69554); the *Paramecium* mitochondrial ORF238 (Pritchard et al., 1990; see Beckman et al., 1992 figure 9 legend) the mitochondrial liverwort ORF322 (to Ccl1 aa residues 492-630) and ORF169 (to Ccl1 aa residues 353-405) (Oda et al., 1992). Significant homology is also obtained to other proteins in the WWD region. Shown is the WWD region of the red alga *Cyanidium caldarium* chloroplast ORF921 (a 306 aa protein; Valentin et al., 1992), HelC of *Rb. capsulatus* (Beckman et al., 1992) and the HelC-like mitochondrial ORF228 from liverwort (Oda et al., 1992). Other ORFs with significant homology to Ccl1 include the *Cryptomonas* plastid ORF301 (unpublished; GenBank accession number X52159); liverwort chloroplast ORF320 (Ohyama et al., 1988); tobacco chloroplast ORF313 (Shinozaki et al., 1986); and the rice chloroplast ORF321 (Hiratsuka et al., 1989). See text, section III, for a description. B. Wisconsin GCG version 7.2 BESTFIT alignment (Devereux et al., 1984) of *Rb. capsulatus* HelC to the liverwort mitochondrial ORF228 (Oda et al., 1992) showing 33% identity and 59% similarity over this region. In addition to ORF228, BLASTP (Altschul et al., 1990) significant homologies to HelC include *B. japonicum* ORF263 (Ramseier et al., 1991), the liverwort chloroplast ORF320 (Ohyama et al., 1988); the *Cryptomonas* chloroplast ORF301 (unpublished; Genbank accession number X52159); the *Cyanidium caldarium* chloroplast ORF921 (Valentin et al., 1992); the tobacco chloroplast ORF313 (Shinozaki et al., 1986) and the rice chloroplast ORF321 (Hiratsuka et al., 1989). (The WWD region of ORF509 has a Poisson Probability score of 0.9998)

been characterized and discussed in a recent review (von Wachenfeldt and Hederstedt, 1992). Briefly, these cytochromes are proposed to be synthesized with a typical prokaryotic signal sequence. Some of these signals are apparently not cleaved but serve to anchor the cytochrome to the membrane. With regards to biogenesis, little is known about the involvement of extragenic factors or the location and timing of assembly. Whether the biogenesis components described for *Rb. capsulatus* (and for *B. japonicum* or eukaryotic organelles—see below) are also present in *Bacillus* and other Gram-positive bacteria remains to be determined.

C. Eukaryotes

1. Mitochondria

The site of eukaryotic ATP synthesis is the mitochondrion. Mitochondrial electron transport pathways are similar to that of some anoxygenic photosynthetic bacteria. These aerobic electron transfer chains include a membrane-bound cytochrome bc_1 complex and soluble cytochrome c that are structurally and functionally analogous to the bacterial types (see Chapters 35 by Gray and Daldal and 34 by Meyer and Donohue). Topologically, these cytochromes are also similar to those in prokaryotes. Cytochrome c_1 is membrane-bound and oriented toward the intermembrane space while cytochrome c is in the mitochondrial intermembrane space. The intermembrane space, located between the mitochondrial inner membrane and outer membrane, is topologically equivalent to the periplasmic space of a Gram-negative bacterium. Transport of the apocytochrome c and c_1 of *S. cerevisiae* and *Neurospora crassa* has been the subject of many exceptional experiments during the last 20 years. These transport pathways have been reviewed (Gonzales and Neupert, 1990). Briefly, both apocytochrome c and c_1 are synthesized in the cytoplasm and posttranslationally transported to the intermembrane space. Apocytochrome c is synthesized without a signal sequence and is brought directly into the intermembrane space by a reaction that is proposed to depend on the ligation of heme to the apocytochrome c within the intermembrane space (see below). The apocytochrome c_1 is synthesized with a bipartite signal sequence which is initially used to enter the mitochondrial matrix where cleavage of the first part of the bipartite signal occurs. The

remaining signal directs the apocytochrome c_1 back across the inner membrane. Heme ligation to apocytochrome c_1 , although it may occur prior to cleavage of the second presequence, is not obligatory for this translocation process.

S. cerevisiae and *N. crassa* mutants in CCHL and cytochrome c_1 heme lyase (CC₁HL) have been characterized and the genes encoding these two lyases have been cloned and sequenced (Dumont et al., 1987; Drygas et al., 1989; Zollner et al., 1992). Accordingly, it is well documented that two separate heme lyases, both of which are present in the intermembrane space, are required for formation of holocytochrome c and c_1 (Nargang et al., 1988; Dumont et al., 1988). Recently, transport of CCHL to the intermembrane space has been characterized (Lill et al., 1992). It is thought that a signal present in the mature CCHL is sufficient for translocation across the outer membrane directly to the intermembrane space.

Certain questions concerning the heme ligation reaction in mitochondria have been answered. In contrast to bacterial systems in which *in vitro* heme lyase activity has not been reported, this activity has been detected *in vitro* in the two eukaryotic systems described above. Although the CCHL is significantly homologous to the CC₁HL and both appear to be membrane bound intermembrane proteins (Zollner et al., 1992; Lill et al., 1992; Dumont et al., 1991; Nicholson et al., 1989), CC₁HL cannot use apocytochrome c as a substrate (Stuart et al., 1990). Interestingly, both CCHL- and CC₁HL-catalyzed ligation reactions require that heme is in the reduced state (Nicholson and Neupert, 1989; Nicholson et al., 1989). This reduction was accomplished by the addition of NADH and FMN in the *in vitro* assays (Nicholson and Neupert, 1989). However, sodium dithionite can replace these reductants (Nicholson and Neupert, 1989) and it is likely that the cysteine residues of apocytochromes c need to be reduced for the ligation reaction to proceed (Enosawa and Ohashi, 1987). The mechanism(s) by which heme and apocytochromes are reduced *in vivo* in the mitochondria is unknown.

Furthermore, the involvement of components besides CCHL and CC₁HL in eukaryote cytochromes c biogenesis remains an open question. The last step of heme biosynthesis occurs in the mitochondrial matrix. How does heme get to the mitochondrial intermembrane space? Recently, searches of the protein and DNA databases with the

Rb. capsulatus Hel and Ccl proteins have resulted in some striking comparisons. A number of mitochondrial genomes have recently been sequenced; these genomes show ORFs that have remarkable similarities to the *Rb. capsulatus* HelB, HelC and Ccl1 proteins. In fact, the *helB*-, *helC*-, and *ccl1*-like genes are adjacent to each other in the liverwort mitochondrial genome (Oda et al., 1992). Examples of these comparisons and references are shown in Fig. 3. The HelC and Ccl1 comparisons to the eukaryotic proteins are particularly identical in a domain, called the 'WWD' domain. These mitochondrial analogies raise obvious questions concerning function. Could the HelABC transport system be required for cytochromes *c* biogenesis (and possibly heme transport) in eukaryotes? Could the Ccl1 protein be required for cytochrome *c* biogenesis in eukaryotes? Two very recent reports note the striking similarity between an *Oenothera* (primrose) mitochondrial Orf577 (Schuster et al. 1993) or a wheat mitochondrial Orf589 (Gonzales et al., 1993) and the *Rb. capsulatus* Ccl1. Both groups show that mRNA editing occurs within these Orfs, especially within the WWD domain, to yield even more homology. Based on these results, the authors conclude that these Orfs may also be involved in cytochromes *c* biogenesis in plant mitochondria.

2. Chloroplasts

Chloroplasts possess a *c*-type cytochrome called cytochrome *f* which is a membrane component of the cytochrome *b₆f* complex, and it is the chloroplast equivalent of the mitochondrial cytochrome *c₁* (for recent reviews on cytochrome *f* see Gray, 1992; for cytochrome *bf* see Hope, 1993 and Anderson, 1992). Proteins encoded by chloroplast genomes from a number of plant species have previously been shown to be homologous to *Rb. capsulatus* Ccl1 (see Fig. 3 for example). Moreover, certain mutations which map to the chloroplast genome of *Chlamydomonas* yield cells that are pleiotrophically deficient in chloroplast *c*-type cytochromes (Howe and Merchant, 1992). Could these mutations be located in the Ccl1-like ORFs encoded in the chloroplast?

V. Future Directions

Much work is required on the folding and assembly pathways of the membrane-bound cytochrome

complexes. What accessory factors are required and what are their functions within the biogenesis pathway for macromolecular cytochrome complexes? When and how is heme incorporated into the complexes? Questions concerning cytochrome *c* biogenesis include what are the exact functions of Ccl and Hel proteins? Are other accessory factors required (e.g., individual heme lyases)? Clearly, multifaceted approaches that include genetics, molecular genetics and biochemistry will be required to answer these and other important questions. The discovery of eukaryotic counterparts to the *Rhodobacter* components underscore the significance of these factors and the use of anoxygenic photosynthetic bacteria as models for these biogenesis pathways.

Summary

Electron transfer between the photosynthetic reaction center and the cytochrome bc_1 complexes is often mediated by a high redox potential soluble cytochrome. In purple non-sulfur bacteria, this electron donor is usually cytochrome c_2 (Cyt c_2), while cyanobacteria and green algae can use the distantly related cytochrome c_6 protein. Genetic and biochemical support for the role of these soluble mediators has been obtained in purple bacteria *Rhodobacter sphaeroides* and *Rb. capsulatus*, and in several cyanobacteria and green algae. However, recent experiments indicate that photosynthetic organisms often contain redundant electron donors to light-oxidized reaction center complexes. For example, soluble or membrane-bound cytochromes can substitute for the normal electron donor, Cyt c_2 , in purple non-sulfur bacteria. In addition, the soluble copper protein, plastocyanin, is interchangeable with cytochrome c_6 in cyanobacteria and green algae even though it is apparently the sole electron donor in green plants.

In contrast, the soluble electron donor is either unknown or presumed to be different in photosynthetic bacteria that lack soluble high potential proteins in the Cyt c_2 family. Spectroscopic analysis indicates this donor could be the high redox potential ferredoxin, HiPIP, in *Rhodocyclus sp.* and members of the *Chromatiaceae* and *Ectothiorhodospiraceae* families. In addition, cytochromes other than Cyt c_2 may reduce reaction center complexes in some photosynthetic bacteria. For example, Cyt c -551 may be the donor in *Ectothiorhodospira sp.*, while related cytochromes could function in *Rc. purpureus* and green bacteria. Finally, the membrane bound copper protein, auracyanin, from the green bacterium *Chloroflexus aurantiacus* could also be responsible for reaction center reduction. In these latter species, the combination of biochemical and genetic analyses have not been used to identify the actual electron donor(s) to reaction center complexes.

I. Introduction

In the broadest sense, photosynthesis may be defined as the conversion of light into chemical energy. In photosynthetic (PS) prokaryotes, this conversion is accomplished by coupling light-driven oxidation of specific chlorophylls or bacteriochlorophylls in a reaction center (RC) complex to subsequent electron transfer through membrane-bound redox components. The resulting formation of a proton gradient by PS membrane redox complexes is used to drive ATP synthesis. In its simplest form, there are two essential membrane-bound components of PS electron transport pathways, the RC and the cytochrome bc_1 (Cyt bc_1) complexes. Function of

these two integral membrane complexes is linked via membrane-diffusible quinones and soluble electron carrier proteins. This chapter discusses the soluble redox proteins which are capable of mediating electron transfer from the Cyt bc_1 complex to a light-oxidized RC complex.

A. Why Do Photosynthetic Cells Use Soluble Electron Carriers?

As described elsewhere in this volume, light-induced electron transfer in the bacterial RC results in the rapid oxidation of a special pair of pigment molecules at the outer or periplasmic side of the PS membrane and the reduction of a quinone on the inner or

cytoplasmic side of this membrane. This so-called special pair of pigment molecules can be either bacteriochlorophyll or chlorophyll in different PS prokaryotes. The role of soluble redox proteins in PS electron flow is to reduce the photo-oxidized special pair (Fig. 1) to a ground state. In order for photosynthesis to generate net biological energy, special pair reduction must occur before the return of an electron from the RC quinone (the so-called 'back reaction'). Since full quinone reduction requires the addition of two electrons, it is generally considered essential that the singly-reduced semiquinone remain bound to the RC until it is fully reduced to quinol by a second electron. Either semiquinone or quinol would be capable of directly reducing the special pair via this back reaction if soluble electron donors were not capable of efficient RC reduction. Once quinone is fully reduced to quinol, it diffuses from the RC through the membrane, where it is oxidized by the Cyt bc_1 complex, which in turn reduces the soluble redox protein that ultimately donates its electron to the special pair. Presumably, the inability to position the respective redox centers of the RC and Cyt bc_1 complexes in close enough proximity make direct electron transfer between these two supramolecular aggregates too slow to compete with the non-productive return of an electron from a reduced quinone species to the oxidized special pair.

The current understanding of bacterial photosynthesis indicates that the RC electron donor must have several characteristics. First, the RC electron donor must be on the proper side of the membrane to reduce the special pair and accept electrons from Cyt c_1 of the Cyt bc_1 complex. In bacterial systems, these donors are found either in the periplasm of Gram-negative bacteria or associated with the outer surface of the cytoplasmic membrane of Gram-positive species. Thus, their genes commonly contain signal sequences to presumably help direct the respective precursor proteins to their proper cellular location (Daldal et al., 1986; Donohue et al., 1986; Brandner and Donohue, 1994; see Chapter 33 by Kranz and Beckman). In addition, these donors should have midpoint potentials between Cyt c_1 and the special pair. Cyt c_1 has a midpoint potential of 265–318 mV in purple bacteria (Gabellini et al., 1982; Guner et

al., 1991; Gray et al., 1992; Hacker et al., 1993), while the midpoint potential of the RC special pair is ~500 mV (Case and Parson, 1973; Gao et al., 1990; Murchison et al., 1993). Thus, the theoretical range of midpoint potentials for soluble electron donors is ~300–500 mV for cells in which these soluble proteins are directly responsible for special pair reduction. In cells that have a membrane-bound tetraheme cytochrome c in the RC (see below), the soluble donors should have midpoint potentials (~300–350 mV) which approximate that of the cytochrome c heme, which is the immediate electron acceptor. Significant deviations from these midpoint potentials for the soluble electron donor are likely to be reflected in the corresponding values for the Cyt bc_1 complex and the RC. In addition, these diffusible proteins often contain a so-called interaction domain to reversibly dock with their membrane-bound electron donor (Cyt bc_1 complex) or acceptor (RC complex). For membrane bound electron donors, there presumably must be a membrane anchor, a 'soluble' or extra-membrane portion, and a flexible arm which permits the interaction domain to flip back and forth from one complex to the other. Finally, to sustain the rate of electron transport necessary to generate a sufficient proton gradient for supporting PS growth, the cellular abundance of these electron donors should approximate that of the RC.

This chapter summarizes what is currently known about proteins which can mediate electron transfer between the Cyt bc_1 complex and the RC special pair. Historically, the ability to monitor light-dependent electron transport reactions in either whole cells, isolated membranes or with purified components provided investigators with a relatively simple way to identify and characterize proteins capable of catalyzing RC reduction. The first part of this chapter summarizes what is known about soluble proteins that are capable of performing this reaction. Next, the mechanisms by which these soluble proteins might interact with their membrane-bound redox partners is discussed. Finally, we summarize how recent molecular genetic of several PS bacterial species has provided the means to test whether those proteins which can participate in RC reduction *in vitro* do, in fact, perform this function *in vivo*. This

Abbreviations: AdhI – Zn-dependent alcohol dehydrogenase; *Cf.* – *Chloroflexus*; ChrR – Cohemin-resistance regulatory protein; Cyt b_6f – cytochrome b_6f ; Cyt bc_1 – ubiquinol Cyt c_2 -oxidoreductase; Cyt c_2 – cytochrome Cyt c_6 – cytochrome c_6 ; *Ec.* – *Ectothiorhodospira*; HiPIP – high potential ferredoxin; isocyt – isocytochrome NAD – nicotinamide adenine dinucleotide; PC – plastocyanin; PrrA – photosynthesis regulatory protein; PS II – Photosystem II; PS – photosynthetic; PS I – Photosystem I; *Rb.* – *Rhodobacter*; RC – reaction center; *Rc.* – *Rhodocyclus*; *Rh.* – *Rhodophila*; *Rp.* – *Rhodospseudomonas*; *Rs.* – *Rhodospirillum*

interdisciplinary approach has shown that cells often contain more than one protein capable of participating in light-driven electron transport *in vivo*. Therefore, this chapter seeks to summarize how genetic and biochemical analysis of PS bacteria has provided new and important insights into the numbers and types of soluble proteins that can reduce RC complexes.

B. The Two Major Classes of Reaction Center Complexes Found in Photosynthetic Cells

To understand how and why PS cells use a variety of soluble proteins to reduce RC complexes, one must remember there are two very different kinds of PS RC complexes (Golbeck, 1993; Chapter 30 by Feiler and Hauska). Thus, the interaction of an electron donor with the RC can vary significantly depending on the type of membrane-bound complexes present.

1. Purple Bacterial Reaction Center Complexes Are Similar to Photosystem II

The purple bacterial RC is the best understood complex from both structural and functional standpoints (Fig. 1, Panel A). At a minimum, it contains similar 30 kDa core membrane-spanning polypeptides (the L and M subunits) which bind the bacteriochlorophyll special pair and the electron acceptor quinones (Deisenhofer et al., 1985). The overall architecture of the core subunits of cyanobacterial and plant PS II complexes appears similar to that of the purple bacterial RC (Michel and Deisenhofer, 1988; Komiya et al., 1988). However, PS II complexes do not interact with soluble cytochromes because they utilize light energy to oxidize water with concomitant quinone reduction. Rather the membrane-bound subunits for water oxidation generate both electrons for PS II reduction and hydrogen ions to contribute to the proton gradient.

There appears to be considerable similarity in the core structure of the RC complex among different bacterial species. For example, the three-dimensional structures of RC complexes from *Rhodospseudomonas (Rp.) viridis* (Deisenhofer et al., 1985) and *Rhodobacter (Rb.) sphaeroides* (Allen et al., 1987; Chang et al., 1991) show that the sequence and organization of these core subunits are similar even though the *Rp. viridis* RC contains an additional 45 kDa membrane-bound tetraheme cytochrome *c* subunit. In addition to *Rb. sphaeroides*, there are

only a few other species which lack a membrane-bound tetraheme cytochrome *c* subunit in the RC; the best characterized are those found in *Rb. capsulatus*, *Rhodospirillum (Rs.) rubrum* and *Rp. palustris* (Rickle and Cusanovich, 1979; Matsuura and Shimada, 1986; Hall et al., 1987; Jones et al., 1990; Bartsch, 1991).

2. Bacterial Reaction Center Complexes That Are Similar to Photosystem I

The cyanobacterial PS I has a pair of non-identical membrane spanning 82 kDa core polypeptides that bind the special pair chlorophylls and a 4-Fe-S cluster that serves as the immediate electron acceptor (Krauss et al., 1993). The green bacterial RC (Fig. 1, Panel B) appears homologous to cyanobacterial and plant PS I complexes except that the green bacterial core subunits are identical to one another (Büttner et al., 1992). Instead of catalyzing light-dependent quinone reduction, this type of RC transfers electrons from the 4-Fe-S cluster to a bound low potential 8-Fe-S ferredoxin subunit (the $F_A F_B$ protein). Ultimately, pyridine nucleotide is reduced via soluble 2-Fe-S or 8-Fe-S ferredoxins and a flavoprotein (FNR). In this case, the generation of a proton gradient may involve additional membrane-bound components such as NADH dehydrogenase (Mi et al., 1992) as well as the Cyt *bc₁* or Cyt *b₆f* complexes.

3. Why Might Bacterial Reaction Center Complexes Contain a Membrane-Bound Tetraheme Cytochrome c?

In species that contain a membrane-bound cytochrome *c* subunit, this cytochrome serves the same function as the soluble electron donors in species that contain only core RC subunits; namely to be the immediate electron donor to the special pair. From current analysis, purple bacterial RC complexes that contain membrane-bound cytochrome *c* subunits appear more common than those where the soluble electron donor interacts directly with the core subunits (Bartsch, 1991). This could suggest that the membrane-bound cytochrome *c* is generally more efficient in reducing the special pair than the soluble proteins present in these species.

Based on the available examples, it seems generally true that the membrane-bound tetraheme cytochrome *c* is missing in species that contain Cyt *c₂*. This might suggest that members of the Cyt *c₂* protein family are

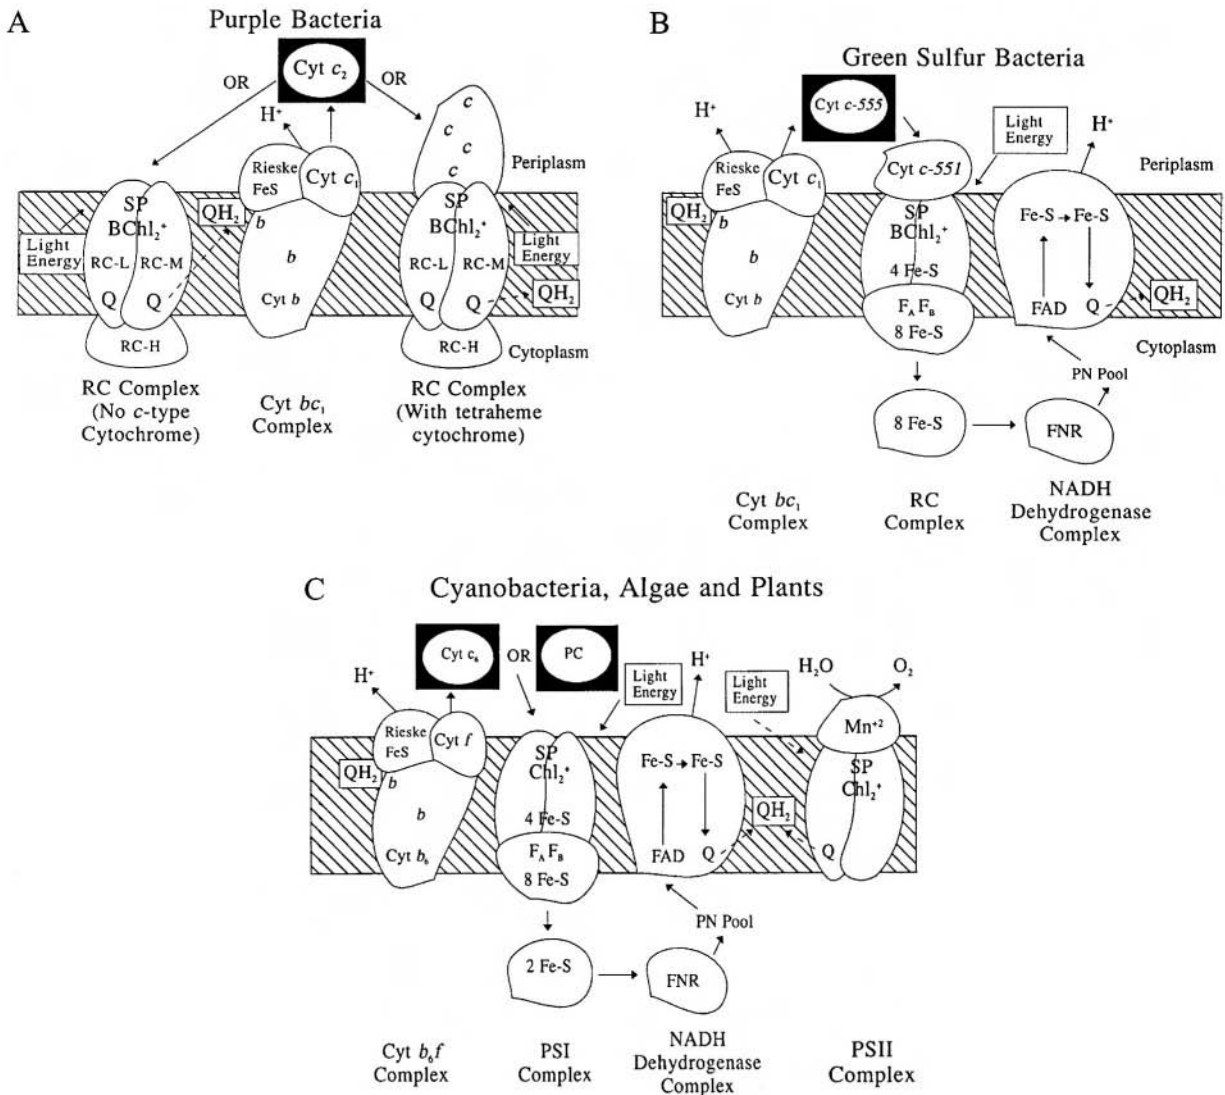

Fig. 1. Different PS electron transfer pathways. In all panels, the PS membrane is represented by diagonal shading.

Panel A: The function of Cyt *c*₂ in RC reduction by purple bacteria. In these organisms, soluble members of the Cyt *c*₂ family accept electrons from a membrane bound Cyt *bc*₁ complex (center). Reduced Cyt *c*₂ then donates electrons to either core subunits of the RC complex (left) or to a specific heme *c* (the so-called heme 2) within a RC complex containing a tetraheme cytochrome *c* subunit (right). Abbreviations: RC-H, RC-M, and RC-L: heavy, medium and light subunits of the RC complex; SP BChl₂⁺: special pair bacteriochlorophyll dimer which is the RC electron acceptor from Cyt *c*₂; Q: quinone; QH₂: quinol; Rieske FeS: Rieske 2-Fe-S subunit of the Cyt *bc*₁ complex; Cyt *c*₁: Cyt *c*₁ subunit of the Cyt *bc*₁ complex; Cyt *b*: diheme membrane spanning Cyt *b* subunit of the Cyt *bc*₁ complex.

Panel B: The function of soluble Cyt *c-551* in RC reduction by green sulfur bacteria. In these organisms, soluble Cyt *c-551* uses electrons from the Cyt *bc*₁ complex to reduce light oxidized RC complexes. Abbreviations: Cyt *c-551*: monoheme cytochrome *c* subunit of the green sulfur bacterial RC complex; 4 Fe-S: electron acceptor 4-Fe-S center of PS I complex; F_AF_B: 8-Fe-S ferredoxin subunit of PS I complex; F_AF_B: 8-Fe-S ferredoxin mediator between F_AF_B and FNR; FNR: soluble ferredoxin NADP⁺ reductase; PN: pyridine nucleotide; FAD: flavin adenine dinucleotide; Fe-S: iron sulfur centers of NADH dehydrogenase complex. All other abbreviations are as in Panel A.

Panel C: The function of cytochrome *c*₆ (Cyt *c*₆) or plastocyanin (PC) as interchangeable electron donors to PS I in cyanobacteria, green algae and plants. In these organisms, Cyt *c*₆ or PC use electrons from the Cyt *b*₆*f* complex to donate light-oxidized PS I complexes. Abbreviations: PS I: pyridine nucleotide reducing photosystem I complex; 4 Fe-S: electron acceptor 4-Fe-S center of PS I complex; F_AF_B: 8-Fe-S ferredoxin subunit of PS I complex; 2 Fe-S: soluble 2 Fe-S ferredoxin mediator; Cyt *b*₆: diheme membrane spanning Cyt *b*₆ subunit of the Cyt *b*₆*f* complex; Rieske FeS: Rieske Fe-S subunit of the Cyt *b*₆*f* complex; Cyt *f*: Cyt *f* subunit of the Cyt *b*₆*f* complex; PS II: oxygen evolving photosystem II; Mn²⁺: water-splitting activity of PS II. All other abbreviations are as in Panels A and B.

at least as effective in reducing the RC as the membrane-bound tetraheme cytochrome *c* subunit. However, there are some exceptions to this generalization. The most well-studied is *Rp. viridis*, which contains both a RC tetraheme cytochrome *c* subunit and soluble Cyt c_2 . Additional exceptions include *Roseobacter denitrificans*, whose Cyt c_2 is closely related to that of *Rb. capsulatus* (Okamura et al., 1987), which has a tetraheme RC cytochrome *c* (Liebetanz et al., 1991). On the other hand, *Rhodomicrobium vannielli*, which contains a Cyt c_2 closely related to that of *Rp. viridis* (Ambler et al., 1979a), appears to lack a membrane-bound cytochrome *c* in its RC (Bartsch, 1991). Furthermore, the *Rp. palustris* type strain appears to lack the tetraheme RC cytochrome *c*, but *Rs. centenum* (which has a closely-related Cyt c_2) appears to have this additional subunit (Bartsch, 1991). From this developing analysis, we might also conclude that species that rely on mediators that are not related to Cyt c_2 (i.e., auracyanin, HiPIP, or other *c*-type cytochromes; see below) contain a membrane-bound cytochrome *c* because these electron donors are not very efficient. Thus, these species may be more primitive in PS electron transport than those which utilize Cyt c_2 for direct and rapid reduction of the RC special pair.

II. What Proteins Participate in Light-Dependent Reaction Center Reduction?

The central problem common to all RC complexes is the necessity to rapidly reduce the photo-oxidized special pair to prevent non-productive back electron transfer from either reduced quinone or the 4-Fe-S cluster. In most cases, productive reduction of the special pair is accomplished by a soluble cytochrome. However, as described below, this function may be assumed by a variety of proteins in different PS bacteria.

The electron donor to RC complexes has often been inferred by spectroscopic examination of characteristic light-dependent absorbance changes after excitation of either whole cells, membranes or isolated components. It should be noted that cytochromes are easy to characterize in this manner, but iron-sulfur proteins and copper proteins have broad absorption peaks of low absorbency, which make their oxidation difficult to monitor *in vivo*. Therefore, in some species potential electron donors

have been identified solely from analyzing their redox properties and cellular abundance. Although each system has its limitations, the following sections describe what proteins are believed to function as electron donors to light-dependent RC complexes in different classes of PS bacteria.

A. Electron Donors From Purple Bacteria

1. Rhodospirillaceae—Species Which Use Members of the Cyt c_2 Family

In most of these bacteria, the soluble electron carrier to the RC special pair is a protein in the Cyt c_2 family. Members of this family are defined as the nearest bacterial homologue to mitochondrial cytochrome *c*. In *Rb. sphaeroides* (Overfield and Wraight, 1980; Rosen et al., 1983; Allen et al., 1987; Tiede and Chang, 1988; Moser and Dutton, 1988; Caffrey et al., 1992), Cyt c_2 binds transiently and reversibly to the RC core subunits. However, electron transfer occurs between Cyt c_2 and heme 2 of the membrane-bound tetraheme cytochrome *c* in *Rp. viridis* (Knaff et al., 1991; Meyer et al., 1993). Even though these soluble cytochromes can interact with dissimilar RC subunits, the ability to monitor light-induced electron transport with mixtures of Cyt c_2 proteins and RC complexes from different sources suggests that at least some of the interactions used for binding and formation of a productive complex are conserved (see Section III).

An ~ 1:2 ratio of Cyt c_2 to RC complexes is sufficient to support PS growth of *Rb. sphaeroides* (Crofts, et al., 1983) and *Rb. capsulatus* (Prince et al., 1986), but the minimal amount of electron donor necessary to support wild type growth rates is not yet clear. Recent genetic analysis has confirmed the role of either soluble or membrane-bound members of the Cyt c_2 family in light-induced electron transport in these two species (Daldal et al., 1986; Donohue et al., 1986; Prince et al., 1986; Donohue et al., 1988; Fitch et al., 1989; Rott and Donohue, 1990; Rott et al., 1993; Jenney and Daldal, 1993; see below). However, other soluble or membrane bound mediators must be used in some purple bacteria because not all of them contain measurable quantities of soluble Cyt c_2 (Bartsch, 1991). As described below, *Rhodocyclus* (Rc.), *Chromatium*, and *Ectothiorhodospira* (*Ec.*) sp. generally lack soluble members of the Cyt c_2 family.

2. *Chromatium vinosum*—Are Cytochrome *c*-551 or HiPIP Electron Donors to Reaction Center Complexes?

The purple bacterium, *Chromatium vinosum*, has also been well studied with respect to light-induced absorbance changes and the involvement of cytochromes in RC reduction (Van Grondelle et al., 1977; Knaff et al., 1980; Coremans et al., 1985). This RC contains a membrane-bound 45 kDa tetraheme cytochrome *c* similar to that of *Rp. viridis* with both high and low potential hemes (Kennel and Kamen, 1971; Case and Parson, 1973; Itoh, 1980). However, this bacterium does not grow aerobically and genetic techniques are lacking to test the role of soluble proteins in RC reduction. Consequently, the identity of soluble proteins that presumably function as reductants for the RC Cyt *c* subunit has rested solely on spectroscopic studies.

Spectroscopic analysis suggests that a high potential soluble, Cyt *c*-551 ($E_m \sim 240\text{--}260$ mV) can donate electrons to the RC (Van Grondelle et al., 1977; Tomiyama et al., 1983; Gray et al., 1983). However, the midpoint potential of purple bacterial Cyt *c*₁ proteins (265–318 mV, Gabellini et al., 1982; Guner et al., 1991; Gray et al., 1992; Hacker et al., 1993) suggest that the redox potential of Cyt *c*-551 may be too low unless this bacterium's Cyt *c*₁ and Rieske iron sulfur proteins have correspondingly lower potentials. Furthermore, the relationship of Cyt *c*-551 to other *c*-type cytochromes is unknown because it has never been purified or sequenced. For example, Cyt *c*-551 may not be a member of the Cyt *c*₂ family or it could lack the proper charge at the interaction domain. Finally, even if its properties were optimal, the concentration of Cyt *c*-551 may be below that needed to allow rates of RC reduction required for PS growth. The recent analysis of *Rb. sphaeroides* Spd mutants provides an example of how PS growth can be limited by low levels of a functional electron donor (see Section IV).

Another possible soluble electron donor in *Chromatium* is the high redox potential ferredoxin, HiPIP. HiPIP is relatively abundant and has a midpoint potential (+330 mV) close to that of the membrane-bound RC cytochrome *c* subunit (Case and Parson, 1973). HiPIP can transfer electrons to the isolated *Chromatium* RC (Kennel et al., 1972), even though its small negative charge at the interaction domain makes this protein a rather poor donor to the purified *Rp. viridis* RC complex (Meyer et al., 1993a). On the

other hand, Knaff et al. (1980) found that HiPIP was not very effective in *Chromatium* RC reduction.

A final candidate for an electron donor to the *Chromatium* RC is a minor high potential cytochrome (Cusanovich and Bartsch, 1969) that has been identified as a diheme cytochrome *c*₄ (Van Beeumen, 1991). Unfortunately, this protein is also not very efficient in electron transfer to RC complexes (Knaff et al., 1980). Therefore, in spite of this extensive search, additional experiments are necessary to identify the actual electron donor to *Chromatium* RC complexes.

3. *Rhodocyclus sp.*—Are Cyt *c*-553 or HiPIP Electron Donors to Reaction Center Complexes?

The purple non-sulfur bacteria in the genus *Rhodocyclus* also contain a RC with a membrane-bound tetraheme cytochrome *c*. The tetraheme cytochrome *c* in *Rc. gelatinosus* RC complexes is easily separated from the other subunits (Clayton and Clayton, 1978; Fukushima et al., 1988; Agalidis and Reiss-Husson, 1992) and the midpoint potentials of the four hemes in the RC cytochrome are comparable to those of *Rp. viridis* (Nitschke et al., 1992). This suggests that a relatively high potential soluble electron donor should exist in this species. However, both *Rhodocyclus sp.* (Bartsch, 1991) and *Rs. salinarum* (Meyer et al., 1990a) appear to lack soluble proteins related to Cyt *c*₂. In fact, *Rc. gelatinosus* and *Rs. salinarum* have no measurable soluble high redox potential cytochromes. These observations suggest that either a soluble mediator is not required or that proteins other than cytochromes must be considered for this role. Notwithstanding these observations, Matsuura et al. (1988) reported that a soluble cytochrome from a strain of *Rc. gelatinosus* was as efficient as horse Cyt *c* in reducing RC preparations that either contained or lacked its membrane-bound tetraheme cytochrome *c* subunit. It is important to note that these two seemingly contradictory sets of results came from studies performed with different strains. Thus, it is possible that some isolates produce different bacterial cytochromes than the type strain (for which the sequence and redox potential of Cyt *c*-551 were determined) or that some isolates may not indeed be *Rc. gelatinosus*. Until these discrepancies are resolved, the nature of the soluble mediator in *Rc. gelatinosus* will remain an open question.

Rc. gelatinosus, *Rc. tenuis*, and *Rs. salinarum* all

contain abundant levels of HiPIP, that might function as a soluble electron donor to the RC. *Rc. gelatinosus* will grow aerobically, so it may be amenable to the types of genetic analyses necessary to identify the electron donor to the RC (see below).

On the other hand, the soluble Cyt *c*-551 of *Rc. gelatinosus* has a redox potential of only ~28 mV (Meyer et al., 1983). It is a minor component, and is related to *Pseudomonas* Cyt *c*-551 (Ambler et al., 1979b). Thus, it would not be able to efficiently couple electron flow from the Cyt *bc*₁ complex to the RC if the Cyt *c*₁ has a potential near 300 mV as found in other species. *Rc. tenuis* contains both HiPIP and an abundant soluble high redox potential, Cyt *c*-553, that is related to *Pseudomonas* Cyt *c*-551 (Ambler et al., 1979b). From their properties, it is possible that either HiPIP or Cyt *c*-553 function interchangeably to reduce RC complexes in this bacterium. Both are positively charged and should interact favorably with the RC, although neither was effective in electron transfer to complexes from *Rp. viridis* (Meyer et al., 1993a). In contrast *Rc. purpureus* does not have HiPIP, but it has a Cyt *c*-553 similar to that found in *Rc. tenuis*. Thus, it is likely that Cyt *c*-553 from *Rc. purpureus* is the sole soluble electron donor to the RC in this species.

4. *Rhodophila globiformis*—Cyt *c*₂ and HiPIP Are Potential Donors to Reaction Center Complexes

The purple bacterium, *Rh. globiformis*, is a relatively interesting example since it contains a RC complex with a membrane-bound tetraheme cytochrome *c* and both Cyt *c*₂ and HiPIP as potential soluble electron donors (Bartsch, 1991; Ambler et al., 1987). *Rp. marina* (Meyer et al., 1990b) and *Rhodomicrobium vannielli* also share these characteristics, although HiPIP is only a minor constituent in the latter species. Presumably, Cyt *c*₂ would be more reactive with the RC than HiPIP and would be the primary electron donor in these species. However, HiPIP could be of greater significance if growth conditions alter its cellular level relative to Cyt *c*₂. In this regard, *Rp. marina* will grow aerobically, so it has the potential for the types of genetic analyses necessary to show what proteins are electron donors *in vivo*. Finally, both Cyt *c*₂ and HiPIP from *Rh. globiformis* have redox potentials >100 mV higher than the average (450 mV for HiPIP and 470 mV for Cyt *c*₂), so it is possible that the membrane bound tetraheme RC

cytochrome *c* and the special pair will have correspondingly higher redox potentials.

5. *Ectothiorhodospira* sp.—Are Cyt *c*-551 and HiPIP Electron Donors to Reaction Center Complexes?

The halophilic purple bacteria in the family Ectothiorhodospiraceae all have a membrane-bound tetraheme cytochrome *c* RC subunit (Lefèbvre et al., 1984; Engelhardt et al., 1986; Bartsch, 1991) although it appears that the cytochrome subunit might be easily dissociated (Leguijt and Hellingwerf, 1991). An apparent characteristic of phototrophic halophiles is that the soluble electron transfer proteins have lower than average midpoint potentials. For example, *Ec. halophila* (Meyer, 1985), *Ec. shaposhnikovii* (Kusche and Trüper, 1984), and *Ec. vacuolata* (unpublished) all have equally abundant isozymes of HiPIP with the lowest redox potentials of proteins in their class (50–250 mV). *Ec. halophila* (Meyer, 1985), *Ec. halochloris* (unpublished), and *Ec. abdelmalekii* (Then and Trüper, 1983) also have a Cyt *c*-551 related to *Pseudomonas* Cyt *c*_s (Ambler et al., 1993) with a low midpoint potential (–7 to +58 mV) similar to those of HiPIP isozymes (Meyer et al., 1983; Then and Trüper, 1983). Finally, *Ec. shaposhnikovii* has a soluble Cyt *c*-553 (549) with a midpoint potential of ~248 mV (Kusche and Trüper, 1984). Thus, if any of these proteins function as electron donors to RC complexes, then it seems likely that both the Cyt *bc*₁ complex and tetraheme RC cytochrome *c* subunit from these bacteria also have lower than average midpoint potentials.

B. Electron Donors from Green Sulfur Bacteria

1. *Chlorobium*—Does Cytochrome *c*-555 Reduce Reaction Center Complexes?

The green bacterial RC found in *Chlorobium* is quite different from that of purple bacteria (Fig. 1, Panel B). In this bacterium, both the bacteriochlorophyll special pair and the electron acceptors have much lower redox potentials (in the vicinity of +250 mV and –600 mV, respectively) than either PS I or purple RC complexes (Fowler et al., 1971; Prince and Olson, 1976; Hurt and Hauska, 1984; Nitschke et al., 1990a; Feiler et al., 1992; Miller et al., 1992). This suggests that both the hypothetical cytochrome *bc*₁ complex and soluble electron donors also have lower midpoint

potentials than the proteins typically found in purple bacteria. The gene sequence of the green bacterial RC shows that it is homologous to PS I and an adjacent gene encodes a protein resembling an 8 Fe-S $F_A F_B$ protein (Büttner et al., 1992). There is a bound cytochrome *c* subunit in the green bacterial RC (redox potential of 165–220 mV). However, the sequence of this structural gene indicates only a single heme binding site on this ~23 kDa protein (Okkels et al., 1992), unlike the 45 kDa *Rp. viridis* tetraheme RC cytochrome *c* subunit.

All species of green sulfur bacteria contain an abundant soluble Cyt *c*-555 (redox potential of 80–160 mV; Fischer, 1988), which could be the soluble electron donor to RC complexes. This protein is not closely related to Cyt c_2 (Van Beeumen et al., 1976). Rather, Cyt *c*-555 is similar to *Ec. halophila* Cyt *c*-551 and cyanobacterial Cyt c_6 (Ambler et al., 1993).

2. Chloroflexus—Copper proteins Reduce Reaction Center Complexes

Chloroflexus aurantiacus has properties of both green and purple bacteria. This moderate thermophile is a facultative aerobe but the presence of light harvesting bacteriochlorophylls and chlorosomes similar to those in *Chlorobium* (Zuber, 1988) led to its classification as a green photosynthetic bacterium, even though all other green bacteria are strict anaerobes. In contrast, *Cf. aurantiacus* contains a RC which is closely related to those of purple bacteria (Bruce et al., 1982; Pierson and Thornber, 1983; Shiozawa et al., 1989; Van Vliet et al., 1991). This RC is surrounded by typical purple bacterial antenna proteins (Zuber, 1988) and it contains a membrane-bound tetraheme cytochrome *c* (Freeman and Blankenship, 1990; Dracheva et al., 1991). A simple explanation for the occurrence of both green and purple bacterial characteristics is that *Chloroflexus* is a hybrid resulting from gene transfer (Blankenship, 1992).

For this chapter, perhaps one of the most interesting characteristics of *Chloroflexus* is that it appears to be gram positive (Meissner et al., 1988) and it lacks detectable soluble cytochromes. Instead, membrane-bound copper proteins, known as auracyanins (McManus et al., 1992), which are easily washed from the membrane, might fill the role usually reserved for soluble cytochromes in electron transfer between the presumed cytochrome bc_1 complex and the RC. Auracyanins are most closely related to the azurin type of copper proteins found in *Pseudomonas*.

Because *Chloroflexus* can grow aerobically, there is a possibility for the types of genetic manipulation necessary to test the role of these copper proteins in RC reduction.

C. Heliobacterium Contains No Known Soluble Electron Donors to the Reaction Center Complex

Heliobacterium appears to have the green bacterial type of RC (Fuller et al., 1985; Prince et al., 1985; Smit et al., 1987; Vos et al., 1989; Nitschke et al., 1990b; Trost et al., 1992) and a RC peptide from this bacterium is homologous to those of plant PS I and green bacterial subunits (Trost et al., 1992). The primary donor has a midpoint potential of +225 mV and the acceptor has a potential of –510 mV (Prince et al., 1985).

There is no evidence for soluble electron donors to RC complexes in *Heliobacterium*. This suggests the existence of a membrane-bound electron donor similar to the apparent situation in *Chloroflexus*. *Heliobacterium* contains several membrane-bound *c*-type cytochromes of ~50, 33, and 20 kDa (Fuller et al., 1985). In addition, a membrane-bound cytochrome *c*-553 (redox potential ~170 mV) is photo-oxidized (Prince et al., 1985). Thus, it is possible that a bound RC cytochrome *c* similar to that found in *Chlorobium* may be present. However, the immediate electron donor to this membrane-bound cytochrome is still unknown.

D. Cyanobacteria, Green Algae, and Chloroplasts Use Cyt c_6 and Plastocyanin as Interchangeable Electron Donors to Photosystem I

Cyanobacteria, algae and plants contain two photosystems that are homologous to either purple bacterial (PS II) or green bacterial (PS I) RC complexes (Fig. 1, Panel C). Because PS II oxidizes water via a non-cyclic electron transport pathway, a soluble electron donor such as Cyt c_2 of purple bacteria is not necessary. The PS I RC, unlike those found in green sulfur bacteria and *Heliobacterium*, does not contain a membrane-bound cytochrome *c* subunit. In addition to reducing pyridine nucleotides in a non-cyclic pathway, PS I is involved in cyclic electron transfer between NADH dehydrogenase and Cyt $b_6 f$ complexes (Mi et al., 1992). In this pathway, PS I complexes interact with the high potential end of the $b_6 f$ complex (the plant and cyanobacterial

version of the Cyt bc_1 complex) via soluble protein mediators. There is overwhelming evidence for a soluble electron donor to light-oxidized PS I complexes.

Cyt c_6 (also called Cyt c -553) or the copper protein plastocyanin (PC) transfers electrons between the b_6f and PS I complexes in many cyanobacteria and green algae (Wood, 1978; Lochau, 1981; Ho and Krogmann, 1984; Sandmann, 1986). The interchangeable function of PC and Cyt c_6 has been confirmed by spectroscopic, genetic and physiological experiments in the cyanobacteria and green algae that are amenable to such interdisciplinary approaches (Merchant and Bogorad, 1987; Briggs et al., 1990; Hill et al., 1991; Nakamura et al., 1992; Bovy et al., 1992; Zhang et al., 1992). However, some species utilize only Cyt c_6 , whereas others (including all green plants) use only PC as an electron donor to PS I.

PC is homologous to other electron transfer copper proteins including auracyanin from *Chloroflexus*, although the latter protein appears closer to the azurins of *Pseudomonas*. There is not likely to be a close evolutionary connection between these copper protein classes because they interact with widely different RC complexes. In contrast, Cyt c_6 appears most closely related to *Chlorobium* Cyt c -555 and *Ectothiorhodospira* Cyt c -551 (Ambler et al., 1993), suggesting a more direct evolutionary link between green sulfur bacteria and cyanobacteria. Cyanobacterial PS I complexes do not have a membrane-bound tetraheme cytochrome c subunit similar to that found in green bacteria. However, it appears that the *psaF* gene product is necessary for binding and efficient electron transfer from PC (Hippler et al., 1989; Wynn et al., 1989).

III. How Do Electron Donors Interact with Membrane-Bound Redox Complexes?

To support PS growth, soluble redox proteins must reversibly interact with membrane bound electron donors (Cyt bc_1 or Cyt b_6f complexes) and acceptors (RC complexes). This suggests that transient binding of these soluble proteins requires a specific interaction with their membrane-bound redox partners. In addition, the ability of these diffusible electron carriers to interact with more than one membrane-bound redox partner raises the question of whether their binding to each complex is mediated by the same interaction domain.

A. Interaction of Cyt c_2 with Reaction Center Subunits

Among PS systems, the most detailed information is available on the interaction between Cyt c_2 and those RC complexes that lack a membrane-bound cytochrome c subunit. Proteins in the Cyt c_2 family have relatively high affinities for these RC complexes ($K_D \approx 1 \mu\text{M}$; Rickle and Cusanovich, 1979; Overfield and Wraight, 1986; Moser and Button, 1988; Venturoli et al., 1990; Tiede et al., 1993). The salt dependence of the rate constant for RC reduction suggests that electrostatic interactions make a significant contribution to the productive interaction between these proteins (Caffrey et al., 1992). Support for the potential contribution of electrostatic interactions also comes from the existence of a net positive charge at the Cyt c_2 interaction domain with either small molecule reactants (Meyer et al., 1984) or proteins (Tollin et al., 1984), the location of lysines on the interaction surface in the available crystal structure of several proteins in this family (Benning et al., 1991), and the expected decrease in either affinity for the cytochrome or its rate of electron transfer when individual lysines are modified chemically (Hall et al., 1987; Long et al., 1989) or genetically (Caffrey et al., 1992). Although some of the highly conserved surface lysines appear to be more important than others, multiple electrostatic interactions must aid formation of a productive complex since no chemical or genetic modification at a single lysine totally abolishes binding or electron transfer to RC complexes.

If electrostatic interactions play a significant role in formation of productive complexes between Cyt c_2 and RC complexes, then one might expect its membrane-bound redox partners to contain a complementary set of charged residues at their interaction domains. The crystal structure of the *Rb. sphaeroides* RC complex indicates the existence of several negatively charged residues on the periplasmic surface (Allen et al., 1987; Chang et al., 1991). Although structural representations of Cyt c_2 docked on a RC complex suggest these residues could represent sites of electrostatic contact (Allen et al., 1987; Tiede and Chang, 1988; Caffrey et al., 1992; Tiede et al., 1993), the orientation of the bound cytochrome differs significantly in individual models. Therefore, the contribution of individual charge pairs predicted by different models to the formation of a

productive complex remains to be proven. Indeed, while considerable attention has been devoted to defining the importance of electrostatics, it is important to note that the binding or rate of electron transfer by various members of this cytochrome family does not correlate directly with the magnitude of the charge difference at the interaction domain. Therefore, forces other than electrostatics (i.e., hydrophobic and van der Waals interactions) are likely to contribute significantly to formation of a productive complex between these redox partners. Currently, *Rb. sphaeroides* is the only genetically-manipulatable PS organism for which a crystal structure for both Cyt c_2 (Allen, 1988; Axelrod et al., 1994) and its membrane-bound redox partner (Allen et al., 1987; Chang et al., 1991) is available. In the absence of co-crystals, this type of detailed information should make *Rb. sphaeroides* an extremely attractive model for future genetic and biochemical analysis of the determinants required for Cyt c_2 docking and electron transfer to RC complexes.

Studies of electron transfer between Cyt c_2 and the *Rp. viridis* RC complex suggests that Cyt c_2 directly binds and donates electrons to the membrane-bound tetraheme Cyt c subunit (Knaff et al., 1991; Meyer et al., 1993). In this case, a negatively charged region of the tetraheme cytochrome c subunit appears to be involved. The structure of the *Rp. viridis* RC cytochrome c subunit indicates that a negatively charged surface exists in the vicinity of the ~ 330 mV c -556 (often called heme 2) that serves as the immediate electron acceptor from Cyt c_2 . However, as was the case for Cyt c_2 electron transfer to simpler RC complexes (see above), electrostatic interactions appear to be only one part of the driving force for the formation of a productive complex between these redox partners.

B. Interaction of Cyt c_2 with Other Photosynthetic Membrane Complexes

The interaction domain of Cyt c_2 used for RC binding appears to be similar to that used for interaction with Cyt bc_1 complexes, since the rates of electron transfer from this donor are often influenced by the same alterations that affect the rates of RC reduction (Hall et al., 1989; Guner et al., 1993). Although these results suggest that electrostatic interactions contribute significantly to the formation of a

productive complex between Cyt c_2 and Cyt bc_1 complexes, structural information on the Cyt c_1 subunit (the immediate electron donor to Cyt c_2) is required to begin identifying the potential site of this interaction.

C. Interaction of Other Soluble Electron Donors with Photosynthetic Membrane Redox Partners

Distantly related cytochromes, HiPIP and azurins are relatively poor electron donors to the *Rp. viridis* RC (Meyer et al., 1993a). In spite of significant differences in their midpoint potentials or net charge at the interaction domain (positive or negative), these soluble electron donors all appear to interact with a similar negatively charged region surrounding heme 2 of the RC tetraheme cytochrome c subunit. These results may suggest that hydrophobic, van der Waals, and electrostatic interactions all contribute to formation of a productive complex. In addition, the lack of a correlation between the redox potential difference of the reactants and the rate constants for electron transfer implies that factors such as distance and orientation between electron donors and acceptors may also contribute to formation of productive complexes and the reaction rate. Considerably less is known about the interaction of PC with either PS I RC complexes or Cyt f subunits of the Cyt b_6f complex. Chemical modification of PS I shows that the requirement for divalent cations, such as magnesium, is to neutralize negative charges on PS I and optimize binding and reaction with PC, which is also negatively charged at its interaction domain (Burkey and Gross, 1981). The kinetics of electron transfer in the complex between Cyt f and PC indicate that some rearrangement of reactants is necessary for rapid electron transfer (Qin and Kostic, 1992; Meyer et al., 1993b). Chemical cross-linking has implicated the interaction of a negatively charged region of spinach PC with both PS I and Cyt b_6f complexes. Specific cross-linking of spinach PC to lysine residues of turnip Cyt f has been found (Morand et al., 1989), while the basic residues of a positively charged region within spinach PsaF have yet to be cataloged (Wynn et al., 1989; Hippler et al., 1989). From this initial analysis, electrostatic interaction between a negatively-charged domain of PC and a positively charged region on the membrane-bound redox partner has been proposed. The

contribution of this type of interaction is likely to be conserved because *Euglena* Cyt c_6 could also be covalently linked to turnip Cyt f (Morand et al., 1989). However, a variety of cyanobacterial Cyt c_6 proteins and a cyanobacterial PC could not be cross-linked to turnip Cyt f . This lack of cross-linking could reflect the lack of an acidic domain in the cyanobacterial proteins or a slightly different arrangement of acidic domains relative to their eukaryotic counterparts. In this regard, several labs have also noted significant sequence differences between the cyanobacterial and plant Cyt f subunits in the regions identified by cross-linking with PC (Ho and Krogmann, 1984; Widger, 1991). Therefore, it is also possible that cyanobacterial and higher plant PC may use a different series of interactions to form productive complexes with their physiological redox partners. In support of this notion, the net charge at the interaction domain in Cyt c_6 and PC was found to be highly variable in different species (Meyer et al., 1987).

IV. What Insights Has Genetics Provided About Electron Donors to Reaction Center Complexes?

Among PS bacteria, Cyt c_2 is the only soluble redox protein whose physiological function has been confirmed both biochemically and genetically (Daldal et al., 1986; Donohue et al., 1988; Rott et al., 1993; Jenney and Daldal, 1993). Genetic analysis of Cyt c_2 function was facilitated by the fact that some PS bacteria grow under conditions where this protein is dispensable. Although this analysis has only been performed to date in *Rb. sphaeroides* and *Rb. capsulatus*, biochemical and genetic (Self et al., 1990; Liang et al., 1991; Donohue and Kaplan, 1991) advances in *Rs. rubrum* suggest this bacterium is currently amenable to similar experiments.

Previous genetic analysis of Cyt c_2 function took advantage of the existing protein sequence to clone the respective structural gene (*cycA*) and construct defined null mutants by marker exchange (Daldal et al., 1986; Donohue et al., 1988; Donohue and Kaplan 1991). In retrospect, there are several reasons why this approach was preferable to random genetic screens for mutant cells lacking Cyt c_2 . First, the relatively small size of the *cycA* locus (<1 kb) predicts that such mutants would represent only a small fraction of any given population. For example, a

screen for *Rb. sphaeroides* strains lacking isocyt c_2 identified only one mutant in over 20,000 independent isolates. Even in this case, the mutation did not directly inactivate this structural gene (*cycI*); rather the loss of isocyt c_2 was due to polarity of the mutation on *cycI* expression (Rott et al., 1993). More importantly, the existence of functionally redundant electron donors to the RC dramatically underscores why *cycA* mutants might not have been isolated in some PS bacteria (Rott et al., 1993; Jenney and Daldal, 1993) and cyanobacteria (Laudenbach et al., 1990) if photosynthetically-incompetent (PS⁻) cells were directly screened for a loss of proteins in the Cyt c_2 family. The following sections briefly describe what new insights into PS electron transport have been obtained by genetically analyzing PC electron donors.

A. Purple Bacteria That Require Members of the Cyt c_2 Family

The inability of *Rb. sphaeroides* Cyt c_2 null mutants to grow under PS conditions and reduce light-oxidized RC complexes (Donohue et al., 1988) confirmed this protein's presumed function in this species. Although analogous *Rb. capsulatus* Cyt c_2 null mutants are PS⁺ (Daldal, et al., 1986), they lack the rapid and complete RC reduction that is diagnostic of electron transfer from Cyt c_2 (Prince et al., 1986). Initially it was proposed that PS growth of *Rb. capsulatus* Cyt c_2 null mutants resulted from direct electron transfer between the Cyt bc_1 and RC complexes (Prince and Daldal, 1987; Prince et al., 1988). However, subsequent biochemical (Jones et al., 1990; Zannoni et al., 1992) and genetic (Jenney and Daldal, 1993) experiments demonstrated that both *Rb. sphaeroides* and *Rb. capsulatus* use different isoforms of Cyt c_2 to support PS growth when *cycA* is inactivated (see below). This is one clear instance where a genetic approach to identifying electron donors to the RC allowed PS bacteria to reveal aspects of their physiology that remained hidden during previous biochemical analysis of wild type cells.

Both *Rb. sphaeroides* and *Rb. capsulatus* grow with virtually wild type growth rates under PS conditions at saturating light intensities when they use an alternative electron donor to the RC. This is true even though the magnitude of RC reduction is considerably lower than that seen in wild type cells (Daldal et al., 1986; Rott and Donohue 1990). This indicates that the rapid RC reduction seen in wild

type purple bacteria is not limiting for PS growth rates at saturating light intensities. In this regard, it may be more significant that the apparent rate of proton pumping through the Cyt bc_1 complex (as estimated by the slow phase of the carotenoid bandshift) is similar in both wild type and mutant cells. Electron transport through the Cyt bc_1 complex is a primary source of the membrane potential under PS conditions, so a simple explanation for the virtually wild type growth rates is that the lesions do not dramatically alter the rate at which these mutants generate a proton gradient from light.

1. *Rb. sphaeroides* Uses a Soluble Isoform of Cyt c_2 as an Alternative Electron Donor to Reaction Center Complexes

In *Rb. sphaeroides*, *spd* mutations allow PS growth of *cyc A* null mutants because they increase the cellular abundance of a soluble Cyt c_2 isoform (isocyt c_2 ; Fitch et al., 1989; Rott and Donohue, 1990; Rott et al., 1992). A simple explanation for the inability of isocyt c_2 to support PS growth of *Rb. sphaeroides cyc A* null mutants in the absence of an *spd* mutation is that these cells contain only ~1 molecule of this protein for every 100 RC complexes. However, the ~25-fold increase in isocyt c_2 levels under PS conditions brought about by the *spd* mutation brings the cellular abundance of this protein close to that of RC complexes (Rott et al., 1992).

Genetic and biochemical experiments confirmed that isocyt c_2 reduces RC complexes in *Rb. sphaeroides* Spd mutants. The accumulation of isocyt c_2 in *Rb. sphaeroides* Spd mutants initially suggested it was responsible for RC reduction in the absence of Cyt c_2 (Rott and Donohue, 1990). The ability of purified isocyt c_2 to reduce light-oxidized RC complexes in vitro supported this notion (V. C. Witthuhn, M. A. Rott, C. A. Wraight and T. J. Donohue, unpublished). In spite of the fact that isocyt c_2 is ~45% identical to *Rb. sphaeroides* Cyt c_2 , these in vitro experiments demonstrated that saturating concentrations of isocyt c_2 reduce RC complexes 50–100 fold slower than Cyt c_2 at low ionic strength. This reduced rate of RC reduction by isocyt c_2 apparently is not due to an altered affinity of RC complexes for this protein. In addition, the salt dependence of RC reduction by isocyt c_2 suggests that it interacts with RC complexes via similar electrostatic contacts with a positive interaction domain. This slow rate of RC reduction by isocyt c_2

appears to be a major reason for the relatively slow kinetics of whole cell PS electron transport seen in Spd mutants (Donohue et al., 1988; V. C. Witthuhn et al., unpublished).

If isocyt c_2 was responsible for PS growth of Spd mutants, then the ability to grow photosynthetically should be lost in a strain lacking this protein. The isolation of a mutant lacking both Cyt c_2 and isocyt c_2 (Rott et al., 1993) confirmed the function of isocyt c_2 in PS electron transport. In addition, it showed that PS growth of *Rb. sphaeroides* Cyt c_2 null mutants required increased cellular levels of isocyt c_2 . All of the data indicate that the failure of previous investigators to discover isocyt c_2 reflects the fact that synthesis of this protein is repressed in wild type cells (Rott et al., 1992). In contrast, isocyt c_2 levels necessary to support PS growth can be obtained either by an *spd* mutation or by placing the isocyt c_2 structural gene under control of a promoter that bypasses negative regulation (Rott et al., 1993).

2. *Rb. capsulatus* Uses a Membrane-Bound Member of the Cyt c_2 Family as an Alternative Electron Donor to Reaction Center Complexes

Although the initial analysis of the *Rb. capsulatus* Cyt c_2 mutant generated by Daldal and co-workers suggested that light-oxidized RC complexes might be directly reduced by the Cyt bc_1 complex (Prince et al., 1986; Prince and Daldal, 1987), subsequent experiments by several groups implicated a membrane-bound *c*-type cytochrome in Cyt c_2 -independent PS growth of this bacterium (Jones et al., 1990; Zannoni et al., 1992). To test this possibility, Jenney and Daldal (1993) used the PS⁻ phenotype of an *Rb. sphaeroides* Cyt c_2 null mutant to screen *Rb. capsulatus* DNA for sequences that allowed PS growth. This screen identified a gene that apparently encodes a membrane-bound member of the Cyt c_2 family (this protein has been called Cyt c_{2s} , but it actually appears to be a membrane-associated isozyme of Cyt c_2 similar to those found in other prokaryotes; Bott et al., 1991). This membrane-bound isoform of Cyt c_2 appears responsible for PS growth of the *Rb. capsulatus* Cyt c_2 null mutant isolated by Daldal and co-workers because a strain lacking both it and Cyt c_2 is unable to grow via photosynthesis (Jenney and Daldal, 1993). In addition, mutants lacking either Cyt c_2 or this membrane-bound isoform of Cyt c_2 are PS⁺, so it appears that either protein is capable of supporting

rates of RC reduction necessary to support PS growth. Estimates of the cellular abundance of this membrane-bound isoform of Cyt c_2 are not yet available in different *Rb. capsulatus* genetic backgrounds. Thus, it is not clear why previous studies of light-induced electron transport in *Rb. capsulatus* failed to detect significant RC reduction by this membrane-bound protein. In this regard, it is possible that electron transport previously ascribed to tightly bound Cyt c_2 in *Rb. capsulatus* spheroplasts was actually due to the membrane-bound isoform of Cyt c_2 (Prince et al., 1975). It has also been suggested that the cellular abundance of the membrane-bound isoform of Cyt c_2 is dependent on nutrient supply, so it is possible that many of the previous experiments used cells grown under conditions where low levels of this protein obscured its contribution to RC reduction (Jones et al., 1990; Zannoni et al., 1992). Finally, Cyt c_2 mutants from another wild type *Rb. capsulatus* strain were PS⁻ (Hudig, et al., 1986) so it is possible that strain differences contributed to the previous failure to detect the function of this membrane-bound isoform of Cyt c_2 in RC reduction.

B. How is Synthesis of Reaction Center Electron Donors Regulated?

In facultative species, chlorophyll-protein complexes are often accumulated only under conditions of low oxygen tension that induce PS membrane synthesis (Kiley and Kaplan, 1988). If the RC electron donor is also not accumulated under non-PS conditions, then its cellular abundance will probably parallel that of chlorophyll-protein complexes. However, when considering how synthesis of RC electron donors might be regulated it is important to remember that these proteins might serve an important physiological function under non-PS conditions. Indeed, the apparent function of *Rb. sphaeroides* Cyt c_2 in aerobic respiration (Gennis, et al., 1982) means that significant levels of this protein are present in cells that lack detectable quantities of PS membrane pigment-protein complexes (Chory et al., 1984).

In many systems, the cellular level of PS membrane complexes is also controlled by changes in light availability (Kiley and Kaplan, 1988). However, in *Rb. sphaeroides* neither Cyt c_2 levels nor the cellular abundance of mRNA specific for this RC electron donor appear to be significantly altered by changes in light intensity (Donohue et al., 1986). These results appear to support the notion that synthesis of RC

electron donors need not be coupled to that of the chlorophyll-protein complexes within the PS apparatus.

From recent studies, some general themes are beginning to emerge on how synthesis of RC electron donors is regulated. The following sections briefly illustrate potential strategies that different PS bacteria use to regulate the synthesis of electron donors to the RC complex. For example, ligand availability can influence the cellular level of RC electron donor. In several cyanobacteria and green algae, the choice between PC and Cyt c_6 as an electron donor to PS I is governed by copper availability. In addition, recent work indicates that *Rb. sphaeroides* couples Cyt c_2 synthesis to the accessibility of this protein's heme ligand. The recent cloning of alternative electron donors to RC complexes from purple bacteria has provided investigators with some insights into how synthesis of these proteins might be regulated.

1. Cyt c_2 Synthesis in Purple Bacteria

In *Rb. sphaeroides*, the normal RC electron donor, Cyt c_2 , also participates in a branch of the aerobic respiratory chain (Gennis et al., 1982). Because of this additional function, *Rb. sphaeroides* Cyt c_2 levels only increase ~2–4 fold under PS conditions (Brandner et al., 1989). Indeed, when one compares the induction of Cyt c_2 to that of chlorophyll-protein complexes during a shift from aerobic to PS growth conditions, the cellular levels of this electron donor do not increase until after chlorophyll-protein complexes are assembled and growth resumes (Chory et al., 1984). From these and other experiments, it appears that the pool of Cyt c_2 present in aerobically grown cells is sufficient to support RC reduction during induction of the PS membrane.

Analysis of Cyt c_2 synthesis in *Rb. sphaeroides* indicates that increased *cycA* transcription under PS conditions contributes significantly to the increased levels of this protein. Several lines of evidence indicate that the Cyt c_2 structural gene (*cycA*) contains several promoters and that transcription from at least one upstream promoter region is increased under conditions that induce synthesis of the PS apparatus (MacGregor and Donohue, 1991; Schilke and Donohue 1992). To test whether this increase in *cycA* transcription could be coupled to changes in heme availability that accompany induction of the PS apparatus (see Lascelles, 1978 for review), β -galactosidase levels from a series of *cycA*'*lacZ*

operon fusions were assayed after tetrapyrrole intermediates were added to cells. From the results of these experiments, it appeared that a negative feedback loop links *cycA* transcription to heme availability because the addition of δ -aminolevulinic acid (ALA), the first committed intermediate in the tetrapyrrole biosynthetic pathway, effectively repressed *cycA* transcription (Schilke and Donohue, 1992).

The existence of this negative feedback loop predicts that mutants in which *cycA* transcription is insensitive to exogenous ALA should have increased expression of this gene. Such regulatory mutants (Chr4) have been isolated (Schilke and Donohue, 1992) and recent data indicates that the ChrR gene product is an activator of *cycA* transcription whose function is poisoned by the addition of exogenous ALA (Schilke and Donohue, 1995). If this were the case, then the ChrR protein in mutants like Chr4 is locked in an active state and can not respond to the signal generated by the addition of ALA. In this regard it is exciting to note that the mutant gene product in Chr4 contains a Cys to Arg substitution in a Cys-X-Y-Cys motif reminiscent of heme binding sites in cytochromes (Schilke and Donohue, 1995). While it is tempting to speculate that this motif represents a target site for the interaction of ChrR with heme or some other tetrapyrrole intermediate produced from ALA, final conclusions await additional physiological and genetic analysis. It will also be interesting to see if ChrR regulates transcription of additional cytochromes or chlorophyll-binding proteins within the PS membrane which are known to respond to the presence of exogenous ALA (Neidle and Kaplan, 1993). Regardless of the number of gene products controlled by ChrR, this negative feedback loop serves a similar function to the systems used by cyanobacteria and green algae that insure that Cyt c_6 is only synthesized when cells are limited for the copper ligand required for PC formation.

Recent genetic experiments suggest that *Rb. sphaeroides* *cycA* transcription requires a second gene product (PrrA) which positively controls transcription of many PS membrane gene products (Erase and Kaplan, 1994). The observation that *cycA* transcription is still induced under PS conditions in ChrR null mutants might suggest that the PrrA pathway is still operative (Schilke and Donohue, 1995). However, additional experiments are required to test whether these two regulatory networks

independently regulate *cycA* transcription.

2. Do Purple Bacteria Control Synthesis of Cyt c_2 Isoforms?

In the few bacterial systems known to contain alternate electron donors to the RC complex, little is known about whether individual proteins are used under specific physiological conditions. In addition, information is lacking about the molecular cues which might regulate synthesis of an individual electron donor to the RC complex.

In *Rb. capsulatus*, levels of the membrane-bound isoform of Cyt c_2 are believed to respond to nutrient conditions (Zannoni et al., 1992). However, the signals mediating this response and the magnitude of the changes in the abundance of this protein have not been elucidated. The ability of *Rb. capsulatus* Cyt c_2 null mutants to grow photosynthetically (Daldal et al., 1986) suggests that levels of this alternative electron donor are sufficiently high to support PS growth in the absence of any other mutation or specific physiological stimulus.

In contrast, *Rb. sphaeroides* Cyt c_2 mutants do not grow photosynthetically because isocyt c_2 synthesis is repressed when cells are grown in a succinate-based minimal medium (Rott et al., 1992). However, *spd* mutations bypass negative regulation of isocyt c_2 synthesis in this medium and allow this protein to accumulate to levels necessary to support PS growth. While sequencing the isocyt c_2 structural gene (*cycl*), it was noted that *cycl* was apparently part of an operon with an open reading frame encoding a typical member of the Zn-dependent alcohol dehydrogenase enzyme family (Rott et al., 1993; R. Barber, M.A. Roth and T. J. Donohue, unpublished). Soluble members of the AdhI family normally function in the oxidation of primary alcohols (Jornvall, et al., 1987). However, recent experiments confirmed that this protein is actually a member of the glutathione-dependent formaldehyde dehydrogenase family of alcohol dehydrogenases (R. Barber et al., unpublished). Since this protein apparently lacks a signal peptide, it seems unlikely that it functions as a direct electron donor to the periplasmic isocyt c_2 protein in a fashion similar to the membrane-bound alcohol dehydrogenase of *Acetobacter pasteurians* (Takemura et al., 1991) and *Gluconobacter suboxydans* (Takeda and Shimizu, 1992). Additional experiments are also required to determine the potential relationship of AdhI to other broad specificity alcohol dehydro-

genes from Rhodospirillaceae (Bamforth and Quayle, 1978).

While there are reports of methanol utilization by some purple bacteria (Quayle and Pfennig, 1975), *Rb. sphaeroides* is one of the few Rhodospirillaceae that can utilize ethanol as sole carbon and energy sources (Imhoff and Trüper, 1984). Although it might be tempting to speculate that isocyt c_2 synthesis might be inducible by the addition of alternate carbon sources to wild type cells, additional experiments are required to determine the potential function of isocyt c_2 . In this regard, cloned genes and defined mutants should facilitate the experiments necessary to determine whether growth in the presence of alternate carbon sources allows increased isocyt c_2 synthesis or whether this protein could contribute to PS electron transport under other physiological conditions in wild type cells. Therefore, in spite of the potential physiological function of isocyt c_2 suggested by the genetic linkage of these two genes, experimental support is currently lacking for a role of isocyt c_2 in any other metabolic pathway.

3. Copper Availability Dictates the Use of Plastocyanin or Cyt c_6

Many oxygenic phototrophs contain a regulatory network to control synthesis of functionally redundant proteins like Cyt c_6 and PC. For example, one third of the cyanobacteria contain Cyt c_6 alone, whereas two thirds contained both proteins (Sandmann, 1986). In contrast, three quarters of the green algae have both proteins while one quarter have only PC. Therefore, it will be interesting to see if bacteria that use copper proteins as electron donors to RC complexes contain a similar regulatory network.

In cyanobacteria and green algae that are able to make both proteins, PC seems to be the preferred electron donor because only copper-limited cells accumulate significant levels of Cyt c_6 . Thus, cells containing both genes only use Cyt c_6 as an electron donor to PS I when they lack the copper ligand required for assembly of an active PC molecule (Merchant and Bogorad, 1987a and 1987b, Bovy et al., 1992). In all of these species tested, transcription of the Cyt c_6 gene is repressed by copper, whereas regulated transcription of the PC gene by copper is found only in some species (Briggs et al., 1990, Hill et al., 1991; Nakamura et al., 1992; Bovy et al., 1992; Zhang et al., 1992). The behavior of this regulatory network suggests that PC is generally a more efficient

electron donor, although the molecular basis for this difference must await completion of the three-dimensional structure of PS I and the appropriate kinetic studies.

V. Future Perspectives

This chapter has attempted to provide a current understanding of the soluble proteins capable of electron transfer to light-oxidized RC complexes. The recent biochemical, structural and genetic analysis of these electron transfer proteins has demonstrated the power and versatility of such an interdisciplinary approach to this important biological question. In addition to providing new ways to address old biological questions, this interdisciplinary approach has uncovered new and exciting areas of inquiry for future research. Hopefully, like most areas of research, these recent advances have demonstrated that model building or the assignment of a function to a given protein from a single type of analysis can be misleading. Rather, we hope this chapter has clearly illustrated that the ultimate confirmation of a protein's function in PS electron transport requires the complementary information gleaned from biochemical, physiological and genetic experiments. Therefore, one challenge for future investigators working with new and exciting species of PS bacteria is to develop the necessary ensemble of structural, biochemical and genetic techniques to unambiguously assign a function to a given protein.

When one considers the explosion of structural, biochemical and genetic information that has occurred since the last review of soluble electron transfer proteins from PS bacteria (Bartsch, 1978), it is clear that remarkable progress has been made on many fronts. Having accumulated this plethora of information, it is also obvious that many important questions remain to be answered about the synthesis, structure and function of proteins that transfer electrons to light-oxidized RC complexes. A further challenge for future researchers is the development of the techniques and experimental systems to answer these important biological questions.

Finally, many of the questions we posed regarding soluble electron donors to the RC have parallels in the function of redox proteins in virtually all energy generating pathways. The unequalled wealth of biophysical data on bacterial PS electron transport, the RC crystal structures, and the rapidly expanding

array of genetic techniques that can be brought to bear on soluble proteins and their membrane-bound redox partners all promise to make PS bacteria a unique system for future analysis of photosynthesis and biological energy generation.

Summary

The ubihydroquinone:cytochrome *c* oxidoreductase (Cyt *bc*₁ complex) is a multisubunit integral membrane protein present in a wide range of organisms. In the photosynthetic bacteria the Cyt *bc*₁ complex is involved in both light driven cyclic electron transfer as well as respiratory electron transfer. It oxidizes ubihydroquinone generated either by the reaction center or the respiratory dehydrogenases and reduces Cyt *c*₂ (or Cyt *c*_v) which then either re-reduces the reaction center or donates electrons to a terminal cytochrome *c* oxidase. During electron transfer, protons are translocated from the cytoplasm to the periplasm and contribute to the formation of an electrochemical gradient used for ATP synthesis. A large body of spectroscopic data supports a Q-cycle

mechanism of electron transfer through the Cyt bc_1 complex. The enzyme is composed of three metal containing subunits, Cyt b , Cyt c_1 and the 'Rieske' iron sulfur protein. The structural genes encoding these three core subunits (designated *pet A, B* and *C* or *fbcF, B* and *C*) have now been cloned and sequenced from several photosynthetic bacteria. Two of them, *Rhodobacter capsulatus* and *Rhodobacter sphaeroides*, have been genetically modified to allow site-directed mutagenesis, and a number of single site mutants have been obtained in each of the three subunits. In recent years, the analyses of both site-directed mutants and spontaneous inhibitor resistant mutants have led to the identification of the ligands to the metal clusters, the general location of the sites of quinone interaction and more accurate folding models of the individual subunits of the complex. This chapter reviews recent biochemical and genetic studies (inclusive of 1994) that have greatly increased our understanding of how the Cyt bc_1 complex functions at the molecular level.

I. Cytochrome bc_1 Complex

A. Physiological Role in Photosynthesis and Respiration

Ubiquinone-cytochrome c oxidoreductase (or the Cyt bc_1 complex) is an integral membrane protein involved in energy transduction in a wide range of organisms (for recent reviews see Prince, 1990; Trumpower, 1990; Cramer and Knaff, 1990; Knaff, 1993; Gennis et al., 1993; Brandt and Trumpower, 1994). The enzyme is a major component of the mitochondrial electron transfer chain and performs a similar function in aerobic prokaryotes (Fig. 1). Anoxygenic photosynthetic prokaryotes contain a Cyt bc_1 complex that is utilized for both light driven electron transfer and dark respiration (Crofts and Wraight, 1983; Dutton, 1986; Prince, 1990; Knaff, 1993). Oxygenic photosynthetic organisms contain a similar redox complex (called the Cyt b_6/f complex) which functions between Photosystems I and II (Hauska, 1986; Cramer et al., 1987; Malkin, 1992). In all cases the complexes oxidize and reduce the lipid soluble two electron carrier (plasto-, ubi- or mena-hydroquinone) in the membrane phase, and reduce a one electron carrier (the water soluble Cyt c or plastocyanin or the newly discovered membrane-associated Cyt c_y [Jenney and Daldal, 1993; Jenney et al., 1994]) at the membrane aqueous interface. During respiration ferrocyt c then donates electrons to Cyt c oxidase (Gray et al., 1994) which catalyzes the four electron reduction of dioxygen to water. On the other hand, during anoxygenic photosynthesis, a

predominantly cyclic process, ferrocyt c re-reduces the photooxidized BChl dimer of the reaction center, resulting in no net redox change (Fig. 1). During electron transfer, charges (electrons and protons) are vectorially transported across the membrane, generating an electrochemical gradient ($\Delta\mu_{H^+}$) used to drive energy requiring processes such as ATP synthesis, active transport and taxis (Dutton, 1986; Prince, 1990).

B. Experimental Advantages of Phototrophs in Studying the Cyt bc_1 Complex

Photosynthetic bacteria, in general, and *Rhodobacter (Rb.) capsulatus* and *Rhodobacter sphaeroides*, in particular, provide important experimental advantages over mitochondria and chloroplasts for studying the structure and function of the Cyt bc_1 complex. First, the bacterial complexes are structurally much simpler, and yet functionally very similar, when compared with those from mitochondria. The bacterial enzymes contain only three or four subunits, while mitochondrial complexes contain several additional subunits of undefined function. Second, in phototrophic organisms the reactions catalyzed by the Cyt bc_1 complex can be measured in situ by flash activation of the photochemical reaction center using either chromatophore membranes or whole cells. The initial events that take place in the reaction center are extremely fast, and this photoactivation provides an oxidant (ferri-cyt c) and a reductant (UQH₂) for the Cyt bc_1 complex allowing the use of time-resolved optical spectroscopy to monitor the internal reactions of the complex. Examples of flash-induced electron transfer kinetics and the corresponding specific reactions are shown in Fig. 2. Further, in response to the change in the electric field across the low dielectric of the membrane (i.e. the membrane potential) caused by charge transfer the absorbance

Abbreviations: *B.* – *Bacillus*; *Br.* – *Bradyrhizobium*; *Cb.* – *Chlorobium*; Cyt – cytochrome; *E.* – *Escherichia*; *N.* – *Neurospora*; *P.* – *Paracoccus*; *Rb.* – *Rhodobacter*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*; UHDBT – undecylhydroxydioxobenzothiazole; UNHQ – undecylhydroxy-naphthoquinone

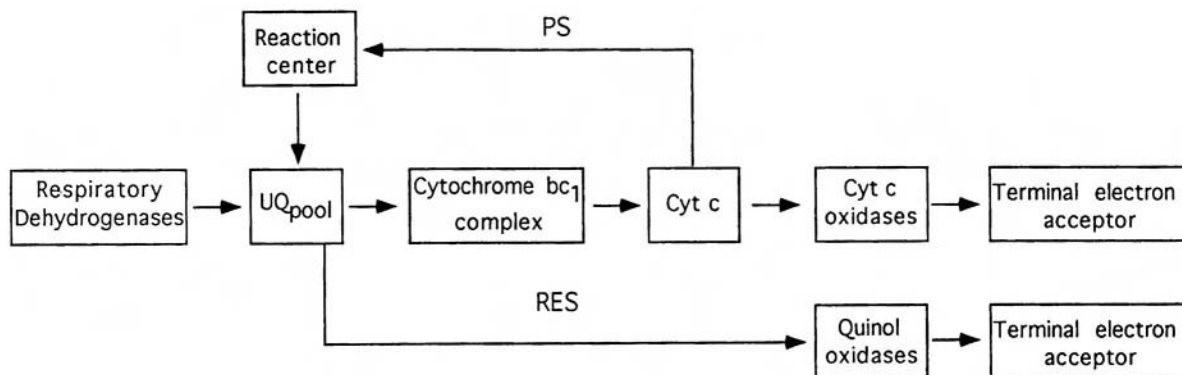

Fig. 1. Schematic representation of energy transduction in bacterial membranes indicating the route of electrons through the various membrane associated and soluble components. In purple bacteria, photosynthetic electron transfer cycles around the reaction center, UQ_{pool} , Cyt *bc*₁ complex and Cyt *c* (*c₂* and *c₁*). Respiratory electron transfer can either be routed to a Cyt *c* oxidase via the Cyt *bc*₁ complex and Cyt *c* or directly to a terminal electron acceptor via a quinol oxidase bypassing the Cyt *bc*₁ complex.

spectra of the membrane-associated carotenoids are shifted (a Stark effect). Thus the electrogenic steps of the internal reactions can be followed spectroscopically on a fast time scale (see for example Matsuura et al., 1983b; Glaser and Crofts, 1984; Robertson and Dutton, 1988). Third, photosynthetic growth of these bacteria is absolutely dependent upon the presence of a functional Cyt *bc*₁ complex, thus mutations affecting the complex can be detected by simply monitoring the growth ability of the mutants (Fig. 1) (Daldal et al., 1987). Yet, non-functional Cyt *bc*₁ complex mutants of facultative phototrophic bacteria are still viable due to the availability of other growth modes independent of the complex (Marrs and Gest, 1973; Zannoni et al., 1976; LaMonica and Marrs, 1976). Appropriate growth conditions (low O_2 in the dark) can be chosen so that the photosynthetic apparatus is induced, thus non-functional mutants can be analyzed in detail. Fourth, for both *Rb. capsulatus* and *Rb. sphaeroides* molecular and genetic tools are available for sophisticated genetic analyses such as ‘gene tagging’ and suppressor analyses. Furthermore in *Rb. capsulatus* the genetic system to be used can be chosen so that a mutant complex is either over-produced to facilitate its physicochemical analysis, or kept at the wild type level to analyze its physiological impact. The overproduction also eases the purification and characterization of the wild type as well as mutant complexes, and allows the detection of very low activity of some mutants which may be otherwise undetected. Finally, the structural genes of most bacterial Cyt *bc*₁ complexes are genetically organized as an operon (with a few exceptions) so that both

classical and reverse genetic approaches are often facilitated. Thus, multidisciplinary approaches encompassing biochemistry, biophysics, molecular biology and genetics can be more easily applied in the bacterial systems. Similar approaches are either not yet available or more difficult to perform in mitochondrial and chloroplast systems.

In this chapter we review the salient features of the Cyt *bc*₁ complex and describe recent mutagenesis work being performed on the complex. Although we mainly focus on the work accomplished using the purple non-sulfur photosynthetic bacteria, which is currently the most advanced, similar approaches are also being pursued in other bacterial systems such as *Paracoccus (P.) denitrificans*, *Bradyrhizobium (Br.) japonicum* and cyanobacteria, as well as yeast and other higher eukaryotes (see for example Graham and Trumpower, 1991).

C. Structure

1. Protein Subunits

While the subunit content of the Cyt *bc*₁ complexes is variable from organism to organism the smallest number is in general found in bacteria. Those complexes from the purple non-sulfur, photosynthetic bacteria *Rb. capsulatus* (Robertson et al., 1993), *Rhodospirillum (Rs.) rubrum* (Wynn et al., 1986; Kriauciunas et al., 1989; Majewski and Trebst, 1990; Purvis et al., 1990; Güner et al., 1991) and *Rhodopseudomonas (Rp.) viridis* (Wynn et al., 1986) contain three polypeptides while *Rhodobacter sphaeroides* contains a fourth subunit of unknown

Fig. 2. Kinetic traces of flash induced electron transfer through the Cyt *bc*₁ complex in the absence (A) and presence (B and C) of specific inhibitors (10 μ M antimycin and 5 μ M myxothiazol). *Rhodobacter capsulatus* chromatophores were poised at an ambient redox potential of 100 mV in 50 mM MOPS, pH 7 containing 100 mM KCl, 6 μ M valinomycin and redox mediators. Below each set of traces is shown a schematic representation of the pathway of electron transfer under the specified conditions. Electron transfer through the reaction center is only shown once in a highly simplified form. The flash point is indicated by an arrow, redox changes in total Cyt *b* are followed by monitoring the wavelength pair 560 nm minus 570 nm while redox changes in total Cyt *c* are followed by monitoring the wavelength pair 550 nm minus 540 nm.

function (Yu et al., 1984; Ljungdahl et al., 1987; Andrews et al., 1990; Purvis et al., 1990; Usui et al., 1990, 1991). Recent immunological evidence suggests that this fourth subunit appears to be a bona fide component of the complex, possibly interacting with quinone and antimycin (Wilson et al., 1985; Yu and Yu, 1987, 1991; Usui et al., 1991; Chen et al., 1994). The Cyt *bc*₁ complexes from the purple sulfur bacteria, *Ectothiorhodospira mobilis* (Leguijt et al., 1993) and *Chromatium vinosum* (Tan et al., 1993) also appear very similar to those from the purple non-sulfur bacteria. It now appears that the bacteria utilizing menaquinone in the Q_{pool} (for example heliobacteria, bacilli and *Chlorobium*-type green bacteria) contain Cyt *bc* complexes with somewhat different properties (Knaff and Malkin, 1976; Kutoh and Sone, 1988; Liebl et al., 1990, 1992; Riedel et al., 1993), perhaps to better to accommodate the approximately 150 mV lower redox midpoint potential of menaquinone in comparison to that of ubiquinone.

Regardless of the total subunit content, all Cyt *bc*₁ complexes contain three core polypeptides, called Cyt *b*, Cyt *c*₁ and the 'Rieske' iron-sulfur protein (FeS), that bind the metal clusters participating in charge separation through the complex. Cyt *b*₆*f* complexes actually contain another subunit referred to as subunit IV, however it is highly homologous to the C-terminal region of Cyt *b* while Cyt *b*₆ is highly homologous to the N-terminal region of Cyt *b*. Thus, Cyt *b*₆ and subunit IV of the chloroplast complex could be considered a 'split' Cyt *b*. A similar situation probably exists in some Gram positive bacteria, such as *Bacillus* PS3 (Kutoh and Sone, 1988 and N. Sone, personal communication) and *Bacillus subtilis* (Sorokine and Erlich, personal communication).

2. Prosthetic Groups and Quinone Binding Sites

The Cyt *b* polypeptide (typically about 45 kDa) is an integral membrane protein with multiple transmembrane helices that contains two spectrochemically distinct molecules of protoheme, Cyt *b*_L and *b*_H, referring to the relatively 'low' (approximately -100 mV in *Rb. capsulatus* and *Rb. sphaeroides*) and 'high' (approximately 50 mV in *Rb. capsulatus* and *Rb. sphaeroides*) redox midpoint potentials (E_{m7}) of the two hemes. Spectroscopic analyses have suggested that both *b* hemes have bis-imidazole ligation (Carter et al., 1981; Salerno et al., 1986; Simpkin et al.,

1989; McCurley et al., 1990; Hobbs et al., 1990), and current folding models of this protein with eight transmembrane helices (see below) use the four universally conserved histidine residues located on the same pair of helices (two in B and two in D) as their ligands.

Cyt *c*₁ (typically about 30 kDa, except in *P. denitrificans* where it is approximately 65 kDa), covalently binds one molecule of heme ($E_{m7} \approx 290$ mV) with the most probable axial ligation of histidine and methionine (Simpkin et al., 1989). The consensus heme binding motif (-Cys-Xaa-Yaa-Cys-His-) is located close to the amino terminus of both Cyt *c*₁ and Cyt *f* of the Cyt *b*₆*f* complex, and these two cysteines covalently link the heme macrocycle to the protein via thioether linkages. Magnetic circular dichroism (MCD) and resonance Raman (RR) measurements suggested that the sixth axial ligand to the heme Fe of Cyt *f* is not methionine but an amine group perhaps from a lysine (Rigby et al., 1988; Davis et al., 1988; Simpkin et al., 1989). Recent 3-D structural analysis of isolated Cyt *f* from turnip has shown that its sixth axial ligand is surprisingly the amino terminus of the protein (Martinez et al., 1992, 1994).

The FeS protein (typically about 20 kDa) has a [Fe_2S_2] cluster with an unusual EPR spectrum and a relatively high E_m value (approximately 260 mV). Spectroscopic analyses have suggested that two histidines and two cysteines are the ligands to the cluster in contrast to the more common four cysteines seen in the ferredoxins (Telser et al., 1987; Powers et al., 1989; Britt et al., 1991; Miki et al., 1991; Gurbiel et al., 1991). The [Fe_2S_2] cluster interacts with the site of hydroquinone oxidation as evidenced by the sensitivity of the EPR spectrum of the cluster to the redox state of the UQ_{pool} and to the occupancy of the Q_o site of the complex (Matsuura et al., 1983a; Robertson et al., 1986; Robertson et al., 1990; Ding et al., 1992).

In addition to these metal-containing cofactors the enzyme has interaction sites for its reaction partners, Cyt *c*₂, Cyt *c*_y (in *Rb. capsulatus*) and ubi(hydro)-quinone. The two quinone binding sites, called Q_o and Q_p , are at least partially located on the Cyt *b* polypeptide and have different catalytic and thermodynamic properties (see the section on the Q-cycle below). The interaction between Cyt *c*₁ and *c*₂ is electrostatic and involves lysine residues on the 'front' face (i.e. the side of the exposed heme edge) of Cyt *c*₂ (Margoliash and Bosshard, 1983; Wynn et

al., 1986; Bosshard et al., 1987; Güner et al., 1993). Differential chemical modification (Hall et al., 1987a,b,c; Hall et al., 1989) and later, site-directed mutagenesis (Caffery et al., 1992; Güner et al., 1993), of these lysines resulted in a perturbation of the Cyt c_1/c_2 interaction and the kinetics of electron transfer. The positions of Cyt c_1 providing the counter charges are unknown but the effective negative charges supplied by Cyt c_1 in the interaction appear approximately the same in *Rb. capsulatus* and *Rp. viridis* (Güner et al., 1993). There are two patches of highly conserved acidic residues on Cyt c_1 in *Rb. capsulatus* (G88 to D107 and V209 to G218) which could be responsible for these interactions (Davidson and Daldal, 1987b). At present the interaction between Cyt c_1 and Cyt c_2 of *Rb. capsulatus* is entirely unknown (Jenney and Daldal, 1993).

D. Q-cycle Mechanism of Charge Separation

1. Inner Reactions

Light-induced electron transfer through the Cyt bc_1 complex is initiated by the very rapid (microsecond) oxidation of Cyt c in the periplasmic space by the photo-oxidized bacteriochlorophyll dimer (P^+) of the reaction center (Fig. 2). Ferricyt c triggers a cascade of events beginning with the oxidation of Cyt c_1 . The latter then oxidizes the $[\text{Fe}_2\text{S}_2]$ cluster, which in turn is reduced by ubihydroquinone bound at a site (Q_o) formed by Cyt b and the FeS protein. The transient semiquinone generated by the one electron oxidation of UQH_2 is unstable and quickly reduces the low potential Cyt b_L . The observation of reduction of Cyt b following the addition of an 'oxidant' (the oxidized $[\text{Fe}_2\text{S}_2]$) led to the proposal of a Q-cycle mechanism of electron transfer through the complex (Wikström and Berden, 1972; Mitchell, 1976). Later, modifications to the Q-cycle were introduced to better describe the pathways of charge separation (Crofts et al., 1983; Ding et al., 1992). Inherent to these models are two separate, independent sites of (hydro)quinone interaction on the enzyme. One site, that of UQH_2 oxidation (Q_o , for proton 'output'), is near the periplasmic surface of the membrane and undergoes a concerted two-electron oxidation by the $[\text{Fe}_2\text{S}_2]$ and Cyt b_L . Ding et al. (1992) have recently analyzed the EPR spectra of ubiquinone extracted- and reconstituted-chromatophores and proposed that two molecules of UQH_2 may occupy the Q_o site. These two sites are called Q_{ow} (Q_o 'weak') and Q_{os} (Q_o

'strong') in reference to their strength for binding UQH_2 .

After the reduction of Cyt b_L , electron transfer occurs in an electrogenic step from Cyt b_L to Cyt b_H . From carotenoid electrochromic shift measurements the distance from Cyt b_L to Cyt b_H is estimated to span more than half of the membrane dielectric (Glaser and Crofts, 1984; Robertson et al., 1988). Cyt b_H is then oxidized by a quinone bound at a second site, called the Q_i site (for proton 'input') forming an antimycin sensitive EPR detectable semiquinone ($Q^{\cdot-}$) species (Ohnishi and Trumppower, 1980; Robertson et al., 1984). Carotenoid bandshift measurements have estimated that the distance between quinone bound at the Q_i site and Cyt b_H represents the remainder of the membrane dielectric. Recently it has been calculated from spin relaxation enhancement of the EPR signal of $Q^{\cdot-}$ by an external spin probe that the semiquinone anion is 6 to 10 Å from the protein surface (Meinhardt and Ohnishi, 1992). Note that a second turnover of the Q_o site is needed for a complete turnover of the Q_i site, and the presence of one Q_{ow} and one Q_{os} may allow two turnovers of the Q_o site without the need of replenishment from the Q_{pool} . Each oxidation of UQH_2 at the Q_o site releases two H^+ into the periplasmic space while reduction of UQ to UQH_2 at the Q_i site results in the consumption of two H^+ from the cytoplasmic side of the membrane. Thus the oxidation and reduction of both an electron and proton carrier on opposite sides of the membrane forms a classical redox loop (Mitchell, 1966), and explains how turnover of the Cyt bc_1 complex contributes to the electrochemical potential difference between the two sides of the membrane.

2. Inhibitors

The use of inhibitors has aided greatly in the elucidation of the pathways of electron transfer through the Cyt bc_1 complex. The most common inhibitors of the Cyt bc_1 complex predominantly affect either the Q_o or Q_i -sites specifically (reviewed in von Jagow and Link, 1986) although they may have additional effects elsewhere (Tsai and Palmer, 1982; Rich et al., 1990; Howell and Robertson, 1993). The Q_o site inhibitors can be subdivided into the methoxyacrylates, which include myxothiazol and mucidin, and the chromones like stigmatellin. The methoxyacrylates inhibit reduction of both Cyt

b_L and the $[\text{Fe}_2\text{S}_2]$ cluster via the Q_0 site but allow turnover of the Q_i site (see Fig. 2 for the effects of the inhibitors on the electron transfer kinetics). Binding of myxothiazol perturbs the EPR spectrum of the $[\text{Fe}_2\text{S}_2]$ cluster, which may be a consequence of displacing Q from the Q_0 site (Ding et al., 1992 and references therein). The hydroxyquinones, which include UHDBT (undecylhydroxydioxobenzothiazole) and UHNQ (undecylhydroxynaphthoquinone), act between the $[\text{Fe}_2\text{S}_2]$ cluster and Cyt c_1 . The mode of action of these quinone analogs appears different from the methoxyacrylates, in that they increase the E_m value of the $[\text{Fe}_2\text{S}_2]$ cluster by approximately 50 mV and inhibit oxidation of the cluster by Cyt c_1 (Matsuura et al., 1983a). The inhibitory effect of stigmatellin also seems to be centered on the $[\text{Fe}_2\text{S}_2]$ cluster since its binding to the Cyt *bc*₁ complex induces a large (approximately 250 mV) increase in the E_m value of this cluster, strongly stabilizing the reduced state and inhibiting oxidation by Cyt c_1 (von Jagow and Ohnishi, 1985). Interestingly, this effect is not observed in menaquinone utilizing Cyt *bc*₁ complexes such as *Heliobacterium chlorum* (Liebl et al., 1990, 1992), *Bacillus* (*B.*) PS3 and *B. firmus* OF4 (Riedel et al., 1993).

Examples of Q_i -specific inhibitors are antimycin, HQNO (heptylhydroxy-quinoline-N-oxide), diuron and funiculosin. All inhibit the oxidation of Cyt b_H by displacing the semiquinone bound at the Q_i site without affecting the oxidation of the first QH_2 at the Q_0 site (Fig. 2, Ohnishi and Trumpower, 1980). Antimycin also induces a red shift in the absorption spectrum of Cyt b_H suggesting that its binding site is close to that heme. Funiculosin causes an increase in the E_m value of Cyt b_H (Howell and Robertson, 1993) and the $[\text{Fe}_2\text{S}_2]$ cluster in mitochondria (Tsai and Palmer, 1982) but the photosynthetic bacteria appear to be immune to the effects of this latter inhibitor both in vivo and in vitro (M. K. Tokito and F. Daldal, unpublished data).

E. Genetic Organization of the Structural Genes of the Cyt*bc*₁ Complex

1. Cloning of the *fbc/pet* Operons

The first structural gene of a Cyt *bc*₁ complex from a photosynthetic bacterium initially thought to be *Rb. sphaeroides* was isolated by Gabellini et al. (1985) using the Rieske iron sulfur gene of *Neurospora* (*N.*)

crassa as a heterologous probe (Harnisch et al., 1985). The determination of the nucleotide sequence of this cloned region indicated that it contained not only the gene for the FeS protein (*fbcF*) but also the structural genes for the Cyt *b* (*fbcB*) and Cyt c_1 (*fbcC*) subunits (Gabellini and Sebald, 1986). S1 mapping and Northern blot analysis indicated that the corresponding mRNA was approximately 2.9 kb long, and proved that these three genes were cotranscribed and constitute an operon (Gabellini et al., 1985; Gabellini and Sebald, 1986).

An independent approach to clone the structural genes of the Cyt *bc*₁ complex was used by Daldal and co-workers with a different purple non-sulfur photosynthetic bacterium, *Rb. capsulatus* (Daldal et al. 1987, Davidson and Daldal, 1987a,b). This organism was chosen due to its amenability to genetic approaches and to the availability of mutants related to bacterial energy transduction isolated by Marrs and co-workers (for a review see Scolnik and Marrs, 1987). One of these mutants, R126, was initially described by Zannoni et al. (1981) as a non-photosynthetic mutant defective in the electron transfer pathways around the Cyt *bc*₁ complex.

Genetic complementation of R126 with the *Rb. capsulatus* chromosomal library of Scolnik and Haselkorn (1984) yielded a plasmid containing the structural genes (*petABC*) for the Cyt *bc*₁ complex. As in the case of Gabellini et al. (1985) this study also indicated that the three structural genes *petA*, *petB* and *petC* corresponding to the FeS, Cyt *b* and Cyt c_1 polypeptides respectively, are organized in the 5' to 3' order. This work also revealed unexpectedly that the sequence obtained by Gabellini and Sebald (1986) was almost identical to the sequence obtained by Davidson and Daldal (1987a), and that the strain used by Gabellini and coworkers was not *Rb. sphaeroides* but was rather a photosynthetic bacterium closely related to *Rb. capsulatus* (Davidson and Daldal, 1987b). The first partial *fbc/pet* sequence of a bona fide *Rb. sphaeroides* strain was reported by Davidson and Daldal (1987b), and the entire sequence from *Rb. sphaeroides* was later completed by Yun et al. (1990).

The isolation of the structural genes led to the construction of Cyt b_{c_1} -minus mutants of *Rb. capsulatus* and *Rb. sphaeroides*, and to the demonstration that a functional Cyt *bc*₁ complex is absolutely essential for photosynthetic growth of these species (Daldal et al., 1987; Yun et al., 1990).

Insertional mutagenesis of these genes further confirmed that they constitute an operon since insertions in the proximal genes are polar to the expression of the distal genes (Daldal et al., 1987). While no other gene related to the Cyt bc_1 complex located at the 3' end of the operon was found insertions near its 5' end negatively affected the growth of *Rb. capsulatus*. Subsequent analysis of this latter region revealed the presence of two additional genes, *petP* and *petR*, whose activities are essential for both photosynthetic and respiratory growth of *Rb. capsulatus* (Tokito and Daldal, 1992). While one of these bc_1 -unrelated genes (*petR*) shows strong homology to *ompR*, the well studied response regulator involved in osmoregulation in *E. coli* (Stock et al., 1989), neither its role in *Rb. capsulatus* nor the role of the preceding gene (*petP*) are known. The strong homology observed infers that they may be regulatory genes involved in sensing some unknown environmental signal(s).

The structural genes of the Cyt bc_1 complex have also been obtained from other purple non sulfur photosynthetic bacteria, *Rp. viridis* (Verbist et al., 1989) and *Rs. rubrum* (Majewski and Trebst, 1990; Shankar et al., 1992) using heterologous probes and were found to form an operon as well. These genes are also available from the non-phototrophs, *P. denitrificans* (Kurowski and Ludwig, 1987), *B. japonicum* (Thöny-Meyer et al., 1988), and the green sulfur photosynthetic bacterium *Chlorobium* (*Cb.*) *limicola* (Schütz et al., 1993) with the exception of Cyt c_1 gene in this latter case. Partial or preliminary genetic data have recently been obtained for the strict aerobes *Bacillus* PS3 and *Bacillus subtilis* (N. Sone, and Sorokin and Ehrlich, respectively, personal communication). In addition, the structural genes have also been cloned and sequenced from the cyanobacterial species *Nostoc* PCC 7906 (Kallas et al., 1988a) and *Synechococcus* PCC 7002 (Widger, 1991; Brand et al., 1992). Hopefully sequence data from two other important branches of the phototrophs, namely the purple sulfur bacteria such as *Chromatium* and the green gliding bacteria such as *Chloroflexus*, will soon be added to this growing database and provide further insight into the structure and function as well as evolution of the Cyt bc_1 complex.

2. Primary Sequences of the Subunits from Different Species

While the operonal organization of the *fbcF* (*petA*), *fbcB* (*petB*) and *fbcC* (*petC*) genes for the three

essential subunits of the Cyt bc_1 complex is generally conserved, some interesting deviations have also been observed (Fig. 3). For example, in *Cb. limicola* *fbcF* and *fbcB* are next to each other, but *fbcC* is not adjacent to this cluster (Schütz et al., 1993). In cyanobacteria *fbcF* and *fbcC* analogues have remained together while the equivalent of the *fbcB* gene was found elsewhere in a split form (Kallas et al., 1988b; Widger, 1991; Brand et al., 1992). In addition, the Cyt b and Cyt c_1 genes of *Br. japonicum* are fused to form a single gene (referred to as *fbcH*) whose product is apparently post-translationally processed to yield a complex with three polypeptide subunits (Thöny-Meyer et al., 1991). Finally, there are approximately 150 additional residues of unknown role at the N-terminal end of Cyt c_1 from *P. denitrificans* (Kurowski and Ludwig, 1987) that are not present in other known species, and whose deletion does not affect drastically either the assembly or the function of the Cyt bc_1 complex (B. Ludwig, personal communication).

The currently available sequences of Cyt b from the photosynthetic bacteria can be divided into two distinct groups based upon the presence or absence of specific deletions (Fig. 4a). Both *Rp. viridis* and *Rs. rubrum* lack the residues from 231 to 237 in the Q_{II} region and between 309 to 326 in the Q_oII region (Shankar et al., 1992). The deletion of either of these regions from *Rb. capsulatus* Cyt b has no drastic effect on the Cyt bc_1 complex (K. A. Gray and F. Daldal, unpublished). Also, helix H present in other bacterial Cyt b is absent from that of *Cb. limicola*. The alignment of the amino acid sequences of the three subunits from photosynthetic species (Fig. 4a, b, c) reveals that while the Cyt b subunit is extremely well-conserved between various species, such pronounced homologies in the other subunits are limited to the metal binding domains of the FeS protein (the C-terminal region) and Cyt c_1 (the N-terminal region) (see also Hauska et al., 1988). An extensive comparison of the primary sequence of Cyt b subunit of the Cyt bc_1 complex from many phylogenetically distinct species has recently been reported (Degli Esposti et al., 1993).

3. Folding Models for the Different Subunits

The determination of the primary sequences of the three subunits of the Cyt bc_1 complex has led to predictions of their secondary structures using various computer programs (Rao and Argos, 1986; Crofts et al., 1987; Brasseur, 1988). These analyses indicated

Fig.3. Genetic organization of the *fbc1pet* operons in various organisms. The organization of the structural genes for the three core subunits of the Cyt *bc*₁ complex are shown schematically. A, B, C and IV represent the genes for the FeS protein, Cyt *b*, Cyt *c*₁ (Cyt *f*) and Cyt *b*₆ subunit IV respectively.

that the Rieske FeS protein is mainly hydrophilic with its two mostly hydrophobic regions being located near the N-terminus and around the [Fe₂S₂] cluster binding region near the C-terminal end of the protein (Fig. 5). While there is no cleaved signal sequence in the FeS protein the bulk of the protein appears to be on the periplasmic face of the membrane. Its amino terminal region has been implicated in binding it to the membrane, although the exact nature of this association is unclear (Li et al., 1981b; Schagger et al., 1987; Gonzalez-Halphen et al., 1988, 1991; Cocco et al., 1991; Theiler and Niederman, 1991; Van Doren et al., 1993b).

Cyt *c*₁ is also mainly a hydrophilic protein but with two hydrophobic helical regions (Fig. 6). The first region corresponds to its membrane translocation signal sequence located at the N-terminus. This sequence is processed during secretion across the cytoplasmic membrane into the periplasm and is not present in the mature protein found in the complex (Gabellini and Sebald, 1986; Yun et al., 1990). The second hydrophobic domain of Cyt *c*₁ (about 15 amino acids delimited by charged residues) located

close to its C-terminal end is thought to anchor the subunit to the cytoplasmic membrane. Limited proteolysis experiments which release the subunit from the membrane in *Neurospora crassa* (Li et al., 1981a) as well as genetic approaches involving the introduction of a stop codon at an appropriate position to prematurely terminate the subunit (Konishi et al., 1991, Gray et al., 1992) are consistent with this topology of Cyt *c*₁ (Fig. 6).

Secondary structure analyses predicted that Cyt *b* is an integral membrane protein with multiple transmembrane helical domains (Fig. 7). While initially it was proposed that it contained nine transmembrane helices (Saraste, 1984; Widger et al., 1984) more refined analyses using several different secondary structure prediction programs (Crofts et al., 1987) revealed that the helix 4 of the initial model is more amphipathic and probably not transmembranous. This extramembranous loop (referred to as helix *cd*) is reminiscent of the amphipathic helix in the purple bacterial photosynthetic reaction center which forms part of the Q_b binding pocket (Deisenhofer et al., 1985; Allen et al., 1988).

Fig. 4b. Continued

Furthermore, a large number of spontaneous Q_0 and Q_i site inhibitor resistant mutants have been mapped to Cyt *b*, and the observed nature and distribution of the sites of these mutations were inconsistent with the nine transmembrane model (Fig. 7a). These findings led several groups to propose a newer model of Cyt *b* with eight transmembrane helices (A to H) by pulling the old helix 4 out of the membrane and reversing the orientation of the following five helices (D to H). The distribution of charged residues of Cyt *b* (inside more positive than the outside, von Heijne et al., 1989) also supports the latter model. There is another large loop on the periplasmic side of the membrane (between the helices E and F) and one large cytoplasmic loop (between helices D and E) which may also contain amphipathic domains.

Indirect experimental proof confirming the

topology of the Cyt *b* polypeptide has also been obtained using alkaline phosphatase (*phoA*) fusions in *Rb. sphaeroides* (Yun et al., 1991b). This frequently used technique has been shown to be reliable in predicting the topology of several *E. coli* membrane proteins (Manoil and Beckwith, 1986), and also to correctly predict the overall topology of the *Rb. sphaeroides* reaction center subunits L and M (Yun et al., 1991b) for which a high resolution structure is available. The data on Cyt *b* clearly indicate that the inside/outside orientation of its first six helices is consistent with the eight helix model predicted from the distribution of inhibitor resistant mutations. However, there is still little information pertinent to the last two helices G and H of Cyt *b* in bacteria. The recent determination of the primary structure of Cyt *b* from *Cb. limicola* indicates that the last helix (H)

Fig. 4c. Continued

Fig. 5. Model of the C-terminal [Fe₂S₂] binding region of the 'Rieske' FeS protein subunit of the Cyt bc₁ complex. Adapted from Davidson et al., 1992a. The boxed residues correspond to the putative ligands of the metal cluster and the circled residues may form a disulfide bridge.

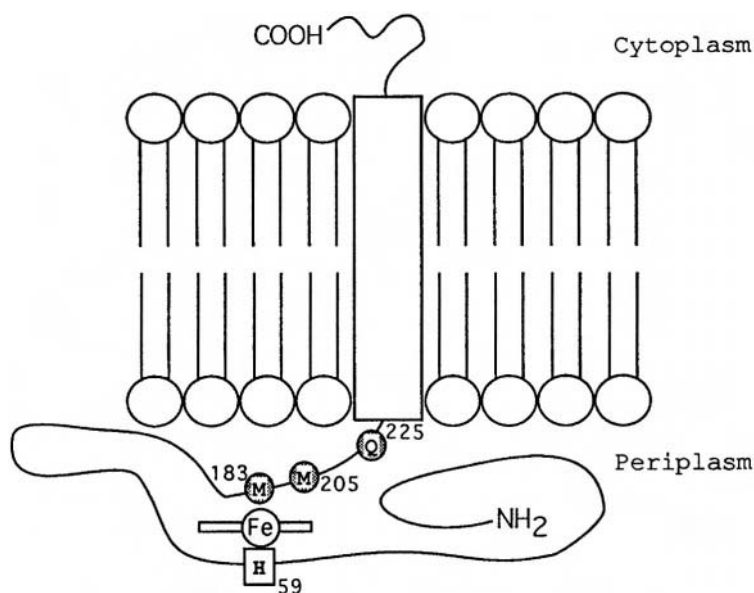

Fig. 6. Folding model of the Cyt *c*₁ polypeptide showing the putative single transmembrane α -helix and the sites of site specific mutations constructed in both *Rb. capsulatus* and *Rb. sphaeroides*. Histidine 59 shown in the box is the fifth axial ligand to the heme Fe, and the circled residue are positions that have been altered by mutagenesis.

may not be present in that polypeptide (Schütz et al., 1993), and it has even been proposed that this helix, in those cases where it exists, may not be entirely transmembranous (Cramer and Trebst, 1991).

It should be noted that although several speculative models for specific portions of each of the subunits have been successfully developed in recent years no crystallography-based direct structural data are yet available for any of them with the exception of the hydrophilic portion of Cyt *f* of turnip chloroplast Cyt *b*₆*f* complex (Martinez et al., 1992, 1994). Unfortunately, the poor homology between Cyt *f* and Cyt *c*₁ may limit the direct application of this important information to the analogous subunits of bacterial and mitochondrial complexes.

II. Mutational Approaches

A combination of molecular genetics to obtain desired mutants designed to test specific hypotheses followed by in-depth biochemical and biophysical analyses is a powerful experimental approach to obtain structural and functional information about membrane-associated complexes. This approach is being used extensively in both *Rb. capsulatus* and *Rb. sphaeroides* to address a number of issues related to the Cyt *bc*₁ complex including the steps of electron

transfer and proton translocation processes, the physicochemical properties and the assembly of the subunits, the active sites of the complex and the validity of current folding models.

A. Spontaneous Mutants

The isolation and molecular genetic characterization of spontaneous mutants has been invaluable to further our knowledge on how the Cyt *bc*₁ complex functions. R126 was one of the earliest *Rb. capsulatus* mutants known to affect electron transfer between Cyt *b* and Cyt *c*₂ (Zannoni and Marrs, 1981). A detailed biochemical analysis by Robertson et al. (1986) indicated that this mutant was kinetically impaired at the Q_o site of the Cyt *bc*₁ complex while its Q_i site function was retained. The mutation in R126 was later determined to be a single amino acid substitution, G158D, located in the transversal helix *cd* of the Cyt *b* polypeptide (Daldal et al., 1989) (Fig. 7).

Another set of spontaneous mutants that has been highly informative for the location of the Q_o site are *Rb. capsulatus* mutants resistant to the Q_o site inhibitors stigmatellin, myxothiazol and mucidin. Several of these have been isolated, and the genetic lesions conferring inhibitor resistance have been determined (Daldal et al., 1989). Similar Cyt *b* mutations have also been obtained in yeast (di Rago

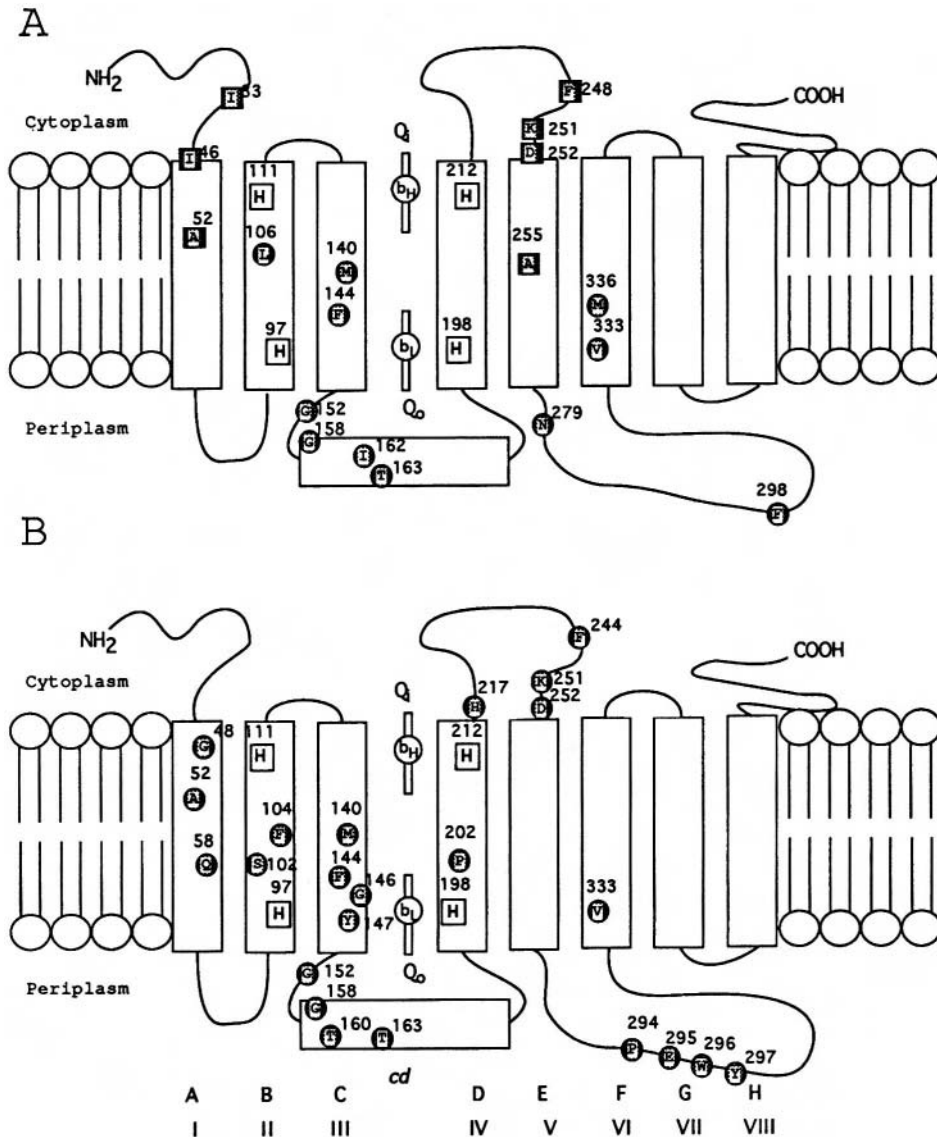

Fig. 7. (a) Eight transmembrane helix folding model of the Cyt *b* polypeptide from *Rhodobacter capsulatus*. Helices have been designated both by letter (A-H) and number (I - VIII). The four histidines (H97, H111, H198 and H212) which provide the axial ligands to Cyt *b*_L and *b*_H are in empty boxes. The filled-in boxes are the locations of spontaneous Q_i site inhibitor resistant loci from yeast and mouse mitochondria and *Rs. rubrum*. The filled-in circles are the locations of spontaneous Q_o site inhibitor resistant loci from *Rb. capsulatus* and yeast and mouse mitochondria. (b) Same as (a) except the highlighted positions are the locations of site specific mutations constructed in both *Rb. capsulatus* and *Rb. sphaeroides*.

et al., 1989) and mouse (Howell and Gilbert, 1988) mitochondria. The great majority of these mutations have been mapped to the Cyt *b* polypeptide and are distributed nonrandomly (Fig. 7a). They are clustered in two distinct domains referred to as Q_oI and Q_oII. The Q_oI region is a very small segment of the Cyt *b* polypeptide, spanning the residues 140 to 163 (in the numbering of *Rb. capsulatus*) containing part of

helix C and most of the amphipathic transversal helix *cd* while the Q_oII region is located towards the C-terminal end of Cyt *b*. In addition, one substitution (L106P) was found located on helix B between the histidines that coordinate heme *b*_H and *b*_L. Robertson et al. (1990) observed that not only was the affinity for inhibitor decreased in these mutants but there was also a weakening of the binding of the

physiological substrate, ubiquinol, at the Q_o site suggesting that the inhibitor and substrate interaction sites share common structural features. The study of the locations and the nature of the inhibitor resistant mutants has led to a speculative model for the Cyt *b* portion of the Q_o site based on the three dimensional structure of the Q_a and Q_b sites of the reaction center (Robertson et al., 1990). In addition, this region of Cyt *b* polypeptide has now been shown to bind ubiquinone by photoaffinity labeling using an azido- Q derivative (He et al., 1994).

Interestingly, not all Cyt *bc₁* inhibitors are active in the photosynthetic bacteria. Since photosynthetic growth of these bacteria is absolutely dependent on the presence of a functional Cyt *bc₁* complex (Daldal et al., 1987) it could be expected that most electron transfer inhibitors also inhibit growth. While this is true for the Q_o site inhibitors it is not the case in *Rb. capsulatus* and *Rb. sphaeroides* for the Q_i site inhibitors. This natural resistance to Q_i site inhibitors in vivo precluded the isolation of spontaneous Q_i inhibitor resistant mutants in *Rb. capsulatus* and *Rb. sphaeroides*. However it has been shown recently that the photosynthetic growth of the purple non-sulfur bacterium *Rs. rubrum* is sensitive to antimycin (Shankar et al., 1992; Uhrig et al., 1994). Antimycin-resistant mutants were isolated using this latter species and lesions responsible for the resistance were identified as the substitutions D252E and D252H (Park and Daldal, 1992; Uhrig et al., 1994). D252 is located near the beginning of helix E in close proximity to mutations conferring resistance to antimycin and diuron in yeast and mouse mitochondrial Cyt *bc₁* complex (di Rago et al., 1986; Howell et al., 1987; di Rago and Colson, 1988; Weber and Wolf, 1988; di Rago et al., 1990). The many Q_i mutations available in mitochondrial Cyt *b* are also clustered in two distinct regions, which could be called by analogy Q_{iII} , consisting of the loop extending into the cytoplasm connecting helix D and E, and Q_{iI} consisting of a stretch close to the amino terminus of the protein also extending into the cytoplasm (Fig. 7a).

B. Site-Directed Mutants

The site directed mutagenesis systems that are developed in both *Rb. capsulatus* and *Rb. sphaeroides* have two components. The first is a deletion background in which the chromosomal copy of the wild type structural genes has been eliminated using

either interposon mutagenesis as in *Rb. capsulatus* (Atta-Asafo-Adjei and Daldal, 1991), or non-replicating suicide plasmids as in *Rb. sphaeroides* (Yun et al., 1990). The use of a deletion background avoids unwanted homologous recombination events that otherwise may yield mixtures of wild type and mutant complexes and complicate the biochemical/biophysical analyses.

The second component of the genetic system is a broad host range plasmid into which the wild type structural genes have been cloned. The mutations are often generated by in vitro mutagenesis techniques and exchanged with their wild type counterparts on this plasmid. Any desired mutation can be efficiently constructed using these systems, and the growing lists of mutants of *Rb. capsulatus* (Tables 1,2 and 3) and *Rb. sphaeroides* (Gennis et al., 1993) are rather impressive. Other phototrophic species are also amenable to similar approaches, and an example is *Rp. viridis* for which a similar system to study the reaction center has recently been described (Laussermaier et al., 1992). Similar deletion and conjugation procedures also work well for the Cyt *bc₁* complex of *Rs. rubrum* (S. Y. Park and F. Daldal, unpublished results) for which genetic systems are also developed to study the reaction center (Hessner et al., 1991), CO dehydrogenase (Kerby et al., 1992) and ribulose biphosphate carboxylase (Hartman et al., 1987).

1. Cytochrome *b* Mutants

Figure 7b and Table 1 show the locations and effects of site directed mutations that are currently available in the Cyt *b* polypeptide, and are grouped into different classes as described below.

a. Q_o site

The majority of the initial work on the Q_o site has been geared towards defining the regions of Cyt *b* affecting UQH_2 oxidation. Clues to the approximate location of the site have come from earlier analyses of spontaneous inhibitor resistant mutants (see above) and the non-photosynthetic mutant of *Rb. capsulatus* R126. One position chosen for detailed study was G158. This site yields a Cyt *bc₁* complex defective in the Q_o site when substituted with aspartate in bacteria (Robertson et al., 1986), or a myxothiazol resistant complex when substituted with alanine in mouse mitochondria (Howell et al., 1988). To define the role

Table 1. Selected Cytochrome *b* Mutants of *Rhodobacter capsulatus*¹

FbcB : F144R ⁸	Ps ⁻	10 ⁻⁷	na	(FBC) ⁺	< 5	Q _o site occupied, a novel EPR <i>g_x</i> signal for FeS seen; no or little QH ₂ oxidation.
FbcB : G152P ⁸	Ps ⁻	10 ⁻⁷	na	(FBC) ⁺	< 5	No detected Q/QH ₂ binding change by EPR <i>g_x</i> signal of FeS; no or little QH ₂ oxidation.
FbcB : G158X ⁷	Ps ⁻	10 ⁻⁷	na	(FBC) ⁺	< 10	Q _o site occupancy is defective; No or little QH ₂ oxidation.
FbcB : T163F, P ⁸	Ps ⁻	10 ⁻⁴ –10 ⁻⁵	na	(FBC) ⁻	0	No subunit of the complex detected in the membrane under steady state growth.

¹ Data from Daldal et al., 1989; Robertson et al., 1990; Ding et al., 1992; Tokito & Daldal, 1993 and Ding et al., unpublished.

² Ps⁺ and Ps⁻ correspond to the photosynthetic growth ability of the mutants on rich medium.

³ Rev indicate the approximate reversion frequency of the mutants to Ps⁺ phenotype; na, not applicable.

⁴ Inh, inhibitor resistance pattern; S and R correspond to Ps⁺ growth ability of the mutants in the presence of My (myzothiazol, 5 × 10⁻⁶ M) and St (stigmatellin, 4 × 10⁻⁶ M).

⁵ Steady state presence (+) or absence (-) of the FeS protein (F), Cyt *b* (B) and Cyt *c*₁ (C) in chromatophore membranes probed immunologically.

⁶ DBH: Cyt *c* reductase activity of chromatophore membranes indicated as a % of that of a wild type strain overproducing Cyt *bc*₁ complex (typically between 3,800 to 5,400 nmol of Cyt *c* reduced/min/mg of protein), nd, not done.

⁷ See Atta-Asafo-Adjei and Daldal (1991) for a list of the G158x substitutions.

⁸ See Tokito and Daldal (1993) for other substitutions in these positions.

of position 158 Atta-Asafo-Adjei and Daldal (1991) substituted it with fifteen different amino acid residues, and observed that all but the A and S substitutions had lower Cyt *c* reductase activities and failed to support photosynthetic growth. While a glycine in this position allows free access of both ubiquinol and myxothiazol into the Q_o site, substitutions with side chains like -CH₃ (A) or -CH₂OH (S) hinders the access of myxothiazol and confers inhibitor resistance. Based on these facts it was proposed that side chains larger than methyl and hydroxymethyl at this position exclude the substrate and lead to nonfunctional mutants. More recent data obtained by EPR spectroscopy, using the [Fe₂S₂] cluster g_x signal to monitor the occupancy of the Q_o site in these mutants, further confirmed this finding (Ding et al., 1992; Ding et al., unpublished).

Other positions in Cyt *b* conferring resistance to Q_o specific inhibitors were also mutagenized extensively (Tokito and Daldal, 1993). These include M140, F144, G152, T163 and V333. All, except for V333, are located in the Q_oI region either in transmembrane helix C or in the *cd* amphipathic helix. In contrast to G158 mutants, most of these mutations yielded photosynthetically competent strains with, however, perturbed rates of UQH₂ oxidation and modified inhibitor recognition. At position 140 the presence of a methyl group on the β carbon atom correlated with myxothiazol and stigmatellin resistance, while position 144 required an aromatic residue to yield a myxothiazol-sensitive Cyt *bc*₁ complex with a high turnover rate (Tokito and Daldal, 1993). An extension of this work has now shown that mutations at positions 158 and 144 perturb the binding of substrate to both the Q_{ow} and Q_{os} domains (Ding et al., unpublished), and the study of these mutants has led to a correlation between the occupancy of the Q_o site (as determined from EPR of the [Fe₂S₂] cluster) and the rate of turnover of the site. On the other hand positions 163 and 333 do not appear to define strong interaction points with myxothiazol though they affect stigmatellin resistance.

Furthermore some mutations at T163 affect the assembly of the complex and in particular the T163F and P mutants are devoid of the three subunits of the Cyt *bc*₁ complex (Tokito and Daldal, 1993). It was proposed that T163 provides a contact point between the subunits based on the fact that suppressors of T163F were found in the other subunits of the complex (see below). This finding was used to orient the

transversal helix *cd* in such a way that the face containing T163 is turned away from the protein interior, thus positioning G158 toward the protein interior of Cyt *b* as proposed earlier (Robertson et al., 1990). Crofts et al. (1992) have also predicted a similar orientation for helix *cd* in a computer generated model of the topology and folding of Cyt *b*. Thus the steric restraints on the residues occupying positions 152 and 158 can be understood since the side chains would project into the UQH₂ binding pocket. More recent work on positions Y147 and T160 are also consistent with this orientation (S. Saribas and F. Daldal, unpublished results).

The loop connecting helix E and F contains the highly conserved -PEWY- span (Hauska et al., 1988). Mutations at these sites in *Rb. sphaeroides* cause a decrease in the rate of UQH₂ oxidation at the Q_o site (Crofts et al., 1992; Table 1). For example the substitution E295Q decreased the rate of Q_o turnover by a factor of approximately 50, but did not prevent photosynthetic growth under laboratory conditions. Considering that the midpoint potential of Cyt *b*_L is more positive in most of the -PEWY- mutants and that some substitutions also confer resistance to Q_o specific inhibitors, it was proposed that this portion of Cyt *b* is also involved in the interaction with UQH₂ at the Q_o site.

b. Ligands of the Cyt b hemes

Mutagenesis of Cyt *b* in *Rb. capsulatus* and *Rb. sphaeroides* has also involved the residues H97, H111, H198 and H212 (Fig. 7), proposed to be the ligands of Cyt *b*_H and *b*_L hemes (Widger et al., 1984; Saraste et al., 1984). These residues were altered in *Rb. sphaeroides* to amino acids unable to coordinate metal ions, and it was shown that all are absolutely essential for photosynthetic growth (Yun et al., 1991a). The substitutions of H111 and H212 led to the selective loss of Cyt *b*_H while those of H97 and H198 resulted in the loss of both hemes. Similar data were also obtained for H212 mutants in *Rb. capsulatus* (F. Daldal, unpublished data). These findings indicated that H212 and H111 are ligands to Cyt *b*_H and H97 and H198 are ligands to Cyt *b*_L. This assignment is totally consistent with the eight transmembrane helices model of Cyt *b*, and indicated that the Q_o site stays fully functional even when Cyt *b*_H is selectively destroyed (Yun et al., 1991a). The opposite of this finding has been seen with R126 where the G158D mutation selectively inactivates the Q_o site while

leaving the Q_i site intact (Robertson et al., 1986). These experiments thus provide clear support for the remarkable functional independence of the quinone interaction sites.

c. Q_i site

Several highly conserved residues thought to be in the vicinity of the Q_i site have been altered (Yun et al., 1992; Crofts et al., 1992; Hacker et al., 1993; Gray et al., 1994). These positions were chosen based on the known location of spontaneous inhibitor (antimycin, diuron and funiculosin) resistant mutations in mitochondrial Cyt *b*, and on their universal conservation in Cyt *b* polypeptides from many phylogenetically different species (Degli-Esposti et al., 1993). The high resolution structure of the quinone binding sites from the *Rb. sphaeroides* photosynthetic reaction center also offers clues to deciphering analogous interactions that may occur between the quinone moiety and the Cyt *b* polypeptide (Allen et al., 1988). In this respect, the Q_b site of the reaction center appears to be a good model for the Q_i site since both sites catalyze similar redox chemistry. Of particular interest is the finding that in the reaction center H190 and S223 of the L-subunit form hydrogen bonds with the quinone carbonyl groups at the Q_b site.

The main effect of the mutations in this region of Cyt *b* is an inhibition of re-oxidation of Cyt b_H following flash activation. This kinetic defect accounts for the observation that these mutants are impaired to various degrees for their photosynthetic growth (from no growth to slow growth). Further, some of these mutations also affect the amount of Cyt b_{150} which is postulated to be a high potential form of Cyt b_H due to a redox interaction between the heme and the quinone bound at the Q_i site (de la Rosa and Palmer, 1983; Salerno et al., 1989; Rich et al., 1990). The increased amount of Cyt b_{150} in those mutants suggested that the interaction of the protein with the quinone bound at the site has been perturbed. Redox titrations of the antimycin sensitive semiquinone have shown that mutations at H217 either highly destabilized (L and D substitutions) or over-stabilized (R substitution) the semiquinone with essentially the same phenotypic effect (Gray et al., 1994). Recent ENDOR data have suggested that the semiquinone at Q_i interacts with the protein via hydrogen bonds, and that the protons of these bonds are exchangeable

with the medium (Salerno et al., 1990). Further, these authors suggest that these interactions could be strong enough to account for the stabilization of the semiquinone, thus modulating the thermodynamic properties of the bound quinone. It was therefore proposed that H217 may, in a manner analogous to H190 of the L-subunit of the reaction center, form a hydrogen bond with the quinone at the Q_i site (Gray et al., 1994). Obviously, a better picture of the quinone binding pocket as well as a detailed kinetic model of quinone catalysis at the Q_i site will emerge as more work is performed in this region of Cyt *b*.

d. Other Regions of Cyt *b*

Some of the other highly conserved Cyt *b* residues have also been altered with the hope of discovering their basis of conservation (Yun et al., 1992). However none of the positions tested thus far appears to be absolutely essential for a functional Cyt *bc*₁ complex. For example, F104 is located in helix B between the two sets of axial ligands to the two hemes and is often modeled to project between them. It is conserved in most Cyt *b* sequences, with the exception of Cyt b_6 from chloroplasts, and Cyt *b* from some protozoans. It had been suggested that the rate of electron transfer between Cyt b_L and b_H may be enhanced by the presence of this aromatic residue (Widger et al., 1984). However, Yun et al. (1992) replaced F104 with I and observed minimal effects on the rates of electron transfer within the Cyt *bc*₁ complex, suggesting that F104 does not function in the rate-determining step of electron transfer.

Another example is P202, which is the only conserved proline within a transmembrane helix (D) in the Cyt *b* polypeptide. The presence of a proline would be expected to change the hydrogen bonding patterns in the helix and may participate in proton translocation via a *cis-trans* isomerization (Brandl and Deber, 1986). However replacement of P202 with the helix-favoring amino acid leucine had only minor effects on the properties of the Cyt *bc*₁ complex (Yun et al., 1992). These examples suggest that conservation of a particular amino acid alone is not sufficient to indicate that it has a specialized role for the function of the Cyt *bc*₁ complex.

2. Rieske Iron Sulfur Protein

On the basis of proteolytic cleavage, the C-terminal

region of the Rieske protein has been implicated in the binding of its [Fe₂S₂] cluster (Li et al., 1981b). This region of the protein contains two groups of highly conserved residues, called box I (CTHLGC) and box II (CPCHGS). In *Rb. capsulatus* these correspond to residues C133 to C138 and C153 to S158 (Fig. 4c). Each box contains two cysteines and one histidine, residues thought to coordinate the cluster. However, considering that the [Fe₂S₂] cluster requires only two N and two S ligands (Gurbiel et al., 1991; Britt et al., 1991) the number of conserved potential ligands exceeds the number needed. Each potential ligand in box I and box II (as well as a non-conserved H159 next to box II and the G137 in box I) have been altered by site directed mutagenesis

(Table 2; Davidson et al., 1992a; van Doren et al., 1993a). Mutations of H159 did not affect the properties of the cluster or the assembly of the complex, and it was concluded that H159 is not a ligand (Davidson et al., 1992a). Substitution of G133 in *Rb. sphaeroides* (G137 in *Rb. capsulatus*) to aspartate yielded a photosynthetically competent strain, but interestingly, with a decreased turnover rate of the Q_o site (van Doren et al., 1993a). On the other hand mutations of either H135 or H156 in *Rb. capsulatus* (and the corresponding residues in *Rb. sphaeroides*) resulted in photosynthetically incompetent strains, and led to the loss of the cluster and degradation of the mutant FeS subunit. It was concluded from these data that the imidazole rings of

^{2,3,4,5} and ⁶ See Table 1 footnotes.

H135 of box I and H156 of box II provide the nitrogenous ligands to the cluster (Fig. 5).

Of the four cysteines mutagenized only C138S (Ohnishi et al., 1993) and C155S (Davidson et al., 1992a) contained a very small amount of a perturbed $[\text{Fe}_2\text{S}_2]$ cluster detectable by EPR, suggesting that these residues are not ligands. Substitutions of the remaining two cysteines (C133 and C153) resulted in a loss of the cluster and very small amounts of detectable apoprotein (Table 2). Sequence comparisons of the *Rb. capsulatus* FeS protein with 'Rieske-type' $[\text{Fe}_2\text{S}_2]$ cluster-containing dioxygenase proteins also suggested that the non-conserved C138 and C155 residues are not the ligands to the $[\text{Fe}_2\text{S}_2]$ cluster (Davidson et al., 1992a; van Doren et al., 1993a), thus leaving C133 and C153 as possible ligands. Considering that substitutions at C155 and C138 highly perturbed the assembly of the complex it was further suggested that they may form a disulfide bond which is essential for the structure of the wild type protein. The overall data has led to a folding model of the binding pocket of the $[\text{Fe}_2\text{S}_2]$ cluster in *Rb. capsulatus* (Fig. 5) (Davidson et al., 1992a). On the other hand, it should be noted that other residues were also proposed as ligands in other systems (Graham and Trumpower, 1991), and the exact nature of the ligands of the $[\text{Fe}_2\text{S}_2]$ cluster has not yet been unequivocally established.

3. Cytochrome c_1 Mutants

Mutagenesis of Cyt c_1 has been geared towards two main goals. One was the identification of the amino acid residue that provides the sixth ligand to the heme Fe. Data from magnetic circular dichroism of Cyt c_1 from mitochondria are consistent with histidine-methionine ligation (Simpkin et al., 1989).

Further, sequence alignments of Cyt c_1 from different species reveal the presence of two highly conserved methionines (M183 and M205 in the numbering of the mature *Rb. capsulatus* protein) near the C-terminal portion of the protein (Fig. 6). Both M183 and M205 have been altered to non-liganding aliphatic residues (M183L and M205V) in Cyt c_1 from *Rb. capsulatus* (Table 3; Gray et al., 1992). The substitution M205V caused no growth defect, and had very minor effects on the enzymatic activity of the Cyt bc_1 complex whereas the substitution M183L had quite drastic effects. The strain containing this mutation was Ps^- while the entire complex was still present in the membrane. Redox titrations of purified complex indicated that the E_{m7} value of the mutant Cyt c_1 was decreased by approximately 390 mV (to -70 mV) as compared to wild type ($E_{m7} \approx 315$ mV). Interestingly while the isolated Cyt c_1 could bind CO its absorption spectrum indicated that it was still at least partially low spin. This suggests that if M183 is indeed the ligand in the wild type protein yet another residue that can be displaced by CO could replace it in the ligation sphere. These results suggest that M183 is more likely than M205 to be the sixth ligand of the heme Fe, and a similar analysis in yeast (Nakai et al., 1990) has also come to the same conclusion. However, this assignment needs to be confirmed by direct structural analyses, especially in light of the recent structure of Cyt f which indicated that the N-terminal amino group of this protein is the sixth ligand of its heme Fe (Martinez et al., 1992, 1994).

A second focus of mutagenesis in Cyt c_1 has been to isolate a truncated, non-membrane anchored form which may be more readily crystallized (Table 3). For this purpose, Konishi et al (1991) engineered a stop codon at position 228 (Q) in *Rb. sphaeroides* Cyt c_1 right before the putative transmembrane anchor,

⁷ *** indicates the presence of a stop codon at position 205.

and were able to detect traces of a soluble form of Cyt *c*₁ which could still donate electrons to Cyt *c*₂. In this mutant, a small amount of a crippled Cyt *bc*₁ complex with relatively unperturbed [Fe_2S_2] and Cyt *b*_H was also detected, suggesting that the absence of Cyt *c*₁ does not entirely destroy the essential architecture of these subunits. On the other hand a similar mutation in *Rb. capsulatus* Cyt *c*₁ as well as an internal deletion eliminating its heme binding site (from residue 32 to 159) has not led to the production of any truncated derivative of Cyt *c*₁ (Gray et al., 1992). This finding suggests that both the signal sequence and bound heme appear necessary for effective translocation of Cyt *c*₁ across the membrane and its insertion into the lipid bilayer.

4. Assembly/Subunit Interaction Mutants

a. Partial Cyt *bc*₁ Complexes

During the characterization of FeS protein mutants it was observed that the cytochromes *b* and *c*₁ were fully present in the intracytoplasmic membranes of *Rb. capsulatus* mutants containing little, or no FeS apoprotein (Davidson et al., 1992a). Further characterization of these mutants have shown that a stable subcomplex with a functional Q_i site could be formed in the absence of a Q_o site (Davidson et al., 1992b). To further examine the stabilizing interactions among the three subunits of the Cyt *bc*₁ complex in the membrane, additional strains which contained deletions of the *fbcFBC* genes in various combinations were obtained. These mutants contained both Cyt *b* and *c*₁ in the absence of the FeS protein in the membrane, consistent with the point mutations affecting box I and box II of the latter subunit. However in the absence of Cyt *c*₁ very little of the remaining subunits were detected, leading to the suggestion that Cyt *c*₁ and Cyt *b* must somehow interact and protect each other from degradation (Davidson et al., 1992b).

Recently Van Doren et al. (1993b) have succeeded in expressing low amounts of the FeS protein in *E. coli* and *Rb. sphaeroides* in the absence of the other two subunits. When the subunit was expressed alone in either *Rb. sphaeroides* or *E. coli* it was located in the cytoplasmic membrane and contained a Rieske-like cluster but with aberrant EPR properties. Further, stigmatellin did not affect the EPR spectrum of the cluster in the absence of the other two subunits. Finally, truncation of the putative transmembrane

anchor by limited proteolysis resulted in a water soluble form of the FeS protein retaining the [Fe_2S_2] cluster. These studies suggested that the Rieske protein is anchored to the membrane via a single transmembrane helix which may interact with helices of the other subunits.

b. Suppressors of a Cyt *b* Mutant

During a systematic analysis of the role on inhibitor recognition and quinol catalysis of the previously defined Q_o-inhibitor positions, two mutations in the Q_oI region of Cyt *b*, T163F and T163P, have been found to affect drastically the overall assembly and in vivo stability of the Cyt *bc*₁ complex (Tokito and Daldal, 1993). Chromatophore membranes of the strains carrying these mutations were devoid of any of the three subunits of the complex. Further, the Ps⁺ phenotype of these mutants was rather unstable, and reverted to a Ps⁺ phenotype very frequently. The basis of the severe effect of these mutations on the assembly and in vivo stability of the Cyt *bc*₁ complex is not clear. However, considering that the 'Rieskeless' mutants of *Rb. capsulatus* can still form a two subunit Cyt *bc*₁ subcomplex the data suggest that these mutations must severely disrupt subunit interactions around the Q_o site. In fact analyses of the Ps⁺ revertants of the T163F mutation indicated that there are at least three genetically different classes of suppressors overcoming its deleterious assembly effect (Tokito and Daldal, in preparation). While one class affects another Cyt *b* residue close to T163 (G182T mutation) two other classes are located in Cyt *c*₁ (R46C) and in the FeS protein (A46T), close to their respective N-terminal regions. If the effect of these suppressor mutations is direct then these findings suggest that the amino terminal domains of these two latter subunits must be close to the Q_oI region of Cyt *b* and contribute to the formation of the Q_o site. The isolation and analysis of more mutations with similar effects are needed to further define the subunit interactions in the Cyt *bc*₁ complex.

III. Conclusions and Perspectives

The Cyt *bc*₁ complex is a paradigm for redox-driven proton translocation and the combination of multidisciplinary approaches including molecular genetic, biochemical and biophysical studies have led in recent years to substantial progress in our

understanding of the structure, function, genetic organization and physiological importance of this enzyme. In particular, our knowledge has been greatly increased by the ever growing set of structural genes from many different organisms. This database now allows meaningful structural and functional comparisons and also points to the possible steps during the evolution of this complex. The primary sequences of the subunits have led to more accurate secondary structural models and to the identification of the ligands for the metal cofactors that have been probed by mutagenesis. Currently while the ligands to Cyt b_L and b_H are known with some confidence strong contenders for the sixth axial ligand of Cyt c_1 and the possible ligands for the $[\text{Fe}_2\text{S}_2]$ cluster of the FeS protein have also been found. The tentative identification of these ligands now raises several other crucial questions. For example, how the protein environment modulates the redox and spectroscopic properties of these metal clusters.

The extensive work using both spontaneous and site directed inhibitor resistant mutants has been very informative in globally defining the regions involved in the interaction with UQH_2 at the Q_o site as well as in establishing the topology of the transmembrane helices of Cyt b . A better picture of the architecture of the Q_i site and the role of the Cyt b residues stabilizing the semiquinone is also beginning to emerge. Working models for the Q_o and Q_i sites are being developed using analogies with the quinone binding sites of the photosynthetic reaction center. Yet, the roles of amino acid residues located in the vicinity of these sites need to be analyzed in depth to define their contributions to the different steps of the catalytic cycle. Although there are a number of mutants now available it should be noted that only 27 positions out of 437 of Cyt b have been probed by mutagenesis with often only one or just a few substitutions at each position. Further, several other areas of Cyt b still need to be explored, in particular very little information is available about the last two transmembrane helices G and H. To date, mutagenesis has been limited to single site changes, and undoubtedly, future experiments could use a judicious combination of multiple, and perhaps large scale, substitutions similar to those currently being carried out in other systems. Finally, the characterization of second site revertants of Ps^- mutants has only been initiated very recently, and has already been extremely informative about the crucial subunit interactions in the complex. Until now while most of

the work has been focused on the Cyt b subunit, comparatively little effort has been devoted to the Rieske FeS protein and Cyt c_1 .

Currently our knowledge about the biogenesis and assembly of the Cyt bc_1 complex is rudimentary at best. In the bacterial case, while we now realize the importance of the in vivo stabilizing interactions between some subunits we are still in the dark about the temporal order of assembly of the subunits, their translocation across the cytoplasmic membrane and the incorporation of their prosthetic groups during biogenesis and maturation. Another important direction for future work could be the issue of unifying the different Cyt bc_1 /Cyt b_6f variants of the oxidoreductases encountered in nature. While there are some distinct differences between these complexes, they catalyze the same overall charge separation processes across the lipid bilayer. Systematic attempts to convert a Cyt bc_1 structure to a Cyt b_6f structure by stepwise molecular engineering, and to analyze the implications of these cumulative mutations would be extremely informative, and attempts in this direction are already underway. Without question these future studies will be greatly enhanced with the availability of a high resolution structure for a Cyt bc_1 complex, and recently several groups have reported promising advances in this direction (Kubota et al., 1991; Yue et al., 1991; Berry et al., 1992; Yu and Yu, 1993; Kawamoto et al., 1994).

While there are so many unanswered questions related to the structure and function of the Cyt bc_1 complex, the well developed molecular genetic and biochemical/biophysical tools available in photosynthetic bacteria will certainly further our understanding of how a Cyt bc_1 complex works as a redox-driven proton pump. Further, the Cyt bc_1 complex will also continue to contribute as a model system to issues with broader implications, such as the investigation of the general phenomenon of membrane protein targeting and insertion, and the coordinated biogenesis and assembly of the multisubunit membrane complexes.

Acknowledgments

We thank our many colleagues who have graciously allowed us to refer to their unpublished work in this review and Dr. Dan Robertson for critical reading of the manuscript. Work in this laboratory is supported by NIH grant GM 38237.

Summary

The X-ray structure of the *Rhodopseudomonas viridis* reaction center has for the first time provided a detailed picture of a reaction center associated cytochrome. Guided by the domain structure visible in this atomic model of the protein, the amino acid sequence of the *Rp. viridis* subunit can similarly be divided up into the respective structurally important segments. A comparison of presently available amino acid sequences for reaction center associated tetraheme subunits in the light of this segmented structure strongly suggests that all these proteins have a common global structure.

Many experimental results obtained on a variety of tetraheme subunits prior to the *Rp. viridis* crystal structure, however, were interpreted to yield a model that looks rather different from this structure. A compilation of these results is presented and alternative interpretations are proposed. It is shown that all experimental data reported so far on tetraheme subunits can be rationalized assuming structural arrangements comparable to that of the crystal structure.

Presently available data on electron transfer properties of cytochrome subunits are summarized.

In addition to the description of tetraheme subunits found in purple and green filamentous bacteria, the possible nature of the respective reaction center associated cytochromes in green sulfur and heliobacteria is discussed.

Present ideas on evolutionary relationships (or lack thereof) among these cytochrome subunits are presented.

I. Introduction

A hypothetical young researcher who entered the subject later than in 1985 probably would have become aware of the presence of such things as reaction center (RC) associated cytochrome subunits while gazing at the glossy, multicolored pictures of the X-ray structure of the *Rhodopseudomonas (Rp.) viridis* RC (e.g. in Deisenhofer et al., 1985). Upon reading these articles, our young researcher might almost be led to believe that the RC associated cytochromes were discovered via the *Rp. viridis* crystal structure. Only occasionally will she or he come across references to older work on this subunit in *Rp. viridis* or in other photosynthetic bacteria. However, having found a way into the past along such cross references, our young scientist is likely to soon become lost in a vast labyrinth of data on RC associated cytochromes (close to a third of the articles in the reference list appeared before 1978).

The resulting confusion of our hypothetical young researcher reflects the trouble with the present state of the art on RC associated cytochromes: Since 1984, a high resolution crystal structure of the cytochrome subunit attached to the *Rp. viridis* RC is at hand and (mainly based on this structure) a wealth of data with respect to electron transfer between and properties of the four hemes within this subunit has been obtained. Nevertheless, no convincing model explaining how the cytochrome subunit functions and why it is there has yet been put forward. On the contrary, many of the results obtained on the *Rp. viridis* cytochrome actually added to the 'mysteriousness' of this protein.

However, this is only one part of the problem. The surprise of the 3-D structure of the tetraheme subunit in *Rp. viridis* was the fact that it provided a picture that looked rather different from what people had anticipated based on previously obtained data on the respective cytochrome subunits from various purple bacteria. Many of the data reported within 25 years of research on RC associated cytochromes actually seemed to contradict the structure. The incomprehensibility of these data as looked at against the background of the *Rp. viridis* structure caused a tendency to willfully ignore these discomfoting

Abbreviations: *Cb.* – *Chlorobium*; *Cf.* – *Chloroflexus*; *Cm.* – *Chromatium*; *EC.* – *Ectothiorhodospira*; E_m – redox midpoint potential; EPR – electron paramagnetic resonance; LD – linear dichroism; *Rb.* – *Rhodobacter*; RC – reaction center; *Rc.* – *Rhodocyclus*; *Ro.* – *Roseobacter*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*; *Tc.* – *Thiocapsa*

results. A wealth of information therefore lies dormant that might well contribute important clues for solving some of the riddles of the cytochrome subunits. One aim of this article is therefore to reexamine and, when necessary reinterpret these data in the light of our present knowledge based on the X-ray structure.

One might be tempted to say: 'Why bother with a superfluous appendix on an RC from a bacterium most people hadn't even noticed before it became the shooting star of photosynthesis due to the crystal structure.' It is certainly true that a few species of purple bacteria grow perfectly well without such a cytochrome subunit. However, in the world of purple bacteria presently known to the microbiologists, these are rather the exceptions than the rule (see for example Matsuura and Shimada, 1990). Even more strikingly, in all eubacterial phyla containing photosynthetic organisms (with the only exception of the cyanobacteria) the great majority of species seem to use an RC associated cytochrome as immediate reductant for the photooxidized primary donor P^+ . Several of these subunits have been proposed to be tetraheme cytochromes, evolutionarily related to each other, while the precise nature of others is under debate. Thus, the advantage conveyed by the presence of a cytochrome subunit (whatever this advantage will turn out to be) seems to be widely appreciated by photosynthetic eubacteria and the molecular evolution of the cytochrome subunits might even be related to the evolution of photosynthetic reaction centers. A second goal of this article is therefore to present an overview of presently available data concerning distribution among species, nature of the cytochromes and evolutionary relatedness.

II. A Brief History of Reaction Center Associated Cytochromes

A. RC Associated Cytochromes: A Segregating Factor in the World of Photosynthetic Bacteria

In whole cells of photosynthetic eubacteria, the photooxidizable pigment (presumably a dimer of BChls in all species) is rereduced by a secondary electron donor in the time range between 100 ns and several hundreds of μ s depending on species (see also Chapter 34 by Meyer and Donohue). This secondary electron donor can either be a soluble redox protein (mostly a small heme protein called cytochrome c_2) or it can be a membrane associated

heme protein which is additionally interpositioned between the soluble components and the photooxidizable pigment.

The phenomenon that some species only contain soluble electron carriers whereas others additionally have membrane-bound electron donors has been well studied already in the 1970s for a range of different organisms (for reviews see Dutton and Prince, 1978 and Dutton et al., 1978).

The degree of membrane-association of the non-soluble cytochromes, however, varies significantly between species. Whereas, for some species this cytochrome was retained even in highly purified RC samples (e.g. Clayton and Clayton, 1978 for *Rp. viridis*), in most species examined so far it is easily released into the aqueous phase during purification procedures (e.g. in *Rhodocyclus (Rc.) gelatinosus*, Prince et al., 1978; for a detailed study of such loss of the tetraheme cytochrome see Fukushima et al., 1988). An experimental distinction between organisms that contain and organisms that lack the RC associated cytochrome is therefore not always a trivial task (see for example the conflicting data reported for *Rp. palustris* by Kihara and Chance, 1969, Kihara and Dutton, 1979 and Matsuura and Shimada, 1986).

B. Distribution Among Species

As already mentioned in the Introduction, the occurrence of membrane-bound cytochromes serving as immediate electron donors to photooxidized P^+ is not confined to purple bacteria. In addition to the proteobacterial phylum (containing the purple bacteria, Stackebrandt et al., 1988), examples for such a situation were found in green filamentous (Bruce et al., 1982), green sulfur (Prince and Olson, 1976) and heliobacteria (Prince et al., 1985) (for a description of the classification of species presently in use see Woese, 1987; also see Chapter 1 by Imhoff).

A compilation of data concerning RC associated cytochromes reported so far in a variety of photosynthetic bacteria is given in Table 1.

C. The Tetraheme Subunits of Purple Bacterial Reaction Centers

It was observed for a number of purple bacterial species that depending on redox conditions (i.e. anaerobiosis or aerobiosis in the case of whole cells)

Spectral data on *R. photometricum*, *R. fulvum*, *R. globiformis*, *Protomonas* sp., *R. tenuis* were furthermore reported by Matsuura & Shimada (1990).

different hemes were oxidized upon illumination. This was interpreted to reflect two different populations of hemes which are both able to reduce P^+ (Parson and Case, 1970). The hemes which were in the reduced state only under anaerobic conditions (the so-called 'low potential' hemes) were able to rereduce P^+ faster than the hemes which had a higher redox potential (i.e. which were in the reduced state already under aerobic conditions). Therefore, these low potential hemes were considered to be closer to P than the high potential ones. The assumed shorter distance between the low potential hemes and the special pair also served to rationalize the phenomenon that photoinduced oxidation of the low potential hemes persisted down to the lowest temperatures attained (2K), whereas there was no stable low temperature photooxidation when only the high potential hemes were reduced prior to illumination (Vredenberg and Duysens, 1964). Below a certain temperature the kinetics of this reaction became virtually temperature-independent leading to the proposal that this low-temperature photooxidation of hemes was the first biological example of electron tunneling (DeVault and Chance, 1966; see also III.C.1.b.).

After a short period of time when numbers up to 9 hemes per RC were reported (Thornber, 1970; Thornber and Olson, 1971; Seibert and DeVault, 1970), the values obtained both spectroscopically and biochemically converged towards four hemes/P, two of which had a high (> 250 mV) and two a low (< 150 mV) redox midpoint potential (Case and Parson, 1971; Clayton and Clayton, 1978). Kennel and Kamen (1971b) demonstrated that in *Chromatium* (*Cm.*) *vinosum* the low and the high potential hemes were located on one polypeptide, thereby preparing the ground for the notion of the 'tetraheme cytochrome subunit.' No conspicuous distinguishing characteristics were observed within the pair of low potential and within the pair of high potential hemes. The four hemes were therefore considered to consist of two twins of hemes suggesting an arrangement displaying some two-fold symmetry with respect to the RC. In such an arrangement, all four hemes were considered to be able to directly reduce P^+ and it was only due to their faster donation reactions (supposedly due to their closer proximity) that the low potential hemes dominated the rereduction process once they were reduced.

This rough picture was refined into a detailed structural model based on data obtained on *Cm.*

vinosum (Tiede et al., 1978). The respective model was characterised by two symmetric pairs of hemes, i.e. one pair of low potential hemes oriented parallel with respect to the membrane and closer to P than the pair of high potential hemes considered to be oriented perpendicular to the membrane plane (see Tiede et al., 1978).

D. The 'New Age'

The scientific community was apparently satisfied with this model (or had possibly become tired of RC associated cytochromes), since from 1978 to 1985 only very few studies were published on this specific subject.

It was not before the mid-80's that the RC associated cytochromes had a glamorous comeback, promoted by major breakthroughs in two rather different fields.

1. The Impact of the Crystal Structure

One breakthrough was the crystallization and subsequent structure determination of the photosynthetic reaction center from *Rp. viridis*, a species that contained an RC associated tetraheme cytochrome (Deisenhofer et al., 1985). This structure showed that the model arrived at in 1978 for the *Chromatium* subunit had hardly anything more in common with the *Rp. viridis* structure than the total of four for the number of hemes (see section III. A. 1.). This led to the question whether the apparent inconsistencies between previous models and the structure of the *Rp. viridis* subunit were due to misleading interpretations of data or to real interspecies differences. Amino acid sequence information appeared to be a first step to address the question of relatedness between the tetraheme subunits from different organisms. Primary sequences for *Chloroflexus aurantiacus*, *Roseobacter denitrificans* and *Rubrivivax gelatinosus* have been obtained providing evidence that, at least for the tetraheme subunits from these three organisms, the global structure elements are comparable to those of the *Rp. viridis* subunit (see III.B.4.).

Furthermore, several of the species for which reported data were in conflict with the *Rp. viridis* crystal structure were reexamined yielding explanations for at least part of the obvious incompatibilities. Most conspicuously, the model featuring two twins of identical hemes was in blatant conflict with the structure of the *Rp. viridis* cytochrome subunit

showing the presence of four individual, *non-equivalent* hemes. Only when they saw the structure, spectroscopists and electrochemists went back to their experimental setups and duly found what this structure had ordered them to find, i.e. differences in spectral parameters, redox midpoint potentials and orientations between the individual hemes of each 'pair' both in *Rp. viridis* and in other species containing a tetraheme subunit (see III.A.2.a and III.B.1./2.).

Whereas in these cases, improved experimental data were required for a reconciliation with the crystal structure, in other cases a mere reinterpretation of published work might be sufficient to this end (see III.B.3.).

Independently, the advantage conveyed by the sound basis of a high resolution crystal structure attracted many research groups to perform in-depth studies of the cytochrome subunit from *Rp. viridis* with respect to spectroscopic, electrochemical and electron transfer parameters (see III.A.2. and III.C.).

2. The New Phylogenetic Landscape of the Eubacteria

The second important re-launching of research efforts on membrane associated cytochrome donors was triggered by profound changes in our conceptions of bacterial taxonomy and phylogeny. Application of approaches based on molecular biology (rRNA catalogues) and phylogenetic tree building algorithms resulted in extensive rearrangements of bacterial taxa that formerly were mainly based on morphology and ecology (Woese, 1987). Since it has been recognized during recent years that RC associated cytochromes are abundant in the world of photosynthetic organisms, these proteins have become important markers in tracing the evolutionary relationships between species and between types of reaction centers (see IV. and V.).

III. Tetraheme Cytochrome Subunits

A. The Special Case: *Rp. viridis*

1. Structure

a. The Global Structure

Since the high resolution structure of the *Rp. viridis*

reaction center including the cytochrome subunit is the topic of an entire chapter in this volume, the reader is referred to this contribution and figures therein for a general outline of the structure (see Chapter 23 by Lancaster et al.). Only features of the X-ray structure dealing specifically with the cytochrome subunit will be discussed in more detail in the following sections.

The tetraheme subunit in *Rp. viridis* consists of 336 amino acid residues, four covalently linked hemes and a covalently attached lipid molecule adding up to a molecular weight of 40.5 kDa. Whereas in the models developed prior to the *Rp. viridis* crystal structure, the cytochrome subunits were thought to be largely membrane-integral (Tiede et al., 1978; Dutton and Prince, 1978; Prince, 1978), the cytochrome seen in the crystal structure appears as an oblong soluble protein which was stuck at one of its ends to the periplasmic surface of the membrane-integral RC core (i.e. the L- and M-subunits, Fig. 1). The interaction surface of the cytochrome subunit with the RC-core amounts to approximately 15 % of the cytochrome's total surface, the remainder being exposed to the aqueous phase of the periplasmic space. The oblong protein harbors the four heme groups which are arranged in a roughly linear row spanning a large part of the periplasmic space and pointing from the far end of the cytochrome subunit right towards the special pair (for the arrangement of the cofactors in the RC, see Chapter 23 by Lancaster et al.). This again is a major difference to the previously assumed two similar, parallel pathways each containing one high and one low potential heme.

The row of hemes breaks the C_2 -symmetry of the RC core's redox centers being inclined by about 30° with respect to the membrane normal. Parts of the cytochrome subunit, however, display an internal C_2 -symmetry with respect to an axis not far from parallel to the membrane plane (see below).

The four hemes in the subunit can be identified either by order of distance from the RC, i.e. heme 1 being closest to the special pair etc., or by the position of the respective heme binding motifs (CXXCH) in the primary sequence. Both conventions are currently in use. To avoid confusion, Roman numerals will be used in the following sections to denote the sequence based, whereas Arabic numerals denote the structure-based nomenclature. Fig. 1a defines the relationship between both systems.

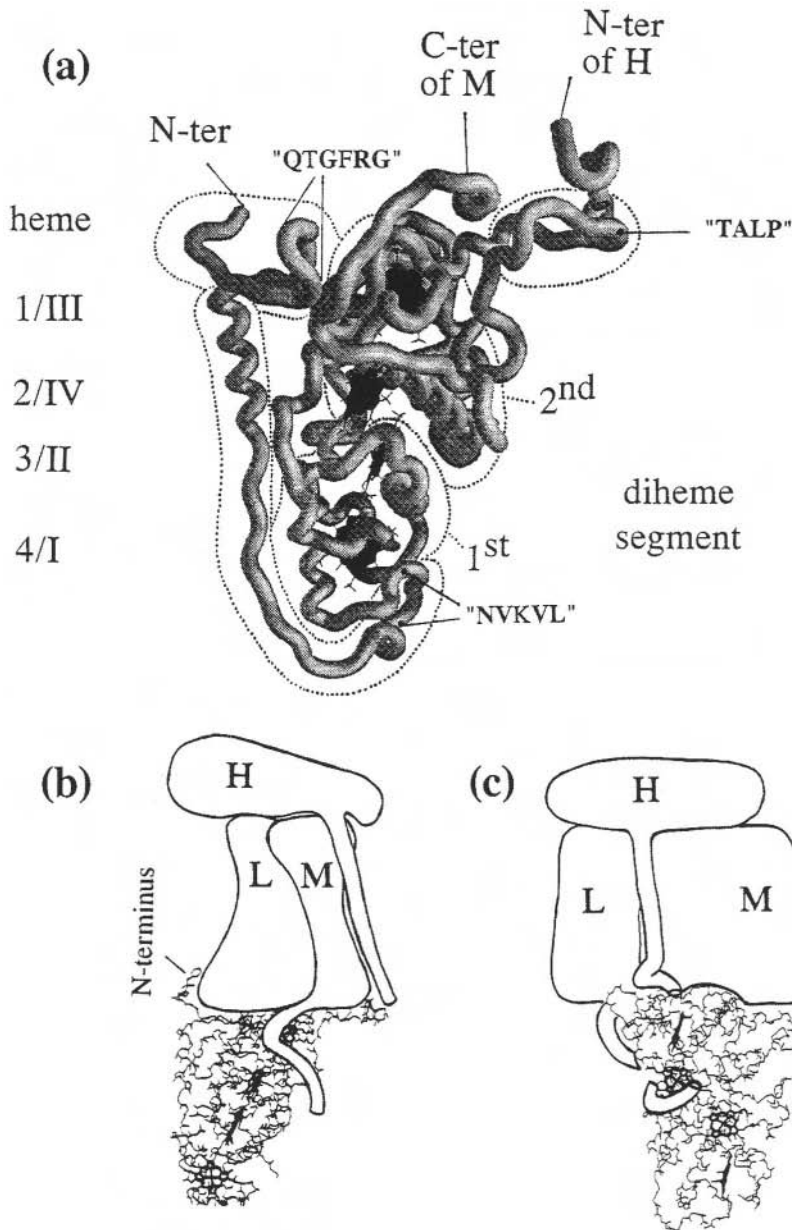

Fig. 1: Molecular models of the tetraheme subunit associated to the *Rp. viridis* reaction center. (a) defines the structure elements referred to in the text and used for the layout of the sequence comparison in Fig. 4. Only the α -carbon backbone and the four heme groups are included. Structurally important (and conserved) peptides are shown in between quotation marks. Arabic numerals refer to increasing distance from the primary donor and Roman numerals follow the heme order within the amino acid sequence as referred to in the text. Note that the pieces of protein backbone labeled 'C-ter of M' and 'N-ter of H' are clipped-off parts of the M- and H- subunits, respectively. (b) and (c) depict the structural association of the cytochrome subunit with the other subunits in the reaction center, viewed from two directions parallel to the plane of the membrane and perpendicular to each other. (a) was produced by S. Grzybek (Freiburg) using the program GRASP developed by A. Nicholls and B. Honig, whereas (b) and (c) were constructed on a PC using the pdViewer software by H.H. Robinson and A.R. Crofts.

b. Breakdown into Structure Elements

As has been pointed out by Deisenhofer et al. (1985),

parts of the tetraheme subunit can be superpositioned onto one another via a C_2 -symmetry operation. Hemes 4/I and 3/II superimpose on hemes 1/III and 2/IV,

respectively, when the lower half of the cytochrome subunit is turned up by 180° about the C_2 -symmetry axis. Equally, the α -helices providing ligands to hemes 4/I and 3/II can be mapped onto the respective parts of the protein surrounding hemes 1/III and 2/IV, respectively. Thus, it appears as if the central part of the tetraheme subunit was made up from two similar building blocks (each of which contains two hemes), arranged in C_2 -symmetry with respect to each other. This symmetry seen on the structural level finds its expression also on the level of the primary sequence of the *Rp. viridis* tetraheme subunit (Weyer et al., 1987a), since higher sequence homologies have been found between the heme-binding regions of the pairs I/III and II/IV than between all other possible pairs.

In addition to the C_2 -symmetric parts liganding the heme groups, the following structural elements (Fig. 1a) can be distinguished (note that in the following discussion of structurally important sequence stretches, the numbering for the protein including the presequence will be used; in this numbering, the mature protein starts at residue number 21).

At the N-terminal end of the protein, the first 24 amino acid residues (residues 21 to 44) run roughly parallel (containing a β -sheet region) to the membrane plane in contact with the L-subunit. Between residue 45 and residue 65, the chain protrudes vertically away from the membrane towards the far end of the subunit. After winding around the bottom of the protein between residues 66 and 82, the chain enters the C_2 -symmetric part discussed above, liganding hemes 4/I and 3/II. This first 'diheme segment' is followed by a long stretch that is not part of the symmetric structure but links the two symmetric segments. Within this sequence stretch, the chain winds back to the periplasmic surface of the RC core and forms a large loop along the plane of the membrane (residues 222–244) in close contact with the M-subunit. From residues 245 on, the second diheme segment is formed and the C-terminal end of the protein disappears in mystery since the last four residues are apparently disordered and do not yield attributable electron density in the structure (Deisenhofer and Michel, 1989).

However, the C_2 -symmetry between the two diheme segments is broken when it comes to the 6th ligand of

Fig. 2: Molecular models of the contact region between the two individual diheme segments in the cytochrome subunit from *Rp. viridis* viewed from directions approximately parallel to the plane of the membrane and mutually perpendicular. Only a few relevant residues (as referred to in the text) have been added to the backbone model. Dotted lines represent bonds from 5th and 6th ligands to the heme irons. The models were produced as detailed for Fig. 1a.

heme 2/IV. An α -helix providing the 6th ligand, a methionine, in the case of hemes I, II and III, is also present in the equivalent position close to heme 2/IV, however, the only methionine (Met 293) in this helix is one helix-turn too far to serve as a ligand for the iron (Fig. 2a,b). Instead, this role is taken over by a histidine residue (His 144) situated on the first diheme segment and within the sequence stretch liganding heme 3/II, i.e. the neighboring heme in the direction of the far end of the subunit. This altered ligation pattern for heme 2/IV has important consequences for the functional properties of the *Rp. viridis* subunit, as will be detailed below.

c. Attachment to and Interactions with the Core of the RC

A rather unusual structural element participating in the attachment of the cytochrome subunit to the membrane is the so-called lipid-anchor. Weyer et al. (1987b) demonstrated that the N-terminal cysteine residue of the mature protein was covalently linked to a diglyceride. Furthermore, the precursor protein (the sequence of which was deduced from the DNA-sequence of the gene; Weyer et al, 1987a) contained a stretch of amino acids around the N-terminus of the protein (residues 17 to 21) which is known as a recognition site for signal peptidase II, a protease that specifically cleaves presequences before lipid-modified cysteines in many bacterial lipoproteins (Weyer et al., 1987a). As can be seen in Figs. 1a and 1b, the N-terminus is close to the plane of the membrane. Since this N-terminus furthermore contacts the membrane at the very periphery of the core of the RC (Fig. 1b), the fatty acids attached to the terminal cysteine seem to be inserted into the membrane to become part of the lipid bilayer. Accordingly, no electron density attributable to the lipid anchor is seen in the X-ray structure (Deisenhofer and Michel, 1989), indicating that the two fatty acids are disordered in the membrane. The lack of specific interaction of the lipid anchor with other parts of the RC makes it rather unlikely that it contributes significantly to the well-determined geometry of the cytochrome-RC complex.

The N-terminal segment consisting of 25 residues is mainly in contact with the L-subunit of the reaction center, whereas the loop region (residues 222–244) connecting the two diheme segments touches the M-subunit but also reaches out of the circumference of the RC core at the periplasmic surface of the

membrane contacting (with the ‘TALP’-sequence) the H-subunit at its N-terminal residues (Fig. 1a,b).

In contrast to this very local interaction between the cytochrome and the H-subunit, a rather extended interaction surface exists between the cytochrome and the C-terminal 20 residues of the M-subunit which run along one side of the cytochrome away from the membrane plane down to a level between the 2nd and the 3rd heme. The sequence segment between residues 276 and 286 of the cytochrome subunit (i.e. the region between the heme binding cysteines of heme 1/III and the flanking α -helix of heme 2/IV) is virtually clamped to the membrane via these 20 N-terminal residues of the M-subunit (Fig. 1a-c).

It is of note, that in *Rhodobacter (Rb.) sphaeroides*, *Rhodospirillum (Rs.) rubrum* and *Rb. capsulatus*, that are all species lacking an RC associated cytochrome, the polypeptide chain of the M-subunit terminates about 20 residues earlier and therefore the respective stretch reaching out into the periplasmic space to grab the cytochrome is missing. By contrast, all M-subunits from purple bacteria that contain the cytochrome subunit and that have been sequenced so far, possess the C-terminal extension. Thus, the (admittedly small) statistical sample of some half a dozen examples presently indicate that the presence of the RC-attached cytochrome subunit and the M-terminal extension are correlated in purple bacteria.

2. Redox Properties

a. The Equilibrium Redox Midpoint Potentials of the Four Hemes

By 1976, it had become clear that there were four hemes functionally associated to the *Rp. viridis* reaction center (Case et al., 1970; Thornber and Olson, 1971; Cogdell and Crofts, 1972; Prince et al. 1976). The high and the low potential hemes, designated Cyt c_{558} and c_{553} , were found to titrate as identical pairs at E_m -values of about +340 mV and –10 mV, respectively, in dark equilibrium redox titrations (Thornber and Olson, 1971). The arrangement of the hemes seen in the X-ray structure (Fig. 1), however, made such a situation hard to believe, since no obvious pairs of identical hemes could be seen in the cytochrome. A subsequent reexamination of the spectral and electrochemical properties of the cytochrome subunit from *Rp. viridis* yielded distinct α -band absorption wavelengths, vibrational spectra

and E_m -values for each of the hemes of the former two 'pairs' (see Table 1; Dracheva et al. 1986; Shopes et al. 1987; Dracheva et al. 1988; Nabadryk et al. 1991). These individual E_m -values have since been confirmed by several independent studies using various different methods (Nitschke and Rutherford 1989; Fritzscht et al. 1989; Alegria and Dutton 1991b; Fritz et al. 1992). Values obtained in these studies are within ± 20 mV of the midpoint potentials first obtained by Dracheva et al. (1988). This range of measured values, however, seems to be at least in part due to using differently treated materials rather than reflecting experimental error. An investigation of the influence of detergents on the E_m -values of the hemes has been presented by Alegria and Dutton (1991a).

In a next step, these four individual, spectrally and electrochemically distinguishable hemes had to be related to the hemes seen in the X-ray structure. The most obvious choice was to arrange the hemes by order of their redox midpoint potentials, i.e. -60 mV \rightarrow $+20$ mV \rightarrow $+320$ mV \rightarrow $+380$ mV \rightarrow special pair (Michel and Deisenhofer, 1986). However, the finding that heme 2/IV had histidines both as 5th and 6th ligands (usually resulting in rather low redox midpoint potentials), whereas all other hemes had histidine-methionine ligation (Weyer et al. 1987), together with comparisons of data obtained on *Rp. viridis* with those previously gained on *Cm. vinosum* quickly raised doubts about this attribution (Dracheva et al. 1988).

Indeed, the consensus of subsequent studies addressing this specific question was the following order of hemes: -60 mV \rightarrow $+320$ mV \rightarrow $+20$ mV \rightarrow $+380$ mV \rightarrow special pair (Nitschke and Rutherford 1989, Fritzscht et al. 1989; Alegria and Dutton 1991b).

From what is known for the organization of typical electron transfer chains, the interposition of a low potential heme in between the two high potential hemes would certainly not have been anticipated. The role of this very heme as well as the 'raison d'être' of the low potential hemes in general, are part of the enigmatic features of the tetraheme subunits (see III.C.3.).

b. Factors Influencing the Redox Potentials of the Hemes

In the case of heme 2/IV with its histidine/histidine-ligation, the correlation between E_m (low, $+20$ mV) and structure seems rather straightforward. Heme 4/

I, however, with its even lower E_m (-60 mV), has histidine/methionine ligands just as the two high potential hemes do, nevertheless being more negative by almost 400 mV. Therefore, other factors must exert a significant impact on the electrochemical properties of the hemes.

Recent progress in computational treatment of continuum electrostatics (Sharp and Honig, 1990), applied to the high resolution crystal structure of the cytochrome subunit provided the first quantitative estimations of factors contributing to the equilibrium E_m -values of the four hemes (Gunner and Honig, 1991). These calculations were able to reproduce the alternating sequence of redox midpoint potentials yielding E_m -values comparable to the experimentally determined potentials. The following conclusions were drawn from these calculations (Gunner and Honig, 1991):

(a) Specific residues and parts of the cofactors (i.e. propionic acid side chains on hemes) were predicted to strongly modulate E_m -values of the hemes. These predictions can serve to suggest promising targets for site-directed mutagenesis. They furthermore can help to rationalize interspecies differences once the respective amino acid sequences are available (see sequence comparisons in III.C.4.).

(b) Taking only the protein into account and neglecting electrostatic interaction between hemes yielded the correct division into low and high potential hemes. In absolute values, however, the experimental data could only be reproduced when heme-heme interactions between the individual hemes were included in the calculations. Electrostatic interaction energies of up to 100 mV were found (for example between heme 3 and the two neighbouring low potential hemes). The important take-home message from this result was that the E_m values measured in equilibrium titrations need not apply to all experimental conditions. For example, using the values given by Gunner and Honig (1991), it can be calculated that the potential of heme 1, i.e. the closest one to the special pair, drops from its experimental E_m of $+380$ mV (when all other hemes are oxidized) to $+289$ mV in a state where hemes 1, 2 and 3 are reduced (see III.C.1. for a further discussion of these effects).

(c) Based on these calculations of electrostatic potentials, effective dielectric constants (ϵ_{eff}) were predicted for all possible pairs of charges within the tetraheme cytochrome. As shown by Gunner and Honig (1990), ϵ_{eff} -values are not identical for all pairs of hemes but rather increase dramatically with increasing distance between the members of the respective pair. This dependence of ϵ_{eff} on distance can be intuitively understood considering the almost rod-shaped geometry of the cytochrome subunit which is surrounded by a medium with high dielectric constant, i.e. water ($\epsilon = 81$). Basic electrostatics predict for such a geometry that electric field lines between two charges with opposite sign will bend out of the low dielectric protein interior (ϵ probably close to 4, see Gunner and Honig, 1991) into the surrounding phase, thereby significantly increasing the effective dielectric constant between the two charges. Accordingly, an ϵ_{eff} of 13 was calculated for the neighboring hemes 1 and 2, whereas this value is as high as 81 for the pair heme 1-heme 4, i.e. for the hemes at the extremes of the oblong cytochrome subunit (see also Moore and Rogers, 1985).

The resulting inhomogeneity of the dielectric medium might help to rationalize apparently incomprehensible data with respect to the contribution of the cytochrome to the buildup of membrane potential (see III.B.3.).

B. The 'Tetraheme Family'

1. The 'Pairs of Hemes' (a Tentative Reinterpretation of Previous Data)

The dogma of pairwise identical high and low potential hemes was somewhat in conflict with experimental data already in the 1970's. Redox titrations of multiple-flash induced cytochrome oxidations showed lower E_m -values for the hemes oxidized in the second flash, compared to what was obtained for the first flash oxidations. These '1st and 2nd flash E_m -values' usually were found at 20 mV above and below the E_m -value of the 'pair' as determined in dark titrations. This discrepancy, however, was resolved by postulating a number n of identical hemes all of which were competent in rereduction of photooxidized P^+ . Apparent E_m values to be expected in such a situation explained the data sufficiently well (Case and Parson, 1971; Jackson

and Dutton, 1973). These considerations made perfect sense as long as their basic assumptions were justified.

We now know that this is not the case for the RC of *Rp. viridis* since only heme 1 seems to be well-placed for efficient electron transfer to the special pair. However, taking the multiple flash titrations curves obtained for *Rp. viridis* at face value instead of passing them through the 'identical hemes algorithm', yields E_m -values in perfect agreement with the midpoint potentials of the individual hemes (see Table I).

Recently, distinct E_m -values for the four hemes have been obtained by EPR for the tetraheme systems from *Cm. vinosum* (Nitschke et al., 1993) and *Re. gelatinosus* (Nitschke et al., 1992). In both cases, the redox midpoint potentials seen in the EPR titrations correspond well to the E_m -values obtained by multiple-flash-induced cytochrome oxidations and electrochromic changes (Table I). This is also true for the tetraheme subunit of *Chloroflexus (Cf.) aurantiacus* (n.b.: *Cf. aurantiacus* is not a purple bacterium but belongs to the green filamentous bacteria) where equilibrium redox titrations (Freeman and Blankenship, 1990; Van Vliet et al., 1991) could be reconciled with multiple flash experiments (Zannoni and Venturoli, 1988).

In short, whereas in the older literature it was assumed that the equilibrium titrations gave correct values and the multiple flash data were 'distorted', the opposite appears to be the case, i.e. multiple flash experiments monitored the 'true' E_m -values of the individual hemes whereas the equilibrium dark titrations actually yielded non-resolved curves.

We assume that this holds true also for other tetraheme systems for which multiple flash data are available but no differentiation in equilibrium titrations has been achieved yet, such as *Thiocapsa (Tc.) pfennigii* (Prince, 1978), *Rp. acidophila* (Matsuura and Shimada, 1980) or *Ectothiorhodospira (Ec.) shaposhnikovii* (Chamorovsky et al., 1985).

Therefore, all tetraheme cytochromes are likely to contain four individual, distinguishable hemes rather than two twins of identical hemes.

2. Heme Orientations in Tetraheme Subunits

Both optical LD- (Verméglio et al., 1989; Fritsch et al., 1989; Alegria and Dutton, 1990, 1991a,b) and EPR spectroscopy (Tiede et al., 1978; Nitschke and Rutherford, 1989; Van Vliet et al., 1991; Nitschke et al., 1992, 1993) have been employed in order to

determine orientations of the hemes with respect to the membrane in RC associated cytochromes.

When applied to the case of *Rp. viridis*, these techniques yielded roughly correct orientations ($\pm 15^\circ$) as judged by comparisons with the crystal structure showing that they have the potential to yield structural information in species for which no crystal structure is available as yet.

Presently, such orientation data are available for *Cm. vinosum*, *Rhodocyclus (Rc.) gelatinosus* and *Cf. aurantiacus* (see Table 1).

The heme orientations (and redox midpoint potentials) determined by EPR for the cytochrome subunit from *Cm. vinosum* (Dutton and Leigh, 1973; Tiede et al., 1978) had contributed significantly to the formulation of the 'pairs-of-hemes'-dogma. Reexaminations of this cytochrome both by LD (Alegria and Dutton, 1990) and by EPR (Nitschke et al., 1993), however, yielded results supporting the presence of four distinguishable hemes and therefore in disagreement with the previously proposed model.

Surprisingly, none of the sets of heme orientations determined in the above mentioned species fitted the pattern of the *Rp. viridis* cytochrome. Even more surprisingly, they all seem rather different from one another.

A tentative model rationalizing these interspecies differences in the light of presently available primary sequences will be presented below (III.B.4.C.).

3. The $\Delta\Psi$ Paradox

The contribution of the RC associated cytochrome to the light-induced generation of membrane potential has been studied in *Cm. vinosum* (Dutton, 1971; Case and Parson, 1973; Itoh, 1980), *Rc. gelatinosus* (Dutton, 1971), *Tc. pfennigii* (Prince, 1978) and *Rs. molischianum* (Nagashima et al., 1993a) by monitoring electrochromic changes of carotenoids and bacteriochlorophylls. Chemical reduction of the high potential hemes prior to the actinic flashes resulted in an additional electrochromic component the extent of which ranged between 0.5 and 1.5 of the change due to charge separation between P and Q_A . The migration of the positive charge from P^+ to the cytochrome therefore seemed to roughly double the dielectric distance between the separated pair of charges. However, at ambient redox potentials where the low potential hemes became reduced, the electrochromic response diminished to a level even below that of the P^+Q^- state (about 60% of this state).

Assuming a homogeneous dielectric medium, this was interpreted to indicate that the low potential hemes were much closer to the special pair than were the high potential hemes (Dutton and Prince, 1978; Tiede et al., 1976; Itoh, 1980; Chamorovsky et al., 1985) or even located in between P and Q_A (Prince, 1978). However, Case and Parson (1973) suggested that the assumption of a dielectrically homogeneous phase harboring the redox centers might be misleading.

Such caution turned out to be fully justified when the crystal structure showed that the *Rp. viridis* cytochrome subunit was not membrane-integral at all but reached far out into the aqueous periplasmic phase. Thus, the relationship between dielectric and spatial distance is predicted to increasingly deviate from linearity the further the positive charge moves out within the tetraheme system into the periplasmic space (cf. III.A.2.b.).

Due to the absence of significant electrochromic shifts in *Rp. viridis*, data with respect to the buildup of membrane potential had to be collected by direct electrometric measurements on proteoliposome-collodion films (Skulachev et al., 1987; Dracheva et al., 1988).

Figure 3 relates the dielectric distances obtained in these studies for the high potential hemes to the distance of charge separation perpendicular to the membrane plane (arrows and values left to the RC in Fig. 3). Assuming a dielectric constant of about 4 for the protein inserted in the membrane (i.e. the RC core), effective ϵ -values of about 6 and about 8 would result from the positions of heme 1 and heme 3, respectively.

Furthermore, using data obtained on *Cm. vinosum* or *Tc. pfennigii* for electron donation from the low potential hemes to P^+ and assuming that the respective electron comes (like it does in *Rp. viridis*) ultimately (i.e. at very low potentials) from the outermost heme 4, would require an ϵ_{eff} of about 20 (note that this and the following considerations rely on the fact that the 2nd heme from P is a low potential heme in *Cm. vinosum* and *Tc. pfennigii*, just as it is in *Rp. viridis*; see also III.B.4.d.).

Published data on the contribution of heme 2 (i.e. the less reducing of the low potential hemes in the case of *Rp. viridis*) are ambiguous. In the study on *Cm. vinosum* by Case and Parson (1973), the pronounced decrease of the electrochromic response seems to titrate with the lowest potential heme, suggesting that donation from the second low

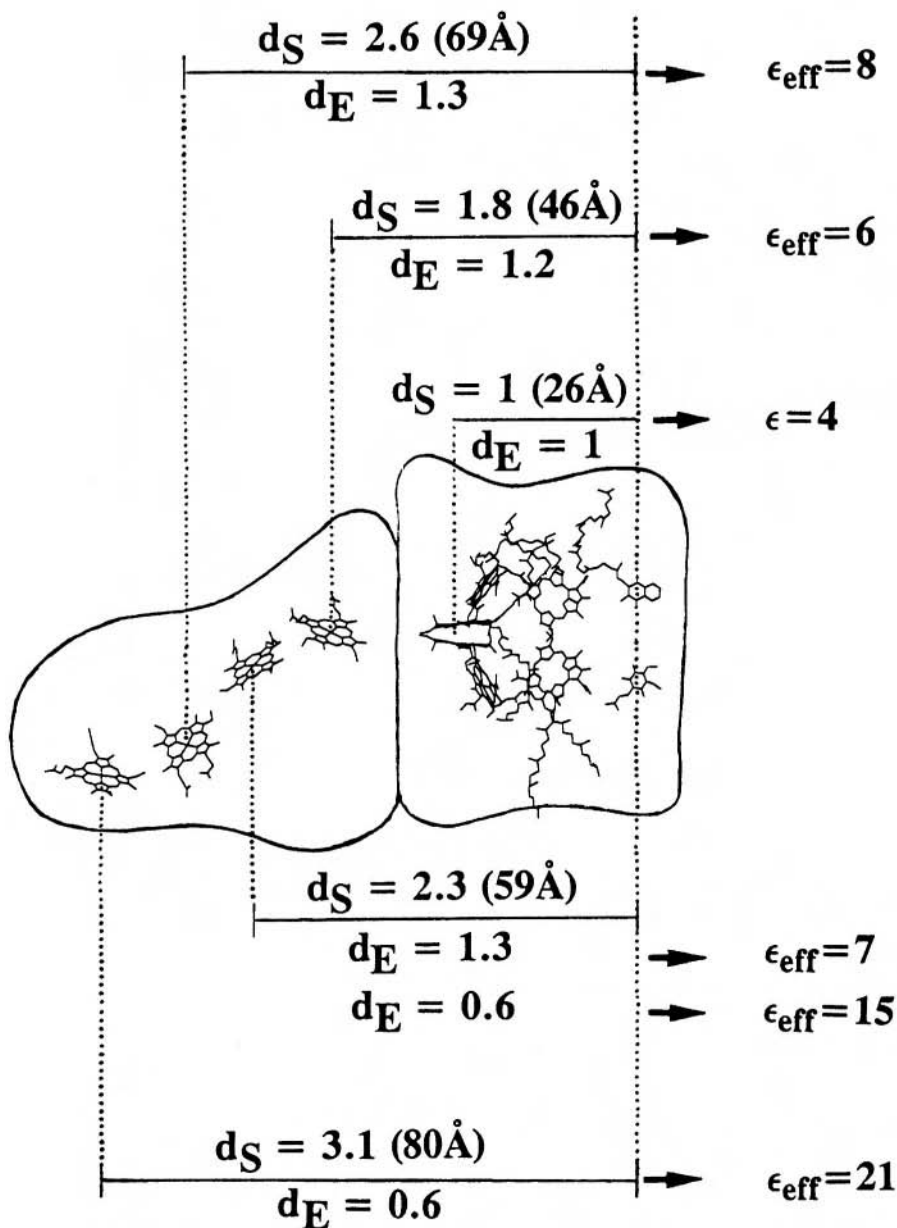

Fig. 3: Schematic model of the *Rp. viridis* reaction center embedded in the membrane (showing only chromophores and the general outline of the protein; the H-subunit is omitted) correlating spatial and dielectric distances for some selected charge separated states. Values for dielectric distances shown to the right of the RC were calculated for electron donation from the high potential hemes in *Rp. viridis* as reported by Dracheva et al. (1988) whereas the values to the left of the RC are averages over data from several species studied with respect to electron donation from the low potential hemes (see text). All spatial distances were taken from the crystal structure of the *Rp. viridis* RC.

potential heme is still approximately as electrogenic as is donation from the high potential hemes. This would predict an ϵ_{eff} of 7, which is just intermediate between those for hemes 1 and 3, i.e. suggesting that the magnitude of ϵ_{eff} is dominated by the distance from the membrane. In Itoh's work on *Cm. vinosum*

(1980) and Prince's study on *Tc. pfennigii* (1978), however, the membrane potential titrates rather with the higher component of the low potential hemes. In that case, ϵ_{eff} must be as high as 15. Since hemes 2 and 4 are rather exposed to solvent (Deisenhofer and Michel, 1989; Gunner and Honig, 1990), the high

and low dielectrics would in this case predominantly depend on solvation energy.

Alternatively, it is possible that in the respective species, heme 4 has a higher E_m than heme 2 (Nitschke and Rutherford, 1994). In that case, the electrochromic response should increase on reduction of the lowest potential heme, an effect which might be rendered difficult to observe by a compensating decrease in efficiency of charge separation due to chemical reduction of Q_A (for indications of such an effect see Nagashima et al., 1993a).

Thus, the presence of a drastically inhomogeneous dielectric medium in the region of the cytochrome subunit as suggested by electrostatic calculations (Gunner and Honig, 1991) can explain why previous interpretations of $\Delta\Psi$ measurements (based on constant ϵ_{eff} -values) yielded models in conflict with the crystal structure.

Once the contributions of the individual hemes to $\Delta\Psi$ formation (e.g. via time-resolved experiments) will be resolved in tetraheme systems for which no crystal structure is available, this method can become a powerful tool for investigating the order of redox potentials in these systems.

4. Sequence Comparisons

a. The 'Building Blocks' of a Tetraheme Cytochrome

By the time of completion of this contribution, the primary sequences of the RC associated cytochromes from *Rp. viridis* (Weyer et al., 1987a), *Cf. aurantiacus* (Dracheva et al., 1991), *Roseobacter (Ro.) denitrificans* (formerly called *Erythrobacter* sp. OCH 114; only a partial sequence is available so far; Liebetanz et al., 1991) and *Rc. gelatinosus* (Nagashima et al., 1993b, 1994) have been published. All four amino acid sequences are indicative of four heme groups bound to the protein by sequence motifs very similar to what is seen in the crystal structure of the *Rp. viridis* cytochrome subunit (see Fig. 4). The amino acid compositions determined for the cytochromes from *Cm. vinosum* (Kennel and Kamen, 1971b) and *Ectothiorhodospira* sp. (Lefèbvre et al., 1984, 1989) agree well with those calculated from the two complete purple bacterial sequences providing additional evidence for structural relatedness of all these proteins.

An alignment of the four sequences is shown in

Fig. 4. This alignment is similar to those proposed by Dracheva et al. (1991) and by Nagashima et al. (1993b, 1994) with one exception: the stretch proposed to form an α -helix parallel to heme IV in *Cf. aurantiacus* is shifted by three residues (i.e. one helix turn) with respect to the other sequences (see below).

Note that the first three sequences are all from purple bacteria, i.e. from species belonging to the proteobacterial phylum, from which the organism shown in the last line, i.e. *Cf. aurantiacus*, is evolutionarily rather distant, according to 16 S rRNA (Woese, 1987).

The sequence stretches corresponding to the structural elements of the *Rp. viridis* subunit as discussed in section III.A. 1 are indicated above the amino acid sequence of the *Rp. viridis* cytochrome (uppermost line). Obviously, the amount of detail permitted in conclusions concerning such structure elements in the other species depends on the quality of the alignment. Whereas this alignment seems to be quite reliable within each of the diheme segments due to the possibility to align heme binding motifs, the conservation of amino acids in other parts of the sequence is rather poor, resulting in a large number of possible alignments with comparable probabilities. To facilitate comparisons with the original articles, the previously proposed alignments for the sequence stretches of low conservation have been adopted. It is of note, however, that these alignments based on homology are not always in line with independent pieces of information. For example, the α -helical part of the segment going down from the N-terminus to the bottom of the cytochrome (see Fig. 1) is correctly predicted (as a Chou-Fasman α -helix) between residues 45 and 56, i.e. PAT...RDA in *Rp. viridis*. The respective stretches with high probability for α -helices align well for the case of *Cf. aurantiacus* (residues 41–51, RAQ...AGA) but badly for that of *Ro. denitrificans* (predicted between residues 59 and 67, HVA...VTR). Secondary structure prediction would therefore suggest that the *Ro. denitrificans* sequence should be shifted by 7 residues with respect to the other species. No α -helix is predicted for *Rc. gelatinosus* in this region of the protein.

The global alignment of the four sequences is nevertheless validated by numerous spots of significant homology throughout the entire sequence and it is therefore likely that the arrangement of structural elements seen in the *Rp. viridis* crystal structure is conserved in the other three species

Fig. 4: Sequence comparison for the tetraheme subunits (including putative precursor peptides) from the purple bacteria *Rp. viridis*, *Rc. gelatinosus* and *Ro. denitrificans* as well as from the green filamentous bacterium *Cf. aurantiacus*. Residues conserved among the purple bacteria and among all four species are marked as bold letters and by bars above the purple bacterial and below the *Cf. aurantiacus* sequences, respectively. The positions of the 'usual' 5th and 6th ligands are indicated by **, whereas the position of the 'unusual' 6th histidine ligand to heme 2/IV is denoted by +. The layout of the representation reflects the structure elements as defined in Fig. 1a and in the text. Only a partial primary sequence is available for *Ro. denitrificans*.

sequenced so far: An N-terminal contact region is followed by a segment protruding away from the membrane towards the far end of the subunit (containing an α -helical part at the beginning and the highly conserved stretch NVXVL at the end), the 1st and the 2nd diheme segments connected by a long stretch of low homology and by a C-terminal patch of variable length with essentially no homology.

The layout of the sequence comparison shown in Fig. 4 is meant to emphasize these structural elements.

Sequence stretches within the two diheme segments have been arranged in order to locate 5th and 6th ligands (i.e. α -helices and CXXCH-patches) at equivalent positions.

In previous alignments Met330 of *Cf. aurantiacus* has been aligned with Met293 of *Rp. viridis*, because Met330 most probably serves as 6th ligand for heme IV in *Cf. aurantiacus* (Dracheva et al., 1991; also see below). An inspection of the crystal structure, however, shows that Gly290 rather than Met293 would be at the correct position for liganding heme IV. Moreover, analysis of internal homology between different heme binding sites in the tetraheme subunit of *Rp. viridis* (Weyer et al., 1987a) also favors alignment of Gly290 in the segment binding heme IV with the 6th ligand Met in the segments binding hemes I–III. The stretch 317–344 in the *Cf. aurantiacus* sequence has been realigned accordingly, i.e. placing Met330 (*Cf. aurantiacus*) at the position of Gly290 (*Rp. viridis*).

b. Attachment to the Reaction Center

Within the N-terminal part interacting with the L-subunit in *Rp. viridis*, a rather conserved patch is found in the purple bacterial cytochromes between residues 31 and 36 (*Rp. viridis* numbering). This conservation of amino acid residues does not extend to the green filamentous bacterium *Cf. aurantiacus*. Moreover, in *Cf. aurantiacus*, the predicted respective stretch of residues is significantly shorter than in the purple bacteria. The recognition sequence for signal peptidase II and an N-terminal cysteine residue are only present in *Rp. viridis* and *Rc. gelatinosus*. Therefore, it seems likely that both *Ro. denitrificans* and *Cf. aurantiacus* do not have the lipid anchor.

Another important piece of sequence contributing to interaction of the cytochrome with the RC is the loop between residues 222 and 244 (*Rp. viridis*). The residues within this loop that are in contact with the N-terminus of the H-subunit (see Figs. 1 and 4) are

fully conserved in the purple bacteria (residues 227–230, ‘TALP’). This homology is absent in *Cf. aurantiacus* in line with the finding that the *Chloroflexus* RC does not contain the H-subunit (Blankenship et al., 1983).

For the short loop clamped to the membrane by the C-terminal ‘arm’ of the M-subunit (see Figs. 1 and 4), i.e. residues 276–280 in *Rp. viridis*, no homologous residues are seen in the other species. However, the *Chloroflexus* sequence has an insertion of 10 amino acid residues at precisely this position, indicating that the respective loop might be more extended than in purple bacteria. It is tempting to correlate such a larger loop with the finding that the C-terminal arm of the M-subunit in *Cf. aurantiacus* is only half as long as it is in purple bacteria (Nagashima et al., 1993b, 1994).

c. Primary Sequence and Heme Orientation

The non-conservation of heme orientations between species has been tentatively attributed (Nitschke et al., 1993) to the low homology in the regions of the cytochrome in contact with the RC and in the stretch that runs along the protein from the N-terminal contact area with the membrane to the far end near heme I. Low conservation in this latter part is certainly also due to its being largely exposed to the aqueous phase resulting in low constraints on mutability. However, the almost twice as long respective stretch in *Cf. aurantiacus* as compared to the purple bacterial sequences is likely to produce an altered tertiary structure in this region of the protein which might entail a tilt angle of the whole subunit different from that in *Rp. viridis*. In that respect it is noteworthy that the possible absence of an α -helical part in this segment in *Rc. gelatinosus* would also result in an altered ‘spatial’ length of the segment, even if the ‘sequence’ length is roughly conserved. For the third species studied with respect to heme orientation, i.e. *Cm. vinosum*, no sequence data are available as yet.

As suggested by the model proposed in Fig. 5, the above discussed local alterations of structural elements could result in heme orientations significantly differing between species while still retaining a globally similar structure of the various tetraheme subunits.

The examination of further species both with respect to structural and sequence data, or site-directed mutagenesis in the respective sequence segments will provide a more solid basis for these

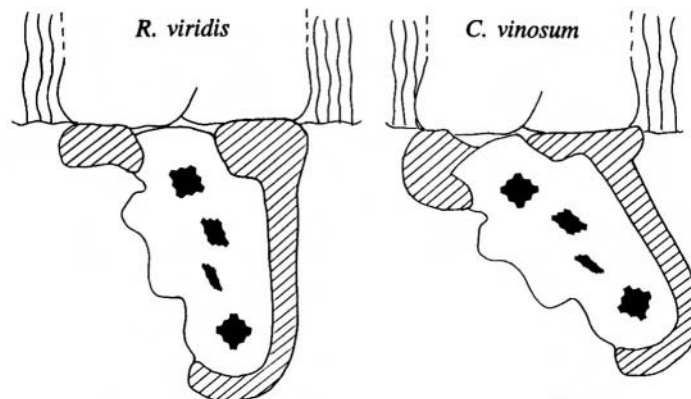

Fig. 5. Comparison of the attachment of the tetraheme subunit from *Rp. viridis* to the RC with a hypothetical structure for this attachment based on data obtained for *Cm. vinosum*. The shaded areas denote the structure elements corresponding to residues 21 to 82 and 163 to 244 in the sequence of the *Rp. viridis* subunit (see Fig. 4). The figure was reprinted with permission from Nitschke et al., 1993).

kinds of considerations.

d. Primary Sequence and Electrochemistry

The 6th ligand of heme IV being histidine instead of methionine in *Rp. viridis* contributes significantly to the fact that this heme has a low redox potential. This histidine is found to be conserved in all three purple bacterial sequences whereas the 'legitimate' 6th ligand methionine is replaced by a conserved glycine (Gly 290 in *Rp. viridis*) the small size of which might be required to facilitate access of the histidine to the heme without major displacements of the α -helix (see Fig. 2). This pattern of conservation indicates that heme 2 is probably a low potential heme in all these species. It therefore seems likely that the alternating sequence of redox midpoint potentials is common to these species. However, it cannot be ruled out that in some of these species the order might be high-low-low-high-special pair.

Whereas histidine as 6th ligand to heme IV is conserved in purple bacterial sequences, it is absent in the sequence of the *Cf. aurantiacus* cytochrome. Since no histidines besides the four His residues contained in the CXXCH-stretches are found in this sequence, the 6th ligand to heme IV must be some other residue, most probably (based on the alignment) Met330. It appears tempting to suggest that this is the reason why no second heme titrating around 0 mV is found in *Cf. aurantiacus* (Zannoni and Venturoli, 1988; Freeman, 1989; Freeman and Blankenship, 1990; Van Vliet et al., 1991). However, already the highest potential heme in the *Cf. aurantiacus* tetraheme subunit has an E_m that is

about 100 mV lower than that of the respective heme in *Rp. viridis*. Therefore, the influence exerted by the protein is obviously too dominant to allow such offhand conclusions. More structural and/or sequence information is required to assay the contributions of various factors on redox midpoint potentials of the four hemes. In this context it is of note that five out of seven residues pointed out by Gunner and Honig (1991) as significantly influencing the E_m -values of the hemes in *Rp. viridis*, are conserved in the purple bacterial sequences, i.e. the arginines 128, 157, 222, 284 and 292. Important pieces of information with respect to this question can also be expected from the primary sequence of the cytochrome subunit in *Rs. molischianum* where three low potential hemes and only one high potential heme have been found (Nagashima et al, 1993a).

C. Electron Transfer Reactions Involving Tetraheme Cytochromes

1. Electron Transfer Involving the Tetraheme Subunit and the RC

a. At Room Temperature

Kinetic parameters of the electron donation from the RC associated cytochromes to the photooxidized special pair have been determined by optical spectroscopy as well as by direct electrical measurements in *Cm. vinosum* (Chance and Nishimura, 1960 ;De Vault and Chance, 1966; Parson, 1969; Kihara and Chance, 1969; Parson and Case, 1970; Seibert and DeVault, 1970; Case et al., 1970;

Dutton et al., 1971; Case and Parson, 1971; Kihara and McCray, 1973), *Cm. minutissimum* (Rubin et al., 1989; Shinkarev et al., 1991), *Ec. shaposhnikovii* (Chamorovsky et al., 1985), *Rc. gelatinosus* (Dutton et al., 1970) and *Rp. viridis* (Case et al., 1970; Holten et al., 1978; Shopes et al., 1987; Dracheva et al., 1986; Skulachev et al., 1987; Dracheva et al., 1988; Gao et al., 1990; Ortega and Mathis, 1992; Ortega and Mathis, 1993).

Whereas in previous publications, kinetics of P^+ -rereduction by the cytochrome in *Rp. viridis* were interpreted to be monoexponential, Ortega and Mathis (1993) recently claimed to be able to distinguish multiple (up to three) kinetic components. Under all experimental conditions, however, there was one phase which was strongly dominant, the rate constants of which being comparable to those reported earlier.

In *Rp. viridis*, when only the highest potential heme (heme 1) is reduced prior to the flash, photooxidized P^+ is rereduced by this heme with a dominant phase of $t_{1/2} = 230$ ns and a minor phase (about 10%) having $t_{1/2} = 2.1$ μ s (Ortega and Mathis, 1993).

When the potential is lowered so that both high potential hemes are reduced (i.e. heme 1 and heme 3), both donation phases from heme 1 to P^+ are sped up to $t_{1/2} = 190$ ns (Holten et al., 1978; Dracheva et al., 1986; Skulachev et al., 1987; Shopes et al., 1987; Dracheva et al., 1988; Ortega and Mathis, 1993) and 1.5 μ s (10%; Ortega and Mathis, 1993). Heme 1 is subsequently rereduced by heme 3 with $t_{1/2}$ of 1.7 μ s (Shopes et al., 1987; Dracheva et al., 1988; Ortega and Mathis, 1993).

At an E_h of -20 mV (i.e. hemes 1, 2 and 3 are reduced), the rereduction of P^+ becomes even faster ($t_{1/2} = 115$ ns, 85% and $t_{1/2} = 670$ ns; Dracheva et al., 1988; Ortega and Mathis, 1993), however, the heme which is seen to be oxidized with the same kinetics is now heme 2. This can be interpreted in two ways, (a) Once the low potential heme 2 is reduced, it donates its electron directly (without passing via heme 1) to P^+ . (b) The kinetics seen for P^+ rereduction corresponds to the oxidation kinetics of heme 1. This oxidation of heme 1, however, is masked by a much faster rereduction of heme 1 by heme 2 (<40 ns; Ortega and Mathis, 1993). (a) seems to be in conflict with considerations based on electron transfer theory (Moser et al., 1992) predicting rates for the direct electron transfer from heme 2 to P^+ that are significantly slower than what is observed (Ortega and Mathis, 1993).

The speed-up of the dominant phase from 230 ns through 190 ns to 115 ns when one, two or three hemes are reduced, can be rationalized by an electrostatic effect of the electrons on hemes 2 and 3 on the driving force for electron transfer from heme 1 to P^+ . Neglecting electrostatic influences on the E_m of P/P^+ , driving forces of 120 mV, 134 mV and 211 mV are predicted by electrostatic calculations (Gunner and Honig, 1991; Ortega and Mathis, 1993) for the respective three states. Assuming these values for ΔG , the measured electron transfer rates agree well with the free-energy-rate-relationship proposed by Moser et al. (1992) for this reaction.

In the other species studied so far, the electron donation seems to proceed slightly slower with values for $t_{1/2}$ varying between 800 ns and 3.5 μ s in different species (see Table I). For a structure identical to that of the *Rp. viridis* RC, large variations in driving force would be necessary to explain the altered rate constants. Such variations are not observed [see Table I, E_m (cytochrome) vs. $E_m(P/P^+)$]. Slight differences in structure resulting in altered distances for electron transfer, however, could rationalize the observed differences in rate constants. Such variability in structure has already been invoked based on the lack of conservation of heme orientation between species (see III.B.4.c.). Rearrangements on the order of 0.2 \AA would be sufficient to yield the observed differences in rate constants (Moser et al., 1992).

Apart from the absolute value of $t_{1/2}$, the electron donation reactions observed in the other species show most of the characteristic features seen in *Rp. viridis*. Electron donation to P^+ is sped up by a factor of two to four upon additional reduction of the low potential hemes in *Cm. vinosum*, *Cm. minutissimum*, *Ec. shaposhnikovii* (Seibsrst and De Vault, 1979; Rubin et al., 1989; Chamorovsky et al., 1985) and *Cf. aurantiacus* (Mulkidjanian et al., 1993).

Furthermore, a somewhat slower electron transfer from the cytochrome to P^+ at potentials where only one high potential heme is reduced as compared to the two-hemes-reduced state as reported for *Rp. viridis* by Ortega and Mathis (1993) has been observed in *Ec. shaposhnikovii* (Chamorovsky et al., 1985) and *Cf. aurantiacus* (Mulkidjanian et al., 1994).

The presence of multiple kinetic phases reported by Ortega and Mathis (1992, 1993) was taken as evidence for heterogeneity in the samples and attributed to conformational substates of the RC.

b. At Cryogenic Temperatures

The following description of the behavior of photooxidation of hemes at low temperatures is presented in an order intended to facilitate a global overview of the data. This order of presentation, however, deviates significantly from the chronological order of discoveries in this field. These discoveries constitute a fascinating period of research in photosynthesis performed by remarkable scientists. Interested readers are referred to more 'historical' presentations, e.g. Don DeVault (1989).

In a state, where one or both of the high potential hemes are reduced but the two low potential hemes are oxidized, lowering the temperature results in a relatively small increase in half-times of cytochrome oxidation in *Ec. shaposhnikovii* (Chamorovsky et al., 1980, 1986), *Cm. vinosum* (Sarai and DeVault, 1984), *Cm. minutissimum* (Rubin et al., 1989) and *Rp. viridis* (Ortega and Mathis, 1993) yielding activation energies in the range of 4–8 kJmol⁻¹. For *Rp. viridis*, an activation energy of 6–8 kJmol⁻¹ was found for the state with only one heme reduced whereas this E_a dropped to 3–5 kJmol⁻¹ when both high potential hemes were reduced prior to the flash (Ortega and Mathis, 1993).

By contrast, the extent of heme oxidized by P⁺ decreases drastically from close to 100% at room temperature to relatively low values below 100 K, i.e. to < 10% in *Cm. vinosum* (Vredenberg and Duysens, 1964; Sarai and DeVault, 1984), 10–20% in *Ec. shaposhnikovii* (Chamorovsky et al., 1980) and roughly 0% in *Cm. minutissimum* (Rubin et al., 1989). For *Rp. viridis*, a broad range of values has been reported by different groups (20% Kaminskaya et al., 1990; 4% by Ortega and Mathis, 1993; close to 0% by Gao et al., 1990 and Nitschke and Rutherford, 1989; for a conflicting EPR result, however, see Hubbard and Evans, 1989). The transition from full to only fractional oxidation of heme occurs in a narrow temperature range (50–70K) in all studies published so far. Again, the absolute value of this 'transition temperature' varies by as much as 80K for the same species (*Rp. viridis*) between groups. From the work of Ortega and Mathis (1993), though, it seems likely that the transition temperature falls in correlation with increasing number of hemes reduced (being 250K with one heme reduced and 210K with two hemes reduced) prior to the flash. This again is indicative of an increase in driving force for electron donation to P⁺ due to electrostatic interactions when

an increasing number of the outer hemes are reduced (see III.A.2.b.).

Reports observing blockage of electron transfer from heme to P⁺ already at room temperatures in the presence of cryoprotectants above a well-defined threshold concentration in *Cm. vinosum* (Kihara and McCray, 1973) or induced by partial dehydration in *Ec. shaposhnikovii* (Chamorovsky et al., 1986) and in *Cm. vinosum* (Kihara and McCray, 1973) might actually observe related effects.

The charge separated (heme^{ox} Q_A⁻) state recombines with halftimes of 500 ms (recombination between heme 1 and Q_A) and 7s (recombination between heme 3 and Q_A) below 200K in *Rp. viridis* (Gao et al., 1990; Kaminskaya et al., 1990). An in-depth study of kinetic and thermodynamic parameters of these recombination reactions has been presented by Gao et al. (1990). A recombination under these conditions has also been observed in *Cm. vinosum*, its kinetics, however, have not been studied (Sarai and DeVault, 1984). Considerable disagreement prevails with respect to the amount of oxidized high potential heme that does not recombine with the electron on Q_A but becomes stably photooxidized below 100K. Values ranging from 40% (Hubbard and Evans, 1989) through 10% (Kaminskaya et al., 1990) down to values below detection (Nitschke and Rutherford, 1989; Gao et al., 1990) have been reported for the case of *Rp. viridis*.

In contrast to what is seen for *Rp. viridis*, *Cm. vinosum*, *Cm. minutissimum* and *Ec. shaposhnikovii*, significant amounts of stable photooxidation of high potential hemes can be observed below 100 K in *Rc. gelatinosus* (Dutton et al., 1971; Nitschke et al., 1992) and in *Cf. aurantiacus*. In *Cf. aurantiacus*, three of the four hemes were seen to undergo stable photooxidation at 4 K (Van Vliet et al., 1991).

The situation changes drastically when one or both of the low potential hemes are additionally reduced prior to illumination. Under these conditions, the major part of the photoinduced charge dipole of heme 2(4)^{ox}–Q_A⁻ does not recombine any more at low temperatures in all species containing a tetraheme subunit, i.e. low temperature photooxidation of the low potential hemes is an *irreversible* process.

In 1960, Chance and Nishimura have shown that in whole cells of *Cm. vinosum*, electron donation rates from the low potential hemes to P were essentially independent of temperature below 100 K. A subsequent study by DeVault and Chance (1966) established the dependence of donation rates in the

temperature range from 300 K down to 30 K, showing that above 100 K, the reaction was described by an activation energy of about 14 kJmol^{-1} whereas it became almost activationless below 100 K. Further experiments on chromatophores and subchromatophore particles (i.e. partially detergent-solubilized material) confirmed the results obtained on whole cells (Dutton et al., 1971). Since in the structural model in use prior to the *Rp. viridis* crystal structure the hemes closest to the special pair were considered to be low potential, a direct donation from these low potential hemes without implication of the high potential hemes was assumed. Electron tunneling from these low potential hemes has been invoked to explain the apparently temperature independent donation reaction at low temperatures (DeVault and Chance, 1966; Hopfield, 1974; Hales, 1976). After the *Rp. viridis* structure was published, alternative explanations were put forward (Bixon and Jortner, 1986, 1989), based on activationless electron transfer rather than tunneling, however, still keeping the idea of direct electron transfer from heme 2 to P^+ .

In contrast to the theories based on direct donation from the low potential hemes, other models are based on the assumption that electron donation to P^+ is likely to proceed via heme 1 under all conditions. In these models, it is proposed that the redox equilibrium between heme 1 and P is temperature dependent, i.e. that below a certain threshold temperature the equilibrium shifts from heme I^{ox} - P^{red} to heme I^{red} - P^{ox} . This would explain the observed sharp drop in efficiency of the donation reaction.

Additional reduction of the low potential heme 2 would in this model result in (a) a lower transition temperature due to a higher driving force and (b) a rapid rereduction of heme 1 during the time interval when the electron resides transiently on P, thereby rendering the donation event irreversible. In this model, the long (ms) donation times under these conditions would reflect the time of equilibration between all states rather than being a true electron transfer rate.

To rationalize the required temperature dependent equilibrium, Kaminskaya et al. (1990) proposed the existence of an excited intermediate state that has to relax via medium reorganization to the thermodynamic equilibrium. At low temperatures, medium reorganization is proposed to become frozen out making the free energy of the transition state the determining factor for the equilibrium between heme 1 and the special pair.

Although more work is required to decide between the various models proposed, the experimentally similar behavior in the electron transfer reactions described above for all species examined, provides further circumstantial evidence for a rather similar structural and electrochemical arrangement of the four hemes in all these tetraheme cytochromes.

2. Rereduction of the Tetraheme Subunit

The rereduction of photooxidized hemes in RC associated cytochromes has been studied *in vivo* in *Cm. vinosum* (van Grondelle et al., 1977), *Ec. mobilis* (Leguijt, 1993) and *Rp. viridis* (Olson and Nadler, 1965; Garcia et al., 1993). Both in *Cm. vinosum* and in *Rp. viridis* under most physiological conditions, this rereduction is probably mediated by a soluble cytochrome ($\text{Cyt } c_2$). Cytochrome c_2 was found to be in turn rereduced by the cytochrome bc_1 complex (Shill and Wood, 1984; Coremans et al., 1985; Tan et al., 1993; Garcia et al., 1993). Halftimes of the dominant phases of electron transfer from cytochrome c_2 to the tetraheme subunits were determined to be $300 \mu\text{s}$ (Coremans et al., 1985) in the case of *Cm. vinosum* and to be $110 \mu\text{s}$ or $40 \mu\text{s}$ (Garcia et al., 1993) for aerobic or anaerobic conditions, respectively, in the case of *Rp. viridis*. In both species, these halftimes were independent of the intensities of subsaturating flashes, indicating that they may not correspond to diffusion controlled, second order processes (van Grondelle et al., 1977; Garcia et al., 1993). The formation of an electron transfer complex between cytochrome c_2 and the tetraheme cytochrome prior to the flash was therefore proposed (Garcia et al., 1993). In *Rp. viridis*, even under anaerobic conditions, no involvement of the low potential hemes was seen. It was therefore argued that under most physiological culture conditions, the low potential hemes do not participate directly in rereduction of the photooxidized special pair (Garcia et al., 1993).

The existence of electron transfer complexes has also been reported using purified reaction center and cytochrome c_2 of *Rp. viridis* (Knaff et al., 1991; Meyer et al., 1993). Complex formation as evidenced by the presence of first order rate constants was only observed at low ionic strengths indicative for an electrostatic nature of this complex. The halftimes for the intra-complex electron transfer reaction ($2600 \mu\text{s}$ according to Knaff et al., 1991 and $530 \mu\text{s}$ according to Meyer et al., 1993) are somewhat longer than those observed *in vivo*. Studies comparing

binding of cytochrome c_2 with either the cytochrome bc_1 complex or the tetraheme cytochrome indicate substantially different docking modes for these two electron transfer complexes (Güner et al., 1993).

Since in *Rp. viridis* the in vivo half-time of donation from cytochrome c_2 to the high potential hemes is an order of magnitude slower than electron transfer from heme 3 to heme 1 within the tetraheme subunit, it was concluded that, if the binding site for cytochrome c_2 was near to heme 1, donation from cytochrome c_2 would always be outcompeted by intrasubunit heme-heme electron transfer. An obligatory donation into heme 3, i.e. the heme with the second highest potential, and consequently a binding site close to this heme was therefore proposed (Meyer et al., 1993) to explain the observed electron transfer events. Molecular modeling studies, however, were interpreted to indicate possible binding sites also near heme 4 (Knaff et al., 1991) and heme 1 (Sogabe et al., 1992).

In the case of a specific strain of *Rc. gelatinosus*, a soluble high potential iron sulfur protein (HiPIP) was recently identified as the physiological electron donor to the RC-associated tetraheme subunit (Schoepp et al., 1994; Schoepp, 1994). The characteristics of inter-protein electron transfer between the HiPIP and the tetraheme subunit were found to resemble those observed for cytochrome c_2 and the cytochrome subunit.

3. What Are Those Tetraheme Subunits Good For?

In the years before the *Rp. viridis* crystal structure, the RC associated cytochromes of purple bacteria were enigmatic on three different levels. (1) Why did RC associated cytochromes exist at all when species like *Rb. sphaeroides* proved that they were dispensable, (2) why was one heme not enough and (3) why were there hemes with redox potentials too low to fit into the cyclic electron transfer scheme. A tentative explanation for (2) and (3) was proposed by the hypothesis that the low potential hemes might serve as entry points for electrons coming ultimately from low potential substrates (for a discussion see Dutton and Prince, 1978), a hypothesis that was as elegant and appealing as it was difficult to check experimentally. Eventually, the crystal structure of the *Rp. viridis* RC and subsequent studies based on this structure provided a wealth of data and another level of mystery, i.e. the question (4) why the four

hemes were arranged in an alternating sequence of redox potentials. The interposition of a low potential heme in between two high potential hemes would not seem to be required for this heme to act as an acceptor for electrons coming from low potential substrates but rather points to a more complicated role of this arrangement, especially since it seems to be conserved at least among the purple bacterial tetraheme subunits (III.B.4.d.). For example, electrostatic interaction energies between two adjacent high potential hemes might be too high to allow efficient electron donation to P^+ under all redox conditions (see III.A.2.b.). Although the *Rp. viridis* crystal structure did not solve these questions, answers seem nevertheless likely to be provided by *Rp. viridis*. The recently described transformation system for this bacterium (Laußermair and Oesterhelt, 1992) allows site-directed mutations to be introduced into the tetraheme subunit, providing a tool to study the importance of the individual hemes and their redox midpoint potentials for in vivo metabolic processes. Complete deletion of the cytochrome subunit might furthermore give hints to the kind of advantage provided by these additional, RC associated cytochrome electron donors.

IV. Nature of RC Associated Cytochromes in Photosynthetic Eubacteria

A. Proteobacteria

The evidence that the RC associated cytochromes in purple bacteria all belong to the 'family' of tetraheme cytochromes appeared to be rather compelling until recently. Conflicting data have been presented for the case of the *Ectothiorhodospira* (Leguijt and Hellingwerf, 1991), where the purification of a protein containing only the low potential hemes was reported. Such a situation would certainly raise interesting questions with respect to the evolution of RC associated cytochromes (Leguijt, 1993). Even so, some caution seems to be appropriate since similar observations have been made in *Cm. vinosum* (Doi et al., 1983; Knaff and Kraichoke, 1983) and in *Tc. pfennigii* (Meyer et al., 1973), the RC associated cytochromes of which are now generally accepted to be members of the tetraheme family (see also III.B.4.a.). Alterations of the physicochemical properties of the hemes induced by detergent treatments have been invoked to explain the observed

phenomena (Meyer et al., 1973). Moreover, the amino acid composition of the cytochrome copurifying with the RC in *Ectothiorhodospira* sp. agrees well with that of other tetraheme cytochromes (Lefèbvre et al., 1984, 1989). Further circumstantial evidence for the cytochrome associated to the *Ectothiorhodospira* RCs being a true tetraheme cytochrome comes from its photochemical behavior (Chamorovsky et al., 1980, 1985, 1986) which is strikingly similar to that observed in *Rp. viridis* (see III.C. 1.).

B. Green Filamentous Bacteria (Chloroflexaceae)

The cytochrome subunit of *Cf. aurantiacus* has been purified and characterized (Freeman and Blankenship, 1990; Meyer et al., 1989; Heibel et al., 1991). A partial amino acid sequence has been obtained by Edman degradation (Freeman, 1989) and subsequently the complete primary sequence was determined from the gene (Dracheva et al., 1991). All these data demonstrate that the *Chloroflexus* cytochrome is a member of the tetraheme family.

C. Green Sulfur Bacteria (Chlorobiaceae)

The nature of the immediate electron donor to P^+ in green sulfur bacteria is presently a matter of debate and both mono- and tetraheme cytochromes have been proposed to fulfill this role.

Four hemes in approximately equal amounts were observed by EPR in membrane fragments of *Chlorobium phaeobacteroides* (Feiler et al., 1989). This was interpreted as evidence for the presence of a tetraheme cytochrome donor in green sulfur bacteria (Nitschke and Rutherford, 1991). This putative tetraheme cytochrome was tentatively identified with a 32 kDa cytochrome *c*-553 found to copurify with the RC (Feiler et al., 1992). The recent purification and characterization of the 32 kDa cytochrome *c*-553 demonstrated, in fact, that this cytochrome is a multiheme protein (Albouy et al., 1994). By contrast, in a preparation of the RC from *Cb. vibrioforme* (Okkels et al., 1992), an 18 kDa cytochrome *c*-551 was observed. Its sequence was determined from the respective gene (named *p**scC*, formerly called *cycA*), demonstrating that it contained only one heme binding motif (Okkels et al., 1992). No sequence homology to tetraheme cytochromes was seen and a (weak) resemblance was only found to the membrane-anchored *cycM* gene product studied in *Brady-*

rhizobium japonicum (Bott et al., 1981). Deletion of the *p**scC* gene seemed to be lethal for the organism (Kjærulff et al., 1993) suggesting an indispensable metabolic function of the gene product. Possibly similar cytochromes were reported in RCs of *Cb. limicola* by Hurt and Hauska (1984; 24 kDa, Cyt *c*-550.5) and Oh-oka et al. (1993; 21 kDa, Cyt *c*-551). The α -band wavelength of 550–551 nm is significantly different from the wavelength (553 nm) of the heme photooxidized in membrane fragments (Olson and Sybesma, 1963; Sybesma and Vredenberg, 1964; Sybesma, 1967; Fowler et al., 1971; Prince and Olson, 1976; Swarthoff and Ames, 1979) and in whole cells (Feiler and Nitschke, unpublished) or the heme components found to be abundant in *Chlorobium* (Gibson, 1961; Fowler et al., 1971), but this might again be due to detergent-induced alterations of spectral properties.

It is of note, however, that in double flash experiments on *Cb. limicola*, Prince and Olson (1976) obtained differing E_m -values for the 1st and 2nd flash-induced cytochrome oxidation reminiscent of the situation found with purple bacterial tetraheme subunits (see III.B. 1.). Two of the four hemes observed in EPR equilibrium titrations (Feiler et al., 1989) had E_m values comparable to those determined in the double flash experiment (see Table I) which was considered as further support for the cytochrome associated to the *Chlorobium* RC being a tetraheme system (Feiler et al., 1989; Nitschke and Rutherford, 1991). Similarly different titration curves for 1st and 2nd flash induced cytochrome oxidation in *Cb. tepidum* were recently interpreted assuming two identical monoheme cytochromes associated with one RC (Okumura et al., 1994). If this model should turn out to be correct, then *Chlorobium* might provide an example where the rationalizing of multiple flash data by assuming two or more identical electron donating cytochromes would eventually be applicable (see III.B.1.). Both the 18 kDa cytochrome *c*-551 and the 32 kDa cytochrome *c*-553 were shown to contain hemes with E_m -values in the range of those of the photooxidized heme(s) (Kjaer et al., 1994; Albouy et al., 1994).

No stable photooxidation of hemes at low temperatures has been observed in green sulfur bacteria.

For a more detailed description of the green sulfur bacterial reaction center, the reader is referred to the contribution by Hauska and Feiler in this volume.

D. Heliobacteria

In Firmicutes (formerly called Gram-positive phylum; see Wayne et al., 1987), the last phylum containing photosynthetic representatives (i.e. the Heliobacteria), data with respect to the immediate electron donor to the RC are scarce. A membrane-bound cytochrome *c*-553 can donate to the photooxidized primary donor with $t_{1/2}$ in the ms-range in membrane fragments (Prince et al., 1985; Smit et al., 1987). The E_m of this heme photooxidized in membranes has been determined to +170 mV (Prince et al., 1985). In whole cells, electron transfer from cytochrome *c*-553 to P^+ is significantly faster and biphasic (Vos et al., 1989). Promising candidates on the level of proteins for being cytochrome *c*-553 are a 50 kDa and a 17 kDa protein which were found in membrane samples (Fuller et al., 1985; Trost and Blankenship, 1990; Nitschke and Liebl, 1992). All purification procedures reported so far yielded photosynthetic reaction centers devoid of cytochrome (Trost and Blankenship, 1989; Van de Meent et al., 1990). From optical spectra, no differentiation into multiple heme components has been achieved so far. In EPR, however, three to four inequivalent hemes were observed in membranes, two of which titrated around 170 mV whereas the other one or two had potentials somewhat below -50 mV (Liebl, Rutherford and Nitschke, unpublished). Multiple flash experiments on whole cells also yielded distinguishable titration curves (Nitschke, unpublished), reminiscent of what is described in III.B. 1. for the case of the tetraheme cytochromes from purple bacteria (however, see IV.C.). Indications for more than one photooxidizable heme in a fraction of RCs have also been reported by Kleinherenbrink and Amesz (1993).

Just as in green sulfur bacteria, no (Nitschke and Rutherford, unpublished) or very low (4%; Smit et al., 1989) photooxidation of hemes at low temperatures (< 100K) has been observed in Heliobacteria (see also Chapter 31 by Amesz on the heliobacterial RC).

V. Some Considerations with Respect to Evolution

Efforts in the fields of structure determination, protein/gene sequencing and functional studies have transformed the subject 'evolution of photosynthetic reaction centers' from an intellectual pastime

discussed in scientific 'salons' into experimental research performed on lab-benches and in CPUs (for a review see Blankenship, 1992). There is some reason to believe that the two types of reaction centers, i.e. RCI (as represented by the green sulfur and heliobacterial RCs as well as PS I) and RCII (as represented by the RCs from purple and green filamentous bacteria as well as PS II) have evolved from a common origin.

In phylogenetic trees based on 16S r-RNA (Woese, 1987), green filamentous bacteria are evolutionarily the earliest photosynthetic phylum to branch off from the tree. Since these organisms were shown to possess a tetraheme cytochrome subunit related to that of purple bacteria (IV.B.) and since some data suggested that the cytochrome subunit in green sulfur and heliobacteria might also be a tetraheme cytochrome (IV.C./D.), it was inferred that the principle of the tetraheme subunit was ancient and that such cytochromes already served as electron donors to the common ancestor of all extant types of reaction centers (Nitschke and Rutherford, 1991).

However, based on inconsistencies of phylogenetic trees constructed from 16S r-RNA and from sequences of the RC-subunits L and M, the conclusion was drawn that the photosynthetic apparatus of *Chloroflexus* might have been imported via lateral gene transfer from an ancestor of the Proteobacteria (Blankenship, 1992). This would mean that the photosynthetic apparatus of *Cf. aurantiacus* cannot be related to the position of the organism within the phylogenetic tree of the eubacteria. This would weaken the significance of the *Chloroflexus* cytochrome subunit being a tetraheme protein with respect to evolutionary scenarios.

Furthermore, recent results suggest that the cytochrome subunit in green sulfur bacteria might be a monoheme cytochrome (IV.C.). On the basis of this finding, an alternative model for the evolution of RC associated cytochromes has been put forward (Kjær et al., 1992). In this model, a monoheme would have been attached to the ancestral reaction center (and would still be present in extant RCI-type reaction centers), subsequently evolving (via two gene duplications) into the tetraheme subunits of purple and green filamentous bacteria.

As pointed out by Okkels et al. (1992), if the green sulfur bacterial subunit was a monoheme cytochrome, then it would also be possible that the ancestral RC was devoid of bound secondary electron donors and mono- or tetraheme cytochromes were captured only

later in evolution by the different descendants of the primordial RC. If the *pscC* gene product should turn out to be the immediate secondary donor to P⁺ in green sulfur bacteria, then the latter hypothesis actually seems more likely than an evolution from a mono- through a di- into a tetraheme cytochrome. From the amino acid sequence of *pscC* it seems clear that not only sequence but also structural homologies are absent between this monoheme and the tetraheme cytochromes. The proposed 6th ligand to the heme, methionine, in *pscC* is located about 30 residues further down towards the C-terminal end of the protein than is the CXXCH-heme binding motif. A heme binding structure element comparable to that seen for all four hemes in the tetraheme subunit (see III.A. 1.b.) would therefore be excluded in *pscC*.

Thus, a number of rather different scenarios for the evolution of the RC associated cytochromes are presently being proposed. This might seem reminiscent of the situation way back in the days of the evolutionary 'salons'. The present situation is nevertheless different in that further data can be expected to gradually exclude some of these scenarios.

Both the hypothesis on the importance of lateral gene transfer (see for example Nagashima et al., 1993b reporting further inconsistencies between phylogenetic trees based on 16S r-RNA and protein sequences) and the controversy on the nature of the RC associated cytochrome in green sulfur bacteria (see Kjærulff et al., 1993, presenting a transformation system for *Chlorobium* which can ultimately allow site-directed mutagenesis to be performed on this organism) are presently under investigation.

Therefore, a much clearer picture for these evolutionary considerations can be expected in the near future and the authors of a review article on RC associated cytochromes to be written in 10 years time will probably shake their heads in wonder about what people could have been imagining in 1993.

Acknowledgments

We thank Drs. J. Amesz, R.E. Blankenship, M.A. Cusanovich, G. Hauska, B. Kjær, F.A.M. Kleinherenbrink, T. Leguijt, P. Mathis, K. Matsuura, A. Ya. Mulkidjanian, K.V.P. Nagashima, N. Okumura, R.C. Prince, H.V. Scheller, J. Shiozawa, D.M. Tiede and A. Verméglio for communicating results prior to publication. Thanks are furthermore due to Drs.

A.W. Rutherford, M.R. Gunner, I. Agalidis, D. Albouy, J. Breton, S. Creuzet, F. Drepper, G. Drews, P.L. Dutton, U. Feiler, M. Hippler, A. Hochkoeppler, P. Joliot, D.B. Knaff, U. Liebl, B. Schoep, J.T. Trost, J. Vachtweil, P. van Vliet and D. Zannoni for stimulating discussions.

Molecular models were produced on a SG computer by S. Grzybek using the GRASP-software (developed by A. Nicholls and B. Honig) and on a PC (with skillful assistance by J. Reichert) using the pdViewer software developed by H.H. Robinson and A.R. Crofts. Coordinates were obtained from the Brookhaven Data Bank (entry 1PRC).

Access to computer facilities was kindly provided by W. Mäntele and M. Wissen.

Summary

The F_0F_1 ATP synthase is responsible for electron-transport coupled ATP synthesis in every living cell, and functions also as a reversible ATPase. It is composed of an integral membrane sector, F_0 , containing four subunits in a stoichiometry of $a_1b_1b'_1c_{6-12}$, and an extrinsic sector, F_1 , containing five subunits in a stoichiometry of $\alpha_3\beta_3\gamma_1\delta_1\epsilon_1$. The detailed structure of the catalytic site and mechanism of action of this very complex enzyme are still unknown. Work by many research groups led to isolation of the whole F_0F_1 complex and the F_1 -ATPase from many bacteria. From *Rhodospirillum rubrum* chromatophores the catalytic $RrF_1-\alpha\beta$ -core complex and the $RrF_1\beta$ subunit have also been isolated. Removal of all $RrF_1\beta$ from the membrane enabled the separation of inactive, but fully reconstitutable β -less *Rs. rubrum* chromatophores. The $RrF_1\gamma$ subunit could be sequentially removed from these chromatophores. All isolated whole and partial complexes and individual subunits have been purified and characterized. Most important results include: 1) Demonstration of a low but continuous light-driven ATP synthesis by purified RrF_0F_1 reconstituted into phospholipid vesicles together with reaction

centers and a cytochrome bc_1 complex purified from the same bacteria. This is a first step towards reconstitution of a functional photosynthetic membrane. 2) Formation and characterization of active hybrid membrane-bound F_1 -ATPases by reconstituting β -less *Rs. rubrum* chromatophores with $F_1\beta$ subunits isolated from *E. coli* EcF_1 and spinach Cf_1 . The restored ATPase activity demonstrated the functional homology of all $F_1\beta$ subunits, but their different response to various known F_1 effectors. 3) Characterization of two binding sites for ATP and ADP on the purified $RrF_1\beta$. One of them, which does also bind P_i , appears to be the catalytic site of the F_1 -ATPase. Recent successful attempts at cloning and functional expression of this $RrF_1\beta$ subunit open up exciting possibilities for future research aimed at elucidating the structure of this catalytic site and identifying amino acid residues essential for assembly of the $F_1\beta$ subunit into an active F_1 -ATPase.

A concerted effort involving biochemical, genetic, electron microscopic and crystallographic techniques will hopefully lead to resolution of the as yet enigmatic mechanism of action of this most important enzyme complex.

I. Introduction

Energy transducing membranes of bacteria, chloroplasts and mitochondria contain F_0F_1 -type proton-translocating ATP synthases that catalyze electron-transport coupled phosphorylation. The coupling mechanism involves utilization of an electrochemical gradient of protons, generated during respiratory or photosynthetic electron-transport, as driving force for the respective oxidative and photosynthetic phosphorylation (Mitchell, 1966). All membrane embedded F_0F_1 ATP synthases can also work in the reverse direction as proton-translocating ATPases, but their major biological function is the synthesis of ATP. This unique metabolic role is reflected in the very unusual structural complexity of the ATP synthases in comparison to other ATPases, as well as in the high degree of conservation of this structure in enzymes from different sources. All F_0F_1 ATP synthases consist of two distinct sectors, termed F_0 and F_1 . F_0 is an integral membrane complex, which mediates transmembrane proton conduction, and F_1 is an extrinsic membrane complex, which when removed from the membrane functions as a water soluble ATPase. However, proton-transport coupled ATP synthesis and hydrolysis occurs only when the F_1 sector is combined with the membrane-bound F_0 sector, hence the widely used term of coupling factor (Racker, 1976).

Each of the two sectors is a complex structure by itself, composed of a number of different subunits with varying stoichiometries. Although the overall function and shape of all F_0F_1 -type enzymes is similar, there are some important differences, especially in regulation of their ATPase activity and in the subunit composition of various F_0 sectors. The enzyme from respiratory bacteria is the least complex, containing three types of F_0 subunits in addition to the conserved structure of five types of F_1 subunits assembled with a stoichiometry of $\alpha_3\beta_3\gamma\delta\epsilon$. The mitochondrial enzyme is the most complex. It contains, besides the five F_1 subunits, up to nine additional types of subunits (Collinson et al., 1994), which form the F_0 sector and link it to the F_1 sector. The photosynthetic F_0F_1 complexes, including those of anoxygenic photosynthetic bacteria, form a separate group with four distinct F_0 subunits (see II. A.1).

A vast amount of structural and functional information obtained through genetic, biochemical and electron-microscopic investigations of various types of F_0F_1 ATP synthases, has led to the formulation of plausible models for the mechanism of action of this group of enzymes (see Section IV). However for elucidation of the exact molecular mechanism of proton-coupled ATP synthesis/hydrolysis much more detailed direct structural information is required. The first published 3.6 Å X-ray crystallographic structure of an F_1 complex was that of rat-liver MF_1

(Bianchet et al., 1991), and recently the structure of bovine heart MF_1 , at 2.8 Å resolution, has also been reported (Abrahams et al., 1994).

This chapter will review the current knowledge about the structure and function of complete and partial F_0F_1 ATP synthase complexes isolated from anoxygenic photosynthetic bacteria, and compare their properties with those of other types of photosynthetic F_0F_1 enzyme complexes. Due to space limitations chromatophore photophosphorylation and proton-coupled ATP hydrolysis will not be discussed, except for a short summary of membrane-bound F_0F_1 activities, that are useful for comparison with the isolated enzyme. Recent comprehensive reviews of the presently available literature on the structure and mechanism of action of F_0F_1 ATP synthases can be found in: Futai et al. (1989); Fillingame (1990); Penefsky and Cross (1991); Cox et al. (1992); Issartel et al. (1992); Hafezi (1993); Boyer (1993). Specific reviews of the chloroplast enzyme include: Strotmann and Bickel-Sandkotter (1984); McCarty and Moroney (1985); Nalin and Nelson (1987); Graber et al. (1990); Jagendorf et al. (1991) and Glaser and Norling (1991). There is only one earlier review on the photosynthetic bacterial enzyme (Baccarini-Melandri and Melandri, 1978).

II. The F_0F_1 Complex

A. Overall Structural Features

1. Organization of Gene Clusters and Gene Sequence Homology

F_0F_1 complexes of anoxygenic photosynthetic bacteria have first been isolated from chromatophores of the purple non-sulfur bacterium *Rhodospirillum rubrum* (Oren and Gromet-Elhanan, 1977; Schneider et al., 1978). As has been observed with the chloroplast CF_0F_1 (see Glaser and Norling, 1991 and references therein), the best purified RrF_0F_1 preparations showed on SDS-PAGE either eight (Bengis-Garber and Gromet-Elhanan, 1979) or at least nine (Muller and Baltscheffsky, 1979) different polypeptide subunits. Nine subunits have also been observed in the RcF_0F_1 complex purified from another purple non-sulfur bacterium *Rhodobacter capsulatus* (Gabellini et al., 1988). These earlier discrepancies in the reported number of subunits in various photosynthetic F_0F_1 complexes have been resolved via gene sequence

analysis, which revealed that RrF_0F_1 , Cf_0F_1 and all other examined photosynthetic F_0F_1 complexes, contain nine distinct polypeptide subunits rather than the eight found in the *Escherichia coli* EcF_0F_1 .

Figure 1 compares the organization of genes encoding F_0F_1 subunits in two anoxygenic photosynthetic bacteria with those of two oxygenic cyanobacteria, plant chloroplasts and *E. coli*. All the genes for the eight EcF_0F_1 subunits form a single operon organized in two sub-clusters encoding the three F_0 a, c and b subunits followed by the five F_1 subunits in the order of $\delta\alpha\gamma\beta$ and ϵ (see Futai et al., 1989 and references therein). Upstream of the F_0 subunit a there is a ninth gene, designated I, encoding a small hydrophobic protein of unknown function that is not assembled into the F_0F_1 complex. In *Rs. rubrum* the genes for the F_0 and F_1 sectors are organized in separate operons. The F_0 operon consists, as in EcF_0F_1 , of genes for I, a, c, b and an additional related but different gene for b' (Falk and Walker, 1988). The second operon consists of the five F_1 genes in the same order as in the *E. coli* operon (Falk et al., 1985). In a related purple non-sulfur bacterium *Rhodospseudomonas blastica* only the F_1 operon has been identified. It contains six genes arranged in the same order as the F_1 genes in *E. coli* and *Rs. rubrum*, except for the presence of an additional unknown gene, designated x, inserted between the γ and β ones (Tybulewicz et al., 1984).

A different organization of two or even three operons encoding nine F_0F_1 subunits has been reported in two closely related cyanobacteria (Fig. 1). In both cases the F_0 operon, as the *Rs. rubrum* F_0 operon, contains two genes for b and b' but in *Synechococcus* 6301 (Cozens and Walker, 1987), it carries also the genes for F_1 subunits δ , α , and γ , whereas in *Synechococcus* 6716 (Van Walraven et al., 1993) it carries only the genes for F_1 δ and α . In this cyanobacterium the gene for γ appears on a completely separate cluster. The genes for F_1 β and ϵ form a separate far apart operon in both cyanobacteria as well as in higher plant chloroplasts. However, in plants and green algae the organization of genes encoding the remaining seven ATP synthase subunits is different, because CF_1 subunits γ , δ and CF_0 subunit II, which is equivalent to b' (Hermann et al., 1993), are encoded in the nucleus (see Jagendorf et al., 1991). So the plastid F_0 operon carries only genes for F_0 subunits IV (a), III (c), I (b) and F_1 subunit α .

The presence of a separate operon encoding the F_1 β and ϵ subunits has recently been reported in the

Fig. 1. Diagrammatic representation of genes encoding F_0F_1 subunits in *E. coli*, anoxygenic photosynthetic bacteria, cyanobacteria and plastid genomes. Modified from Falk et al. (1985), Falk and Walker (1988) and Van Walraven et al., (1993). Separate operons are indicated by dashed lines. White boxes denote F_1 genes; black boxes - F_0 genes and shaded boxes denote genes encoding proteins that do not appear in the F_0F_1 complex.

green sulfur bacterium *Chlorobium limicola*, but the organization of the other genes coding for F_0F_1 subunits is as yet unknown (Xie et al., 1993). The green photosynthetic bacteria, unlike the purple bacteria, utilize a reaction center related to Photosystem I of cyanobacteria and chloroplasts (see chapter by Feiler and Hauska). It would therefore be very interesting to find out whether the organization of the genes encoding other F_0F_1 subunits is also similar in *Cb. limicola* and in cyanobacteria.

Some general features observed in all examined species include the highly significant homology between their β subunits (>40% sequence identity in 20 different β subunits) and to a lesser extent α subunits (Futai et al., 1989). A functional homology has also been demonstrated among β subunits isolated from various sources (see III.B.2). A comparison of the sequences of F_0F_1 subunits from all photosynthetic sources with available sequences of plant and bovine mitochondria (Cozens and Walker, 1987; Falk et al., 1988) indicates rather clearly that both mitochondrial enzymes are more closely related to the enzyme from the anoxygenic photosynthetic bacteria than to any other group. They show >70% sequence identity in their α and β subunits and >40% in their F_0 *c* subunits. The chloroplast enzyme on the other hand is more closely related to the cyanobacterial one, showing >70% sequence identity in their α subunits and >80% in their β and F_0 III (*c*) subunits.

2. Subunit Stoichiometry, Structure and Topology

The stoichiometry of the F_0F_1 subunits has been investigated in detail in *E. coli* and chloroplast

complexes. This involved careful determination of molecular weights of each individual subunit and of purified F_0F_1 , F_1 , and F_0 complexes, as well as estimation of relative amounts of each subunit in radioactively labeled complexes (McCarty and Moroney, 1985; Futai et al., 1989; Glaser and Norling, 1991 and references therein). An identical pattern of F_1 subunit stoichiometry of $\alpha_3\beta_3\gamma\delta\epsilon$ has been established for both bacterial and chloroplast complexes. The subunit stoichiometry of the respective F_0 complexes is less certain, especially for the F_0 *c* subunit. The presently proposed ratios are $a_1b_2c_{6-12}$ for EcF_0 , and $a_1b_1b'_1c_{6-12}$ for CF_0 . The main difference between both types of enzymes is in the assembly per complex of two identical *b* subunits in EcF_0 as compared to one of each of the non-identical homologues *b* and *b'* in CF_0 . The subunit stoichiometry of F_1 and F_0F_1 complexes isolated from various photosynthetic bacteria has not been examined in detail. At present the identical numbers obtained for EcF_0F_1 and CF_0F_1 suggest that the basic overall subunit stoichiometry and structure of at least all bacterial and chloroplast F_0F_1 complexes is very conserved.

Low resolution information on the overall shape of what we recognize now as the membrane-bound RrF_0F_1 complex, has been obtained already in 1965 by electron microscopic examination of negatively stained *Rs. rubrum* chromatophores (Low and Afzelius, 1965). Their pictures suggested the presence of protruding knobs of 120 Å diameter, that are located on the outside surface of the chromatophores. These structures have been observed on all examined energy-transducing membranes, and their release upon removal of the membrane-bound ATPase

activity by washing with EDTA, suggested that they are morphological representations of the coupling factor- F_1 sector of the membrane-bound F_0F_1 ATP synthase complex (see Racker, 1976). This suggestion was ascertained by experiments with antibodies raised against the purified coupling factor F_1 -ATPase isolated from *Rs. rubrum* (Berzhorn et al., 1975) and from *Rb. capsulatus* (Prince et al., 1975). The antibodies agglutinated chromatophores but not spheroplasts, thus demonstrating that the F_1 sector of the F_0F_1 -ATPase is located exclusively outside the chromatophore membrane. Further immunological studies compared the effect of antibodies prepared against the RrF_1 and its purified native β subunit (Philosoph and Gromet-Elhanan, 1981a, see also III.B.1). Both types of antibodies agglutinated the *Rs. rubrum* chromatophores, suggesting that the $F_1 \beta$ subunit is located on the external part of RrF_1 (see Fig. 2).

No further structural work has been reported on the F_0F_1 from any photosynthetic bacterium. But electron microscopic examinations of detergent-solubilized F_0F_1 ATP synthases from *E. coli*, chloroplasts and mitochondria led to formulation of two-dimensional structural models for the F_0F_1 (Gogol et al., 1987; Graber et al., 1990; Walker et al., 1990; Pedersen and Amzel, 1993). These models propose a tripartite structure containing a headpiece, identified as the F_1 sector, a short stalk and a basepiece, identified as the F_0 sector. The stalk is probably composed of subunits or parts of subunits that connect the F_1 to the F_0 (see Fig. 2). Electron microscopy has also succeeded in defining the gross arrangement of subunits within the F_1 complex, revealing a hexagonal arrangement of the large subunits enclosing a mass suggested to be one or more of the small γ , δ , and ϵ subunits. Studies with CF_1 labeled with monoclonal antibodies against the $CF_1 \alpha$ subunit, demonstrated the binding of three antibodies at an angle of 120 degrees per CF_1 molecule. This observation verified the stoichiometry of $\alpha_3\beta_3$, and indicated that the α and β subunits are arranged in alternating positions (see Graber et al., 1990).

The X-ray crystallographic structure at 3.6 Å resolution of rat liver MF_1 gives a more detailed picture of the organization of the α and β subunits (Bianchet et al., 1991). They are arranged in two interdigitated layers, each containing a trimeric array of one type of subunit. The α trimer starts below the β trimer, which in turn protrudes about 15 Å above the α one, and both α and β subunits have similar

ellipsoidal shapes. A different picture has recently been reported for the bovine heart MF_1 structure at 2.8 Å resolution (Abrahams et al., 1994). It is clear that a higher resolution crystallographic structure of these, as well as additional types of F_1 complexes, including the photosynthetic ones, is needed.

We know less about the overall shape of the F_0 sector. But from the primary structure of the F_0 subunits and their hydrophobic profiles, including those reported for the *Rs. rubrum* F_0 subunits (Hoppe and Sebald, 1984; Falk and Walker, 1988), secondary structural models for their orientation in the membrane have been deduced (see Fillingame, 1990; Graber et al., 1990; Glaser and Norling, 1991; Deckers-Herbestreit and Altendorf, 1992). Subunit c has two hydrophobic stretches, thought to span the membrane in a hairpin-like structure, linked by a polar loop projecting towards the F_1 sector. A conserved acidic residue, glutamic acid in *Rs. rubrum* (Hoppe and Sebald, 1984), within the C-terminal hydrophobic region is the site of DCCD-binding, that results in inhibition of proton translocation and thus of coupled ATP synthesis and hydrolysis. Subunit b, and the related b' in RrF_0F_1 and other examined photosynthetic enzymes, have a hydrophobic N-terminal domain, while the rest of the protein is hydrophilic (Falk and Walker, 1988). This structure has been interpreted as indicating that the two copies of b in *E. coli* (Deckers-Herbestreit and Altendorf, 1992) or the two homologous b and b' in the photosynthetic enzymes (Otto and Berzborn, 1989) are anchored in the membrane via their two N-terminal parts in association with the transmembrane segments of subunits c and a. The remaining hydrophilic part is proposed to protrude into the cytoplasm and interact with F_1 subunits. Subunit a is the largest F_0 subunit, and the least resolved in structure. It is extremely hydrophobic and various reports suggest that it inserts in the membrane with 5 to 8 membrane spanning α -helices. A schematic model of the overall F_0F_1 shape with a more detailed presentation of the organization of $F_1 \alpha$ and β subunits and the suggested arrangement of the F_0 subunits is given in Fig. 2.

B. Catalytic Properties of the Membrane-Bound F_0F_1

Chromatophores of most photosynthetic bacteria effectively catalyze both ATP synthesis and hydrolysis. Rates of ATP synthesis in absence of any

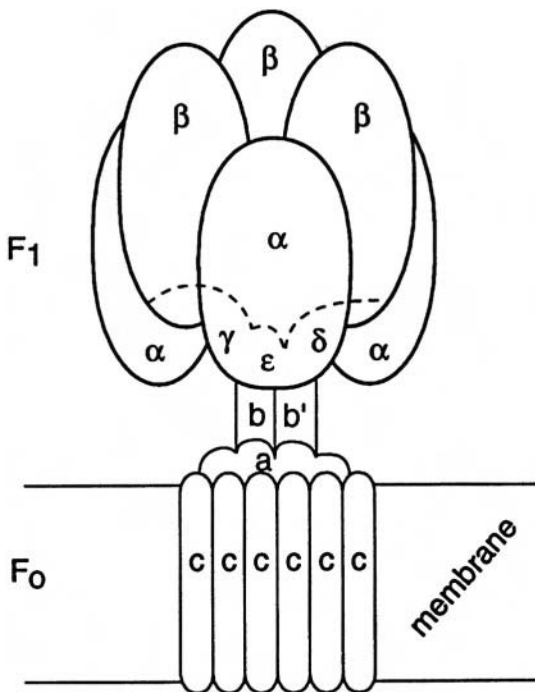

Fig. 2. A schematic model of the subunit organization in photosynthetic F_0F_1 ATP synthases. See text for explanations.

added electron carriers vary between 80–200 $\mu\text{mol/hr}$ per mg BChl for both *Rs. rubrum* and *Rb. capsulatus*. Addition of PMS increases these rates to 800–1200 in the first and 400–500 in the second (Gromet-Elhanan and Gest, 1978; Baccarini-Melandri et al., 1979; Gromet-Elhanan and Weiss, 1989). In contrast to chloroplasts, chromatophores also hydrolyze ATP in the dark at relatively high rates in the presence of either Mg^{2+} or Ca^{2+} . These rates reach 30 and 10%, respectively of the rates of photophosphorylation (Baccarini-Melandri and Melandri, 1978; Gromet-Elhanan and Weiss, 1989). Most chromatophore membrane-bound ATPase activities do not respond to the activation treatments employed in chloroplasts, such as tryptic digestion or illumination. Only in special cases, when the dark rates are very low, as in *Chromatium vinosum* chromatophores (Gepshtein and Carmeli, 1974), has tryptic digestion been shown to cause a large stimulation.

All chromatophore bound ATP synthesis and hydrolysis activities are inhibited by energy-transfer inhibitors that were shown to block proton-translocation through the F_0 sector (Hoppe and Sebald,

1984). DCCD is a general inhibitor of all membrane-bound F_0F_1 , including chromatophore F_0F_1 complexes. It does also inhibit the isolated F_1 -ATPase, but at much higher concentrations and different conditions (see III. A.3). Oligomycin is a much more selective inhibitor. It inhibits the mitochondrial membrane-bound and solubilized MF_0F_1 , but not MF_1 , and is completely ineffective towards the chloroplast CF_0F_1 . Oligomycin does inhibit the membrane-bound ATP synthesis and hydrolysis activities of RrF_0F_1 as effectively as the mitochondrial MF_0F_1 activities (Johansson et al., 1971). It is somewhat less effective in various *Rhodobacter* chromatophores (Melandri and Baccarini-Melandri, 1971; Müller et al., 1982), and completely ineffective in *Chromatium* chromatophores (Gepshtein and Carmeli; 1974).

Uncouplers exert a different effect. They stimulate the Mg^{2+} -ATPase activity, while inhibiting photophosphorylation in all chromatophore membranes. Illumination in presence of uncouplers causes further stimulation of the Mg^{2+} -ATPase activity, especially at very high ratios of $\text{Mg}^{2+}/\text{ATP}$ (Edwards and Jackson, 1976; Slooten and Nuyten, 1981). Recently a transient stimulation of 10 to 15 fold was reported, when uncouplers were added immediately after the illumination. The rate of the transient Mg^{2+} -ATPase observed in this case was two fold higher than the rate of ATP synthesis (Turina et al., 1992).

The Ca^{2+} -ATPase activity is much less responsive to uncoupler stimulation than the Mg^{2+} -ATPase. This difference between Ca^{2+} and Mg^{2+} has been traced to their effect on H^+ -translocation by the membrane-bound RrF_0F_1 complex (Casadio, 1988; Gromet-Elhanan and Weiss, 1989). In the presence of Mg^{2+} , and also Mn^{2+} , the RrF_0F_1 complex catalyzes both ATP synthesis and hydrolysis as well as ATP-induced H^+ -translocation, but in the presence of Ca^{2+} it catalyzes only ATP hydrolysis, which is *not* coupled to H^+ -translocation. Further studies have indicated that the inability of Ca^{2+} to maintain the coupling process is not due to opening of a proton leak in its presence, but rather to the inability of bound CaATP to lead to a conformational change that opens up the pathway for proton translocation through the F_0F_1 complex during catalysis (Gromet-Elhanan and Weiss, 1989; Strid and Nyren, 1989). These findings direct attention to the earlier kinetic analysis of the membrane bound F_0F_1 -ATPase activity in *Chromatium* (Gepshtein and Carmeli, 1977) as well as in *Rs.*

rubrum (Oren and Gromet-Elhanan, 1979). The cation-ATP complex was shown to be the substrate for ATP hydrolysis in both bacteria and free Mg^{2+} , but not free Ca^{2+} , was a very efficient competitive inhibitor. It is thus clear that Mg^{2+} -ions play an important regulatory role in proton-coupled ATP hydrolysis.

The chromatophore membrane-bound RrF_0F_1 has been shown to synthesize ATP in the dark at the expense of an artificially imposed electrochemical proton gradient composed of both a ΔpH and a $\Delta\psi$ (Leiser and Gromet-Elhanan, 1974). This capacity, first observed in chloroplasts (Jagendorf and Uribe, 1966), helped confirm the basic concepts of the chemiosmotic theory (Mitchell, 1966). It has also been very useful in establishing the capacity of the detergent-solubilized purified F_0F_1 preparations for $\Delta\bar{\mu}H^+$ -driven ATP synthesis after their reconstitution into phospholipid vesicles (see II.C.2).

C. Resolution and functional reconstitution

1. Purification and properties of isolated F_0F_1 -ATPases

Highly purified F_0F_1 complexes have been obtained from *Rs. rubrum* (Bengis-Garber and Gromet-Elhanan, 1979; Müller and Baltscheffsky, 1979, and Slooten and Vanderbranden, 1989a), *Rb. capsulatus* (Gabellini et al., 1988) and recently also from the green non-sulfur bacterium *Chloroflexus aurantiacus* (Yanyushin, 1991). The procedures used for solubilization and purification have been adapted from those developed for the detergent solubilized mitochondrial and chloroplast enzymes. The earlier preparations employed the mitochondrial procedure (Tzagoloff and Meagher, 1971) of solubilization by Triton X-100, and purification of the concentrated extract by glycerol gradient centrifugation. Additional steps of ion-exchange chromatography or gel filtration (Bengis-Garber and Gromet-Elhanan, 1979; Schneider et al., 1979) yielded the most active purified F_0F_1 preparations reported to date in photosynthetic bacteria (Table 1). More recent preparations used the procedure introduced by Pick and Racker (1979) for extraction and purification of CF_0F_1 , in which the F_0F_1 is solubilized by a combination of octylglucoside and cholate (or deoxycholate) and purified by ammonium sulfate fractionation and sucrose gradient centrifugation. All isolated and purified bacterial

Table 1. Summary of ATPase activities of the *Rs. rubrum* membrane-bound and detergent solubilized RrF_0F_1 , the purified water soluble five subunit RrF_1 , and the RrF_1 - $\alpha\beta$ -dimer

Type of assayed enzyme ¹	ATPase activity assayed with ²		Inhibition (%) of Mg^{2+} -ATPase by oligomycin
	Mg^{2+}	Ca^{2+}	
(U/mg of protein)			
RrF_0F_1:			
membrane-bound	0.2	0.1	90
purified	1.8	3.3	70
Purified $RrF_1$³:			
assayed by itself	1.3	8.6	<5
assayed with OG	8.2	1.8	ND
RrF_1 - $\alpha\beta$	0.09	0.08	ND

¹ Data for RrF_0F_1 are modified from Bengis-Garber and Gromet-Elhanan (1979), for purified RrF_1 from Weiss et al. (1994), and for the RrF_1 - $\alpha\beta$ -dimer from Andralojc and Harris (1993).

² ATPase activity was assayed with 4 mM ATP and either 2 mM $MgCl_2$ or 4 to 8 mM $CaCl_2$, except for RrF_1 - $\alpha\beta$ where 200 μ M ATP and 5 mM $MgCl_2$ or $CaCl_2$ were used. When indicated 5×10^{-5} M oligomycin was added. One unit (U) of activity is defined as the number of μ mol of P_i released per min at 35 °C. ND – not determined.

³The activity of purified RrF_1 was determined either in absence or presence of 16 mM octylglucoside (OG) in the assay medium.

F_0F_1 complexes were shown to retain the characteristic DCCD-sensitive Mg^{2+} -ATPase activities of their parent chromatophore membrane-bound enzymes (see II.B).

An extensive characterization of the catalytic properties of the isolated, as compared to the membrane-bound F_0F_1 -ATPase, has been carried out with the RrF_0F_1 . As is illustrated in Table 1 the membrane-bound enzyme is both a Mg^{2+} - and Ca^{2+} -dependent ATPase, its Mg^{2+} -ATPase activity being two to three fold faster than the Ca^{2+} -ATPase one (Johansson et al., 1971; Bengis-Garber and Gromet-Elhanan, 1979 and see II.B). Both activities are retained also in the detergent solubilized enzyme, but the Ca^{2+} -ATPase is purified to a much greater extent than the Mg^{2+} -ATPase activity, so that the finally purified complex shows a two fold higher Ca^{2+} -ATPase activity. Table 1 shows also that the water soluble RrF_1 -ATPase is predominantly a Ca^{2+} -ATPase (see III.A.2). In *Rb. capsulatus* only the Mg^{2+} -ATPase activity of the purified F_0F_1 complex has been followed, and found to be five to ten fold slower than that of purified RrF_0F_1 (Gabellini et al., 1988).

Optimal ratios of 0.2–0.5 $\text{Mg}^{2+}/\text{ATP}$ and 1–3 $\text{Ca}^{2+}/\text{ATP}$ were found for both membrane-bound and solubilized RrF_0F_1 (Oren and Gromet-Elhanan, 1979) as well as for RrF_1 (see III.A.2.). The results summarized in Table 1 have been obtained with these ratios. The lower optimal ratio of $\text{Mg}^{2+}/\text{ATP}$ reflects the fact that free Mg^{2+} -ions are, whereas Ca^{2+} -ions are not potent competitive inhibitors of the membrane-bound (see II.B) as well as the solubilized RrF_0F_1 . Here the K_i for free Mg^{2+} -ions is 7 μM , whereas free Ca^{2+} -ions do not inhibit even at 10mM (Oren and Gromet-Elhanan, 1979).

The nucleotide specificity of soluble RrF_0F_1 and of the membrane-bound complex are very similar. The preferential substrate is ATP, but GTP and, to a lesser extent ITP, are also hydrolysed (Schneider et al., 1979). Table 1 illustrates that both bound and soluble RrF_0F_1 -ATPase activities are very sensitive to the energy-transfer inhibitor oligomycin, that does not inhibit the water soluble RrF_1 -ATPase (Oren and Gromet-Elhanan, 1977 and 1979; Schneider et al., 1978). The RrF_0F_1 -ATPase is the only F_0F_1 -ATPase in both groups of bacterial and photosynthetic enzymes that is as sensitive to oligomycin and rutamycin as the mitochondrial MF_0F_1 complex (see II. B). The RrF_0F_1 Ca^{2+} -ATPase is somewhat less sensitive than the Mg^{2+} -ATPase in both membrane-bound (Johansson et al., 1971) and solubilized states (Oren and Gromet-Elhanan, 1977).

2. Reconstitution of Proton-Coupled ATP-Linked Activities

F_0F_1 complexes isolated and purified from various photosynthetic bacteria have been reconstituted into phospholipid vesicles and found to catalyze, as the membrane-bound enzyme, a number of proton-coupled ATP-linked reactions. These range from ATP-dependent quenching of acridine dye fluorescence (Schneider et al., 1980; Slooten and Vanderbranden, 1989a), to $^{32}\text{P}_i$ -ATP exchange, and finally to $\Delta\bar{\mu}\text{H}^+$ -dependent net ATP synthesis (see II. B). All these reactions were inhibited by the energy-transfer inhibitors oligomycin and DCCD as well as by uncouplers. Reconstitution of isolated RrF_0F_1 (Bengis-Garber and Gromet-Elhanan, 1979) and RcF_0F_1 (Gabellini et al., 1988) into phospholipid vesicles, enabled catalysis of $^{32}\text{P}_i$ -ATP exchange at reproducible but low rates, amounting to 23 and 5 nmol ATP formed/min per mg of RrF_0F_1 and RcF_0F_1 respectively. Ten-fold higher rates, similar to those

observed with reconstituted CF_0F_1 (Pick and Racker, 1979), have recently been obtained with the *Chloroflexus* enzyme, upon its reconstitution into liposomes prepared with intrinsic lipids isolated from the same bacterium (Yanyushin, 1991). The use of lipids prepared from the same bacterium was earlier found to yield higher $^{32}\text{P}_i$ -ATP exchange activities as well as $\Delta\bar{\mu}\text{H}^+$ -driven ATP synthesis in a reconstituted cyanobacterial F_0F_1 complex (Van Walraven et al., 1983; 1986). Purified RrF_0F_1 reconstituted into phospholipid vesicles is also capable of ATP synthesis at the expense of artificially applied ΔpH plus $\Delta\psi$ (Slooten and Vandenbranden, 1989b). The amount of ATP formed in this discontinuous system, 80 mol/mol enzyme, is similar to that obtained with reconstituted CF_0F_1 (Pick and Racker, 1979).

Continuous net ATP synthesis was first obtained with a purified RrF_0F_1 reconstituted together with purple membrane bacteriorhodopsin into phospholipid vesicles (Oren et al., 1980). The light-induced ATP synthesis was proportional to the amount of RrF_0F_1 and bacteriorhodopsin (at a 1:1 ratio) and linear for at least 20 min of illumination. The maximal rate of ATP synthesis of 8.4 nmol/min per mg of protein obtained in this system is low, but 10 to 30 fold higher rates have been obtained when RrF_0F_1 was reconstituted into soybean liposomes together with monomeric bacteriorhodopsin (Wagner et al., 1987). Concomitantly measured rates of light-driven proton translocation enabled the calculation of H^+/ATP stoichiometries in this reconstituted system. The constant ratio of H^+/ATP of 5.2, that was obtained under saturating light intensities, is lower than the value of H^+/ATP of 3 obtained in native membranes (Ferguson and Sorgato, 1982). Net continuous ATP synthesis has also been obtained upon reconstitution of the purified RrF_0F_1 together with an energy-linked pyrophosphatase, partially purified from the same bacterium (Nyren and Baltscheffsky, 1983). The maximal rate of this PP_i -driven ATP synthesis was 25 nmol of ATP/min per mg of protein and it was sensitive to a variety of uncouplers and inhibitors of both the RrF_0F_1 -ATPase and the pyrophosphatase.

A more ambitious system for coreconstitution of cyclic electron transport and photophosphorylation has been developed by Gabellini et al. (1989). They have coinorporated into phospholipid vesicles purified preparations of the *Rb. capsulatus* reaction center, cytochrome bc_1 complex, and RcF_0F_1 , and obtained light-driven ATP synthesis at a rate of 36 nmol ATP/min per mg of RcF_0F_1 . A rate of up to 55

nmol/min per mg of protein has been reported in an earlier developed system for coreconstitution of chloroplast Photosystem I reaction centers and CF_0F_1 , where the cyclic electron transport was completed with the artificial redox component PMS (Hauska et al., 1980). Although the reported maximal rates amount to only about 0.3–3% of the rates of photophosphorylation observed in native chromatophores (see II. B), when calculated by using the two different published ATP synthase contents of coupled chromatophores (see III.A.1), this is a first step towards reconstitution of a functional photosynthetic membrane.

III. The F_1 -ATPase

A. General Features of the Whole F_1 Complex

1. Isolation and Purification

F_1 -type ATPases have been isolated from *Rb. capsulatus* (Baccarini-Melandri et al., 1970), *Cm. vinosum* (Hochman and Carmeli, 1971), *Rs. rubrum* (Johansson, 1972), *Rb. sphaeroides* (Reed and Raveed, 1972), *Rp. palustris* (Müller et al., 1982), and *Cf. aurantiacus*, (Yanyushin, 1988). The methods employed for complete detachment of the F_1 complex from the chromatophore membrane vary depending on the tightness of its attachment to the membrane-bound F_0 sector. A 10 min incubation in a low ionic strength buffer was sufficient for elimination of practically all the photophosphorylation from *Cm. vinosum* chromatophores, enabling the separation of fully resolved chromatophores and a supernatant from which the solubilized CvF_1 -ATPase has been purified (Gepshtein et al., 1978). In *Rb. capsulatus* a similar incubation, even in presence of 1 mM EDTA, decreased phosphorylation by only 50%, and for an 85% decrease a 90 sec sonication in presence of EDTA was required. In *Rs. rubrum* chromatophores this harsher treatment decreased the endogenous phosphorylation by 80% (Johansson, 1972), but the PMS-supported phosphorylation by less than 50% (Gromet-Elhanan, 1974a). It is thus clear that sonication in a low ionic strength buffer in presence of EDTA releases in *Rs. rubrum* not only the F_1 -ATPase but also electron transport components that are bypassed in the presence of PMS (Gromet-Elhanan, 1977).

Up to now no satisfactory procedure has been

developed for preparing *Rs. rubrum* chromatophores that are completely devoid of the whole F_1 complex and show no extensive damage of their electron transport chain. In the absence of such F_1 -depleted chromatophores it is impossible to determine the F_1 content of coupled chromatophores by the method developed in chloroplasts (Strotmann et al., 1973) of assaying their ATPase activities before and after removal of the F_1 -ATPase, as compared to the activity of the removed F_1 . Calculations based on other methods yielded for *Rs. rubrum* chromatophores values of 9.1 mmol of RrF_1 /mol BChl (Norling et al., 1989) and 0.9 mmol RrF_1 /mol BChl (Andralojc and Harris, 1993). Differences in the light intensity at which the *Rs. rubrum* cultures were grown were suggested as a possible reason for this 10 fold difference in the calculated RrF_1 content. But the relevant light intensities were not stated for any one of the published estimates. So a reliable determination of the RrF_1 content will require a careful examination of light intensity dependent changes in the ratios of total protein and RrF_1 -ATPase protein/BChl.

RrF_1 as well as other bacterial F_1 -ATPases were usually removed from their parent chromatophores by drastic treatments that did not enable isolation of resolved chromatophores. These involve either aqueous extraction of acetone powders of coupled chromatophores (Baccarini-Melandri and Melandri, 1971) or the chloroform extraction technique developed by Beechey et al (1975) for removal of the MF_1 -ATPase, and introduced by Webster and Jackson (1978) for isolation of RrF_1 . In many cases the drastic extraction procedures and even some purification procedures yielded F_1 complexes containing only four, or even three, subunits. Thus, in *Cm. vinosum* the δ subunit was present in the crude extract, but only a small amount of it remained in the purified CvF_1 -ATPase (Gepshtein et al., 1978). The purified *Cf. aurantiacus* F_1 -ATPase is also depleted of the δ subunit (Yanyushin, 1988). The δ subunit is relatively easily dissociated from various CF_1 and EcF_1 complexes during extraction and/or purification, and in its absence the F_1 -ATPase can bind to resolved membranes, but does not restore phosphorylation (McCarty and Moroney, 1985; Glaser and Norling, 1991; Futai et al, 1989). Indeed the crude CvF_1 containing the δ subunit could, whereas the purified δ -less CvF_1 could not, restore phosphorylation to resolved *Cm. vinosum* chromatophores (Gepshten and Carmeli, 1974; Gepshtein et al., 1978). A five subunit F_1 has not, as yet, been

purified from these two bacteria.

Conflicting data earlier reported with the RrF_1 seem in retrospect to reflect a similar case of loss of one or more of the small single copy subunits upon extraction and purification. Thus, RrF_1 purified from an acetone powder extract (Johansson et al., 1973) was found to contain five subunits with molecular weights of α -54,000; β -50,000; γ -32,000; δ -13,000 and ϵ -7,500 (Johansson and Baltscheffsky, 1975). Identical numbers were also reported by Soe et al. (1978). The molecular weights of the first three subunits correspond to those calculated by Falk et al. (1985) from predicted protein sequences, but the last two subunits show much lower molecular weights than the calculated δ -19,500 and ϵ -14,300. These purified RrF_1 -ATPases were not assayed for restoration of phosphorylation activity to resolved chromatophores, so it was not realized that their content of δ and ϵ could be questionable. Later, Müller et al. (1979) reported that they could purify only a four subunit RrF_1 -ATPase complex, composed of α , β , γ , and δ , from a similar acetone powder extract. They could, however, purify a five subunit RrF_1 from a chloroform extract, and the molecular weights of these subunits did correspond to those calculated by Falk et al. (1985). In light of these results, it seems possible that the enzyme purified and assayed by Johansson and Baltscheffsky (1975) and Soe et al. (1978) could be composed of α , β , γ , and either ϵ or a split δ . F_1 complexes purified from acetone extracts of *Rp. palustris* and *Rb. sphaeroides* (Müller et al., 1982) show also molecular weights of 13,000 for δ and 8,000 for ϵ , that do not correspond to those calculated from the predicted protein sequence of their close relative *Rp. blastica* (Tybulewicz et al., 1984).

The chloroform extraction does also yield variable results. Webster and Jackson (1978) have reported that their crude chloroform extract could *not* restore phosphorylation to partially resolved EDTA-treated *Rs. rubrum* chromatophores and purified from it only a three subunit RrF_1 containing α , β , and γ . Müller et al. (1979) state on the other hand that the chloroform extract from which they have purified the five subunit RrF_1 was prepared as described by Webster and Jackson. It is thus clear that both the acetone and chloroform extraction procedures used in the earlier reported attempts at solubilization and purification are not ideal.

A milder technique of extraction, using a much lower amount of chloroform than that employed by

Beechey et al (1975), has been introduced by Fisher et al. (1981). This technique was employed for extraction and purification of a five subunit RrF_1 (Norling et al., 1988). Protein sequencing of the N-termini of all five subunits has established that they are products of the earlier sequenced *Rs. rubrum* genes. So this extraction technique seems to provide at present the best available procedure for obtaining purified five subunit F_1 complexes from photosynthetic bacteria. It should however be emphasized that up to now none of the extensively purified five subunit F_1 complexes from any photosynthetic bacterium have been assayed for their capacity to restore photophosphorylation in resolved chromatophores.

F_1 -ATPases have also been prepared from a number of cyanobacteria, including *Mastigocladus laminosus* (Binder and Bachofen, 1979); *Synechococcus* 6716 (Lubberding et al., 1981); *Spirulina platensis* (Hicks and Yocum, 1986a) and *Anacystis nidulans* (Nemoto et al., 1990). Most cyanobacterial complexes could be removed from the membrane by incubation in low ionic strength buffers without or with 1 mM EDTA, but the usual Beechey-type chloroform extract has also been used. Both extraction methods enabled the purification of five subunit F_1 complexes for *Spirulina* and *Anacystis*, but from the other cyanobacteria only four subunit F_1 -ATPases, lacking the δ subunit, have been purified.

2. Catalytic Properties of Isolated F_1 -ATPases

The F_1 complexes isolated from various photosynthetic bacteria exhibit a rather varying spectrum of properties. Thus the partially purified RcF_1 has a very weak Mg^{2+} -ATPase activity of $0.16 \mu\text{mol}/\text{min} = (\text{u})/\text{mg}$ of protein, and no measurable Ca^{2+} -ATPase activity (Melandri and Baccarini-Melandri, 1971). Its inactivity as Ca^{2+} -ATPase seems to be due to loss of this activity rather than to latency, as in Cf_1 , because a) it could not be stimulated by treatments, such as heat or trypsin, that enhance the Ca^{2+} -ATPase activity of Cf_1 , and b) unlike in chloroplasts, the membrane-bound RcF_0F_1 is rather an active Mg^{2+} and Ca^{2+} -dependent ATPase (see II.B). So although this partially purified RcF_1 could restore some photophosphorylation to resolved *Rb. capsulatus* chromatophores (Baccarini-Melandri and Melandri, 1971) it has not been subjected to any further purification or characterization. The partially purified CvF_1 exhibits low but reproducible Ca^{2+} - and Mg^{2+} -

dependent ATPase activities that are stimulated five-fold on addition of trypsin to the assay medium. The Ca^{2+} -ATPase activity is 3 fold higher than the Mg^{2+} -ATPase activity (Gepshtein and Carmeli, 1977), and amounts to 9U/mg of protein in the highly purified four subunit CvF_1 (Gepshtein et al., 1978).

All purified RrF_1 preparations show, unlike RcF_1 and CvF_1 , relatively high native Ca^{2+} -ATPase activities in absence of trypsin (Soe et al., 1978; Müller et al., 1979, and Table 1), but their Mg^{2+} -ATPase activities vary depending on the extraction procedure. The acetone extracted enzymes show no Mg^{2+} -ATPase activity (Johansson et al., 1973; Soe et al., 1978; Müller et al., 1979), whereas the various chloroform extracted and purified five subunit RrF_1 complexes, exhibit some Mg^{2+} -ATPase activity (Müller et al., 1979; Norling et al., 1988). When assayed at an optimal ratio of Mg/ATP of 0.2 to 0.5 it amounts to about 15% of the Ca^{2+} -ATPase activity (Müller et al., 1979; Weiss et al., 1994, see Table 1). This range of Ca^{2+} - and Mg^{2+} -ATPase activities is very similar to those of activated CF_1 from which the ϵ subunit has been removed (McCarty and Moroney, 1985).

In both activated ϵ -depleted CF_1 and native RrF_1 the low Mg^{2+} -ATPase activity has been stimulated by addition of certain anions (Nelson et al., 1972; Webster et al., 1977) or detergents (Soe et al., 1978 and 1980; Pick and Bassilian, 1982) to the assay medium. With anions, such as malate or sulfite, the Mg^{2+} -ATPase is highly stimulated while the Ca^{2+} -ATPase is either unaffected (Nelson et al., 1972), or even somewhat stimulated (Webster et al., 1977). Detergents, on the other hand, inhibit the Ca^{2+} -ATPase activity while stimulating the Mg^{2+} -ATPase activity. Recent examinations of these two opposite effects, using octylglucoside as the detergent, revealed that the stimulation is dependent on the ratio of Mg^{2+} /ATP. At high Mg^{2+} /ATP ratios higher concentrations of octylglucoside are required for stimulation of the Mg^{2+} -ATPase activity than for inhibition of the Ca^{2+} -ATPase one (Norling et al., 1988). But at optimal Mg^{2+} /ATP ratios of 0.2 to 0.5 both inhibition and stimulation occur at identical and very low concentrations of octylglucoside. A 50% effect is obtained at 5 mM octylglucoside, a concentration well below its critical micellar concentration (Weiss et al., 1994, see Table 1). These results indicate that the effect of octylglucoside cannot be restricted to relief of inhibition by free Mg^{2+} -ions. It must also have a more direct effect on the affinity of the RrF_1 cation binding site towards Ca^{2+} and Mg^{2+} . A similar

almost complete conversion of the RrF_0F_1 and RrF_1 from a mostly Ca^{2+} -dependent into a mainly Mg^{2+} -dependent enzyme, has been obtained when ATP was replaced by 1, N^6 -etheno ATP (Schafer et al., 1980).

The ATPase activity of the purified *Rp. palustris*, *Rb. sphaeroides* and *Cf. aurantiacus* enzymes has also been extensively characterized (Müller et al., 1982 and 1983; Yanyushin, 1988). All complexes are active Ca^{2+} -ATPases, and exhibit a Mg^{2+} -ATPase activity, amounting to about 40% of their Ca^{2+} -ATPase activities, that can be stimulated by sulfite and octylglucoside. None of these activities is stimulated by trypsin. The nucleotide specificity of these enzymes is similar; the preferential substrate is ATP, but GTP, UTP, and to a lesser extent CTP, are also hydrolyzed, especially in presence of Ca^{2+} -ions.

A kinetic analysis of the partially purified CvF_1 (Gepshtein and Carmeli, 1977) and the completely purified RrF_1 (Müller et al., 1979) and RsF_1 (Müller et al., 1983) revealed that in all complexes, as in the membrane-bound and isolated RrF_0F_1 (see II.B. and II.C.1), the cation-ATP complex is the functional substrate for ATP hydrolysis. The kinetic parameters obtained for $(CaATP)^{2-}$ are very similar in all examined complexes. The K_m for $(CaATP)^{2-}$ is between 0.2–0.5 mM, the K_i for free ATP is 0.5 to 1.0 mM, and the K_i for free Ca^{2+} -ions is 5 to 8 mM. The kinetic parameters for $(MgATP)^{2-}$ show however large differences. Thus, the K_m for $(MgATP)^{2-}$ is 1 mM in CvF_1 and RsF_1 , but only 30 μ M in RrF_1 . The K_i for free ATP is similar in all complexes - about 1 mM, but the K_i for free Mg^{2+} -ions is again very different, although in this case it is around 10 to 20 μ M in both CvF_1 and RrF_1 but 0.65 mM in RsF_1 . The reason for these differences has not been clarified.

Some general catalytic properties of these isolated bacterial F_1 -ATPases do, however, emerge from the above summary. They are not latent ATPases and do not respond to the CF_1 activation treatments, except for CvF_1 , which is stimulated by trypsin. They are also both Ca^{2+} - and Mg^{2+} -ATPases with a higher Ca^{2+} -dependent activity, except for RcF_1 whose activities are not clear. These enzymes thus form a separate group between the very active EcF_1 -ATPase, that has a much higher Mg^{2+} - than Ca^{2+} -ATPase activity (Dunn and Heppel, 1981), and the tightly regulated latent CF_1 (McCarty and Moroney, 1985).

All isolated cyanobacterial F_1 -ATPases, unlike most photosynthetic bacterial ones, are rather latent enzymes. Their Ca^{2+} -ATPases, as the chloroplast

CF_1 -ATPase, is stimulated 5 to 10 fold by trypsin. They show also a very low Mg^{2+} -ATPase activity that can be stimulated 10 to 20 fold by methanol (Binder and Bachofen, 1979; Lubberding et al., 1981; Hicks and Yocum, 1986b; Nemoto et al., 1990). But except for the *Spirulina* enzyme, the cyanobacterial F_1 -ATPases do not respond to additional treatments, such as heat and DTT, that elicit ATPase activity in latent chloroplast CF_1 . The molecular basis of thiol activation involves the reduction of a disulfide bond between cysteines 199 and 205 in the spinach CF_1 γ subunit (McCarty and Moroney, 1985; Glaser and Norling, 1991). These two cysteines are rather specific to plant chloroplast γ subunits, since all other F_1 γ subunit sequences reported to date, including those of various *Synechococcus* strains, as well as of *Rs. rubrum* and *Rp. blastica*, do not contain them (see Van Walraven et al., 1993 and references therein). In light of the positive response of the *Spirulina* enzyme to DTT (Hicks and Yocum, 1986b) it would be most interesting to find out whether the *Spirulina* F_1 γ subunit sequence contains these two cysteines.

3. Nucleotide Binding and Chemical Modifications

The determination of the number of nucleotide binding sites in various purified F_1 -ATPases and their characterization played a major role in formulating the presently prevailing hypothesis for the mechanism of action of the F_0F_1 ATP synthase-ATPase complex (Boyer, 1987 and 1993). The maximal number of nucleotide binding sites retained on MF_1 and EcF_1 after passage through gel filtration centrifuge columns is six (Futai et al., 1989; Penefsky and Cross, 1991 and references therein). In CF_1 such nonequilibrium binding measurements revealed the presence of four sites (Xue et al., 1987; Shapiro et al., 1991a) and only under strict equilibrium conditions have six sites been recently observed (Girault et al., 1988; Shapiro et al., 1991b). Three of the sites can readily exchange bound nucleotides for medium nucleotides and are suggested to have a catalytic role, whereas the three less exchangeable sites are referred to as noncatalytic (Penefsky and Cross, 1991).

The number and properties of nucleotide binding sites on RrF_1 and CF_1 have recently been compared with enzymes depleted of all loosely bound nucleotides by passage through three successive centrifuge columns (Weiss et al., 1994). They still

contain 1.6 mol of ADP plus 0.1 mol of ATP/mol of CF_1 , and 1.5 mol of ATP plus 1.1 mol of ADP/mol of RrF_1 . After incubation with saturating concentrations of Mg^{2+} -AMP-PNP, followed by removal of all excess and loosely bound nucleotides, both enzymes have been found to retain up to four mol of tightly bound nucleotides/mol F_1 . In RrF_1 they include 2.3 mol of AMP-PNP, practically no ADP, and all the 1.5 mol of ATP/mol RrF_1 that were retained on the depleted RrF_1 . So in RrF_1 about two of the observed four nucleotide binding sites do exchange with medium AMP-PNP and two are occupied by nonexchangeable ATP molecules. The lower maximal number of four occupied nucleotide binding sites retained after column centrifugation on the photosynthetic CF_1 and RrF_1 , as compared to six in the respiratory MF_1 and EcF_1 , is probably due to faster K_{off} constants of two of the Mg-dependent nucleotide binding sites on RrF_1 and CF_1 . They might lead to the much lower Mg^{2+} -ATPase activities of the photosynthetic F_1 -ATPases.

The location of nucleotide binding sites has been studied in respiratory and chloroplast F_1 -ATPases with labeled nucleotide affinity probes or photo-reactive nucleotide analogs and, where available, with isolated F_1 subunits. These studies have revealed that all nucleotide binding sites reside exclusively on the F_1 α and β subunits (Vignais and Lumardi, 1985; Futai et al., 1989; Penefsky and Cross, 1991). Some of these reagents that inhibit F_1 -ATPase activity are also known to modify specific amino acid residues. The effect of such reagents as well as of other inhibitors of F_1 -ATPase activity have been studied mainly with RrF_1 .

DCCD is a hydrophobic carboxyl group reagent, which inhibits all types of F_0F_1 -ATPases by binding specifically to the conserved carboxyl residue within the C-terminal hydrophobic segment in the F_0 c subunit (Hoppe and Sebald, 1984). Gepshtein et al., (1978) were the first to observe that DCCD can also inhibit the purified CvF_1 Ca^{2+} -ATPase activity. Further experiments with [^{14}C] DCCD have established that it does indeed bind to and inactivates all examined F_1 -ATPases (Vignais and Lunardy, 1985). Khanan-shvili and Gromet-Elhanan (1983b) have shown that DCCD inactivates purified RrF_1 in a time- concentration- and pH-dependent manner. Complete inhibition requires binding of 1 mol of [^{14}C]DCCD/mol of RrF_1 , suggesting that inactivation is associated with modification of one essential carboxyl group in the RrF_1 complex. The inhibition of both membrane-

bound and isolated RrF_1 by another, hydrophilic carboxyl group modifier, WRK, has also been proposed to be due to modification of one essential carboxyl group on RrF_1 (Ceccarelli and Vallejos, 1983). But since a previous modification with WRK did not prevent binding of [^{14}C] DCCD, these two reagents seem to modify two different carboxyl groups on RrF_1 . This suggestion has indeed been corroborated by studies with the isolated $RrF_1 \beta$ subunit (see III.B.3).

The adenine analogue NBf-Cl does also inhibit both membrane-bound and soluble F_1 -ATPase from various sources (Vignais and Lunardy, 1985). In *Rs. rubrum* it inhibits photophosphorylation and the membrane-bound Mg^{2+} -ATPase activity as well as the Ca^{2+} -ATPase activity of soluble RrF_1 , in a DTT-reversible manner (Khananshvilii and Gromet-Elhanan, 1983a). Isolated RrF_1 binds covalently [^{14}C] NBf-Cl with an accompanying increase in absorbance at 385 nm, indicative of a tyrosyl-0-NBf bond. Full protection of the inhibition of the $RrF_1 Ca^{2+}$ -ATPase by NBf-Cl has been obtained in presence of 5 mM P_i (Cortez et al., 1983). Another reagent that effectively inhibits the $RrF_1 Ca^{2+}$ -ATPase activity is the histidine reagent DEPC. Complete inactivation is obtained on modification of 2 to 3 histidine residues per molecule of RrF_1 (Khananshvilii and Gromet-Elhanan, 1983c).

Various other known inhibitors of F_1 -ATPases have also been reported to inhibit the $RrF_1 Ca^{2+}$ -ATPase. These include azide (Johansson et al., 1973), aurovertin (Gromet-Elhanan, 1974b; Ravizzini et al., 1975), efrapeptin (Webster et al., 1977) and quercetin (Weiss et al., 1994). Some inhibitors seem to exert a similar effect on all types of F_1 -ATPases, while others, such as aurovertin, efrapeptin and tentoxin, are more specific. Aurovertin is a fluorescent compound which inhibits MF_1 and EcF_1 ATPase activities. Its fluorescence is enhanced when it binds to these enzymes, and undergoes marked changes on addition of nucleotides, that have been used to monitor nucleotide binding sites on the sensitive F_1 -ATPases (Vignais and Lunardy, 1985). Aurovertin has been found to inhibit the RrF_1 -ATPase, but no accompanying changes in its fluorescence could be observed (Gromet-Elhanan, 1974b).

The effects of efrapeptin and tentoxin on the Ca^{2+} - and Mg^{2+} -ATPase activities of RrF_1 and activated CF_1 have recently been compared under identical assay conditions (Weiss et al., 1994). Efrapeptin was found to be a much more effective inhibitor of RrF_1 than CF_1 . Half maximal inhibition of both Ca^{2+} - and

Mg^{2+} -dependent RrF_1 -ATPase activities is obtained with a ratio of 1.6 mol of efrapeptin/mol of RrF_1 , whereas for CF_1 a thirty fold higher ratio is required, RrF_1 is thus as sensitive to efrapeptin as the mitochondrial F_1 -ATPase (Cross and Kohlbrenner, 1978), while the lower sensitivity of CF_1 is similar to that reported for the *E. coli* enzyme (Wise et al., 1983). Tentoxin, on the other hand, is a very potent species specific inhibitor of CF_1 (Steele et al., 1976; Selman and Durbin, 1978). Half maximal inhibition of the spinach CF_1 -ATPase activities are obtained at a concentration below 0.1 μM tentoxin. All RrF_1 ATPase activities are however completely resistant to tentoxin concentrations of up to 300 μM under all assay conditions used (Weiss et al., 1994; see also III.B.2). The membrane-bound and isolated F_1 -ATPase of the cyanobacterium *Anacystis nidulans* has recently been reported to be as sensitive to tentoxin as spinach CF_1 (Ohta et al., 1993).

B. Individual F_1 Subunits and Partial Complexes

1. Isolation and Reconstitution of Single Subunits

The complex structure of the F_0F_1 ATP synthase and its soluble F_1 -ATPase sector (see Fig. 2) impedes studies aimed at elucidating the structure of their catalytic sites and mechanism of action. A precise determination of the function of each subunit is a prerequisite for achieving this goal. Two main methods have been developed for the isolation of single F_1 subunits in a native, active state. The first involves partial or complete dissociation of the F_1 complex, followed by separation and purification of the dissociated subunits. Complete dissociation of all five F_1 subunits was reported for F_1 from various respiratory bacteria, and reassociation of mixtures of such isolated subunits led to isolation of partial active complexes (Futai and Kanazawa, 1983, and references therein). There are no reported attempts to dissociate F_1 -ATPases isolated from photosynthetic bacteria. With CF_1 only a partial dissociation was achieved, enabling up to now isolation and purification of $CF_1 \beta$ containing about 5% of $CF_1 \alpha$ (Richter et al., 1986).

The second method developed in *Rs. rubrum* chromatophores involves selective removal of individual subunits or partial complexes from the membrane-bound F_1 -ATPase. Incubation of chroma-

tophores with 2M LiCl followed by 2M LiBr led to sequential removal of all their $\text{RrF}_1\beta$ and γ subunits, leaving inactive, but fully reconstitutable β -less and β , γ -less chromatophore membranes (Philosoph et al., 1977; Khananshvili and Gromet-Elhanan, 1982). The thoroughly washed LiCl-treated chromatophores, retain about 5% of their ATP synthesis and hydrolysis activities, but over 80% of their capacity to take up protons during light-induced electron transport. Their lost ATP-linked activities could be restored by more than 80% after reconstitution with three volumes of the dialyzed LiCl-extract (Binder and Gromet-Elhanan, 1974).

The $\text{RrF}_1\beta$ removed by extraction of *Rs. rubrum* chromatophores with LiCl and purified by ammonium sulfate fractionation and gel filtration (Philosoph et al., 1977) or ion-exchange chromatography (Gromet-Elhanan and Khananshvili, 1986) could rebind to the LiCl-treated chromatophores and restore their lost ATP-linked activities, but showed no measurable ATPase activity. A previous claim for a significant ATPase activity in a similarly prepared $\text{RrF}_1\beta$ (Harris et al., 1985) has recently been explained as due to contamination by the $\text{RrF}_1\alpha\beta$ -ATPase (Andralojc and Harris, 1992; see III.B.5). Antibodies prepared against the purified $\text{RrF}_1\beta$ did agglutinate control active *Rs. rubrum* chromatophores, but not the washed LiCl-treated inactive ones (Philosoph and Gromet-Elhanan, 1981b). These antibodies could also form precipitin lines with whole native RrF_1 , but not with a four subunit RrF_1 , composed of α , γ , δ , and ϵ , that has been solubilized from the washed LiCl-treated chromatophores (Philosoph and Gromet-Elhanan, 1981b). These results indicate that *all* the $\text{RrF}_1\beta$ subunit has indeed been removed from the thoroughly washed LiCl-treated β -less *Rs. rubrum* chromatophores.

Optimal conditions for rebinding of purified $\text{RrF}_1\beta$ to β -less chromatophores, which lead to restoration of 70–90% of their lost ATP synthesis and hydrolysis activities, require the presence of at least 2 mM ATP and 20 mM MgCl_2 during the long reconstitution at 35 °C, but much lower concentration of MgCl_2 for assays of restored activity (Gromet-Elhanan, 1974a; Philosoph et al., 1977). Under these conditions the reconstitution of a fixed amount of β -less chromatophores with increasing amounts of $\text{RrF}_1\beta$ follows a simple saturation curve, and results in a similar degree of restoration of photophosphorylation and Ca^{2+} - and Mg^{2+} -ATPase activities (Khananshvili and Gromet-Elhanan, 1982). For restoration of 50% of

these activities a ratio of 1.0 μg of $\text{RrF}_1\beta/\mu\text{g}$ BChl is required.

Further extraction of β -less *Rs. rubrum* chromatophores by LiBr removed one additional subunit, $\text{RrF}_1\gamma$, that was purified by ammonium sulfate fractionation and hydroxyapatite chromatography (Philosoph et al., 1981). The resulting doubly extracted chromatophores have, of course, no ATP-linked activities, but can be restored to about 65% by reconstitution with both purified $\text{RrF}_1\beta$ and $\text{RrF}_1\gamma$, although not with either one alone (Khananshvili and Gromet-Elhanan, 1982). These LiCl-LiBr doubly extracted chromatophores are therefore defined as β , γ -less chromatophores. Reconstitution of β , γ -less chromatophores by the missing subunits was optimal at pH 6.2, and required the presence of 20 mM MgCl_2 (Philosoph et al., 1981; Gromet-Elhanan et al., 1981). Because the reconstitution of β -less chromatophores with $\text{RrF}_1\beta$ was similar between pH 6.2 and 8.0, both systems could be compared under identical conditions. All assays of restored activity were, however, conducted at their optimal pH 8.0.

Incubation of chloroplast thylakoid membranes from various plants with LiCl resulted in release of $\text{CF}_1\beta$ together with varying, but large amounts of $\text{CF}_1\alpha$ and traces of the single copy γ , δ , and ϵ subunits. The ratio of released $\text{CF}_1\alpha/\text{CF}_1\beta$ varied from 0.7–0.8 in spinach (Avital and Gromet-Elhanan, 1990, 1991), to 0.5 in lettuce and 0.2–0.3 in tobacco (Avni et al., 1991). Fractionation of the spinach LiCl-extract led to isolation of pure $\text{CF}_1\beta$, a $\text{CF}_1(\alpha\beta)$ complex, and small amounts of various larger partial CF_1 complexes, but no pure $\text{CF}_1\alpha$ (Avital and Gromet-Elhanan, 1991; Sokolov et al., 1992; and see III.B.2 and III.B.5). Washed LiCl-treated spinach thylakoids, as the *Rs. rubrum* LiCl-treated chromatophores, lost >95% of their photophosphorylation capacity. But, because of the more drastic removal of CF_1 subunits, the reconstitution of the treated thylakoids with their LiCl-extract restored at the most 20% of the lost activity (Avital and Gromet-Elhanan, 1991).

In light of the observed release of large amounts of $\text{CF}_1\alpha$ from LiCl-treated chloroplasts, we have reexamined the *Rs. rubrum* LiCl-extracts for presence of $\text{RrF}_1\alpha$ by Western immunoblotting with mixtures of anti $\text{RrF}_1\alpha$ and $\text{RrF}_1\beta$. The ratio of $\text{RrF}_1\alpha/\text{RrF}_1\beta$ appearing in these extracts varied between 0.03–0.15 (Weiss and Gromet-Elhanan, unpublished). The small amount of $\text{RrF}_1\alpha$ extracted by LiCl together with *all* the $\text{RrF}_1\beta$, is partly associated in an $\text{RrF}_1(\alpha\beta)$ complex (Andralojc and Harris, 1993; and see

III.B.5). It is also the source of the $\sim 5\%$ $RrF_1\alpha$ found to accompany the purified $RrF_1\beta$ preparations which can by themselves restore activity to the β -less chromatophores (Weiss and Gromet-Elhanan, unpublished). Purified preparations of $RrF_1\beta$ containing $<1\%$ of $RrF_1\alpha$, as well as purified expressed $RrF_1\beta$, that has no trace of the α subunit can restore the β -less RrF_0F_1 activity only when supplemented with $\sim 5\%$ of $RrF_1\alpha$ (see also III.B.2 and 4).

2. Hybrid F_1 -ATPases: Formation and Characterization

The inactive, but fully reconstitutable, β -less *Rs. rubrum* chromatophores from which all $RrF_1\beta$ has been removed provide a uniquely suitable system for testing the capacity of $F_1\beta$ subunits, isolated from various other sources, for reconstitution of active hybrid membrane-bound F_1 ATPases. Two such active hybrids have been formed with isolated $EcF_1\beta$ (Gromet-Elhanan et al., 1985) and spinach $CF_1\beta$ that contained about 5% of $CF_1\alpha$ (Richter et al., 1986). Pure $CF_1\beta$ containing no trace of $CF_1\alpha$ could not form an active hybrid when reconstituted by itself into β -less *Rs. rubrum* chromatophores (Avital and Gromet-Elhanan, 1991; Avni et al., 1991). It could, however, do so when supplemented by trace amounts of a pure $CF_1(\alpha\beta)$ complex, at a ratio of 0.1 μg of $CF_1(\alpha\beta)$ /1 μg of BChl (Avni et al., 1991). These traces of $CF_1(\alpha\beta)$ were inactive by themselves. It was therefore suggested that the $CF_1\alpha$ component of the added $CF_1(\alpha\beta)$ exerts a chaperonin-like function of keeping $CF_1\beta$ in the correct folding during the reconstitution at 35 °C with 20 mM MgCl_2 (see III.B.1).

All types of $EcF_1\beta/RrF_1$ and CF_1/RrF_1 hybrids could restore 50 to 140% of the Mg^{2+} -ATPase activity, but less than 10% of the photophosphorylation activity obtained in β -less chromatophores reconstituted with their homologous $RrF_1\beta$. Moreover in the hybrids, unlike in the homologous enzyme, the restored Mg^{2+} -ATPase activity was not coupled to H^+ -translocation. In this respect the hybrid Mg^{2+} -ATPase activities are rather similar to the Ca^{2+} -ATPase activity of the control membrane-bound RrF_0F_1 , which has been shown to be completely disconnected from H^+ -translocation (see II.B). These results indicate that in the hybrid enzymes the RrF_1 catalytic site is restored, but its connection with others subunits is not tight enough to trigger proton translocation

through the membrane-bound RrF_0 sector. The relatively high Mg^{2+} -ATPase activity of the hybrid enzymes thus suggests that they might enable leakage of the protons released during ATP hydrolysis to the outside medium, rather than translocate them inside through the F_0 sector. Experimental evidence for this suggestion is provided by the finding that both hybrid Mg^{2+} -ATPases, unlike the homologous RrF_1 Mg^{2+} -ATPase, are not stimulated by uncouplers (Richter et al., 1986; Gromet-Elhanan, 1988).

The hybrid enzymes retain specific properties of their parent F_1 -ATPases that enable clear identification of the activity of each one of them. Thus only the EcF_1/RrF_1 hybrid Mg^{2+} -ATPase is inhibited by anti EcF_1 antibodies and insensitive to sulfite, and only the CF_1/RrF_1 hybrid is inhibited by tentoxin. Indeed, the $CF_1\beta/RrF_1$ hybrid is as sensitive to tentoxin as the CF_1 -ATPase, being fully inhibited by 0.1 μM , whereas the native RrF_1 -ATPase is resistant even to 10^4 -fold higher concentrations (see III.A.3). So the complete elimination of restored ATPase activity in the $EcF_1\beta/RrF_1$ and $CF_1\beta/RrF_1$ hybrids in presence of anti EcF_1 and tentoxin, respectively demonstrate the absence of any remaining homologous RrF_1 activity. These findings reinforce an earlier conclusion that *all* the $RrF_1\beta$ has been removed from the β -less *Rs. rubrum* chromatophores (see III.B.1).

3. Nucleotide Binding Sites on Isolated $F_1\beta$ Subunits

The finding of six nucleotide binding sites on various F_1 -ATPases that are located exclusively on the $F_1\alpha$ and β subunits (Futai et al., 1989; Penefsky and Cross, 1991), together with the conserved stoichiometry of $\alpha_3\beta_3$ (see II.A.2), led to the suggestion that each of these subunits contains a single nucleotide binding site. These sites were designated as catalytic or noncatalytic according to their exchangeability with medium nucleotides, and since nucleotide affinity probes were shown to label the β subunits of many F_1 -ATPases under conditions that led to loss of activity, the catalytic sites were assumed to be located on the β subunits.

Direct binding studies with labeled ATP or ADP have indeed revealed the presence of a single nucleotide binding site on the $F_1\alpha$ and β subunits isolated from two respiratory bacteria (Futai et al. 1989). In isolated $RrF_1\beta$ such direct binding studies have however identified *two* different binding sites for either ATP (Gromet-Elhanan and Khananshvilii,

1984) or ADP (Khananshvili and Gromet-Elhanan, 1984), one being Mg-independent and the other Mg-dependent (Table 2). These results questioned the validity of the proposed model of a single binding site on each α and β subunit. To accommodate these findings with the overall number of six nucleotide binding sites per F_1 molecule, one of the two nucleotide binding sites on the β subunit, the Mg-independent site, has been suggested to reside at an interface between the α and β subunits (Gromet-Elhanan and Khananshvili, 1984). These binding properties have also been observed in pure expressed RrF₁ β that has no trace of the α subunit (see III.B.4).

Further evidence for this suggestion came from ³²P_i binding tests, which revealed only one Mg-dependent P_i binding site on RrF₁ β (Khananshvili and Gromet-Elhanan, 1985a, see Table 2), and from the effect of chemical modification of RrF₁ β by DEPC and WRK (Khananshvili and Gromet-Elhanan, 1985b). Table 2 illustrates that DEPC did not affect the binding of ADP to both sites on RrF₁ β , nor its capacity to rebind to β -less chromatophores, but inhibited completely the Mg-independent binding of P_i, the binding of ATP to its Mg-dependent site, and the capacity of the modified rebound RrF₁ β to restore ATP synthesis in the reconstituted chromatophores. These results have thus identified the Mg-dependent ATP and P_i binding site on RrF₁ β as the catalytic site and the Mg-independent site as the noncatalytic one (Khananshvili and Gromet-Elhanan, 1985b). More recent studies on the photolysis of 2-azidoadenine nucleotides bound at either catalytic or noncatalytic sites on MF₁, EcF₁, and CF₁ have indicated that the β subunit was labeled in all cases (Boyer, 1987). These findings suggested the presence of at least parts of the adenosine moiety of both nucleotide binding sites on the F₁ β subunit, and the possible sharing of one (Penefsky and Cross, 1991) or even both sites (Gromet-Elhanan, 1992) by the α and β subunits.

Occupation of the nucleotide binding sites on Rr β by ADP, ATP and P_i was found to induce large conformational changes, that could be followed by their effect on trypsin sensitivity of the isolated subunit (Khananshvili and Gromet-Elhanan, 1986). Two distinct types of changes were obtained: one on occupation of the Mg-independent nucleotide binding site, that is further stabilized by MgADP, the other on binding of MgATP or MgP_i, suggesting that it is induced by occupation of the γ -phosphoryl subsite in the Mg-dependent catalytic site on the β subunit.

Table 2. Nucleotide binding to and restored ATP synthesis by native and diethylpyrocarbonate modified RrF₁ β ¹

Assayed activity	Type of assayed RrF ₁ β	
	native	modified
Substrate binding ²		
[³ H]ADP	1.88	1.76
[³ H]ATP	1.84	0.78
³² P _i	0.93	0.01
Restored ATP synthesis ³	647	37

¹ Modified from Khananshvili and Gromet-Elhanan (1985b).

² Binding stoichiometry in mol/mol of RrF₁ β , assayed in presence of MgCl₂.

³ ATP synthesis in μ mol/hr per mg of BChl, recorded in β -less chromatophores reconstituted with native or DEPC modified RrF₁ β .

Purified RrF₁ β was found to bind [¹⁴C]NBf-Cl and [¹⁴C]DCCD, with a binding stoichiometry of 1 mol of either reagent/mol of RrF₁ β (Khananshvili and Gromet-Elhanan, 1983a,b). The NBf-modified RrF₁ β , unlike the DEPC or WRK modified subunit, did rebind to the β -less chromatophores and restored all their lost ATP-linked activities as efficiently as native unmodified RrF₁ β , whereas the DCCD-modified subunit lost its capacity to rebind to the β -less chromatophores. Moreover, modification of RrF₁ β by either DCCD or NBf-Cl had little effect on its capacity to bind ADP, ATP and P_i (Khananshvili and Gromet-Elhanan, 1985b). These results indicate that DCCD and WRK modify two different carboxyl groups on isolated RrF₁ β (see III.A.3). The WRK modified carboxyl group is located within the catalytic site, while the DCCD modified carboxyl group is essential for rebinding of the isolated RrF₁ β to the β -less chromatophores (see III.B.4).

4. Cloning and Expression of F₁ β Subunits

The large number of direct assays for binding of nucleotides, P_i and various modifying reagents by isolated RrF₁ β , together with its capacity to rebind to β -less chromatophores and restore their ATP-linked activities, make RrF₁ β an especially interesting candidate for studies aimed at identifying the amino acid residues essential for these activities. A most promising approach towards this goal is the use of site directed mutagenesis, which requires cloning and expression of the RrF₁ β gene. This technique can also ensure the absence of contamination by other F₁ subunits in the expressed protein.

Baltscheffsky et al., (1992) have recently reported on the cloning of the RrF₁ β gene, and its expression

as a soluble fusion protein in *E. coli*. Activity tests have not been reported yet for this expressed $RrF_1\beta$. In another attempt (Nathanson and Gromet-Elhanan, 1994), cloning and functional expression of wild type and Glu 195 mutant $RrF_1\beta$ has been achieved. The expressed β subunits, that are free of any contaminating $RrF_1\alpha$, could bind ATP as the native $RrF_1\beta$ (III.B.3), but could not restore ATP-linked activity to β -less *Rs. rubrum* chromatophores. They could, however, do so when supplemented with traces of about 5% of $RrF_1\alpha$, as has been shown for native $RrF_1\beta$ containing <1% of $RrF_1\alpha$ (III.B.1) and for pure $CF_1\beta$ containing no trace of $CF_1\alpha$ (III.B.2). The $RrF_1\beta$ Glu 195 \rightarrow Gly mutant, unlike the wild type native or expressed $RrF_1\beta$, could form only an unstable assembled RrF_0F_1 , that dissociated upon centrifugation (Nathanson and Gromet-Elhanan, 1994). Glu 195 in $RrF_1\beta$ is identical to Glu 192 in $EcF_1\beta$ and Glu 199 in $MF_1\beta$ that are modified by DCCD (Yoshida et al., 1982). The findings that both the Glu 195 \rightarrow Gly mutant and the DCCD modified $RrF_1\beta$ (see III.B.3) form unstable assembled F_0F_1 complexes indicate that the fully conserved Glu 195 in $RrF_1\beta$ does play an important role in the assembly of the β subunit into a stable F_1 complex.

Three recent reports describe the cloning and expression of chloroplast $CF_1\beta$ genes from *Chlamydomonas reinhardtii* (Blumenstein et al., 1990), Spinach (Chen et al., 1992) and maize (Wang et al., 1992). The expressed $CF_1\beta$ polypeptide, unlike the expressed $RrF_1\beta$, appeared in insoluble inclusion bodies. It was solubilized in all cases by 4M urea. Slow removal of the urea by stepwise dialysis restored a functional $CF_1\beta$, that could bind the nucleotide analog TNP-ATP (Chen et al., 1992).

5. Isolation, Structure and Function of minimal catalytic F_1 Complexes

$F_1(\alpha\beta)$ complexes, containing equimolar ratios of the α and β subunits, have been shown to function as active ATPases, with rates varying between 1 to 10% of those found in their parent F_1 -ATPases. The individually isolated α and β subunits show about 100 fold lower rates than those of the $F_1(\alpha\beta)$ complexes (Gromet-Elhanan, 1992 and references therein). Such complexes have either been assembled from a 1:1 mixture of cloned and expressed $TF_1\alpha$ and β subunits (Kagawa et al., 1989; Miwa and Yoshida, 1989) or isolated from LiCl extracts of spinach (Avital and Gromet-Elhanan, 1991) and lettuce

chloroplasts (Avni et al., 1991), and *Rs. rubrum* chromatophores (Andralojc and Harris, 1992).

The $TF_1\alpha$ and β subunits were found to assemble into $\alpha_3\beta_3$ -hexamers in absence of MgATP, but the hexamers dissociated into $\alpha\beta_1$ -dimers in presence of MgATP (Harada et al., 1991). So in an ATPase assay medium a varying mixture of both structures exists. The $RrF_1(\alpha\beta)$ complex appeared as an $\alpha_1\beta_1$ -dimer on size exclusion HPLC in presence of MgATP and removal of Mg^{2+} -ions caused complete dissociation of this dimer into the monomeric α and β subunits (Andralojc and Harris, 1992). The $CF_1(\alpha\beta)$ complex is very unstable and dissociates into monomers upon dilution and/or removal of ATP. A stabilized CF_1 - $\alpha_3\beta_3$ -hexamer has recently been isolated by gel filtration chromatography (M. Sokolov and Z. Gromet-Elhanan, unpublished).

All types of isolated $F_1(\alpha\beta)$ complexes are active ATPases. They exhibit however lower rates of catalysis than their parent F_1 -ATPases (see Table 1) and are resistant to inhibition by azide. The $CF_1(\alpha\beta)$ is also resistant to inhibition by tentoxin (Gromet-Elhanan and Avital, 1992). These properties suggest that the single copy F_1 subunits are not required for assembly of these $F_1(\alpha\beta)$ core complexes nor for their activity. They are however responsible for the 10 to 100 fold increased rates and for the different properties of the whole F_1 -ATPases. The $F_1(\alpha\beta)$ complexes can therefore provide an important tool for elucidating the role of the single copy subunits in the structure and function of the F_1 -ATPase.

An interesting result obtained with the $CF_1(\alpha\beta)$ and $RrF_1(\alpha\beta)$ complexes is their capacity to bind to the inactive LiCl-treated *Rs. rubrum* chromatophores and restore their activity (Avital and Gromet-Elhanan, 1991; Andralojc and Harris, 1992, 1993). The activity restored by each complex is identical to that restored by the respective isolated $F_1\beta$ subunits, which contained about 5% $F_1\alpha$ (see III.B.1 and 2). Thus the homologous $RrF_1(\alpha\beta)$ restored both ATP synthesis and hydrolysis, whereas the $CF_1(\alpha\beta)$ restored only ATP hydrolysis, that is fully sensitive to inhibition by tentoxin (Avital and Gromet-Elhanan, 1991; Gromet-Elhanan and Avital, 1992). It is not clear as yet whether these $F_1(\alpha\beta)$ complexes bind as a complex to the depleted membranes or dissociate during the reconstitution step which is conducted in 20 mM $MgCl_2$ at 35 °C (see III.B.1).

One reported difference between $CF_1(\alpha\beta)$ and $RrF_1(\alpha\beta)$ is the 10-fold lower ratio of 0.1 μg $RrF_1\alpha\beta$ / μg BChl as compared to 1 μg $CF_1(\alpha\beta)$ / μg BChl

required for 50% restoration of activity to the LiCl-treated chromatophores (Andralojc and Harris, 1993; Avital and Gromet-Elhanan, 1991). The reason for this difference can be traced to the different types of LiCl-treated chromatophores used in both cases. Andralojc and Harris (1993) studied the rebinding of $RrF_1-\alpha_1\beta_1$ to 'LiCl-washed' chromatophores in which they found, according to their nucleotide binding properties, more than 50% of the β subunits still attached to the chromatophore membrane. Avital and Gromet-Elhanan (1991) used, on the other hand, thoroughly washed β -less chromatophores from which *all* the β subunit has been removed (see III.B.1). When pure $CF_1\beta$, containing no trace of $CF_1\alpha$, was added to these β -less chromatophores it could rebind, but could not restore any ATPase activity (see III.B.2). These β -less chromatophores containing bound inactive $CF_1\beta$ are similar to the 'LiCl-washed' chromatophores, containing large amounts of attached but inactive $RrF_1\beta$, that have been used by Andralojc and Harris (1993). The ATPase activity of these $CF_1\beta$ containing β -less chromatophores could indeed be restored upon addition of a low ratio of $0.1 \mu\text{g } CF_1(\alpha\beta)/\mu\text{g BChl}$ (Avni et al., 1991).

The above described results indicate that the attached $RrF_1\beta$ present in the 'LiCl-washed' membranes (Andralojc and Harris, 1993), as the pure $CF_1\beta$, added to the β -less chromatophores (Avni et al., 1991), are activated by added traces of the respective $F_1(\alpha\beta)$ complexes. These activated $RrF_1\beta$ and $CF_1\beta$ subunits restore the same level of activity to β -less chromatophores as the $RrF_1\beta$ and $CF_1\beta$ containing about 5% of their respective $F_1\alpha$ subunits. It is, therefore, clear that restoration of activity in all LiCl-treated chromatophores does *not* require stoichiometric amounts of α and β subunits. For an accurate determination of whether this activation reflects a chaperonin-like function of $F_1\alpha$ (Avni et al., 1991) labeled $CF_1(\alpha\beta)$ and $RrF_1(\alpha\beta)$ complexes will be required.

IV. Mechanism of Action of the F_0F_1 ATP Synthase

A complete resolution of the mechanism of action of the ATP synthase requires the presence of detailed information on its structure, as well as on the pathway of proton-translocation through the whole enzyme complex and on the specific mode of coupling of this proton-transport to ATP synthesis. Although the

general features of the F_0F_1 structure have been elucidated (see II.A.2 and Fig. 2), the detailed organization of its catalytic sites is as yet unknown. Also, the role of F_0 in proton-translocation through the membrane is clear, and the detailed pathway for their translocation through this sector is being elucidated (Fillingame, 1990). But there is almost no information on if and how protons move from the F_0 sector to the F_1 sector, or on how they affect the catalytic energy-linked steps. All proposed models for the mechanism of action of the ATP synthase are therefore still at a rather speculative stage.

The hypothesis for which considerable experimental evidence exists, and that is currently the most widely used, is the binding change mechanism (see Boyer, 1987 and 1993 and Penefsky and Cross, 1991). It is based on the existing information on the presence of three catalytic sites in the F_0F_1 ATP synthase (see III.A.3) and their location mainly on the F_1 β subunits (see III.B.3). The basic features of this model have evolved from a large body of data collected from studies with MF_0F_1 , CF_0F_1 , and some respiratory bacterial enzymes. Very few mechanistic studies have been conducted with the photosynthetic bacterial enzymes, so only the overall features will be presented below. They are as follows:

1. The $\Delta\bar{\mu}H^+$ driving force is not required for the final step of ATP synthesis at each catalytic site.
2. Energy is required to promote the release of product, ATP, from the site of synthesis and to enable the binding of substrate, ADP and P_i , to another site.
3. The energy-linked substrate binding and product release occur simultaneously at separate catalytic sites, that must therefore interact during the catalytic event.

This hypothesis thus suggests that the newly formed product is tightly bound to the catalytic site. The energy driving its loosening and final release does also tighten the binding of a new substrate at an alternate site, where product is formed with no additional energy input. Thus, during catalysis each site changes its ligand affinity properties, hence the definition of binding change mechanism (Boyer, 1987 and 1993). The involvement of protons in this mechanism is linked with a proposed rotation of an aggregate of subunits, possibly the internally located

$\gamma\delta\epsilon$ subunits, against a complex of the remaining $\alpha_3\beta_3c_{6-12}$ subunits. There is however no direct evidence for this rotation mechanism.

The recently isolated $F_1(\alpha\beta)$ catalytic core complexes provide important tools for further investigation of the above proposed mechanism of action. A kinetic investigation of stable, non-dissociating $\alpha_3\beta_3$ -hexamers could establish whether the specific alternation of sites is dependent on the presence of the single copy subunits.

Summary

Some species of anoxygenic photosynthetic bacteria possess transhydrogenase and NADH dehydrogenase enzymes that are closely related to equivalent enzymes from animal mitochondria. Both are membrane proteins which couple redox reactions of the nicotinamide nucleotides to the translocation of hydrogen ions. Transhydrogenase catalyses the reversible transfer of reducing equivalents between NAD(H) and NADP(H); it has a low proton pumping stoichiometry. Probably under most conditions NADH dehydrogenase serves to transfer reducing equivalents from NADH to ubiquinone; it has a high proton pumping stoichiometry. Both enzymes are very active in chromatophore membranes isolated from cells of *Rhodobacter* and *Rhodospirillum* species grown anaerobically in the light, but their physiological function during phototrophic growth is not clear. Transhydrogenase may be involved in the transfer of reducing power between the cytoplasmic NAD(H) and NADP(H) pools, governed by the transmembrane proton electrochemical gradient (Δp), and in response to the metabolic needs of the cell. It might have a lesser role in the generation or regulation of Δp . During aerobic growth in the dark, NADH dehydrogenase undoubtedly serves as a major generator of Δp ; during phototrophic growth it might be essential for the oxidation of highly reduced carbon substrates by auxiliary oxidants such as nitrate or dimethylsulfoxide, or it might be expressed in 'readiness' for the return to dark aerobic growth.

Interest in NADH dehydrogenase in photosynthetic bacteria will increase as gene sequences become available and, perhaps, in response to the need to elucidate the role of the related protein in chloroplasts from higher plants. Present studies are limited by the lack of a purification procedure for the enzyme. Transhydrogenase,

on the other hand, is amenable to study. In many ways it presents an excellent model for the study of other ion-translocating membrane proteins, particularly in photosynthetic membranes where its activity can be measured by spectroscopy with good time resolution.

I. Introduction

A. The Reactions Catalysed by Transhydrogenase and NADH Dehydrogenase

Proton-translocating transhydrogenase (H^+ -Thase) catalyses the transfer of reducing equivalents (hydride ion equivalents) between NAD(H) and NADP(H) coupled to the translocation of protons across a membrane,

where x is the stoichiometry of H^+ translocated per H^- equivalent transferred between the nucleotides. There are no scalar protons associated with the net reaction. Recent reviews on transhydrogenase have been published by Rydstrom et al. (1987), Jackson (1991) and Yamaguchi and Hatefi (1992).

NADH dehydrogenase (NADH-DH), more properly called NADH:ubiquinone oxidoreductase and sometimes, especially in mitochondria, referred to as 'complex I', catalyses the transfer of reducing equivalents from NADH to ubiquinone coupled to the translocation of protons across a membrane,

where n is the stoichiometry of H^+ translocated per $2e^-$ transferred from NADH to UQ. A scalar proton is associated with the net reaction. Recent reviews on NADH-DH can be found (Ragan, 1987; Weiss and Friedich, 1991; Weiss et al., 1991; Yagi, 1991, 1993; Fearnley and Walker, 1992; Walker, 1992).

Both enzymes are found in the inner membranes of animal and plant mitochondria and the cytoplasmic membranes of many bacteria. In the anoxygenic

photosynthetic bacteria, H^+ -Thase has been studied in some detail in *Rhodobacter (Rb.) capsulatus* and *Rhodospirillum (Rs.) rubrum* but, in other organisms from the group, the available information is sketchy. There have been few investigations into the properties of NADH-DH from photosynthetic bacteria but this situation might change in view of the resurgence of interest in the enzyme from mitochondria and the finding that there may be homologues of some subunits of mitochondrial complex 1 in the chloroplast genome. Unfortunately, the enzyme from photosynthetic and other bacteria has been difficult to isolate in a form that can actively transport protons (Berks and Ferguson, 1991). Remarkably, the functions of H^+ -Thase and of NADH-DH during phototropic growth are not well understood (Jackson and McEwan, 1993). However, both are present at high activities during chemoheterotrophic and photoheterotrophic growth. They are both directly coupled to the proton electrochemical gradient (Δp), the primary energetic intermediate of the bacterial cell, and to the redox state of the nicotinamide nucleotide pools. Some speculations as to the function of H^+ -Thase and NADH-DH will be offered at the end of the chapter.

B. Historical Perspective

The discovery of H^+ -Thase and NADH-DH in photosynthetic bacteria followed on rapidly from research into the mechanism of energy coupling in animal mitochondria during the 1960's.

Keister and Yike (1966, 1967b) and Orlando et al. (1966) described 'energy-linked' transhydrogenation from NADH to NADP^+ in chromatophores from a number of species of photosynthetic bacteria. The reaction proceeded at a low rate in darkened suspensions of chromatophores but was substantially increased by ATP, PPi or light. The acceleration was blocked by uncoupling agents. From these observations and from the effects of specific inhibitors, for example antimycin, on the light-driven reaction and oligomycin on the ATP-driven reaction, it was concluded that transhydrogenation was coupled to the consumption of 'the high energy intermediate,

Abbreviations: AcPdAD⁺ – acetyl pyridine adenine dinucleotide; *E.* – *Escherichia*; H^+ -Thase – proton-translocating nicotinamide dinucleotide transhydrogenase; *N.* – *Neurospora*; NADH-DH – NADH dehydrogenase; *Rb.* – *Rhodobacter*; *Rs.* – *Rhodospirillum*; Δp – proton electrochemical gradient

X~I'. Subsequent appreciation that the high energy intermediate is in fact a proton electrochemical gradient led to the recognition that transhydrogenase is a proton pump, confirmed by Rydstrom (1979) and Earle and Fisher (1980) with the purified mitochondrial enzyme reconstituted into liposomes. An equivalent experiment with purified transhydrogenase from photosynthetic bacteria was not reported until recently (Jackson et al., 1991).

It has long been known that several species of the anoxygenic photosynthetic bacteria are capable of oxidative growth in the dark under aerobic conditions. It was realized in the 1950's and 1960's that chromatophores, for example from *Rs. rubrum*, *Rb. sphaeroides* and *Rb. capsulatus*, had respiratory activity with NADH as an electron donor. The activity was shown to be inhibited by rotenone and piericidin A and might thus be related to NADH-DH from mitochondria. The existence of an energy coupling site at the level of NADH-DH in chromatophores was indicated by the observation of 'energy-linked reversed electron flow' first, in *Rs. rubrum* (Keister and Yike, 1967a) and then in *Rb. capsulatus* (Klemme, 1969); reduction of NAD⁺ by succinate was observed only if chromatophores were supplied with ATP, PPi or light; uncoupling agents inhibited the reaction. Although the clear implication of these findings would now be that chromatophore NADH-DH is a proton pump, a direct demonstration of this, either in chromatophores, or in a reconstituted system is still required.

II. The Structure of Transhydrogenase

Until recently most work on the structure of H⁺-Thase had been carried out with the enzymes from

mitochondria and *Escherichia coli* but information is now emerging on the somewhat different structure of the *Rs. rubrum* protein.

A. The Structure of Transhydrogenase from Mitochondria and *E. coli* as a Paradigm for the Enzyme from Photosynthetic Bacteria?

The amino acid sequences for H⁺-Thase from *E. coli* and mitochondria have been predicted from the nucleotide sequences of the genes and the cDNA, respectively (Clarke et al., 1986; Yamaguchi et al., 1988; Ahmad et al., 1992). It is established that the *E. coli* enzyme comprises two polypeptides (α , Mr 54000 and β , Mr 49000) which in the active enzyme probably form an $\alpha_2\beta_2$ structure (Clarke and Bragg, 1985; Hou et al., 1990). The mitochondrial enzyme is a dimer of two identical polypeptides (Anderson and Fisher, 1981; Persson et al., 1987). When the α and β polypeptides of H⁺-Thase from *E. coli* are arranged contiguously there is a clear similarity in sequence with the mitochondrial enzyme. Hydropathy profiles indicate that both enzymes might be organised in three large domains—see Fig. 1 (Clarke et al., 1986; Yamaguchi et al., 1988). In mitochondria, domain I (approximately 400 amino acids at the N-terminus) and domain III (approximately 200 amino acids at the C-terminus) are relatively hydrophilic and are thought to protrude from the membrane whereas domain II (approximately 400 amino acids at the center of the polypeptide) is strongly hydrophobic and might comprise up to 14 trans-membrane helices. In *E. coli* the structure is similar except that there is a 'break' in the polypeptide chain within the hydrophobic domain II. Experiments with proteases and with specific antibodies raised to segments of the protein indicate that domains I and

Fig. 1. The domain structure of transhydrogenases from mitochondria, *E. coli* and *Rs. rubrum* and homology with alanine dehydrogenase.

III protrude from the same side of the membrane - the matrix side in mitochondria (Yamaguchi and Hafeji, 1991) and the cytoplasmic side in *E. coli* (Tong et al., 1991). There is no evidence for the existence of prosthetic groups in H^+ -Thase from any source.

There is clear evidence from analysis of steady-state kinetics (Hanson, 1979; Homyk and Bragg, 1979; Enander and Rydstrom, 1982; Lever et al., 1991) that there are separate sites on H^+ -Thase for NAD^+ or NADH and for $NADP^+$ or NADPH. Substrates bound at the NAD(H) site donate or receive H^- equivalents to or from the 4A position of the nicotinamide ring whereas substrates bound at the NADP(H) site donate or receive H^- equivalents to or from the 4B position (Kawasaki et al., 1964; Griffiths and Robertson, 1966; Lee et al., 1965).

There is presently considerable interest in the identification of the two nucleotide binding sites in H^+ -Thase. There is a clearly recognizable $\beta\alpha\beta$ 'Rossmann fold' in domain I (Clarke et al., 1986; Yamaguchi et al., 1988) which has been predicted to be the NAD(H) site on the basis of a G-G-G motif. However, recent findings (Lilly et al., 1991) suggest that there may be exceptions to what was thought to be a general rule for the specificity of nucleotide binding. Some experiments with radiolabeled dicyclohexyl-carbodiimide and 5'-[p-(fluorosulfonyl)benzoyl] adenosine were taken to support the view that the NAD(H) site lies within domain I and also to indicate that the NADP(H) site is in domain III (Wakabayashi and Hafeji, 1987a,b). However, other studies with radiolabelled 8-azido-AMP are less conclusive (Hu et al., 1992).

B. The Unique Structure of Transhydrogenase in Rhodospirillum rubrum

Consistent with the existence of stretches of very hydrophobic amino acids in their sequences, the H^+ -Thases from mitochondria and from *E. coli* require detergent for solubilization. The enzyme from *Rb. capsulatus* has a polypeptide composition that resembles the one from *E. coli* and it too has the character of a membrane protein (Lever et al., 1991). However, in an elegant series of papers, Fisher and colleagues showed that the structure of transhydrogenase in *Rs. rubrum* is different. When chromatophores from this organism were washed by centrifugation through low ionic strength buffer,

light-dependent transhydrogenation was abolished. The supernatant fraction, though inactive itself, was fully able to restore the reaction to depleted chromatophores (Fisher and Guillory, 1969a,b). In the intact chromatophore membranes, the 4A to 4B stereospecific transfer of H^- from NADH to $NADP^+$ was similar to that found for the mitochondrial enzyme, indicating that it is the same type of transhydrogenation reaction (Fisher and Guillory, 1971a). It was supposed that H^+ -Thase in *Rs. rubrum* is composed of a water soluble protein, Th_s , and a membrane-bound component, Th_m , which can be reversibly associated. The recombination of Th_s with Th_m was dependent on the presence of low concentrations of nicotinamide nucleotides (Fisher and Guillory, 1971b). The potential of the system for the study of H^+ -Thase was exemplified by experiments in which Th_s and washed, depleted chromatophores were separately treated with protein modification reagents and then reconstituted with the untreated complementary component (Fisher et al., 1975; McFadden and Fisher, 1978; Jacobs and Fisher, 1979; Palmer et al., 1993).

As the primary amino acid sequences for H^+ -Thases from *E. coli* and mitochondria became available and, with them, predictions of the domain structure of the enzymes (Clarke et al., 1986; Yamaguchi et al., 1988), it became of interest to re-evaluate the relationship with the transhydrogenase from *Rs. rubrum*. It was conceivable that Th_s could correspond to either of the predominantly hydrophilic domains I or III, or to an activating protein factor for transhydrogenase unique to this bacterium. Purification of Th_s from *Rs. rubrum* and analysis of the nucleotide sequence of the gene have led to a solution of this problem.

In earlier work, only partial purification of Th_s and Th_m had been achieved (Konings and Guillory, 1972; Jacobs et al., 1977) but we recently described a procedure that routinely leads to small quantities of highly-purified material (Cunningham et al., 1992b). It makes use of the fact that other peripheral proteins can be displaced from *Rs. rubrum* chromatophores by washing in the presence of $NADP^+$ and then Th_s can be specifically removed by centrifugation in the absence of nucleotide. Further purification is then achieved by ion-exchange and affinity dye chromatography. The protein is assayed on the basis of its ability to restore light-driven transhydrogenase to depleted chromatophores. It runs predominantly as a

single band, Mr 43000 Da, on SDS-PAGE but appears to be dimeric under non-denaturing conditions. The complete purification of Th_m still remains to be achieved. The solubilization procedure is particularly demanding, with only two detergents being successful of more than thirty tried (Palmer et al., 1993). Some purification was achieved by ion exchange and affinity dye chromatography but the small quantity of available material limited further success.

The N-terminal amino acid sequence of the 43 kDa polypeptide of Th_s (Cunningham et al., 1992b), and of proteolytic fragments derived therefrom, show clearly that it is related to domain I of the mitochondrial and *E. coli* proteins. The nucleotide sequence of the gene (Williams et al., 1994) leads us to expect that the relationship of the *Rs. rubrum* protein to other members of the family is as shown in Fig. 1. The essential difference with *E. coli* transhydrogenase is that the *Rs. rubrum* protein has three polypeptides. In addition to that, in the strongly hydrophobic domain II, there is an additional 'break' between domain II and the relatively hydrophilic domain I. This is nicely consistent with the view that domain I protrudes from the cytoplasmic side of the membrane. Evidently, under physiological conditions the domain I polypeptide of *Rs. rubrum* is bound to domains II and III by interactions that depend on the occupation of the nicotinamide nucleotide sites. In the absence of nucleotides, the domain I protein, Th_s, dissociates from domains II and III. In the presence of nucleotides, it can be rebound (Cunningham et al., 1992a).

Although the predicted amino acid sequences of H⁺-Thase from *E. coli* and mitochondria have been available for some time, there had been no reported sequence similarities with other proteins except in the region of the nucleotide binding region. However, it transpires (Cunningham et al., 1992) that domain I of H⁺-Thase has close similarities with the recently-published sequences of alanine dehydrogenase from *Bacillus* sp. (Kuroda et al., 1990). Alanine dehydrogenase catalyses the reversible reductive amination of pyruvate to alanine with NAD(P)H. It is a soluble enzyme, widespread in bacteria, and is generally thought to be cytoplasmic, although alanine dehydrogenase from *Mycobacterium tuberculosis* (for which amino acid sequence is now available, Anderson et al., 1992) is secreted from the cells during growth. The implications of these observations for the structure, mechanisms and evolution of alanine

dehydrogenase and H⁺-Thase are extremely interesting. Possibly H⁺-Thase evolved from interaction between a soluble alanine dehydrogenase-like protein and an intrinsic membrane protein with a capacity for proton translocation.

III. Bioenergetics and Kinetics of Transhydrogenase

A. Transhydrogenase is a Simple Proton Pump

The primary energy-conserving process in phototrophic bacteria is the chemiosmotic proton circuit utilising the photosynthetic electron transport chain as a generator and the H⁺-ATP synthase as a consumer of Δp. However, as an experimental system this can sometimes be complex and, in contrast, electron transport → Δp → H⁺-Thase, is relatively simple. For example, the dependence of the rate of ATP synthesis in chromatophores on the value of Δp indicates that the activity of the H⁺-ATP synthase may be modulated by interactions with the electron transport system (Baccarini-Melandri et al., 1977; Venturoli and Melandri, 1982) but the reaction catalysed by H⁺ Thase, operating in the 'forward' direction (Eq. (1)), has a unique dependence on Δp regardless of whether Δp is varied with uncoupling agents or with inhibitors of electron transport (Cotton et al., 1987). Thus, H⁺ Thase can be treated as a simple and independent proton pump.

Furthermore, as in other membrane systems, the chromatophore H⁺-ATP synthase is not only driven by, it is also regulated by, Δp: increase in Δp leads to a conformationally-activated enzyme. This is most clearly demonstrated by experiments in which an increase in Δp upon illumination causes an accelerated rate of ATP hydrolysis (Melandri et al., 1972). In contrast, when conditions were chosen greatly to favor the 'reverse' transhydrogenase reaction (Eq. (1)), even up to substantial values of Δp there was no increase in the rate of reaction for any incremental increase in Δp (Palmer and Jackson, 1992). Thus, there is no evidence that transhydrogenase can be switched between relatively active and inactive states.

B. Steady-State and Transient-State Kinetics of Transhydrogenase

The kinetic mechanism for the reduction, by NADPH,

of AcPdAD^+ (an analogue of NAD^+ , whose reduced form, AcPdADH , has a characteristic absorbance band at 363 nm), has been determined for membrane-bound and solubilized preparations of H^+ -Thase from *E. coli*, mitochondria and *Rb. capsulatus* (Hanson, 1979; Homyk and Bragg, 1979; Enander and Rydstrom, 1982; Lever et al., 1991). The reaction proceeds by random addition of substrates to give a ternary complex with the enzyme. The substrate binding reactions appear to reach equilibrium. Thus, despite some speculations to the contrary (see Fisher and Earle, 1982), there is little evidence to support a substituted enzyme ('ping-pong') mechanism or for the existence, in the absence of substrates, of a reduced enzyme intermediate. The transfer of H^- equivalents between the bound nucleotide substrates on the ternary complexes might be direct - at least it is clear that the transferred H^- does not exchange with water protons (Lee et al., 1965).

The relationship between the rate of transhydrogenation, from NADH to thio-NADP^+ (an analogue of NADP^+), and Δp in steady-state, when the nucleotides were in excess, has been examined in chromatophores of *Rb. capsulatus* (Cotton et al., 1989; Jackson, 1991). The data were consistent with a simple scheme in which an increase in $\Delta\psi$ ($= \Delta p$ in the conditions of the experiment) gives rise to an increase in a single rate constant in the reaction sequence, i.e. there is only a single step responsible for energy transduction. At high values of $\Delta\psi$ this step is saturated and a reaction component unaffected by $\Delta\psi$ becomes rate-limiting. The dependence of the relationship on pH was complex. There was little to choose between two models of energy transduction: (i) $\Delta\psi$ is transformed by a 'proton well' within the enzyme into a $\Delta p\text{H}$ (Mitchell, 1969). The elevated concentration of H^+ at catalytic center, at the bottom of the well, would lead to an accelerated rate of a single component in the reaction. (ii) $\Delta\psi$ increases the rate constant for the movement of charge within the enzyme across the membrane dielectric. The charge displacement would be coupled to a single component in the catalytic reaction.

To date there have been no reports of any transient-state kinetic analyses with solubilised H^+ -Thase from any source but these would assuredly be of value in understanding the mechanism of the enzyme. An experiment with chromatophores from *Rb. capsulatus* was described in which transhydrogenation from NADH to thio-NADP^+ was measured at the onset of illumination (Palmer and Jackson, 1990). Because,

under these conditions, Δp rose rapidly (within a few milliseconds) to a high value, resolution of a hitherto undetected component in the transhydrogenase reaction was possible: a burst ($t_{1/2} \sim 6$ ms) of thio- NADPH formation was recorded prior to the establishment of the steady-state rate. On the assumption that, under de-energized conditions before illumination, the nucleotide substrates reached binding equilibrium on the enzyme, the existence of the burst was simply explained. The rapid increase in Δp upon illumination caused acceleration of a single rate constant (see above) and hence the rapid formation of thio- NADPH on the enzyme during its first turnover. Release of product (thio- NADPH or NAD^+) was rate-limiting in the steady-state reaction during subsequent turnovers. On this basis, it was calculated that H^+ -Thase must be in excess of 0.12 mol/mol of photosynthetic reaction centers (about 1.2 enzymes per chromatophore) and, thus, k_{cat} was in the region of 20s^{-1} . This figure is consistent with an estimation of the turnover number of H^+ -Thase based on the yield of transhydrogenation by chromatophores during trains of short flashes (Palmer et al., 1991).

C. The H^+/H^- Ratio of Transhydrogenase

A consensus was reached that the H^+/H^- ratio (the ratio of the number of protons translocated across the membrane per hydride ion equivalent transferred between the nucleotide substrates) was 1.0 for mitochondrial transhydrogenase (Fisher and Earle, 1982; Rydstrom et al., 1987). A ratio of 1.0 can be easily accommodated by several types of reaction mechanism (Jackson, 1991). Chromatophores provide a good system for the measurement of H^+/H^- ratios for transhydrogenase since they can be energized conveniently with light and because their electrochromic absorbance changes provide a rapid measure of membrane potential and of membrane ion flux. Published experiments have led to ratios in the region of 0.4–0.7 (Cotton et al., 1989; Jackson et al., 1990; Palmer and Jackson, 1992; Bizouarn and Jackson, 1993). In recent work using chromatophores from a strain of *Rs. rubrum* that over-expresses transhydrogenase, and a rapid mixing procedure that permitted initial rate measurements of proton translocation with negligible contamination by 'leaks,' it emerged that the true ratio is probably 1.0 (T. Bizouarn, L. A. Sazanov, S. Aubourg and J. B. Jackson, unpublished).

D. Comment on the Mechanism of Transhydrogenase

Many authors have favored mechanisms of action of transhydrogenase in which energy coupling between the proton electrochemical gradient and the chemical reaction of hydride transfer is mediated by conformational changes in the protein (Rydstrom et al., 1981; Fisher and Earle, 1982; Yamaguchi and Hatefi, 1989). Specifically, it has been suggested that energy-dependent changes in the binding of the nucleotide substrates are critical in the energy-transduction process (see Fig. 2). The enzyme may function as a dimer (Anderson and Fisher, 1981; Persson et al., 1987; Hou et al., 1990) and interaction between the monomeric units might be indicated by observations that transhydrogenase displays 'half of the sites' reactivity (Phelps and Hatefi, 1984, 1985). Studies on the cyclic reduction of AcPdAD⁺ by NADH in the presence of either NADP⁺ or NADPH in purified solubilized transhydrogenase from *Rb. capsulatus* (Palmer et al., 1993) and *E. coli* (Hutton et al., 1994) have revealed that, at low pH, or after inhibition by dicyclohexyl carbodiimide, NADP(H) is very tightly bound by the enzyme. The pH dependence of the cyclic reactions suggest that binding/release of NADP(H) to/from the protein are accompanied by the binding/release of a proton. It was proposed that these proton binding and release reactions might, in the membrane-bound enzyme be components of proton translocation.

IV. Structure of NADH Dehydrogenase

As a guide to the structure of NADH dehydrogenase in photosynthetic bacteria, the enzyme from other organisms will be briefly considered. It is the most complex of the respiratory proteins in animal mitochondria. It comprises in the region of 40 different polypeptides, all of which have now been sequenced (Arizmendi et al., 1992). The enzyme from *Neurospora crassa* contains more than 30 polypeptides, some of which have been sequenced (Weiss et al., 1991). Clear similarities between the sequences of some of the polypeptides are emerging. In both enzymes most of the polypeptides are nuclear encoded. A minority, mostly hydrophobic polypeptides, are encoded in the mitochondrial DNA.

NADH-DH from both sources has one FMN which might be the immediate electron acceptor for NADH

and at least four iron-sulfur centers, N-1 to N-4 (Ingledeew and Ohnishi, 1980; Beinert and Albracht, 1982; Wang et al., 1991). Centers N-1, N-3 and N-4 have low redox potentials (E_{m7} in the region of -250 mV), whereas N-2, with a midpoint potential around -100 mV, may be an electron donor to ubiquinone. The location of the Fe-S clusters on individual peptides of the bovine complex has been predicted on the basis of sequence motifs (Walker, 1992). The complex from beef heart might also contain a single, tightly-bound ubiquinone (Burbaev et al., 1989).

NADH-DH can be resolved into smaller complexes by a variety of means. After treatment of the enzyme from beef-heart with chaotropic reagents, it can be fractionated into a 'flavoprotein' fragment and an 'iron-protein' fragment, which are both water-soluble, and a 'hydrophobic protein' (Hatefi, 1985; Ragan, 1987). The bovine enzyme can alternatively be split by detergent treatment into two subcomplexes, 'I α ' and 'I β ', which are thought to correspond to the peripheral and the intrinsic membrane domains (Finel et al., 1992). When mitochondrial protein synthesis is inhibited in *N. crassa*, a 'small form' of NADH-DH is produced (Friedrich et al., 1989) which appears to correspond to the combined flavoprotein fragment and iron-protein fragment of the beef-heart enzyme. Alternatively, when the organism is grown under Mn limitation, the membrane component is accumulated (Schmidt et al., 1992). Three-dimensional image reconstruction of electron micrographs of the intact

Fig. 2. Conformational coupling in transhydrogenase. The enzyme is shown as a dimer with two binding sites for acetylpyridine adenine dinucleotide (APAD⁺/APADH) and for NADP⁺/NADPH. The nucleotides may be weakly bound (–) or strongly bound (▶) to the enzyme. Proton translocation is shown to accompany the change in nucleotide binding affinity.

and small form of *N. crassa* NADH-DH indicate that the enzyme is L-shaped, with the hydrophobic part of the protein within the membrane corresponding to one arm, and the extrinsic peripheral arm protruding into the mitochondrial matrix (Hofhaus et al., 1991). All the known redox centers of NADH-DH are located in the peripheral polypeptides of the complex (Weiss and Friedrich, 1991; Schmidt et al., 1992; Walker, 1992).

Sequence comparisons of the polypeptides of NADH-DH have revealed some interesting evolutionary relationships with bacterial redox enzymes. A part of the water-soluble NAD⁺-reducing hydrogenase from *Alcaligenes eutrophus* (actually the α dimer, which binds FMN and two [4Fe-4S] clusters) is related to subunits in the small form of NADH-DH from *N. crassa* and the flavoprotein and iron-protein fragments of the beef heart enzyme (Pilkington et al., 1991). In other studies it has been shown that there may be sequence homologies between some of the hydrophobic polypeptides of NADH-DH and the membrane-spanning regions of glucose dehydrogenase, a ubiquinone-reducing enzyme from *Acinetobacter calcoaceticus*, and formate hydrogen lyase from *E. coli* (Weiss and Friedrich, 1991).

The difficulties of isolating NADH-DH from photosynthetic and indeed other bacteria have been the main reason for the lack of progress in understanding the structure of the bacterial enzyme (Berks and Ferguson, 1991). An NADH dehydrogenase, purified from membranes of *Rb. capsulatus* by Ohshima and Drews (1981), seems structurally not to resemble the mitochondrial type of enzyme (class NDH-1, in the terminology of Yagi, 1991). However, the inhibitor sensitivity of NADH-dependent respiration in chromatophores of *Rb. capsulatus* and its coupling to Δp (Klemme, 1969; Berks and Ferguson, 1991), the presence of Fe-S centers N1-N4 (Zannoni and Ingledew, 1983; Meinhardt et al., 1989) and, recently, the identification of two genes of *Rb. capsulatus* which code for proteins that are homologous to polypeptides from mitochondrial complex I (Dupuis, 1992) all testify to the existence of an NDH-1 enzyme in this bacterium. It seems very likely that the next advances in our understanding the structure and mechanism of NADH-DH in photosynthetic bacteria will come from molecular genetics (eg. Dupuis, 1992) but in the longer term it will be necessary to develop a protocol for solubilizing and purifying the protein.

Yagi (1986) and George and Ferguson (1984) have made some progress with the NADH-DH from the related non-photosynthetic bacterium *Paracoccus denitrificans* and, very recently, a preparation of the enzyme from *E. coli* has been described (Leif et al., 1993). The impetus for further research is that precedents with other electron transport systems suggest that the bacterial complexes may be simpler and easier to study than their mitochondrial counterparts and this is born out by the fact that the NADH-DH from *E. coli* has only 14 polypeptides.

V. Integration Of NADH Dehydrogenase and Transhydrogenase in Metabolism

A remarkable feature of many species of photosynthetic bacteria is their versatility (Madigan and Gest, 1979). However, information about their metabolic profiles is often very limited. Not even during photoheterotrophic growth in the species commonly used for studies of photosynthetic electron transport, are the central metabolic pathways clearly established. In that they are coupled to Δp and can also affect the redox state of the nicotinamide nucleotide pools, NADH-DH and H⁺-Thase can, in principle, have profound effects on metabolism but, because of the lack of precise definition of the ongoing pathways, their exact function is not clear. The following discussion is intended to indicate what possible roles these enzymes might play and in what way their activities must be regulated.

A. The Function of NADH Dehydrogenase

During chemoheterotrophic growth of organisms such as *Rb. sphaeroides*, *Rb. capsulatus* and *Rs. rubrum* under aerobic conditions in the dark, it seems likely that NADH-DH serves to input electrons from NADH to the respiratory chain and contribute to the generation of Δp across the cytoplasmic membrane (Fig. 3). Consistent with this, *Rb. capsulatus* M-1, a mutant with defective NADH-DH, is unable to grow under these conditions (Marrs and Gest, 1973). It also seems likely that the enzyme functions in an analogous manner when these organisms grow in the dark and obtain their energy by anaerobic respiration, for example with nitrous oxide, trimethylamine-N-oxide or dimethylsulphoxide as electron acceptors (Yen and Marrs, 1977; Madigan and Gest, 1979; Schulz and Weaver, 1982; McEwan et al., 1985).

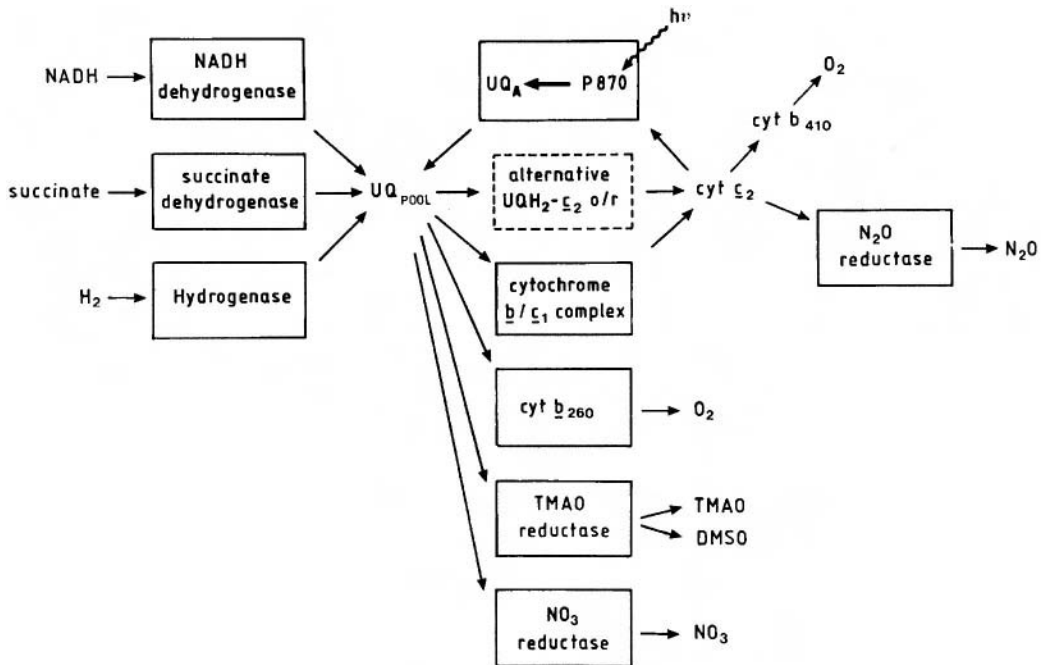

Fig. 3. The electron transport pathways of *Rb. capsulatus*. See Ferguson et al., 1987 and Richardson et al., 1991.

The function of NADH-DH during photoheterotrophic growth is not known. It has a high activity in chromatophores from photoheterotrophically-grown bacteria but the M-1 mutant of *Rb. capsulatus* grows rapidly with malate as carbon source during photosynthetic conditions. Malate is presumably metabolized by the pathways shown in Fig. 4: NADH generated in the first step of malate metabolism (Tayeh and Madigan, 1987) could be reoxidized (a) during carbohydrate synthesis, (b) during re-fixation of CO₂ by the Calvin cycle (note that triosephosphate dehydrogenase is NADH-dependent in *Rb. sphaeroides*, Lascelles, 1960), (c) during production of storage polymers, or (d) by H⁺-Thase (see below). Thus, it is understandable why, on malate, NADH-DH is not essential to maintain the balance of the NAD⁺-NADH pools. It might have been expected that NADH-DH would be necessary during photoheterotrophic growth on succinate, to reoxidize the bound FADH₂ of succinate dehydrogenase by energy-linked reversed electron transport via the ubiquinone pool, although the M-1 mutant is reported to grow normally under these conditions (Marrs and Gest, 1973). When anaerobic, phototrophic growth on highly-reduced substrates, such as propionate and butyrate is facilitated by auxiliary electron acceptors such as trimethylamine-

N-oxide, dimethylsulphoxide, nitrate or nitrous oxide (Richardson et al., 1988), then NADH-DH is probably involved in the transfer of reducing equivalents (Fig. 3). It is therefore predicted that the M-1 mutant of *Rb. capsulatus* would not grow phototrophically under anaerobic conditions with propionate (or butyrate) and auxiliary oxidant, but this has not been tested.

Because NADH-DH links the cytoplasmic NAD⁺/NADH pools with the membrane phase UQ/UQH₂ pools, and since the redox state of the latter can critically influence the rate of cyclic electron transport (Venturoli et al., 1986), the enzyme could, in principle, be involved in the regulation of photosynthesis. It might supply or withdraw reducing equivalents to or from the quinone pool, under the control of Δp , and thus modulate the cyclic electron transport rate. Indeed, unless the NADH-DH is itself subject to regulation, or unless the nicotinamide nucleotide pools and the quinone pools are somehow compartmentalized, then it is difficult to escape the conclusion that there will be a tendency towards redox equilibration. If the H⁺/2e⁻ ratio of NADH-DH is 4.0 (see Weiss and Friedrich, 1991) and Δp is 250 mV, then the redox potential difference between NAD⁺/NADH and UQ/UQH₂ at equilibrium would be 500 mV. The advantage to the bacterial cell could be

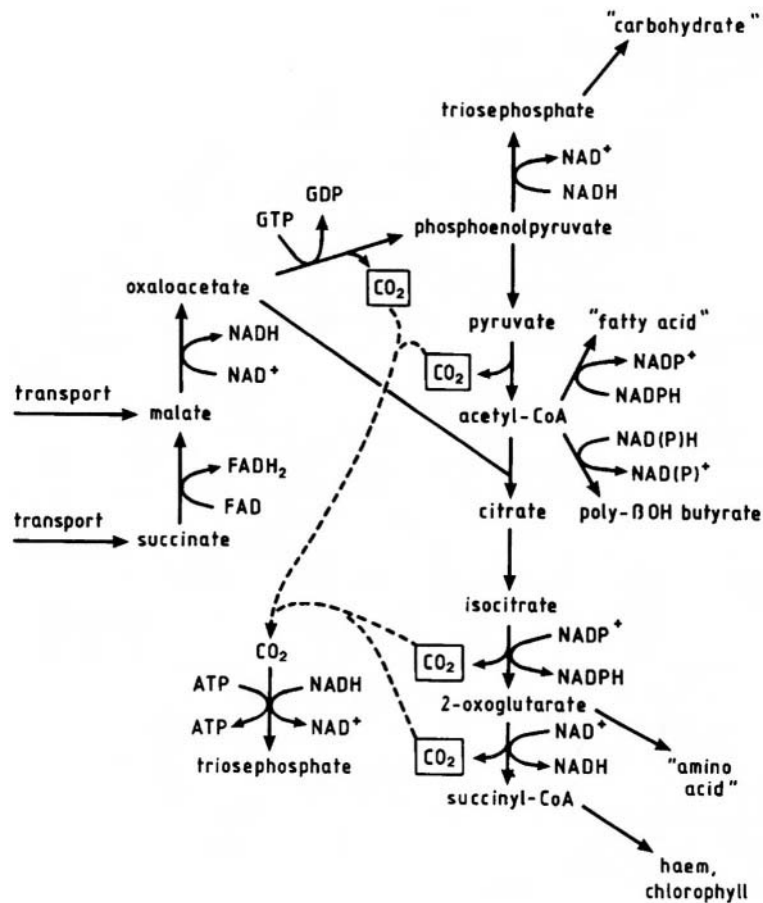

Fig. 4. The balance of reducing power in intermediary metabolism during anaerobic phototrophic growth on malate or succinate (a plausible scheme).

that this provides a vehicle by which carbon metabolism, via the redox state of NAD^+/NADH , might exert control on photosynthetic electron transport. At low values of Δp (eg. when bacteria are exposed to only low light intensities) and particularly with relatively reduced carbon sources, there is evidence (Jones et al., 1990) that the resulting low potential of the UQ pool restricts the rate of light-driven cyclic electron transport. Oxidation of the UQ pool with the auxiliary oxidants, nitrate, nitrous oxide or trimethylamine-N-oxide under these conditions increases the cyclic electron transport rate.

B. The Function of Transhydrogenase

The function of H^+ -Thase in photosynthetic bacteria (or indeed in other bacteria) is not clear. However, in *Rb. capsulatus* the enzyme is expressed constitutively

at high levels during chemotrophic and phototrophic growth on a variety of carbon and nitrogen sources (Jackson and Cotton, unpublished) and, in view of its interaction with Δp and the redox state of the nicotinamide nucleotide pools, it seems likely that it has a key role in metabolism. It is probably involved in balancing the supply of NADH and NADPH for biosynthesis and detoxification in the cell, dependent on the supply of reduced nucleotides from catabolic dehydrogenases and on the value of Δp (Jackson and McEwan, 1993).

Although experimental proof for bacteria is unavailable, it is widely thought that NAD(H) is maintained in the oxidized state in the cell and NADP(H) in the reduced state. The action of H^+ -Thase would contribute to this separation using the energy of Δp . For an H^+/H^- ratio of 1.0 and a Δp of 200 mV, the redox potential difference at equilibrium would be about 100 mV, in which case the ratio of

[NAD⁺]/[NADH] would be about 2300 times greater than the ratio of [NADP⁺]/[NADPH]. This situation favors the action of the catabolic dehydrogenases, which are mainly (though not universally) NAD⁺-linked, and reductive biosynthetic reactions and detoxification reactions, which generally require NADPH. A role for H⁺-Thase in this context might be particularly acute during anaerobic photosynthetic growth (as distinct from growth under aerobic conditions) since NADH cannot be oxidized by the respiratory chain. Even so, this function of H⁺-Thase might not be essential, since NADH might also be reoxidized by the NAD⁺-linked triose phosphate dehydrogenase during refixation of CO₂ (Ormerod and Gest, 1962) or during the synthesis of energy storage polymers (Eidels and Preiss, 1970). Furthermore, H⁺-Thase is not the only enzyme capable of generating NADPH at substantial rates; NADP⁺-linked dehydrogenases, for example isocitrate dehydrogenase (Beatty and Gest, 1981; Leyland and Kelly, 1991), can also fulfill this role. In *E. coli*, there are clear indications that there are indeed several metabolic sources of cytoplasmic NADPH, including H⁺-Thase (Hanson and Rose, 1980). The importance of the transhydrogenase pathway in this context might be to provide a regulatory link between Δp and biosynthesis (Fig. 4).

It is also possible that H⁺-Thase could serve in the opposite sense, to transfer reducing equivalents from NADPH (generated by NADP⁺-specific dehydrogenases) to NADH, for example if the supply of the N-source were limiting and it therefore became desirable to divert carbon towards the production of storage compounds such as glycogen or beta-hydroxybutyrate. At least in some bacteria the enzymes catalyzing these reactions prefer NADH to NADPH (Haywood et al., 1988). Of course this reaction of H⁺-Thase would be depressed at high values of Δp . Under these conditions of N-limitation, and in order to permit continued metabolic turnover, NADH is also re-oxidized by H⁺ in the production of H₂ by nitrogenase (Hillmer and Gest, 1977).

Transhydrogenase might also participate in the generation or utilization of Δp (Jackson and McEwan, 1993). However, as there is increasing evidence that the H⁺/H⁻ ratio for the enzyme is only 1.0 (Section III.C), it would seem that transhydrogenase is not a very effective Δp generator or consumer; its major function is more likely to be in the distribution of reducing equivalents between the NAD(H) and NADP(H) pools, *biased* by Δp (see above). Perhaps

in some circumstances its proton-translocating properties are directly important. Conceivably during short periods of energy deprivation it might operate in reverse (cf. Eq. (1)) and pump H⁺ outwards across the cytoplasmic membrane to maintain Δp . Because of the non-Ohmic conductance of the bacterial membrane (Golby et al., 1990), H⁺-Thase could support a low but substantial Δp , enough to support some essential maintenance functions, such as the cellular osmotic balance, even despite a low H⁺/H⁻ ratio. Another possibility (Jackson and McEwan, 1993) is that pairs of dehydrogenases operating cyclically would lead to continued generation of NADH and NADP⁺ as substrates for H⁺-Thase in the forward direction. This would represent a 'futile' or 'substrate' cycle that might be important in the control of metabolic flux or even as a 'valve' for the dissipation of Δp in a process that would contribute to 'metabolic uncoupling' or 'overflow metabolism' (Tempest and Neijssel, 1984).

VI. Concluding Remarks

NADH-DH and H⁺-Thase are both involved in the coupling of the redox chemistry of the nicotinamide nucleotides to proton translocation across the cytoplasmic membrane of at least some species of anoxygenic photosynthetic bacteria. The metabolic role of neither of these enzymes is known with certainty but it is likely that they function in different capacities in different metabolic states. They are both clearly related to the equivalent enzymes in mitochondria. Difficulties in the development of a good solubilization and purification procedure for NADH-DH have limited studies on this enzyme. H⁺ Thase, on the other hand, is rather easy to purify from the photosynthetic bacteria and indeed its unique properties in *Rs. rubrum* make it a good system for study.

Summary

Most photosynthetic bacteria can grow photoautotrophically using inorganic sulfur compounds (i. e. sulfide, sulfur, polysulfides, thiosulfate, or sulfite) as electron donors for CO₂ fixation. The different types of phototrophs that use sulfur compounds as electron donors, and their varying sulfur-oxidizing capabilities are briefly described. Several species of purple sulfur bacteria can also grow aerobically or microaerophilically as chemolithotrophs, oxidizing sulfur compounds to obtain energy as well as electrons for CO₂ reduction. They share this ability with nonphotosynthetic sulfur bacteria such as thiobacilli. Although thiobacilli are not

particularly closely related to purple sulfur bacteria, studies on sulfur oxidation by thiobacilli have yielded information that may be relevant to sulfur oxidation by photosynthetic bacteria. A variety of enzymes catalyzing sulfur oxidation reactions have been isolated from photosynthetic bacteria, and possible pathways for sulfur oxidation involving those enzymes are discussed. Except for flavocytochrome *c* and sulfide-quinone reductase, which catalyze electron transfer from sulfide to cytochrome *c* and quinone, respectively, the *in vivo* electron acceptors used by the sulfur-oxidizing enzymes are generally unknown. So far, no enzyme has been isolated that catalyzes oxidation of elemental sulfur, and some new possibilities for how elemental sulfur is oxidized are considered. Finally, some suggestions for future research are made that use metabolically versatile purple bacteria to examine donation of electrons by sulfur compounds to the electron transport chain, active transport of ionic sulfur compounds, and the molecular genetics of sulfur-oxidizing enzymes.

I. Introduction

Photosynthetic bacteria, other than the chlorophyll *a*-containing cyanobacteria, do not photochemically generate a sufficiently strong oxidant to use water as an electron donor. Thus many of them grow simply as photoheterotrophs, using light as the source of energy for converting organic nutrients to metabolic products (Gest, 1993). Others, however, find environmental niches in which sulfide, polysulfide or elemental sulfur, or thiosulfate is available. Sulfide is typically generated by sulfate-reducing bacteria, which reduce sulfate in oxygen-depleted environments such as sediments or stagnant lower levels in stratified lakes and lagoons (Postgate, 1984). Sulfide spontaneously reduces oxygen as it diffuses upward, thus expanding the anaerobic zone. When light reaches such habitats, photoautotrophic sulfur bacteria proliferate.

Inorganic sulfur compounds are concentrated sources of electrons at a low redox potential (see Table 1). Sulfide, for example, donates 8 electrons while being oxidized to sulfate at an overall midpoint redox potential (E_0') of -215 mV at pH 7. For thiosulfate, $E_0' = -245$ mV for its 8-electron oxidation to sulfate. A variety of enzymes participate in the oxidation of these electron donors, with sulfur compounds of intermediate redox states being formed

in the process. This chapter will review what is known about the sulfur-oxidizing capabilities of different bacterial species and the enzymes mediating their sulfur oxidation reactions. As will become apparent, much remains to be learned about the biochemistry of sulfur oxidation, and some thoughts about possible future experiments in this area will also be presented.

The low redox potentials for oxidation of sulfide and thiosulfate imply that a substantial amount of energy can also be obtained through aerobic oxidation of these electron donors. In fact thiotrophy (i. e. chemolithotrophic growth using energy derived from oxidation of inorganic sulfur compounds) is fairly widespread among the prokaryotes, occurring both among the Archaea (*Sulfolobus*, for example) and the Bacteria. This wide distribution of thiotrophy may indicate that it appeared at an early stage in the evolution of life, but comparative information about the structures of the enzymes involved is needed to decide between that possibility and the alternative

Table 1. Redox potentials of sulfur compounds

Redox couple	E_0' (mV)
$\text{SO}_4^{2-}/\text{SO}_3^-$	-515
$\text{S}_2\text{O}_3^{2-}/\text{HS}^- + \text{HSO}_3^-$	-400
S^0/HS^-	-260
$2\text{SO}_4^{2-}/\text{S}_2\text{O}_3^{2-}$	-245
$\text{SO}_4^{2-}/\text{HS}^-$	-215
$\text{SO}_4^{2-}/\text{S}^0$	-200
$\text{HSO}_3^-/\text{HS}^-$	-115
APS/AMP + HSO_3^-	-60
$\text{HSO}_3^-/\text{S}^0$	-40
$\text{S}_4\text{O}_6^{2-}/2\text{S}_2\text{O}_3^{2-}$	+25

Tabulated values are from Brune (1989) and from Wood (1988). The latter also has a useful discussion of redox potentials for reactions involving elemental sulfur as a function of its activation state in sulfur globules.

that the requisite enzymes of (thiotrophic) Archaea and Bacteria evolved independently. Among the Bacteria, chemolithotrophy via aerobic oxidation of sulfide, elemental sulfur, or thiosulfate is characteristic of the thiobacilli, a diverse group of which some are economically important because of their ability to oxidize and solubilize mineral sulfide ores and because of the damage to concrete and limestone or marble structures caused by the acidity produced during their sulfur oxidation reactions (Fischer, 1988). Interestingly, several species of purple sulfur bacteria resemble the thiobacilli in that they can also grow on sulfur as chemolithotrophs.

II. Types of Anoxygenic Phototrophs and Their Sulfur-Oxidizing Capabilities

Figure 1 shows a current scheme for the phylogeny of bacteria based on 16S ribosomal RNA sequences. Taxonomy/phylogeny of the anoxygenic phototrophs is discussed in detail by Imhoff (Chapter 1) and is discussed here only as it relates to their sulfur-oxidizing capabilities.

A. Purple Photosynthetic Bacteria

The best known anoxygenic phototrophs belong to a large and diverse bacterial phylum called the Proteobacteria (previously referred to as the purple bacteria) (Stackebrandt et al., 1988). The Proteobacteria have been subdivided into four groups, designated α , β , γ , and δ (Woese, 1987), although recent RNA analyses (Lane et al., 1992) suggest that the genera *Campylobacter* and *Thiovulum* belong to a fifth (ϵ) subdivision branching off near the root of the δ subdivision (Fig. 1). The classical purple sulfur bacteria (family Chromatiaceae), and their close relatives the Ectothiorhodospiraceae, belong to the γ subdivision. Both families form coherent groups on the basis of 16S rRNA sequences as well as the classical taxonomic criteria of cellular morphology and physiology.

1. Chromatiaceae

The Chromatiaceae are easily distinguished by the presence of microscopically observable, highly refractile globules of elemental sulfur that form

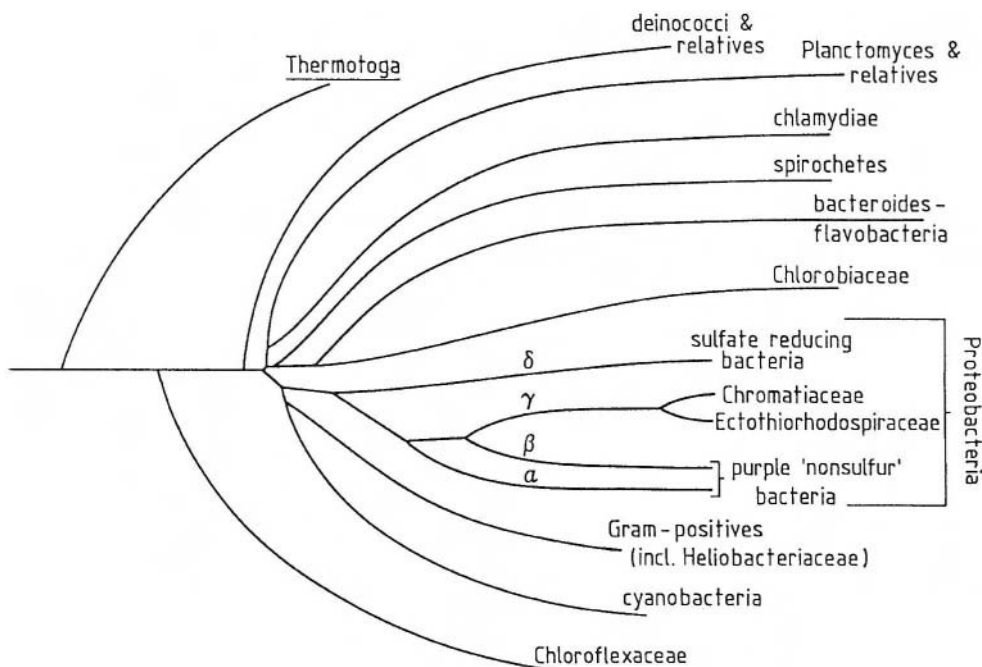

Fig. 1. Phylogenetic scheme for the domain Bacteria showing the positions of the different types of photosynthetic bacteria within the different bacterial phyla. Subdivisions are indicated within the Proteobacteria to indicate the relative positions of the Chromatiaceae, Ectothiorhodospiraceae, and the purple 'nonsulfur' bacteria. (Slightly modified from Brune, 1989).

intracellularly when they are grown on sulfide or thiosulfate. The sulfur in these globules exists in a metastable liquid state at room temperature, possibly due to the presence of polysulfides which give the sulfur a somewhat hydrophilic character and prevent its crystallization (Steudel et al., 1990). Sulfur globules isolated from *Chromatium vinosum* contain about 5% protein on a dry weight basis, and evidence was presented that this protein forms a monolayer enclosing the sulfur globule (Schmidt et al., 1971; Nicolson and Schmidt, 1971). A recent analysis of *Cm. vinosum* sulfur globules showed that three major proteins could be purified by high pressure liquid chromatography, two with molecular masses of about 10.5 kDa and one with a mass of about 8.6 kDa (Brune, in preparation). Similar proteins were isolated from sulfur globules of *Thiocapsa roseopersicina*, and N-terminal sequencing showed them to be homologous to the *Cm. vinosum* proteins. These proteins are rich in glycine and tyrosine and have weakly repetitive sequences, making it likely that they are structural rather than enzymatic.

Sulfur globules in the Chromatiaceae are generally considered to be cytoplasmic. However, electron micrographs by Remsen (1978) show chromatophores opening into the space enclosing sulfur globules. Since the interior of chromatophores of purple photosynthetic bacteria is thought to be continuous with the periplasm, this implies a periplasmic location for the sulfur globules, at least at some stage of their formation. Remsen (1978) suggested that sulfur-filled chromatophores coalesce followed by disintegration of their lipid bilayer membranes to eventually form sulfur globules that are separated from the cytoplasm only by the surrounding proteinaceous membrane.

The sulfur-oxidizing capabilities of the Chromatiaceae are summarized in Table 2. Most of these data were discussed previously (Brune, 1989), so only some general observations and new information will be discussed here.

On the basis of their sulfur metabolism, the Chromatiaceae can be divided into two groups (Imhoff, 1992a). One, consisting of the large-celled *Chromatium* species (*buderi*, *okenii*, *warmingii*, *weissei*), *Cm. tepidum*, *Thiospirillum jenense*, *Thiocapsa pfennigii*, *Lamprobacter modestohalophilus*, and the *Thiodictyon* species, requires sulfide or elemental sulfur (S⁰) both as a photosynthetic electron donor and as a source of sulfur for

biosynthesis. These do not use thiosulfate as an electron donor, and cannot grow aerobically. The other group, which includes most of the small-celled *Chromatium* species and *Thiocapsa roseopersicina*, is more versatile. Most use thiosulfate, and some also use sulfite as an electron donor. Assimilatory sulfate reduction is common in this group (although it is absent in *Cm. minus*, *Cm. salexigens*, the *Amoebobacter* species, and *Thiospirillum winogradskyi*), allowing them to grow photoheterotrophically with sulfate as the sulfur source. Generally they can grow as chemolithotrophs using aerobic oxidation of reduced sulfur compounds as their source of energy and electrons for CO₂ fixation (Kondratieva et al., 1976, Kämpf and Pfennig, 1980, 1986; de Wit and van Gernerden, 1990, Overmann and Pfennig, 1992). Some can even grow as chemoorganotrophs, although they may require sulfide or thiosulfate due to a suppression of sulfate assimilation by aerobic conditions (Kondratieva et al., 1981).

Although not included in Table 2 because the small number of investigations of its use do not represent a comprehensive survey, two species of Chromatiaceae, namely *Cm. vinosum* and *Thiocapsa roseopersicina*, have been shown to use polysulfide (average chain length 3–4 S atoms) as a photosynthetic electron donor (van Gernerden, 1987, Steudel et al., 1990, Visscher et al., 1990). Cultures grown on sulfide oxidize polysulfide to sulfate (with intermediate accumulation of elemental sulfur globules) without any lag and show a high affinity for polysulfide. A possible role of polysulfides as intermediates during oxidation of sulfide to elemental sulfur was discussed previously (Brune, 1989).

Recently some organic sulfur compounds have also been shown to function as electron donors for photosynthetic growth of some Chromatiaceae. Visscher and Taylor (1993) found that *Tc. roseopersicina* could decompose mercaptomalate to fumarate + H₂S and mercaptopropionate to acrylate + H₂S and then use the liberated sulfide as an electron donor. This ability was shared by an as yet unclassified *Rhodospseudomonas* species that, unlike *Tc. roseopersicina*, could also assimilate the fumarate or acrylate formed in the decomposition reaction. Previously, Visscher and van Gernerden (1991) reported that dimethylsulfide functioned as an electron donor for photosynthetic growth of *Tc. roseopersicina*, being oxidized to dimethyl sulfoxide, which is not further metabolized.

Table 2. Sulfur oxidizing capabilities of the anoxygenic phototrophs

I. Proteobacteria

A. Chromatiaceae

- Oxidize H_2S and S^0 to SO_4^{2-} .
Chromatium buderi, *Cm. okenii*, *Cm. tepidum*, *Cm. warmingii*, *Cm. weissei*, *Lamprocystis roseopersicina*, *Thiocapsa pfennigii*, *Thiocystis gelatinosa*, *Thiocystis violacea*, *Thiodictyon bacillosum*, *Thiodictyon elegans*, *Thiopedia rosea*, *Thiospirillum jenense*, *Thiospirillum winogradskyi* †,(a).
- Oxidize H_2S , S^0 and $\text{S}_2\text{O}_3^{2-}$ to SO_4^{2-} .
Amoebobacter pedioformis, *Amoebobacter purpureus*, *Cm. gracile*, *Cm. minus*, *Cm. minutissimum*, *Cm. purpuratum*, *Cm. violascens*, *Thiocapsa roseopersicina* *.
- Oxidize H_2S , S^0 , $\text{S}_2\text{O}_3^{2-}$, and SO_3^{2-} to SO_4^{2-} .
Amoebobacter pendens, *Amoebobacter roseus*, *Cm. salexigens* (b), *Cm. vinosum*, *Thiocapsa halophila* (c).

B. Ectothiorhodospiraceae

- Oxidize H_2S to S^0 .
Ectothiorhodospira halochloris, *Ec. abdelmalekii*.
- Oxidize H_2S and S^0 to SO_4^{2-} .
Ec. marismortui (d).
- Oxidize H_2S , S^0 , and $\text{S}_2\text{O}_3^{2-}$ to SO_4^{2-} .
Ec. halophila, *Ec. shaposhnikovii*, *Ec. vacuolata*.
- Oxidize H_2S , S^0 , $\text{S}_2\text{O}_3^{2-}$, and SO_3^{2-} to SO_4^{2-} .
Ec. mobilis.

C. Purple 'nonsulfur' bacteria.

- Oxidize H_2S to S^0 .
Rhodobacter capsulatus, *Rb. sphaeroides*, *Rhodospirillum mediosalinum* (e), *Rs. rubrum*, *Rp. marina* #.
- Oxidize H_2S to $\text{S}_4\text{O}_6^{2-}$.
Rhodomicrobium vanneilii
- Oxidize $\text{S}_2\text{O}_3^{2-}$ to $\text{S}_4\text{O}_6^{2-}$.
Rhodopila globiformis †
- Oxidize H_2S and $\text{S}_2\text{O}_3^{2-}$ to SO_4^{2-} .
Rb. sulfidophilus, *Rp. palustris*.
- Oxidize H_2S , S^0 , and $\text{S}_2\text{O}_3^{2-}$ to SO_4^{2-} .
Rb. adriaticus, *Rb. euryhalinus* (f), *Rb. veldkampii*, *Rp. sulfoviridis*.

II. Green Sulfur Bacteria

A. Chlorobiaceae

- Oxidize H_2S and S^0 to SO_4^{2-} .
Ancalochloris perfilievii, *Chlorobium limicola*, *Cb. chlorovibrioides*, *Cb. phaeobacteroides*, *Cb. vibrioforme*, *Chloroherpeton thalassium*, *Pelodictyon clathratiforme*, *Pelodictyon luteolum*, *Pelodictyon phaeum*, *Prosthecochloris aestuarii*, *Prosthecochloris phaeoasteroides*.
- Oxidize H_2S , S^0 , and $\text{S}_2\text{O}_3^{2-}$ to SO_4^{2-} .
Cb. limicola f. *thiosulfatophilum* †, *Cb. tepidum* (g), *Cb. vibrioforme* f. *thiosulfatophilum* †, *Pelodictyon phaeoclathratiforme* (h).

III. Green Gliding Bacteria

A. Chloroflexaceae (i)

- Oxidize H_2S to S^0 .
Chloroflexus aurantiacus, *Oscillochloris trichoides*..

Tabulated data are taken from Brune (1989) supplemented with information from the following: (a) Overmann et al., 1992; (b) Caumette et al., 1988; (c) Caumette et al., 1991; (d) Oren et al., 1989; (e) Kompantseva and Gorlenko, 1984; (f) Kompantseva, 1985; (g) Wahlund et al., 1991; (h) Overmann and Pfennig, 1989; (i) Madigan and Brock, 1975, and see text.

† One strain also oxidizes thiosulfate.

* Some strains also oxidize sulfite.

Thiosulfate also formed during sulfide oxidation.

† Oxidation reaction observed during photomixotrophic growth.

‡ These strains also oxidize tetrathionate to sulfate.

2. *Ectothiorhodospiraceae*

As the name implies, species of the family Ectothiorhodospiraceae deposit elemental sulfur extracellularly during sulfide oxidation. The Ectothiorhodospiraceae are halophilic and alkalophilic phototrophs, typically being found in salt lakes or marine tidal pools (Imhoff, 1992b). Polysulfides, which are stabilized by alkaline conditions, have been found to accumulate during sulfide oxidation and are attributed to a chemical reaction between sulfide and sulfur. Alternatively, polysulfides may be intermediates in the oxidation of sulfide to sulfur.

16S rRNA sequences indicate that the Ectothiorhodospiraceae can be divided into two subgroups, one consisting of the extreme halophiles *Ec. halochloris*, *Ec. abdelmalekii* (both of which contain BChl *b*), and *Ec. halophila*, and the other containing the remainder of the *Ectothiorhodospira* species (Trüper, 1987). The two BChl *b*-containing species have the most limited sulfur-oxidizing capabilities, oxidizing sulfide only to elemental sulfur while growing photomixotrophically (i. e. with both CO₂ and an organic carbon source). They are incapable of photoautotrophic growth (Then and Trüper, 1984). The remaining species oxidize sulfide and sulfur to sulfate, and except for *Ec. marismortui*, also use thiosulfate as an electron donor. Kusche (1985) found that elemental sulfur is not an intermediate during thiosulfate oxidation by *Ec. shaposhnikovii*, an observation that probably can be generalized to other thiosulfate-oxidizing Ectothiorhodospiraceae.

None of the species of Ectothiorhodospiraceae are able to grow as chemolithotrophs, although two species, *Ec. mobilis* and *Ec. shaposhnikovii*, can grow as chemoorganotrophs if sulfide or thiosulfate is supplied as a sulfur source (Kondratieva et al., 1981). The same two species are the only Ectothiorhodospiraceae able to assimilate sulfate when growing anaerobically as photoheterotrophs.

3. Purple 'Nonsulfur' Bacteria

Purple photosynthetic bacteria belonging to the α and β subdivisions of the Proteobacteria were formerly placed together in the family Rhodospirillaceae (also called the purple nonsulfur bacteria because of their predominantly photoheterotrophic growth mode). Ribosomal RNA sequence comparisons show that many species of 'Rhodospirillaceae' are more closely related to non-photosynthetic bacteria than to each other. Family designations are

not used in the latest edition of *The Prokaryotes*, which discusses the α division phototrophs ('*Rhodospirillum* and related genera') and the β division phototrophs (the genera *Rhodocyclus* and *Rubrivivax*) in separate chapters (Imhoff and Trüper, 1992; Trüper and Imhoff, 1992). *Rhodocyclus* and *Rubrivivax* apparently are incapable of using reduced sulfur compounds as photosynthetic electron donors and will not be discussed further here.

Generally speaking, the α division photosynthetic Proteobacteria (here called α purple phototrophs) are photoheterotrophs, and with a few exceptions, were generally considered incapable of growing photoautotrophically with reduced sulfur compounds as electron donors. That perception changed when Hansen and van Gemerden (1972) demonstrated that *Rhodopseudomonas palustris*, *Rhodospirillum rubrum*, *Rhodobacter sphaeroides* and *Rb. capsulatus* could grow photoautotrophically in a chemostat when sulfide was supplied continuously at a low concentration (below 0.5 mM for the first three and 2 mM for *Rb. capsulatus*). The higher sulfide concentrations typically used in the culture media of purple and green sulfur bacteria prevent the growth of these species. It is now known that all species of *Rhodobacter* can grow photosynthetically with sulfide as the electron donor, and one species, *Rb. sulfidophilus*, resembles the true sulfur bacteria in its tolerance of high sulfide concentrations.

The diverse sulfur-oxidizing capabilities of the α purple phototrophs are summarized in Table 2. Most of these data have been discussed previously (Fischer, 1988; Brune, 1989), although the ability of *Rs. rubrum* and *Rb. sphaeroides* to grow photolithotrophically on thiosulfate was reported only recently by Wang et al. (1993), who noted an increase in turbidity of the bacterial culture which they attributed to formation of elemental sulfur. This suggests that the products of thiosulfate oxidation are S⁰ and SO₄²⁻. An interesting aspect of the work by Wang et al. (1993) is that CO₂ fixation in *Rs. rubrum* and *Rb. sphaeroides* does not require rubulose-1,5-bisphosphate carboxylase and thus does not proceed via the Calvin cycle, which is usually used for purple bacterial CO₂ fixation.

4. Relationship of Photosynthetic to Nonphotosynthetic Sulfur Bacteria

Included with the purple photosynthetic bacteria in the phylum Proteobacteria are such nonphotosynthetic sulfur bacteria as the thiobacilli, beeggiatoas, and a group of so-called 'morphologically conspic-

ous' sulfur bacteria, of which only *Thiovulum* has been obtained in pure culture (La Rivière and Schmidt, 1992). The thiobacilli were originally grouped together solely on the basis of their ability to grow chemolithotrophically with reduced inorganic sulfur compounds as respiratory substrates. Physiological and biochemical characterizations (Kelly, 1989) as well as ribosomal RNA sequences (Lane et al., 1992) indicate that the thiobacilli do not form a coherent taxonomic group. Most of them belong to the β branch of the Proteobacteria, where the relatively well studied species *Thiobacillus ferrooxidans*, *Tb. thiooxidans*, *Tb. neapolitans*, and *Tb. tepidarius* cluster together in one group. RNA sequences indicate that *Tb. thioiparus* is somewhat related to *Rhodocyclus purpureus*, while *Tb. perometabolis* is related to *Rubrivivax gelatinosus*. However, as noted above, neither of those β branch phototrophs can oxidize reduced sulfur compounds.

Tb. versutus (and two marine thiobacilli isolated from hydrothermal vent environments) appear to be fairly closely related to *Rb. capsulatus* (Lane et al., 1992) (and thus presumably also to *Rb. sulfidophilus*, which has fairly well developed sulfur-oxidizing capabilities). A periplasmic enzyme complex has been isolated from *Tb. versutus* that oxidizes thiosulfate (and sulfite) to sulfate with a *c*-type cytochrome as the electron acceptor (Kelly, 1989). Too little is known about the biochemistry of thiosulfate oxidation in those species of *Rhodobacter* able to use it to know if they contain enzymes like those in *Tb. versutus*. Unlike *Tb. versutus*, none of the *Rhodobacter* species grow chemolithotrophically on thiosulfate (Kondratieva, 1989).

Considering the ability of some species of Chromatiaceae to grow aerobically or micro-aerophilically in the dark on thiosulfate or sulfide, it is surprising that they have no close relatives that, having lost the ability to carry out photosynthesis, grow as chemolithotrophs. The nonphotosynthetic

sulfur bacteria in the γ branch of Proteobacteria include *Beggiatoa*, a genus of filamentous bacteria that characteristically form periplasmic intracellular sulfur globules when grown in the presence of sulfide and oxygen. Many of these, however, cannot actually grow autotrophically on sulfide (Nelson, 1989). Also included in the γ branch are several sulfur bacteria that occur in symbiotic associations with marine invertebrates living near hydrothermal vents and *Thiothrix*. They appear to be more closely related to the fluorescent pseudomonads than to the purple sulfur bacteria (Lane et al., 1992).

The lack of a close relationship between the purple sulfur bacteria and the thiobacilli indicated by ribosomal RNA sequence comparisons is consistent with the differences in their sulfur oxidation pathways. Unlike the purple sulfur bacteria, most thiobacilli (*Tb. versutus* is an exception) oxidize thiosulfate to tetrathionate en route to sulfate, and can grow with tetrathionate as the electron donor (Kelly, 1989). This difference is revealed in the different biphasic oxygen uptake curves for thiobacilli and Chromatiaceae growing on thiosulfate. *Thiocystis violacea* and *Cm. vinosum* consume one molecule of oxygen per two molecules of thiosulfate in a rapid, initial phase of oxygen uptake in which 2 S⁰ and 2 SO₄²⁻ are formed (Overmann and Pfennig, 1992). In typical thiobacilli (e.g. *Tb. acidophilus*, *Tb. ferrooxidans*, *Tb. thiooxidans*, *Tb. neapolitanus*, and *Tb. tepidarius*), oxygen uptake is also biphasic, but 4 S₂O₃²⁻ are consumed per O₂ with 2 S₄O₆²⁻ being the product of their oxidation in the rapid initial phase of oxygen consumption (Lu and Kelly, 1988a, Meulenberg et al., 1992; Pronk et al., 1990). Similar experiments indicate that the acidophilic archaeon *Sulfolobus* has a thiosulfate oxidation pathway similar to that of the thiobacilli (Nixon and Norris, 1992).

Several species of sulfate-reducing bacteria were recently found to oxidize sulfide and thiosulfate under aerobic conditions (Dannenberg et al., 1992). Like the purple sulfur bacteria, the thiosulfate-oxidizing species *Desulfovibrio desulfuricans* does not form tetrathionate as an intermediate and is thought to reductively cleave thiosulfate initially to sulfide and sulfite. The sulfate reducing bacteria belong to the δ group of the Proteobacteria (Woese, 1987).

B. Green Sulfur Bacteria

The green sulfur bacteria, or Chlorobiaceae, form a coherent taxonomic group (resembling in this respect the Chromatiaceae and the Ectothiorhodospiraceae) and are the characteristic members of a separate bacterial phylum (Woese, 1987). They differ from the purple photosynthetic bacteria both in their primary photochemical processes and in their carbon metabolism (Amesz, 1991). All are photoautotrophs, although acetate and a few other simple organic substrates also can be assimilated when CO₂ is present. Assimilatory sulfate reduction is lacking, so reduced sulfur compounds are required as sulfur sources as well as photosynthetic electron donors.

The sulfur-oxidizing capabilities of the Chloro-

biaceae are summarized in Table 2. Until recently, only two strains, namely *Chlorobium limicola* f. *thiosulfatophilum* and *Cb. vibrioforme* f. *thiosulfatophilum* were known to oxidize thiosulfate. These strains are also the only phototrophs known to use tetrathionate as an electron donor and to be able to photochemically disproportionate elemental sulfur into H_2S and $\text{S}_2\text{O}_3^{2-}$, with the latter product probably being formed via reaction of a SO_3^{2-} intermediate with elemental sulfur (Trüper et al., 1988). Recently two other green sulfur bacteria that use thiosulfate as an electron donor have been discovered, namely *Pelodictyon phaeoclathratiforme* (Overmann and Pfennig, 1989) and *Cb. tepidum* (Wahlund et al., 1991). So far, the tetrathionate-utilizing and sulfur-disproportionating capabilities of those species have not been reported. None of the Chlorobiaceae are known to use SO_3^{2-} as a photosynthetic electron donor.

C. Green Gliding Bacteria

The family Chloroflexaceae, or green gliding (green 'nonsulfur') bacteria, belongs to a phylum which, according to 16S rRNA sequence data, branched off early in the evolutionary history of Bacteria. The only species of that family that has been obtained in pure culture and characterized biochemically is *Chloroflexus aurantiacus*, a thermophile capable of slow photoautotrophic growth while oxidizing sulfide to elemental sulfur (Madigan and Brock, 1975; Pierson and Castenholz, 1992). Several other species, particularly in the genera *Heliothrix*, *Oscillochloris*, and *Chloronema* are often found in sulfide-containing environments, and Gorlenko (1988) has reported that *Oscillochloris trichoides* grows photoautotrophically while oxidizing sulfide to sulfur. *Cf. aurantiacus* resembles the purple phototrophs in its primary photochemistry and reaction center structure (Blankenship, 1992).

III. Electron Transport in Purple and Green Sulfur Bacteria

A. Purple Bacteria

Electron transport in the photosynthetic Proteobacteria (purple bacteria) is basically cyclic (Fig. 2A). A photochemical reaction center complex integral to the photosynthetic membrane uses light

energy to transfer electrons from a periplasmic *c*-type cytochrome (and perhaps a high potential iron-sulfur protein [HiPIP] in some species, particularly in the family Ectothiorhodospiraceae) (Bartsch, 1991; Leguijt, 1993) to a quinone within the membrane. Quinone reduction occurs near the cytoplasmic membrane surface and is accompanied by uptake of protons (one per electron) from the cytoplasm (see chapter by Okamura and Feher). The cycle is completed when electrons are transferred to a periplasmic cytochrome (or HiPIP) via a membrane-spanning cytochrome *bc₁* complex (Trumpower, 1990). Quinol oxidation releases protons into the periplasmic space.

Due to a cycle of quinone reduction as well as oxidation by the cytochrome *bc₁* complex, 2 H^+ per electron are translocated from the cytoplasm to the periplasm, creating a gradient in the chemical potential of hydrogen ions ($\Delta\mu\text{H}^+$) across the cytoplasmic membrane. This H^+ ion gradient drives ATP synthesis (photophosphorylation) and reduction of NAD^+ to NADH with quinol as the reductant. NADH and ATP are used to reduce CO_2 to carbohydrate via the reductive pentose phosphate pathway (Calvin cycle).

Electrons drained from the reduced quinone pool to reduce NADH (and ultimately CO_2) are replaced in the photosynthetic sulfur bacteria by oxidation of inorganic sulfur compounds. Given the redox potentials of the sulfur compounds used as photosynthetic electron donors, these electrons can be transferred initially either to a periplasmic cytochrome *c* or directly to the quinone pool within the membrane. In the former case, subsequent quinone reduction would occur photochemically, resulting in charge transfer through the membrane and contributing to the transmembranous $\Delta\mu\text{H}^+$. The energetic differences between these two cases have been discussed previously (Brune, 1989).

Electron transport in the Chloroflexaceae is basically similar to that in purple bacteria (Amesz, 1991), but CO_2 fixation follows a different pathway (see Chapter 40 by Sirevåg).

B. Green Sulfur Bacteria

Electron transport in the green sulfur bacteria is fundamentally different from that in the purple bacteria in that the membrane-spanning photochemical reaction center transfers electrons completely through the membrane from a periplasmic

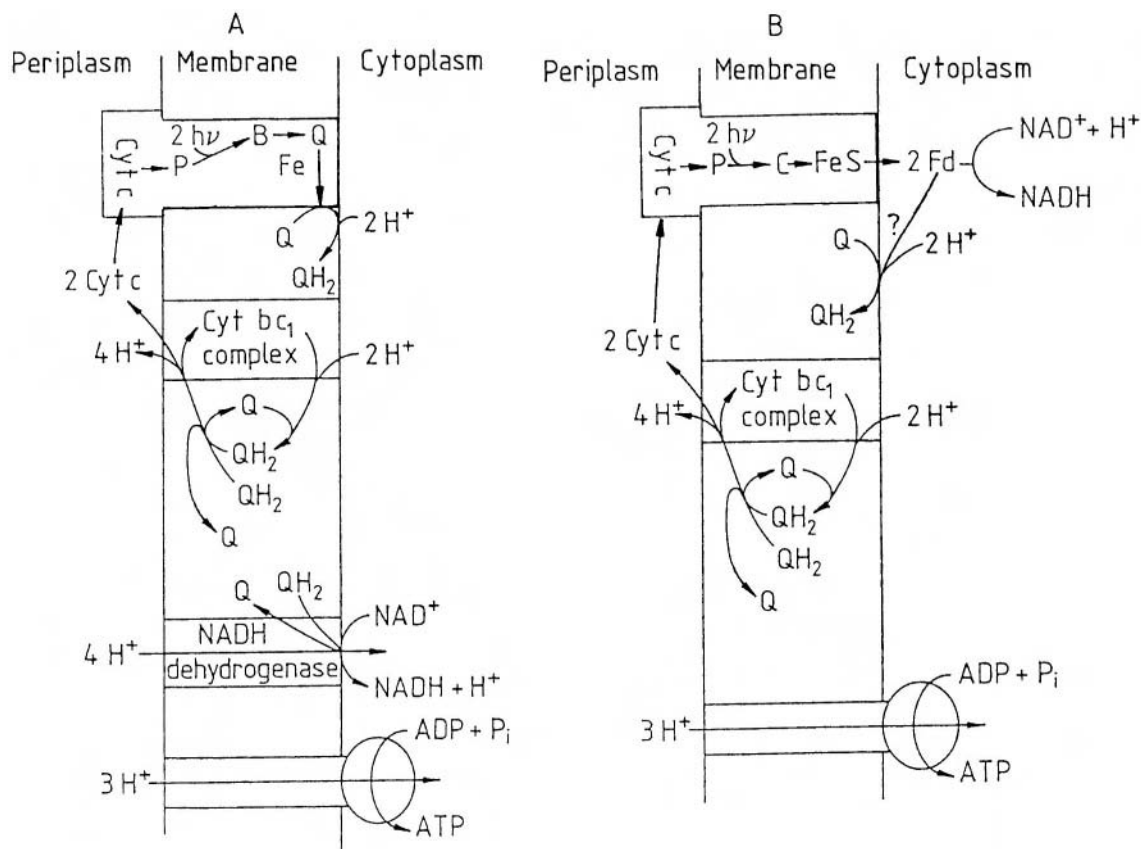

Fig. 2. Electron transport pathways in purple bacteria (A) and in green sulfur bacteria (B). Abbreviations: B, bacteriopheophytin molecule acting as initial electron acceptor in purple bacteria; C, bacteriochlorophyll *c*-like initial electron acceptor in green sulfur bacteria; Cyt, cytochrome, Fd, ferredoxin; FeS, iron-sulfur cluster acting as early electron acceptor; $h\nu$, photon of light absorbed to drive the initial electron transfer reaction; P, bacteriochlorophyll dimer acting as the primary electron donor; Q, quinone. A question mark next to the arrow from Fd to Q in (B) indicates that this electron transfer reaction has not been established, although it is likely to occur during cyclic electron transport. Because quinones and NAD^+ require two electrons for reduction, the electron transfer events shown here are those resulting from two sequential excitations of the reaction center pigments. Both green and purple bacteria are shown as having a bound cytochrome associated with the reaction center complex, although in some purple bacterial species, this cytochrome is missing. Note that logical sites for entry of electrons from inorganic sulfur compounds into the photosynthetic electron transport chain are the pool of quinones within the membrane or cytochrome *c* in the periplasm.

cytochrome *c* to a cytoplasmic ferredoxin molecule (Fig. 2B). Ferredoxin, a low-potential iron-sulfur protein, reduces pyridine nucleotides in a reaction catalyzed by ferredoxin- NAD^+ reductase (Kusai and Yamanaka, 1973; Knaff and Buchanan, 1975). CO_2 reduction in the green sulfur bacteria uses reduced ferredoxin, NADH, and NADPH as electron donors and occurs via a reductive tricarboxylic acid cycle (see Chapter 40 by Sirevåg for further details).

Like the purple bacteria, the green sulfur bacteria contain a cytochrome *bc*₁ complex (Hurt and Hauska, 1984) and quinones (menaquinone and chlorobium quinone) that can participate in cyclic electron

transport. Electrons from inorganic sulfur compounds can enter the electron transport chain either via a periplasmic cytochrome *c* or via the quinone pool within the photosynthetic membrane. In the latter case, electron transfer would be via the cytochrome *bc*₁ complex to a periplasmic cytochrome *c* and then via the reaction center to ferredoxin and NAD(P). A similar pathway for electron transport in green bacteria was presented by Okumura et al. (1994) who examined the kinetics of cytochrome *c* oxidation and rereduction during cyclic and noncyclic electron transport in the thermophilic green sulfur bacterium, *Chlorobium tepidum*.

Fig. 3. Sulfide and thiosulfate oxidation pathways. Catalytic enzymes are indicated by numbers next to the reactions that they catalyze. 1 flavocytochrome *c*; 2 sulfite reductase; 3 APS reductase + ADP- or ATP-sulfurylase; 4 sulfite:acceptor oxidoreductase; 5 rhodanese; 6 thiosulfate reductase; 7 thiosulfate:acceptor oxidoreductase; 8 sulfide-quinone reductase. Question marks indicate reactions for which a catalytic enzyme is not yet known. (Slightly modified from Brune, 1989).

IV. Pathways of Sulfide and Thiosulfate Oxidation and Catalytic Enzymes

Enzymes able to catalyze sulfur oxidation reactions have been isolated from various species of photosynthetic bacteria and the reactions they catalyze arranged into possible sulfur oxidation pathways, bearing in mind the intermediates observed in bacterial cultures and what intermediates might be stable en route to sulfate formation (for reviews, see Trüper and Fischer, 1982; Fischer, 1988, 1989; Trüper, 1989; and Brune, 1989). One such pathway is shown in Fig. 3.

Only two intermediates are shown during sulfide oxidation, namely elemental sulfur, which accumulates as sulfur globules during sulfide oxidation by all species of green and purple sulfur bacteria (but not in some α purple phototrophs), and sulfite. Although sulfite formation has been observed only in *Rb. sulfidophilus* (Neutzling et al., 1985), enzymes that can catalyze its formation and consumption have been isolated from a variety of photosynthetic bacterial species. Possibly sulfite is not observed in other species because it is formed in the cytoplasm and is further oxidized to sulfate before it can escape to the external medium. The inability of most phototrophs to use sulfite as a photosynthetic electron donor could also be explained by its consumption in the cytoplasm together with impermeability of the cell membrane to it.

Thiosulfate oxidation is thought to proceed through the same intermediates as are formed during sulfide oxidation, except in special cases in which tetrathionate is the end product of its oxidation. The enzymes catalyzing the sulfur transformations shown in Fig. 3 are discussed below.

A. Oxidation of Sulfide to Elemental Sulfur

1. Flavocytochrome *c*

The distribution of flavocytochrome *c* among the photosynthetic bacteria and its chemical and catalytic properties were discussed in detail in a recent review (Brune, 1989; see also Meyer and Cusanovich, 1989, and Bartsch, 1991). Recently it was also shown to be present in *Amoebobacter pediformis* (Fischer and Ufken, 1991). What is important for the present discussion is that flavocytochromes *c* can catalyze electron transfer from sulfide to a variety of small *c*-type cytochromes, including cytochrome *c*-555 from *Cb. limicola* f. *thiosulfatophilum* (Yamanaka and Kusai, 1976) and cytochrome *c*-550 from *Cm. vinosum* (Davidson et al., 1985) which are thought to donate electrons to the reaction centers in those species.

The best-studied flavocytochromes are those from *Cb. limicola* f. *thiosulfatophilum* and from *Cm. vinosum*. Both contain a 46–47 kDa flavoprotein subunit and a smaller hemoprotein subunit. The

hemoprotein subunit of the *Cb. limicola* flavocytochrome contains a single heme group and has a molecular mass of 10 kDa (van Beeumen et al., 1990), while in the *Cm. vinosum* flavocytochrome it is larger (21 kDa) and contains two heme groups (van Beeumen et al., 1991). Electron transfer from sulfide is initially to the flavin group and is followed by intramolecular electron transfer to the heme group(s) (Tollin et al., 1982; Cusanovich et al., 1985), which then reduce various cytochromes *c*. A recent crystal structure of flavocytochrome *c* from *Cm. vinosum* (Chen et al., 1994) has provided new insights into electron transfer between the flavin and heme cofactors, and also revealed a disulfide bond near the flavin that may participate in sulfide oxidation. Knaff and coworkers (Davidson et al., 1985, 1986) have shown that interaction between the flavocytochrome heme subunits and cytochrome *c* is electrostatic, and is inhibited at high ionic strength with concomitant inhibition of flavocytochrome-catalyzed cytochrome *c* reduction.

Van Beeumen and coworkers (1990, 1991) have obtained complete amino acid sequences for the hemoprotein subunits of the *Chlorobium* and the *Cm. vinosum* flavocytochromes as well as N-terminal sequences for the flavoprotein subunits. The *Cm. vinosum* hemoprotein apparently evolved by fusion of the genes for two different ≈ 10 kDa hemoproteins, rather than by gene duplication, since the two halves of that hemoprotein exhibit only 7% sequence identity. The N-terminal half of the *Cm. vinosum* hemoprotein appears to be related to the *Chlorobium* hemoprotein, with which it has 39% sequence identity. The flavoprotein subunits are also homologous, with their N-terminal sequences being about 60% identical. Recently the protein sequence data were used to isolate and clone the genes encoding the *Cm. vinosum* hemoprotein and about 25% of the flavoprotein (Dolata et al., 1993). The translated gene sequences revealed that both flavocytochrome subunits have signal peptide leader sequences that are absent in the mature proteins, implying a periplasmic location.

Not all bacteria that oxidize sulfide to elemental sulfur have a flavocytochrome *c*. For example flavocytochromes have not been found in any of the *Ectothiorhodospiraceae* or in *Tc. pfennigii* (Bartsch, 1991) or in *Cm. warmingii* (Wermter and Fischer, 1983). The green sulfur bacteria *Cb. vibrioforme* (the non-thiosulfate-utilizing strain) and *Pelodictyon luteolum* also lack flavocytochromes (Steinmetz et al., 1983).

In spite of these indications that flavocytochrome *c*

is not necessary for sulfide oxidation, it is difficult to assign another function to it in those species in which it occurs. The low midpoint redox potentials of its flavin and heme prosthetic groups (0 to +100 mV) (Tollin et al., 1982) and its ability to mediate electron transfer to small periplasmic cytochromes *c* are most consistent with a role in transferring electrons from a periplasmic substrate to the reaction center. Although flavocytochromes *c* form complexes with sulfite and thiosulfate (Meyer et al., 1988, 1991), neither appears to be oxidized by the flavocytochrome, leaving sulfide as the most likely of the normally encountered substrates. Possibly there are parallel sulfide oxidation pathways. The large redox potential drop when electrons are transferred via flavocytochrome *c* to the reaction center would keep flavocytochrome *c* in a highly oxidized state, creating a high affinity system for sulfide oxidation, especially at low sulfide concentrations. This might be important in environments in which bacteria have to compete for sulfide. The fact that flavocytochrome *c* is constitutive (at least in *Cm. vinosum*) (Bartsch, 1978) would keep sulfide-starved cells ready to oxidize sulfide as soon as it was encountered. This high affinity system might supplement an energetically more efficient system involving electron transfer from sulfide to quinone via a sulfide-quinone reductase (see below).

Cytochromes without flavin prosthetic groups have also been proposed to mediate electron transfer from sulfide to the reaction center (see Fischer, 1984 and Brune, 1989, for discussion of the older literature). Recently Leguijt and coworkers (Leguijt, 1993) found that a low potential ($E_m = +25$ mV) membrane bound cytochrome *c* in *Ectothiorhodospira mobilis* is reduced by sulfide with a half-time of 465 ms. They proposed that this cytochrome, which is in turn oxidized by the reaction center in less than 5 μ s, mediates sulfide oxidation in that species. As noted above, periplasmic sulfide oxidation by such a mechanism could contribute to the transmembranous $\Delta\mu H^+$ required for NAD^+ reduction and ATP synthesis. In fact, sulfide stimulated formation of the transmembranous $\Delta\mu H^+$ when *Ectothiorhodospira mobilis* cells were illuminated (Leguijt, 1993), although the sensitivity of this stimulation to inhibitors of the cytochrome bc_1 complex present in *EC. mobilis* (Leguijt et al., 1993) was not tested.

2. Sulfide-Quinone Reductase

Recently Shahak and coworkers provided a new

perspective on photosynthetic bacterial sulfide oxidation when they developed an assay for and then isolated an enzyme catalyzing electron transfer from sulfide to plastoquinone in the facultatively anoxygenic cyanobacterium *Oscillatoria limnetica* (Arieli et al., 1991; Shahak et al., 1992b,c). They named this enzyme sulfide-quinone reductase, or SQR. Subsequent work showed that analogous enzymes are present in the green sulfur bacterium *Cb. limicola* f. *thiosulfatophilum* and in *Rb. capsulatus* (Shahak et al., 1992a,b,c). Earlier experiments by Brune and Trüper (1986) showing nonphotochemical reduction of ubiquinone by sulfide in *Rb. sulfidophilus* can now be explained by assuming that SQR is also present in that species. The *O. limnetica* enzyme has a molecular weight of 57,000 (from SDS-PAGE) (Shahak et al., 1992b,c) and contains a flavin prosthetic group that probably mediates electron transfer from sulfide to quinone (Y. Shahak, personal communication). Its K_m for sulfide is 4 μM (Arieli et al., 1991), a value comparable to that of flavocytochrome *c*-552 from *Cm. vinosum* (Fukumori and Yamanaka, 1979). Preliminary N-terminal protein sequence data on the *O. limnetica* and *Rb. capsulatus* enzymes indicate that they are homologous proteins with FAD-binding domains near their N-terminal ends (Y. Shahak, personal communication).

The *Oscillatoria*, *Chlorobium*, and *Rhodobacter* enzymes exhibit different sensitivities to various quinone analog inhibitors (Shahak et al., 1992a,b), a result consistent with the occurrence of different quinone acceptors in these species. The sensitivity of SQR in *Cb. limicola* to antimycin A and NQNO probably accounts at least partly for the previously observed sensitivity of photochemical electron transport from sulfide to those inhibitors in membranes isolated from that species (Knaff and Buchanan, 1975; Shill and Wood, 1985).

The experimental evidence for SQR in such different species as *O. limnetica*, *Cb. limicola*, and *Rb. capsulatus* raises the possibility that this enzyme is present in all sulfide-oxidizing phototrophs. Electron transfer from sulfide to quinone in the Chromatiaceae was previously suggested based on the energetics of chemolithotrophic growth of *Tc. roseopersicina* and *Cm. vinosum* (Brune, 1989).

B. Oxidation of Sulfide and Sulfur to Sulfite

Oxidation of sulfur is a problem in bacterial photosynthesis in that no enzyme has been found

that catalyzes this reaction. Some recent observations on sulfur oxidation by thiobacilli may be relevant to the reaction in phototrophs. A variety of thiobacilli form elemental sulfur as an intermediate during sulfide and tetrathionate oxidation (Javor et al., 1990; Meulenberg et al., 1992; Pronk et al., 1990). Subsequent sulfur oxidation is completely inhibited by the sulfhydryl reagent N-ethyl maleimide (NEM). The effect of NEM on sulfur oxidation is specific; oxidations of thiosulfate, trithionate, and even tetrathionate (as measured by oxygen uptake rates) were not affected. Analogous experiments on photosynthetic bacteria have not yet been carried out.

Bacon and Ingledew (1989) found that *Tb. ferrooxidans* cells formed H_2S from added sulfur (and, less efficiently, H_2Se from red selenium). They proposed that the S_8 rings of elemental sulfur were activated by a two electron reduction to give an enzyme-bound polysulfide, i. e. $\text{Enz} + \text{S}_8 + 2e^- \rightarrow \text{Enz}-\text{S}-\text{S}_6-\text{S}^-$. The enzyme-bound polysulfide is subsequently oxidized to eight sulfate ions in a manner not specified. The sulfide detected in their experiments was thought to be a product formed from a side reaction of the enzyme-bound polysulfide. Sulfhydryl groups are strong nucleophiles that readily attack elemental sulfur to form polysulfides (Roy and Trudinger, 1970), and if the enzyme reacts with sulfur via one or more cysteine SH groups, the inhibition by NEM would be expected. Analogous schemes for activation of elemental sulfur by reaction with glutathione have been proposed previously (Oh and Suzuki, 1980).

Sulfur oxidation in thiobacilli is also inhibited by uncouplers and by cytochrome *bc*₁ complex inhibitors such as myxothiazole and HQNO (Beffa et al., 1992a,b; Meulenberg et al., 1992; Pronk et al., 1990). Inhibition by uncouplers may indicate an energy requirement for sulfur activation, while the inhibitor data could indicate either that electron transfer from sulfur to oxygen occurs via the cytochrome *bc*₁ complex or that coupled electron transfer through the complex is needed to provide energy for activation. Analogous experiments on sulfur oxidation by purple sulfur bacteria that can grow as chemolithotrophs have not yet been done.

Even if elemental sulfur is reductively activated (which, from a redox point of view, is a step backward), this information per se provides little insight into how it is further oxidized to sulfite or sulfate. An alternative possibility might be that

Fig. 4. Possible initial steps for oxidation of elemental sulfur. So far, the enzymes catalyzing the reactions shown here have not been isolated, although there is evidence for polysulfide formation during sulfur oxidation in some sulfur-oxidizing bacteria.

polysulfides are formed by initial oxidation of elemental sulfur followed by ring opening and hydrolysis of the resulting sulfane monosulfonate (Fig. 4). Oxidation of S₈ to S₈O might be catalyzed by an enzyme analogous to that catalyzing the oxidation of dimethyl sulfide to dimethyl sulfoxide that occurs in some purple sulfur bacteria (Visscher and Van Gemerden, 1991). A second oxidation, yielding S₈O₂ followed by hydrolytic ring opening to form ⁻S-S₆-SO₃²⁻ and subsequent hydrolysis to ⁻S-S₅-S⁻ + SO₄²⁻ could generate a polysulfide without an initial reduction reaction. The intermediate S₈O proposed in this scheme has been synthesized and characterized, while S₈O₂ is unstable, decomposing to SO₂ and S₇ (Steudel, 1984). Spontaneous hydrolysis of sulfane monosulfonates at room temperature is slow (Steudel et al., 1988) and enzymes catalyzing this reaction are unknown. However, enzymes catalyzing the analogous hydrolyses of trithionate and tetrathionate have been found in thiobacilli (Meulenberg et al., 1992; Lu and Kelly, 1988b). A similar pathway for sulfur oxidation was suggested earlier (Kodama and Mori, 1968).

1. Sulfite Reductase

Sulfite reductase is an enzyme which, as its name implies, can catalyze reduction of sulfite to sulfide. It occurs in bacteria and in some algae where it participates in assimilatory reduction of sulfate for incorporation into sulfur-containing amino acids, coenzyme A, etc. (Schiff and Fankhauser, 1981), and in sulfate-reducing bacteria, where it participates in dissimilatory sulfate reduction (Thauer, 1989).

Kobayashi et al. (1978) and Schedel et al. (1979) found that sulfite reductase was also present in extracts of *Cm. vinosum* cells grown photoautotrophically on sulfide and CO₂, and the latter obtained the enzyme in about 80% purity. Schedel et al. (1979) suggested that the enzyme catalyzed sulfide oxidation, rather than sulfite reduction, and noted that it was undetectable in cells grown photoheterotrophically on malate with sulfate as the sulfur source. There is no information about the electron acceptor for sulfide oxidation via sulfite reductase, and in fact enzyme activity was measured as sulfite reduction.

Analysis of the isolated enzyme indicated that it contained siroheme and Fe-S prosthetic groups as is characteristic of sulfite reductases. SDS-PAGE revealed approximately equal amounts of two subunits, with molecular masses of 37 and 43 kDa. Schedel et al. (1979) suggested an α₄β₄ structure for the enzyme in approximate agreement with a molecular weight of 280,000 determined by gel filtration.

Much has been learned about the mechanism of action of sulfite reductases from extensive studies done on the assimilatory enzyme from *E. coli*. Although it is beyond the scope of this review to discuss that work in depth, a few conclusions from it are relevant. The *E. coli* enzyme is a large (nearly 700 kDa) α₈β₄ complex in which the 8 α subunits contain FAD and FMN prosthetic groups that transfer electrons from NADPH to the siroheme-containing β subunits (Siegel et al., 1982). The sulfite-binding β subunit can be isolated using chaotropic agents, and its crystal structure has been determined (McRee et al., 1986). The crystal structure indicated that the

siroheme and Fe_4S_4 prosthetic groups are only 4.4 Å apart, and probably share a cysteine sulfur ligand. The side of the siroheme group away from the Fe_4S_4 cluster is solvent exposed, and is thought to bind sulfite via ligation of its sulfur atom to the siroheme iron (Young and Siegel, 1988). A similar arrangement of the siroheme and Fe_4S_4 prosthetic groups and for substrate binding has been proposed for a smaller (27 kDa) sulfite reductase isolated from *Desulfovibrio vulgaris*, although in that case the bridging ligand between the siroheme and Fe_4S_4 prosthetic groups appears to be a sulfide ion (Tan and Cowan, 1991). This configuration allows concerted transfers of electron pairs between the enzyme and bound substrate molecules, and is probably a general feature of both assimilatory and dissimilatory sulfite reductases.

Trüper (1984) has suggested that sulfite reductase can catalyze oxidation of elemental sulfur and of polysulfides as well as sulfide. Zero-valent sulfur is a likely intermediate between sulfite and sulfide in the reaction catalyzed by sulfite reductase and conceivably could be transferred to that enzyme from a polysulfide chain by a sulfane sulfur transferase. Alternatively, a cycle (see below) can be written in which sulfite produced by sulfite reductase (4) is used to activate elemental sulfur via nucleophilic attack (1) to form a transient sulfane monosulfonic acid that, as noted in the discussion of Fig. 4, could be hydrolyzed (2) to form sulfate + a polysulfide. Disproportionation of polysulfides to elemental sulfur and sulfide (3) is a thermodynamically favored reaction, and could regenerate the sulfide substrate for a second round of sulfite formation via sulfite reductase (4). The series of reactions in this cycle is as follows:

With some modifications, this scheme might also apply to the polythionate-utilizing thiobacilli, and in fact Schedel and Trüper (1979, 1980) isolated and characterized a sulfite reductase from *Tb. denitrificans* which they suggested was also involved in sulfur oxidation. In the acidophilic thiobacilli, dispropo-

portionation of the sulfane monosulfonic acid formed in reaction (2) to form polythionates + polysulfides would also have to be included, as well as hydrolysis reactions involving the polythionates. It is known that polythionates are most stable at acidic pH values (Le Faou et al., 1990), which may account for their occurrence in the sulfur globules of acidophilic thiobacilli such as *Tb. ferrooxidans*. (Steudel et al., 1987, 1988; Steudel, 1989). Polythionates have also been detected in sulfur globules formed by the thiosulfate-oxidizing *Chlorobium* species (Steudel et al., 1988).

A key feature of the proposed cycle is that sulfite acts as the reductant for activation of sulfur to a polysulfide [reactions (1) and (2)], with sulfite being oxidized to sulfate in the process. Reaction (1) is well known in sulfur chemistry (Roy and Trudinger, 1970). In the presence of excess sulfite, subsequent reactions yield thiosulfate, which could account for the observed formation of small amounts of thiosulfate as a side product during sulfide oxidation by *Cm. vinosum* (Steudel et al., 1990) and by the thiosulfate-utilizing species of *Chlorobium* (Fischer, 1984). Oxidation of sulfite by sulfur might also account for the inability of many photosynthetic sulfur bacteria to grow using sulfite alone as the electron donor.

2. Sulfite Formation by Other Enzymes

A sulfite reductase like the *Cm. vinosum* enzyme has not yet been found in any other bacterial species, making it questionable whether or not this enzyme has any general role in photosynthetic bacterial sulfide (or sulfur) oxidation. Sugio et al. (1987, 1989) have isolated a very different enzyme from *Tb. ferrooxidans* that also catalyzes oxidation of sulfide to sulfite with Fe^{3+} as the electron acceptor. Best results were obtained with sulfide produced at constant low levels by the reaction of elemental sulfur with glutathione (Sugio et al., 1989). No redox active prosthetic group has yet been identified for that 46 kDa enzyme, which contains two identical 23 kDa subunits. Although ferric ions are not plausible electron acceptors in phototrophs, the midpoint potential for oxidation of sulfide to sulfite (-115 mV at pH 7) is sufficiently low that a variety of other electron acceptors might be used by an analogous photosynthetic bacterial enzyme, if one exists.

Another possibility that perhaps should be considered is oxidation of sulfur via persulfide (R-S-

S-H) and S-sulfo-, or Bunte salt, ($R-S-SO_3^{2-}$) intermediates. This would involve redox transformations that are essentially the reverse of those occurring during assimilatory sulfite reduction in *Chlorella* and in higher plants (Schiff and Fankhauser, 1981; Fischer, 1988). Westley and Westley (1991) have noted that the pool of sulfane sulfur, including elemental sulfur and persulfides, in animal tissues is in rapid equilibrium in the presence of glutathione and can be assayed via rhodanese-catalyzed thiocyanate formation (see below for further discussion of rhodanese.) Such an equilibrium might possibly supply persulfides for further oxidation. Currently, however, there is no experimental evidence for this kind of sulfur oxidation pathway in any bacterial species.

C. Oxidation of Sulfite to Sulfate

Although hypothetical mechanisms for sulfite oxidation have been mentioned in the previous section, other sulfite oxidation reactions have been suggested, and enzymes that catalyze them have been isolated and characterized. These enzymes will be considered briefly in the sections below.

1. APS Reductase

APS reductases occur in sulfate reducing-bacteria where they catalyze the reductive cleavage of adenosine-5'-phosphosulfate, or APS, to form AMP (adenosine-5'-monophosphate) and sulfite (Thauer, 1989). They have also been found in some thiobacilli (Takakuwa, 1992) and in several species of purple and green sulfur bacteria (Trüper and Fischer, 1982; Fischer, 1989) where their function is assumed to be an oxidative binding of sulfite to AMP, giving APS as the product. Typically enzyme activity is measured as AMP-dependent sulfite oxidation with ferricyanide as the electron acceptor. With most of the APS reductases, *c*-type cytochromes can also be used as electron acceptors. The *in vivo* electron acceptor is unknown. Although APS is also an intermediate in assimilatory sulfate reduction, it is not reduced by APS reductase in that process; thus APS reductases are generally regarded as dissimilatory enzymes.

Sulfate can be liberated from APS in a subsequent reaction with inorganic phosphate in which ADP is formed (Trüper, 1989, Fischer, 1989). That reaction is catalyzed by the enzyme ADP sulfurylase. Alternatively, APS may react with pyrophosphate in

an ATP sulfurylase-catalyzed reaction giving ATP and sulfate as the products. In either case, part of the free energy from hydrolysis of the phosphosulfate anhydride bond ($\Delta G_0' = -21 \text{ kcal/mol}$) (Thauer et al., 1977) is conserved by formation of a phosphate anhydride bond. When ADP is the product, AMP can be regenerated in the reaction $2\text{ADP} \rightarrow \text{AMP} + \text{ATP}$, which is catalyzed by adenylate kinase.

APS reductases have been found in several species of Chromatiaceae, in which they are usually membrane bound (Trüper and Fischer, 1982; Schwenn and Biere, 1979), a factor which has inhibited their isolation and purification. The enzyme from *Tc. roseopersicina* strain 6311 is an exception, and was purified by Trüper and Rogers (1971). Recently, Dahl and Trüper (1989) also described an isolation procedure for the membrane-bound enzyme from *Tc. roseopersicina* strain M1. APS reductases have also been isolated from two green sulfur bacteria, namely *Cb. limicola* f. *thiosulfatophilum* (Kirchoff and Trüper, 1974) and *Cb. vibrioforme* f. *thiosulfatophilum* (Khanna and Nicholas, 1983). Both were obtained from the soluble fraction from broken cells. APS reductases apparently do not occur in any of the α purple phototrophs and are either absent or present at very low levels in the Ectothiorhodospiraceae (Trüper and Fischer, 1982; Fischer, 1989). They also were reported not to occur in *Cm. gracile* or *Cm. purpuratum* (Trüper and Fischer, 1982).

The photosynthetic bacterial enzymes are generally similar to those from thiobacilli and from sulfate-reducing bacteria (Takakuwa, 1992). All contain FAD and Fe-S prosthetic groups and have molecular masses near 200 kDa. The enzyme from *Tc. roseopersicina* was also reported to contain two heme groups per molecule (Trüper and Rogers, 1971). Recently, however, Wang (1991) presented the following arguments that the heme groups belong to a contaminating protein that copurifies with the *Tc. roseopersicina* enzyme: (1) Adding sulfite + AMP to the enzyme gave spectral changes indicating flavin and Fe-S reduction, but did not affect the oxidized heme absorbance, and (2) The heme absorbance in different fractions from the APS reductase band collected during chromatography on hydroxyapatite was not proportional to enzyme activity.

Very little is known about the subunit structure of the APS reductases from either photosynthetic bacteria or thiobacilli. Bramlett and Peck (1975) found that the 220 kDa enzyme from the sulfate-reducing bacterium *Desulfovibrio (Dv.) vulgaris*

consisted of 70 and 20 kDa subunits and proposed a 3 to 1 stoichiometry in which each 70 kDa subunit bound a Fe_4S_4 group while the single 20 kDa subunit bound FAD. This composition was consistent with the staining intensities of the protein bands on polyacrylamide gels and with the iron, sulfur, and FAD analyses. Wang (1991) also found 70 and 20 kDa subunits for the *Tc. roseopersicina* enzyme, possibly suggesting a subunit structure similar to that of the *Dv. vulgaris* enzyme. However, nonheme iron and acid labile sulfur contents of APS reductases from photosynthetic bacteria (Trüper and Rogers, 1971; Khanna and Nicholas, 1983) and thiobacilli (see Takakuwa, 1992 for a table) are sufficient only for the presence of one or two Fe_4S_4 clusters per FAD group in those enzymes. Two would be reasonable to accept the two electrons released during sulfite oxidation.

On the basis of EPR and spectroscopic data, Peck and Bramlett (1982) proposed a catalytic mechanism for APS reductase in which SO_3^{2-} initially formed a complex with the flavin. This then reacts with AMP to yield APS, releasing two electrons that are transferred via the flavin to the Fe_4S_4 centers. A kinetic analysis of AMP-dependent ferricyanide reduction catalyzed by the *Tc. roseopersicina* enzyme (Wang, 1991) indicated a ping-pong type mechanism in which AMP and sulfite first reacted with the enzyme (probably to reduce its prosthetic groups) to form an intermediate which then reacted with ferricyanide. This mechanism is consistent with that proposed for the *Dv. vulgaris* enzyme by Peck and Bramlett (1982).

2. Sulfite: Acceptor Oxidoreductase

Often extracts from photosynthetic bacteria have been observed to catalyze an AMP-independent reduction of ferricyanide as well as (or instead of) the APS reductase catalyzed reaction. This reaction may be catalyzed by an enzyme called sulfite: acceptor oxidoreductase, or sulfite oxidoreductase for short. Because APS reductase is not found in the Ectothiorhodospiraceae or in the α purple phototrophs, it has been suggested that sulfite oxidation in those groups is catalyzed by this enzyme.

Sulfite is a strong reducing agent ($E_0' = -515$ mV for the sulfate/sulfite couple), and nonenzymatic artifacts are a problem when assaying ferricyanide reduction. For example, Dahl and Trüper (1989) found a membrane-associated activity in two *Tc.*

roseopersicina strains that was not destroyed by boiling, indicating that it was not enzymatic.

Sulfite oxidoreductases have been found in almost all photosynthetic bacteria examined (Fischer, 1989), but in some cases it is not clear what controls were performed. Dahl and Trüper (1989) reported that only one of the three strains of *Tc. roseopersicina* that they examined contained a true heat sensitive sulfite oxidoreductase. That enzyme, which was present at only low levels, used cytochrome *c* as the electron acceptor and gave no activity with ferricyanide. In isotope fractionation experiments on *Cm. vinosum*, Fry et al. (1985) noted a change from a preferential formation of $^{34}\text{SO}_4^{2-}$ (an inverse isotope effect) to preferential formation of $^{32}\text{SO}_4^{2-}$ during sulfite oxidation. They interpreted this result as indicating competition for sulfite between two different enzymes, possibly APS reductase and sulfite oxidoreductase. *Cm. vinosum* was previously reported to contain a 68 kDa protein with sulfite oxidoreductase activity (see Neutzling et al., 1985). So far, nothing is known about the prosthetic groups or the in vivo electron acceptors of any of the photosynthetic bacterial sulfite oxidoreductases.

Several species of thiobacilli have been shown to contain sulfite: acceptor oxidoreductases in which the preferred electron acceptor is cytochrome *c* (Takakuwa, 1992). These are molybdoproteins in which molybdenum is complexed with an organic cofactor called molybdopterin (see Takakuwa, 1992, for a proposed structure). The *Tb. versutus* enzyme appears to be part of a larger periplasmic enzyme complex that catalyzes oxidation of thiosulfate to sulfate, and it is not clear that sulfite oxidation is actually the function of sulfite oxidase in that complex (Lu and Kelly, 1984). *Tb. versutus* and *Tb. pantophora* require molybdenum to grow on thiosulfate (Friedrich et al., 1986), and transposon insertional mutants of the latter species that are unable to synthesize molybdopterin are also unable to grow on thiosulfate (Chandra and Friedrich, 1986; Mittenhuber et al., 1991). Sulfide oxidation is also abolished in these mutants. Whether or not any phototrophs have an analogous molybdenum requirement is not known.

D. Thiosulfate Oxidation

Basically, three different initial reactions have been considered for oxidation of thiosulfate in photosynthetic bacteria. These are (1) oxidation to tetrathionate by a thiosulfate: acceptor oxido-

reductase, (2) reduction to sulfite and sulfide by a rhodanese or thiosulfate reductase, and (3) hydrolysis to sulfide and sulfate. These will now be discussed briefly in that order.

1. Thiosulfate: Acceptor Oxidoreductases

In 1966, Smith reported that *Cm. vinosum* oxidized thiosulfate to tetrathionate in a mildly acidic culture medium (pH = 6.25). Similarly, *Rp. palustris* was found to oxidize thiosulfate to tetrathionate when its concentration in the culture medium exceeded 10 mM (Trüper, 1984). Neither these nor any other purple bacteria have been found to oxidize tetrathionate further, however, making it unlikely that this oxidation reaction is on the main pathway of thiosulfate oxidation. In fact, Smith (1966) reported that tetrathionate inhibited the normal oxidation of thiosulfate to sulfate as well as growth of *Cm. vinosum*.

Enzymes that catalyze reduction of various electron acceptors (i. e. ferricyanide, various cytochromes, and a high potential iron-sulfur protein, or HiPIP) by thiosulfate have been isolated from *Cm. vinosum* and from *Rp. palustris*. That work was reviewed previously (Brune, 1989), and that review can be consulted for further information. If tetrathionate is in fact the product of thiosulfate oxidation in these reactions, then they are unlikely to play any significant role in the complete oxidation of thiosulfate to sulfate. Therefore they will not be considered further here.

Two strains of *Chlorobium* are able to use tetrathionate as an electron donor, but there is no evidence that it is an intermediate in thiosulfate oxidation. Experiments with thiosulfate labelled with ^{35}S either in the sulfane ($^{35}\text{SSO}_3^{2-}$) or sulfone ($\text{S}^{35}\text{SO}_3^{2-}$) position indicated that *Cb. vibrioforme* f. *thiosulfatophilum* rapidly released the sulfone sulfur as sulfate, while the sulfane sulfur was retained (probably as elemental sulfur) with the bacterial cells upon filtration (Khanna and Nicholas, 1982). Acidophilic thiobacilli apparently contain enzymes able to hydrolyze tetrathionate to thiosulfate, sulfur, and sulfate (Meulenberg et al., 1992), and it may be that a similar enzyme is present in these *Chlorobium* strains. In this case, tetrathionate would be metabolized via thiosulfate, rather than *vice versa*.

2. Rhodanese and Thiosulfate Reductase

Rhodanases are thiosulfate: cyanide sulfur trans-

ferases, meaning that they transfer the sulfane sulfur atom of thiosulfate to CN^- , generating SO_3^{2-} and SCN^- as the products (Westley, 1988). The best-studied rhodanese is the 33 kDa enzyme from bovine liver, for which a high-resolution crystal structure has been obtained (Hol et al., 1983), providing useful insights into the catalytic mechanism of rhodanese. The initial reaction is between thiosulfate and a cysteine at the active site of the enzyme to form a cysteine persulfide (Cys-SSH) and sulfite, which is released into the medium. The persulfide form of the enzyme is rather stable, and was in fact the form crystallized. The enzyme persulfide can transfer the bound sulfane sulfur to a variety of thiophilic acceptors such as cyanide, various thiols, and, by reversal of the initial reaction, sulfite. The preferred substrate for the mammalian enzyme is cyanide, and thiocyanate formation catalyzed by rhodanese is important as a means of cyanide detoxification (Westley, 1988). Cerletti (1986) has argued that another important function of rhodanases is to generate sulfide for assembly of Fe-S centers in iron-sulfur proteins. Reaction with a thiol generates a persulfide from which sulfide may be released by reaction with a second thiol; i. e. $\text{RSSH} + \text{R}'\text{SH} \rightarrow \text{RSSR}' + \text{H}_2\text{S}$. An intramolecular disulfide is formed if the sulfane sulfur is transferred to a dithiol, such as dihydrolipoic acid.

Thiosulfate reductases are similar to rhodanases in their mode of action, but do not catalyze reactions of the persulfide with cyanide. The best characterized of these is a 17 kDa enzyme from yeast for which a useful substrate is glutathione (Chauncey et al., 1987). It first binds the thiol (e.g. GSH) and then catalyzes its reaction with thiosulfate to form a persulfide (e.g. GSSH) and sulfite, both of which then dissociate from the enzyme. Formation of sulfide can then occur in an uncatalyzed reaction with a second thiol, resulting in a net reduction of thiosulfate to sulfite + sulfide. Alternatively the persulfide can react with cyanide in an uncatalyzed reaction, causing thiosulfate reductases to have a low apparent rhodanese activity (Westley, 1988).

The overall reaction for thiosulfate reduction catalyzed by either rhodanese or thiosulfate reductase is as follows:

Trüper and Pfennig (1966) demonstrated that *Tc. roseopersicina* could form sulfide from thiosulfate

in the dark by flushing the H_2S produced from the cell suspension into a zinc acetate trap with a stream of argon, but were unable to detect sulfite. Sulfide was not produced by broken cells, possibly because of a need for cellular metabolism to produce the reduced thiol needed for thiosulfate reduction. Subsequently Khanna and Nicholas (1982) detected formation of both sulfite and sulfide from thiosulfate in a suspension of *Cb. vibrioforme* f. *thiosulfatophilum* cells by trapping them as complexes with N-ethylmaleimide.

Smith and Lascelles (1966) isolated a rhodanese from *Cm. vinosum* and reported that it had a K_m for thiosulfate of 0.6 mM and a K_m for cyanide of 20 mM. Hashwa (1975) later partially purified both a rhodanese and a thiosulfate reductase from the same species, and determined the molecular weight of the rhodanese to be 45,000 while that of the thiosulfate reductase was 90,000. The thiosulfate reductase had a K_m for dihydrolipoic acid of 1.25 mM and an apparent K_m for cyanide of 3.3 mM. Steinmetz and Fischer (1985) isolated two rhodaneses from *Cb. limicola* f. *thiosulfatophilum*, the main one of which was a 39 kDa protein with a K_m for thiosulfate of 0.25 mM and a K_m for cyanide of 5 mM. Previously, Trüper and Fischer (1982) had reported that neither rhodanese nor thiosulfate reductase occurred in the non-thiosulfate utilizing strains of *Cb. limicola* and *Cb. vibrioforme*, while both enzyme were present in the strains able to grow on thiosulfate (See also Trüper et al., 1988). This observation suggests a specific role for the enzymes isolated by Steinmetz and Fischer (1985) in thiosulfate oxidation.

It has sometimes been suggested that an enzyme like rhodanese might also mediate dissociation of thiosulfate into sulfur and sulfite. While it is possible that the sulfane sulfur of a persulfide could be transferred to a sulfur globule, Wood (1988) has pointed out that the equilibrium constant for the overall process strongly favors thiosulfate formation rather than dissociation. Consequently, dissociation of thiosulfate into sulfite and sulfur is unlikely, unless there is an input of energy.

It should be emphasized that rhodaneses (and thiosulfate reductases) are widely distributed enzymes, whose occurrence is not limited to bacteria that oxidize thiosulfate. They are versatile enzymes, and may be employed by the organisms that have them for a variety of purposes (Cerletti, 1986). Utilization of thiosulfate as a photosynthetic electron donor may well be one of these purposes. If they

really are key enzymes in thiosulfate utilization, it is then necessary to study them further to see what distinguishes the enzymes (or their biochemical environment) in phototrophs able to oxidize thiosulfate from those in species unable to do so.

3. Thiosulfate Hydrolysis

Hydrolysis of thiosulfate to form sulfate and sulfide directly occurs with a $\Delta G_0'$ of -5.2 kcal/mol (Bak and Pfennig, 1987) and thus is thermodynamically favorable. Nearly 30 years ago, Trüper and Pfennig (1966) considered the possibility that an enzyme catalyzing this reaction might be involved in thiosulfate utilization by photosynthetic bacteria. However, an enzyme able to catalyze that reaction has never been isolated, and the possibility has received little further attention. The discovery of enzymes in thiobacilli able to hydrolyze $S-SO_3^{2-}$ bonds in trithionate and tetrathionate (Meulenberget al., 1992) is perhaps indirect evidence that a thiosulfate hydrolyzing enzyme in phototrophs should not yet be completely ruled out.

V. Considerations for Future Research

The metabolic versatility of some species of photosynthetic bacteria is a feature that makes them uniquely useful for studies on oxidative sulfur metabolism. It is also a feature that in my opinion has been underexploited in the work done so far. Several species of purple sulfur bacteria, notably *Tc. roseopersicina*, but also several others (see Overmann and Pfennig, 1992, for example) can grow as photoheterotrophs, photoautotrophs, or as chemolithotrophs. When growing as chemolithotrophs, these bacteria presumably utilize a linear electron transport chain from the inorganic sulfur compounds acting as electron donors to oxygen. The site of electron donation to this electron transport chain might logically be at either the ubiquinone or the cytochrome *c* level. In principle, inhibitors of electron transfer through cytochrome bc_1 complexes, which mediate electron transfer from ubiquinone to cytochrome *c*, could distinguish between these possibilities. Knaff and coworkers have partially characterized the components of the electron transport chain in microaerobically grown *Cm. vinosum* cells (Wynn et al., 1985) as well as the cytochrome bc_1 complex in phototrophically grown cells (Tan et al., 1993).

Measurements of oxygen uptake rates in the presence and absence of cytochrome *bc*₁ inhibitors have been done with thiobacilli (e.g. Lu and Kelly, 1988a; Beffa et al., 1992b), but not yet with chemolithotrophic purple sulfur bacteria.

In thiobacilli, energy generation and sulfur oxidation are coupled processes. This is a disadvantage for studying active transport of the oxidizable sulfur substrates. Phototrophs, on the other hand, obtain energy from light which is converted via cyclic electron transport to a transmembranous H⁺ ion gradient and eventually ATP. This energy can be used for active transport of substrates like thiosulfate and sulfite in the absence of oxidation reactions if CO₂, the terminal electron acceptor in photosynthesis, is omitted from the cell suspension. (H₂S, at pH values near its pK₁ of 7.04, is uncharged and probably can freely diffuse through the membrane with slight accumulation on the more alkaline side of the membrane.) So far, nothing is known about transport of sulfur compounds into photosynthetic bacterial cells. Such information is of course relevant to the locations of the enzymes that oxidize these substrates.

The metabolic versatility of many purple sulfur bacteria (and of the α purple phototrophs able to grow photoautotrophically on sulfide and thiosulfate) makes dissimilatory sulfur metabolism optional. Thus mutants of these species lacking enzymes required for sulfur oxidation could grow as photoheterotrophs (or chemoorganotrophs, in some cases). Transposon mutagenesis, which was used to generate mutants of *Thiosphaera pantotropha* unable to oxidize thiosulfate and sulfide (Chandra and Friedrich, 1986; Mittenhuber et al., 1991) should also be applicable to sulfur-oxidizing purple bacteria. This approach might also be useful as a first step toward developing procedures for gene transfer and recombination in the purple sulfur bacteria.

Molecular biological methods can also be used to isolate and clone genes encoding known proteins thought to have key roles in sulfur metabolism. Examples are APS reductase from *Tc. roseopersicina* and sulfite reductase from *Cm. vinosum*. Partial protein sequences of purified subunits of these enzymes can be used to design oligonucleotide probes that can in turn be used to isolate and clone the genes encoding these enzymes. Complete protein sequences for the enzymes can be derived from the gene sequences. The cloned genes can also be used as probes in Northern blots to study regulation at the transcriptional level as well as for gene mapping. An

interesting possibility is that many of the genes for enzymes with specific functions in sulfur oxidation may be clustered together to facilitate their joint regulation.

Eventually it should be possible to use the cloned genes to generate mutants lacking these enzymes by homologous recombination events (Saunders, 1992; Hunter and Mann, 1992). This might be done by interrupting the cloned gene by inserting an antibiotic resistance cartridge, using this construct to transform wild-type cells, selecting transformants for antibiotic resistance, and testing the colonies obtained for the presence of the enzyme in question by Western blotting (assuming that an antibody specific for the enzyme has been prepared). Sulfur oxidation pathways in bacteria are complex, and some reactions may be catalyzed by more than one enzyme. *Cb. limicola* f. *thiosulfatophilum* contains both flavocytochrome *c* and sulfide quinone reductase, for example. In such cases sulfur oxidation may still occur even when an enzyme normally involved in the process has been eliminated. If so, examining the physiological and biochemical consequences of the mutation may reveal what benefit is derived by the organism from the presence of parallel oxidation reactions. The situation is of course more straightforward when alternative reactions do not exist and mutagenesis eliminates the ability to oxidize a particular sulfur substrate.

It should be apparent from the preceding discussion that much remains to be learned about dissimilatory sulfur metabolism in photosynthetic bacteria. Nevertheless, new techniques in molecular genetics as well as in biochemistry and biophysics make it likely that future research in this field will be rewarded with definitive new results.

Summary

The only common feature of the two families of green bacteria, Chlorobiaceae (green sulfur bacteria) and Chloroflexaceae (green gliding bacteria), is their type of light harvesting chlorophyll and the organization of these pigments into chlorosomes. In most other respects, including metabolism, photosynthetic apparatus and phylogeny, they are very different and far apart. Each of the two most studied genera possesses a unique pathway for autotrophic fixation of CO₂: the reductive tricarboxylic acid cycle used by *Chlorobium* and the newly discovered 3-hydroxypropionate cycle used by *Chloroflexus*.

The two pathways are described in detail and the experimental evidence for their existence is given. Likewise are the experimental approaches used to elucidate these pathways discussed and evaluated. The biochemical reactions participating in the pathways are considered in relation to the nature of the photosynthetic apparatus of the organisms and their ecology.

The current knowledge of the metabolism of organic compounds in *Chlorobium* and *Chloroflexus* is reviewed, and the accumulation of glycogen and its breakdown in *Chlorobium* is discussed in detail.

Assuming that life originated in a primordial sea of abiotically produced organic molecules, and taking into account phylogenetic relationships based on 16S rRNA analysis, the possible development by retroevolution of the metabolic pathways used by the green sulfur bacteria and the green gliding bacteria is discussed.

I. Introduction

The members of the two families of green bacteria, the green sulfur bacteria (*Chlorobiaceae*) as represented by *Chlorobium*, and the green gliding bacteria (*Chloroflexaceae*) as represented by *Chloroflexus*, can grow photoautotrophically with CO₂ as the sole carbon source. In addition they are able to utilize organic compounds for growth. Whereas *Chlorobium* is able to assimilate organic compounds to a limited degree and only in the presence of CO₂ and an inorganic electron donor, *Chloroflexus* grows on a variety of carbon sources both anaerobically in the light and aerobically in the dark.

A profound difference between *Chlorobium* and *Chloroflexus* is the nature of their photosynthetic apparatus. In spite of the fact that they both contain chlorosomes and have the same types of bacteriochlorophyll, *Chlorobium* possesses a PSI type reaction center, whereas that of *Chloroflexus* is of the PS II type. Because of the very low (~ -0.9 V) redox potential of the primary acceptor in *Chlorobium*, the reaction center is able to photoreduce ferredoxin and therefore reducing power for the reduction of pyridine dinucleotides is easily available. In *Chloroflexus* the redox potential of the primary acceptor is less negative (~ -0.5 V), and as a result *Chloroflexus* has to reduce pyridine dinucleotides by reverse electron transport in a similar way as the purple bacteria. A detailed discussion of the reaction centers of green sulfur bacteria and purple bacteria, to which the *Chloroflexus* reaction center is most clearly related, appears in Chapters 30 and 23 by Feiler and Hauska, and Lancaster et al., respectively.

The nature and availability of reducing power determine to a large extent the biochemical reactions which are possible in a cell. Thus the differences in the photosynthetic apparatus of *Chlorobium* and *Chloroflexus* are reflected not only in their carbon metabolism but also in their ecology and evolution.

II. Mechanisms of Autotrophic Carbon Dioxide Assimilation

The formation of organic material from carbon

Abbreviations: A. – *Anacystis*; Cb. – *Chlorobium*; Cf. – *Chloroflexus*; Fd – ferredoxin; NMR – nuclear magnetic resonance; 3-PGA – 3-phosphoglyceric acid; PS – Photosystem; RuBisCO – ribulose 1,5-bisphosphate carboxylase; TCA – tricarboxylic acid

dioxide by autotrophic organisms can be expressed in the following way:

where (CH₂O) is a rough expression of cell material.

The ability to grow autotrophically is widespread in nature and is the common feature of higher plants and algae. This mode of life is also found among members of several groups of prokaryotes, notably the phototrophic prokaryotes.

In phototrophic organisms, the ATP and reducing power needed to form organic material from carbon dioxide are produced as a result of electron transport initiated by light reactions. In the case of higher plants, algae and cyanobacteria, the ultimate H-donor in photosynthesis is H₂O, whereas reduced sulfur compounds or molecular hydrogen serve as reductants for green and purple bacteria.

During evolution of autotrophic organisms, several routes of assimilation of CO₂ have developed, each with its own biochemical reactions requiring its own enzymes and reducing power of a specific nature. The most widespread mechanism is the reductive pentose phosphate cycle or Calvin cycle (Bassham 1979) which is found in higher plants, algae and most known groups of autotrophic prokaryotes. In green bacteria, however, two alternative cyclic mechanisms of CO₂ assimilation have evolved: the reductive tricarboxylic acid (TCA) cycle in *Chlorobium*, first proposed by Evans et al. (1966), and the 3-hydroxypropionate pathway suggested by Holo (1989) for *Chloroflexus*. Recently the latter pathway has been supported by the biochemical studies in the laboratory of Georg Fuchs (Eisenreich et al., 1993; Strauss et al., 1993; Strauss and Fuchs, 1993), but has also been contested by Ivanovsky et al. (1993).

A. Experimental Approaches Employed in Studying the Path of Carbon Dioxide in Autotrophic Organisms

Proof for the operation of a cyclic biochemical mechanism should be based on several lines of evidence. Among these are (i) demonstration of activity of the necessary enzymes in cell-free extracts in amounts consistent with the rate of corresponding metabolism in intact cells; (ii) the appearance of radioactivity in intermediate compounds in a manner consistent with the operation of the cycle when

radioactive substrate is added to the cells; (iii) inhibitors specific for enzymes of the cycle should have the expected effect in terms of lowered overall rates and accumulation of intermediates.

In addition to *enzymic studies* and the effect of specific *inhibitors* on known reactions, *short-term labeling* experiments are useful in studying the path of carbon in autotrophic organisms. Such experiments were originally employed by Calvin and coworkers (see Bassham, 1979) when they elucidated the path of carbon in algae by exposing cells to $^{14}\text{CO}_2$ for various periods of time before they were killed and analyzed for stable, radioactive products. Cells which have a functional reductive pentose phosphate cycle, give a characteristic pattern of distribution of the radioisotope. After very short exposures (1s) to $^{14}\text{CO}_2$, most of the radioactivity is recovered in the first stable product of CO_2 -fixation, 3-PGA. The relative amount of radioactivity in this compound decreases with time as other intermediates in the cycle are formed from it. Thus, when the percentage of total activity in 3-PGA is plotted against time, a characteristic negative slope is obtained after the initial rise. However, it should be pointed out that if an organism has more than one CO_2 fixation reaction, as is the case for green bacteria, the picture obtained from such experiments is much more complex and difficult to interpret.

Long-term labeling experiments, combined with subsequent degradation of individual intermediates, have also proven a valuable experimental tool to elucidate the mechanism of CO_2 fixation in *Chlorobium* as well as in *Chloroflexus*.

Carbon isotope fractionation studies are based on the fact that some enzymes which use CO_2 as substrate, i. e. ribulose 1, 5-bisphosphate carboxylase (RuBisCO) show a much greater preference for $^{12}\text{CO}_2$ than for the slightly heavier $^{13}\text{CO}_2$ (Whelan et al., 1973). Thus organisms which use different carboxylation reactions for initial CO_2 -fixation can be distinguished by comparing their carbon isotope composition after autotrophic growth.

The fact that the genes coding for RuBisCO have been isolated from various organisms and appear to be conserved in evolution, makes these genes and their transcripts valuable markers in the identification of carboxylation reactions in various organisms.

B. Carbon Dioxide Fixation in *Chlorobium*

It was long assumed that the mechanism of CO_2 fixation in *Chlorobium* was the reductive pentose

phosphate cycle. This assumption was based on reports that RuBisCO was present in cell free extracts of *Cb. limicola* (Smillie et al., 1962; Tabita et al., 1974). However, it is now firmly established that the mechanism of CO_2 fixation in *Chlorobium* is the reductive tricarboxylic acid (TCA) cycle, which is depicted in Fig. 1. This cycle was proposed by Evans et al. (1966) on the basis of the discovery in phototrophic bacteria and other anaerobes of two new ferredoxin dependent carboxylation reactions:

catalyzed by pyruvate synthase and α -oxoglutarate synthase, respectively (Evans and Buchanan, 1965; Buchanan and Evans, 1965). These two reactions make possible a reversal of the reactions of the TCA cycle and result in the net synthesis of one molecule of acetyl-CoA from two molecules of carbon dioxide. Of the acetyl-CoA formed, some is removed for biosynthesis while some reenters the cycle.

One major obstacle to the proposed reductive TCA cycle was the report that a key enzyme, citrate lyase, could not be detected in cell free extracts of *Chlorobium* (Beuscher and Gottschalk, 1972). However, the finding of an ATP-linked citrate lyase in *Chlorobium* (Ivanovsky et al. 1980) and evidence from long-term labeling experiments combined with degradation of radioactive intermediates (Fuchs et al., 1980a,b), strongly supports its presence.

Originally the reductive TCA cycle was thought to be an additional mechanism to the reductive pentose phosphate cycle in *Chlorobium*, and it was suggested that its main function was to form precursors for the synthesis of amino acids, lipids and porphyrins while the reductive pentose phosphate cycle accounted for carbohydrate formation (Evans et al., 1966). However, inconsistency of data regarding the presence of RuBisCO (Tabita et al., 1974; Buchanan and Sirevåg, 1976; Sirevåg et al., 1977; Takabe and Akazawa, 1977) made the role of the reductive pentose phosphate cycle questionable. Several lines of evidence, including short-term labeling experiments (Sirevåg, 1974), use of washed cells and inhibitors (Sirevåg and Ormerod, 1970a,b), long-term labeling experiments (Fuchs et al., 1980b) and isotope fractionation studies (Quandt et al., 1977, 1978;

Fig. 1. The reductive tricarboxylic acid cycle of *Chlorobium* as proposed by Evans et al. (1966).

Sirevåg et al., 1977), indicate that the reductive TCA cycle is the sole mechanism of CO_2 fixation in this organism and that the product of the cycle, acetyl-CoA, can be directly converted to carbohydrate (Sirevåg, 1975). Furthermore, when the gene for RuBisCO from *Rhodospirillum rubrum* was used as a probe, no hybridization with *Chlorobium* DNA was detected (Shively et al. 1986). The same negative results were obtained when the RuBisCO genes from *Anacystis nidulans* were used.

C. Carbon Dioxide Fixation in *Chloroflexus*

Like most phototrophic bacteria, *Chloroflexus* is able to grow photoautotrophically with CO_2 as the

sole carbon source. Slow photoautotrophic growth on sulfide was first reported by Madigan et al. (1974), and later sulfide was shown to be an electron donor in photosynthesis of *Chloroflexus* (Madigan and Brock, 1975, 1977). *Cf. aurantiacus* is also able to use molecular hydrogen for reduction of CO_2 and grows well photoautotrophically on H_2 and CO_2 (Sirevåg and Castenholz, 1979, Holo and Sirevåg, 1986).

Stimulation by ribulose-1,5-bisphosphate of $^{14}\text{CO}_2$ -uptake has been reported using cell-free extracts of photoheterotrophically grown *Cf. aurantiacus* (Madigan and Brock, 1977; Sirevåg and Castenholz, 1979). However, when cell-free extracts of cells grown photoautotrophically with H_2 as an electron donor were tested for RuBisCO activity, this enzyme

was not detected. Furthermore, short-term labeling experiments with $^{14}\text{CO}_2$, use of inhibitors in combination with various ^{14}C -labeled substrates, and $^{13}\text{C}/^{12}\text{C}$ isotope fractionation studies indicate that the Calvin cycle does not operate in *Cf. aurantiacus* (Holo and Sirevåg, 1986; Holo and Grace, 1987; Holo, 1989). This is in agreement with the findings that *Cf. aurantiacus*-DNA did not hybridize with RuBisCO genes from either *Rs. rubrum* or *A. nidulans* (Shively et al., 1986)

The possibility that *Chloroflexus* might have a reductive TCA cycle similar to that of *Chlorobium* for fixation of CO_2 has been examined. It was found that one of the key enzymes of this cycle, pyruvate synthase, which catalyzes the formation of pyruvate from acetyl-CoA and CO_2 (see Fig. 1) is present in *Cf. aurantiacus*, whereas the other enzymes specific for the complete reductive TCA cycle were lacking (Holo and Sirevåg, 1986). Thus in *Cf. aurantiacus* acetyl-CoA is synthesized from CO_2 by a mechanism different from that of *Chlorobium*.

In order to investigate whether acetyl-CoA was formed from CO_2 by a $\text{C}_1 + \text{C}_2$ mechanism or by a cyclic pathway in *Cf. aurantiacus*, long-term labeling experiments were performed in which autotrophically grown cells were allowed to metabolize ^{13}C -labeled acetate under conditions where metabolism of acetate by the tricarboxylic acid cycle and the glyoxylate cycle was inhibited. When the labeling pattern was analyzed by ^{13}C -NMR, the results indicated a novel metabolic cycle in *Cf. aurantiacus* in which acetyl-CoA acted both as a product and an intermediate (Holo and Grace, 1987). Later Holo (1989) found that 3-hydroxypropionate was excreted by cells grown photoautotrophically under conditions which favored accumulation of metabolic intermediates. On this basis he suggested that under photoautotrophic conditions, *Cf. aurantiacus* converts acetyl-CoA to 3-hydroxypropionate which might serve as an intermediate in a CO_2 fixation pathway where it gives rise to malate and succinate.

Support for this hypothesis was obtained by Strauss et al. (1992) who observed that autotrophically grown cells of *Chloroflexus* excreted succinate and large amounts of 3-hydroxypropionate in the late exponential to stationary phase. When these workers labeled growing cultures of *Cf. aurantiacus* with $[1, 4\text{-}^{13}\text{C}]\text{succinate}$ and analyzed the various cell constituents by ^{13}C -NMR spectroscopy to determine the distribution of ^{13}C in various cell constituents, their results were consistent with the role of 3-

hydroxypropionate as an intermediate metabolite in a CO_2 fixation mechanism.

The operation in *Cf. aurantiacus* of a cyclic CO_2 fixation mechanism involving 3-hydroxypropionate has recently been contested by Russian workers (Kondratieva et al., 1992; Ivanovsky et al., 1993) who have proposed an alternative mechanism shown in Fig. 2. The key enzyme of this cycle is an ATP-dependent malate lyase (EC 4. 1. 3. 24) and the net product of the cycle is glyoxylate. These authors explain the finding by Holo (1989) that 3-hydroxypropionate is excreted by *Cf. aurantiacus* by suggesting that this compound is a dead-end product synthesized from acetate by a side path. However, a serious objection to the mechanism proposed by Ivanovsky et al. (1992) is that it is not in accord with the labeling pattern obtained previously (Holo and Sirevåg, 1986; Holo and Grace, 1987; Holo, 1989) and more recently (Strauss et al., 1992; Eisenreich et al., 1993; Strauss and Fuchs, 1993).

The possibility that 3-hydroxypropionate might be an intermediate in a cyclic CO_2 fixation mechanism has very recently been tested further by Fuchs and coworkers by long-term labeling experiments (Eisenreich et al., 1993). The relative ^{13}C content of individual carbon atoms in various amino acids and nucleosides was determined by ^{13}C -NMR spectroscopy after growing *Cf. aurantiacus* in the presence of $[1\text{-}^{13}\text{C}]\text{3-hydroxypropionate}$, $[1\text{-}^{13}\text{C}]\text{acetate}$, or $[2\text{-}^{13}\text{C}]\text{acetate}$ in addition to $^{12}\text{CO}_2$. From the labeling patterns obtained, the ^{13}C labeling of central metabolic intermediates like trioses and dicarboxylic acids were deduced. These experiments showed clearly that when growing cells of *Cf. aurantiacus* were fed $[1\text{-}^{13}\text{C}]\text{3-hydroxypropionate}$ over several generations, this compound served as a precursor for all cell compounds, a finding which can only be explained if 3-hydroxypropionate functions as an intermediate in the central metabolism of the organism. Their data obtained with labeled acetate also confirmed the possible role of 3-hydroxypropionate as an intermediate in the novel cyclic mechanism of CO_2 fixation which is shown in Fig. 3.

To test the operation of this cycle further, Strauss and Fuchs (1993) undertook enzymic studies and were able to demonstrate activity of all the enzymes necessary for the operation of the novel CO_2 fixation cycle. In this 3-hydroxypropionate cycle, acetyl-CoA is carboxylated to malonyl-CoA and then reductively converted via 3-hydroxypropionate to propionyl-CoA. This in turn is carboxylated and

Fig. 2. The pathway for autotrophic CO₂ assimilation in *Chloroflexus aurantiacus* proposed by Ivanovsky et al. (1993)

converted via succinyl-CoA to malyl-CoA, which is cleaved to acetyl-CoA and glyoxylate in a reaction catalyzed by malyl-CoA lyase (EC 4. 1. 3. 24). Acetyl-CoA reenters the cycle whereas glyoxylate is its net fixation product. Thus, the two different autotrophic CO₂ fixation mechanisms which have been proposed for *Cf. aurantiacus* both have the same net product, glyoxylate (Figs. 2 and 3).

How glyoxylate might be further metabolized into important central metabolic intermediates has not yet been fully elucidated. However, on the basis of enzymic studies, Ivanovsky et al. (1993) have suggested that glyoxylate is converted into 3-PGA in reactions involving the serine and the glycine pathway.

III. The Assimilation of Organic Carbon

In chemoorganotrophic organisms, organic substrates have a dual role in that they serve both as an energy source and as a carbon source. This is not necessary in phototrophic bacteria where sufficient ATP as well as reducing power are provided by the reactions of their photosynthetic apparatus. Thus when exogenous organic compounds enter such cells, they can be assimilated directly into cell material resulting in both an increased rate of growth and a high yield of cell mass.

We have seen that the nature of the photosynthetic apparatus through the type of reducing power it

makes available to the organism, determines the mechanism by which CO₂ is fixed in green bacteria. In its turn, as will be seen, the nature of these mechanisms has a bearing on the metabolism of organic compounds in these bacteria.

A. Metabolism of Organic Compounds in Chlorobium

The green sulfur bacteria are characterized as being obligately anaerobic and absolutely dependent on light, carbon dioxide and oxidizable sulfur or hydrogen for growth. Larsen (1953) investigated the possible participation of some simple organic compounds in the photometabolism of *Cb. thio-sulfatophilum* and found that they did not support growth. This was long before it was understood on the biochemical level. Later, however, it was recognized by Sadler and Stanier (1960) that *Chlorobium* was able to assimilate some simple organic compounds in the light, provided that CO₂ and a source of reducing power were present. Today our knowledge of the reductive TCA cycle makes it possible to explain biochemically the inability of *Chlorobium* to grow photoheterotrophically. In addition to functioning as a mere mechanism of CO₂ fixation, the intermediates of this cycle (Fig. 1) also provide the cells with the necessary organic precursors for synthesis of fatty acids (from acetyl-CoA), amino acids (from pyruvate, α -oxoglutarate and oxalo-

Fig. 3. The 3-hydroxypropionate cycle suggested by Holo (1989) for autotrophic CO_2 assimilation in *Chloroflexus aurantiacus* as presented by Strauss and Fuchs (1993).

acetate) and carbohydrates (from pyruvate). However, since α -oxoglutarate dehydrogenase is not present in *Chlorobium* (Beatty and Gest, 1981), this cycle can only function in the reductive direction and therefore organic compounds cannot be oxidized to provide CO_2 or reducing power.

Among the various organic compounds which can be assimilated by green sulfur bacteria are acetate, propionate, pyruvate, lactate, glutamate and glucose. Of these, acetate is by far the best substrate for growth. When this compound is added to the inorganic medium normally used for photoautotrophic growth, the growth rate as well as the yield are almost doubled. In view of the fact that acetyl-CoA is the immediate product of the reductive tricarboxylic acid cycle, this is not surprising. Presumably acetate in the medium is taken up by the cells and immediately converted to acetyl-CoA (Sirevåg and Ormerod, 1970b).

Evidence indicating that exogenous acetate is metabolized in this fashion was in fact provided by Hoare and Gibson (1964) before the reductive TCA

cycle was proposed as a mechanism of CO_2 fixation in green sulfur bacteria. These workers grew *Chlorobium* in a medium containing ^{14}C -acetate and CO_2 . The labeling pattern obtained when amino acids from protein of such cells were isolated and degraded, are in keeping with the assimilation of acetate *via* the now established reductive TCA cycle.

The photometabolism of propionate was investigated in detail by Larsen (1951), who discovered that *Chlorobium* is able to form succinyl-CoA from propionate. Thus after carboxylation and activation, the carbon atoms of propionate participate in the reductive TCA cycle. Later this knowledge proved valuable when radioactively labelled propionate was used in long term labeling experiments to gain evidence for the operation of the reductive TCA cycle in *Chlorobium* (Fuchs et al. 1980b).

The growth response of green sulfur bacteria to organic nutrients in the environment was investigated in detail by Kelly (1974). In addition to numerous amino acids, formate and glucose were readily

assimilated in the presence of light, CO_2 and thiosulphate. The labeling patterns among cell constituents after assimilation of ^{14}C -labelled substrates indicated that the pathway of intermediary metabolism for these compounds in *Chlorobium* are similar to those known in many other organisms.

B. Metabolism of Organic Compounds in Chloroflexus

In contrast to green sulfur bacteria, the green gliding bacteria are able to utilize a variety of organic compounds for growth both under anaerobic conditions in the light and aerobically in the dark. These organic compounds include acetate, pyruvate, lactate, butyrate in addition to C_4 dicarboxylic acids, some alcohols, sugars and amino acids (Madigan et al. 1974). The natural habitat of the *Chloroflexaceae* is hot springs where they live in close association with other microorganisms which liberate a variety of organic compounds (Bauld and Brock, 1974). Thus the nutritional versatility of the green gliding bacteria reflects their ecology.

In order to examine whether the oxidative TCA cycle plays any role in the metabolism of *Chloroflexus*, fluoroacetate was used. In aerobic cells with a functional TCA cycle, this compound is converted to fluorocitrate which in turn inhibits aconitase and thus causes accumulation of citrate (Morrison and Peters, 1954). The results from such experiments indicated that this cycle operates in *Chloroflexus* under anaerobic as well as aerobic conditions (Sirevåg and Castenholz, 1979).

The metabolism of acetate in *Chloroflexus* was studied in detail in cells grown photoheterotrophically with acetate as the sole organic carbon source. In cell-free extracts from such cells, the specific activity of the key enzymes of the glyoxylate cycle, isocitrate lyase and malate synthase, was 5-fold higher than in extracts from cells grown in a complex medium. These findings together with results from experiments with inhibitors, indicated that operation of the glyoxylate cycle was necessary for acetate utilization in *Chloroflexus* (Løken and Sirevåg, 1982).

IV. Carbon Containing Reserve Materials and Endogenous Metabolism

In nature, phototrophic organisms are always exposed to regular variations in the supply of energy. Such

variations are the case not only during the 24 hours (day/night), but also during the year (summer/winter). In the case of *Chlorobium*, the latter situation is dramatic since this organism frequently lives deep down (6 m or greater) in meromictic lakes, which might be covered by ice and snow for several months during the year (in Norway). It is therefore not surprising that phototrophic organisms have the capacity under favorable conditions to convert their carbon source into reserve materials, which can serve as maintenance under less favorable conditions. During balanced growth, the phototrophic bacteria usually form only small amounts of reserve materials, whereas such compounds usually accumulate in bacterial cells when carbon and energy are in excess, as under conditions of nitrogen starvation.

Among the phototrophic bacteria there are two carbonaceous reserve materials formed; glycogen and poly- β -hydroxybutyrate. Green sulfur bacteria such as *Chlorobium* are able to synthesize only glycogen, whereas the green gliding bacteria such as *Chloroflexus* appear to have the capacity to synthesize both. The type of storage material formed in the latter appears to be dependent on the conditions in the environment (Sirevåg and Castenholz, 1979).

A. Glycogen

Glycogen is a polymer in which numerous glucose residues are joined together by α -(1, 4)-glucosidic linkages into long chains which are branched, with α -(1, 6) linkages at the branch points.

The biosynthesis of glycogen in bacteria occurs via several reactions. First ADP-glucose is formed from ATP and α -glucose-1-P in a reaction catalyzed by ADP-glucose pyrophosphorylase (EC 2. 7. 7. 27) (in eukaryotic cells the corresponding reaction involves UTP). Two additional enzymes are further required; bacterial glycogen synthase (ADP-glucose: 1, 4-glucan transferase, EC 2. 4. 1. 21) which catalyzes the transfer of ADP-glucose to an α -glucan primer to form the α -(1, 4) linkages in the polymer. Finally, the 'branching enzyme' (α -1, 4-glucan-6-glycosyl transferase, EC 2. 4. 1. 18) forms the α -(1, 6) linkages by transferring part of an outer chain into the 6-position of a glucose residue further into the molecule.

It has been found that glycogen biosynthesis is regulated at the step where ADP-glucose is synthesized, and the properties and regulation of ADP-glucose pyrophosphorylase has been studied

in detail in numerous bacteria by Preiss and coworkers (Preiss, 1984; Preiss and Romeo, 1989). Based on the nature of activators of the enzyme from various sources, seven groups of ADP-glucose pyrophosphorylases are recognized of which ADP-glucose pyrophosphorylase from *Chlorobium* belongs to the group activated by pyruvate and fructose-6-P (Preiss, 1984). That these specific compounds are activators of ADP-glucose phosphorylase in *Chlorobium* is not surprising in view of the fact that in this green sulfur bacterium pyruvate is a central metabolite which is directly converted to glucose (Sirevåg and Ormerod, 1970a). Furthermore, it has been shown that in *Chlorobium*, glucose is formed by the reactions of gluconeogenesis where fructose-6-P is an intermediate (Sirevåg, 1975; Paalme et al., 1982).

In prokaryotic as well as in eukaryotic cells, glycogen is deposited within the cells in the form of rosette-like non membrane-bound granules made up of smaller particles (Candy, 1980). When the deposition of glycogen in cells of *Chlorobium* was examined by electron microscopy of thin sections stained specifically for carbohydrate, results corresponding to this general picture were obtained (Sirevåg and Ormerod, 1977). The size of the granules in *Chlorobium* was limited to 30 nm and as the glycogen content of the cells increased, the number, rather than the their size, increased. When cells of *Chlorobium* containing polyglucose are incubated in the dark, the polymer is broken down. Experiments using electron microscopy and labeling with ^{14}C -acetate revealed that degradation of polyglucose occurs in such a way that all granules are subject to degradation simultaneously, and the polyglucose which has been formed most recently in the light becomes the first to be metabolized in the dark (Thorud and Sirevåg, 1982).

In his pioneering work on the green sulfur bacteria, Larsen (1953) investigated the endogenous dark metabolism of *Chlorobium* and found that washed cells evolved CO_2 and H_2S and produced acid in the dark. Later it was shown that resting cells of *Chlorobium* form glycogen in the light when incubated with CO_2 and a suitable hydrogen donor, and that the formation is increased by the addition of acetate (Sirevåg and Ormerod, 1970b). When washed cell suspensions enriched in glycogen are incubated in the dark, the glycogen decreases with time and organic acids such as acetate, propionate, caproate, and succinate are excreted into the medium. When glycogen-rich cells were incubated without a

hydrogen donor, the level of glycogen decreased regardless of whether the cells were incubated in the dark or in the light. Since the products formed from polyglucose under the two different conditions are not the same, it has been suggested that glycogen serves as an energy source in the dark and as a source of reducing power in the light (Sirevåg and Ormerod 1977).

Although no detailed investigation of biosynthesis and storage of glycogen in *Chloroflexus* has been performed, it has been shown that washed cells of *Cf. aurantiacus* make glycogen as a reserve material from acetate and several other organic compounds (Sirevåg and Castenholz, 1979; Holo and Sirevåg, 1989).

B. Poly- β -Hydroxybutyrate

Poly- β -hydroxybutyrate is a linear polymer of D- β -hydroxybutyric acid and its molecular weight may be as high as several hundred thousand (Lundgren et al. 1965). In *Rs. rubrum* this polymer is synthesized from acetylCoA via β -hydroxybutyrate without the involvement of acyl carrier protein (Moskowitz and Merrick, 1969), and is deposited as large (up to 400 nm) intracellular granules which are surrounded by a thin, non-unit membrane (Boatman, 1964).

Results which indicated that *Chloroflexus* produced poly- β -hydroxybutyrate as reserve material during photoheterotrophic growth was obtained by chemical analysis as well as by electron microscopy by Pierson and Castenholz (1974). In experiments with washed cells of *Cf. aurantiacus* it was shown that this organism forms significant amounts of poly- β -hydroxybutyrate from acetate provided an inorganic hydrogen donor, H_2 , was present. In the absence of the hydrogen donor, polyglucose was formed instead (Sirevåg and Castenholz. 1979).

VI. Evolution of Metabolic Pathways Involved in Carbon Metabolism of Green Bacteria

Three fundamentally different mechanisms exist for the fixation of CO_2 under autotrophic conditions in phototrophic prokaryotes: the Calvin cycle (see Chapter 41 by Tabita) used by purple bacteria and cyanobacteria, the reductive TCA cycle (Fig. 1) used by green sulfur bacteria, and the very recently discovered 3-hydroxypropionate cycle (Fig. 3) used by green gliding bacteria. In some nonphototrophic

bacteria an additional autotrophic mechanism of CO₂ fixation occurs, the acetyl-CoA pathway, which is noncyclic and used by homoacetogens, methanogens, and most autotrophic sulfate reducers (Fuchs, 1989). The fact that completely different reactions participate in these four CO₂ fixation pathways makes it unlikely that they are derived from a common ancient mechanism. Instead they have probably evolved independently at different times during evolution to meet various needs in different organisms. Thus, when discussing evolution of the CO₂ fixation pathways in green bacteria one has to take into account what is known about the evolution of the organisms themselves and their phylogenetic relationship.

Based on sequence similarities in 16S ribosomal RNA from eubacteria, Woese (1987) introduced a now widely accepted classification scheme which contains 10 phyla. Results from this type of analysis show a deep divergence between *Chlorobium* and *Chloroflexus*, indicating that they are phylogenetically far apart (Gibson et. al 1985). Accordingly, on the evolutionary tree based on 16S rRNA analysis *Chloroflexus* and *Chlorobium* are separated into two different phyla, of which that containing *Chloroflexus* branches off very early. In this connection it should be pointed out that Blankenship (1993) recently presented an evolutionary tree based on information from reaction center sequence data, where the position of *Chloroflexus* is much closer to the purple bacteria than in the well known evolutionary tree of Woese (1987). However, regardless of their individual phylogenetic positions, it is clear that most evidence so far indicate that the only major character common to the Chlorobiaceae and the Chloroflexaceae is their type of light-harvesting bacteriochlorophylls and the organization of these pigments into chlorosomes. That these organisms share such important properties can however be explained by lateral gene transfer as was pointed out by Blankenship (1993). On this background it is therefore not surprising that two separate pathways for the fixation of CO₂ have evolved in the green sulfur bacteria and the green gliding bacteria.

The widely accepted idea that life originated in a primeval sea, containing a wide variety of abiotically produced organic compounds was put forward independently by Oparin in 1924 (Oparin 1953) and Haldane in 1929. It has also been widely accepted that no molecular oxygen was present in the atmosphere surrounding the primeval sea, and accordingly the first organisms must have been

anaerobes. Presumably they were chemoorganotrophs, dependent on abiotically produced organic molecules as their source of carbon and energy. Since no inorganic electron acceptors were believed to be present, it is likely that these first organisms were fermentative.

Recently, the theory of a chemoorganotrophic origin of life has been challenged by Wächtershäuser (1992) who has proposed a chemolithotrophic origin of life as an alternative. According to this theory, the source of reducing power for a chemolithotrophic origin as well as for early evolution is the oxidative formation of pyrite (FeS₂) from hydrogen sulfide and either ferrous ions or iron sulfide: $\text{FeS} + \text{HS}^- \rightarrow \text{FeS}_2 + \text{H}^+ + 2\text{e}^-$

Two different views have been put forward to explain the evolution of biosynthetic pathways. Horowitz (1945) speculated that metabolic pathways may have been constructed in a backwards manner by so called retroevolution. In line with this hypothesis, the activities of primitive organisms deprived the primeval seas of organic nutrients, resulting in a changed environment. As biochemically important substances were depleted, it became essential for survival of the organisms to develop the ability to convert other organic compounds into the depleted ones. Thus, selection would favor those organisms which acquired the ability to affect such conversions. On this background it is not difficult to envisage that the autotrophic way of life emerged early in evolution when organic nutrients became limiting. The other point of view, put forward by Granick (1965), implies that the intermediates in the biosynthetic pathway of a complex molecule like chlorophyll are thought to be the final products of biosynthetic pathways of earlier evolutionary forms. As was pointed out by Blankenship (1992) both of these concepts may in part be valid.

Founded on the ideas of a chemoorganotrophic origin of life and retroevolution in addition to evidence from paleomicrobiology and biogeochemistry, molecular phylogeny and comparative biochemistry, the generally accepted time sequence of metabolic evolution is the following:

In the context of this scheme and assuming that the basic reactions of intermediary carbon metabolism in the ancient fermentative organisms were anaerobic, Weitzman (1985) has developed a possible pattern for the evolution of the tricarboxylic acid cycle. This work was to a large extent based on the speculations by Dillon (1981) who proposed a strictly biosynthetic evolutionary route by stepwise retroevolution. Starting from three key amino acids; glycine, aspartate and glutamate, the possible evolution of the TCA cycle and the glyoxylate cycles are described. As the environment became depleted of these amino acids, organisms evolved which could produce these compounds by amination of the corresponding α -oxoacids; glyoxylate, oxaloacetate and α -oxoglutarate. In order to have a supply of oxaloacetate, malate was converted to oxaloacetate in the next step in the scheme of Dillon (1981), whereas malate in turn was formed from glyoxylate and an activated acetyl group. Since *Chloroflexus* uses the reactions of the tricarboxylic acid as well as the glyoxylate cycles under anaerobic conditions in the light (Sirevåg and Castenholz, 1979; Løken and Sirevåg, 1982), these retroevolutionary speculations are very interesting in connection with the proposal that *Chloroflexus* might have branched off very early in evolution (Woese, 1987). The central role of glyoxylate in the scheme of Dillon (1981) is especially intriguing in view of the fact that glyoxylate is the product of the newly discovered 3-hydroxypropionate cycle (Fig. 3) for autotrophic CO₂ fixation in *Chloroflexus* (Holo, 1989; Strauss and Fuchs, 1993).

Taken together, our present knowledge of carbon metabolism in *Chloroflexus* is in accord with the hypothesis that the green gliding bacteria branched off very early in evolution.

If the TCA cycle and the glyoxylate cycle first evolved in an organism like *Chloroflexus*, it is not difficult to envisage how the reductive TCA cycle might have evolved from the TCA cycle. It was pointed out by Weitzman (1985) that once a photosynthetic mechanism evolved which could photoreduce ferredoxin, the possibility existed to produce pyruvate and α -oxoglutarate by the synthase reactions described earlier herein. Thus, the TCA cycle could be run reductively in reverse and function not only as a mechanism for the production of important organic metabolites, but also as a mechanism for the fixation of CO₂ as well. This is exactly what is the case in *Chlorobium*.

To investigate the possible evolutionary relation-

ship of carbon metabolism in various phototrophic bacteria, we have studied the molecular properties of the enzyme malate dehydrogenase (MDH). In addition to its central role in the intermediary metabolism of most if not all organisms, this enzyme is also necessary in the CO₂ fixation pathway of *Chlorobium*. Analysis of the amino acid sequence of the N-terminal end of MDH from *Cb. vibrioforme*, *Cb. tepidum*, *Cf. aurantiacus*, and *Hb. gestii* showed an identical glycine motif (GXGXXG) in the dinucleotide binding domain of the enzyme from each organism (Rolstad *et al.* 1988, Charnock *et al.* 1992). Recent unpublished results show the same pattern for MDH from *Rs. rubrum*. This specific motif is different from that of all other MDHs sequenced to date, but is characteristic for other types of dehydrogenases and particularly for lactate dehydrogenases (LDH). Sequencing of the *mdh* structural genes of green sulfur bacteria and green gliding bacteria further indicate that in all other properties, except for the substrate binding domain, these MDHs resemble LDHs (Sirevåg, unpublished results). However the difference is small, since only three specific amino acids in the substrate binding domain determines the specificity of dehydrogenases (Wilks *et al.* 1988). Since lactic acid is a typical fermentation product, it is reasonable to assume that LDH appeared earlier in evolution than MDH. On this basis it is not difficult to envisage that the MDHs from green bacteria and possibly purple bacteria and heliobacteria are in principle LDHs which have evolved into MDHs by substituting specific amino acids in the substrate binding domain.

Summary

Purple photosynthetic bacteria exhibit great diversity in the metabolism of simple carbon compounds. In this chapter, the reactions and metabolic schemes that the organisms, particularly purple nonsulfur bacteria, employ to break down and/or assimilate one-carbon, two-carbon, three-carbon, and four-carbon compounds and sugars is examined. Knowledge of the biochemistry and physiology of carbon metabolism and its molecular control has benefited somewhat from the application of recombinant DNA approaches, yet there are significant gaps in our understanding of how catabolic and anabolic reaction sequences are integrated. By contrast, great advances have been made relative to the biochemistry of CO₂ fixation, due primarily to recent enzymological, molecular, and structural studies of the key enzyme, RubisCO. Indeed the enzyme from *Rhodospirillum rubrum* has become the paradigm for such work. The ability to prepare recombinant enzymes that catalyze additional key steps of CO₂ fixation should result in similar advances concerning these proteins in the future. Facile genetic manipulation of mutant *Rhodobacter* and *Rhodospirillum* strains has already resulted in the uncovering of alternative CO₂ assimilatory routes that replace the Calvin cycle, and prospects for gaining an understanding of the biochemistry and molecular control of both schemes should follow. The latter studies probably would not

be possible with other organisms, further attesting to the versatility of the purple nonsulfur bacteria for investigating basic metabolic processes. This chapter considers the current state of our knowledge of carbon dioxide fixation and carbon metabolism in purple bacteria.

I. Introduction

Purple photosynthetic bacteria, including the purple nonsulfur (PNS) and purple sulfur (PS) bacteria, represent a diverse group of organisms which exhibit great versatility in their carbon metabolism. Indeed, this metabolic versatility and the ability to grow under a variety of conditions present wonderful opportunities to study the biochemical and molecular basis for metabolic control. The PNS bacteria are particularly noteworthy in this regard, as these organisms are probably the most metabolically diverse organisms found in nature (Madigan and Gest, 1979). In this chapter, an overview of both heterotrophic and autotrophic carbon metabolism of purple bacteria is presented; this review focuses on developments since this topic was last reviewed (Fuller, 1978; Kondratieva, 1979) and stresses aspects of control and metabolic regulation in PNS bacteria.

A. Redox Balance and Carbon Metabolism

Under phototrophic growth conditions, purple photosynthetic bacteria must be supplied with an exogenous electron donor and an electron acceptor. Indeed, the organisms are exquisitely sensitive to the redox potential of the electron donor. The use of highly reduced electron donors; e.g., H_2 , propionate, or butyrate by purple nonsulfur bacteria has a profound effect on the flow of carbon in these cells

Abbreviations: α KDGH – α -ketoglutarate dehydrogenase; AMP – adenosine monophosphate; *cbb* – Calvin, Benson, Bassham; *Cm.* – *Chromatium*; *Cpn* – chaperonin; DMSO – dimethylsulfoxide; ED – Entner-Doudoroff pathway; EMP – Embden-Meyerhof-Parnas pathway; FBP – fructose 1,6-bisphosphate; GPD – glyceraldehyde phosphate dehydrogenase; GS – glutamine synthetase; ICL – isocitrate lyase; KDG – 2-keto-3-deoxygluconate; MSX – methionine sulfoximine; PC – pyruvate carboxylase; PEP – phosphoenolpyruvate; PEPCK – PEP carboxykinase; 3-PGA – 3-phosphoglyceric acid; 3-PGAL – 3-phosphoglyceraldehyde; PGK – phosphoglyceric acid kinase; PK – pyruvate kinase; PNS – purple nonsulfur; PRK – phosphoribulokinase; PS – purple sulfur; *Rb.* – *Rhodobacter*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*; *Rv.* – *Rubrivivax*; RubisCO – RuBP carboxylase/oxygenase; Ru-5-P – ribulose-5-phosphate; RuBP – ribulose 1,5-bisphosphate; SBP – sedoheptulose 1,7-bisphosphate; TCA – tricarboxylic acid

since under such conditions CO_2 may serve as both carbon source and electron acceptor. Thus, for purposes of this discussion it must be stressed that metabolic control of carbon flow is inexorably linked to the need for these organisms to balance or maintain redox poise.

II. Central Pathways for Organic Carbon Metabolism

In addition to CO_2 , a number of organic carbon sources will support the growth of purple bacteria. For purple nonsulfur bacteria, such carbon compounds may support both aerobic chemotrophic or anaerobic phototrophic metabolism; the purple sulfur bacteria generally favor strictly anoxygenic growth conditions, but there are well documented reports where some strains have been shown to grow under aerobic conditions (Kondratieva et al., 1976).

A. Formate, Methanol, and CO Metabolism

There are a number of instances where one-carbon compounds, other than CO_2 , are actively metabolized. Certainly, formate may be used as a growth substrate by a number of aerobic chemolithotrophic bacteria. In such organisms, formate dehydrogenase catalyses the oxidation of formate to CO_2 , which is then assimilated via the Calvin cycle (Quayle and Keech, 1959). Amongst the purple nonsulfur bacteria, *Rhodopseudomonas palustris* has been classically considered as the one strain which may actively metabolize and grow on formate under photosynthetic conditions (Qadri and Hoare, 1968). Strains of *Rp. palustris* apparently contain an inducible soluble formate dehydrogenase (Qadri and Hoare, 1968), the activity of which is enhanced by either FAD or FMN (Yoch and Lindstrom, 1968). An inducible particulate hydrogenase is also synthesized to assist in oxidizing hydrogen formed from formate (Qadri and Hoare, 1968).

Another one carbon substrate that may be photoassimilated by some strains is methanol. Enrichment in methanol-bicarbonate medium resulted primarily in the isolation of strains of

Rhodocyclus gelatinosa (now *Rubrivivax gelatinosus*) and *Rp. acidophila* (Quayle and Pfennig, 1975); in all cases the pH optimum for growth on methanol was considerably higher than for other carbon sources. Bicarbonate (or CO₂) is absolutely required as an electron acceptor for growth since methanol is considerably more reduced than cell material. Several other Rhodospirillaceae were found to grow in a methanol-bicarbonate medium but *Rp. acidophila* appeared the most active. Interestingly, formate also supported the growth of *Rp. acidophila*, however other C₁ compounds such as methylamine or formaldehyde did not. Formate was also able to substitute for bicarbonate as the required electron acceptor. Further analyses showed that one molecule of CO₂ is required for every 2 molecules of methanol assimilated to cellular carbon (CH₂O):

Under these growth conditions, ribulose biphosphate carboxylase/oxygenase (RubisCO) is increased some 6-fold over cells grown with succinate. Subsequent studies showed that methanol is anaerobically oxidized to formaldehyde, then to formate, and eventually to CO₂, with the Calvin cycle used for the assimilation of CO₂ (Sahm et al., 1976). In this case, the Calvin cycle is also used to facilitate the transfer of excess reducing power from methanol to CO₂. As will be discussed later, RubisCO thus serves both as a key enzyme for carbon assimilation as well as an important catalyst that allows CO₂ to function as an electron acceptor.

An extremely interesting system for the oxidation of carbon monoxide to CO₂ has been described in *Rhodospirillum rubrum* (Bonam et al., 1984). Previous studies had shown that various photosynthetic bacteria grow in the presence of CO (Hirsch, 1968) and *Rhodocyclus (Rubrivivax) gelatinosus* grows anaerobically in the dark on CO as sole carbon and energy source (Uffen, 1976). The *Rv. gelatinosus* CO-oxidizing system is membrane bound and yields both CO₂ and H₂ (Uffen, 1983); presumably CO₂ is assimilated via RubisCO and the Calvin cycle but this has not been conclusively established as yet. It is interesting that light-grown *Rv. gelatinosus* does not oxidize or assimilate CO. By contrast, *Rs. rubrum* synthesizes both CO dehydrogenase and a CO-insensitive hydrogenase in the light when cells are exposed to CO (Bonam et al., 1989). This inducible CO dehydrogenase has been thoroughly characterized

and found to be a nickel-containing monomeric enzyme often associated with a small Fe/S protein (Bonam and Ludden, 1987; Ensign and Ludden, 1991). Moreover, the structural genes, *cooF* and *cooS*, encoding the Fe/S protein and CO dehydrogenase, respectively, are present in a single transcriptional unit with part of the *cooH* gene (presumably encoding the CO-induced hydrogenase) upstream from *cooF*, which is found in a different transcriptional unit. There is also evidence for a fourth open reading frame whose partial deduced amino acid sequence suggests a protein with an ATP-binding site motif (Ensign and Ludden, 1991). Together, the biochemical results and the *cooHFS* genetic organization suggested an analogy to the *E. coli* formate hydrogenlyase system (Kerby et al., 1992), since *Rs. rubrum* is known to couple H₂ synthesis to formate oxidation (Gorrell and Uffen, 1977). Further experiments of this interesting system should establish whether the *Rs. rubrum* enzyme and associated proteins may catalyze more elaborate functions, such as the well-described acetyl CoA synthase reaction of CO dehydrogenase from homoacetogenic and methanogenic bacteria (Wood, 1991).

B. Acetate and 2-Carbon Metabolism

The pathways and reactions that purple bacteria, particularly PNS bacteria, use to metabolize acetate are clouded with uncertainty and controversy. All, or virtually all, PS and PNS bacteria grow on acetate (Thiele, 1968; Madigan, 1988). Exactly how this occurs, however, may vary in different strains. In *Chromatium*, a modified glyoxylate cycle lacking malate dehydrogenase is present (Fuller et al., 1961). This organism decarboxylates malate to form pyruvate via an NADP⁺-linked malic enzyme; pyruvate may then be used for carbohydrate synthesis through the mediation of an acetyl-CoA dependent pyruvate carboxylase and the enzyme phosphoenolpyruvate (PEP) carboxykinase. In the PNS bacteria, the situation is much more complicated. In 1960, Kornberg and Lascelles (1960) reported that isocitrate lyase (ICL) was present in extracts of acetate or butyrate-grown *Rp. palustris* or *Rb. capsulatus* cultured under both phototrophic or chemotrophic growth conditions. However, both *Rb. sphaeroides* and *Rs. rubrum* contained very low levels of this key glyoxylate cycle enzyme, yet the two organisms grew well with acetate. A later report indicated that *Rb. capsulatus* lacked ICL (Albers and Gottschalk,

1976). Moreover, Payne and Morris (1969a) state that acetate-grown aerobic cultures of *Rb. sphaeroides* failed to incorporate [2-¹⁴C] acetate into glyoxylate, glycolate, or glycine, suggesting that this organism uses a novel pathway to metabolize acetate. The early work of Hoare (1963), which showed that *Rs. rubrum* incorporated acetate into glutamate, would also tend to discount the glyoxylate cycle. Subsequent studies verified that three different strains of *Rb. sphaeroides* were ICL⁻, while four *Rb. capsulatus* strains were shown to be ICL⁺ (Willison, 1988). As pointed out by Willison (1988), the ICL⁻ phenotype appears to be reminiscent of the situation observed with various methylotrophic bacteria and *Thiobacillus versutus*, which is both ICL⁺ and ICL⁻ depending on whether the organism is cultured anaerobically or aerobically, respectively (Claassen and Zehnder, 1986). Complicating this situation further, using an assay based on the colorimetric determination of the dinitrophenylhydrazone of glyoxylate, Blasco et al. (1989) were able to detect significant levels of ICL activity in *Rb. sphaeroides*, *Rs. rubrum*, as well as *Rb. capsulatus*. These authors contend that the continuous spectrophotometric assays previously employed may have led to difficulties in accurately measuring this enzyme. Perhaps the variance in ICL activity measured in different laboratories (with different strains) may be related to a faster adaptation by some strains to acetate, which seems in two cases to be related to acetate-dependent growth (Blasco et al., 1989; Nielsen and Sojka, 1979). When an acetate-adapted mutant became the dominant strain in cultures of *Rb. capsulatus* St. Louis, the levels of ICL also increased dramatically (Nielsen and Sojka, 1979). Furthermore, unlike ICL, malate synthase was shown to be constitutive in *Rb. capsulatus* E1F1 (Blasco et al., 1989; 1991). Exhaustion of acetate from cultures resulted in a rapid loss of ICL activity which was dependent on active photosynthesis. Restoration of activity required the addition of acetate and de novo protein synthesis (Nielsen et al., 1979). Taking these studies further, Blasco et al., (1991) found that there was a 3-fold increase in ICL activity after washed acetate-grown logarithmic *Rb. capsulatus* E1 F1 cells were resuspended in fresh media containing 1 mM acetate. As described for the St. Louis strain, cultures which became depleted for acetate rapidly lost ICL activity. Perhaps such phenomena are related to the divergent reports of ICL in PNS bacteria.

C. Pyruvate and 3-Carbon Metabolism

Virtually all purple photosynthetic bacteria are able to grow on pyruvate under photoheterotrophic growth conditions. As an important hub in microbial metabolism (Gest, 1981), the reactions leading to and from pyruvate have attracted some interest in PNS bacteria, particularly since these organisms readily grow both aerobically and anaerobically. There are several ways for PNS bacteria to metabolize pyruvate. Several species have been shown to degrade pyruvate under phototrophic conditions via pyruvate decarboxylase to form CO₂, acetaldehyde and acetoin (Qadri and Hoare, 1967) and most, if not all, species contain pyruvate dehydrogenase (Willison, 1988). *Rs. rubrum* uses both PEP synthase and PEP carboxylase to convert pyruvate to oxaloacetate and these reactions are important anaplerotic enzymes of the reductive tricarboxylic acid cycle, which are present in this organism (Buchanan et al., 1967). However, *Rb. sphaeroides* and *Rb. capsulatus* contain no PEP carboxylase or PEP synthase (Payne and Morris, 1969b; Willison, 1988) and pyruvate phosphate dikinase was not found in *Rb. capsulatus* (Willison, 1988). In *Rb. sphaeroides* and *Rb. capsulatus*, pyruvate carboxylase (PC), which is absolutely dependent on acetyl CoA for activity, is found at significant levels in both phototrophically and chemotrophically grown cells. Furthermore, PC negative mutants of both species were unable to grow on pyruvate or other compounds metabolized through pyruvate. Thus, even though both *Rb. sphaeroides* and *Rb. capsulatus* contained PEP carboxykinase (PEPCK) (Payne and Morris, 1969b; Willison, 1988), it is apparent that these organisms cannot use PEPCK to produce oxaloacetate. Rather, this enzyme, in vivo, must function to produce PEP and, as pointed out by Payne and Morris (1969b), *Rb. sphaeroides* (and *Rb. capsulatus*) is '...wholly reliant upon its pyruvate carboxylase to supply the C₄-dicarboxylic acids required during growth on carbon sources which only yield phosphoenolpyruvate and/or pyruvate.' Thus, it is apparent that PC is an important enzyme in *Rb. sphaeroides* and *Rb. capsulatus*; the enzyme has recently been purified to homogeneity from *Rb. capsulatus* and its gene cloned (the first prokaryotic PC gene to be isolated) (H.V. Modak and D.J. Kelly, personal communication). If the PEPCK reaction runs solely or predominately in the direction of PEP, there must be other enzyme(s)

in the cell whose activity pulls the PEPCK reaction towards PEP. An excellent candidate is pyruvate kinase (PK), which has been detected and partially purified from *Rs. rubrum* (Klemme, 1973), *Rb. sphaeroides* (Klemme, 1974), and *Rb. capsulatus* (Willison, 1988; Schedel et al., 1975). The enzymes from the three sources have surprisingly different properties although they each show classic allosteric regulation. For example, the *Rs. rubrum* enzyme is highly sensitive to inorganic phosphate, which is an allosteric inhibitor at fairly low levels ($K_i = 50 \mu\text{M}$) (Klemme, 1973). This sensitivity to phosphate is not exhibited by the *Rb. capsulatus* enzyme where the K_i was calculated to be 6.5 mM (Klemme, 1974). However, fumarate strongly inhibits the *Rb. capsulatus* PK and enhances the sigmoidal behavior at varying concentrations of PEP. The *Rb. sphaeroides* enzyme closely resembles the *Rb. capsulatus* enzyme with respect to its kinetic properties (Schedel et al., 1975). The most interesting and intriguing property of the *Rb. sphaeroides* and *Rb. capsulatus* PK enzymes is their cold lability, which appears to be due to a rapid, reversible and a slow, irreversible process that presumably involves dissociation-reassociation of enzyme protomers (Schedel et al., 1975). This important enzyme deserves to be studied in greater detail since it functions at the crossroads of important metabolic pathways of PNS bacteria. Other reactions involving pyruvate that have been demonstrated in PNS bacteria are malic enzyme (Fuller et al., 1961), pyruvate synthase (Buchanan et al., 1967), and pyruvate flavodoxin reductase (Brostedt and Nordlund, 1991). Finally, as previously discussed, *Rs. rubrum* shows the interesting capacity to grow fermentatively on pyruvate in the dark (Gorrell and Uffen, 1977) to form propionate (Kohlmiller and Gest, 1951), H₂ (Uffen and Wolfe, 1970), and formate (Schön and Voelskow, 1976), with formate subsequently metabolized to CO₂ and H₂. Pyruvate formate lyase appeared to be the key enzyme of the fermentation and formate hydrogen lyase is required for the generation of H₂; the appearance of different fermentation end products seems to be dependent on the growth conditions (Schön and Voelskow, 1976).

PNS bacteria show differential abilities to photometabolize propionate, as 33 strains of *Rb. capsulatus* grew in a propionate-CO₂ medium while *Rb. sphaeroides* did not (Weaver et al., 1975). CO₂ is absolutely required for growth on propionate, as it is

for all reduced electron donors. In *Rs. rubrum* the metabolism of propionate has been studied in great detail; this 3-carbon compound is assimilated to succinate via a propionyl CoA carboxylase whose activity and/or synthesis is shut down in cells grown in a malate medium (Knight, 1962).

Like propionate, another 3-carbon substrate, glycerol, supports the growth of some PNS bacteria but not others. Thus, Van Niel found that *Rb. sphaeroides* and *Rp. palustris* could grow on glycerol while *Rb. capsulatus* and *Rhodocyclus (Rubrivivax) gelatinosus* could not (van Niel, 1944). Some years later, Lueking et al. (1976) isolated a spontaneous mutant of *Rb. capsulatus* after several rounds of selection that had 'gained' the ability to grow on glycerol. Under photosynthetic conditions, CO₂ is absolutely required, as might be expected for bacteria grown on such a reduced substrate. In this strain, glycerokinase and pyridine nucleotide independent L- α -glycerophosphate dehydrogenase activities were found to be elevated several fold over the wild-type strain. The mutant, strain L₁, contained constitutive levels of these enzymes, as the difference in activity levels of cells grown on malate compared to cells grown on glycerol-CO₂ was not great (Lueking et al., 1976). A subsequent study has shown that gain-of-function glycerol-catabolizing mutants of *Rb. capsulatus* can easily be selected by subculturing wild-type strains on media containing mixtures of malate and glycerol (Spear and Sojka, 1984).

By contrast, *Rb. sphaeroides*, which naturally grows on glycerol, followed a diauxic growth response in a malate-glycerol medium and exhibited a typical repression/induction response relative to the glycerol catabolizing enzymes in a malate and glycerol medium, respectively (Pike and Sojka, 1975). Since the authors indicate that there is no evidence for a specific glycerol transport system in *Rb. sphaeroides* and *Rb. capsulatus*, it would appear that strain L₁ is a mutant that has lost the capacity to control the expression of the glycerol catabolizing enzymes (Lueking et al., 1976). As will be discussed later, this scenario is similar to the gain in the ability of *Rb. sphaeroides* strain 16 to use CO₂ as an electron acceptor when malate is the carbon source (Wang et al., 1993a).

Lastly, strains of *Rb. capsulatus* and *Rhodocyclus vannielii* were found to actively photometabolize and grow on acetone; again, as expected, growth was CO₂-dependent due to the reduction

level of acetone (Madigan, 1990). No growth was obtained under dark aerobic or dark anaerobic conditions. Earlier studies described work with other interesting isolates, since lost, capable of quantitative conversion of isopropanol to acetone and CO_2 . Unpublished results from our own laboratory had previously indicated that high levels of RubisCO may be obtained in *Rb. capsulatus* cells grown with a variety of reduced substrates and alcohols, including acetone.

D. Butyrate and the Metabolism of Other Reduced Fatty Acids

In previous sections, the absolute requirement of exogenous CO_2 for the growth of PNS bacteria on reduced organic compounds such as methanol, propionate, glycerol, and acetone was stressed. However, it is well known that PNS bacteria grow better, with faster doubling times and to higher density, when C_4 dicarboxylic acids such as malate or succinate are used as the electron donor. Such compounds, along with pyruvate and lactate, and other common growth substrates are more oxidized than the intracellular milieu; the cells thus do not require an exogenous electron acceptor. Indeed, in an insightful study over 60 years ago, Muller found that organisms growing at the expense of oxidized organic acids, such as acetate or malate, showed a significant net release of CO_2 into the growth medium. For acetate and malate, 0.17 and 1.2 moles of CO_2 were produced per mole of substrate consumed, respectively; for succinate, somewhat more reduced than malate, the value dropped to 0.7 (Muller, 1933). When reduced electron donors, such as butyrate, were used, addition of CO_2 to the growth medium was required and 0.7 mole of CO_2 was utilized per mole of butyrate consumed. Thus, even though acetate and butyrate are rapidly assimilated under phototrophic growth conditions, presumably to form large amounts of poly- β -hydroxybutyrate (PHB) and other cellular constituents, metabolism of the two growth substrates obviously cause profound physiological changes. As discussed by Stanier et al., (1976), the synthesis of PHB from acetate is a reductive process involving the metabolic sequences of the TCA cycle:

However, synthesis of PHB from butyrate is an oxidative process:

Under anaerobic conditions, there must be a readily available hydrogen acceptor and, obviously, this must be supplied exogenously because the cells will not grow without the addition of CO_2 in the form of bicarbonate, with CO_2 subsequently reductively assimilated to carbohydrate $(\text{CH}_2\text{O})_n$. Thus, butyrate photoassimilation is coupled to CO_2 fixation:

This last equation readily explains how PNS bacteria are able to grow on reduced fatty acids, and probably relates to the CO_2 requirement of bacteria cultured on other reduced carbon sources as well. At one time, it was thought that organic carbon served mainly as a H-donor for CO_2 fixation (van Niel, 1941). However, the discovery (Gest and Kamen, 1949) that PNS bacteria may evolve copious quantities of H_2 when grown on organic carbon caused a reevaluation of Van Niel's hypothesis on the role of organic carbon. Indeed as stated by Gest (1951): "The accessory (organic) 'hydrogen donor' required in bacterial photosynthesis ordinarily does not undergo a simple one-step oxidation; it generally supplies carbon intermediates, other than CO_2 , which are directly used by the cell for synthetic purposes. This is apparently true for practically all classes of organic 'hydrogen donors.'" "Indeed, it should be stressed that CO_2 need not be a major carbon source at all under such growth conditions since it is easily replaced by other exogenous electron acceptors that have no ability to function directly in carbon assimilation (Richardson et al., 1988). The importance of RubisCO and the Calvin cycle to this whole question of balancing the redox state of the cell is discussed in Sections III.D and IV.A.

E. Sugar Metabolism

Most, if not all, PNS bacteria are able to grow on one or more of the common sugars; in some cases the ability or inability to use fructose is characteristic of the species (Madigan, 1988). PS bacteria are much

more restrictive in their ability to metabolize sugars (Thiele, 1968). For purposes of this discussion, the metabolism of glucose and fructose by *Rb. sphaeroides* and *Rb. capsulatus* has been the best described. Both organisms transport these sugars via the phosphotransferase system (Saier et al., 1971). Early studies by Szymona and Doudoroff (1960) had indicated that *Rb. sphaeroides* uses a modified version of the classic Entner-Doudoroff pathway to metabolize glucose. In this scheme, no phosphorylated intermediates are employed (Conway, 1992) and this 2-keto-3-deoxygluconate (KDG) bypass proceeds as shown in Eq. (5).

In *Rb. capsulatus*, glucose is degraded by the Entner-Doudoroff pathway but fructose metabolism proceeds through the Embden-Meyerhof pathway (Eidels and Preiss, 1970; Conrad and Schlegel, 1974; 1977a,b). In the latter instance, a specific 1-phosphofructokinase is substantially induced under both phototrophic and aerobic growth modes in the presence of fructose (Conrad and Schlegel, 1974). This enzyme is encoded by the *fruK* gene (Wu et al., 1991) which is part of the *fru* operon, composed of other genes that specify enzymes of fructose metabolism (Wu and Saier, 1990; Wu et al., 1990). Interestingly, some homology of an internal portion of FruK to a region of RubisCO large subunits containing residues involved in ribulose 1,5-bisphosphate (RuBP) binding was noted. In *Rb. sphaeroides*, fructose is metabolized via both the Entner-Doudoroff (ED) and Embden-Meyerhof-Parnas (EMP) pathways; aerobically, the cells predominantly use the ED pathway, while under phototrophic conditions, fructose was metabolized by the EMP pathway (Conrad and Schlegel, 1977a). Glucose-grown cells employed only the ED pathway under both phototrophic and aerobic chemotrophic growth conditions (Conrad and Schlegel (1977a). These results are quite fascinating, especially in *Rb. sphaeroides*, as they point to sophisticated molecular controls over the expression of enzymes of sugar dissimilation that are dependent on both the growth substrate and the levels of oxygen. Conditions which lead to the induced metabolism of either glucose or fructose should result in the repression of enzymes of the Calvin cycle, which is involved in carbohydrate

biosynthesis. More than likely when the Calvin cycle (*cbb*) operons are switched on, the sugar dissimilatory system will be off. A fruitful area of investigation would be to isolate regulatory elements which control or influence the molecular 'switching' between carbohydrate synthesis and catabolism. Such studies might also relate to the control of oxidant-dependent sugar fermentation catalyzed by both *Rb. sphaeroides* and *Rb. capsulatus* (Madigan et al., 1980). This special type of energy conversion is discussed in the Chapter by Zannoni of this volume.

Finally, any discussion of heterotrophic metabolism (summarized in Fig. 1), under both aerobic or phototrophic growth conditions, must consider that the TCA cycle plays an essential role in the metabolism of all PNS bacteria. In *Rb. capsulatus*, it was found that molecular oxygen regulates through a rather specific effect on the synthesis of the α -ketoglutarate dehydrogenase (α KGDH) enzyme complex; low basal levels of α KGDH found under phototrophic growth conditions are presumably required to generate sufficient succinyl CoA for the biosynthesis of metalloporphyrins required for photosynthesis (Beatty and Gest, 1981a). Aerobic metabolism, however, exacts a high requirement for reduced pyridine nucleotide for ATP biosynthesis. Thus, α KGDH is induced under aerobic conditions and the levels of isocitrate dehydrogenase and citrate synthase are also elevated (Beatty and Gest, 1981b).

III. Calvin Reductive Pentose Phosphate Pathway

Classic label incorporation experiments performed many years ago (reviewed in Tabita, 1988) established that, much like green plants, PS and PNS bacteria assimilate ¹⁴C₂ primarily into 3-phosphoglyceric acid (3-PGA). The kinetics of incorporation, plus the identification of additional products of CO₂ fixation unequivocally established that the Calvin-Benson-Bassham reductive pentose phosphate cycle is the major route for CO₂ reduction (Glover et al., 1952; Stoppani et al., 1955). With regard to the PNS bacteria it is interesting that the conditions under which the cells were grown (in a medium containing malate as

Fig. 1. Composite reactions of central carbon metabolism in purple nonsulfur bacteria. ED, Entner Doudoroff pathway; EMP, Embden-Meyerhof pathway; Calvin, Calvin reductive pentose pathway; TCA, tricarboxylic acid cycle. Modified from Conrad and Schlegel (1977a) and Willison (1988).

electron donor and primary carbon source) result in a net release of CO_2 into the growth medium (section II C). Thus, at least part of the CO_2 produced as a result of the metabolism of the oxidized carbon source is assimilated through the Calvin pathway. Presumably under these conditions the Calvin cycle is used more as an anaplerotic carbon assimilatory route. These studies were followed by the actual demonstration of RubisCO activity in extracts of *Rs. rubrum* and *Chromatium* sp. (Fuller and Gibbs, 1959). Based on the time-dependent isolation of labeled intermediates of the pathway, as well as measurement of several enzyme activities, a cyclic pathway was established (Fig. 2). Aside from the pyridine nucleotide specificity of the glyceraldehyde phosphate dehydrogenase reaction, the scheme is the same in prokaryotes and eukaryotes. There are two unique

reactions, those catalyzed by RubisCO, the actual CO_2 assimilatory enzyme, and phosphoribulokinase, which catalyses the ATP-dependent phosphorylation of ribulose 5-phosphate (Ru-5-P) to form RuBP. In PNS bacteria, one enzyme, fructose 1,6-/sedoheptulose 1,7- bisposphatase, catalyzes the removal of inorganic phosphate from fructose 1,6-bisphosphate (FBP) and sedoheptulose 1,7-bisphosphate (SBP), respectively. Examination of the reactions involved in the metabolism and reduction of 3-PGA indicate many familiar enzymes of intermediary metabolism. These reactions are devoted to the regeneration of the CO_2 acceptor, RuBP, with the net result that one molecule of triose phosphate is produced from three molecules of CO_2 . In the following discussion, the properties of each of the important enzymes are reviewed and considered in conjunction with the

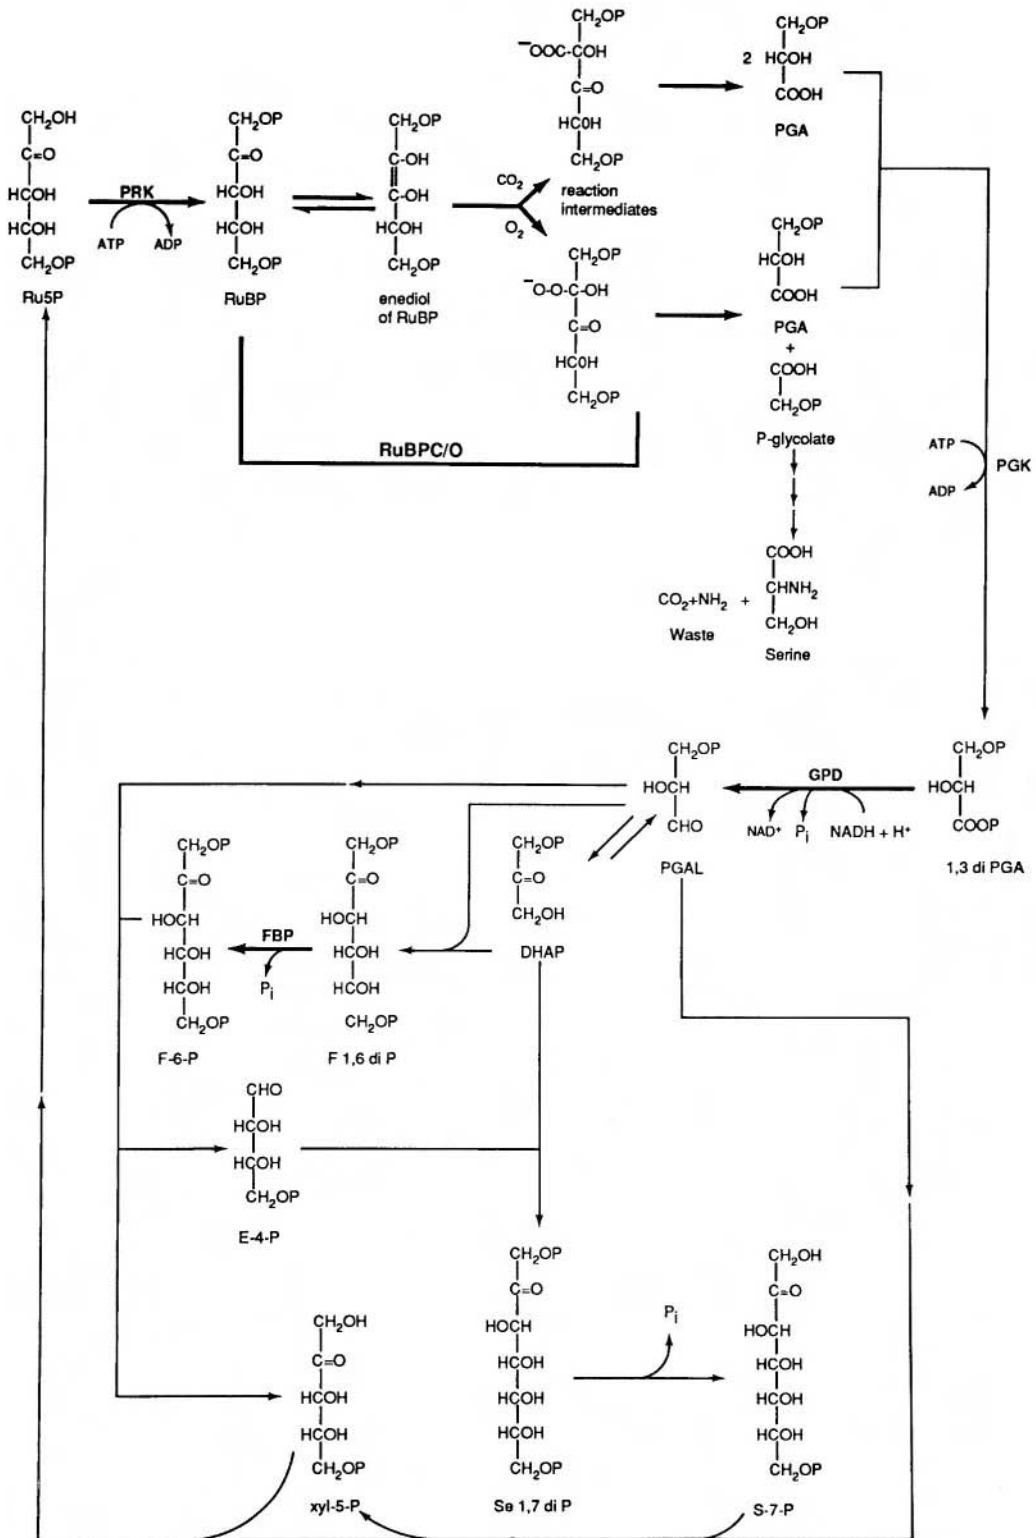

Fig. 2. Calvin reductive pentose phosphate pathway, highlighting the two reactions catalyzed by RubisCO (RuBPC/O). Other key enzymes including phosphoribulokinase (PRK), phosphoglyceric acid kinase (PGK), glyceraldehyde phosphate dehydrogenase (GPD), aldolase (FBA), and fructose biphosphatase (FBP) are highlighted. From Tabita (1988), with permission.

regulation of CO₂ assimilation by purple photosynthetic bacteria.

A. RubisCO

This important catalyst has generated considerable interest over the years, mainly due to its capacity to catalyze the first reaction of two competing metabolic pathways, the Calvin reductive CO₂ assimilatory pathway and an oxidative pathway involving the oxygenolysis of RuBP and subsequent oxidative metabolism of phosphoglycolate, the product of RuBP oxygenolysis. The two major physiological reactions catalyzed by RubisCO (Fig. 2), carboxylation and oxygenolysis, are catalyzed by a single protein at a single active site; the overall significance of both reactions to agricultural productivity has resulted in this enzyme becoming one of the most intensely studied of all proteins. RubisCO is the most abundant protein found in nature (Ellis, 1979) and is an extremely poor catalyst with a k_{cat} of about 3 sec⁻¹, undoubtedly a contributing factor to its massive synthesis in organisms that employ the Calvin cycle to grow with CO₂ as sole carbon source. The enzyme itself may be isolated as a complex hexadecameric protein (type I or form I RubisCO) comprised of eight large (catalytic) subunits (M_r of about 55,000) and eight small subunits (M_r about 15,000). The type I enzyme thus has an L₈S₈ arrangement of subunits. Type II (form II) RubisCO, found in several PNS bacteria (Tabita, 1988), is comprised of only large subunits (either L₂, L₄, or L₈). The large subunits from both types are unrelated, a fact that was first noted when the deduced amino acid sequence of the type II enzyme of *Rs. rubrum* was compared to various type I large subunits (Nargang et al., 1984) and when peptide maps of the large subunits of form I and form II proteins of *Rb. sphaeroides* were compared (Gibson and Tabita, 1985). Subsequently the genes of the two distinct *Rb. sphaeroides* proteins were sequenced (see Chapter by Gibson) and the deduced amino acid sequences clearly showed that there was only about 25% identity. Moreover, the form I and form II RubisCO genes are found on separate chromosomal genetic elements (Suwanto and Kaplan, 1989). A recent review traces the history of the discovery of the different structural forms of RubisCO in photosynthetic bacteria (Tabita, 1988).

The type II RubisCO from *Rs. rubrum*, which is a simple homodimer of large subunits (Tabita and McFadden, 1974b), has become the paradigm for

structure-function studies of this enzyme (Schneider et al., 1990). Indeed one of the more interesting findings has been the universality of the dimer as a basic structural motif, even in more complex type I RubisCO enzymes. Thus in the type I enzyme, there are essentially four *Rs. rubrum*-like dimers that form the octameric core of the protein, most accurately depicted as an (L₂)₄ arrangement (Knight et al., 1990). Decorating both the top and bottom of the octameric core are 4 small subunits, such that the L₈S₈ structure in reality is an (L₂)₄(S₂)₄ type structure. The active site is formed from the interface between the N-terminal domain of one subunit and the α/β barrel of the C-terminal domain of the second subunit of the dimer with at least two subunits required to form the complete active site (Schneider et al., 1990; Knight et al., 1990; Schreuder et al., 1993). Like most α - β barrel enzymes, various loops appear to be extremely important for catalysis; for RubisCO loop 6 is particularly cogent since this 11-amino acid region appears to be involved with stabilizing the carboxy and peroxy intermediates that form during the carboxylase and oxygenase reactions, respectively. Of particular importance in this region is Lys-329 of the *Rs. rubrum* enzyme (Lys-334 of type I RubisCO), which is absolutely required for activity (Hartman and Lee, 1989) and whose function appears to be influenced by other residues found in loop 6 or which contact loop 6 (Spreitzer, 1993). Although not within the purview of this review, various aspects of the structure of RubisCO that relate to its function have greatly influenced the experimental approaches that have been taken by various groups to elucidate the catalytic mechanism and the basis for CO₂/O₂ specificity. For more information on this interesting topic, the reader is directed to several papers that relate to the X-ray structure of RubisCO (Schneider et al., 1990; Knight et al., 1990; Schreuder et al., 1993).

1. Biochemical Properties of RubisCO from Purple Photosynthetic Bacteria

Before catalysis may proceed, RubisCO must first be activated. This involves carbamylation of the ϵ -amino group of Lys-191/Lys-201 with 'activator' CO₂ in a slow, rate-determining step, followed by the rapid addition of divalent cation to form a stable ternary complex, which then may catalyze either the carboxylation or oxygenolysis of RuBP (see Eq. (6)) where E represents RubisCO; C is CO₂; M is divalent

cation; R is RuBP; O is oxygen; and P is product (Miziorko and Lorimer, 1983). This basic catalytic pathway is obligatory for all sources of RubisCO and readily illustrates the well described competition of CO₂ and O₂ for the enzyme bound enediolate of RuBP. It should also be noted that in many instances RuBP prevents activation by forming a tight E-R complex, basically locking the enzyme in a conformation that prevents the obligatory carbamylation (activation). The capacity to form the E-R complex is a property which accentuates differences between type II enzymes and most type I enzymes. For the *Rs. rubrum* type II enzyme, early studies indicated that preincubation with RuBP does not drastically inhibit activity (Tabita and McFadden, 1974a; Christeller and Laing, 1978; Whitman et al., 1979). These differences are readily illustrated by comparing the responses of the form I and form II *Rb. sphaeroides* enzymes (Fig. 3). The only known type I enzymes that do not show RuBP-mediated inhibition are the enzymes isolated from cyanobacteria (Tabita, 1994). In addition to differences in the response to RuBP, type I and II enzymes show pronounced differences in their sensitivity to phosphorylated metabolites such as 6-phosphogluconate (Tabita and McFadden, 1972; Gibson and Tabita, 1977; 1979; Whitman et al., 1979). Perhaps the most impressive differences in catalytic properties involve comparisons of the Michaelis constants, particularly for CO₂ and O₂, and the $V_{\text{CO}_2}K_{\text{O}_2}/V_{\text{O}_2}K_{\text{CO}_2}$ ratio or substrate specificity factor (τ). Jordan and Ogren (1981) compared the substrate specificity factor and kinetic constants of RubisCO from a number of photosynthetic organisms. This ratio (τ) contrasts the relative rates of the carboxylase and oxygenase reactions at any given CO₂ and O₂ concentration and is derived from the equation (Laing et al., 1974):

$$\begin{aligned}
 v_{\text{CO}_2}/v_{\text{O}_2} &= (V_{\text{CO}_2}K_{\text{O}_2}/V_{\text{O}_2}K_{\text{CO}_2})([\text{CO}_2]/[\text{O}_2]) \\
 &= \tau([\text{CO}_2]/[\text{O}_2])
 \end{aligned} \tag{7}$$

where V_{CO_2} and K_{CO_2} represent the maximal velocity and Michaelis constant, respectively, for CO₂; V_{O_2} and K_{O_2} are the maximal velocity and Michaelis constant for O₂; and v_{CO_2} and v_{O_2} are the initial velocities for the carboxylase and oxygenase reactions, respectively. Using a simultaneous and sensitive dual label assay to measure the two activities,

Fig. 3. Time course of *Rb. sphaeroides* form I (A) or form II (B) RubisCO activity after preincubation in the presence of 0.4 mM RuBP (○) or 10 mM Mg²⁺ and 20 mM HCO₃⁻ (●). From Gibson and Tabita (1979), with permission.

it was found that the type II enzymes from *Rs. rubrum* and *Rb. sphaeroides* have considerably lower τ values than the enzyme from higher plants. Indeed there seems to be a gradation in the τ values from higher plants to type II enzymes. Interestingly the τ value for the form I enzyme of *Rb. sphaeroides* resembled values obtained for eukaryotic green algal enzymes, but was somewhat lower than the plant enzyme. The major reason for the low τ value of the two type II enzymes appears to be primarily due to the high K_{CO_2} for these enzymes, which also appears to be true of the low specificity factor cyanobacterial, vent symbiont (Stein and Felbeck, 1993), and *Chromatium* (Jordan and Chollet, 1985) enzymes. More recently the substrate specificity value for several additional microbial enzymes have been determined and these data, along with results summarized from earlier studies are compared (Table 1). In all cases, the spinach enzyme has been used as an internal

standard and all τ values are based on the double label assay; the type I enzymes have been grouped according to their amino acid sequence relatedness. Obviously, there is a great need for additional determinations amongst the bacterial type I RubisCO subclasses, particularly for additional PS photosynthetic bacterial and sulfur bacterial enzymes of Type IA and for PNS bacterial and chemolithotrophic bacterial enzymes of Type IC. Now that additional Type II enzymes have been isolated (English et al., 1992; Chung et al., 1993), it will be important to determine their sequence and the relevant kinetic constants so that comparisons may be made. The most important question facing RubisCO biochemists continues to involve elucidation of the determinants which influence CO_2 and O_2 substrate specificity. As noted earlier, the importance of loop 6 is well appreciated. However, it is also apparent from site-directed mutagenesis and genetic studies (Hartman

Table 1. Classification of diverse RubisCO enzymes^a

RubisCO type	Organism	$V_{CO_2}K_{O_2}/V_{O_2}K_{CO_2}(\tau)^b$	K_{CO_2} (μM)
Type IA	<i>Thiobacillus ferrooxidans</i>	N.D. ^c	N.D.
	Vent symbiont	30	80
	<i>Chromatium vinosum</i>	40	35
Type IB	<u>Cyanobacteria</u>

	<i>Thiobacillus denitrificans</i> II	10	250
	<i>Hydrogenovibrio marinus</i>	N.D.	N.D.

^a RubisCO enzymes have been classified according to their sequence relatedness; only those enzymes for which sequence information and/or kinetic data are available are presented.

^b Values (rounded and averaged) obtained from the dual label assay except the *Anabaena* and vent symbiont enzymes. From Jordan and Ogren (1981); Jordan and Chollet (1985); Lee et al. (1991); Read and Tabita (1992 a,b; 1994); Chung et al. (1993); Larimer and Soper (1993); Stein and Felbeck (1993); Horken and Tabita (unpublished); Hernandez and Tabita (unpublished).

^c Not determined

and Harpel, 1993, 1994; Spreitzer, 1993) that other unknown determinants remain to be discovered. A good representative sample of τ values for additional bacterial enzymes, in which the sequence is known, should give some idea as to what regions have been altered. Indeed, recent studies and comparisons of this type have pointed to several distinct changes in residues that may influence loop 6 of several nongreen algal RubisCOs, enzymes which all have τ values higher than plant RubisCO (Read and Tabita, 1992a,b; 1994). These comparisons, in conjunction with X-ray modeling studies and computer programs that can simulate perturbations or influences in the active site, will be most important for designing future enzyme engineering approaches. Obviously, if one could design the perfect RubisCO, it would be highly active and possess a high substrate specificity. At present, genetic engineering approaches have resulted in the isolation of RubisCO enzymes with altered, and even increased substrate specificity, however the enzymes uniformly exhibit low k_{cat} values (reviewed in Spreitzer, 1993; Hartman and Harpel, 1993,1994).

2. Biosynthesis and Assembly of RubisCO

It is apparent that the complexity of RubisCO from photosynthetic bacteria ranges from the simple dimeric structure of the *Rs. rubrum* type II enzyme to the hexadecameric type I structure found in most purple photosynthetic bacteria. At this time, only *Rs. rubrum* contains the simple dimer; this structural form has not been isolated from any other photosynthetic bacterium, not even from other species purported to be members of the genus *Rhodospirillum* (Tabita, 1988). The fact that all other type II enzymes from PNS bacteria that have been described are found as higher aggregates, implies that the *Rs. rubrum* dimer is unusual and lacks some key assembly determinant(s) that prevent assembly into higher aggregated forms. Inasmuch as the recombinant *Rs. rubrum* enzyme is assembled into an active dimer in *Escherichia coli* (Sommerville and Sommerville, 1984), the assembly determinants must be related to the specific sequence. The same may be said for the *Rb. sphaeroides* form II enzyme, in which aggregates ranging from dimers to structures greater than L₈ may be found (Gibson and Tabita, 1977) as well as the apparently native tetrameric/hexameric structure formed in vivo by both the parent organism and *E. coli* (Tabita et al., 1986). The preparation of truncated recombinant *Rs. rubrum* enzymes by site-directed

mutagenesis indicated that removal of the C-terminal tail section of the protein resulted in its assembly to dimers, octamers, or both, depending on the site of truncation (Ranty et al., 1990). The L₈ mutant proteins exhibited very low levels of activity and the removal of the C-terminal helical regions appeared to expose new hydrophobic surfaces to solvent. Thus, the authors postulate that the newly exposed hydrophobic surfaces interact to form the higher aggregate. This hypothesis seemed valid since the introduction of a polar residue within the new hydrophobic region resulted in the formation of dimers. Analogous work yielded an 18-residue truncated protein (Morell et al., 1990) whose properties were totally different from the 17-residue truncation prepared by Ranty et al., (1990). In the 18-residue truncated mutant enzyme, activity was quite similar to the wild-type protein and formed the usual dimer structure. The 18-residue truncation contains a new C-terminal Leu which replaces the Tyr-Pro C-terminus of the 17-residue truncation. However, as pointed out by the authors, it is difficult to understand how these sequence differences yield such profound structural and catalytic differences (Morell et al., 1990). In any case, these studies illustrate that localized structural determinants of the large subunits directly influence the final assembly product.

Previous studies on the biosynthesis of RubisCO from *Chromatium vinosum* have shown that the synthesis of both large and small subunits is synchronized and maximized under autotrophic growth conditions in the presence of reduced sulfur compounds (Kobayashi and Akazawa, 1982a,b). A constant ratio of large and small subunits was achieved throughout the induction. Taken together, these results were interpreted to indicate that the synthesis of the two subunits is coordinately regulated. Although similar studies have not been performed for other type I bacterial enzymes, it would be fairly safe to predict that similar results would be obtained. Indeed, now that it is known that the large and small subunit genes of all type I RubisCO enzymes (*cbbL* and *cbbS*) (Tabita et al., 1992) are cotranscribed as part of an operon in all bacteria (Tabita, 1988), the molecular basis for the *Chromatium* findings is readily apparent.

Despite the obvious requirement for specific residues on the large subunits, research on the assembly of RubisCO has taken on a whole new, more complicated and more interesting dimension. These studies have primarily focused on the simple

dimeric enzyme from *Rs. rubrum*, where it has been shown that accessory proteins or 'molecular chaperones' (Ellis, 1990) are required to assist the assembly of unfolded monomers or nascent polypeptide chains along a pathway that favors the formation of the correctly folded and properly arranged active dimer (Goloubinoff et al., 1989a,b). Complexes of chaperones and newly synthesized proteins are often found to be associated in the cell. These can then dissociate, often through the mediation of other proteins and the energy obtained from ATP hydrolysis, to form the final functional oligomeric protein and free chaperone protein. For RubisCO, there is an interesting history relative to the discovery of the 'RubisCO-binding protein' (Barraclough and Ellis, 1980; Roy et al., 1982) and its remarkable homology to the product of the *groEL* gene of *E. coli* (Hemmingsen et al., 1988), which along with *groES*, comprise the *groEL* heat shock operon (Zeilstra-Ryalls et al., 1991). Both the *Rs. rubrum* and cyanobacterial RubisCO genes, *cbbM* and *rbcLrbcS*, respectively, when expressed in *E. coli*, were shown to require the GroEL (cpn60) and GroES (cpn10) proteins for proper assembly in vivo (Goloubinoff et al., 1989a), and for the *Rs. rubrum* protein, in vitro as well (Goloubinoff et al., 1989b; Viitanen et al., 1990). Homologs of cpn60 have been isolated from *Chromatium vinosum* (McFadden et al., 1989; Torres-Ruiz, 1989, 1992) and *Rb. sphaeroides* (Watson et al., 1990; Terlesky and Tabita, 1991) and the *groE* genes from both organisms have been isolated and sequenced (Ferreira et al., 1993; Lee, Terlesky, and Tabita, unpublished). In each case, the cpn60 levels were shown to vary according to the growth conditions, following the same pattern exhibited for RubisCO synthesis (McFadden et al., 1989; Terlesky and Tabita, 1991). The *Cm. vinosum groE* genes were functional in *E. coli*; indeed, in a very interesting experiment, lambda clones containing the *Cm. vinosum* genes were shown to form plaques in a *groE* host strain of *E. coli*, indicating that the *Chromatium* genes could replace the well-known requirement of the *E. coli* genes for bacteriophage assembly (Zeilstra-Ryalls et al., 1991). Moreover, expression of the *Cm. vinosum* genes in *E. coli* was enhanced by heat-shock and a putative heat shock promoter was identified. The *Cm. vinosum* cpn60 and cpn10 proteins, or mixtures of these proteins and *E. coli* chaperonin proteins, were effective in enhancing productive assembly of the *Rs. rubrum*, *Synechococcus*, and *Cm. vinosum* RubisCO enzymes in *E.*

coli (Ferreira et al., 1993). Since the L₂ dimer is the basic structural motif (Andersson et al., 1989), a model for chaperonin-mediated RubisCO assembly for the *Rs. rubrum* dimer (type II) and type I cyanobacterial enzymes has been proposed (Goloubinoff et al., 1989a). For *Rb. sphaeroides*, containing a more aggregated type II enzyme, as well as the conventional L₈S₈ type I enzyme, a similar assembly pathway is envisioned (Fig. 4) that shows the involvement of the products of the form I and form II operons, and the *groE* operon for RubisCO assembly in this organism. Although the form I and form II operons are located on the separate chromosomal elements of *Rb. sphaeroides* (Suwanto et al., 1989), it is not known at this juncture where the *groE* operon maps. As discussed above, the levels of cpn60 are maximized under growth conditions that favor maximum RubisCO synthesis (Terlesky and Tabita, 1991), however, the molecular basis for this observation has not been elucidated. Finally, *Cm. vinosum* RubisCO, presumably encoded by one of the two sets of type I RubisCO genes found in this organism (Viale et al., 1989), was isolated in both the L₈S₈ and L₈ forms, with the L₈ form presumably derived from the L₈S₈ enzyme and fully active in the absence of small subunits (Torres-Ruiz and McFadden, 1985, 1987). Although the N-terminal amino acid sequence of the large subunit of these two enzymes is identical, it differs somewhat from the amino acid sequences deduced from the two type I large subunits genes of this organism (Kobayashi et al., 1991). This potentially interesting system has not been studied further. If it is verified that L₈ subunits are fully active, current perceptions as to the requirements of small subunits for catalysis (Andrews, 1988; Lee and Tabita, 1990; Smrcka et al., 1991) will need to be revised as will the ability of type I large subunits to form assembly domains that favor activity.

3. In vivo Regulation of RubisCO Activity

As a key enzyme in CO₂ assimilation, there have been several attempts to relate physiological responses to the activity of RubisCO. Perhaps the first indication that the activity of the enzyme might be regulated in vivo came from studies with *Chromatium* and *Thiopedia* (*Thiocapsa*) spp. (Hurlbert and Lascelles, 1963). When thiosulfate-bicarbonate grown *Chromatium* was transferred to a medium containing pyruvate,

Fig. 4. Integration of form I and form II RubisCO expression and assembly with *groE* transcription and synthesis of chaperonin proteins. Based on the model of Goloubinoff et al. (1989a). L', S', cpn10', and cpn60' refer to the unfolded forms of these proteins after they are produced as nascent proteins. The dashed arrows and question mark (?) refer to assembly steps that have not been shown to be chaperonin-associated.

a rapid decrease in RubisCO activity was obtained that was dependent on protein synthesis. It was further shown that cells placed in a thiosulfate-pyruvate (mixotrophic) growth medium blocked the normal increase in RubisCO activity characteristic of cells growing solely in a thiosulfate-bicarbonate medium. So long as there was oxidizable thiosulfate in the mixotrophic growth medium, the level of activity remained constant. Depletion of thiosulfate led to a rapid decrease in RubisCO activity. Excess CO₂, as well as pyruvate, was subsequently shown to affect the level of activity (Kobayashi and Akazawa, 1982a). These results clearly indicate that some alteration of the enzyme occurs in the cell, either through the binding of some inhibitor or through some modification in the structure of the enzyme. Various phosphorylated metabolites are known to

modulate the activity of RubisCO (Tabita, 1988), and the intracellular level of many of these metabolites correlates with enzyme activity in two different cyanobacteria (Pelroy and Bassham, 1972, 1976). Most interesting, these effectors appeared to be able to regulate the activity of the enzyme in the intracellular milieu as opposed to in vitro (Tabita and Colletti, 1979). In *Rs. rubrum*, in situ assays of toluene-permeabilized cells indicated that the affinity of the enzyme for RuBP was lower than the enzyme assayed in vitro (Störro and McFadden, 1983). Taken together, these in situ activity measurements indicated that the enzyme microenvironment, obviously different in situ and in vitro, influences RubisCO activity. Certainly in plants, several additional factors contribute to the modulation of RubisCO activity in vivo, including light-dependent synthesis of tightly-

binding specific inhibitors (Gutteridge et al., 1986; Berry et al., 1987) and the enzyme RubisCO activase (Portis, Jr. 1992). Whether these rather specific inhibitory compounds and/or RubisCO activase play any role in the control of RubisCO activity in purple photosynthetic bacteria, remains to be determined.

In *Rb. sphaeroides*, the inactivation/reactivation of RubisCO in vivo appears to play an important role in modulating activity. Much like *Cm. vinosum* (Hurlbert and Lascelles, 1963), the addition of organic compounds, particularly pyruvate, to photolitho-autotrophically-grown (1.5% CO₂/98.5% H₂) cultures, results in a drop in RubisCO activity. This effect was mimicked in autotrophic cultures after the concentration of CO₂ was raised from the usual 1.5% to 6% (Jouanneau and Tabita, 1987). Immunological assays indicated that the levels of both form I and form II RubisCO protein remained constant during the time activity was lost, suggestive of some modulation of enzyme activity not related to protein degradation. Isolation and separation of inactivated from active enzyme further indicated that only the form I RubisCO was affected. Complicating things, the inactivated form I enzyme exhibited a marked propensity to become reactivated in vitro (Jouanneau and Tabita, 1987). Subsequent studies showed that inactivation occurred by some process that was reversible in vivo, since activity recovered soon after the cells consumed pyruvate or α -ketoglutarate from the growth medium in the presence of protein synthesis inhibitors (Wang and Tabita, 1992a). Reversibility of inactivation, however, occurred only when the culture medium contained saturating levels of ammonia; if the cells depleted the available ammonia during the time they metabolized added pyruvate, recovery did not occur. Subsequent studies showed that blockage of the major ammonia assimilatory enzyme, glutamine synthetase (GS), with the specific inhibitor methionine sulfoximine (MSX), prevented the recovery of pyruvate-mediated inactivation (Wang and Tabita, 1992b). Indeed, recovery occurred only at concentrations of MSX that failed to completely inhibit in situ GS activity. These results were interpreted to indicate that the intracellular ratio of glutamine/ α -ketoglutarate, which effectively defines the nitrogen status of bacteria and initiates a complex regulatory cascade in many organisms including *Rb. sphaeroides* (Wang and Song, 1989), may contribute to the regulation of both the carbon and nitrogen assimilatory systems of this organism. Studies with a RubisCO deletion mutant

of *Rb. sphaeroides* showed that there was specificity of the inactivation system for *Rb. sphaeroides* form I RubisCO. This was determined after expressing several diverse type I RubisCO genes in the *Rb. sphaeroides* RubisCO deletion strain (Wang and Tabita, 1992a). Moreover, expression of the form I *Rb. sphaeroides* genes in a *Rs. rubrum* RubisCO deletion strain did not result in pyruvate-mediated inhibition of form I RubisCO in this environment, suggesting that this inactivation system may be unique to *Rb. sphaeroides*, although other interpretations of these results are possible (Wang and Tabita, 1992a). Finally, the inactivated form I RubisCO was purified to homogeneity and the propensity of the purified enzyme to become reactivated in vitro found to closely parallel what had been found with partially purified preparations. Interestingly, the purified inactivated enzyme was shown to exhibit mobility on both nondenaturing and sodium dodecyl sulfate gels different from that of the active enzyme prepared from cells not treated with organic acids. However, the Michaelis constants for RuBP, CO₂, or O₂ were not significantly altered. Several factors were found to lead to activation in vitro, including increases in temperature, the levels of Mg²⁺, and the levels of ATP; the latter two compounds were shown to mediate reactivation in a time-dependent and concentration-dependent process which appeared to be reversible (Wang and Tabita, 1992a,c). Concomitant with the recovery of enzymatic activity, the migration of the inactivated form I RubisCO on gels changed from a pattern that was characteristic of inactivated enzyme to a pattern that was identical to that of the active protein. It was further found that the form I enzyme and cpn60 formed a complex in the presence of ATP making it apparent that the form I enzyme contained a specific ATP-binding site that might contribute to both regulation of activity as well as to the assembly of active enzyme. These results emphasize that some powerful negative effector must be produced in vivo to maintain the enzyme in the inactivated state during the time that the form I RubisCO becomes inactivated after the addition of pyruvate to cultures; otherwise the enzyme would become activated and remain activated by the high intracellular nucleotide pool (Wang and Tabita, 1992c).

To further understand in vivo inactivation of form I RubisCO, it is necessary that the nature and mechanism of the apparent modification be characterized further. Moreover, it is necessary that some genetic component of the system become

identified. The demonstration that inactivation is reversible *in vivo* (and *in vitro*) and depends on important physiological parameters such as the nitrogen status of the cells, lends credence to the assumption that this is an important physiological mechanism to regulate RubisCO activity in *Rb. sphaeroides*.

Another system for posttranslational modification of RubisCO activity was demonstrated to occur in *Rs. rubrum*. Not surprisingly, O₂ readily inhibits the photoassimilation of CO₂ in PNS bacteria (Khanna et al., 1981), and *Chromatium* and *Rs. rubrum* will excrete glycolate (derived from the oxygenase activity of RubisCO) in the presence of O₂ in the light by a process that is inhibited by CO₂ (Asami and Akazawa, 1974; Störro and McFadden, 1981). Beyond competition for enzyme-bound enediolate, it seems likely that O₂ control might involve RubisCO directly. Thus it was not surprising that from 70–80% of the RubisCO activity was lost when *Rs. rubrum* cells were exposed to atmospheric levels of oxygen over a 12–24 h period (Cook and Tabita, 1988). The quantity of RubisCO protein, determined immunologically and on SDS gels, did not decrease during the time activity was lost. Only after prolonged periods of incubation with oxygen did enzyme degradation occur, suggesting that the inactivated enzyme becomes 'marked' for proteolytic processing, much like *E. coli* GS (Levine et al., 1981). Unlike the organic acid-mediated response noted earlier, oxygen-mediated inactivation of RubisCO appears to be due to some form of irreversible modification mediated by some gene product(s) found in *Rs. rubrum* (Cook and Tabita, 1988). An artificial model system with purified *Rs. rubrum* RubisCO was established to mimic the oxidative modification of the enzyme. This ascorbate-FeSO₄ system established that a reactive oxygen species is generated which interacts at a specific site on the noncarbamylated enzyme from several sources; carbamylation protects against inactivation (Cook et al., 1988). In the PS bacterium *Thiocapsa roseopersicina*, it was found that thiosulfate and sulfide were oxidized under both anaerobic photolithoautotrophic and aerobic chemolithoautotrophic growth conditions, in each case using RubisCO and the Calvin cycle to assimilate CO₂ (Kondratieva et al., 1976). Thus, it is apparent that in this organism, a similar O₂-mediated inactivation process does not occur.

Finally, Turner and Mann (1986) found that the major phosphoprotein detected in *Rhodomicobium*

vannielii had a M_r of 55,000; this was subsequently proposed to be the large subunit of type I RubisCO based on immunoprecipitation and sucrose density gradient centrifugation experiments (Mann and Turner, 1988). Phosphotyrosine was the modified amino acid identified, however at this time there is no indication that the phosphorylated tyrosine is part of a discrete peptide that coincides with a known RubisCO sequence or that the modified enzyme has been affected in its catalytic activity. The authors provide evidence that the large subunit is phosphorylated and present in a large molecular weight complex prior to its assembly into the mature holoenzyme (Mann and Turner, 1988). Perhaps these results relate to the complexation of cpn60 and form I RubisCO in *Rb. sphaeroides* (Wang and Tabita, 1992c). In any case, further progress on this potentially interesting posttranslational modification of the *Rm. vannielii* enzyme is awaited with great interest.

4. Enzyme Engineering of RubisCO and Mutant Selection

Thus far, type I (*cbbLcbbS*) and type II (*cbbM*) RubisCO genes from *Rs. rubrum*, *Rb. sphaeroides*, and *Cm. vinosum* have been expressed in *E. coli* and purified recombinant proteins have been prepared in each instance (Somerville and Sommerville, 1984; Viale et al., 1985; Gibson and Tabita, 1986; Tabita et al., 1986; Viale et al., 1990). Obviously, this is an obligatory first step before studies may be undertaken to modify or engineer the properties of RubisCO via site-directed mutagenesis. A thermostable RubisCO was prepared from *Chromatium tepidum* (Heda and Madigan, 1988, 1989) and this system might be effectively employed to elucidate the molecular basis for thermal stability or for determining how τ is affected by temperature. To date, only the *Rs. rubrum* *cbbM* gene has been subject to substantial modification, with the result that an impressive amount of work has been produced which has greatly improved our understanding of the mechanism of catalysis (reviewed in Hartman, 1992; Hartman and Harpel, 1993). However, the *Rb. sphaeroides* and *Cm. vinosum* *cbbLcbbS* genes are excellent potential systems for genetic engineering because they encode enzymes that are fairly well characterized, yet they have substantially different properties compared to the more heavily studied cyanobacterial type I system (Tabita, 1994), including different substrate specificity values (Table 1) and the capacity to form

Fig. 5. Construction of a RubisCO double deletion mutant of *Rb. sphaeroides*. (A) The form I gene cluster; (B), the form II gene cluster. The portions of sequence removed within the RubisCO structural genes and the deletion-insertion derivative plasmids used for construction of the deletion mutants are indicated below each cluster. Plasmid diagrams below the maps are drawn to scale to indicate the approximate amount of homologous DNA on either end of the plasmid resistance cartridge insert (hashed lines). From Falcone and Tabita (1991), with permission.

inhibitory E-R complexes. The *Rb. sphaeroides* RubisCO deletion strain, prepared by inserting antibiotic resistant cartridges within the remaining RubisCO gene coding sequences (Fig. 5), has also proven to be a valuable host for the expression of foreign RubisCO genes, using either a specific promoter-vector system or the promoter specific to the RubisCO genes being expressed (Falcone and Tabita, 1991; Falcone and Tabita, 1993a). The value of RubisCO deletion strains of *Rb. sphaeroides* (Falcone and Tabita, 1991) and *Rs. rubrum* (Falcone and Tabita, 1993b), strains 16 and I-19, respectively, lies in the fact that these strains may be complemented to photolithoautotrophic growth via the expression of different RubisCO genes, such that the growth properties of the complemented strain reflects the idiosyncrasies of the expressed RubisCO. For example, *Rb. sphaeroides* strain 16, when it synthesizes the *Synechococcus* 6301 enzyme, does not grow at low CO₂ levels, due to the inherently poor Michaelis constant for CO₂ of the cyanobacterial enzyme (Falcone and Tabita, 1991). In addition, various cyanobacterial mutant and hybrid enzymes that have weak catalytic activity, exhibit very poor growth rates (Hernandez and Tabita, unpublished). Such results suggest that methods to select additional mutant enzymes may be developed by randomly mutagenizing the RubisCO genes of interest, followed by transformation and complementation of strains 16 or I-19 with the mutagenized DNA. Subsequent growth, under environmental conditions that favor the trait desired, should result in the selection of

novel mutant enzyme forms. It is anticipated that biological selection of RubisCO mutations using photosynthetic bacterial hosts will result in the isolation of a number of interesting mutant forms of RubisCO that should greatly supplement those that may be isolated using the *Chlamydomonas* system (Spreitzer, 1993). Moreover the bacterial system provides a facile approach to screen the in vivo consequences of changes in RubisCO substrate specificity made by in vitro genetic engineering.

B. Phosphoribulokinase (PRK)

PRK, the other unique enzyme of the Calvin cycle, has recently received increased scrutiny. The enzyme from *Rb. capsulatus* was the first preparation of electrophoretically homogenous enzyme to be isolated from any source (Tabita, 1980). Early studies with partially purified *Cm. vinosum* PRK had indicated that the enzyme exhibited complex properties, including sigmoidal substrate saturation curves indicative of allosteric behavior (Hart and Gibson, 1971). However, unlike the enzyme from PNS bacteria (Rindt and Ohmann, 1969; Tabita, 1980; Rippel and Bowien, 1984; Tabita, 1988), the *Cm. vinosum* enzyme does not require NADH for activity; in this respect the *Cm. vinosum* enzyme resembles the enzyme of oxygen-evolving photosynthetic organisms (Tabita, 1980; 1987). Furthermore, the activity of enzymes isolated from all purple bacteria is negatively regulated by compounds such as AMP, 3-PGA, 3-PGAL, and PEP (Tabita, 1988).

Beyond these observations, thorough kinetic characterization of homogenous bacterial PRK has not appeared in the literature as yet. With respect to the PNS bacteria, PRK genes have now been cloned from *Rb. sphaeroides* (Gibson and Tabita, 1987; Hallenbeck and Kaplan, 1987), *Rs. rubrum* (Falcone and Tabita, 1993b), and *Rb. capsulatus* (G.C. Paoli, J.S. Shively, and F.R. Tabita, unpublished). Interestingly, there are two PRK enzymes in *Rb. sphaeroides*, the products of the *cbbP_I* and *cbbP_{II}* genes (formerly *prkA* and *prkB*), which are found on Calvin cycle operons I and II; recombinant PRKI and PRKII have each been purified to homogeneity after expression of the respective genes in *E. coli*. In the host organism, the enzyme is isolated as a tight complex of the individual PRKI and PRKII subunits (Gibson and

Tabita, 1987), yet each individual PRK enzyme appears to be functional in *Rb. sphaeroides* since mutations in *cbbP_I* or *cbbP_{II}* allow for phototrophic growth with CO₂ as carbon source and/or electron acceptor (Gibson et al., 1990; Hallenbeck et al., 1990; Gibson et al., 1991). Analysis of the deduced amino acid sequence of bacterial *cbbP* genes from *Rb. sphaeroides* (Gibson et al., 1990; Gibson et al., 1991), *Alcaligenes eutrophus* (Kossmann et al., 1989), and *Xanthobacter flavus* (Meijer et al., 1990), indicates very close homology. Interestingly, however, only slight sequence homology of bacterial PRKs towards the plant (Milanez and Mural, 1988; Lloyd et al., 1991), algal (Roesler and Ogren, 1990), or cyanobacterial (Su and Bogorad, 1991) enzymes is apparent; for example the plant enzymes share only

Fig. 6. Conserved amino acid sequence regions (A,B,C, and D) in PRK from various sources; RsI and RsII, *Rb. sphaeroides* form I and form II PRK (Gibson et al., 1990; 1991); Ae, *A. eutrophus* (Kossmann et al., 1989); Xf, *X. flavus* (Meijer et al., 1990); Sp, spinach (Milanez and Mural, 1988); Wh, wheat (Lloyd et al., 1991); Ch, *Chlamydomonas reinhardtii* (Roesler and Ogren, 1990); Syn, *Synechocystis* PCC6803 (Su and Bogorad, 1991). Identical residues (●) and conservative amino acid replacements (○) are shown.

13% identity towards the *Rb. sphaeroides* proteins. However, now that four different bacterial genes have been sequenced, along with four different PRK genes from oxygen-evolving organisms, it is apparent there are regions which do show some similarity (Fig. 6). Of particular interest are regions A and B of Fig. 6, which have been implicated in ATP-binding and Ru-5-P binding, respectively (Krieger et al., 1987; Roessler et al., 1992; Sandbaken et al., 1992). Asp-42 and Asp-169 appear to be excellent candidates for the active site base or divalent cation ligand, respectively (Charlier et al., 1994). The tetrapeptide Glu-Gly-Leu-His is conserved in all known PRK enzymes (region C) but thus far its significance is not apparent, however a recent study indicated that Glu-131 of this conserved tetrapeptide may be involved with allosteric NADH activation (Charlier et al., 1994). The interesting F227S mutation in the *Synechocystis* PRK, which renders this cyanobacterium light sensitive (Su and Bogorad, 1991), is not conserved in bacterial enzymes. Finally, PRK was isolated as a complex with FBPase (*cbbF* gene) from extracts of autotrophically-grown *Rs. rubrum* (Joint et al., 1972); the close juxtaposition of the structural genes for these two enzymes in *Rs. rubrum* (Falcone and Tabita, 1993b) and *Rb. sphaeroides* (6 bases separate *cbbP_I* and *cbbF_I* and three bases separate *cbbP_{II}* and *cbbF_{II}*) and their cotranscription (Gibson et al., 1990, 1991) suggests that such complexes may form after these proteins are synthesized on the ribosome.

C. Other Enzymes of the Calvin Cycle

The organization of Calvin cycle structural genes into discrete operons in *Rb. sphaeroides* and *Rs. rubrum* has led to the isolation, cloning and sequencing of many of the relevant genes (Gibson and Tabita, 1987; Hallenbeck and Kaplan, 1987; Gibson and Tabita, 1988; Gibson et al., 1990; Gibson et al., 1991; Falcone and Tabita, 1993b). Moreover, recombinant FBPase, transketolase, and glyceraldehyde phosphate dehydrogenase have been prepared from *E. coli*, and the ability to produce recombinant ribulose 5-phosphate-3-epimerase and aldolase is apparent as well. Thus, these enzymes might now be studied in depth, as there is a paucity of information relative to the properties of these important catalysts (however, see Springgate and Stachow, 1972a,b). Future developments are awaited with great interest.

D. Metabolic Control of Calvin Cycle Enzyme Synthesis

The first indication that the synthesis of RubisCO is regulated came from the work of Lascelles (1960), who showed that synthesis immediately stopped when phototrophically grown *Rb. sphaeroides* cells were incubated under aerobic conditions. These results led to the hypothesis that the oxidation state of some intracellular metabolite might regulate enzyme synthesis. This insightful analysis of the physiological results have become even more pertinent now that there is some understanding of the molecular biology of the process, since it is apparent that the promoters

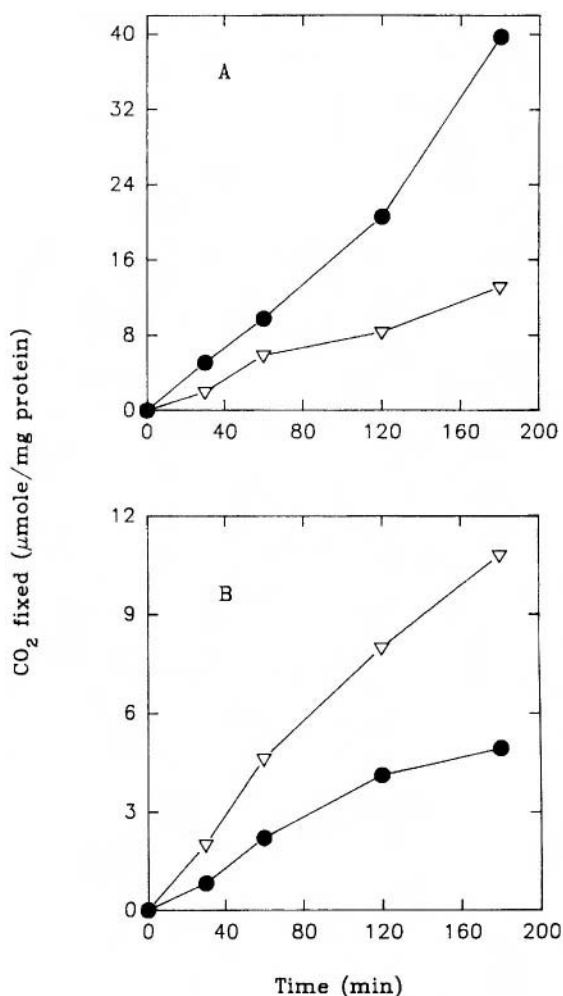

Fig. 7. Whole-cell CO₂ fixation in *Rb. sphaeroides* cells grown (A) photolithoautotrophically in a 1.5% CO₂-H₂ atmosphere or (B) photoheterotrophically in a mineral salts malate medium with CO₂ as the electron acceptor. CO₂ fixation assays were performed with hydrogen (●) or malate (▽) as the electron donor. From Wang et al. (1993a), with permission.

that control gene expression are oxygen regulated (see Chapter by Bauer). These initial results have been confirmed and extended to other PNS bacteria (Anderson and Fuller, 1967a,b; Hicughi and Kikuchi, 1969). As discussed earlier, there is an absolute requirement for HCO₃⁻ (CO₂) when PNS bacteria are grown with reduced carbon sources/electron donors. Not unexpectedly, this is reflected by an increase in whole-cell CO₂ fixation by resting cells. Interestingly, when *Rb. sphaeroides* was grown under photoheterotrophic conditions, the photoheterotrophic growth substrate (malate) was the preferred electron donor in whole-cell CO₂ fixation assays (Fig. 7). However, photolithoautotrophically grown cells preferentially use H₂ as electron donor. These results indicate that the metabolism and/or utilization of malate and H₂ are subject to induction/repression. From the foregoing, it is not surprising that RubisCO synthesis is markedly stimulated when PNS bacteria are cultured with reduced electron donors. This is illustrated by the data compiled in Table 2, where RubisCO specific activity and protein levels were compared in several strains using representative oxidized and reduced electron donors. The ability of these organisms to derepress synthesis is particularly evident in *Rs. rubrum*, where up to 50% of the soluble protein is RubisCO. Presumably the extremely high levels of RubisCO, far beyond what is required to support either the observed growth rate or the

observed in vivo CO₂ fixation rates (Sarles and Tabita, 1983; Wang et al., 1993b), may be important to remove excess reducing power (Wang et al., 1993a) or possibly for scavenging CO₂ from the media since the K_{CO2} of RubisCO is relatively high (Table 1). Both *Rs. rubrum* and *Rb. sphaeroides* were recently shown to grow photolithoautotrophically using either thiosulfate or sulfide as electron donors. Under these growth conditions, both organisms drastically reduce the levels of RubisCO protein (Table 2), and these results, combined with the fact that RubisCO negative strains are able to grow using either thiosulfate or sulfide in the complete absence of organic carbon, suggested that these organisms may use some alternative means to reduce CO₂ (Wang et al., 1993b). It is also apparent that *Rb. sphaeroides* (Jouanneau and Tabita, 1986) and *Rb. capsulatus* (Shively et al., 1984) preferentially synthesize form I RubisCO at low levels of CO₂. In *Rp. blastica*, specific synthesis of form I RubisCO occurred at the late logarithmic growth phase in cells grown in a butyrate-bicarbonate growth medium (Dow, 1987). Further, [³⁵S] methionine incorporation studies indicated that the form II *Rp. blastica* enzyme was expressed only at high levels of CO₂. Differential regulation of the synthesis of form I and form II RubisCO in *Rb. sphaeroides*, *Rb. capsulatus*, and *Rp. blastica* clearly indicates that there are separate molecular signals that influence the synthesis of these distinct proteins.

Table 2. Growth substrate dependent synthesis of RubisCO in purple nonsulfur photosynthetic bacteria

Complicating this further, under certain conditions, form I and form II RubisCO synthesis in *Rb. sphaeroides* is under the influence of some common regulatory locus, since mutations that affect the synthesis of one enzyme are compensated by the overproduction of the other enzyme (Falcone and Tabita, 1988; 1991; Hallenbeck et al., 1990; Gibson et al., 1991). The isolation of the *cbbR* gene, a transcriptional activator gene which controls both form I and form II RubisCO synthesis in *Rb. sphaeroides* (Gibson and Tabita, 1993), promises to provide answers relative to the molecular basis of this interesting interdependent regulation. By the same token, it is apparent that other genes must separately control form I and form II RubisCO synthesis. Other key enzymes of the Calvin cycle, particularly PRK and FBPase, are also found at higher levels in cells grown under conditions which favor maximum RubisCO synthesis (Anderson and Fuller, 1967a; Gibson et al., 1991).

Two separate RubisCO negative strains were isolated in *Rb. sphaeroides* (Hallenbeck et al., 1990; Falcone and Tabita, 1991). Each strain was incapable of growing using CO₂ as electron acceptor when either organic carbon (i.e., malate or succinate) or molecular hydrogen were used as electron donors. However, both mutants could grow under photoheterotrophic conditions when dimethylsulfoxide (DMSO) was added to the growth media and used as the electron acceptor. Presumably, the inability of the RubisCO negative strains to grow photoheterotrophically is related to the capacity of RubisCO and the Calvin cycle to function as an electron sink to maintain a proper redox balance under these growth conditions (also see Richardson et al., 1988). Moreover, even reduced electron donors, such as butyrate, support growth of the RubisCO deficient strains when DMSO is used as electron acceptor, further substantiating the proposed redox balancing role of the Calvin cycle. However, it is not clear whether this suggested function for the Calvin cycle applies under photolithoautotrophic growth conditions where H₂ is the electron donor. Recent experiments (Wang et al., 1993a) addressed this issue when the effects of DMSO on whole cell CO₂ fixation, RubisCO activity, and RubisCO synthesis were examined in form I and form II RubisCO deletion mutants of *Rb. sphaeroides* grown in a H₂/CO₂ atmosphere. Both strains were influenced by the addition of DMSO, but form II RubisCO activity (in the form I deletion mutant) was influenced

considerably, such that there was a loss of RubisCO activity which greatly exceeded a slight decrease in RubisCO protein. In the form II deletion strain, there was a much diminished effect on CO₂ fixation and form I RubisCO activity. These experiments are entirely consistent with the proposal that considerable amounts of RubisCO (particularly form II RubisCO) may be utilized to maintain the redox balance of the cell when the organism uses highly reduced electron donors, such as molecular hydrogen. Finally, as noted previously, the PS bacteria *Chromatium* and *Thiopedia* maximize RubisCO synthesis under autotrophic conditions as well (Hurlbert and Lascelles, 1963; Kobayashi and Akazawa, 1982a,b).

IV. Alternative CO₂ Assimilatory Routes

The Calvin cycle is obviously the predominant CO₂ assimilatory path employed by phototrophic and chemolithotrophic organisms in the biosphere. However, there are many notable exceptions to the Calvin scheme in several diverse bacteria, particularly in the photosynthetic green sulfur bacterium, *Chlorobium*, and diverse chemolithoautotrophic bacteria (see Chapter 40 by Sirevåg). In the purple photosynthetic bacteria (i.e., *Chromatium* and *Rs. rubrum*), several early studies, including determinations of the initial products of CO₂ fixation and several enzyme measurements, had indicated that these organisms assimilate significant amounts of CO₂ via alternative (nonCalvin) routes, specifically the reductive tricarboxylic acid (TCA) cycle (Buchanan et al., 1964; 1967). Unlike the green bacteria, PS and PNS bacteria also employ the Calvin cycle, which implies that these organisms may be able to regulate the use of each of these pathways under certain conditions; it was also suggested that the reductive TCA cycle might serve an auxiliary role in providing carbon skeletons in *Rs. rubrum* (Tabita, 1988). More recent studies with RubisCO deletion strains of *Rs. rubrum* and *Rb. sphaeroides* (strains 16 and 16PHC) extend the early biochemical studies and confirm the importance of alternative CO₂ fixation pathway(s). From strain 16, which cannot grow phototrophically using malate or H₂ as electron donors when CO₂ is the electron acceptor (Falcone and Tabita, 1991), a strain was selected that maintained the RubisCO negative phenotype yet was capable of photoheterotrophic growth on malate with CO₂ as electron acceptor. This strain, 16PHC, had

the exact same phenotype as *Rs. rubrum* strain I-19. Strain 16PHC exhibited significant rates of whole-cell CO₂ fixation; moreover wild-type *Rb. sphaeroides* cells exhibited rates of whole-cell CO₂ fixation that greatly exceeded whole-cell RubisCO activity. These observations with the mutant and wild-type strains thus suggested that considerable CO₂ fixation occurs in the absence of a functional Calvin cycle (Wang et al., 1993a). Furthermore, the CO₂ fixation capacity (about 30% of the wild-type) is repressed by the addition of the alternate electron acceptor DMSO and is induced upon DMSO removal. Strain 16, although not capable of photoheterotrophic growth on C₄ acids with CO₂ as electron acceptor, could grow with CO₂ as electron acceptor when pyruvate or acetate is used as the electron donor (Y. Qian and F.R. Tabita, unpublished). Since C₄ cleavage reactions have recently been postulated to be essential to generate CO₂ acceptor molecules in the green bacterium *Chloroflexus* (Strauss et al., 1992; Ivanovsky et al., 1993), it seems plausible that strain 16PHC has somehow overcome this defect. Recent studies indicate that the 16PHC phenotype is accompanied by major changes in its protein profile, suggestive of some alternation of a major regulatory system under conditions of active CO₂ fixation (H. Modak and F.R. Tabita, unpublished). The importance of alternative CO₂ fixation reactions was greatly strengthened by the finding that all the RubisCO negative mutants of *Rb. sphaeroides* and *Rs. rubrum* (strains 16, 16PHC, and I-19) could grow photolithoautotrophically, using CO₂ as the sole carbon source, in a medium containing either thiosulfate or sulfide as electron donor (Wang et al., 1993b). It is interesting that photolithoautotrophic growth of the RubisCO deficient strains is possible only with electron donors of higher redox potential than hydrogen. The recent demonstration of photolithoautotrophic growth by PNS bacteria using reduced iron compounds as the source of reducing power (Widdell et al., 1993) suggests that compounds of intermediate redox potential might be important to support growth and CO₂ fixation in environments where hydrogen and organic substrates are unavailable. It would appear that only RubisCO is capable of disposing of the excess reducing power generated by hydrogen-dependent growth, suggesting that the enormously high levels of RubisCO synthesized under these growth conditions might be exceedingly important for this function. As noted earlier, the levels of RubisCO synthesized in a 1.5% CO₂/98.5

H₂ atmosphere are far in excess of what both *Rs. rubrum* and *Rb. sphaeroides* require for carbon assimilation and growth. Both the Calvin cycle and the alternative CO₂ assimilatory pathway must be under metabolic control in the two organisms, since the RubisCO activity levels and the amount of RubisCO protein are significantly reduced in thiosulfate-grown wild-type cells (Table 2). Thus, it is not surprising that conditions which allow for CO₂-dependent growth of the RubisCO deficient strains result in repression of RubisCO synthesis in the wild-type. Beyond the fundamental questions of metabolic control of the alternative and Calvin CO₂ fixation pathways, the finding that some alternative CO₂ fixation scheme could take the place of the Calvin pathway and support photolithoautotrophic growth raises interesting questions relative to the evolution of CO₂ assimilatory schemes. Perhaps the PNS bacteria represent an evolutionary link between bacteria which use the reductive TCA cycle (Evans et al., 1966), the hydroxypropionate pathway (Holo, 1989; Strauss et al., 1992; Ivanovsky et al., 1993;) or the non-cyclic reductive acetyl Co A/carbon monoxide dehydrogenase pathway (Fuchs, 1989) and more evolutionary advanced organisms. Indeed, the chloroplasts of the green alga *Chlamydomonas reinhardtii* were recently shown to contain the ferredoxin-linked enzymes of the reductive tricarboxylic acid cycle (Chen and Gibbs, 1992). In this context, it would be interesting to determine whether cyanobacteria which are capable of anoxygenic photosynthesis (Padan, 1979) employ the reductive TCA cycle or alternative reactions to fix CO₂ under these growth conditions. In any case, it would appear that the original hypothesis of Lascelles (1960), that RubisCO and the Calvin cycle play an important role in providing redox balance for the cell, has gained added significance. The development of the Calvin reductive pentose phosphate pathway and the acquisition of RubisCO could be a very important evolutionary event since this would enable organisms to thrive under a much wider spectrum of environmental growth conditions than organisms that fix CO₂ solely by using other pathways. The capacity for photosynthetic metabolism would thus be much enhanced and substrates other than reduced iron and sulfur compounds could be employed as reductants to support CO₂ assimilation. Although it is recognized that the purple nonsulfur photosynthetic bacteria are probably the most metabolically versatile organisms found in nature (Madigan and Gest, 1979; Madigan,

1988), recent studies provide additional support for the great adaptability of these bacteria.

V. Conclusions

The purple photosynthetic bacteria are capable of diverse modes of carbon catabolism and anabolism. This is particularly true of the PNS bacteria, which provide excellent systems for the study of fundamental aspects of carbon metabolism and its regulation at the biochemical and molecular levels. Indeed, recent studies indicate that common regulatory elements may serve to control biosynthetic CO₂ assimilation and the degradation of fixed carbon compounds and it is anticipated that this will become a fruitful area for future investigation. The enzymes of carbon metabolism have been studied to some extent, but only RubisCO has attracted the attention of a large number of enzyme chemists, resulting in a deep understanding of how this enzyme functions. Nevertheless, key questions remain concerning the basis for gas substrate specificity and the mechanisms PNS bacteria use to regulate activity in vivo. Other key catalysts deserve future scrutiny, and with the cloning, sequencing, and expression of virtually all the structural genes of the Calvin cycle, it is anticipated that these enzymes will be the focus of considerable future in depth study. The role of chaperonin proteins in enzyme assembly is also a burgeoning field and many questions remain unanswered relative to how purple bacteria use these accessory proteins for placing complex oligomeric proteins in the proper conformation for efficient catalysis. Finally, it has become apparent that PNS bacteria may use alternative means to fix CO₂; these pathway(s) may support autotrophic growth in the absence of a functional Calvin cycle. Elucidation of the nature of these alternative reactions and their biochemistry is in progress, with the expectation that an understanding of the metabolic control of both CO₂ assimilatory paths will be forthcoming.

Acknowledgments

Support from the National Institutes of Health, Department of Energy, and the Department of Agriculture is gratefully acknowledged. I particularly wish to thank my students, postdoctoral associates,

and colleagues for their inspiration and many contributions.

Summary

Anoxygenic phototrophic bacteria conduct many specialized metabolic processes but one of the most important is nitrogen fixation, the reduction of N₂ to NH₃. Nitrogen fixation is catalyzed by the enzyme nitrogenase which is widely distributed among anoxygenic phototrophs. The most comprehensive understanding of N₂ fixation in photosynthetic bacteria is among the nonsulfur purple bacteria, where the capacity to fix N₂ is nearly universal. In this group N₂ fixation occurs both in the light and in darkness and nitrogenase expression and activity is highly regulated. Available evidence indicates that N₂ fixation is fairly widespread among purple and green sulfur bacteria and probably universal among heliobacteria. By contrast, the thermophilic phototroph *Chloroflexus aurantiacus*, a very few purple nonsulfur bacteria and green sulfur bacteria, and the 'aerobic phototrophs' are not diazotrophic. The recently discovered bacteriochlorophyll-containing rhizobia are also nitrogen fixers but their status as anoxygenic phototrophs is at present unclear. Although the ecological significance of N₂ fixation by anoxygenic phototrophs is unknown, the widespread distribution of these organisms in nature and the fact that most species are diazotrophic, suggests that they may well be significant, particularly in specialized environments such as microbial mats and paddy soils.

I. Background

The biological utilization of dinitrogen (N_2) as a source of cell nitrogen is a process called *nitrogen fixation* and is a property of only certain prokaryotes. In the fixation process, N_2 is reduced to NH_3 and the latter converted into organic form. Nitrogen fixation is catalyzed by the enzyme complex *nitrogenase* (Burris and Roberts, 1993). The biochemistry and genetics of nitrogen fixation in anoxygenic photosynthetic bacteria is discussed in detail in Roberts and Ludden (1992) and in Chapter 43 of this volume by the same authors. The present chapter documents the occurrence of nitrogen fixation in anoxygenic phototrophs, compares the efficacy of this process in different species where possible, and discusses the potential ecological ramifications of N_2 fixation by photosynthetic bacteria as it relates to their competitiveness in aquatic and terrestrial habitats. For a general treatment of the microbiology of N_2 fixation the reader is referred to the excellent reviews by Eady (1992) and Young (1992).

A. Discovery of N_2 Fixation in Anoxygenic Photosynthetic Bacteria

The first hint that anoxygenic photosynthetic bacteria could fix molecular nitrogen emerged 45 years ago during an investigation of light-dependent H_2 production in the purple nonsulfur bacterium *Rhodospirillum rubrum* (Gest and Kamen, 1949). Cells growing photosynthetically on malate with glutamate as nitrogen source evolved large quantities of H_2 (now known to be a result of nitrogenase activity, see Chapter 43 by Ludden and Roberts) while parallel cultures grown on ammonia did not. In experiments with resting cells, glutamate-grown cells also photoproduced H_2 and this process was strongly inhibited by N_2 ; the latter was a major clue that *Rs. rubrum* was capable of nitrogen fixation (Kamen and Gest, 1949). Confirmation of this was made by measurement of the fixation of $^{15}N_2$ into cells of *Rs. rubrum* and other species of purple bacteria (Lindstrom et al., 1949), and several papers appearing shortly afterwards suggested that the capacity to fix nitrogen was widely distributed among purple and green bacteria (Lindstrom et al., 1950, 1951; Newton and Wilson, 1953).

Abbreviations: Cf. – *Chloroflexus*; Cm. – *Chromatium*; Rb. – *Rhodobacter*; Rc. *Rhodocyclus*; Rs. – *Rhodospirillum*; Tc. – *Thiocapsa*

Since the early 1950s studies of particular species of anoxygenic phototrophs and one major survey (Madigan et al., 1984) of nitrogen fixation in purple nonsulfur bacteria have indicated that most but not all species can fix N_2 and that in addition, some species are naturally 'strong' nitrogen-fixers (i.e., grow rapidly on N_2) while other species are more feeble in this connection (see e.g., Madigan et al., 1984). Such differences in efficacy of N_2 fixation may reflect the ecological importance of N_2 fixation to particular species but is undoubtedly also a reflection of genetic and metabolic differences between species of photosynthetic bacteria as well.

B. Nitrogenases

For many years it was thought that molybdenum was absolutely required for N_2 fixation because of its central importance as a metal cofactor of nitrogenase (Bishop and Premakumar, 1992; Burris and Roberts, 1993). However it is now clear that biological N_2 fixation can proceed in the absence of molybdenum through the activity of *alternative nitrogenases* that lack this element (see Bishop and Premakumar, 1992 for a recent review).

All nitrogenases consist of two proteins, dinitrogenase and dinitrogenase reductase. Iron is present along with molybdenum in classical dinitrogenase (referred to as nitrogenase-1). In addition to nitrogenase-1, two non-molybdenum nitrogenases have been described, including one in which vanadium substitutes for molybdenum in dinitrogenase (called nitrogenase-2) and another in which iron only is present in dinitrogenase (nitrogenase-3). Dinitrogenase reductases from all forms of nitrogenase contain iron as a metal cofactor. Each form of nitrogenase is coded for by its own distinct gene complex but significant amino acid sequence homology exists among the three forms of nitrogenase, especially among dinitrogenase reductases (Bishop and Premakumar, 1992).

Among anoxygenic photosynthetic bacteria alternative nitrogenases have been documented in only four species. Iron-only (nitrogenase-3) type nitrogenases have been characterized from the purple nonsulfur bacteria *Rhodobacter capsulatus* (Schneider et al., 1991; Shüddekopt, et al., 1993) and from *Rhodospirillum rubrum* (Lehman and Roberts, 1991). Physiological evidence for alternative nitrogenase systems, presumably of the nitrogenase-3 type but not proven unequivocally as such, has also emerged

from studies of *Rhodospirillum fulvum* (Gogotov, et al., 1991) and *Heliobacterium gestii* (Kimble and Madigan, 1992b). Curiously, experiments with *Rhodobacter sphaeroides*, a close relative of *Rb. capsulatus* (Woese et al., 1984a), indicated that this species lacked an alternative nitrogenase system (Gogotov et al., 1991). In addition, to the author's knowledge no reports of alternative nitrogenases from purple or green sulfur bacteria have been published. It can thus be concluded that alternative nitrogenases are present in at least some anoxygenic phototrophs and are of the nitrogenase-3 type. As in nonphotosynthetic bacteria, alternative nitrogenases presumably allow species of photosynthetic bacteria to continue diazotrophic growth in environments limiting in molybdenum but containing sufficient iron to otherwise satisfy the needs of nitrogen fixation.

C. Physiological Prerequisites for N₂ Fixation by Photosynthetic Bacteria

Photosynthetic purple bacteria show remarkable metabolic diversity and are capable of growing both phototrophically (anaerobic/light) and in darkness by both respiration and fermentation (Madigan and Gest, 1979; Madigan, 1988; see also Chapter 41 by Tabita). *Rhodobacter capsulatus* shows particularly well-developed abilities in this connection, being capable of growth under five distinctly different growth modes: photoautotrophic, photoheterotrophic, chemoorganotrophic by aerobic respiration, chemoorganotrophic by fermentation, and chemolithotrophic with H₂ as electron donor (O₂ as electron acceptor, Madigan and Gest, 1979). Diazotrophic growth by *Rb. capsulatus* is possible under at least the first four of these conditions.

1. The Effect of Light

In the original discovery of N₂ fixation in photosynthetic bacteria (Gest and Kamen, 1949; Kamen and Gest, 1949), photoheterotrophic growth conditions were employed. All purple nonsulfur bacteria capable of N₂ fixation (see Section II) grow best diazotrophically under photoheterotrophic conditions (Madigan et al, 1984). However, many purple bacteria can also grow photoautotrophically with H₂, S₂O₃²⁻, H₂S, Fe⁰, or some other inorganic substance as electron donor (Madigan, 1988); N₂ fixation is also possible under these conditions.

Dark *aerobic* growth of purple nonsulfur bacteria

has been known since before the classic study of van Niel (1944), but dark *anaerobic* growth, either by fermentation (Uffen and Wolfe, 1970; Madigan and Gest, 1978) or by various anaerobic respiratory means (see Chapter 44 by Zannoni) was only discovered more recently. Once dark anaerobic growth of purple bacteria was established (Madigan and Gest, 1978) it was possible to test hypotheses (Meyer et al., 1978a,b) suggesting an obligatory link between photosynthesis and N₂ fixation in these organisms. The lack of any such connection was clearly shown in experiments where *Rb. capsulatus* was grown anaerobically in darkness with fructose as sole carbon and energy source and N₂ as sole nitrogen source (growth under these conditions also requires the presence of an 'accessory oxidant', such as dimethyl sulfoxide (DMSO), to allow for catabolism of the fructose, see Madigan and Gest, 1978; Madigan et al., 1980, and Chapter 44 of this volume by Zannoni). Under dark anaerobic conditions diazotrophic growth of *Rb. capsulatus* occurred and cell suspensions readily reduced acetylene to ethylene (a common assay of nitrogenase activity) in darkness (Fig. 1 and Madigan et al., 1979). Dark anaerobic nitrogen fixation has also been reported in the heliobacteria. Anaerobic cultures of all species of heliobacteria continue to fix N₂ and grow slowly in darkness (Kimble and Madigan, 1992a) via fermentation of pyruvate, yielding acetate and in some species H₂ (Kimble et al., 1994).

To the author's knowledge, no report of dark anaerobic N₂ fixation by purple *sulfur* bacteria has been published, although dark microaerobic growth (on ammonia) of some species is possible (Kämpf and Pfennig, 1980) and several of these also fix N₂ microaerobically in darkness (Jouanneau et al., 1980; Kämpf and Pfennig, 1986). The ability of green sulfur bacteria to fix N₂ in darkness is unknown; to date, no one has successfully grown these organisms in darkness under *any* growth conditions. Photosynthetically-grown cell suspensions of *Chlorobium* species incubated in darkness showed essentially no nitrogenase activity (Heda and Madigan, 1986a). However, should conditions for dark growth of green sulfur bacteria be discovered, N₂ fixation will probably be possible here as well.

2. The Effect of Oxygen

Although nitrogenase is obviously protected from oxygen inactivation during *anaerobic* growth photosynthetically or in darkness (see Fig. 1), *aerobic*

Fig. 1. Anaerobic growth of *Rhodobacter capsulatus* strain B10 in darkness with N_2 as sole nitrogen source. The mineral salts growth medium contained fructose as sole carbon and energy source and dimethyl sulfoxide (DMSO) as electron acceptor. Gas phases consisted of $N_2:CO_2$ (95:5) (●) or argon (○). Cultures in side-arm flasks were incubated in total darkness at 33 °C; 200 Klett units are equal to approximately 650 μ g of bacterial dry weight per milliliter. Suspensions of cells grown in this fashion readily reduced acetylene to ethylene. (From Madigan et al., 1979.)

dark growth on N_2 is problematic. Relatively little O_2 is required to inactivate preexisting nitrogenase in *Rb. capsulatus* (Hochman and Burris, 1981) and other purple bacteria (Madigan et al., 1984), and O_2 is also a potent repressor of nitrogenase synthesis in facultatively aerobic bacteria including purple bacteria (Burris and Roberts, 1993). Thus, to achieve aerobic dark diazotrophic growth, photosynthetic bacteria must receive sufficient O_2 to carry out respiration (for ATP production) while at the same time prevent inactivation and/or repression of synthesis of nitrogenase.

Conditions for aerobic diazotrophic growth of anoxygenic phototrophs were first described by Siefert and Pfennig (1980) using auxanographic techniques. When molten agar media is seeded with a culture of a photosynthetic bacterium and then allowed to solidify, O_2 and N_2 diffuse downward and respiratory growth on N_2 is observed as a tight band of cells a defined distance from the agar surface; the band represents the only zone in the agar tube where O_2 levels are compatible with both diazotrophy and

respiration (Fig. 2). Interestingly, however, because of differences in respiratory potential among species of purple bacteria, the distance from the agar surface that the growth band appears varies considerably. Species such as *Rb. sphaeroides*, which grow well at full oxygen tensions, form growth bands much nearer the surface than do extremely microaerophilic species, such as *Rs. molischanum* (Fig. 2). Using auxanographic methods, dark microaerobic N_2 fixation occurred in all diazotrophic purple nonsulfur bacteria tested except for one strain of *Rs. fulvum* (Madigan et al., 1984) and also occurred among certain species of Chromatiaceae (Kämpf and Pfennig, 1986).

II. Nitrogen Fixation by Purple and Green Bacteria

This section is divided into four parts, each developed around a summarizing table listing the species of photosynthetic bacteria in which N_2 fixation has been documented. In addition, where data are available, an indication of the relative efficacy of the N_2 fixation process as measured by in vivo nitrogenase activities in each species is given; such data identify the 'stronger' and 'weaker' N_2 -fixing species of photosynthetic bacteria (see Madigan et al. 1984).

A. Purple Nonsulfur Bacteria

In a major survey of 18 species of purple nonsulfur bacteria performed in my laboratory over 10 years ago all but one species, *Rhodocyclus purpureus*, were found capable of N_2 fixation (Madigan et al., 1984). Species of *Rhodobacter*, such as *Rb. capsulatus* and *Rb. sphaeroides*, expressed high levels of nitrogenase in vivo and grew most rapidly on N_2 , while species like *Rhodopseudomonas palustris* and *Rhodospila globiformis* expressed comparatively low nitrogenase levels and grew only very slowly on N_2 (Table 1). A correlation between in vivo specific nitrogenase contents and growth rate was observed in this study, and strains of *Rb. capsulatus* consistently showed the highest specific nitrogenase activities and shortest generation times for photoheterotrophic growth on N_2 (Madigan et al., 1984). This finding supports the observation that enrichment cultures for purple nonsulfur bacteria using the ability to fix N_2 as selective agent commonly result in *Rhodobacter* species, especially *Rb. capsulatus* (Gest et al., 1985). Since the study of Madigan et al. (1984) was

Fig. 2. Photograph of microaerobic dark growth of various species of anoxygenic phototrophic bacteria with N_2 as the nitrogen source. Cultures were seeded into molten agar tubes of a mineral salts/malate medium lacking combined nitrogen, quickly cooled to solidify the agar, and incubated in air and total darkness. Growth is indicated by the pigmented band of cells (e.g., see arrow in A) located at various distances from the agar surface. Organisms are: A, *Rhodospirillum molischianum* ATCC 14031; B, *Rhodopseudomonas viridis* DSM 133; C, *Rhodospirillum fulvum* DSM 2860; D, *Rhodobacter sphaeroides* 2.4.1.

undertaken, several new species of purple nonsulfur bacteria have been described and their nitrogen-fixing status, if known, is included in Table 1.

Only two species of purple nonsulfur bacteria have been shown by growth and acetylene reduction experiments to be incapable of N_2 fixation. These include *Rc. purpureus* (Masters and Madigan, 1983; Madigan et al., 1984), and the Dead Sea halophile, *Rhodospirillum sodomense* (Mack et al., 1993). Subsequent probing of DNA from both of these species with a *nifH* gene probe (*nifH* codes for dinitrogenase reductase) that hybridizes strongly with DNA from other species of purple bacteria confirmed that *Rc. purpureus* and *Rs. sodomense* lacked *nif* genes, thus explaining their failure to fix N_2 (PW Ludden, GP Roberts and MT Madigan, unpublished results). It is possible that the unusual habitat of *Rc. purpureus* and *Rs. sodomense*, a swine waste lagoon rich in ammonia and amines (Pfennig, 1978) and the Dead Sea (Mack et al., 1993), respectively, have for some reason(s) selected for an inability to fix N_2 in these phototrophs.

An interesting situation exists in regard to N_2 fixation in the moderately halophilic species *Rhodospirillum salexigens*. This organism was

originally described as a glutamate auxotroph (Drews, 1981), however experiments in my laboratory showed this to be unfounded (Rubin and Madigan, 1986). Although *Rs. salexigens* grows well either phototrophically or chemotrophically (aerobic/dark) in media containing glutamate as nitrogen source, utilization of ammonia or N_2 as sole nitrogen source is also possible. For unknown reasons substitution of NH_4Cl for glutamate in mineral media containing acetate (the preferred carbon source for *Rs. salexigens*, Drews, 1981) leads to a rapid rise in pH and cessation of growth. However, modifications to the medium, particularly the addition of pyruvate in addition to acetate, stabilized pH and supported good growth of *Rs. salexigens* on either ammonia or on N_2 (Rubin and Madigan, 1986).

Table 1 summarizes the microbiology of N_2 fixation in purple nonsulfur bacteria.

B. Purple Sulfur Bacteria (*Chromatiaceae* and *Ectothiorhodospiraceae*)

Documentation of N_2 fixation in purple sulfur bacteria is sketchy outside of a few species of the genus *Chromatium*. *Chromatium vinosum* has been well

Most values from Madigan et al., 1984.

studied as to its N₂-fixing capabilities and was the first phototrophic bacterium in which consistently active nitrogen-fixing cell-free extracts were obtained (Winter and Arnon, 1970). In vivo studies of nitrogenase in *Cm. vinosum* have also shown that the organism employs the ammonia 'switch-off effect' to control nitrogenase activity, as in purple nonsulfur

bacteria (Gotto and Yoch, 1985). In addition to *Cm. vinosum*, dinitrogen fixation has been documented in six other species of *Chromatium*, four species of *Ectothiorhodospira*, two species of *Thiocapsa*, and in a single species each of the genera *Amoebobacter*, *Thiocystis*, and *Lamprobacter* (Zakhvataeva et al., 1970; Postgate, 1982; Caumette et al., 1985; Ventura

^b Capable of nitrogen fixation microaerobically in darkness, see Kämpf and Pfennig (1986)

et al., 1988; Pfennig and Trüper, 1989; Young, 1992). Of these organisms, *Tc. roseopersicina* is probably the most widespread in nature and is frequently found as a component of microbial mats (see Chapter 4 by van Gemerden and Mas) where it may be a major nitrogen-fixing species.

The capacity for N₂ fixation has not been reported for species of *Lamprocystis*, *Thiodictyon*, *Thiopedia*, *Thiorhodovibrio* and *Thiospirillum*. Thus the family Chromatiaceae obviously needs more study as regards nitrogen fixation. The current status of N₂ fixation in purple sulfur bacteria is summarized in Table 2.

C. Green Sulfur Bacteria (*Chlorobiaceae*)

Our knowledge of nitrogen fixation in green sulfur bacteria is somewhat more developed than that of purple sulfur bacteria, although the story is far from complete. Clear evidence for N₂ fixation has been obtained with several species of *Chlorobium* and with single species each of the genera *Pelodictyon*, *Prosthecochloris* and *Chloroherpeton* (see Table 3 and Bergstein et al., 1981; Heda and Madigan, 1986a,b; 1988; Rodionov et al., 1986; Gibson et al.,

1984). Interestingly, like purple bacteria, nitrogen-fixing cultures of *Chlorobium* species showed ammonia 'switch-off of nitrogenase activity (Heda and Madigan, 1986a; Rodionov et al., 1986; Wahlund and Madigan, 1993), indicating that this form of regulation, apparently universal among nitrogen-fixing purple bacteria (see Chapter 43 by Ludden and Roberts), extends also to the green sulfur bacteria, a phylogenetically distinct lineage from that of the purple bacteria (Gibson et al., 1985; Oyaizu et al., 1987).

The moderately thermophilic green sulfur bacterium *Chlorobium tepidum* (Wahlund et al., 1991) is an excellent nitrogen-fixing bacterium. This organism, which has a generation time of as little as 2 hr on ammonia, also grows rapidly on N₂ and intact cells contain extremely high levels of nitrogenase (Wahlund and Madigan, 1993). In a study of the mesophilic green bacterium *Cb. limicola* Heda and Madigan (1986a) also observed high levels of nitrogenase in vivo. These facts, coupled with the observations that *Cb. limicola* strongly derepressed nitrogenase when grown on glutamate as nitrogen source yet did not photoproduce H₂ (Heda and

Madigan, 1986a) and that nitrogenase from this organism did not cross-react immunologically with that of other diazotrophs (Heda and Madigan, 1988), warrants more thorough characterization of the nitrogenase system of green sulfur bacteria.

Interestingly, despite the good nitrogen-fixing properties of *Chlorobium tepidum*, its thermophilic counterpart among purple sulfur bacteria, *Chromatium tepidum* (Madigan, 1984, 1986), was found incapable of N₂ fixation (Madigan, 1986) despite its apparent possession of *nif* genes (PW Ludden, GP Roberts and MT Madigan, unpublished results). The reason for the lack of growth on N₂ by *Chromatium tepidum* remains unknown. Although N₂ fixation in *Chlorobium tepidum* was found to require elevated levels of sulfide (which was otherwise not required for growth of this thiosulfate-utilizing green bacterium, Wahlund et al, 1991; Wahlund and

Madigan, 1993), elevated levels of sulfide do not support N₂ fixation in *Chromatium tepidum*. *Chlorobium tepidum* grows on N₂ up to its growth temperature maximum of 52 °C (Wahlund and Madigan, 1993) and this is the highest temperature reported for N₂ fixation by any green sulfur bacterium.

The current status of N₂ fixation in green sulfur bacteria is summarized in Table 3.

D. Green Nonsulfur Bacteria (Chloroflexaceae)

Although phenotypically resembling green sulfur bacteria in terms of pigments and the production of chlorosomes, green nonsulfur bacteria (the *Chloroflexus* group, see Chapter 3 by Pierson and Castenholz) are phylogenetically unrelated to green sulfur bacteria (Gibson et al., 1985; Oyaizu et al., 1987). Study of the N₂-fixing potential of four strains

of *Chloroflexus aurantiacus* showed the organism to be totally unable to fix N_2 (Heda and Madigan, 1986b). This result was supported by the complete absence of hybridization of *Cf. aurantiacus* DNA to a *nifH* probe (PW Ludden, GP Roberts and MT Madigan, unpublished results). *Cf. aurantiacus* grows well on any of several amino acids (Heda and Madigan, 1986b) including ones that normally allow for derepression of nitrogenase in purple bacteria (Arp and Zumft, 1983). Despite this, however, cultures of *Cf. aurantiacus* grown on amino acids or on growth-limiting levels of ammonia failed to reduce acetylene or photoproduce H_2 (Heda and Madigan, 1986b). One published report of growth of *Cf. aurantiacus* in a medium lacking combined nitrogen, presumably at the expense of N_2 (Gallon and Chaplin, 1987), has not been confirmed in my laboratory, and it is possible that the slight growth observed was due to trace levels of fixed nitrogen compounds in the medium (J.R. Gallon, personal communication).

Weak but detectable N_2 fixation has been reported (Keppen et al., 1989) in the newly described green filamentous bacterium *Oscillochloris trichoides*, which is phylogenetically related to *Cf. aurantiacus* (Keppen et al., 1994). Thus it is possible that N_2 -fixing *Cf. aurantiacus* strains exist but have thus far not been cultured. Temperature is obviously not a barrier here because fixation in thermophilic green sulfur bacteria (Wahlund and Madigan 1993) and thermophilic heliobacteria (Kimble et al., 1995) occurs within the temperature range of optimal growth of *Chloroflexus* (50–55 °C). Because of the more extreme thermophilic character (growth up to 72 °C, see Chapter 3 by Pierson and Castenholz) and unique phylogeny (Gibson et al., 1985; Oyaizu et al., 1987) of *Chloroflexus*, the properties of N_2 -fixing species, if they exist, should be very interesting.

E. Heliobacteria (*Heliobacteriaceae*)

All known species of heliobacteria fix nitrogen (Kimble and Madigan, 1992a; Kimble et al., 1995). *Heliobacillus mobilis* appears to be the best N_2 -fixing species presently in culture, both in terms of its ability to grow rapidly on N_2 and in expression of nitrogenase (Kimble and Madigan, 1992a). Even thermophilic heliobacteria are diazotrophic and fix N_2 up to 55°C (Kimble et al., 1995). Thus nitrogen fixation may be of strong selective advantage to heliobacteria in their soil, and especially rice soil, habitat (see Chapter 2 by Madigan and Ormerod).

All species of heliobacteria examined by Kimble and Madigan (1992a) and Kimble et al. (1995) were subject to ammonia 'switch-off' of nitrogenase activity. This finding in the heliobacteria, which phylogenetically are Gram-positive bacteria (Woese et al., 1985), suggests that this form of enzyme regulation is of such strong survival value for anoxygenic phototrophic bacteria that it has evolved across deep evolutionary lines from Gram-negative to Gram-positive phototrophs (ammonia 'switch-off' in heliobacteria is the first such instance reported from Gram-positive bacteria, Kimble and Madigan 1992a). Finally, as previously discussed (see Section IB), alternative (non-molybdenum) nitrogenases are present in certain heliobacteria, the best example being *Heliobacterium gestii* (Kimble and Madigan, 1992b).

A summary of nitrogen-fixation in heliobacteria is given in Table 4.

III. Phototrophic Rhizobia and Other Bacteriochlorophyll *a*-Containing Species

A number of *Rhizobium* species have been discovered that contain bacteriochlorophyll *a*. These, along with the 'aerobic phototrophs' (see below) have been termed 'quasi-photosynthetic bacteria' by Gest (1993) because they share certain properties with true anoxygenic phototrophs but lack many other characteristic traits (e.g. the ability to grow anaerobically, see Chapters 6 by Shimada and 7 by Fleischman et al. for a description of these organisms).

Bacteriochlorophyll *a*-containing *Rhizobium* species (now referred to as *Photorhizobium* species, see Chapter 7 by Fleischman et al.) nodulate the stems of several different, primarily tropical, leguminous plants. As is well-known, a prime physiological characteristic of *Rhizobium* is its ability to fix N_2 , and evidence exists that *Photorhizobium* fixes N_2 both in association with host plants in stem nodules and *ex planta* in pure culture in the laboratory. It is hypothesized that photophosphorylation by *Photorhizobium* at least partially supports the energy needs of N_2 fixation in stem nodules; this in turn would reduce the energy drain on the plant leading to more efficient symbiotic nitrogen fixation.

Several aerobic BChl *a*-containing bacteria have been isolated by Japanese workers and others in the last 15 years. These organisms, referred to as 'aerobic phototrophs', are mainly marine and grow best under

fully aerobic conditions (Shiba and Harashima, 1986, and see also Chapter 6 by Shimada). However, no evidence for N₂ fixation by aerobic phototrophs has emerged and gene probe experiments (using a *nifH* probe) carried out on two species failed to show any hybridization of the probe to their chromosomal DNA (PW Ludden, GP Roberts and MT Madigan, unpublished results). Thus, all available evidence suggests that the 'aerobic phototrophs' are nondiazotrophic.

IV. Ecological Aspects of N₂ Fixation by Anoxygenic Photosynthetic Bacteria

With the exception of a few well studied lake ecosystems where mass developments of anoxygenic phototrophic bacteria occur (see review of Madigan, 1988 and Chapter 4 of this volume by van Gemerden and Mas), few data are available on the contributions of photosynthetic bacteria to the carbon balance of aquatic or terrestrial habitats. Much the same can be said about nitrogen fixation. A few reports of in situ nitrogen fixation by photosynthetic bacteria have been published (see e.g. Kobayashi et al., 1967; Habte and Alexander, 1980; Bergstein et al., 1981), but too little data exist to generalize on a global basis.

The nitrogen-fixing activities of photosynthetic bacteria in specialized habitats such as paddy soils or microbial mats, however, may be very ecologically significant (Kobayashi and Haque, 1971). In a detailed report on the distribution of nitrogen-fixing

microorganisms in paddy soils of Southeast Asia, Kobayashi et al. (1967) clearly implicated anoxygenic phototrophs, particularly purple nonsulfur bacteria, as contributors to the nitrogen economy of these soils. A later study of N₂ fixation in rice soils by Habte and Alexander (1980) employed acetylene reduction methods and showed more directly the importance of anoxygenic photosynthetic bacteria to the fertility of paddy soils. Presumably photosynthetic bacteria growing in such environments utilize organic substrates leached from the rice plants or H₂S as electron donors for reduction of N₂ to ammonia. In addition, microbial mats (see Chapter 4 by van Gemerden and Mas) can be major sources of N₂ fixation by anoxygenic phototrophs; the common occurrence of the diazotroph *Thiocapsa roseopersicina*, a purple sulfur bacterium with well developed aerobic/dark metabolic capacities (Jouanneau et al., 1980) in such habitats suggests that this organism is a major contributor to fixed nitrogen inputs therein.

Another link between the paddy soil environment and photosynthetic bacteria is the recent discovery of the heliobacteria. These anoxygenic phototrophs are terrestrial organisms and are particularly abundant in rice soils (see Chapter 2 by Madigan and Ormerod for a discussion of the heliobacteria). Because heliobacteria are active nitrogen-fixers (Kimble and Madigan, 1992a,b; Kimble et al., 1995) and also capable of dark growth (Kimble et al., 1994), it is likely that these organisms contribute fixed nitrogen to paddy soil environments (see also Madigan, 1992

for a discussion of the ecology of heliobacteria).

The ability of photosynthetic bacteria to fix N_2 can be used to advantage in their enrichment. This is particularly true of purple nonsulfur bacteria (Gest et al., 1985) and heliobacteria (Madigan, 1992), however experiments in this laboratory have shown that diazotrophic enrichments also work for the isolation of purple and green sulfur bacteria (unpublished results and Heda and Madigan, 1986a). Combining these observations with the fact that results thus far have shown that most photosynthetic bacteria can fix N_2 (see Section II), it stands to reason that N_2 fixation is of ecological importance to anoxygenic phototrophs, at least under certain environmental conditions, and that their diazotrophic capacity allows them to compete better in their aquatic and terrestrial habitats. However, now that phylogenetic probes, biomarker analyses, and other highly specific analytical methods are available for characterizing the microbiology of virtually any habitat, it would be worthwhile to investigate the N_2 -fixing activities of photosynthetic bacteria in situ using these modern techniques. Only from well controlled field studies that specifically target a group or groups of anoxygenic phototrophs will the real contributions of these organisms to the nitrogen economy of soils and waters be known.

V. Concluding Remarks

In conclusion it can be stated that N_2 fixation is a universal property of heliobacteria and nearly universal among purple nonsulfur bacteria; however, much is yet to be learned about this major physiological process in other groups of anoxyphototrophs. It will be of interest in future years to test more isolates of photosynthetic bacteria for the capacity to fix N_2 , especially new species isolated from extreme environments or from marine environments (the latter of which have only been minimally explored, Imhoff 1983; Mangels et al., 1986; Wynn-Williams and Rhodes 1974), and to better understand the nature and distribution of alternative nitrogenases among anoxygenic phototrophs. Such studies will yield a more complete picture of the diazotrophic systems of photosynthetic bacteria and should complement our new evolutionary insight into these organisms, born with the advent of ribosomal RNA sequencing (Woese, 1987; 1992).

The prominence of purple bacteria as likely ancestors of the majority of known Gram-negative bacteria (see Woese et al 1984a, b, and reviews of Woese 1987, 1992) and the heliobacteria of Gram-positive bacteria (Woese et al., 1985) mandates that we understand important metabolic processes such as N_2 fixation in anoxygenic phototrophs in considerably more detail.

Acknowledgments

Work on N_2 fixation in photosynthetic bacteria in my laboratory has been supported by the United States Department of Agriculture and the National Science Foundation. I thank Linda Kimble for unpublished results.

Summary

Most photosynthetic bacteria are capable of nitrogen fixation and the biochemistry and genetics of nitrogen fixation have been studied extensively in a few of these. Both the traditional, molybdenum-dependent, nitrogenase and the third alternative form of nitrogenase have been found in anoxygenic phototrophs and the properties of these are similar to those in heterotrophic nitrogen fixers. The *nif* genes for the molybdenum nitrogenase system and the *anf* genes for the alternative nitrogenase system have been isolated. Nitrogenase activity in some photosynthetic bacteria is regulated by reversible ADP-ribosylation at arg 101 of the dinitrogenase reductase protein, which prevents it from transferring electrons to the dinitrogenase protein. ADP-ribosylation of dinitrogenase is catalyzed by dinitrogenase reductase ADP-ribosyl transferase (DRAT) and the removal of ADP-ribose is performed by dinitrogenase reductase activating glycohydrolase (DRAG). These are encoded by the *draT* and *draG* genes, respectively.

I. Background and Historical Introduction

A. Discovery of Nitrogen Fixation by Photosynthetic Bacteria

Nitrogen fixation by photosynthetic bacteria was discovered by Gest and Kamen during their investigation of H_2 evolution by *Rhodospirillum rubrum* (Gest and Kamen, 1949; Kamen and Gest, 1949) and Kamen provides a dramatic recounting of the discovery in his autobiography (Kamen, 1986). They found that N_2 was not an inert gas when used as the gas phase over cells of *Rs. rubrum* grown on glutamate as the nitrogen source, and subsequent studies confirmed the ability of *Rs. rubrum* and other photosynthetic bacteria to utilize N_2 as the sole nitrogen source (Gest et al., 1950). As a final confirmation, a culture of *Rs. rubrum* was brought to the laboratory of R. H. Burris in Madison for a mass spectrometric demonstration that $^{15}N_2$ was incorporated into cellular nitrogen (Lindstrom et al., 1949).

Gest and Kamen also observed that the uptake of N_2 by actively fixing *Rs. rubrum* cells was inhibited by NH_4^+ (Gest, Kamen et al., 1950). While this observation was not explained at the time, it led to studies by others that eventually demonstrated the regulation of nitrogenase activity by reversible ADP-ribosylation (reviewed here and in Ludden and Roberts, 1989). Although Gest and Kamen did not realize that the H_2 evolution they observed was, in fact, mediated by nitrogenase, Gest was the first to speculate that nitrogenase might function as an H_2 -evolving enzyme (Ormerod and Gest, 1962). Gest's hypothesis was confirmed by Burns and Bulen (1965), who demonstrated H_2 evolution by the isolated nitrogenase enzyme. The discovery of nitrogen fixation by *Rs. rubrum* led to the description of growth on N_2 in many photosynthetic bacteria (Lindstrom et al., 1949, 1950). While this will be discussed in more detail in this volume in Chapter 42 by Madigan, it is worth noting here that the ability to fix nitrogen is the rule rather than the exception among photosynthetic bacteria, in contrast to the distribution of the ability to fix nitrogen among other genera of prokaryotes.

Abbreviations: ADP-ribose, ; ADPR – Adenosinediphospho-ribose; *anf* – designation for genes involved in nitrogen fixation by alternative nitrogenase; DRAG – Dinitrogenase reductase activating glycohydrolase; DRAT – Dinitrogenase reductase ADP-ribosyltransferase; FeMo-co – Iron Molybdenum-cofactor of nitrogenase; *nif* – designation for genes involved in nitrogen fixation by molybdenum nitrogenase

Following Gest and Kamen's work, Schick (1971) carried out extensive investigations of N_2 fixation by *Rs. rubrum* using manometric methods, as his experiments predated the acetylene reduction technique. Schick confirmed the inhibition of N_2 uptake by ammonium in *Rs. rubrum* and also showed that N_2 uptake is typically light-dependent.

B. Early Work on Isolated Nitrogenases From Photosynthetic Bacteria

Schneider et al. (1960) adapted the method of Carnahan et al. (1960) to achieve the first success at detecting nitrogenase activity in extracts of a photosynthetic bacterium. However, activity in these *Rs. rubrum* extracts was low and unpredictable. Consistently active preparations were obtained by Burns and Bulen (1966) when they removed the membrane fraction from their extracts. The usefulness of the removal of membranes is surprising in light of current knowledge of the regulation of nitrogenase activity (section IIC below) in which an enzyme involved in activation of nitrogenase is found in this fraction. However, when this fraction is exposed to air, it becomes inhibitory and it is possible that methods for excluding air were less refined in earlier studies than those available now. They also found that inclusion of Mg^{2+} in 2.5-fold excess over ATP in the assay mixture greatly stimulated activity (Burns and Bulen, 1966) and it was subsequently discovered that addition of 0.5 mM Mn^{2+} along with high Mg^{2+} in the assay amplified this stimulation (Ludden and Burris, 1976).

Munson and Burris (1969) then found that the most consistently active preparations were obtained from cells grown in an N-limited chemostat under an atmosphere of H_2 . In these studies, it was also discovered that the activity in extracts was non-linear, with increased activity observed at later time points (Munson and Burris, 1969). This was interpreted as indicating that some inhibition of nitrogenase activity was being overcome. Now it is known that ADP-ribose is being removed from dinitrogenase reductase during the assay (see below) and this results in activation of the enzyme. All attempts at purification of nitrogenase from these extracts resulted in the loss of activity.

While purification of nitrogenases from other organisms was achieved, there was little or no progress with nitrogenases from phototrophs. Most of the effort went toward the purification of nitrogenases from *Rs. rubrum* and the purple sulfur bacterium,

Chromatium vinosum. Winter and Arnon (1970) obtained consistently active preparations from *Cm. vinosum* and Winter and Ober (1973) found that a particulate form of *Cm. vinosum* nitrogenase could be sedimented by high-speed centrifugation. This particulate nitrogenase was reminiscent of the particulate nitrogenase from *Azotobacter vinelandii* isolated by Bulen and coworkers (Silverstein and Bulen, 1970), but the *Cm. vinosum* enzyme lost activity upon solubilization. Unfortunately, this particulate nitrogenase has not been investigated further.

The reason for the problem of nitrogenase purification from *Rs. rubrum* was clarified when a third factor for the nitrogenase system was discovered. This 'Activating Factor' as it was called by the Madison group (Ludden and Burris, 1976), or 'Membrane Component' as it was called by the Stockholm group (Nordlund et al., 1977), was associated with the chromatophore fraction of extracts and could be released by treatment of the pelleted fraction with 0.5 M NaCl. This fraction is now called Dinitrogenase Reductase Activating Glycohydrolase (DRAG) (Pope et al., 1986) and is discussed in more detail in section IIC. DRAG activity requires a free divalent metal, with Mn^{2+} being most effective, thus explaining the results with metal additions to the nitrogenase assays.

C. Biochemistry and Genetics of Nitrogenases

1. Molybdenum Nitrogenases

a. Enzymology

Nitrogenases catalyze the MgATP and reductant-dependent reduction of N_2 to ammonium as shown in Eq. (1), reviewed in (Burris, 1991; Burris and Roberts, 1993).

In this reaction, n is $\geq 2/e^-$. H_2 is produced as an obligate product of the reaction in which N_2 is reduced and thus the requirement for 8 electrons (Simpson and Burris, 1984).

Nitrogenases consist of two proteins, the dinitrogenase protein (also known as the MoFe protein or component 1 and abbreviated by the initials of the organism from which it is derived and the number

one; i.e. Rr1 is the dinitrogenase from *Rs. rubrum*) and the dinitrogenase reductase protein (also known as the Fe protein or component 2 and abbreviated as, for example, Rr2). The dinitrogenase protein is the product of the *nifK* and *D* genes (Roberts et al., 1978) and exists as an $\alpha_2\beta_2$ tetramer containing 2 molecules of the iron-molybdenum cofactor (FeMo-co) (Shah and Brill, 1977) and two Fe_8S_8 clusters known as P-clusters (Bolin et al., 1993; Dean et al., 1993). The structures of these prosthetic groups have recently become known as a result of the solution of the crystal structure of the dinitrogenase protein from *Azotobacter vinelandii* (Kim and Rees, 1992). The composition of FeMo-co is $MoFe_7S_9$ Homocitrate (Shah and Brill, 1977; Hoover et al., 1987) and its structure is shown in Fig. 1. FeMo-co is liganded to the α (NIFD) subunit of the dinitrogenase protein via his441 as a sixth ligand to Mo and cys275 as a 4th ligand to the Fe atom most distant from the Mo atom of the molecule. The P clusters were originally thought to exist as unusually-liganded Fe_4S_4 clusters, but are now known to be Fe_8S_8 clusters. The P clusters bridge the α and β subunits of the enzyme and are liganded by cys α 62,88,154 and cys β 70,95,153. Each molecule of FeMo-co is approximately 16 Å from one P cluster and 69 Å from the other molecule of FeMo-co in the protein and, thus, the dinitrogenase tetramer is thought of as two $\alpha\beta$ pairs functioning independently.

FeMo-co is the site of substrate binding and reduction, although neither process is yet understood. The general role of FeMo-co is based on the observation by Smith and coworkers that the dinitrogenase from *nifV* mutants shows aberrant substrate reduction properties and those aberrant properties can be transferred to another molecule of dinitrogenase by the transfer of the FeMo-co center alone (McLean and Dixon, 1981; Hawkes et al., 1984). It was later shown that homocitrate is produced for FeMo-co synthesis in cells that have a functional *nifV* gene and that the unusual properties arise from substitution of other organic acids for homocitrate in FeMo-co in *nifV* mutants (Hoover et al., 1989; Imperial et al., 1989). When various organic acids were substituted for homocitrate in FeMo-co in vitro, dinitrogenases with altered properties were also obtained.

Dinitrogenase reductase is an α_2 dimer of the *nifH* product (St. John et al., 1975). This protein has several roles in the overall nitrogen fixation process, including the specific transfer of electrons to the dinitrogenase protein (Ljones and Burris, 1972; Orme-Johnson et al., 1972). Dinitrogenase reductase

Fig. 1. The structure of the iron molybdenum-cofactor (after Kim and Rees, 1992).

contains a single Fe_4S_4 cluster and bridges the two subunits of the protein through its ligation by cys98 and cys132 of each subunit (Hausinger and Howard, 1983). The biosynthesis of the Fe_4S_4 cluster of dinitrogenase reductase has recently been shown to involve the *nifS* gene product (Zheng et al., 1993; Zheng and Dean, 1994). Dinitrogenase reductase has binding sites for two molecules of MgATP and one molecule of MgADP (Tso and Burris, 1973) and these sites are distal from the Fe_4S_4 cluster of the enzyme (Georgiadis et al., 1992). The MgADP binding site is competitive with one MgATP binding site. The crystal structure of the dinitrogenase reductase protein from *Azotobacter vinelandii* has recently been determined and the structure reveals relatively little interaction of the two subunits other than at the region surrounding the site of Fe_4S_4 cluster ligation (Georgiadis et al., 1992).

Both nitrogenase proteins are extremely oxygen-labile and organisms have devised various physiological strategies to overcome this problem. In the case of the anoxygenic photosynthetic bacteria, nitrogenase synthesis is strongly repressed in the presence of oxygen. Organisms with high respiratory rates, such as *Rb. capsulatus*, are able to tolerate higher levels of oxygen coincident with active

nitrogen fixation (Meyer et al., 1987), but continued exposure of *Rb. capsulatus* cells to high levels of oxygen results in oxidative destruction of the nitrogenase proteins.

Nitrogenases will reduce a variety of triply- and doubly-bonded molecules in addition to the physiologically relevant substrate, N_2 (Rivera-Ortiz and Burris, 1975). In the absence of any other substrate, the enzyme will reduce protons to H_2 gas at a rate of electron flow through the enzyme equivalent to the rate when the enzyme is saturated with N_2 . This ATP-dependent hydrogenase activity creates a physiological problem for nitrogen-fixing organisms because ATP and reductant are consumed without nitrogen fixation. This activity also creates experimental problems, because it is never possible to isolate and study the fully reduced form of the dinitrogenase protein—as soon as it is reduced, it will transfer electrons to protons. The reduction of acetylene to ethylene is a 2 electron reaction and is the basis of an extremely useful assay for nitrogenase because the product, ethylene, can be easily quantitated by gas chromatography (Stewart et al., 1967). Unlike N_2 , acetylene can completely suppress H_2 evolution by nitrogenase and this should be taken into account when using the results of the acetylene

reduction assay to estimate the amount of N_2 fixed by nitrogen-fixing cultures, CN^- , N_3^- , N_2O , CH_3CN , cyclopropene and diazerene are also substrates for nitrogenase (Rivera-Ortiz and Burris, 1975; McKenna et al., 1979). H_2 is a specific inhibitor of the N_2 reduction assay (Burris, 1985) and CO inhibits the reduction of all substrates except protons (Rivera-Ortiz and Burris, 1975).

The dinitrogenase protein exhibits a nondescript UV-visible spectrum from < 300 nm to beyond 800 nm; the difference spectrum between the oxidized and reduced forms of the protein is not significant (Shah and Brill, 1973). The dinitrogenase reductase protein also has a broad spectrum, but it has a distinct shoulder that shows a significant difference between the oxidized and reduced forms at 430 nm, and changes in the spectrum have been used to follow the oxidation state of the protein (Ljones and Burris, 1972). The dinitrogenase protein has a unique EPR spectrum with g values at 4.3, 3.65 and 2.01 (Eady et al., 1972; Orme-Johnson et al., 1972; Zumft et al., 1974). The signal at 3.65 is unique in nature and can even be detected in vivo (Shah et al., 1973). This signal is referred to as the M center as it arises from the magnetic center of the protein, the FeMo-co. Upon reduction of dinitrogenase by dinitrogenase reductase, the signals at g 4.3 and 3.65 disappear. The P clusters are not observed in EPR under normal conditions but can be seen in oxidized forms of the enzyme. Dinitrogenase reductase has an EPR spectrum in the $g = 2$ region (Eady et al., 1972; Orme-Johnson et al., 1972; Zumft et al., 1974). The spectrum is axial and becomes more rhombic upon binding of MgATP to the protein. EPR spectroscopy was employed to establish the sequence of electron transfer between nitrogenase proteins. Both dinitrogenase and dinitrogenase reductase have been investigated with Mössbauer and ENDOR spectroscopy (Münck et al., 1975; Hoffman et al., 1982; Ventures et al., 1986).

The features described above for molybdenum nitrogenases have been determined primarily using non-photosynthetic organisms, especially *Azotobacter vinelandii*, *Clostridium pasteurianum* and *Klebsiella pneumoniae*, and apparently these features are retained in the properties of photosynthetic species. Nitrogenases from *Rs. rubrum* (Ludden and Burris, 1978), *Rb. capsulatus* (Hallenbeck et al., 1982b) and *Cm. vinosum* (Albrecht and Evans, 1973) have been purified and characterized, and crude

extracts with nitrogenase activity or partially purified nitrogenases have been prepared from a number of other phototrophs. Purification of nitrogenases from phototrophs is performed under anaerobic conditions using methods developed for heterotrophic diazotrophs but the large amount and small size of the membrane material requires additional, high speed centrifugation of the crude extract. Photosynthetic bacteria grown under nitrogen-fixing conditions also store large amounts of poly- β hydroxybutyric acid that is hydrolyzed upon breakage of the cells. The ionization of the hydroxybutyric acid monomers can result in a drastic lowering of the pH of the extract and high buffer concentrations (100–200 mM) are required to maintain the pH of extracts.

The physiological electron donor to nitrogenase has been unambiguously established only in *K. pneumoniae* where the *nifJ* gene product, pyruvate: flavodoxin oxidoreductase, and the *nifF* product, flavodoxin, perform the task of supplying low potential electrons to nitrogenase (Nieva-Gomez et al., 1980; Shah et al., 1983). A pyruvate:ferredoxin oxidoreductase has been isolated from *Rs. rubrum* and a gene with significant sequence similarity to the *K. pneumoniae nifJ* gene has been isolated (Brostedt and Nordlund, 1991). However, mutations in the *nifJ* gene of *Rs. rubrum* do not render the organism Nif^- . Similarly, several ferredoxins that are capable of donating electrons to nitrogenase in vitro have been isolated from *Rs. rubrum* and from *Rb. capsulatus*, but none of these has been demonstrated to be the in vivo electron donor (Hallenbeck et al., 1982a; Meyer et al., 1987). Recently a *nif*-specific flavodoxin has been identified in *Rb. capsulatus* and shown to have the ability to transfer electrons to dinitrogenase reductase (Yakunin et al., 1993). A flavodoxin that accumulates under conditions of iron starvation has been isolated from *Rs. rubrum*, but it is not known if this protein plays any role in nitrogen fixation (Cusanovich and Edmondson, 1971).

It is possible that the physiological electron donor to nitrogenase in phototrophs may vary depending on the conditions of growth. For example, *Rs. rubrum* is able to grow and fix nitrogen under fermentative conditions with pyruvate as the carbon and energy source (Uffen and Wolfe, 1970; Madigan et al., 1979; Schultz et al., 1985). Under these conditions, a system like that in *K. pneumoniae* might be expected, whereas a light-dependent system might operate under photosynthetic growth conditions. As noted

below, Schmel et al. (1993) have recently described a set of genes in *Rb. capsulatus* whose encoded products apparently function as electron donors to nitrogenase. Further biochemical analysis of the gene products should clarify this assignment.

The interaction of the dinitrogenase reductase protein with its electron donor has been an unstudied area, but one of potential importance to the phototrophs. The site for regulation of the dinitrogenase reductase protein by reversible ADP-ribosylation (see IIA below) is near the Fe_4S_4 cluster of the enzyme. It is reasonable to suggest that the electron-donating proteins, whatever they be, bind at or near the same site. It will be interesting to determine if ADP-ribosylation disrupts the ability of the dinitrogenase protein to be reduced by ferredoxins and flavodoxins; it is known that the modified protein can be reduced by low molecular weight reductants such as dithionite (Ludden and Burris, 1979).

b. Gene Organization for the Mo-Nitrogenase

The genes for the Mo-nitrogenase system of a phototroph have only been well-described in the case of *Rb. capsulatus*, largely through the work of the laboratories of Klipp (Moreno-Vivian et al., 1988), Haselkorn (Ahombo et al., 1986) and Vignais (Ahombo et al., 1986) [reviewed in Dean and Jacobson (1993) and Haselkorn (1986)]. The genes that are necessary for the expression and function of the Mo-nitrogenase fall into three non-contiguous gene clusters, termed A, B, and C.

Region A contains 26 open reading frames (ORFs) that are apparently organized into six transcriptional units (Klipp et al., 1988; Fonstein et al., 1992). Eleven of these have homologs in the *nif* cluster of *K. pneumoniae* and three others are similar to ORFs found in the *nif* region of *Azotobacter vinelandii*.

Immediately adjacent to these *nif* gene homologs in Region A is a set of genes that have been termed *mfA-F* (for *R*hodobacter *n*itrogen *f*ixation) (Schmehl et al., 1993). While these genes are not homologous to any sequences stored in available data banks, their sequences suggest that many encode either membrane proteins or contain cysteine motifs typical of iron-sulfur proteins. Both mutational analyses and the effects of metronidazole suggest that the encoded proteins are involved in electron transport to nitrogenase. The authors have speculated that the encoded proteins form a complex and that it might either serve as an oxido-reductase for an unknown

substrate or utilize membrane potential as a source of reductant for nitrogenase (Schmehl et al., 1993).

Region B contains the *nifHDK* genes, which encode dinitrogenase and dinitrogenase reductase, and also 'second' copies of *nifA*, *nifB*, and *nifU* that duplicate the same functions found in region A. Finally, this region contains *nifR4*, which encodes a *nif*-specific sigma factor (Jones and Haselkorn, 1989).

Region C contains *nif*-specific homologs of *ntrBC*, termed *nifR2* and *nifR1*. This regulatory system is discussed in detail in Chapter 56 in this volume by Kranz and Cullen on the regulation of nitrogen fixation.

Immediately adjacent to Region B is a cluster of six ORFs, designated *modABCD* and *mopAB*, whose products appear to be involved in molybdenum transport and perhaps other aspects of molybdenum processing (Wang et al., 1993). While the precise roles of the different gene products are unknown and the phenotypes of mutants are not identical, in general the presence of these genes is important for both molybdenum uptake and for the molybdenum repression of the alternative nitrogenase in *Rb. capsulatus*.

2. Alternative Nitrogenase Systems

a. Enzymology

Following the description of the alternative nitrogenases in *Azotobacter vinelandii* by Bishop (Bishop et al., 1980; Premakumar et al., 1989; Bishop and Premakumar, 1992) non-molybdenum nitrogenases have been described in a number of organisms, including the photosynthetic bacteria. To date, only the iron-only (third alternative) nitrogenases have been described in the photosynthetic bacteria and these have been purified from *Rb. capsulatus* (Schneider et al., 1991) and *Rs. rubrum* (Davis and Ludden, unpublished results). Like the alternative nitrogenases from *Azotobacter vinelandii* and *A. chroococcum*, the dinitrogenase proteins from *Rs. rubrum* and *Rb. capsulatus* contain a third (δ , the product of *anfG*) subunit with a molecular weight of approximately 20 kD (Schneider et al., 1991). The alternative nitrogenase systems from *Rb. capsulatus* and *Rs. rubrum* reduce protons well, N_2 at a rate sufficient to sustain growth, and acetylene very poorly. The maximal rate of N_2 reduction by the alternative system is 10% of the rate observed with the molybdenum nitrogenase. The enzymes are extremely

labile and purification is difficult. The alternative dinitrogenase proteins from photosynthetic bacteria do not accept electrons from the dinitrogenase reductases from the molybdenum systems. The alternative dinitrogenase reductases are effective in transferring electrons to the molybdenum dinitrogenase. Like the alternative nitrogenases from other systems (Dilworth et al., 1987), the alternative nitrogenases of phototrophs reduce acetylene to ethylene and ethane. Approximately 2–5% of the product of acetylene reduction is ethane.

In both *Rb. capsulatus* and *Rs. rubrum*, the alternative dinitrogenase reductases are substrates for regulation by the reversible ADP-ribosylation systems described below (Lehman and Roberts, 1991; Masepohl et al., 1993). The proteins can be modified in vivo and in vitro. Thus, the alternative nitrogenase does not serve as an unregulated back-up to the molybdenum nitrogenase. This result predicts that the dinitrogenase reductase of each system contains an arginine residue at position 101.

The UV-visible and EPR spectra of the alternative dinitrogenase reductases are similar to those of the dinitrogenase reductases of the molybdenum system. The $g = 3.65$ EPR signal attributed to FeMo-co in the molybdenum system is lacking in the alternative system. The *Rs. rubrum* alternative dinitrogenase exhibits a signal in the $g = 2$ region with no apparent higher field signals. The spectra of the *Rb. capsulatus* protein are reported to be complex and include a signal like that of the *Rs. rubrum* alternative dinitrogenase as well as additional signals in the $g = 4$ region (Schneider et al., 1991).

A cofactor analogous to FeMo-co can be isolated from the *Rs. rubrum* alternative dinitrogenase protein (Ludden, Davis and Shah, unpublished results). This cofactor contains no molybdenum, but will replace FeMo-co in the activation of apo-dinitrogenase (lacking FeMo-co) of the molybdenum nitrogenase. The *Rs. rubrum* alternative dinitrogenase reductase also contains homocitrate, presumably in its cofactor. The reported iron and acid-labile sulfur contents of the alternative dinitrogenase proteins are significantly less than those of the molybdenum dinitrogenase proteins and thus it is possible that they contain fewer or different clusters than the molybdenum dinitrogenase. Alternatively, it is possible that the fully active proteins contain a full complement of metal clusters, but that these clusters are more labile and thus lost during purification.

b. Gene Organization for the Alternate Nitrogenase

Among phototrophs, alternate nitrogenase systems have been genetically well-characterized only in *Rb. capsulatus*. In this organism, Klipp and coworkers (Schüddekopf et al., 1993) have used mutational analysis to identify the genes for the alternate dinitrogenase and dinitrogenase reductase as well as a number of other loci important for their function.

The region encoding the components of the alternate nitrogenase (*anfHDGK*) has been cloned and sequenced and display the greatest similarity to the *anf* genes of *Azotobacter vinelandii*. Immediately upstream of this region appears to be a homolog of *anfA* of *Azotobacter vinelandii*, suggesting that it encodes a regulator for the *anf* region. In addition to this locus, random transposon mutagenesis identified at least ten additional restriction fragments wherein insertions appear to specifically result in an **Anf**⁻ phenotype, although the nature of the encoded functions is currently unknown.

Finally, the Klipp lab has performed a rather thorough analysis of the 32 genes and open reading frames that fall in Regions A, B and C of the *nif* gene clusters noted in section IC1b, with the goal of identifying those necessary for functionality of the alternate system (Schüddekopf et al., 1993). The results indicate that the products of *nifB* and *nifV* are critical for both systems, as are those of the regulatory genes, *nifR1*, *nifR2*, and *nifR4*. Surprisingly, at least four other ORFs, scattered among the *nif*-specific genes, are also necessary for both systems, and predicted amino acid sequences suggest that the products might form a membrane complex involved in electron transport to both nitrogenase systems (Schmehl et al., 1993).

The genes for the alternate nitrogenase of *Rs. rubrum* have also been cloned, although sequence and mutational analysis have not been performed (Lehman and Roberts, 1991).

II. Regulation of Nitrogenase by Reversible ADP-ribosylation

A. Model for Regulation of Nitrogenase by Reversible ADP-ribosylation

The current understanding of the reversible ADP-ribosylation of dinitrogenase reductase in *Rs. rubrum*

MODEL FOR REGULATION OF DINITROGENASE REDUCTASE

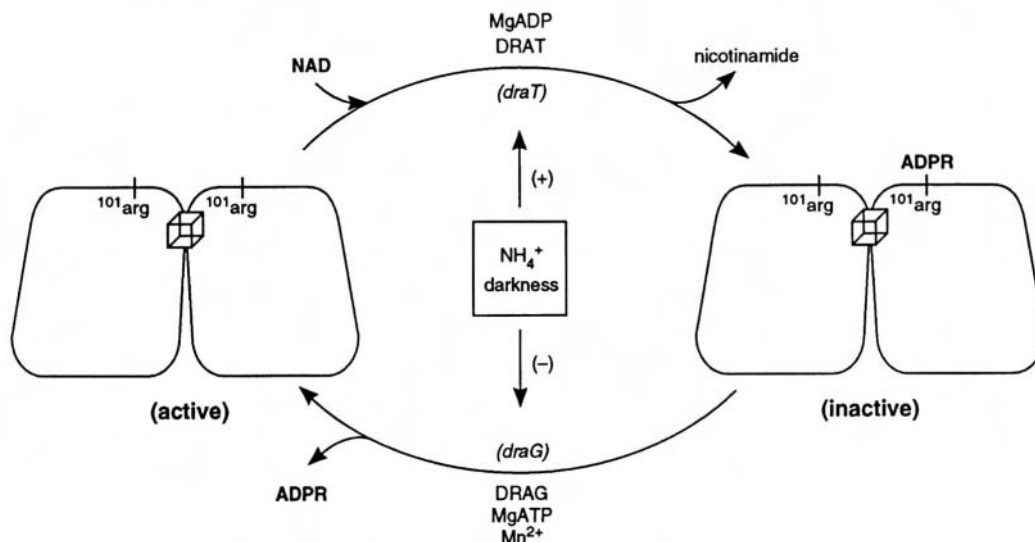

Fig. 2. Model for the reversible ADP-ribosylation of dinitrogenase reductase in *Rhodospirillum rubrum*.

and related organisms is shown in Fig. 2. In this model, active dinitrogenase reductase is inactivated by ADP-ribosylation at arg 101 through the action of dinitrogenase reductase ADP-ribosyl transferase (DRAT) in an NAD- and MgADP-dependent reaction in response to darkness or a source of fixed nitrogen. Only one of the two potential sites for ADP-ribosylation is modified at one time. When the culture is re-illuminated or the source of fixed nitrogen is depleted, ADP-ribose is removed by hydrolysis from the protein by dinitrogenase reductase activating glycohydrolase (DRAG) in a MgATP- and M²⁺-dependent reaction. Dinitrogenase reductase is activated by the removal of ADP-ribose.

B. Isolation and Identification of ADP-ribose and Effects on Dinitrogenase Reductase

Once DRAG had been discovered (Section IB above), it was possible to purify the nitrogenase from *Rs. rubrum* and to follow the purification by monitoring activity of the dinitrogenase reductase after activation. The protein was purified by methods similar to those employed for other, active dinitrogenase reductases and it had several properties and the characteristic brown color of other dinitrogenase reductases. Thus it appeared that the inactive form of dinitrogenase

reductase from *Rs. rubrum* was normal but required activation, and the hypothesis that it existed in a modified form was developed. Phosphatase-resistant phosphate was detected on the inactive protein and an analysis of the UV-visible spectrum of the protein revealed a shoulder at 265 nm that could not be explained by the known amino acid content of the enzyme (dinitrogenase reductases contain no tryptophan). Tests for adenine nucleotide and for pentoses were positive and it was concluded that the enzyme was modified by a nucleotide. Originally it was thought that the adenine moiety alone was removed upon activation (Ludden and Burris, 1979), but further studies showed that the entire nucleotide was removed upon activation (Pope et al., 1986).

The inactive form of the protein was found to migrate as two bands of equal staining intensity on SDS gels and the conversion of the slower migrating band to the single band observed for active enzyme was correlated with activation (Preston and Ludden, 1982). It was found that the band conversion could also be affected by heating the protein at pH above 8.0 (Dowling et al., 1982). This observation was applied to the isolation of the nucleotide which could be thermally released from the protein and purified by affinity chromatography on boronate affinity resin by virtue of the binding of the cis hydroxyls of the

compound to the resin (Pope et al., 1985b). Alternatively, the modified dinitrogenase reductase was treated with proteases and the peptidyl nucleotide was purified on the boronate resin. In each case, the nucleotide was further purified by HPLC.

The identity of the compound as ADP-ribose was established by mass spectrometric and NMR analyses (Pope et al., 1985a). The peptide with bound nucleotide was sequenced and found to have the sequence gly-X-gly-val-ile-thr and the amino acid analysis of the material indicated the presence of a single arginine, presumably the X component of the sequence. This sequence is highly conserved in dinitrogenase reductases and is found uniquely at positions 100–105 of the sequence (Pretorius et al., 1987). It was of immediate interest that arg101 was only 3 amino acids removed from cys98 which had been proposed as one site of ligation of the Fe_4S_4 cluster to the protein by Hausinger and Howard (1983) (cys132 being the other site of ligation). It was originally confusing why only one of the two subunits became modified, but the recent crystal structure by Georgiadis et al. (1992) shows that the two arg101 residues are close to each other near the site of interaction of the two subunits. This suggests that the reason only one subunit becomes modified is that once one site is modified, the other site is not accessible to the modifying enzyme.

The attachment of the ADP-ribose group was established as an N-glycosidic linkage to the guanidinium N of arginine by mass spectrometry (Pope et al., 1985a) and it was determined that the ADP-ribose-arginine bond in the α configuration may be cleaved by DRAG (Pope et al., 1986). However, there is mutarotation around the N-glycosidic bond and it becomes a 60:40 mixture of α : β with a $t_{1/2}$ of approximately 6 hours (Pope et al., 1987). The β anomer of the glycosidic bond is inaccessible to DRAG.

ADP-ribosylation of dinitrogenase reductase inhibits its ability to transfer electrons to dinitrogenase. The modified protein is able to bind MgATP and undergoes the conformational shift evidenced by the MgATP-dependent loss of the Fe_4S_4 center to chelators (Ludden and Burris, 1979; Ludden et al., 1982). The EPR signal of the modified protein is identical to that of the unmodified enzyme and thus, ADP-ribosylation has no observable direct effect on the Fe_4S_4 center (Ludden and Burris, 1979). The modified protein does not inhibit the ability of unmodified protein to transfer electrons to dinitro-

genase, and thus it is suggested that modification renders the protein unable to bind to dinitrogenase. Evidence in support of this was obtained when it was shown that modification of the dinitrogenase reductase from *Clostridium pasteurianum* prevented that protein from forming the tight, inhibitory complex with dinitrogenase from *Azotobacter vinelandii* that had been reported by Emerich and Burris (1976; Murrell et al., 1988). Removal of the ADP-ribose with DRAG restored the inhibition. ADP-ribosylation does not appear to block its role in FeMo-co synthesis or FeMo-co insertion, as both of these activities can be observed in vitro with the ADP-ribosylated form (Shah et al., 1988); it should be noted that it is difficult to determine if absolutely all of the dinitrogenase reductase has been ADP-ribosylated and thus it is possible that the FeMo-co synthesis and insertion activities are supported by a small amount of unmodified protein in the mixture. ADP-ribosylation of dinitrogenase reductase does not make the protein less sensitive to oxygen.

C. Isolation and Characterization of DRAG and DRAT

1. Isolation of DRAG

DRAG was the first component of the regulatory system to be identified and it was purified based on its ability to activate dinitrogenase reductase even though the mechanism of this activation was not known (Saari et al., 1984). The predominant amount of DRAG was found in the pellet fraction after high speed centrifugation of the crude extract. It has been assumed that DRAG is associated with the chromatophore membranes of the extract and this is likely the case, but it remains a possibility that DRAG is bound to some other macromolecular complex in the extract, as no further characterization of the binding has been performed. DRAG can be eluted from the pellet fraction with 0.5 M NaCl in buffer and remains stable in its soluble form (Ludden and Burris, 1976). It should not be assumed that DRAG is bound to the photosynthetic membrane in the living cell, as the ionic strength of the cell cytoplasm is likely to be sufficiently high to elute the enzyme.

The ability to elute the enzyme from the membrane with salt was employed in the purification of DRAG. Repeated washing of the enzyme with buffer removed many contaminating proteins, allowing DRAG to be eluted rather specifically and in good yield with a 30-

fold purification. Following desalting, the enzyme was further purified by chromatography on DEAE-cellulose, hydroxylapatite, reactive red agarose and finally by gel filtration on G-75 Sephadex. The enzyme was purified 12,000-fold to homogeneity and runs as a single band on SDS gels with a molecular weight of 32,000 (Saari et al., 1984). The protein migrates anomalously on gel filtration columns and early estimates gave the molecular weight of the enzyme as approximately 20 kD (Gotto and Yoch, 1982a). The correct molecular weight of the enzyme was established when the sequence of the protein was deduced from the sequence of its gene (Fitzmaurice et al., 1989); this value confirmed that obtained by SDS PAGE analysis of the purified enzyme (Saari et al., 1984).

DRAG was originally found to be very oxygen-labile and was always purified under strict anaerobic conditions, including the presence of the oxygen scavenger sodium dithionite in all buffers (Ludden and Burris, 1976; Nordlund et al., 1977; Zumft and Nordlund, 1981). More recently, it has been discovered that the enzyme is stable to oxygen provided that it is purified in the absence of sodium dithionite (Nielsen et al., 1994). Upon exposure of the dithionite-containing solution to oxygen, hydrogen peroxide is formed, to which DRAG is particularly sensitive, especially in the presence of Mn^{2+} , its metal cofactor. ADP-ribose protects the enzyme from hydrogen peroxide attack, suggesting that the damage by hydrogen peroxide occurs near the active site of the enzyme. Dithiothreitol is required for stability of the enzyme, but does not protect against the loss of DRAG activity in the presence of hydrogen peroxide and Mn^{2+} . Under anaerobic conditions, Mn^{2+} was found to increase the stability of the enzyme and thus is included in the buffers used during purification. The preferred protocol for DRAG purification calls for use of cold, degassed buffer containing Mn^{2+} but lacking dithionite.

Although ADP-ribosylated dinitrogenase reductase and DRAG are both present in crude extracts, the dinitrogenase reductase remains ADP-ribosylated because the activation reaction requires MgATP and divalent metal. The binding of Mn^{2+} to DRAG is not very tight and, upon extraction, the divalent metal is diluted away from the enzyme. Similarly, the nucleotide concentration in crude extracts is much lower than needed to lead to significant activation. Munson (1969) first noted the non-linear time course

of nitrogenase assays with crude extracts of *Rs. rubrum*, and this can now be explained as a result of the inclusion of MgATP in the assay mix. The MgATP is required for nitrogenase activity and, in the case of *Rs. rubrum* extracts, also allows activation of the enzyme.

The nucleotide involved in activation of dinitrogenase reductase by DRAG is thought to bind to the ADP-ribosylated form of dinitrogenase reductase. The interaction of MgATP with ADP-ribosylated dinitrogenase reductase was demonstrated using Walker and Mortenson's assay to follow the MgATP-dependent release of the iron-sulfur center to iron chelators (Ludden and Burris, 1979; Gotto and Yoch, 1982b). MgATP is not hydrolyzed in stoichiometric amounts during the activation of dinitrogenase reductase. MgATP is not required for the removal of ADP-ribose from the oxygen-denatured form of dinitrogenase reductase (Ludden and Burris, 1979) or from low molecular weight substrates such as the ADP-ribosylated hexapeptide obtained by protease treatment of ADP-ribosylated dinitrogenase reductase (Pope et al., 1986; Saari et al., 1986). Thus it is thought that the nucleotide exerts its effect on the process by binding to the substrate (dinitrogenase reductase) rather than to DRAG. The available evidence indicates that MgATP does not bind to DRAG, although these studies were hindered by the lack of appreciable quantities of the purified enzyme. MgADP is known to inhibit the activity of dinitrogenase reductase and it also inhibits the activation of dinitrogenase reductase by DRAG.

The free divalent metal is thought to bind directly to DRAG and play a catalytic or regulatory role in the DRAG reaction. Burns and Bulen (1966) first noted the stimulatory effect of high Mg^{2+} on the activity of crude extracts of *Rs. rubrum* and then it was discovered that low levels of Mn^{2+} provided even greater stimulation (Ludden and Burris, 1976). Guth and Burris (1983) performed a careful analysis of the stimulation of DRAG by Mg^{2+} and Mn^{2+} and came to the conclusion that the role of Mg^{2+} was to release any Mn^{2+} present in the reaction mixture for DRAG activity. Nordlund and Noren (1984) tested various metals for activity with DRAG and found that Mn^{2+} was the most effective, followed by Fe^{2+} and then Mg^{2+} . It has not been established which of these metal ions functions in vivo, and experiments with Mn-depleted medium have given ambiguous results. One mM Mn^{2+} in excess over the ATP concentration

in the assay will saturate the divalent metal requirement for DRAG (Saari et al., 1986).

The substrate specificity of DRAG has been investigated in detail. The enzyme will carry out the hydrolysis of N-glycosidic bonds and is specific for the α anomer (Pope et al., 1986). DRAG does not perform the lyase reaction reported for the enzyme that removes the terminal ADP-ribose moiety of polyADP-ribosylated histones (Oka et al., 1984). As noted above, DRAG will cleave ADP-ribose from tri- and hexapeptides purified from the protease hydrolysate of ADP-ribosylated dinitrogenase reductase with K_m s of 11–12 μM and a V_{max} equivalent to that for ADP-ribosylated dinitrogenase reductase (Pope et al., 1986; Saari et al., 1986). ADP-ribosylarginine is a very poor substrate for DRAG with a K_m of 2 mM, whereas $N\alpha$ -dansyl- $N\omega$ -ADP-ribosylarginine is a very good substrate with a K_m of 12 μM . Blocking the amino group of the arginine molecule is essential for good activity of DRAG while blocking the carboxyl group has little effect. The enzyme is non-specific with respect to the nucleotide and hydrolyzes dansylarginine-guanosine diphosphoribose as well as the ADP-ribosylated compound. However, DRAG will not cleave the N-glycosidic bonds of compounds that lack the adenosine group or analogs such as the dansylated forms of phosphoribosylarginine or ribosylarginine. The fluorescent etheno analog of ADP-ribose attached to the dansylarginine methylester (ϵ -ADPR-DAME) is an effective substrate that also provides a sensitive assay for the enzyme (Pope et al., 1987). The fluorescence of the ϵ -ADPR-DAME molecule is quenched while both the etheno adenine and the dansyl groups are attached to the same molecule, but become highly fluorescent upon cleavage. DRAG will also cleave ADP-ribose from cholera toxin-modified histones, suggesting that it will recognize ADP-ribose attached to proteins (presumably at arginine) at a variety of sequences, since the gly-arg-gly-val-ile-thr motif is not present in histones.

The K_m for the natural substrate (74 μM) of DRAG is higher than that determined for a number of the low molecular weight substrates (11–15 μM). The true K_m for ADP-ribosylated dinitrogenase reductase may be lower by one-half because the N-glycosidic bond between arginine and ADP-ribose is subject to mutarotation and, during purification, there is sufficient time for the bond to mutarotate to an approximately 60:40 mix of α and β anomers; DRAG is specific for the α linkage. A K_m of 40 μM for

ADP-ribosylated dinitrogenase reductase would be in the physiological range, as dinitrogenase reductase is estimated to be present in the cell at a concentration approaching 100 μM .

2. Isolation of DRAT

Once the modifying group for inactive dinitrogenase was identified as ADP-ribose, an NAD-dependent reaction analogous to the cholera toxin-catalyzed modification of G proteins was sought. Lowery et al. (1986) identified an activity that would transfer label from α - ^{32}P -NAD to dinitrogenase reductase. This label was susceptible to removal by DRAG, and peptide analysis revealed that arg101 was the sole and unique site of modification. Antibodies against DRAG were unreactive with the ADP-ribosyl transferase activity and it was concluded that the two activities resided on distinct gene products (Lowery and Ludden, 1988). This conclusion was confirmed biochemically when the amino terminal amino acid sequences of the DRAT and DRAG proteins were shown to be different, and genetically when the genes for the two enzymes were isolated (Fitzmaurice et al., 1989). The new enzyme was named Dinitrogenase Reductase ADP-ribosyl Transferase (DRAT) and its gene designated *draT*.

DRAT activity was found in the soluble fraction of extracts and it was found to be stable to oxygen although otherwise less stable than DRAG activity. The enzyme was purified by sequential ion exchange (DEAE cellulose), dye matrix affinity (reactive red agarose), gel filtration chromatography steps followed by ion exchange HPLC (Lowery and Ludden, 1988). Like DRAG, the enzyme is very non-abundant and a 20,000-fold purification of the enzyme was required.

DRAT uses β -NAD as the donor for ADP-ribose and releases stoichiometric amounts of nicotinamide (Lowery and Ludden, 1988). The enzyme will not transfer the ADP-ribose moiety of NADH or NADPH but will utilize etheno-NAD and nicotinamide guanine dinucleotide as donors. The only known acceptors of ADP-ribose from DRAT are the dinitrogenase reductases. The sequences of dinitrogenase reductases are remarkably conserved in nature, and the region surrounding the site of ADP-ribosylation is nearly constant. All dinitrogenase reductases tested to date have arginine at the position analogous to arg101 in the *Rs. rubrum nifH* product and are substrates for DRAT, with the exception of the dinitrogenase reductases from *Azospirillum*

amazonense (for which the sequence is not known) (Lowery and Ludden, 1988) and from mutants with changes at arg101 or immediately adjacent residues (Chang et al., 1988; Lowery et al., 1989; Lehman and Roberts, 1991; Pierrard, 1993). The alternative dinitrogenase reductase (the *anfH* gene product) from *Rs. rubrum* is reversibly modified in vivo and thus is presumed to be modified by DRAT (Lehman and Roberts, 1991). The specificity of DRAT is in marked contrast to the ability of the arginine-specific toxins to modify a wide range of proteins. DRAT exhibits no detectable NADase activity, also in contrast to the toxin ADP-ribosyl transferases and the turkey erythrocyte ADP-ribosyl transferase isolated by Moss (Watkins et al., 1987). Small molecules, including the peptide gly-arg-gly-val-ile-thr do not accept NAD from DRAT (Lowery and Ludden, 1988). The products of the reactions of DRAG, with its small molecule substrates, do not serve as acceptors. DRAT is unable to recognize oxygen-denatured dinitrogenase reductase, suggesting that a native conformation of the substrate protein is essential.

The modification of *Rs. rubrum* dinitrogenase reductase is highly dependent on the presence of ADP in the reaction mixture (Lowery and Ludden, 1989). DRAT-dependent incorporation of label from ³²P-NAD into dinitrogenase reductase can be observed, but only a small amount of the total dinitrogenase reductase protein becomes ADP-ribosylated in the absence of ADP. In the presence of ADP, it is possible to quantitatively convert dinitrogenase reductase into its ADP-ribosylated form. The measured *K_m* for NAD in the presence of ADP and saturating amounts of dinitrogenase reductase is approximately 2 mM, while the measured *K_m* for NAD under the same conditions but in the absence of ADP is at least 20-fold higher. ADP is thought to exert its effect by binding to dinitrogenase reductase rather than DRAT because DRAT will effectively modify the dinitrogenase reductase protein from *Azotobacter vinelandii* in the absence of ADP. In this case, the measured *K_m* for NAD in the absence of ADP is approximately 1 mM and 30–50 μ M in the presence of ADP.

The nucleotide requirements for DRAT and DRAG suggest a role for these nucleotides in the regulation of the DRAT/DRAG system. However, no consistent change in ATP/ADP ratio has been shown to correlate with changes in the modification status of dinitrogenase reductase in vivo (Paul and Ludden, 1984; Nordlund and Hoglund, 1986). Based on in vitro

studies, the ATP/ADP ratio that is thought to occur in vivo would seem to predict: 1) a continuous turnover of ADP-ribose on the dinitrogenase reductase protein in vivo, and 2) significant inhibition of nitrogenase activity. Neither of these predictions can be verified; in fact, the evidence shows the opposite. Perhaps there is a level of compartmentation or organization of the nitrogenase proteins and their regulators that has not yet been detected.

D. Genetic Analysis of the dra System of Regulation in Rs. rubrum and Rb. capsulatus
