Kluwer Academic Publishers

Anoxygenic Photosynthetic Bacteria

Advances in Photosynthesis

VOLUME 2

Series Editor:

GOVINDJEE

*Department of Plant Biology
University of Illinois, Urbana, Illinois, U.S.A.*

Consulting Editors:

Jan AMESZ, *Leiden, The Netherlands*
James BARBER, *London, United Kingdom*
Robert E. BLANKENSHIP, *Tempe, Arizona, U.S.A.*
Norio MURATA, *Nagoya, Japan*
Donald R. ORT, *Urbana, Illinois, U.S.A.*

Advances in Photosynthesis provides an up-to-date account of research on all aspects of photosynthesis, the most fundamental life process on earth. *Photosynthesis* is an area that requires, for its understanding, a multidisciplinary (biochemical, biophysical, molecular biological, and physiological) approach. Its content spans from physics to agronomy, from femtosecond reactions to those that require an entire season, from photophysics of reaction centers to the physiology of the whole plant, and from X-ray crystallography to field measurements. The aim of this series of publications is to present to beginning researchers, advanced graduate students and even specialists a comprehensive current picture of the advances in the various aspects of photosynthesis research. Each volume focusses on a specific area in depth.

The titles to be published in this series are listed on the backcover of this volume.

Anoxygenic Photosynthetic Bacteria

Edited by

Robert E. Blankenship

Contents

Preface

xxiii

Part I: Taxonomy, Physiology and Ecology

1	Taxonomy and Physiology of Phototrophic Purple Bacteria and Green Sulfur Bacteria	1–15
	<i>Johannes F. Imhoff</i>	
	Summary	1
	I. Introduction	1
	II. General Aspects of Taxonomy	3
	III. General Aspects of Physiology	4
	IV. Description of the Groups	5
	References	11
2	Taxonomy, Physiology and Ecology of Heliobacteria	17–30
	<i>Michael T. Madigan and John G. Ormerod</i>	
	Summary	17
	I. Introduction	18
	II. Taxonomy of Heliobacteria	19
	III. Physiology	23
	IV. Ecology and Isolation of Heliobacteria	27
	Acknowledgments	29
	References	29
3	Taxonomy and Physiology of Filamentous Anoxygenic Phototrophs	31–47
	<i>Beverly K. Pierson and Richard W. Castenholz</i>	
	Summary	32
	I. Introduction	32
	II. Taxonomy and Phylogeny	33
	III. Physiology	36
	Acknowledgment	44
	References	44
4	Ecology of Phototrophic Sulfur Bacteria	49–85
	<i>Hans Van Gemerden and Jordi Mas</i>	
	Summary	50
	I. Introduction	50
	II. Characteristic and Vertical Structure of the Habitats	50

III. Distribution and Abundance of Phototrophic Sulfur Bacteria in Nature	53
IV. Contribution of Phototrophic Sulfur Bacteria to Primary Production	56
V. Growth Rates in Nature	58
VI. Loss Processes	60
VII. Growth Balance, Maximum Biomass and Production in Phototrophic Communities	63
VIII. Environmental Factors Affecting Growth and Survival of Phototrophic Sulfur Bacteria	63
IX. Case Studies	72
X. Concluding Remarks	78
Acknowledgments	79
References	79
5 Ecology of Thermophilic Anoxygenic Phototrophs	87–103
<i>Richard W. Castenholz and Beverly K. Pierson</i>	
Summary	87
I. Introduction	88
II. Chemical and Geographical Diversity of Thermal Habitats	93
III. Principal Habitats of Thermophilic Anoxygenic Phototrophs and the Environmental Requirements: Case Studies	94
References	101
6 Aerobic Anoxygenic Phototrophs	105–122
<i>Keizo Shimada</i>	
Summary	105
I. Introduction	106
II. Habitats and Culture	106
III. Photosynthetic Apparatus	108
IV. Pigments and Other Components	111
V. Photosynthetic Activity and Electron Transfer System	113
VI. Regulation of Pigment Synthesis	116
VII. Evolution and Taxonomy	118
Acknowledgments	120
References	120
7 Bacteriochlorophyll-Containing <i>Rhizobium</i> Species	123–136
<i>Darrell E. Fleischman, William R. Evans and Iain M. Miller</i>	
Summary	124
I. Introduction	124
II. Relationship of Bacteriochlorophyll-containing <i>Rhizobium</i> Species to Other Bacteria	126
III. Characteristics of <i>Aeschynomene Rhizobium</i> BTAi 1 Grown <i>ex planta</i>	127
IV. Characteristics of Photosynthetic <i>Rhizobium</i> in the Symbiotic System	131
V. Conclusions	134
Acknowledgments	135
References	135

Part II: Molecular Structure and Biosynthesis of Pigments and Cofactors

8	Biosynthesis and Structures of the Bacteriochlorophylls	137–151
	<i>Mathias O. Senge and Kevin M. Smith</i>	
	Summary	137
	I. Introduction	137
	II. Structural Chemistry of the Bacteriochlorophylls	138
	III. Biosynthesis of the Bacteriochlorophylls	141
	IV. Degradation of the Bacteriochlorophylls	149
	Acknowledgments	149
	References	149
9	Biosynthesis and Structures of Porphyrins and Hemes	153–177
	<i>Samuel I. Beale</i>	
	Summary	153
	I. Introduction	154
	II. The Early Common Steps	154
	Acknowledgments	170
	References	170
10	Lipids, Quinones and Fatty Acids of Anoxygenic Phototrophic Bacteria	179–205
	<i>Johannes M. Imhoff and Ursula Bias-Imhoff</i>	
	Summary	180
	I. Introduction	180
	II. Polar Lipids and Fatty Acids	183
	III. Apolar Lipids	198
	References	201

Part III. Membrane and Cell Wall Architecture and Organization

11	Anoxygenic Phototrophic Bacteria: Model Organisms for Studies on Cell Wall Macromolecules	207–230
	<i>Jürgen Weckesser, Hubert Mayer and Georg Schulz</i>	
	Summary	208
	I. Introduction	208
	II. Definition, Function, and Constituents of the Cell Wall	208
	III. Phylogenetic Relevance of Cell Wall Constituents	209
	IV. Structure of Lipopolysaccharide (LPS)	217
	V. Contribution of the Lipopolysaccharides (LPS) of Purple Bacteria to Endotoxin Research	219
	VI. Porin	221
	VII. External Envelope Layers	222
	VIII. Concluding Remarks	223
	References	226

12	Structure, Molecular Organization, and Biosynthesis of Membranes of Purple Bacteria	231–257
	<i>Gerhart Drews and Jochen R. Golecki</i>	
	Summary	231
	I. Introduction	232
	II. Structure and Supramolecular Organization of Cytoplasmic and Intracytoplasmic Membranes	233
	III. Biosynthesis of Membranes and the Assembly of the Functional Complexes of the Photosynthetic Apparatus	242
	Acknowledgments	251
	References	251
13	Membranes and Chlorosomes of Green Bacteria: Structure, Composition and Development	259–278
	<i>Jürgen Oelze and Jochen R. Golecki</i>	
	Summary	259
	I. Introduction	260
	II. Ultrastructure	260
	III. Chemical Composition	264
	IV. Supramolecular Organization of Chlorosomes	267
	V. Development of the Photosynthetic Apparatus	268
	VI. Open Questions	274
	Acknowledgments	275
	References	275
14	Organization of Electron Transfer Components and Supercomplexes	279–295
	<i>André Verméglio, Pierre Joliot and Anne Joliot</i>	
	Summary	279
	I. Introduction	280
	II. The Versatile Metabolism of the Rhodospirillaceae	281
	III. Regulation of the Biosynthesis of the Electron Transfer Components	282
	IV. Short Term Interactions Between Photosynthetic and Respiratory Activities	284
	V. Organization of the Electron Carrier Proteins into Supercomplexes	287
	References	292

Part IV: Antenna Structure and Function

15	Theory of Electronic Energy Transfer	297–313
	<i>Walter S. Struve</i>	
	Summary	297
	I. Introduction	298
	II. The Weak Coupling Limit	298
	III. Unified Theory for Energy Transfer	303
	IV. Temperature Dependence of Energy Transfer	309
	Acknowledgments	312
	References	312

16	Structure and Organization of Purple Bacterial Antenna Complexes	315–348
	<i>Herbert Zuber and Richard J. Cogdell</i>	
	Summary	316
	I. Structure and Function of Antenna Complexes from Purple Bacteria	316
	II. Structure and Function of Antenna Polypeptides from Purple Bacteria. General Aspects	320
	III. Amino Acid Sequences (Primary Structure) of Antenna Polypeptides. Sequence Homologies, Structural and Functional Features	321
	IV. Structural and Functional Variability of the Antenna Polypeptides and Pigments within the Antenna Complex	328
	V. Possible Structural Organization of Polypeptides and BChl Molecules in the Antenna Complex Derived from Primary Structure Data (Primary Structure Models): Considerations on the Three-Dimensional Structure of Antenna Complexes	331
	Note Added in Proof	342
	Acknowledgments	344
	References	344
17	Kinetics of Excitation Transfer and Trapping in Purple Bacteria	349–372
	<i>Villy Sundström and Rienk van Grondelle</i>	
	Summary	349
	I. Introduction	350
	II. Pigment-Protein Organization in LH1 and LH2	350
	III. Spectroscopy of the LH1 and LH2 Light-Harvesting Antennae	352
	IV. Energy Transfer in LH2-Less Purple Bacteria	356
	V. Energy Transfer in LH2-Containing Purple Bacteria	361
	VI. Energy Transfer in Isolated Light-Harvesting Complexes and Mutants	363
	References	366
18	Singlet Energy Transfer from Carotenoids to Bacteriochlorophylls	373–384
	<i>Harry A. Frank and Ronald L. Christensen</i>	
	Summary	373
	I. Introduction	374
	II. The Electronic Structure of Carotenoid Excited States	374
	III. The Dynamics of Carotenoid Excited States	378
	IV. Implications for Energy Transfer	380
	Acknowledgments	381
	References	382
19	Coupling of Antennas to Reaction Centers	385–398
	<i>Arvi Freiberg</i>	
	Summary	385
	I. Introduction	386
	II. The Concept of a Photosynthetic Unit	386
	III. Structure and Organization of Real Photosynthetic Systems	387
	IV. Trapping of Energy by the Reaction Center	388
	V. Detrapping of Excitation Energy from the Reaction Center	391
	VI. Pigment-Protein Couplings According to High Hydrostatic Pressure Studies	393
	VII. Concluding Remarks	395
	Acknowledgments	396
	References	396

20	Antenna Complexes from Green Photosynthetic Bacteria	399–435
	<i>Robert E. Blankenship, John M. Olson and Mette Miller</i>	
	Summary	400
	I. Introduction	400
	II. Chlorosome Composition	401
	III. In vitro Aggregates of Chlorosome Chlorophylls	408
	IV. Spectroscopic Probes of Chlorosome Structure	410
	V. Structural Models for Pigment and Protein Organization in Chlorosomes	413
	VI. Kinetics and Pathways of Energy Transfer in Chlorosomes	418
	VII. The Fenna-Matthews-Olson (FMO) Bacteriochlorophyll <i>a</i> Protein	422
	VIII. Redox Modulation of Energy Transfer in Green Photosynthetic Bacteria	426
	IX. Evolutionary Considerations	427
	Acknowledgments	428
	References	428
21	Structure-Function Relationships in Core Light-Harvesting Complexes (LHI) As Determined by Characterization of the Structural Subunit and by Reconstitution Experiments	437–471
	<i>Paul A. Loach and Pamela S. Parkes-Loach</i>	
	Summary	438
	I. Introduction	439
	II. The Structural Subunit of LHI	440
	III. Reconstitution of Subunit Complexes and LHI from Separately-Isolated Components	449
	IV. Probing the BChl Binding Site by Reconstitution with BChl Analogs	452
	V. Reconstitution of Car to Form Wild-Type LHI with BChl <i>a</i> and Polypeptides of <i>Rb. sphaeroides</i> and <i>Rs. rubrum</i>	454
	VI. Reconstitution of LHI-type Complexes Using Mixed Polypeptides	456
	VII. Probing Structural Requirements for Formation of the Subunit Complex and LHI by Reconstitution with Modified Polypeptides	457
	VIII. Analysis of Stabilizing Interactions in Subunit Complexes	459
	IX. Analysis of Stabilizing Interactions in LHI	460
	X. Implications for the Structure of the Subunit Complexes	461
	XI. Minimal Structural Requirements to Form LHI	464
	XII. Interaction of LHI with RC	466
	Acknowledgments	467
	References	467
22	Genetic Manipulation of the Antenna Complexes of Purple Bacteria	473–501
	<i>C. Neil Hunter</i>	
	Summary	473
	I. Introduction	474
	II. The Effect of Genetic Alteration of Antennas on the Morphology of Intracytoplasmic Membranes	478
	III. The Use of LH1-Only and LH1-RC Mutants to Facilitate Biochemical and Structural Studies	478
	IV. The Use of Antenna Mutants to Simplify Spectroscopic Studies of Antenna Complexes in a Membrane Environment	480
	V. Site-Directed Mutagenesis of Bacterial Light Harvesting Complexes	487
	VI. Heterologous Expression of LH Genes in <i>Rhodobacter sphaeroides</i>	495
	VII. Concluding Remarks	495
	References	496

Part V: Reaction Center Structure, Electron and Proton Transfer Pathways

23	The Structures of Photosynthetic Reaction Centers from Purple Bacteria as Revealed by X-Ray Crystallography	503–526
	<i>C. Roy D. Lancaster, Ulrich Ermler and Hartmut Michel</i>	
	Summary	503
	I. Introduction	504
	II. Structural and Functional Overview	505
	III. Arrangement of the Cofactors	506
	IV. The Structure of the Protein Subunits	508
	V. Cofactor Conformation and Protein-Cofactor Interactions	512
	VI. The Structure of Mutant Reaction Centers	521
	VII. Conclusions	523
	References	523
24	The Pathway, Kinetics and Thermodynamics of Electron Transfer in Wild Type and Mutant Reaction Centers of Purple Nonsulfur Bacteria	527–557
	<i>Neal W. Woodbury and James P. Allen</i>	
	Summary	528
	I. Introduction	528
	II. The Reaction Center of <i>Rhodobacter sphaeroides</i>	529
	III. Reaction Center Mutants	531
	IV. The Ground State Optical Spectrum of Reaction Centers	532
	V. The Spectral and Kinetic Properties of P*	533
	VI. The State P*	538
	VII. The Product of Initial Charge Separation	540
	VIII. Electron Transfer to the Primary Quinone	542
	IX. Electron Transfer from the Primary to Secondary Quinone	543
	X. The Thermodynamics of Reaction Center Electron Transfer	543
	XI. Reaction Center Symmetry and the Direction of Electron Transfer	545
	XII. The Pathway and Mechanism of Initial Electron Transfer	547
	XIII. The Role of the Reaction Center Protein in Electron Transfer	551
	Acknowledgments	552
	References	552
25	Theoretical Analyses of Electron-Transfer Reactions	559–575
	<i>William W. Parson and Arieh Warshel</i>	
	Summary	559
	I. Introduction	560
	II. Phenomenological Descriptions of Electron-Transfer Reactions	562
	III. Microscopic Calculations of Electron-Transfer Parameters	564
	Acknowledgments	572
	References	572

26	Proton-Coupled Electron Transfer Reactions of Q_B in Reaction Centers from Photosynthetic Bacteria	577–594
	<i>M. Y. Okamura and G. Feher</i>	
	Summary	577
	I. Introduction	578
	II. Structure of the Bacterial Reaction Center Near the Q_B Site	579
	III. The Quinone Reduction Cycle	580
	IV. Properties of the Quinones	581
	V. Effects of Site-Directed Mutagenesis on Electron and Proton Transfer Rates	583
	VI. Mechanism of Proton Coupled Electron Transfer	587
	VII. Pathways for Proton Transfer	589
	Note Added in Proof	590
	Acknowledgements	590
	References	590
27	The Recombination Dynamics of the Radical Pair P^+H^- in External Magnetic and Electric Fields	595–626
	<i>Martin Volk, Alexander Ogrodnik and Maria-Elisabeth Michel-Beyerle</i>	
	Summary	596
	I. The Magnetic Field Effect	596
	II. Temperature Dependent Recombination Dynamics of P^+H^- in Native RCs of Various Photosynthetic Bacteria	598
	III. The Effect of Genetic Mutations on the Recombination Dynamics of P^+H^-	611
	IV. Recombination Dynamics of P^+H^- in an External Electric Field	612
	V. Observation of the Recombination Dynamics of P^+H^- in Delayed Fluorescence: Evidence for an Energetic Inhomogeneity of P^+H^-	615

	V. Electrochemically-Induced FTIR Difference Spectra	634
	VI. Vibrational Modes of the Quinones and Their Host Sites	635
	VII. RC-Associated Cytochromes	642
	VIII. Conclusions	643
	Acknowledgments	643
	References	644

29	Bacterial Reaction Centers with Modified Tetrapyrrole Chromophores <i>Hugo Scheer and Gerhard Hartwich</i>	649–663
	Summary	649
	I. Introduction	650
	II. Selectivity of the Exchange	650
	III. Static Spectroscopy of Reaction Centers with Modified Pigments	655
	IV. Stabilization	658
	V. Time-Resolved Spectroscopy	658
	VI. Open Problems and Outlook	659
	Appendix: Updated Procedure for Pigment Exchange	659
	Acknowledgments	660
	References	660
 30	 The Reaction Center from Green Sulfur Bacteria <i>Ute Feiler and Günter Hauska</i>	 665–685
	Summary	666
	I. Introduction	666
	II. Composition of the Reaction Center	667
	III. Electron Transfer Within the Reaction Center	670
	IV. Genes Encoding Reaction Center Proteins	675
	V. Comparison with Other Reaction Centers	678
	VI. Conclusions	681
	Acknowledgments	681
	References	682
 31	 The Antenna-Reaction Center Complex of Heliobacteria <i>Jan Amesz</i>	 687–697
	Summary	687
	I. Introduction	688
	II. Pigments and Spectral Properties	688
	III. The Primary Electron Donor and the Antenna-Reaction Center Complex	689
	IV. The Primary Charge Separation	691
	V. Transfer and Trapping of Excitation Energy	692
	VI. Secondary Electron Transport	693
	VII. Concluding Remarks	694
	References	695
 32	 Biochemical and Spectroscopic Properties of the Reaction Center of the Green Filamentous Bacterium, <i>Chloroflexus aurantiacus</i> <i>Reiner Feick, Judith A. Shiozawa and Angelika Ertlmaier</i>	 699–708
	Summary	699
	I. Introduction	700
	II. Biochemical Composition of the <i>Chloroflexus aurantiacus</i> Reaction Center	700
	III. Structure-Function Relationships of the RC Complex	702
	IV. The Primary Photochemistry	704
	V. Summary and Conclusions	706
	Acknowledgments	706
	References	706

Part VI: Cyclic Electron Transfer Components and Energy Coupling Reactions

33	Cytochrome Biogenesis	709–723
	<i>Robert G. Kranz and Diana L. Beckman</i>	
	Summary	709
	I. Introduction: Topological and Biosynthetic Distinctions Among Cytochromes	710
	II. Transport of Apocytochromes to the Appropriate Subcellular Locations	711
	III. Components Required Specifically for Cytochrome <i>c</i> Biogenesis	712
	IV. Synthesis of <i>c</i> -Type Cytochromes in Other Bacteria and in Eukaryotes: Analogous Components	717
	V. Future Directions	721
	Acknowledgments	721

Preface

The editors are proud to present *Anoxygenic Photosynthetic Bacteria* to students and researchers in the field of photosynthesis. We feel that this book will be the definitive volume on non-oxygen evolving photosynthetic bacteria for years to come, as it is literally loaded with the most recent information available in this field. Contributors were given the freedom to develop topics in depth, and although this has led to a lengthy volume, readers can be assured that nothing of significance in the field of anoxygenic photosynthetic bacteria has been neglected.

We have organized the book along ten major themes: (1) Taxonomy, physiology and ecology, (2) Molecular structure of pigments and cofactors, (3) Membrane and cell wall structure, (4) Antenna structure and function, (5) Reaction center structure and electron/proton pathways, (6) Cyclic electron transfer, (7) Metabolic processes, (8) Genetics, (9), Regulation of gene expression, and (10) Applications. For each theme, several chapters, written by leading experts in the field, combine to paint a detailed picture of the current state of affairs of research in that area. The editors have also tried to provide ample cross-references between chapters to help guide the reader to all of the coverage on a particular topic.

The last time a comprehensive volume on anoxygenic photosynthetic prokaryotes was published was in 1978. This was the landmark volume *The Photosynthetic Bacteria*, edited by R. K. Clayton and W. R. Sistrom, and published by Plenum Press in New York. That book brought together in one place the state of current knowledge on the ecology, physiology, taxonomy, ultrastructure, biochemistry, biophysics and genetics of this diverse group of bacteria. As a testament to its value as a reference book, every copy of *The Photosynthetic Bacteria* that any of the three editors of the present volume have ever seen was tattered from years of almost constant use and stained with coffee and cell extracts of various colors. *The Photosynthetic Bacteria* had a

tremendous impact on a generation of scientists in many disciplines and will remain a classic for many years to come.

Thus it was with some trepidation that we undertook what was in essence the same task that faced Clayton and Sistrom 17 years earlier. The field has changed dramatically in that time in nearly every one of the areas mentioned above, perhaps most noticeably in the area of genetics and related topics. A single chapter on this subject sufficed in 1978, whereas 14 of the 62 chapters in the present volume have 'gene' or 'genetic' in the title and nearly every chapter makes use of information obtained using mutants.

Another area of bacterial photosynthesis that has seen tremendous progress in 17 years is structural studies. There is only one protein structure determined using X-ray diffraction that appears as a figure in the 1978 volume, whereas dozens of structural figures are included in this volume, including reaction centers, antenna complexes, electron transfer proteins and porins. An even more dramatic difference is that there is only a single, partial amino acid sequence in the 1978 volume, while there are literally hundreds of sequences in this book. The emphasis in every area covered in this book, from taxonomy and ecology all the way to biophysics has continually shifted more and more toward analysis at the molecular level.

This is the second volume in a series titled 'Advances in Photosynthesis,' with Govindjee as the series editor. The series provides an up to date account of all aspects of the process of photosynthesis. A statement of the scope of the series and a list of previous and upcoming titles can be found on the back cover.

We would like to dedicate this volume to Howard Gest, who is unquestionably the father of modern research involving photosynthetic bacteria. He has also greatly influenced the careers of each of the editors as either a collaborator, mentor or colleague and to all of us as a friend.

Special thanks go to Larry Orr, without whose

extraordinary talents and hard work this effort could never have come to fruition. Larry prepared all the camera ready copy and is primarily responsible for the layout and 'look' of the book.

Finally, we thank our wives, Liz, Nancy and Chris and children, Larissa, Sam, Scott and Kevin for their patience and understanding of the time needed to complete this volume.

B

C

D

Color Plate 1. (A) Section through a microbial mat consisting of a top cover of the cyanobacterium *Synechococcus* overlaid by *Chloroflexus*. The cut is about 15 cm across and the water temperature ~60 °C. This is the source of *Chloroflexus aurantiacus*, strain OK-70-f, Kahneeta Hot Springs, Oregon. (B) Upper limits of *Chloroflexus* as a distinct undermat at ~68 °C. The outflow from the spring is at about 73 °C, and the siliceous sinter is dominated by *Synechococcus* until the edges cool to about 68 °C where the *Chloroflexus* undermat accretes (more orange on photograph). Buffalo Spring, White Creek drainage, YNP. (C) *Chloroflexus* as a photoautotroph (orange-red streamers) growing at a temperature of ~ 64–62 °C on primary sulfide in Badstofuhver, Hveragerdi, Iceland. The sulfide is quite depleted by about 62 °C, at which point the green mat of the cyanobacterium, *Chlorogloeopsis* 'high temperature form' (formerly referred to as *Mastigocladus* 'HTF') appears (see Castenholz, 1973a). (D) *Heliothrix oregonensis* as an aerotolerant mat above a deep green cyanobacterial layer in a non-sulfidic Kahneeta hot spring (Oregon); temperature ~ 50 °C. (See Chapter 5, pp 89–90, Figs. 1–4.)

CPI

A

B

C

Color Plate 2. (A) *Chlorobium tepidum* mat (green cover) in highly sulfidic 'Travelodge Stream', Rotorua, New Zealand. The temperature is 45 °C in the foreground, with a pH usually in the range of 5.3–6.2 (see Castenholz et al., 1990). (B) Facultatively anoxygenic *Oscillatoria* cf. *amphigranulata* in small sulfidic spring WH-1 (Cirque-1), Whakarewarera, New Zealand. Temperature at the grey-green edge of the cyanobacterium was ~56 °C. *Thiobacillus*-like whitish-yellow streamers occurred upstream to about 68 °C (see Castenholz, 1976). (C) Inverted *Chloroflexus* mat at about 61–62 °C in Ystihver Stream, Húsavík, North Iceland. The primary sulfide which supports the photoautotrophic *Chloroflexus* is lowered within the mat, so that an underlayer of oxygenic cyanobacteria (*Chlorogloeopsis* 'high temperature form') occurs at about 1 mm below the *Chloroflexus* (see Jørgensen and Nelson, 1988). (See Chapter 5, pp. 92–98, Figs. 5, 6, 8.)

A

B

Color Plate 3-Upper. (A) Exposed *Chromatium tepidum* in a nighttime view of a 45–48 °C mat of Hunter’s Hot Springs, Oregon. In daytime the *Chromatium* forms an underlayer beneath the brownish-red cyanobacterium *Oscillatoria terebriformis*, which descends below the *Chromatium* at night (see Richardson and Castenholz, 1987). (B) Daytime view of the same area as (A), with *O. terebriformis* forming the mat surface, but with *Chromatium* swarming into the water in the can which is open at both ends, but which had been darkened by a top lid a few hours earlier. (See Chapter 5, p. 100, Figs. 10–11.)

A

B

Color Plate 3-Lower. (A) Phase contrast optical microscope image of Nile Blue stained cells of *Bacillus cereus*. (B) Same as A, but activated by 450 nm light showing specific fluorescence of PHA. Spores do not fluoresce and note that not all cells contain PHA. This is a very specific reaction and can give a quantitative measure of PHA from fluorescence intensity. (See Chapter 60, p. 1247, Fig. 1.)

Color Plate 4. Structure representations of porins from *Rhodospseudomonas blastica* and *Rhodobacter capsulatus*; (A) Space-filling model of the porin from *Rp. blastica* DSM 2131 as established at 2.0 Å resolution (Kreusch et al., 1994). The view is perpendicular to the membrane plane, the three pore eyelets are clearly visible. Hydrogens are not considered in this model. (B) Secondary structure of one subunit of the major porin from *Rb. capsulatus* 37b4 as viewed from the threefold symmetry axis. The external medium is at the top, the periplasm at the bottom. The 16 β -strands are given by blue arrows and the 3 short α -helices by orange helices. The long 43-residue loop inserting into the barrel is obvious. The interface part of the barrel is rather low while the membrane-facing part is high. The 'rough' barrel end at the top and the 'smooth' barrel end at the bottom can be visualized clearly. (See Chapter 11, p. 224, Fig. 9.)

Color Plate 5. (Continued from Color Plate 4.) (C) Color-coded projection of one subunit from the *Rb. capsulatus* 37b4 porin onto the membrane plane. Aromatic side chains are yellow; positively and negatively charged side chains are red and dark blue, respectively. The interface and the threefold symmetry axis are at the bottom. Obviously, the rim of the pore eyelet is lined by positively charged side chains protruding from the interface area of the barrel juxtaposed to negatively charged side chains from the 43-residue loop running into the barrel interior. Most likely these charges form an electric field that facilitates permeation of polar solutes and hinders nonpolar ones. (D) Detail of the construction of the pore eyelet of the *Rb. capsulatus* porin. The amino acid residues are given in the usual color code, the fixed water molecules by crosses and the calcium ions by balls. Hydrogen bonds are indicated by dashed lines. 'Fixation' of the water molecules means that they are clearly visible in the X-ray structure analysis at the high resolution of 1.8 Å. This implies that water molecules are accommodated at the water positions most of the time. Still, these water molecules can move away. It should be noted that there is a defined network of hydrogen bonded water molecules at the eyelet leaving a rather small nonstructured cross-section in the center. (See Chapter 11, p. 224, Fig. 9.)

A

B

Color Plate 6. (A) Cytoplasmic view of the LH2 antenna complex from *Rhodospseudomonas acidophila*. The protein is shown in purple, with BChl molecules in green and carotenoid in yellow. For further details see McDermott et al. (1995). (B) The LH2 complex from *Rhodospseudomonas acidophila* viewed perpendicular to the symmetry axis. The periplasmic surface of the membrane is at the top and the cytoplasmic surface is at the bottom. The α helical parts of the protein are shown as purple ribbons. BChl B850 molecules are shown in red, with B800 molecules in green and carotenoids in yellow. For further details see McDermott et al. (1995). (See Chapter 16, p. 343, Figs. 21–22.)

A

B

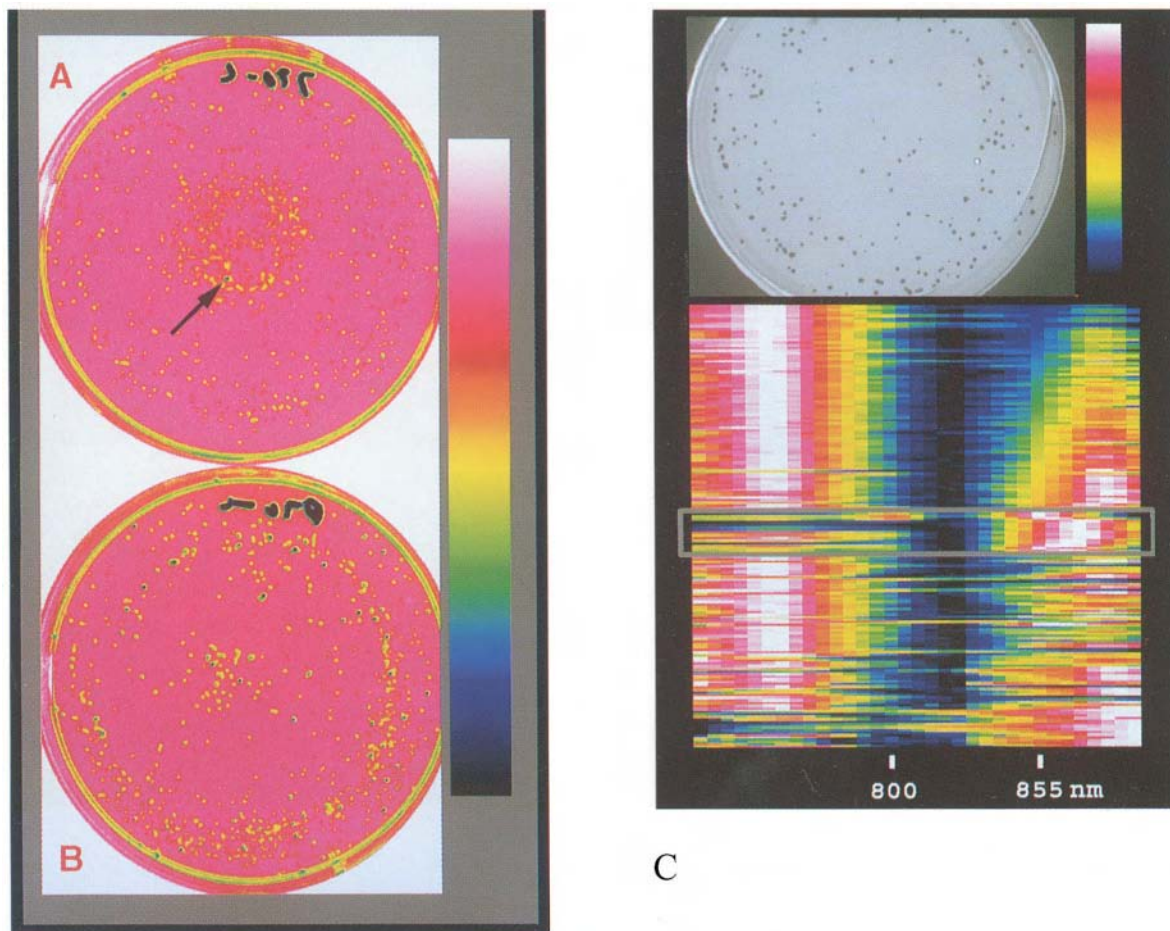

Color Plate 7. (A) The photosynthetic reaction center from *Rp. viridis*. The protein subunits are depicted in form of a smoothed ribbon diagram with the C subunit in green, the L subunit in brown, the M subunit in blue, and the H subunit in purple. The cofactors are represented as atomic models with carbon atoms in yellow, nitrogen atoms in blue, oxygen atoms in red, and magnesium and iron atoms in grey. Figs. 1, 2, 10, and 11 were generated with the computer program package O (Jones et al., 1991). (B) Superposition of the reaction center cofactors from *Rp. viridis* (green) and *Rb. sphaeroides* (red). The phytyl side chains of the bacteriochlorophyll and bacteriopheophytin molecules have been omitted for the sake of clarity. (See Chapter 23, p. 507, Figs. 1–2.)

Color Plate 8-upper. Orthogonal views of the Q_B site: Six different structures are superimposed. The color coding is as follows: Q282 (multi-colored: carbon atoms are yellow, nitrogen atoms are blue, oxygen atoms are red), 1PRC (green), 2RCR (dark blue), 4RCR (brown), 1PSS (light blue) and 1PCR (purple). The dashed red lines indicate hydrogen bonds in the Q282 structure. (See Chapter 23, p. 517, Fig. 10.)

Color Plate 8-lower. The 'water chain' from the cytoplasm to the Q_B site in the reaction centers of *Rp. viridis* (left) and *Rb. sphaeroides* (right), respectively. The protein backbones of the subunits are displayed in green, the water molecules in red. Also shown are the Q_B molecules and the protonatable amino acid residues lining the 'water chain'. (See Chapter 23, p. 520, Fig. 11.)

Color Plate 9. Pseudocolored image of bacterial colonies expressing mutagenized LHII complexes, taken at 860 nm, wherein TSM and conventional CCM are compared. (A) shows a spread of colonies from the conventional seven site CCM library with one positive colony (indicated by the arrow). This was the only positive colony observed in a set of similar spreads totaling approximately 4000 colonies. (B) shows a typical spread from the analogous TSM library. Approximately 6% of the colonies are classified as positive. Images were recorded using a radiometrically calibrated CCD camera. Gray scale values were rescaled and linearly mapped to pseudocolors to enhance the differences in optical density, i.e., higher ODs are mapped to darker pseudocolors. (C) Color contour map showing the spectral diversity of a seventeen site combinatorial library affecting amino acid residues near the β -subunit BChl (dimer) binding site. The upper left panel shows a monochrome image taken at 400 nm of a typical spread of colonies. The upper right hand panel shows a color bar; black corresponds to the lowest absorbance and white corresponds to the highest absorbance. The lower panel is a color contour map generated by DIS where the horizontal axis corresponds to wavelength (730–890 nm) and the vertical axis is colony number. Each horizontal row represents a spectrum encoded by pseudocolor. Spectra of BChl binding mutants are enclosed in the gray box. Mutants are displayed in ‘full deflection’ mode so each row scales from black to white. Nine percent of the colonies (15 out of 168) were judged to assemble LH antennae. Several categories of spectra are observed: 1) pseudo WT (i.e., dimer peak at 855 nm, monomer peak at 800 nm), 2) pseudo-WT mutants with a 5 nm red shift of the dimer band, 3) pseudo-LHI (i.e., 10–15 nm shift of the dimer band and reduced or missing monomer peak), 4) a mutant showing a single peak at 855 nm, and 5) mutants absorbing mainly at 760 nm (due to free BChl in the membrane) which are classified as ‘nulls’. (See Chapter 61.)

Color Plate 10. Correlation of sequence data with spectra from a combinatorial mutagenesis experiment on LHII near the β -subunit BChl (monomer) binding site. This color contour map is displayed in 'absolute' mode with the highest absorbance on the image set to white (OD = 0.72) and the lowest absorbance on the image set to black (OD = 0.05). The top spectra is WT which shows stronger absorption than these mutants. The amino acid sequence for each mutant is displayed to the right of its spectrum. Only amino acids different from the WT sequence are listed. The position indicated in red did not include the WT Tyr in the target set. (See Chapter 61.)

Chapter 1

Taxonomy and Physiology of Phototrophic Purple Bacteria and Green Sulfur Bacteria

Summary

Anoxygenic phototrophic bacteria have always attracted scientists because of their coloration and ability to perform photosynthesis in the absence of air and without producing oxygen. Despite this common feature of these bacteria, variation in morphological, physiological and molecular properties, including molecular structures of the photosynthetic pigments and the photosynthetic apparatus, is great. This chapter will give a short introduction into the diversity of green sulfur and phototrophic purple bacteria, list some important properties of the species, and indicate important physiological features.

I. Introduction

The most striking and common property of all purple and green phototrophic bacteria is their ability to carry out anoxygenic photosynthesis on the basis of bacteriochlorophyll mediated processes. The various anoxygenic phototrophic bacteria contain several types of bacteriochlorophylls and a variety of carotenoids as pigments, which function in the transformation of light into chemical energy and give cultures a distinct coloration varying with the pigment content from various shades of green, yellowish-green, brownish-green, brown, brownish-red, red, pink, purple, and purple-violet to even blue (carotenoidless mutants of some species containing

bacteriochlorophyll *a*). Characteristic absorption maxima of bacteriochlorophylls and major carotenoid groups of anoxygenic phototrophic bacteria are shown in Tables 1 and 2. Photosynthesis in anoxygenic phototrophic bacteria depends on oxygen-deficient conditions, because synthesis of the photosynthetic pigments is repressed by oxygen (bacteria like *Erythrobacter longus* are exceptions to this rule). Unlike cyanobacteria (including *Prochloron* and related forms) and eukaryotic algae, anoxygenic phototrophic bacteria are unable to use water as an electron donor and oxygen is not produced. They use only one photosystem and require electron donors of lower redox potential than water. Most characteristically, sulfide and other reduced sulfur

Table 1. Characteristic absorption maxima of different bacteriochlorophylls in living cells^a

Bacteriochlorophyll	Esterifying alcohol ^b	Characteristic absorption maxima (nm)
<i>a</i>	P,Gg	375, 590, 800-810, 830-890
<i>b</i>	P,Gg ^c	400, 605, 835-850, 1015-1035
<i>c</i>	F ^d	335, 460, 745-760
<i>d</i>	F	325, 450, 725-745
<i>e</i>	F	345, 450-460, 715-725
<i>g</i>	F	370, 419, 575, 670, 780-790

^a Data are collected from Brockmann and Lipinski (1983), Gloe et al. (1975), Michalski et al. (1987) and Pfennig (1978).

^b Esterifying alcohol: P, phytol; Gg, geranylgeraniol; F, farnesol.

^c In *Ectothiorhodospira halochloris* and *Ectothiorhodospira abdelmalekii* phytadienol was found (Steiner et al., 1981; also R. Steiner, personal communication).

^d In *Chloroflexus aurantiacus* a straight-chain aliphatic stearyl alcohol (C-18) is esterified to the propionic acid side chain (Gloe and Risch, 1978).

Table 2. Major carotenoid groups of anoxygenic phototrophic bacteria^a

Biosynthetic group	Major components
Normal spirilloxanthin series	Lycopene, rhodopin, spirilloxanthin
Rhodopinal series	Lycopene, lycopenal, lycopenol, rhodopin, rhodopinal, rhodopinol
Alternative spirilloxanthin series	Hydroxyneurosporene, spheroidene, spheroidenone (spirilloxanthin)
Okenone series	Okenone
Isorenieratene series	β -Carotene, isorenieratene
Chlorobactene series	γ -Carotene, chlorobactene

^a Data are taken from Schmidt (1978).

compounds, but also hydrogen and a number of small organic molecules, are used as photosynthetic electron donors. Quite recently even growth with reduced iron as electron donor has been demonstrated with some phototrophic purple bacteria (Widdel et al., 1993).

Besides this common theme of photosynthesis, anoxygenic phototrophic bacteria are an extremely heterogeneous eubacterial group, on the basis of morphological, physiological and molecular data. According to their phenotypic properties we distinguish between the green sulfur bacteria, the green nonsulfur bacteria, the purple sulfur bacteria, the purple nonsulfur bacteria and the heliobacteria. On the basis of 16S rRNA analyses major eubacterial groups have been defined (Woese et al., 1985a). Among these, one is represented by the cyanobacteria, one by the green sulfur bacteria, one by *Chloroflexus* and 'relatives', and one by the phototrophic purple bacteria and their 'relatives'. On the basis of their 16S rRNA, the recently discovered *Heliobacterium*

chlorum (Gest and Favinger, 1983) and *Heliobacillus mobilis* (Beer-Romero et al., 1988) do not fit into the aforementioned groups, but are related to certain Gram-positive bacteria (Woese et al., 1985c; Beer-Romero and Gest, 1987). Heliobacteria are considered in Chapter 2 by Madigan and Ormerod.

A quite remarkable group of bacteria, containing bacteriochlorophyll, but unable to grow phototrophically under anaerobic conditions, is represented by a number of Gram-negative aerobic marine bacteria (Sato, 1978; Shiba et al., 1979; Nishimura et al., 1981; Trüper, 1989). The best studied of these bacteria is *Erythrobacter longus* (Shiba, 1991), which can synthesize bacteriochlorophyll *a*, form intracytoplasmic membranes, and has reaction center complexes similar to those of other purple bacteria (Harashima et al., 1980; Shimada et al., 1985; Iba et al., 1988). In contrast to all previously known phototrophic purple bacteria, synthesis of bacteriochlorophyll *a* and carotenoids in aerobic phototrophs is stimulated by oxygen (Harashima et al., 1980). Shiba (1984) demonstrated that *Roseobacter denitrificans* (formerly designated as *Erythrobacter* strain OCH 114) effectively uses light to increase the cellular ATP level and the rate of incorporation of

Abbreviations: *Cm.* – *Chromatium*; *Ec.* – *Ectothiorhodospira*; *Rb.* – *Rhodobacter*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*

CO₂. According to 16S rRNA analyses, *Erythrobacter longus* belongs to the alpha subgroup of the Proteobacteria, and appears distantly related to other bacteria of this group, such as *Rhodobacter* and *Rhodospseudomonas* species (Woese et al., 1984a). These bacteria and also a recently discovered bacteriochlorophyll containing *Rhizobium* sp. (Evans et al., 1990) are treated in separate chapters (see Chapters 6 and 7 by Shimada and Fleischmann et al., respectively). In this chapter we consider the green sulfur bacteria and the phototrophic purple bacteria.

II. General Aspects of Taxonomy

Traditionally, differentiation of species, genera and even families of phototrophic bacteria was based on a number of morphological properties, such as cell form and size, flagellation and intracytoplasmic membrane structures, on pigment composition, DNA base ratio, and also physiological properties such as carbon and nitrogen substrate utilization and ability to respire aerobically and anaerobically in the dark, among others (Pfennig and Trüper, 1974; Trüper and Pfennig, 1981; Imhoff and Trüper, 1989). Especially some significant features of dissimilatory sulfur metabolism, such as the ability to oxidize sulfide, the preference to grow photoautotrophically with sulfide as electron donor (compared to photoheterotrophic growth), the formation of sulfur globules inside or outside the cells, and the oxidation of extracellular elemental sulfur have been used as criteria to distinguish between major groups of the phototrophic purple and green bacteria (Molisch, 1907; Baven-damm, 1924; Pfennig and Trüper, 1971; Imhoff 1984a; Pfennig, 1989a, b; Gibson et al., 1984).

Also, chemotaxonomic methods have been applied to the taxonomy of phototrophic bacteria and have supported the heterogeneity of this group. The cellular composition of polar lipids, fatty acids, and quinones was found to be useful for their taxonomic characterization. Principal differences in the composition of these compounds were found among the major groups, and even the recognition of species was possible by comparing the composition of these membrane constituents (Imhoff et al., 1982; Imhoff, 1982, 1984b, 1988, 1991; Hansen and Imhoff, 1985). The lipids and quinones of phototrophic bacteria are considered in detail in Chapter 10 by Imhoff and Imhoff. Also, other molecular information, such as lipopolysaccharide structure, size and sequence of

cytochromes *c*, and 16S rRNA oligonucleotide catalogues and sequence data can be used to determine similarity and taxonomic relations among species. The lipid A structure of the lipopolysaccharides shows significant differences among members of the purple nonsulfur bacteria (Weckesser et al., 1974, 1979; Mayer, 1984); it is quite similar among all the Chromatiaceae (Meißner et al., 1988b), though differences occur between *Ec. halophila* and less halophilic *Ectothiorhodospira* species (Meißner et al., 1988c; Zahr et al., 1992). Lipid A was absent from *Chloroflexus* (Meißner et al., 1988a).

With the aid of sequencing techniques of proteins and nucleic acids, molecular data became available which were used for the analysis of phylogenetic relatedness of bacterial strains. The best record of phylogeny is conserved in the primary sequences of nucleic acids and proteins, and attempts to compare phylogenetic relatedness have been made by quantitative comparison of sequence data of both kinds of macromolecules. Because of the available methods, proteins were the first macromolecules considered in the phylogenetic relationships of various bacteria. Among the phototrophic prokaryotes, *c*-type cytochromes and ferredoxins are two examples of such proteins. On the basis of primary sequence and tertiary structure of the *c*-type cytochromes a first 'phylogenetic tree' of the phototrophic purple bacteria was constructed (Dickerson, 1980).

More recently, nucleic acid sequences of the 16S rRNA have been widely used to trace bacterial phylogeny. This molecule is universally distributed among prokaryotes and is considered to be phylogenetically quite conservative. The method has developed from a mere comparison of oligonucleotide catalogues derived by digestion of the molecule with T1 RNase (Zablen and Woese, 1975). With the development of techniques to completely sequence the 16S rRNA molecule, total information of its nucleic acid sequence is now available for comparison. Although this method is superior to all previous attempts of tracing phylogenetic relations because of the universal distribution of ribosomal RNA and the amount of sequence information, it considers only a single molecule of the whole bacterium. To judge the systematic position of a bacterium, the combination of results obtained by different methods—with the support of 16S rRNA sequence data—appears to be the best approach.

III. General Aspects of Physiology

Besides the unifying property to perform light dependent and bacteriochlorophyll-mediated energy transduction, the metabolic capabilities of phototrophic eubacteria and, in particular, of phototrophic purple bacteria, show great diversity. High versatility is not only found among the different species of this group of bacteria, but also in single species which can adapt to a variety of different growth conditions.

Photoautotrophic growth is typical of purple and green sulfur bacteria, while photoheterotrophic growth is typical of purple nonsulfur bacteria. All green sulfur bacteria, almost all purple sulfur bacteria, and also many representatives of the purple nonsulfur bacteria grow under photoautotrophic conditions with either reduced sulfur compounds or hydrogen as electron donors. Many phototrophic purple bacteria are able to grow photoheterotrophically using organic substrates as electron donors and carbon sources. Also, chemolithotrophic growth (aerobically in the dark) has been demonstrated in several species (Madigan and Gest, 1979; Siefert and Pfennig, 1979; Kämpf and Pfennig, 1980). Chemoheterotrophic growth in the presence of oxygen is common among purple nonsulfur bacteria, but is also found in some purple sulfur bacteria.

While some species are very sensitive to oxygen, others grow equally well under aerobic conditions in the dark at the full oxygen tension of air. Under anaerobic dark conditions, growth of some species is also supported by respiratory electron transport in the presence of nitrate, nitrite, nitrous oxide, dimethylsulfoxide (DMSO), or trimethylamine-N-oxide (TMAO) as electron acceptors (for reviews see Ferguson et al., 1987, and Chapter 44 by Zannoni in this volume). In the absence of external electron acceptors a number of substrates allow for energy generation and slow growth by a fermentative metabolism.

In addition to these diverse methods for energy generation, there is considerable variation in the utilization of carbon, nitrogen and sulfur compounds for assimilatory and dissimilatory purposes, as well as in the enzymatic reactions and pathways involved in these processes.

Organic carbon sources have principally different functions under phototrophic, respiratory and fermentative conditions. Under phototrophic growth conditions they serve primarily as a source of cellular carbon, but in addition may function as an electron source for photosynthetic electron transport. In the

presence of inorganic electron donors they may be exclusively photoassimilated. During phototrophic growth the citric acid cycle serves a biosynthetic purpose and a complete cycle is actually not required under these conditions. Indeed, a number of purple sulfur bacteria lack oxoglutarate dehydrogenase and a complete citric acid cycle (Kondratieva, 1979). During respiratory growth the major part of the carbon source is completely oxidized. Reactions of the citric acid cycle are involved in substrate oxidation and one would expect elevated enzymatic activities of the cycle under these conditions. Indeed, *Rb. capsulatus* activities of citrate synthase, isocitrate dehydrogenase and, in particular, oxoglutarate dehydrogenase are increased during respiratory growth (Beatty and Gest, 1981). During fermentative growth, substrates or storage products are oxidized incompletely on a large scale. Reduced organic compounds and/or hydrogen are excreted in order to achieve redox balance of the cell.

Various purple bacteria show great variation in their capability to photoassimilate organic carbon compounds and to grow photoheterotrophically. A group of metabolically specialized, obligately phototrophic and strictly anaerobic Chromatiaceae, including *Chromatium okenii*, *Cm. weissei*, *Cm. warmingii*, *Cm. buderi*, *Cm. tepidum*, *Thiospirillum jenense*, *Lamprocystis roseopersicina* and *Thiodictyon elegans*, photoassimilate only acetate and pyruvate and this only in the presence of CO₂ and sulfide. Endogenous fermentation, as it occurs in *Cm. vinosum* (Van Gemerden, 1968), should be possible, though this has not been demonstrated. Chemotrophic growth has not been found with *Cm. okenii* (Kämpf and Pfennig, 1980), but high respiration rates with intracellular sulfur as the electron source have been reported (Kristjansen, 1988). Also, *Cm. warmingii* and *Thiocapsa pfennigii*, both unable to grow chemotrophically, oxidize intracellular sulfur with oxygen as the terminal acceptor (Kämpf and Pfennig, 1986).

Others, such as the small-celled *Chromatium* species and the majority of the purple nonsulfur bacteria utilize a variety of different organic carbon sources. Intermediates of the tricarboxylic acid cycle in addition to acetate and pyruvate are generally used. Other organic acids, amino acids, fatty acids, alcohols, carbohydrates and even aromatic carbon compounds support growth of many purple nonsulfur bacteria. One of these metabolically highly versatile bacteria is *Rb. capsulatus*. This species can grow photoautotrophically with sulfide or hydrogen as the

electron donor, chemoautotrophically with hydrogen, photoheterotrophically with a variety of organic compounds as electron and carbon sources, chemoheterotrophically at the expense of respiratory electron transport-driven energy generation with oxygen, nitrate, nitrous oxide, dimethylsulfoxide or TMAO as electron acceptors, and finally also by fermentation of organic substrates.

The diversity of the carbon metabolism of phototrophic bacteria is also demonstrated by the assimilation pathway of acetate, which is a substrate for green sulfur bacteria and almost all phototrophic purple bacteria. It is assimilated by almost all purple nonsulfur bacteria (*Rp. globiformis* does not grow with acetate) and even by the most specialized Chromatiaceae. The metabolism of acetate assimilation, however, is quite different among the species. In many phototrophic purple bacteria the primary reaction of acetate metabolism is the ATP-dependent formation of acetyl-CoA, which is the substrate for further reactions. In *Cm. vinosum*, as in most purple bacteria, the two key enzymes of the glyoxylate cycle, isocitrate lyase and malate synthase, are present and acetate is assimilated via this pathway. The cycle is, however, unusual in *Cm. vinosum* in so far as malate dehydrogenase is lacking, but the reaction catalyzed by malic enzyme followed by carboxylation of pyruvate (pyruvate carboxylase) results in the formation of oxalacetate. Unlike most of the acetate assimilating phototrophic purple bacteria *Rs. rubrum* does not have an active glyoxylate cycle. Isocitrate lyase is not present. Conversion of acetate to oxalacetate by two carboxylation reactions from acetate to pyruvate (with pyruvate synthase) and further to oxalacetate is possible (Buchanan et al., 1967). In *Rubrivivax gelatinosus*, however, photo-assimilation of acetate is via the serine-hydroxy-pyruvate pathway (Albers and Gottschalk, 1976). In the green sulfur bacteria neither a Calvin Cycle nor an oxidative tricarboxylic acid cycle are operating (Kondratieva, 1979; Fuchs et al., 1980a, b). In *Chlorobium limicola* pyruvate is formed from Acetyl-CoA by a ferredoxin-dependent pyruvate synthase. Further reactions involve carboxylation to oxaloacetate (phosphoenolpyruvate synthetase) and reactions of the reductive tricarboxylic acid cycle and of gluconeogenesis.

Detailed discussions of the carbon, sulfur, and nitrogen metabolism of anoxygenic phototrophic bacteria is given in additional chapters of this volume.

IV. Description of the Groups

A. Green Sulfur Bacteria (*Chlorobiaceae*)

The phototrophic green sulfur bacteria form a tight phylogenetic group, separated from other phototrophic bacteria and also from known chemotrophic bacteria (Gibson et al., 1985). They are characterized by non-motile, spherical, ovoid or vibrio shaped cells. All species lack flagella; some have gas vesicles. Only *Chloroherpeton thalassium* is motile by gliding and in addition forms gas vesicles; a further difference from all other species of this group is the carotenoid composition, with γ -carotene as major component. Physiological properties and results of 16S rRNA analyses led to the inclusion of *Chloroherpeton* into this group (Gibson et al., 1985). Some properties of the green sulfur bacteria are shown in Table 3.

We distinguish green and brown species of green sulfur bacteria. The green species contain bacteriochlorophyll *c* or *d* and the carotenoid chlorobactene and OH-chlorobactene as light-harvesting pigments (Gloe et al., 1975; Schmidt, 1978). The brown species have bacteriochlorophyll *e* and the carotenoids isorenieratene and β -isorenieratene as light-harvesting pigments (Liaaen-Jensen, 1965). The different pigment content is responsible for differences in the light absorption properties. The brown species have a broader absorption range, between 480 and 550 nm, which apparently is of ecological significance (see Chapter 4 by Van Gemerden and Mas).

In contrast to the phototrophic purple bacteria, green sulfur bacteria and green nonsulfur bacteria do not have intracytoplasmic membrane systems. They contain special structures called chlorosomes (or chlorobium vesicles in the older literature), which are attached to the internal face of the cytoplasmic membrane, carry the light-harvesting pigments, and represent large and powerful antenna systems (Cohen-Bazire et al., 1964; Staehelin et al., 1978, 1980). Chlorosomes contain the major photosynthetic pigments of green sulfur bacteria (see Chapter 20 by Blankenship et al.). The reaction centers of phototrophic green bacteria are located in the cytoplasmic membrane at the attachment sites of the chlorosomes. The localization of the small amounts of bacteriochlorophyll *a* that are present in these bacteria is mainly restricted to the reaction centers and protein complexes of the so-called baseplate, which connects the chlorosome with the cytoplasmic

Table 3. Characteristic properties of green sulfur bacteria^a

Abbreviations: o – no data available; BChl – bacteriochlorophyll.

carotenoids: cl – chlorobactene; irt – isorenieratene; β -irt – β -isorenieratene; γ -c – γ -carotene.

salt response: F – fresh water isolates; numbers give optimum salinity of isolates from brackish or marine habitats.

^a Data were collected from: Gibson et al. (1984); Gorlenko and Lebedeva (1971); Overmann and Pfennig (1989); Trüper and Pfennig (1981); Wahlund et al. (1991).

membrane (Stahelin et al., 1980; Amesz and Knaff, 1988). Small amounts (about 1% of the total) of bacteriochlorophyll *a* have also been found inside the chlorosomes (Gerola and Olson, 1986).

All green sulfur bacteria (Chlorobiaceae) have highly similar physiological capacities. They are metabolic specialists, strictly anaerobic and obligately phototrophic. All species grow photoautotrophically with CO₂ as sole carbon source. In the presence of sulfide and CO₂ only acetate and pyruvate are assimilated as organic carbon sources. CO₂ is assimilated via reactions of the reductive tricarboxylic acid cycle (Evans et al., 1966; Fuchs et al., 1980a, b; Ivanovsky et al., 1980; see also Chapter 40 by Sirevåg). Sulfide is used as electron donor and sulfur source and is oxidized to sulfate with the intermediate accumulation of elemental sulfur globules outside the cells. Some strains also use thiosulfate and

molecular hydrogen as photosynthetic electron donors. Most species require vitamin B₁₂ as growth factor.

B. Purple Bacteria

In all purple bacteria the photosynthetic pigments and the photosynthetic apparatus are located within a more or less extended system of intracytoplasmic membranes that is considered as originating from and being continuous with the cytoplasmic membrane. These intracytoplasmic membranes consist of small fingerlike intrusions, vesicles, tubules or lamellae. The major photosynthetic pigments are bacteriochlorophyll *a* or *b* and various carotenoids of the spirilloxanthin, rhodopinal, spheroidene (alternative spirilloxanthin), or okenone series (Schmidt, 1978).

Molisch (1907) distinguished two types of phototrophic purple bacteria as belonging to the order Rhodobacteria. In the Thiorhodaceae, all purple bacteria that are able to form globules of elemental sulfur inside the cells were grouped and in the Athiorhodaceae all purple bacteria which lack this ability were placed. These two groups have been maintained for a long time and were renamed later to Chromatiaceae (Bavendamm, 1924) and Rhodospirillaceae (Pfennig and Trüper, 1971), respectively.

Later, purple sulfur bacteria became known that accumulate elemental sulfur outside their cells (Pelsh, 1937; Trüper 1968). They were included in the Chromatiaceae as the genus *Ectothiorhodospira* in the eighth edition of Bergey's Manual (Pfennig and Trüper, 1974) but later considered as a separate family the Ectothiorhodospiraceae (Imhoff, 1984a), which comprise purple sulfur bacteria that form sulfur globules outside the cells. Now the Chromatiaceae exclusively comprise those phototrophic sulfur bacteria able to deposit elemental sulfur inside the cells (Imhoff, 1984a), which is in agreement with Molisch's (1907) definition of the 'Thiorhodaceae'.

The analysis of 16S rRNA sequences revealed deep branches among different groups of the phototrophic purple bacteria as well as the close relationship of some phototrophic purple bacteria with certain nonphototrophic chemoheterotrophic bacteria (Gibson et al., 1979; Stackebrandt and Woese, 1981). The name Proteobacteria, as a new class, has been proposed for all purple bacteria and their purely chemotrophic relatives (Stackebrandt et al., 1988). The Proteobacteria are subdivided into four subgroups called α , β , γ , δ (Woese, 1987; Woese et al., 1984a, b, 1985 b). The first three subgroups contain non-phototrophic as well as phototrophic representatives; for the δ subgroup phototrophic representatives are so far unknown. So far only one purely chemotrophic bacterium has been found which clusters within the closely related species of Chromatiaceae and Ectothiorhodospiraceae (Adkins et al., 1993). According to 16S rRNA analyses, both of these families form fairly well separated groups within the γ -subgroup of the Proteobacteria. In contrast, the purple nonsulfur bacteria are an extremely heterogeneous group of bacteria, which belong to the α - and β -subgroups of the Proteobacteria and which in many cases are more similar (on a 16S rRNA data basis) to purely chemotrophic bacteria than to themselves. Therefore, the use of a true

family name has been abandoned and the popular name Purple Nonsulfur Bacteria proposed to be used for this group (Imhoff et al., 1984, Imhoff and Trüper, 1989).

The α -subgroup contains species of the genera *Rhodospirillum*, *Rhodopila*, *Rhodopseudomonas*, *Rhodomicrobium*, and *Rhodobacter* in different branches. Specific high similarities exist between *Paracoccus denitrificans* and the *Rhodobacter*-group (Gibson et al., 1979), between *Nitrobacter winogradskyi* and *Rp. palustris* (Seewaldt et al., 1982), and between *Aquaspirillum itersonii* and *Azospirillum brasilense* and the *Rhodospirillum*-group (Woese et al., 1984a). High similarities between *P. denitrificans* and *Rb. capsulatus* were also revealed by cytochrome c_2 amino acid sequences (Ambler et al., 1979). In addition, lipid A structures and internal membrane structures show great similarities between *Nb. winogradskyi* and *Rp. palustris* (Mayer et al., 1983).

The β -subgroup contains the species that have been rearranged into the genus *Rhodocyclus* (Imhoff et al., 1984). *Rhodocyclus gelatinosus* has been transferred recently to *Rubrivivax gelatinosus* (Willems et al., 1991). This species appears specifically related to *Sphaerotilus natans*, while *Rc. tenuis* is closely related to *Alcaligenes eutrophus* (Woese et al., 1984b). A bacterium that has been known as the '*Rhodocyclus gelatinosus*-like group' (Hiraishi and Kitamura, 1984) has been described as a new genus and species *Rhodoferax fermentans* (Hiraishi et al., 1991). Also this genus most likely belongs to the β -subgroup.

These data support the idea that ancestors of present day phototrophic prokaryotes are among the most ancient of eubacteria and they further point to several lines of development of non-phototrophic bacteria from phototrophic ancestors.

1. Chromatiaceae

The Chromatiaceae Bavendamm 1924 comprise those phototrophic bacteria that, under the proper growth conditions, deposit globules of elemental sulfur inside their cells (Imhoff 1984a). This family is a quite coherent group, as shown by the similarity of 16S rRNA molecules (Fowler et al., 1984) and lipopolysaccharides (Meißner et al., 1988b). All but one species (*Thiocapsa pfennigii*) have the vesicular type of intracytoplasmic membranes. Many species are able to grow under photoheterotrophic conditions,

some species grow as chemolithotrophs, and a few species also grow chemoheterotrophically (Gorlenko, 1974; Kondratieva et al., 1976; Kämpf and Pfennig, 1980). Many species are motile by means of flagella, some have gas vesicles, and only *Thiocapsa* species completely lack motility. We distinguish two major physiological groups of Chromatiaceae, metabolically specialized and versatile species. Among the specialized species are *Chromatium okenii*, *Cm. weisssei*, *Cm. warmingii*, *Cm. buderi*, *Cm. tepidum*, *Thiospirillum jenense*, *Thiocapsa pfennigii*, and the gas-vacuolated species of the genera *Lamprocystis* and *Thiodictyon*. These species depend on strictly anaerobic conditions and are obligatory phototrophic. Sulfide is required; thiosulfate and hydrogen are not used as electron donors. Only acetate and pyruvate (or propionate) are photoassimilated in the presence of sulfide and CO₂. They do not grow with organic electron donors and chemotrophic growth is not possible. None of these species assimilates sulfate as a sulfur source. The versatile species photoassimilate a greater number of organic substrates and also grow in the absence of reduced sulfur sources with organic substrates as electron donors for photosynthesis. Most of these species are able to grow with sulfate as the sole sulfur source. They also can grow under chemolithotrophic conditions. Among these species are the small-celled *Chromatium* species, *Thiocystis violacea*, *Thiocapsa roseopersicina*, *Lamprobacter modestohalophilus*, and *Amoebobacter* species. Characteristic properties of Chromatiaceae are shown in Table 4.

2. Ectothiorhodospiraceae

The Ectothiorhodospiraceae Imhoff 1984 are phototrophic sulfur bacteria that, during oxidation of sulfide, deposit elemental sulfur outside the cells. They are distinguished from the Chromatiaceae by lamellar intracytoplasmic membrane structures, by significant differences in polar lipid composition (Imhoff et al., 1982), and by the dependence on saline and alkaline growth conditions (Imhoff, 1989). *Ectothiorhodospira halophila* is the most halophilic eubacterium known and even grows in saturated salt solutions. All species are motile by polar flagella and *Ectothiorhodospira vacuolata* in addition forms gas vesicles. The slightly halophilic species such as *Ec. mobilis*, *Ec. shaposhnikovii* and *Ec. vacuolata* and the moderately and extremely halophilic species such as *Ec. halophila*, *Ec. abdelmalekii* and *Ec.*

halochloris form two distinct groups of species (Stackebrandt et al., 1984; Imhoff, 1989) that should be separated taxonomically. Some properties of *Ectothiorhodospira* species are shown in Table 5.

3. Purple Nonsulfur Bacteria

The group of the purple nonsulfur bacteria (Rhodospirillaceae Pfennig and Trüper 1971) is by far the most diverse fennig of the phototrophic purple bacteria (Imhoff and Trüper, 1989). This diversity is reflected in greatly varying morphology, internal membrane structure, carotenoid composition, utilization of carbon sources, and electron donors, among other features. The intracytoplasmic membranes are small, fingerlike intrusions, vesicles, or different types of lamellae. Most species are motile by flagella; gas vesicles are not formed by any of the known species. Some properties of purple nonsulfur bacteria are shown in Tables 6 A and B.

The preferred growth mode of all species is photoheterotrophic under anaerobic conditions in the light with various organic substrates. Many species also are able to grow photoautotrophically with either molecular hydrogen or sulfide as electron donor and CO₂ as the sole carbon source. Most of these species oxidize sulfide to elemental sulfur only (Hansen and Van Gernerden, 1972). In *Rhodobacter sulfidophilus* and *Rhodopseudomonas palustris* sulfate is the final oxidation product and is formed without accumulation of elemental sulfur as an intermediate (Hansen, 1974; Hansen and Veldkamp, 1973). Three species *Rhodobacter veldkampii*, *Rhodobacter adriaticus*, and *Rhodobacter euryhalinus*, are known to deposit elemental sulfur outside the cells, while oxidizing sulfide to sulfate (Hansen et al., 1975; Neutzling et al., 1984; Hansen and Imhoff, 1985; Kompantseva, 1985).

Most representatives can grow under microaerobic to aerobic conditions in the dark as chemoheterotrophs, a few also as chemolithotrophs. Some species are very sensitive to oxygen, but most species are quite tolerant of oxygen and grow well under aerobic conditions in the dark. Under these conditions synthesis of photosynthetic pigments is repressed and the cultures are faintly colored or colorless. Even under phototrophic growth conditions (anaerobic/light) many species exhibit considerable respiratory capacity. Respiration under these conditions is inhibited, however, by light. The fact that considerable respiratory activity is expressed

Table 4. Characteristic properties of Chromatiaceae^a

Abbreviations: o – not determined; (B₁₂) – vitamin B₁₂ strongly enhancing growth, but not absolutely required; –1 – hydrogenase present, but growth with H₂ not demonstrated. Utilization of organic carbon: minus sign (–) – only acetate and pyruvate (or propionate) are photoassimilated; plus sign (+) – other carbon sources are used as well. Carotenoids: la – lycopenal, lo – lycopanol, ly – lycopene, ok – okenone, ra – rhodopinal, rh – rhodopin, ro – rhodopinol, rv – rhodovibrin, sp – spirilloxanthin, ts – 3,4,3',4', tetrahydrospirilloxanthin.

Abbreviations and references: see Table 6B.

* It has recently been proposed to transfer this species to a new genus, as *Rhodocista centenaria* (Kawaski et al., 1992).

also under phototrophic growth conditions enables these bacteria (e.g. *Rhodobacter capsulatus*, *Rhodobacter sphaeroides*, *Rubrivivax (Rhodocyclus) gelatinosus*, *Rhodospirillum rubrum*) to switch immediately from phototrophic to respiratory metabolism when environmental conditions change.

Some species also may perform a respiratory metabolism anaerobically in the dark with sugars and either nitrate, dimethyl-sulfoxide, or trimethylamine-N-oxide as electron sink, or though poorly – with metabolic intermediates as electron acceptors (fermentation).

Table 6B. Characteristic properties of purple nonsulfur bacteria (Rhodospirillaceae): The genera *Rhodopseudomonas*, *Rhodocyclus*, *Rhodoferax*, and *Rubrivivax*^a

Abbreviations: o – not determined; ICM – structure of intracytoplasmic membrane system: V – vesicles, L – lamellae, S – stacks, T – tubes, N – none detected. Salt response: F – fresh water species; M – marine species; H – halophilic species. Sulfide oxidation to: S^o – elemental sulfur only; S^o/Sul – sulfate with intermediate formation of extracellular elemental sulfur globules; Sul – sulfate without formation of S^o. Vitamins: b – biotin, n – niacin, t – thiamine, paba – p-aminobenzoic acid, YE – yeast extract, AA – amino acids; vitamins in brackets are required only by some strains, paba* – p-aminobenzoic acid stimulatory. Carotenoids: kts – ketocarotenoids, ly – lycopene, ly* – 1,2 dihydrolycopene, neu – neurosporene, neu* – 1,2 dihydroneurosporene, ra – rhodopinal, rag – rhodopinal glucoside, rg – rhodopin glucoside, rh – rhodopin, rv – rhodovibrin, se – spheroidene, sn – spheroidenone, sp – spirilloxanthin.

^a Data are collected from: Drews (1981); Eckersley and Dow (1980); Favinger et al. (1989); Hansen (1974); Hansen and Imhoff (1985); Hiraishi et al. (1991); Imhoff (1983); Janssen and Harfoot (1991); Kompantseva (1985); Kompantseva (1989); Kompantseva and Gorlenko (1984); Mack et al. (1993); Neutzling et al. (1984); Nissen and Dundas (1984); Schmidt (1978); Schmidt and Bowien (1983); Stadtwald-Demchick et al. (1990a); Stadtwald-Demchick et al. (1990b); Trüper and Pfennig (1981); Willems et al. (1991).

¹ *Rhodopseudomonas rutila* (Akiba et al., 1983) is now considered as a subjective synonym of *Rp. palustris* (Hiraishi et al., 1992).

One or more vitamins are generally required as growth factors, most commonly biotin, thiamine, niacin, and p-aminobenzoic acid; these compounds are rarely needed by species of the Chromatiaceae and Ectothiorhodospiraceae, which may require vitamin B₁₂ as sole growth factor. Growth of most purple nonsulfur bacteria is enhanced by small amounts of yeast extract, and some species have complex nutrient requirements.

A number of changes have recently been made concerning the taxonomy of purple nonsulfur bacteria, and are noted here. *Rhodopseudomonas blastica* has been recognized as a species of the genus *Rhodobacter*, *Rhodobacter blastica* (Kawasaki et al., 1993). The correct name should be *Rhodobacter blasticus* because *Rhodobacter* is a *masculinum nomen*. *Rhodobacter marinus* has been described as a new species (Burgess et al., 1994) and in parallel,

not considering this new species, the marine species of *Rhodobacter*, *Rb. adriaticus*, *Rb. euryhalinus* and *Rb. sulfidophilus* have been transferred to the new genus *Rhodovulum* with *Rhodovulum sulfidophilum* as type species (Hiraishi and Ueda, 1994a). *Rhodopseudomonas rosea* has been transferred to the new genus *Rhodoplanes*, as *Rhodoplanes roseus* and was designated as the type species of this genus (Hiraishi and Ueda, 1994b). In addition, a new species of this genus, *Rhodoplanes elegans* has been described (Hiraishi and Ueda, 1994b).

Summary

Heliobacteria are anoxygenic phototrophs that contain bacteriochlorophyll *g* as their sole chlorophyll pigment. These organisms are primarily soil residents and are phylogenetically related to Gram-positive bacteria, in particular to the endospore-forming *Bacillus/Clostridium* line. Some species of heliobacteria produce heat resistant endospores containing dipicolinic acid and elevated Ca²⁺ levels. Heliobacteria can grow photoheterotrophically on a limited group of organic substrates and chemotrophically (anaerobically) in darkness by pyruvate or lactate fermentation; they are also active nitrogen-fixers. Their photosynthetic system resembles that of photosystem I of green plants but is simpler, containing a small antenna closely associated with the reaction center located in the cytoplasmic membrane; no chlorosomes typical of the green sulfur bacteria or differentiated internal membranes typical of purple bacteria are found in the heliobacteria. Heliobacteria are apparently widely distributed in rice soils and occasionally found in other soils. The ecology of heliobacteria may be tightly linked to that of rice plants, and the ability of heliobacteria to produce

[†] This chapter is dedicated to Professor Howard Gest within whose laboratory the heliobacteria were first discovered and whose infectious enthusiasm for the photosynthetic bacteria has stimulated many current workers in this field.

endospores probably has significant survival value in the highly variable habitat of rice soils. The unique assemblage of properties shown by the heliobacteria has necessitated creation of a new taxonomic family of anoxygenic phototrophic bacteria, the Heliobacteriaceae, to accommodate organisms of this type.

I. Introduction

For well over a hundred years microbiologists have used the enrichment culture technique successfully to search for new kinds of bacteria. On very rare occasions a bacterium may turn up in such a culture which has properties so unprecedented that a new taxonomic family has to be created to accommodate it. Such was the remarkable discovery of *Heliobacterium chlorum* (Gest and Favinger, 1983). The discovery was made through a combination of serendipity and insight, and for microbiologists and biochemists familiar with this field, the event was of great interest because the new organism was so unlike any of the known phototrophic bacteria. *Hb. chlorum* had a novel type of chlorophyll, BChl *g*, and it had neither the chlorosomes of green bacteria nor the membrane invaginations of most purple bacteria. And of profound importance was the revelation, on the basis of 16S rRNA sequences (Woese et al., 1985), that *Hb. chlorum* belonged to the Gram-positive bacteria and was thus phylogenetically related more to the Bacillaceae than to other phototrophic bacteria.

Heliobacterium chlorum was isolated from garden soil on the campus of Indiana University, Bloomington. Subsequently it was discovered that the soil of rice fields is a rich source of heliobacteria. *Heliobacillus mobilis* (Beer-Romero and Gest, 1987), *Heliobacterium gestii* (Ormerod et al., 1990), and several other heliobacteria strains were all isolated from the same sample of dry, rice field soil from Chainat province Thailand. Several isolates have also been obtained from hot springs. Today the heliobacteria may be viewed as being soil residents and primarily (but not exclusively) tropical organisms. They have simple nutritional requirements and are efficient nitrogen fixers (Kimble and Madigan, 1992a,b). A series of observations on various heliobacterial strains aroused suspicions that these organisms might have a resistant resting stage and eventually it was shown beyond any doubt that at

least some heliobacteria can form heat resistant endospores (Ormerod et al., 1990).

One of the most striking characteristics of heliobacteria is the visible absorption spectrum of the cells (Fig. 1), which is due to the presence of BChl *g* (Brockmann and Lipinski, 1983; Michalski et al., 1987; see Fig. 2 for structure). This molecule, which was unknown prior to the discovery of heliobacteria, shows a number of interesting structural features. For example, BChl *g* resembles BChl *b* in having an ethylidene group on C8 (Fig. 2) which in the presence of oxygen and light isomerizes to give a vinyl group. Since BChl *g* has a second vinyl group on C3, the product of the isomerization is a molecule which is very similar to chlorophyll *a* (Brockmann and Lipinski, 1983; Michalski et al., 1987). This transition from BChl *g* to chlorophyll *a* presumably accounts for the dramatic change from brownish green to emerald green in cultures of heliobacteria exposed to oxygen (Gest and Favinger, 1983). Another interesting feature of BChl *g* is the long chain alcohol esterified to the propionic acid side chain at C17³, which is farnesol (Michalski et al., 1987). In all other known phototrophs, membrane bound chlorophylls (the cytoplasmic membrane is the location of BChl *g* in heliobacteria) contain a 20C alcohol, either phytol or the less saturated geranylgeraniol. Farnesol is only present in the chlorosome BChls of green sulfur bacteria. The significance of farnesol in the

Fig. 1. Absorption spectra of intact cells (solid line) and acetone extracts (dashed line) of *Heliobacterium medesticaldum* strain 1ce1. Spectra were performed anaerobically (from Kimble et al., 1995).

membrane-bound BChl *g* of the heliobacteria is unknown.

The fact that the reaction center of heliobacteria is of the photosystem I type has important physiological consequences for these organisms. On the one hand, the highly reducing coenzyme(s) generated by the RC can drive biosynthetic reactions of a kind which require powerful reductants. On the other hand, these reduced coenzymes can react with oxygen to form toxic radicals. In the light, therefore, heliobacteria are very sensitive to oxygen and the effect is probably exacerbated by the presence in their membrane lipids of a very high proportion of unsaturated fatty acids (Imhoff, 1988; Beck et al., 1990; Aase et al., 1994). The structure of the heliobacterial reaction center is detailed in Chapter 31 by Ames.

In this chapter we shall concentrate on aspects of the heliobacteria which are not dealt with in other chapters, such as taxonomy, physiology, and ecology. Consideration of the properties of the strains of heliobacteria that have already been isolated in pure culture indicates that many of their basic characteristics are very similar. This makes classification of heliobacteria difficult and there is now an acute need for a proper consideration of how to proceed with the taxonomy of this growing family of phototrophic bacteria. The next section describes the current state of affairs concerning the taxonomy of this group.

II. Taxonomy of Heliobacteria

The family Heliobacteriaceae (Beer-Romero and Gest, 1987) comprises all species of anoxygenic phototrophic bacteria that contain BChl *g*. All organisms that fit this definition lack BChls *a*, *b*, *c*, *d* or *e* (Madigan, 1992). At present two genera are recognized in the family Heliobacteriaceae, *Heliobacterium* and *Heliobacillus*. The genus *Heliobacterium* contains the species *Hb. chlorum*, the first of the heliobacteria discovered (Gest and Favinger, 1983), the endospore-forming species *Hb. gestii* and *Hb. fasciatum* ('*Hb. fasciculum*', Ormerod et al., 1990), and the thermophilic species, *Hb. modesticaldum* (Kimble et al., 1995). However, because of several unique properties including its phylogenetic position, the present authors will formally describe *Hb. fasciatum* as a new genus of heliobacteria, *Heliophilum* (as *Hp. fasciatum*), in a future publication, thus this organism will be referred to as such herein. In addition to containing BChl *g*, all heliobacteria

are strict anaerobes, at least when grown phototrophically, are rod-shaped or spiral in morphology, and are motile by either gliding or flagellar means (Madigan, 1992, and Table 1).

A. General Description

The number of strains of heliobacteria isolated to date is probably in the region of fifty. Not all of these cultures have survived. Most heliobacteria are motile rods or spirilla with flagella, either peritrichous, as in *Hc. mobilis*, or polar/subpolar as in *Hb. gestii*. *Heliobacterium chlorum* is unique in being motile by gliding (Gest and Favinger, 1983). All heliobacteria that have been examined share a number of physiological properties. They have a characteristic absorption spectrum (Fig. 1) and *Hb. chlorum*, *Hb. gestii*, and *Hc. mobilis* are photosynthetically and spectroscopically indistinguishable (Table 1). Heliobacteria utilize a rather limited range of simple organic substrates as carbon sources photoheterotrophically. No heliobacteria have been shown to grow autotrophically but they can use hydrogen, and one strain can use H₂S (Starynin and Gorlenko, 1993) as reductant in the assimilation of organic substrates. All heliobacteria require biotin and some are dependent on a reduced source of sulfur (Beer-Romero, 1986; Stevenson, 1993).

Although the heliobacteria are phylogenetically Gram-positive, they do not stain as such. Their cell wall has no typical lipopolysaccharide components (Beck, et al., 1990; Aase et al., 1994). Many heliobacteria show a marked tendency to form spheroplasts and lyse in the late log or stationary phase of growth. The extent of this depends on the strain and in some cases the growth medium. The phenomenon of lysis may be related to the unusual nature of the cell wall; no outer membrane is present in these organisms and their peptidoglycan content is very low compared to that of other Gram-positive bacteria (Beer-Romero et al., 1988). That the peptidoglycan layer of heliobacteria is either not as thick or as strong as that of other Gram-positive bacteria is also apparent from the exquisite sensitivity shown to penicillin by these organisms: *Hb. chlorum* and *Hc. mobilis* are one thousand times more sensitive to penicillin G than is *Bacillus subtilis* (Beer-Romero et al., 1988). Additionally, it is possible that autolysins, induced around the time of sporulation to free the spore from the sporangium (as is known to occur in *Bacillus*, Joliffe et al., 1981), are also produced by

certain heliobacteria and contribute to premature lysis. Cell lysis is a nuisance in experimental work with heliobacteria and some of the newer isolates are more stable in this regard (see below).

A large fraction of the heliobacteria that have been isolated to date have been observed to form endospores. However, it has been repeatedly observed that cultures of heliobacteria newly isolated from enrichment cultures may sporulate heavily on plates or in liquid medium, but that upon repeated transfer the occurrence of spores begins to diminish and eventually becomes very low. *Heliobacterium chlorum* and *Heliobacillus mobilis* have not been reported to produce endospores. However, because other species of heliobacteria do sporulate it is possible that conditions for sporulation of *Hb. chlorum* and *Hc. mobilis* have not yet been discovered. This possibility is supported by preliminary experiments in the laboratory of one of us (MTM) which have shown that a small fraction of cultures of *Hb. chlorum* and *Hc. mobilis* tested do survive pasteurization (80 °C for 15 min), suggesting that sporulation may occur in these species but only at low levels. Despite this, microscopic examination of hundreds of cultures of *Hb. chlorum* and *Hc. mobilis* has never revealed the presence of endospores.

Endospore-formation has been clearly demonstrated in *Hb. gestii* and *Hp. fasciatum* (Fig. 3, and Ormerod et al., 1990), in the *Hc. mobilis*-like isolate of Starynin and Gorlenko (1993), in strain HY3 of Kelly (Pickett et al., 1994), in the HD7 strain of *Hb.*

Fig. 3. Electron micrograph of a raft of *Heliophilum fasciatum* cells negatively stained with phosphotungstate.

gestii isolated by Pfennig (personal communication and own observations), and in the thermophilic species, *Hb. modesticaldum* (Kimble et al., 1995). In liquid cultures of *Hb. gestii*, disintegrating sporangia form clumps containing large numbers of spores (Fig. 4) and in some strains it has been observed that the sporangia are swollen and spindle-shaped like those of many clostridia (Ormerod, unpublished).

The process of sporulation has been studied in *Hb. gestii* (Torgersen, 1989; Ormerod et al., 1990) and in strain BR-4 (Starynin and Gorlenko, 1993). Endospores in *Hb. gestii* are subterminal and cylindrical, measuring about $1 \times 2 \mu\text{m}$ (Figs. 4 and 5), and are produced in various amounts in aged cultures. By contrast, spores of *Hp. fasciatum* are longer than those of *Hb. gestii*. Spores of strain BR-4 (Starynin and Gorlenko, 1993) are similar in morphology to those of *Hb. gestii* and *Hp. fasciatum* and also, as in these species, located subterminally. Heliobacterial endospores are heat resistant, withstanding 100 °C for a few minutes (Ormerod et al., 1990; Starynin and Gorlenko, 1993). In addition, spores of *Hb. gestii* have been shown to contain dipicolinic acid, the signature molecule of bacterial endospores, as well as six times the Ca^{2+} content of vegetative cells (Torgersen, 1989; Ormerod et al., 1990). These observations indicate that heliobacterial spores are similar to those of Bacillaceae. Starynin and Gorlenko (1993) showed that the number of spores produced in strain BR-4 was greatest at pH 9 and that ripening and release of the spores from the sporangium was stimulated by oxygen.

B. New Isolates

In the past few years one of us (MTM) has enriched

Fig. 4. Phase-contrast micrograph of accumulated endospores of *Heliobacterium gestii* with remains of sporangia.

Fig. 5. Electron micrograph of a thin section of an endospore of *Heliobacterium gestii*. A multilayered wall similar to that found in Bacillaceae surrounds a typical cortex (courtesy of Y.A. Torgersen, 1989).

and isolated several new heliobacteria from soil habitats and hot springs (see Section IVB). Of 16 newly isolated strains, 14 were rod-shaped, resembling *Hc. mobilis*, and two were spirilla, resembling *Hb. gestii* (Stevenson, 1993). The new isolates were obtained from soils from the USA and from Thailand and Iceland, although positive enrichments (but not pure cultures) were also obtained with soils from Venezuela, Spain, Japan and Australia. Most of these isolates have not been thoroughly characterized except for their carbon and nitrogen nutrition. In brief, all of them grew photoheterotrophically on pyruvate or lactate and most also utilized acetate. Butyrate was used by about half of the isolates, and one strain of *Hb. gestii* (strain THAI 15-1 isolated from Thailand paddy soil), also grew photoheterotrophically on sugars. Strain THAI 15-1 grew on glucose, fructose, galactose and maltose, but grew to highest cell yield on fructose of all sugars tested. These results indicate that sugar-utilizing heliobacteria exist, although they are apparently not common. The two Icelandic isolates, one a rod and one a spirillum, were thermophilic, capable of growth above 50 °C; four similar strains were isolated from Yellowstone hot springs (Kimble and Madigan, 1994). The thermophilic isolates have been described as a new species of the genus *Heliobacterium*, *Hb. modesticaldum* (Kimble et al., 1995). As has been found with recognized species of heliobacteria (Kimble and Madigan, 1992a), all new isolates grew on N₂ as sole nitrogen source as well as on ammonia. All of the isolates also used glutamine as a nitrogen source while the sugar-degrading strain THAI 15-1 also grew well on asparagine.

Most of the new isolates of heliobacteria described above were obtained from enrichment cultures that

employed a pasteurization step (80 °C, 15 min) before incubation. Despite this, many of the pure cultures obtained were not observed to sporulate. Although most of the rod-shaped isolates resemble *Hc. mobilis*, assignment of any of them to genus and species rank will require further characterization.

C. The Family Heliobacteriaceae

With the description of the new genus and species *Heliobacillus mobilis* by Beer-Romero and Gest (1987), the family Heliobacteriaceae was established to group together anoxygenic phototrophs that contain BChl *g*. The establishment of family rank for these organisms was fully justified on the basis of the phenotypic and ecological properties of the heliobacteria, and was further confirmed by ribosomal RNA sequencing studies which showed that these phototrophs have Gram-positive evolutionary roots, unlike those of any other anoxygenic phototrophic bacteria (Woese et al., 1985; Woese, 1987). Comparisons of the 16S rRNA sequences of *Hb. chlorum*, *Hc. mobilis*, and *Hb. gestii*, show them all to be fairly closely related and to belong to the 'low GC' (*Bacillus/Clostridium*) subdivision of the Gram-positive bacteria (Woese et al., 1985; Beer-Romero, 1987; Beer-Romero and Gest, 1987; Woese, 1987), specifically to the *Desulfotomaculum* group (Redburn and Patel, 1993; Woese, personal communication to MTM). Phylogenetic analysis of *Hp. fasciatum* (Woese and Madigan, unpublished) showed it to be

sufficiently distinct from all species of *Helio-bacterium* and from *Hc. mobilis* to have its own genus, *Heliophilum*; formal publication of this name is forthcoming.

In summary (Table 1) heliobacteria can be defined as (1) anoxygenic phototrophic bacteria that show evolutionary relationships to Gram-positive bacteria, (2) that contain BChl *g* but no other BChls, (3) that lack the chlorosomes of green sulfur bacteria and *Chloroflexus* and the intracytoplasmic membranes of purple bacteria, (4) that are strictly anaerobic, and (5) that apparently reside chiefly in soil (see Section IVA). Other unifying properties of note in Table 1 are the fact that the G + C content of DNA from heliobacteria clusters tightly within the range of 50–55%, all species require biotin as a growth factor, and all have relatively high growth temperature optima as compared to most purple or green bacteria.

III. Physiology

A. Phototrophic Growth

Although the heliobacteria have been known for only a decade or so, a good deal of research has already been carried out on them. Much of this research has understandably been concerned with the structure and functioning of the unique reaction center of these organisms, which is of the photosystem I type. The antenna of heliobacteria is directly associated with the polypeptides of the RC in the cytoplasmic membrane and is limited to about 35 molecules of BChl *g* per RC (see Chapter 31 in this volume by Ames). There are indications (Trost, 1990) that a light regulated peripheral antenna is absent but the results of Beer-Romero (1986) and of Torgersen (1989) suggest that total BChl content of the cells varies inversely with the light intensity, as in

other anoxygenic phototrophs. As a result of the small size of the antenna, heliobacteria grow best at high light intensities (Beer-Romero, 1986; see also Section IVB).

The heliobacterial RC consists of a protein dimer. The primary electron donor is designated P798 and the first stable product of the RC is most likely a reduced ferredoxin-like coenzyme which acts as the main connecting link between the RC and the biosynthetic metabolism of the cell. P798 becomes reduced back to the ground state by a cytochrome, which is itself reduced by organic or inorganic electron donors. Examples of the latter are molecular hydrogen (Ormerod, unpublished) and sulfide (Starynin and Gorlenko, 1993). It is assumed that the RC can also create a proton motive force through cyclic electron transfer via the membrane cytochrome *bc₁* complex (see Chapter 31 by Ames). This provides the illuminated cell with a source of energy for motility, transport, and ATP synthesis.

Flagellated heliobacteria show the 'shock movement' typical of phototrophic purple bacteria—they reverse direction of swimming on encountering darkness. This phenomenon has been termed *scotophobotaxis* (H. Gest, personal communication). The large, rod shaped cells of *Hp. fasciatum* associate to form parallel bundles that move as a unit, by polar flagella (Fig. 3). The bundles, which consist of a few to hundreds of rods, show a characteristic rolling motion (Ormerod et al., 1990), and are scotophobotactic, indicating that some form of communication between individual cells in the bundle may exist. Microscopic observation of aggregating cells suggests that the flagella adhere to each other first, followed by the body of the cell in longitudinal fashion. An interesting observation concerning flagella is that in old cultures of flagellated heliobacteria objects are present which look like spirilla with pointed ends. On examination in the electron microscope, these

Fig. 6. Electron micrograph of an aggregate of cast off flagella from a lysed culture of *Hb. gestii* negatively stained with phosphotungstate.

can be seen to be accumulations of flagella (Fig. 6).

Phototrophic growth of heliobacteria depends on anaerobic conditions. Some strains of heliobacteria have been observed to swim away from oxygen, but in some strains, exposure to oxygen in bright light can lead to catastrophic damage to the cell protoplast in a matter of seconds. This has been observed microscopically in *Hb. gestii* and *Hp. fasciatum* as the sudden development of transverse striations in the cell, indicating destruction of the cytoplasmic membrane. Presumably strong reductants from the RC react with oxygen to form toxic oxygen species which destroy the unsaturated fatty acids in the membrane.

On the basis of 16S rRNA sequences (Woese et al., 1985) heliobacteria may be considered to be phototrophic clostridia. The main difference between the two is, of course, that the clostridia are chemotrophs and obtain chemical energy for growth by fermentation of organic substrates while heliobacteria, which also grow on organic substrates, are phototrophs, and get energy from light. In view of the distinct phylogenetic relationship between the two organisms, we should be on the lookout for clostridial traits in the carbon metabolism of heliobacteria. One such trait, fermentative growth (see Section IIIB), has already been discovered (Kimble et al., 1994).

With these considerations in mind, we can examine the possible assimilatory pathways for the various substrates heliobacteria are known to utilize and view these against the background of what is known of heliobacterial enzymes. One heliobacterial enzyme, malic dehydrogenase has been characterized (Charnock et al., 1992). Until recently nothing was known about other heliobacterial enzymes, but significant findings have been reported by Kelly and his coworkers (Pickett et al., 1994) and it is now possible to outline how carbon assimilation may proceed in heliobacteria.

Pickett et al. (1994) detected activities of pyruvate and 2-oxoglutarate synthases in cell-free extracts of heliobacteria. This finding is noteworthy because the products of these two reactions are quantitatively the most important of all the biosynthetic precursor metabolites in the cell. Since the two reactions are driven by reduced ferredoxin (or its equivalent), one can envisage direct coupling of the RC to carbon assimilation. Other enzymes detected in heliobacteria were PEP synthetase, PEP carboxykinase, malate dehydrogenase, fumarase, fumarate reductase, and

isocitrate dehydrogenase; enzymes not detected included citrate synthase, ATP-citrate lyase, aconitase, pyruvate dehydrogenase, 2-oxoglutarate dehydrogenase, and ribulose biphosphate carboxylase.

The range of carbon sources that heliobacteria can utilize is apparently very limited. The reason for this is not known, but the failure to observe autotrophic growth may be due to the apparent lack of key enzymes of the reductive pentose phosphate (Calvin) cycle or the reductive tricarboxylic acid cycle in extracts of cells of heliobacteria. Most heliobacteria that have been tested can grow on acetate. In the experiments of Pickett et al. (1994) the fate of the label from 2-¹³C acetate was studied by mass spectrometry of amino acids obtained by hydrolysis of cell protein. Alanine and aspartate were labelled primarily in C₃, indicating that acetate assimilation proceeds initially as in *Chlorobium*, by reductive carboxylation to pyruvate and further carboxylation to oxaloacetate. However, the labeling in glutamate was in C₂ and C₄ with a smaller amount in C₃. If acetate had been assimilated reductively via succinate, as it is in *Chlorobium*, the labeling would have been equally distributed between C₃ and C₄. As discussed by Pickett et al. (1994), the labeling pattern suggests that acetate assimilation had occurred via citrate, even though citrate synthase and aconitase could not be detected in cell free extracts.

In *Hb. gestii* growth on acetate depends on the presence of molecular hydrogen (Ormerod, unpublished results). The conversion of acetate to glutamate requires reducing power, particularly if it proceeds via succinyl CoA, and hydrogen can supply the electrons for this. In heliobacteria that do not require an electron donor for acetate assimilation (e.g. *Hc. mobilis*), oxidation of some of the acetate beyond 2-oxoglutarate would have to occur to meet this requirement. How this is done is not clear. It is probably a sluggish process, as indicated by the fact that acetate accumulates during growth on pyruvate (Pickett et al., 1994). Such accumulations are not encountered in other phototrophic bacteria, such as purple bacteria, and may reflect the phylogenetic kinship of heliobacteria with the clostridia (Woese et al., 1985). Added 2-¹³C pyruvate gave a labeling pattern consistent with a route of incorporation involving reductive assimilation to glutamate via succinate. The positions of ¹³C in isoleucine formed in the presence of labelled acetate or pyruvate indicated synthesis via citramalate rather than the usual threonine (Pickett et al., 1994). This mechanism

Fig. 7. Photograph of plate cultures of *Heliobacillus mobilis* (a) Colonies of photoheterotrophically grown cells (b-e) Colonies of chemotrophically grown cells (b) pyruvate/yeast extract medium; (c) pyruvate defined medium; (d) lactate/yeast extract medium; (e) yeast extract (only) medium. Plates for chemotrophic growth were incubated anaerobically in darkness for 4 days ($N_2/CO_2/H_2$ headspace). From Kimble et al. (1994).

has been found in a few other bacteria, including *Chlorobium* (Nesbakken et al., 1988).

Hb. gestii can grow photoheterotrophically on ethanol and CO_2 (Ormerod, unpublished results) and several heliobacteria can grow on butyrate plus CO_2 , (see e.g. Madigan, 1992). Ethanol is presumably oxidized to acetyl CoA with the liberation of 4H which can then be used for assimilation via pyruvate synthase. Conversion of butyrate to two molecules of acetyl CoA would provide enough electrons for assimilation of only one of these to cell material (CH_2O) via pyruvate synthase. In this case, the rest of the reducing equivalents would have to come from the oxidation of some of the acetyl CoA. Lactate seems to be universally utilized by heliobacteria (Table 1) and its conversion into cell material is presumably via pyruvate; sugars are used by only a very few strains (Stevenson, 1993).

In summing up this section it may be said that heliobacteria grow photoheterotrophically at high light intensities on a limited range of organic substrates. Assimilation of these involves reductive carboxylations driven in large part by reduced ferredoxin from the RC. The electrons for this may come from oxidation of the substrates themselves or from H_2 or H_2S .

B. Chemotrophic Growth

In the original description of *Heliobacterium chlorum* Gest and Favinger (1983) concluded that this organism was an obligate phototroph. This was also the conclusion of Beer-Romero and Gest (1987) concerning *Heliobacillus mobilis* and of Ormerod et al. (1990) concerning *Heliobacterium gestii* and *Heliophilum fasciatum*. However, during the course of studies of N_2 fixation in heliobacteria (see Section IIIC and Kimble and Madigan, 1992a) it was discovered that heliobacteria were not obligate phototrophs, but can grow anaerobically in darkness at the expense of pyruvate (Fig. 7). Slow dark growth occurs in rich media containing 60–80 mM pyruvate, 0.2–0.5% yeast extract, and 40 mM of the organic buffer MOPS (3-N-morpholinopropane sulfonic acid) (Kimble et al., 1994).

From these experiments it was concluded that (1) dark growth of *Hc. mobilis* is pyruvate dependent (Fig. 7), (2) acidic and gaseous products including acetate, H_2 and CO_2 are produced, and (3) aerobic chemotrophic growth does not occur. Dark growth has also been studied by Kelly and his coworkers (Pickett et al., 1994) in *Heliobacterium* sp., strain HY3. They showed that in addition to pyruvate, lactate could also support dark growth of this strain

(unlike in *Hc. mobilis*, see Fig. 7 and Kimble et al., 1994), and that dark growth of strain HY3 was almost as fast as phototrophic growth. From an ecological point of view, dark growth on lactate is significant because lactate is a common product of chemotrophic fermentation.

A survey of all known species of heliobacteria and several new unclassified strains (see Section IVA) showed them all capable of pyruvate-dependent dark growth (Kimble et al., 1994). Growth in darkness requires strictly anaerobic conditions, as is true of phototrophic growth, but it has been observed that heliobacteria exposed to microaerobic conditions in darkness retain viability for long periods; thus the strictly anaerobic nature of these organisms is most pronounced in the light (Kimble et al., 1994).

The energy-generating mechanism(s) of chemotrophic pyruvate-grown heliobacteria appears to be pyruvate fermentation yielding acetate. Acidic products produced by dark-grown cells lower the pH of even well-buffered media by 1 unit or more (Kimble et al., 1994). In addition, cultures of *Hc. mobilis* produce $H_2 + CO_2$ from the dark metabolism of pyruvate whereas *Hb. gestii* produces CO_2 but no H_2 . Pickett et al. (1994) detected high levels of pyruvate:ferredoxin oxidoreductase activity in cells of chemotrophic pyruvate-grown *Hc. mobilis* and this is presumably the mechanism of energy conservation and acetate production. Dark diazotrophic growth of *Hc. mobilis* has also been achieved but growth rates and cell yields under these conditions are very low.

Heliobacteria thus have at least one metabolic strategy for growth in darkness and this makes good ecological sense considering that they are soil phototrophs and receive only intermittent illumination in nature. However, dark fermentation and growth of heliobacteria on pyruvate or lactate is also of benefit to basic researchers as it makes possible molecular genetic studies of photosynthesis in strains of these organisms that carry otherwise lethal mutations in photosynthesis genes.

C. Nitrogen Fixation

The original description of *Heliobacterium chlorum* indicated that the organism appeared in enrichment cultures designed to select for N_2 -fixing anoxygenic phototrophs and that pure cultures grew on N_2 as sole source of nitrogen (Gest and Favinger, 1983). Since that time we have surveyed the nitrogen-fixing potential of heliobacteria (Kimble and Madigan,

1992a,b; Kimble et al., 1995; Kimble and Madigan unpublished results) and have shown that all representatives tested can fix N_2 but that the efficacy of the process varies dramatically among species. *Heliobacillus mobilis* and a new heliobacterial isolate that resembles *Hc. mobilis*, strain AR2P1 (from an Arkansas, USA, rice soil) grow rapidly on N_2 and express high levels of nitrogenase as measured in vivo (Kimble and Madigan, 1992a; Stevenson, 1993; Stevenson et al., 1993). Because *Hc. mobilis*, like strain AR2P1, was obtained from a rice soil, it is possible that a significant portion of the photosynthetic nitrogen fixation that occurs in paddy field soils (most of which is known to be due to free-living nitrogen-fixing bacteria; Buresh et al., 1980) is due to heliobacteria. By contrast, under the same growth conditions in which *Hc. mobilis* grew well on N_2 , *Hp. fasciatum* grew only poorly, suggesting that conditions for diatrophism may differ among species of heliobacteria.

All the heliobacteria examined by Kimble and Madigan (1992a) were subject to regulation of nitrogenase activity by ammonia. This phenomenon, called the ammonia 'switch-off' effect, is a universal feature of anoxygenic phototrophic bacteria (Ludden and Roberts, 1989) and is presumably a means for rapid inactivation of nitrogenase activity in the presence of excess ammonia; such regulation serves to conserve reductant and ATP. Ammonia 'switch-off' of nitrogenase activity in heliobacteria was the first observation of this form of enzyme control in Gram-positive bacteria.

An alternative (non-molybdenum) nitrogenase was detected in cells of *Hb. gestii* but not in *Hb. chlorum* or *Hc. mobilis* (Kimble and Madigan, 1992b). In this study cells of *Hb. gestii* were transferred repeatedly in media containing only Fe^{3+} as a nitrogenase metal cofactor; vanadium did not stimulate iron-dependent growth (Kimble and Madigan, 1992b). Additional evidence for a Mo-independent nitrogenase system in *Hb. gestii* emerged from acetylene (C_2H_2) reduction experiments where ethane (C_2H_6) as well as ethylene (C_2H_4) was produced by cell suspensions grown on N_2 in the absence of Mo; C_2H_6 production was Mo repressible (Kimble and Madigan, 1992b). This pattern is typical of alternative nitrogenase systems of other diazotrophs (Bishop and Premakumar, 1992). Whether the alternative nitrogenase(s) of *Hb. gestii* are of the iron-only or vanadium-iron types could not be resolved in the studies of Kimble and Madigan (1992b), but a nitrogenase 3 (iron-only type) was

suggested on the basis of the accumulated evidence.

Alternative nitrogenases apparently function as backup systems for diazotrophic growth of organisms whose habitats are periodically or permanently deficient in Mo. The alternative nitrogenase of *Hb. gestii* may thus have ecological significance for this organism in its natural habitat, paddy field soil (Ormerod et al., 1990), where Mo deficiency is often a problem due to metal leaching under acidic conditions (Bishop and Joerger, 1990).

IV. Ecology and Isolation of Heliobacteria

A. Habitats of Heliobacteria

The ecology and distribution of heliobacteria in nature is now becoming clear. On the basis of isolations made to date beginning with that of *Heliobacterium chlorum* (Gest and Favinger, 1983), virtually all reported isolates of heliobacteria have been obtained from soils (Beer-Romero and Gest, 1987; Ormerod et al., 1990; Madigan, 1992; Stevenson, 1993; Stevenson et al., 1993; Pickett et al., 1994). Indeed, enrichment studies (see below) suggest that with the exception of the hot springs isolate of Starynin and Gorlenko (1993), the Yellowstone hot springs isolates of Kimble and Madigan (Kimble and Madigan, 1994; Kimble et al., 1995) and a strain isolated from an Oregon hot spring by R.W. Castenholz (personal communication to JGO), soil may be the *only* habitat of heliobacteria.

In an extensive series of enrichment cultures carried out in the laboratory of MTM, positive heliobacterial enrichments were obtained only from soil. From over 100 soils tested, 22 were positive for heliobacteria. Of some 20 aquatic samples tested in the same way, including freshwater lakes, ponds, marsh waters, raw sewage, and several marine and salt marsh samples, none yielded heliobacteria (Stevenson et al., 1993). In addition, it should be mentioned that heliobacteria were never reported (before 1983) from the thousands of enrichment cultures for anoxygenic phototrophic bacteria that have been made by various workers over the years. However, it is possible that enrichments which had turned green may have contained heliobacteria that were mistaken for green algae or cyanobacteria and discarded. Thus, although all indications are that heliobacteria are terrestrial phototrophs, more enrichments using selective methods for heliobacteria but with aquatic samples

are needed to further support this.

Rice field soils appear to be major habitats for heliobacteria. Of 16 new isolates obtained in enrichment studies, 9 were from such soils (Stevenson et al., 1993). In addition, *Heliobacillus mobilis*, *Heliobacterium gestii* and *Heliophilum fasciatum* all originated from rice soils (Beer-Romero and Gest, 1987; Ormerod et al., 1990). Dry paddy field soil in particular appears to be a good source of heliobacteria (Ormerod et al., 1990; Madigan, 1992; Stevenson et al., 1993). This suggests that these strictly anaerobic organisms have evolved strategies for surviving drying and any resultant exposure to oxygen; endospore production is clearly one such strategy. In recent enrichment studies (Stevenson, 1993) soil moisture, pH, and ammonia levels were measured in attempts to define the optimal physicochemical parameters in soils for heliobacteria. Heliobacteria-positive soil samples ranged from 0.1–66% in soil moisture content, 4.2–8.4 in pH, and 0.3–135 μg ammonia/g dry soil. Thus, dry soils are not required for recovery of heliobacteria (although most successful soils were dry), acidic soils can contain heliobacteria, and, although N_2 fixation may be of survival value to heliobacteria, they are also indigenous to soils containing sufficient ammonia to repress nitrogenase synthesis. In addition, although tropical soils (for example, Far Eastern and African paddy field soils) were the best sources of heliobacteria, the organisms were also present in temperate soils (for example Minnesota, Arkansas, Texas [USA] and Italy) and even in soils from near the Arctic Circle (Iceland; Stevenson et al., 1993; Kimble et al., 1995; Kimble and Madigan, unpublished).

Heliobacteria are thus clearly ecologically distinct from green and purple bacteria, which are generally found in aquatic environments (Madigan, 1988; Pfennig, 1989; see also Chapter 4 by Van Gemerden and Mas, this volume). Although nonsulfur purple bacteria are present in some soils (Gest et al., 1985), like purple and green sulfur bacteria, their primary habitats are aquatic (Madigan, 1988). The ability of at least some heliobacteria to sporulate is likely related to their soil habitat, as other endospore-forming bacteria are primarily soil organisms as well. Sporulation would allow heliobacteria to survive the alternate flooding and extreme drying of paddy field soils, and the changing moisture levels experienced in most other soils.

It may also be significant to the ecology of

heliobacteria that all species fix molecular nitrogen (Kimble and Madigan, 1992a,b). In rice soils, nitrogen fixation by heliobacteria may be an important factor in providing combined nitrogen for rice plants. Perhaps rice plants excrete organic substances that are used by heliobacteria in exchange for fixed nitrogen. If true, this would suggest interesting agricultural applications for heliobacteria in improving soil fertility.

B. Enrichment and Isolation of Heliobacteria

Enrichment of heliobacteria begins with soil as inoculum. Dry soil is suitable, and as discussed above, may even be desirable. From enrichment studies (Ormerod et al., 1990; Stevenson, 1993; Stevenson et al., 1993), it has become clear that dilute complex media at neutral pH or defined media containing lactate or acetate are most suitable for enrichment of heliobacteria. Yeast extract solution (0.2–0.3% w/v, pH 7) seems to be the best for primary isolation (Stevenson et al., 1993; Kimble et al., 1995).

In establishing enrichments for heliobacteria, one should take some precautions as to anaerobic conditions. When growing phototrophically, the heliobacteria are strict anaerobes (Madigan, 1992). Thus, media pre-reduced by storage for several days in contact with the $N_2 : H_2 : CO_2$ atmosphere of an anaerobic glove box, or alternatively, boiled for several minutes and sealed under an anaerobic gas before autoclaving (Hungate method), are helpful for obtaining positive enrichments. However, since heliobacterial spores are oxygen resistant, the job of removing the oxygen in enrichments can be left to aerobic heterotrophs in the inoculum; once these have used up the oxygen, any heliobacteria will begin to grow. If crude enrichments are obtained, however, strictly anaerobic conditions must be maintained thereafter in order to obtain pure cultures of heliobacteria.

Light and temperature can also be selective enrichment factors. Heliobacteria cannot grow at as low a light intensity as purple and green bacteria do, but they tolerate high light intensities quite well (Beer-Romero, 1987; Madigan, 1992; Kimble and Madigan, unpublished results; Ormerod, unpublished observations). Thus 5,000–10,000 lux (incandescent) illumination is recommended for primary isolations. Enrichment temperatures around 40 °C should be used as an additional selective factor for heliobacteria

(all heliobacteria isolated thus far grow up to at least 42 °C) and to discourage growth of purple bacteria. A final selective factor which is frequently essential for isolating heliobacteria from many soils is to pasteurize the soil sample used in the enrichment. Pasteurization eliminates problems with competing organisms, in particular nonsulfur purple bacteria such as *Rhodospseudomonas palustris*. It has been observed that if an enrichment for heliobacteria gets overtaken by purple bacteria, heliobacteria never develop (Stevenson, 1993).

Positive enrichments for heliobacteria generally appear as slimy green clumps of cells typically located at the soil/liquid or glass/liquid interface; only weak growth is usually observed in the bulk medium (in fact the bulk medium may not become pigmented, thus one must look carefully for signs of heliobacteria before concluding that an enrichment is negative). Microscopically, pasteurized enrichments generally contain a variety of sporulating organisms including heliobacteria and clostridia. Endospore-forming heliobacteria are usually some of the largest cells in enrichments and spores, if present, are typically located either centrally or subterminally (Stevenson et al., 1993). If an enrichment is suspected of being positive for heliobacteria, it should immediately be streaked on plates of the same medium within an anaerobic chamber and then incubated photosynthetically in anaerobic jars (streaking plates in air followed by anaerobic incubation rarely yields heliobacteria). The presence of heliobacteria on plates is signaled within 2–3 days by the formation of greenish or brown-green colonies. These can be picked and restreaked (anaerobically) to obtain pure cultures. Most isolates can be purified by this method; however, some strains have required streaking on plates of medium solidified with washed agar or Gelrite[®], a nonagar-based solidifying agent, in order to be obtained in axenic culture. Further details of enrichment methods for isolating heliobacteria and recipes for a variety of media for growing pure cultures of heliobacteria are given in Madigan (1992) and in Gest et al., (1985).

Finally, it should be mentioned that because enrichment cultures of heliobacteria generally contain chemotrophic spore-forming bacteria, the chances of some of these being present as contaminants in 'purified' cultures of heliobacteria, even after plating, must always be considered. Therefore, the presence of spores in some heliobacterial cultures does not necessarily indicate the identity of the spores. The

surest way of determining this is to observe scotophobotaxis in motile sporangia. When the microscope light is shaded momentarily, a swimming heliobacterial sporangium cell usually reverses its direction. Having ascertained the identity of the spores, further steps in purification can be carried out as described above.

C. Contrasts of Heliobacteria with Purple and Green Bacteria

Any consideration of the ecology of heliobacteria must take into account other phototrophic bacteria which can compete with them in one way or another. Heliobacteria are primarily soil organisms preferring relatively high light intensities; this clearly separates them from the classical purple and green bacteria which are mainly aquatic and able to grow, particularly in the case of the green sulfur bacteria, at very low light intensities. Since they are most commonly found in the soil of rice fields, heliobacteria may have some sort of special relationship with rice plants. The considerable quantities of methane produced in rice field soils would in general preclude the presence of significant amounts of sulfide in them. The heliobacteria present in rice soils are therefore probably not exposed to competition from phototrophic sulfur bacteria in this environment. Instead, competition most likely exists with purple nonsulfur bacteria, which like heliobacteria live a photoheterotrophic lifestyle, and with cyanobacteria, which are common in rice soils (Buresh et al., 1980; Habte and Alexander, 1980).

Habte and Alexander (1980) showed that purple bacteria were present in rice field soils, and these may become dominant in enrichment cultures inoculated with such soils, especially if a fresh, moist sample is used. Rice fields are waterlogged and anaerobic during the growth season, so the ability to tolerate oxygen shown by some purple bacteria would scarcely be of advantage here, as it is in stratified lakes (De Wit and Van Gernerden, 1990). It may therefore be that the cardinal heliobacterial property in this regard is spore formation; endospores would allow for survival of heliobacteria during the dry season and upon return of flooded conditions would serve as inoculum for rapid development of a heliobacterial microflora.

The absorption properties of heliobacteria may also be of ecological advantage. Absorption spectra of heliobacteria have a major peak at about 790 nm.

This absorption peak is unique for heliobacteria and would allow them to grow beneath a layer of cyanobacteria. It is also interesting to note that from a phylogenetic standpoint heliobacteria show closer relationships to the cyanobacteria than to any group of anoxygenic phototrophic bacteria (Woese, 1987). Perhaps the obligately anaerobic heliobacteria and the oxygen-producing cyanobacteria have more intimate ecological relationships in rice soil and other soils than one would at first suspect. The discovery of such relationships awaits more thorough understanding of the microbial ecology of photosynthesis in the rice soil environment.

Acknowledgments

The research of MTM on heliobacteria has been supported by the United States Department of Agriculture (USDA) Competitive Grants Program. JGO received support from the Research Council of Norway. We thank Linda Kimble for supplying unpublished results.

[†] We dedicate this chapter to William R. Sistrion (deceased September, 1993) whose ideas and discussions contributed in many important ways to the discovery and characterization of the BChl-containing filamentous bacteria.

Summary

The filamentous anoxygenic phototrophs are a diverse group of photosynthetic bacteria that are of particular evolutionary significance. The best known species is the thermophilic *Chloroflexus aurantiacus*. This organism is a prominent member of hot spring microbial mat communities. Because it forms a deep division in the eubacterial line of descent and because it has an interesting combination of characteristics found in very different and diverse groups of phototrophic prokaryotes, it is of particular significance in addressing questions of evolutionary importance.

There are several other strains of filamentous photosynthetic bacteria from a wide range of environments that are substantially different from *Cf. aurantiacus* yet have enough similarity in fundamental photosynthetic features to be likely relatives. Sequence data (16S rRNA) are needed to define the phylogenetic range of the family Chloroflexaceae. Some of the interesting biology of the diverse filamentous phototrophs is discussed in this chapter along with the taxonomic and phylogenetic problems they present.

The physiology of *Cf. aurantiacus* is intriguing in several respects. The recently described autotrophic CO₂ fixation pathway involving 3-hydroxypropionate is unlike any other known autotrophic mechanism. *C. aurantiacus* is also unique among all groups of phototrophs in lacking the capacity for nitrogen fixation. The regulation of pigment synthesis in response to changing growth conditions is particularly interesting due to the presence of two different photosynthetic pigments located in different sub-cellular environments. The fact that *Cf. aurantiacus* is a thermophile provides another dimension of complexity to its physiology. It is also quite resistant to UV radiation. Some of its characteristics may be relicts from Precambrian ancestors.

I. Introduction

The anoxygenic filamentous phototrophic bacteria are a large and diverse group of microorganisms (Table 1). They are discussed together in this chapter primarily for convenience but also because they share some similarities in structure and metabolism. Although we are not prepared to argue strongly that the filamentous character is a particularly significant trait to the overall taxonomy of this diverse group of organisms, it does appear that many of these bacteria may in fact bear a relatively close relationship to each other. The organisms discussed in this review include the members of the family Chloroflexaceae and the other anoxygenic filamentous phototrophs of uncertain affiliation.

The family Chloroflexaceae includes the genera *Chloroflexus*, *Oscillochloris*, and *Chloronema*. Only one species, *Chloroflexus aurantiacus*, has been described in substantial detail from the extensive study of pure cultures. A new thermophilic species is currently under study and may be described soon (Satoshi Hanada, personal communication). We will review the taxonomy of this group and the physiology of all the genera, including the well-studied *Cf. aurantiacus*, the lesser known species of the 'green

Chloroflexus' (Strain GCF), the mesophilic *Chloroflexus*, the marine and hypersaline *Chloroflexus*-like organisms (MCLOs), and the species of *Oscillochloris* and *Chloronema*.

We will also review the other anoxygenic filamentous phototrophs of uncertain affiliation. These organisms include the described species *Heliobacterium oregonensis* (no relationship to the 'Heliobacteria'), the thermophilic red filamentous bacteria, and the hypersaline filamentous purple bacteria.

Our approach will be topical. For each topic considered, we will first discuss the well-studied *Cf. aurantiacus* followed by a review of what is known about the other filamentous phototrophs.

Much of the physiology of *Cf. aurantiacus* will be discussed in greater detail in other chapters which we will cross-reference where appropriate. We bring a particular perspective to this review. Our objective is to identify problems of interest in the ecophysiology and evolutionary biology of this group of organisms. We have long recognized the existence of many poorly understood and possibly related phototrophic bacteria that are important to our overall understanding of the phylogeny of phototrophs and the origin and evolution of photosynthesis. We hope to increase awareness of and interest in the study and successful isolation of a much greater diversity of phototrophs to increase the database for the development of future evolutionary theories.

Abbreviations: BChl – bacteriochlorophyll; BPh – bacterio-pheophytin; *Cf.* – *Chloroflexus*; MCLo – Marine *Chloroflexus*-like organism

Table 1. Anoxygenic filamentous phototrophs¹

Organism	Morphology	Pigments	Metabolism	Habitat	References
<i>Cf. aurantiacus</i>	gliding filaments 0.5-1.5 μm diam.	BChl <i>a</i> and <i>c</i>	photoheterotrophy some photoautotrophy (sulfide-dependent or hydrogen-dependent)	neutral to alkaline thermal springs undermat, surface mat, or unispecific mat	see Pierson and Castenholz, 1992 for review of references
<i>var. mesophilus</i>				mats in freshwater stratified lakes	Gorlenko, 1976; Pivovarova and Gorlenko, 1977
Marine <i>Chloroflexus</i> - like organisms	gliding filaments 1.0-2.0 μm diam.	BChl <i>a</i> and <i>c</i>	photoheterotrophy photoautotrophy?	marine intertidal salt marsh sediments	Mack and Pierson, 1988
Marine <i>Chloroflexus</i> - like organisms	gliding filaments variable diam.	BChl <i>c</i> BChl <i>a</i> ?	undetermined	hypersaline marine mats often in association with <i>Microcoleus chthonoplastes</i>	D'Amelio et al., 1989 Palmisano et al., 1989 Stolz, 1983, 1990
Marine <i>Chloroflexus</i> - like organisms	gliding filaments 1.2-3.0 μm diam	BChl <i>a</i> and <i>c</i> or <i>d</i>	photoautotrophy photoheterotrophy?	hypersaline marine mats (a) as distinct layer beneath surface layer of cyanobacteria (b) as surface layer mixed with <i>Spirulina</i> and <i>Beggiatoa</i>	Larsen et al., 1991 Pierson et al., 1994
<i>Heliothrix oregonensis</i>	gliding filaments 1.5 μm diam.	BChl <i>a</i>	photoheterotrophy	Alkaline thermal springs lacking sulfide. Surface mat above cyanobacteria	Pierson et al., 1984, 1985

Marine purple filaments	gliding filaments 0.8-0.9 μm diam.	undeter- mined	undetermined	hypersaline mats in association with <i>Microcoleus chthonoplastes</i>	D'Amelio et al., 1987
<i>Chloronema</i>	gliding filaments 2 μm diam.	BChl <i>d</i>	undetermined	planktonic freshwater	Gorlenko, 1988
<i>Oscillochloris</i>	gliding filaments 1.0-5.5 μm diam.	BChl <i>c</i>	undetermined	surface of freshwater sulfide-containing muds marine?	Gorlenko, 1988 Keppen et al., 1993a

¹ All the organisms listed in this table are reviewed in more detail in Pierson and Castenholz, 1992.

II. Taxonomy and Phylogeny

A. Problems With This Group

Establishing a meaningful taxonomy and understanding the phylogeny of the filamentous phototrophs are two tasks beset with problems unique to this group of organisms. It is apparent from ecological studies and field observations of the natural history of several habitats that the anoxygenic filamentous phototrophs comprise a large and diverse group

(Table 1). From this group only one species has been successfully isolated and sustained in pure culture and has been subjected to extensive analyses. Other 'species' have been studied as natural populations, in dual or mixed cultures, or in pure cultures which have been difficult to maintain and were subsequently lost, or in cultures that have not been readily available to many labs. Consequently, the broadly based phenotypic data needed to construct useful taxa and the arrays of nucleic acid sequences needed to construct meaningful phylogenies are lacking. Thus,

while abundant data on natural history, microscopy, and ultrastructure tantalize us with the obvious recognition of numerous diverse species of interest, the very limited availability of pure cultures frustrates our understanding of this group.

B. Taxonomy of Chloroflexaceae

The thermophilic *Chloroflexus aurantiacus* (Pierson and Castenholz, 1974a) is still the only genus and species of the Chloroflexaceae that has been described on the basis of axenic cultures that are readily available. *Chloronema* (Dubinina and Gorlenko, 1975) and *Oscillochloris* (Gorlenko and Pivovarova, 1977) are the two other genera included in this family. The description of *Chloronema* was not based on cultured material. Recently a culture of *Oscillochloris trichoides* was isolated and made available (Keppen et al., 1993). Trüper (1976) proposed Chloroflexaceae as a family with affinities to the Chlorobiaceae (green sulfur bacteria) and included the two families in the suborder Chlorobiineae. Bacteria in the family Chloroflexaceae were described as filamentous, phototrophic bacteria with gliding motility, Gram-negative, flexible cell walls, and bacteriochlorophyll (BChl) *a* and BChl *c*, *d*, or *e*.

Problems with the description of this taxon exist. Although Gram staining reactions appear to be negative, neither the ultrastructural appearance nor the chemistry of the cell wall of *Cf. aurantiacus* is typical of other Gram-negative bacteria (Knudsen et al., 1982; Jürgens et al., 1987; see also Chapter by Weckesser and Golecki). '*Oscillochloris chrysea*' was Gram-positive and had a thick peptidoglycan layer with no outer membrane (Gorlenko, 1988, 1989a). Some of the marine *Chloroflexus*-like organisms we have been studying stain Gram-positive or Gram-variable and appear to lack an outer membrane (B. Pierson, unpublished).

In recognition of the probable significance of the true filamentous morphology of these phototrophs, we have referred to them as photosynthetic flexibacteria (Pierson and Castenholz, 1992). In *Bergey's Manual of Systematic Bacteriology*, Pfennig (1989) proposed the group 'multicellular filamentous green bacteria' to include the genera *Chloroflexus*, *Chloronema*, *Oscillochloris*, and *Heliothrix*. The genus *Heliothrix*, however, differs significantly from the other three genera in lacking chlorosomes and BChl *c*, *d*, or *e*. Consequently the appropriateness of this taxonomic grouping as a family is weakened.

Further difficulties have arisen with the utility of this proposed grouping due to physiological constraints included in the description. The description emphasizes that all members of the group are facultatively aerobic and preferentially use organic substrates in their metabolism. It further states that reduced sulfur compounds are not important electron donors for laboratory cultures. These proposed taxa and less formal groupings may be unnecessarily restrictive at a time when very few laboratory cultures have actually been available for study. Field studies of apparently related organisms have revealed a tolerance for high levels of sulfide, as well as a capacity for sulfide dependent autotrophy. Studies on pure cultures have shown that one strain of *Chloroflexus*, the GCF strain (Giovannoni et al., 1987) is not facultatively aerobic.

Our discussion of the range of physiologies present in filamentous phototrophs presented in this chapter will support our suggestion that at this time the most useful grouping of these organisms is as photosynthetic flexibacteria or anoxygenic filamentous phototrophs. The term green non-sulfur bacteria should be dropped. It is potentially very misleading. The analogy to purple sulfur and non-sulfur bacteria breaks down on phylogenetic grounds. The two 'groups' of purple bacteria are closely related phylogenetically, at least as members of the vast array of Proteobacteria. The two groups of green bacteria are not. The term filamentous green bacteria is appropriate when referring to the three genera *Chloroflexus*, *Chloronema*, and *Oscillochloris* but not *Heliothrix*. The term 'gliding green bacteria' should be dropped because this would include *Choroherpeton* which is not filamentous, but does glide and is closely related to the green sulfur bacteria and not to *Chloroflexus*.

C. Phylogeny and Evolution

On the basis of 16S rRNA catalogs and complete sequence data, it was concluded that *Chloroflexus aurantiacus* forms a very deep division within the eubacterial line of descent (Oyaizu et al., 1987; Woese, 1987). Other organisms included in the same grouping with *Cf. aurantiacus* are *Herpetosiphon aurantiacus*, a filamentous gliding non-photosynthetic bacterium, and *Thermomicrobium roseum*, another non-photosynthetic bacterium. *Thermus thermophilus* may also be fairly closely related (Hartmann et al., 1989). The two most interesting

aspects of the position of *Chloroflexus* on the eubacterial tree are its lack of phylogenetic closeness to any other groups of phototrophs and the depth of its branch on the tree. Its position as the deepest division of all the phototrophs suggests its ancestors diverged earlier than those of any of the other phototrophs.

Heliothrix oregonensis has been described on the basis of studies of natural populations and a coculture with the non-phototrophic *Isosphaera pallida* (Pierson et al., 1984a). On the basis of 16S and 5S rRNA sequence data, *Heliothrix oregonensis* is phylogenetically close to *Cf. aurantiacus* and is not at all close to any of the other phototrophic bacteria (Pierson et al., 1985; Weller et al., 1992). *Heliothrix oregonensis*, however, is not a 'green' bacterium and is excluded from the taxon Chloroflexaceae as currently defined. Analysis of 5S rRNA from *Oscillochloris trichoides* also supports greater phylogenetic closeness to the *Chloroflexus* group than to any other phototrophic bacteria (Keppen et al., 1993b). The closeness of *Herpetosiphon aurantiacus* to *Chloroflexus* on the basis of 16S rRNA analysis reinforces the idea of the significance of filamentous morphology in defining this group and lends credence to our suggestion that for the time being all filamentous phototrophs should be grouped together. However, *Thermomicrobium roseum*, which is also in this group, is not filamentous, hence weakening this argument.

There are several serious problems plaguing these phylogenetic interpretations, however. Some could be solved quite readily. First, only two strains of *Cf. aurantiacus* have been analyzed for 16S rRNA sequences. It is desirable to do other strains since potentially significant phenotypic variations do exist, for example, between the two most studied strains, J-10-fl and OK-70-fl. The facultatively autotrophic and sulfide-dependent thermophilic strain, GCF (green *Chloroflexus*), has not been analyzed. Sequence data are also lacking for the mesophilic freshwater strain first described by Gorlenko (1976) and Pivovarova and Gorlenko (1977) and for *Chloronema* and *Oscillochloris*. Likewise, phylogenetic data are lacking for the uncultured marine strain (Mack and Pierson, 1988) and the hypersaline strains that are not yet axenic but will be briefly described in this chapter. With the availability of PCR technology, a comprehensive phylogenetic analysis of all of these filamentous anoxygenic phototrophs could be undertaken and would greatly

enhance our understanding of the relationships of these organisms to each other and to other phototrophs.

The necessity of a more extensive analysis of 16S rRNA based phylogeny within this group is further enhanced by two other analyses which are not readily resolved with the current paucity of phylogenetic data. The relative position of some groups of phototrophs in the eubacterial tree has been challenged recently on the basis of 5S rRNA sequence data (Van den Eynde et al., 1990). The 5S RNA data corroborated the close relationship of *Cf. aurantiacus* to *Thermomicrobium roseum* but excluded *Herpetosiphon aurantiacus* from this group in contrast to the 16S RNA data. Furthermore, the 5S RNA data produced a tree in which the cyanobacterial-plastid cluster of phototrophs and the green sulfur bacterial cluster of phototrophs both formed earlier branches or deeper divisions than the *Chloroflexus* cluster. Analysis of 23S rRNA sequences (Woese et al., 1990), however, supports earlier 16S rRNA data suggesting a close relationship between the green sulfur bacteria and the flavobacterial group and reinforcing the early branch points suggested by the 16S rRNA data (Woese, 1987). These findings have particular significance for evolutionary interpretations. Such conflicts must be resolved in order to interpret phylogeny with confidence. One important step in solving these problems is to increase the resolution of the system by including a larger number of data sets. As it currently stands, the phylogenetic grouping with *Cf. aurantiacus* contains only two unequivocal members, both of which are thermophiles. Many of the other, perhaps related, bacteria that are not yet sequenced are not thermophiles, and it seems likely that thermophily will not be a unifying characteristic of the group. More analyses as suggested above could lead to a larger, more stable grouping, in which the branch point might be determined with greater confidence.

Further confusion in interpreting phylogenetic relationships, and certainly in interpreting the evolution of phototrophs and photosynthesis, has been introduced with recent analysis of evolutionary relationships among the reaction center genes (Blankenship, 1992). The two fundamental types of reaction centers are distributed among the various groups of phototrophs in ways that preclude any simple linear explanation of the evolution of the reaction centers within and among the different groups. Gene duplications followed by lateral gene

transfer and divergence may account for the extant distribution of these pigment-protein complexes. *Cf. aurantiacus*, despite its apparent early divergence from the other eubacteria as suggested by the 16S rRNA data, does not appear to possess an ancestral reaction center. It would be most interesting to acquire data on the functional nature and molecular sequence of the reaction centers from the other filamentous anoxygenic phototrophs. The details of photosynthetic reaction centers from anoxygenic phototrophic bacteria are covered in several chapters of this book.

Thermophilic *Cf. aurantiacus* is but one species within a very large and probably quite diverse group of filamentous phototrophic bacteria that are likely to be significant to our understanding of the early evolution of photosynthesis. Its thermophily and its frequently cited chimeric nature in photosynthetic properties may prove to be the exceptions rather than the rule among these bacteria. We must bear in mind that these characteristics have been important in defining the taxa to which *Chloroflexus* belongs only because by chance it was the first, and remains so far the only, species that has been readily isolated and cultured. The very recent availability of pure cultures of *O. trichoides* will pose new challenges to the extant taxonomic systems (Keppen et al., 1993a).

III. Physiology

Most of our understanding of the physiology of the filamentous phototrophs is based on studies of *Cf. aurantiacus*. Studies of other organisms will also be mentioned where appropriate. The type species *Cf. aurantiacus* is a thermophile with an optimum temperature for growth between 52 and 60 °C (Pierson and Castenholz, 1974a). It is a common and abundant inhabitant of neutral to alkaline hot springs with or without sulfide over a wide temperature range up to about 70–72 °C. Occurrence above 66 °C has been observed only when associated with cyanobacteria that grow at higher temperatures (see Chapter 6 by Castenholz and Pierson). It is usually associated with cyanobacteria. Its distribution in natural habitats, general ecology, isolation, and laboratory culture, as well as some aspects of its physiology have recently been reviewed (Pierson and Castenholz, 1992; see Chapter 5 by Castenholz and Pierson). Green *Chloroflexus* (GCF) is found as nearly pure mats devoid of cyanobacteria in a limited

number of hot springs containing sulfide over the temperature range of 50 to 66 °C (Giovannoni et al., 1987). *Heliothrix oregonensis* is also a thermophile found much less commonly than *Chloroflexus* in alkaline hot springs where it is occasionally very abundant. Its optimum temperature for metabolic activity is between 50 and 55 °C. All three of these thermophilic filamentous phototrophs are found naturally as major visible components of microbial mats that usually contain various unicellular or filamentous cyanobacteria. In springs devoid of sulfide, *Chloroflexus* commonly forms a distinct orange layer beneath a surface layer of oxygenic cyanobacteria. Since no sulfide-tolerant cyanobacteria are known above temperatures of 56 °C, mats with primary sulfide at this temperature and above are dominated by presumably autotrophic *Chloroflexus* which exists as a surface layer or a unispecific mat up to about 66 °C. *Heliothrix* often forms a flocculant surface layer above cyanobacteria in mats where sulfide is absent. For a short review of ecological conditions that support these phototrophs, see Castenholz (1988).

Mesophilic *Cf. aurantiacus* with a temperature optimum of 20–25 °C was found as a component of microbial mats growing on mud containing some sulfide at the bottom of stratified freshwater lakes (Gorlenko, 1976; Pivovarova and Gorlenko, 1977).

Marine *Chloroflexus*-like organisms (MCLOs) have been observed in a large number of marine and hypersaline environments containing biogenic sulfide (Pierson and Castenholz, 1992). They are prominent members of microbial mat communities containing other phototrophs such as purple and green sulfur bacteria and a top layer of cyanobacteria. Such habitats are characterized by steep and dynamic microgradients of oxygen, sulfide, and light. Species of *Beggiatoa* are frequently found in association with the MCLOs which may migrate on a diel basis in response to changing gradients. Although mesophilic, some of these populations are exposed to internal mat temperatures above 40 °C in shallow habitats exposed to full sun in the summer.

Oscillochloris species have been collected primarily from sulfide-containing freshwater mats over a temperature range of 10 to 20 °C, often in association with purple and green sulfur bacteria and species of *Beggiatoa* (Gorlenko, 1989a). Cultures of *Oscillochloris trichoides* were isolated from the sediment of a sulfide-containing spring in the Caucasus (Keppen et al., 1993a).

Unlike the other filamentous phototrophs, the known *Chloronema* species is mesophilic and planktonic, occurring in freshwater lakes with low sulfide and high ferrous iron content (Gorlenko, 1989b). It was found below the chemocline in an anoxic zone along with species of purple and green sulfur bacteria.

There are two other anoxygenic filamentous phototrophs that occur in microbial mat communities. BChl *a*-containing filaments form a prominent red layer deep in microbial mats in some alkaline hot springs (Castenholz, 1984). Like *Heliothrix*, these bacteria lack chlorosomes and BChls *c*, *d*, or *e* (Pierson et al., unpublished). The gliding filaments appear to be photoheterotrophic and contain abundant membranes similar in appearance to those of *Ectothiorhodospira* species (Boomer et al., 1990). Ultrastructurally similar filaments occur in hypersaline microbial mats in association with the cyanobacterium *Microcoleus chthonoplastes* (D'Amelio et al., 1987).

A. Carbon Metabolism

1. Heterotrophy vs. Autotrophy

Cf. aurantiacus grows most rapidly as a photoheterotroph. Autotrophic capability has been demonstrated in some strains (Madigan et al., 1974; Madigan and Brock, 1975), but is slower than photoheterotrophic growth. Both sulfide (Madigan and Brock, 1977a) and hydrogen (Holo and Sirevåg, 1986) can serve as electron donors for CO₂ fixation. Although most strains appear to grow slowly autotrophically in the lab, sulfide-dependent photoautotrophy has been demonstrated in natural hot spring populations of *Chloroflexus* (Giovannoni et al., 1987; Jørgensen and Nelson, 1988).

2. Autotrophic CO₂ Fixation Pathways

The pathway for CO₂ fixation has been difficult to identify (Madigan and Brock, 1977a; Sirevåg and Castenholz, 1979) until recently when it became clear that *Cf. aurantiacus* possesses a novel autotrophic pathway not found in any other organisms. Initial studies on the nature of this pathway suggested that acetyl-CoA was formed from CO₂ directly and that 3-hydroxypropionate was an intermediate in the pathway (Holo and Grace, 1987 and 1988; Holo, 1989). Carboxylation of acetyl-

CoA was suggested as a means to produce pyruvate (Holo and Grace, 1988).

Further studies on the CO₂ fixation pathway in *Cf. aurantiacus* (DSM 636) which is the same strain (OK-70-fl) studied by Holo and associates, have led to a postulated pathway in which two carboxylation steps result in the net formation of glyoxylate which is assimilated into cellular carbon, and the regeneration of acetyl-CoA which is the primary CO₂ acceptor molecule (Strauss et al., 1992; Strauss and Fuchs, 1993; Eisenreich et al., 1993; see Fig. 3 in Chapter 40 by Sirevåg). A different pathway has been proposed from studies of *Chloroflexus* strain B-3 (Ivanovsky et al., 1993; see Fig. 2 in Chapter 40 by Sirevåg). The two proposed pathways are similar in their first and last steps, but the intermediary reactions, including the second carboxylation step, are different.

In both proposed pathways the first carboxylation reaction uses acetyl-CoA as the acceptor molecule. The product of this reaction in the 3-hydroxypropionate cycle (Strauss et al., 1992) is malonyl-CoA, which is converted via 3-OH-propionate to propionyl-CoA which is the acceptor molecule for the second carboxylation reaction. In the cycle proposed by Ivanovsky (1993), the first carboxylation reaction produces pyruvate which is converted to phosphoenolpyruvate which serves as the acceptor molecule for the second carboxylation step. In the 3-hydroxypropionate cycle, propionyl-CoA is carboxylated to methylmalonyl-CoA which is converted to malyl-CoA, perhaps via succinate and malate.

Consistent with these proposed pathways is the presence in *Cf. aurantiacus* of a substantial corrinoid fraction, 85% of which is in the form of coenzyme B₁₂ (Stupperich et al., 1990). This corrinoid could be the prosthetic group of a methylmalonyl-CoA mutase involved in the reaction sequence from propionyl-CoA to succinyl-CoA (Stupperich et al., 1990). In the last reaction of the proposed cycle, the malyl-CoA is cleaved to glyoxylate, regenerating the acetyl-CoA (Strauss et al., 1992).

In the cycle proposed by Ivanovsky et al. (1993), the second carboxylation reaction produces malate via oxaloacetate. Ivanovsky et al. (1993) have shown that the terminal reaction producing glyoxylate is dependent on ATP and CoA. The major differences in the two cycles are the pyruvate vs. 3-OH-propionate routes as the primary carboxylation products and the oxaloacetate vs. succinate paths to malate following the second carboxylation step. Further work on the

enzymology of each of the specific reactions, including regulatory sites, is needed to clarify the pathway of autotrophy in *Cf. aurantiacus*. Both proposed CO₂ fixation pathways represent significant differences in autotrophic mechanisms from all other known organisms and point to the importance of *Cf. aurantiacus* in studies on the evolution of photosynthesis.

No evidence for a reversed TCA cycle, typical of green sulfur bacteria, or for the Calvin Cycle, typical of purple bacteria, has been found in *Cf. aurantiacus*. However, key enzymes of the Calvin Cycle (ribulose-bisphosphate carboxylase and phosphoribulokinase) have recently been reported in autotrophically grown cells of *Oscillochloris trichoides*, suggesting that the filamentous green bacteria are metabolically diverse (Ivanovsky, 1993).

3. Other Aspects of Carbon Metabolism

Heterotrophy and other aspects of carbon metabolism have recently been reviewed (Pierson and Castenholz, 1992). Suggested pathways for the assimilation of autotrophically produced glyoxylate into cellular carbon and other aspects of carbon metabolism are reviewed in Chapter 40 by Sirevåg.

4. Carbon Metabolism in Other Filamentous Phototrophs

Little is known of the carbon metabolism in the other anoxygenic phototrophic filamentous bacteria. Field studies revealed photoheterotrophy in the thermophilic *Heliobacterium oregonensis* (Pierson et al., 1984; Castenholz and Pierson, 1989). Photoheterotrophy appeared to be the dominant form of metabolism in *Cf. aurantiacus* var. *mesophilus* (Gorlenko, 1976). Both photoautotrophic and photoheterotrophic activity were demonstrated in a marine *Chloroflexus*-like organism in field studies (Mack and Pierson, 1988). Strong light-dependent uptake of ¹⁴C-bicarbonate has been observed in hypersaline *Chloroflexus*-like organisms (Pierson et al., 1994), suggesting sulfide-dependent autotrophy as their major metabolism in situ.

B. Nitrogen Metabolism

1. Nitrogen Fixation

The process of nitrogen fixation in anoxygenic

phototrophic bacteria is reviewed elsewhere in this volume (see Chapter 42 by Madigan and 43 by Ludden and Roberts). *Cf. aurantiacus* is most notable for its total lack of nitrogen fixing ability (Heda and Madigan, 1986), a characteristic that distinguishes it from all other major groups of phototrophs. While the antiquity of the *Chloroflexus* divergence remains in question, this absence of diazotrophy would be consistent with the idea that the ancestors of *Chloroflexus* diverged from the ancestral phototrophic bacteria before the evolution or acquisition of nitrogenase in the phototrophs.

Reports of nitrogen fixation in a recently isolated strain of *Oscillochloris trichoides* are of particular interest (Keppen et al., 1989; Keppen et al., 1993a,b). No nitrogenase activity occurred in the thermophilic strains of *Cf. aurantiacus*, but the strain Dg6 of *O. trichoides* had nitrogenase activity when grown in media with glycine, asparagine or in an atmosphere of N₂. Because the phylogenetic closeness of *O. trichoides* and *Cf. aurantiacus* remains to be determined, we are not certain what the significance of this finding is to the evolution of nitrogen metabolism among the filamentous phototrophs.

2. Other Aspects of Nitrogen Metabolism

Studies on nitrogen metabolism in *Cf. aurantiacus* (Heda and Madigan, 1986) revealed that nitrate did not support growth of the strains tested but that NH₄⁺ did. Among organic nitrogen compounds several amino acids also functioned as nitrogen sources for some strains, but proline, adenine, and urea did not serve as nitrogen sources for any of the strains tested (Heda and Madigan, 1986).

Pathways of nitrogen metabolism have been relatively little studied in *Cf. aurantiacus*. The pathway for ammonia assimilation involves glutamine synthetase only (Kaulen and Klemme, 1983). The lack of glutamate synthase activity remains to be clarified (Klemme, 1989).

Amino acid metabolism and regulation have been the subject of some degree of research. Within the microbial mat environment a considerable array of organic substrates is available and *Chloroflexus* appears to be able to metabolize several amino acids for both carbon and nitrogen sources with good growth on casein hydrolysate or glutamate (Pierson and Castenholz, 1974) or aspartate (Madigan et al., 1974). Glutamate (glu), alanine, and isoleucine (ile) are the main constituents of the intracellular amino

acid pool when cells are grown on minimal medium (Klemme et al., 1988). Although the concentration of glu is high, the ratio of ile to glu is unusually high in *Chloroflexus* (Klemme et al., 1990). Two different enzymes with L-threonine (L-serine) dehydratase activity were found (Laakmann-Ditges and Klemme, 1986 and 1988). The casein hydrolysate can be replaced by a mixture of glutamate and the amino acids of the 'aspartate' (met, lys, thr) and the 'ilv' (ile, leu, val) groups (Klemme et al., 1990). Aspartate kinase from *Chloroflexus* has a complex regulation system and is strongly inhibited by threonine (Klemme et al., 1990).

The utilization of amino acids in *Chloroflexus* grown in undefined media in batch culture or in chemostats at different dilution rates is quite complex. It is clear that physiological conditions of cultures will change when grown under these different conditions as preferential uptake of different amino acids occurs (Oelze et al., 1991). The relationship of growth phase in batch culture or the dilution rate in a chemostat to the uptake of glu is particularly significant since glu is the precursor to BChl synthesis. These authors also found that the commonly used buffer in medium for growing *Chloroflexus*, gly-gly, is preferentially consumed by batch cultures in the later stages of growth. Ser, ala, and glu each stimulated growth and pigment synthesis (Oelze and Söntgerath, 1992), and ser was the best substrate tested for both growth and bacteriochlorophyll synthesis.

Much remains to be learned about the enzymology and regulation of the amino acid and inorganic nitrogen metabolism in *Chloroflexus aurantiacus*. Very little is known about nitrogen metabolism in any of the other filamentous anoxygenic phototrophs.

C. Sulfur Metabolism

Cf. aurantiacus can use a variety of compounds including cysteine, glutathione, methionine, sulfide, and sulfate as a source of nutrient sulfur during photoheterotrophic growth (Krasil'nikova, 1987). Sulfate is the best source for biosynthesis although thiosulfate may also be used (Krasil'nikova, 1987; Kondrat'eva and Krasil'nikova, 1988). High levels of ATP sulfurylase activity were found with optimal activity at 60–70 °C (Krasil'nikova, 1987).

The use of sulfur compounds as electron donors in photosynthesis has been reviewed elsewhere (see Chapter 39 by Brune). Madigan and Brock (1975) and Giovannoni et al. (1987) showed that sulfide was

oxidized to elemental sulfur that adhered to and accumulated outside the cells during both photoheterotrophic and photoautotrophic growth.

Sulfide can also be used as an electron donor for photoautotrophic growth of *Oscillochloris trichoides* (Keppen et al., 1993a) and appears to support photoautotrophy in the hypersaline marine *Chloroflexus*-like organisms (Pierson et al., 1994).

D. Aspects of Energy Metabolism

1. Phototrophy vs. Chemotrophy

Cf. aurantiacus appears to grow best in nature as a photoheterotroph. Its growth rates and yields in pure culture are highest when grown anaerobically in the light on complex organic media. Aerobic growth in the dark occurs but is slower and has lower yields (Pierson and Castenholz, 1974b). Krasil'nikova and Kondrat'eva (1987) reported that fermentation occurs anaerobically in the dark and products from the fermentation of glucose included acetate, pyruvate, lactate, malate, ethanol, and formate. Even those strains which will grow photoautotrophically (such as the GCF strain) grow best as photoheterotrophs (Giovannoni et al., 1987). The latter strain could tolerate exposure to oxygen but did not grow aerobically in the dark, appearing to be an obligate phototroph.

A thorough analysis of the capacity of *Cf. aurantiacus* for anaerobic respiration remains to be done. Thiosulfate may serve as an electron acceptor in some strains with the accompanying production of hydrogen sulfide (Kondrat'eva and Krasil'nikova, 1988).

The metabolic versatility of *Cf. aurantiacus* may be a definite advantage in its microbial mat habitat in thermal springs. The mat community usually includes oxygenic cyanobacteria growing above and within the *Chloroflexus* layer. Conditions in such a mat fluctuate on a diel basis (Revsbech and Ward, 1984). During the day, such mats are highly oxic. During darkness and low light periods, the mats become anoxic. The cyanobacteria may produce a large variety of organic compounds that can be assimilated by *Chloroflexus* both in the light and in the dark (Anderson et al., 1987; Bateson and Ward, 1988; Teiser and Castenholz, unpublished data; Ward et al., 1984). In hot springs containing primary sulfide, sulfide-tolerant cyanobacteria do not occur at temperatures above 56 °C and *Chloroflexus* may

grow above this temperature (to 66 °C) alone as a photoautotroph (Castenholz, 1988; see also Chapter 5 by Castenholz and Pierson). Various physiologically significant environmental factors such as oxygen, light, and organic compounds are likely to have important roles directly or indirectly in regulating the metabolism of *Chloroflexus*.

2. ATPase

ATP synthase has been isolated from *Cf. aurantiacus* strain A (Microbiology Culture Collection, Moscow State University). The F_1 factor was isolated first and shown to have ATPase activity (Yanyushin, 1988). Further characterization revealed that it was very similar to the enzyme isolated from other eubacteria although the *Chloroflexus* enzyme had only four subunits rather than five in the catalytic F_1 portion (Yanyushin, 1991). The four subunits are of molecular masses 62,53,36, and 16 kD in a stoichiometry of 3:3:1:1. The proton-channel F_0 factor was composed of three subunits. The enzyme was unusually stable (Yanyushin, 1988). While *Chloroflexus* appears to have a few differences in its ATP synthase from those of other organisms, the enzymes are fundamentally similar.

3. Hydrogenase

A hydrogenase that is loosely associated with the cell membranes occurs in *Cf. aurantiacus* strain A (Microbiology Culture Collection, Moscow State University) (Serebryakova et al., 1989). This hydrogenase is a constitutive enzyme that removes electrons from hydrogen during photoautotrophic growth and releases molecular hydrogen produced during fermentation of glucose and pyruvate by cultures grown anaerobically in the dark. Significant inactivation of cellular hydrogenase did not occur below 80 °C, reflecting an ability of the cell environment to stabilize the enzyme (Serebryakova et al., 1989). Maximum activity of the enzyme was at 65 °C (Serebryakova et al., 1989). The enzyme contains an iron-sulfur cluster and nickel and has ferredoxin as its natural electron donor (Serebryakova et al., 1990). It differs from the sulfide-inactivated membrane-bound enzyme described by Drutschmann and Klemme (1985) from strain OK-70-fl and from the hydrogenase of green sulfur bacteria (Serebryakova et al., 1990). The hydrogenase was inhibited by CO and NO but not by C_2H_2 (Serebryakova and Gogotov, 1991).

E. Pigmentation

One of the most interesting aspects of the physiology of photosynthesis in *Cf. aurantiacus* lies in the diversity, synthesis, and regulation of its pigments.

1. Diversity and Function of Pigments

Cf. aurantiacus contains BChl *c* in its chlorosomes as the primary light-harvesting pigment. It contains smaller amounts of BChl *a* (B800 and B865 complexes) in the membrane which also function in light-harvesting and in transfer of energy from the chlorosomes to the membrane-bound reaction centers which contain BChl *a* and BPh *a*. A specialized BChl *a* absorbing at 792 nm is associated with the baseplate of the chlorosome at the attachment site to the membrane. In addition to the bacteriochlorophylls, *Cf. aurantiacus* also contains carotenoids: β -carotene, γ -carotene, and hydroxy- γ -carotene-glucoside comprising 80–95% of the total carotenoids in anaerobically grown cells and echinenone and myxobactone constituting 75% of the carotenoids in aerobically grown cells (K. Schmidt, personal communication; Schmidt et al., 1980; Halfen et al., 1972).

Based on analyses of mat layers, the marine and hypersaline *Chloroflexus*-like organisms appear to contain BChl *c* absorbing between 747 and 755 nm or BChl *d* or *e* absorbing between 710 and 725 nm plus BChl *a* (Mack and Pierson, 1988; Pierson et al., 1994; Palmisano et al., 1989; Des Marais et al., 1992). Evidence for the same pigments has also been found in highly enriched cultures (Pierson et al., 1994). Evidence for γ -carotene as a biomarker for MCLOs in hypersaline microbial mats has been reported (Palmisano et al., 1989; Des Marais et al., 1992). *Chloronema* appears to contain BChl *d*, but also contains small amounts of BChl *c* or *e* and presumably BChl *a* (Gorlenko, 1989b). *Oscillochloris* contains BChl *c* and *a* (Keppen et al., 1993a).

Heliothrix oregonensis and the red thermophilic filaments of mats in Yellowstone National Park contain only BChl *a*. The latter contain a BChl *a* which has absorption maxima at 910 and 807 nm (Boomer et al., 1990).

The light-harvesting BChl *c* of *Cf. aurantiacus* is actually a diverse assemblage of several different isomers and is found as esters of five different alcohols: geranylgeraniol, phytol, and stearyl as well as the non-isoprenoid alcohols cetol and oleol (Fages et al., 1990).

Knowledge of the identity, evolutionary origin, and adaptive variation in the light-harvesting chlorosome BChls of green sulfur bacteria and *Chloroflexus* has been progressing in recent years. It has become clearer that changes may occur in the structure of these chlorophylls in a species of *Chlorobium* when cultured for prolonged periods under low light conditions (Broch-Due and Ormerod, 1978; Bobe et al., 1990). Enzymatic methylation of BChl *d* may result in conversion to BChl *c* with a red-shift in absorption maxima from about 714 nm to around 740 nm (Bobe et al., 1990). This transition has been documented in some species of green sulfur bacteria while maintained in long-term culture at low light intensities. Because small amounts of BChl *d* have been detected in *Cf. aurantiacus* (Brune et al., 1987), it is suggested that a similar transition may have occurred in this species. It is not clear whether such changes represent adaptive responses or genetic evolutionary changes. The presence of such transitions and two major forms of BChl (*c* and *d*) in the same organism as well as the isomers and different alcohol esters provide a diversity of pigment molecules within *Cf. aurantiacus*. All of these pigments are found in the chlorosomes and the increased alkylation occurring at low light levels could increase the pigment levels attainable by providing more hydrophobic character and hence closer packing of the pigment molecules (Bobe et al., 1990).

2. Synthesis and Regulation of Pigments

Synthesis of bacteriochlorophylls in *Cf. aurantiacus* is via the C_5 pathway from glutamate as in the oxygenic cyanobacteria and green sulfur bacteria (Swanson and Smith, 1990; Oh-hama et al., 1991; Kern and Klemme, 1989; Avissar et al., 1989). This appears to be the more ancestral pathway for the synthesis of bacteriochlorophylls (Oh-hama et al., 1991).

Cf. aurantiacus grows under conditions of great environmental flux (see Section III. D.1 of this Chapter and Chapter 5 by Castenholz and Pierson). It is not surprising that these environmental parameters have a regulatory influence on the metabolism of *Cf. aurantiacus*. Pigment synthesis is affected by oxygen, light, growth rate, and organic substrates. Photosynthetic activity and growth are also affected by these parameters. The array of pigments present in *Cf. aurantiacus* and the alterations

that occur to their relative specific contents due to changes in environmental parameters and stage of growth and rate of growth, result in highly varied absorption spectra. Thus, one must consider carefully the conditions of growth and stage of growth when reporting spectra for *Cf. aurantiacus* in culture (Pierson and Castenholz, 1974b; Kharchenko, 1992).

Natural populations of *Cf. aurantiacus* adapted to low light intensities show photoinhibition when incubated in higher light intensities (Madigan and Brock, 1977b). In culture, growth rate increased and bacteriochlorophyll synthesis decreased in response to higher light intensities (Pierson and Castenholz, 1974b). Other early studies on the effects of light and oxygen on cultures of *Cf. aurantiacus* (Sprague et al., 1981a, 1981b; Schmidt et al., 1980; Feick et al., 1982) showed that bacteriochlorophyll synthesis is reduced in the presence of oxygen and is induced under anoxic conditions, even in the dark. The structure of the photosynthetic apparatus is also affected by oxygen. Lowering the oxygen partial pressure increased the level of BChl *c* and the number and size of chlorosomes. However, the change in ratio of BChl *c* to BChl *a* indicated differential regulation of these two pigments. Increasing light intensity was accompanied by an increase in growth rate (Pierson and Castenholz, 1974b; Oelze and Fuller, 1987).

Using chemostat-grown cultures Oelze and Fuller (1987) showed that the specific contents of both BChl *a* and *c* increased with decreasing growth rate.

Golecki and Oelze (1987) showed that the number of chlorosomes and the percentage of cell membrane surface area covered by baseplates correlated directly with the specific content of BChl *a*. As the specific content of BChl *a* increased linearly, the specific content of BChl *c* increased exponentially. This increase in BChl *c* is structurally accommodated by increasing the volume of the chlorosomes, the density of the BChl *c* molecules within the chlorosomes, and the number of chlorosomes (Golecki and Oelze, 1987). While the effects of growth rate, light, and oxygen on pigment levels and ultrastructure are complex, results of more recent studies are beginning to clarify some of the physiological aspects of this system.

In an effort to elucidate the mechanisms of regulation by light and oxygen on synthesis of both bacteriochlorophylls *a* and *c*, Oelze (1992) has studied the impact of these factors on parts of the C_5 biosynthetic pathway. By using batch cultures and

serine-limited growth in chemostat cultures, it was shown that gabaculine, which inhibits the first step in 5-aminolevulinic acid (ALA) synthesis, inhibits BChl *c* synthesis more than BChl *a* synthesis. Oxygen produced the same effect as gabaculine, thus reducing the BChl *c* to *a* ratio. Light also appeared to act as a control on ALA formation lowering the BChl *c* to *a* ratio.

Other parts of the pathway may also be affected by oxygen since addition of ALA to aerated cultures produced higher levels of coproporphyrin but not BChl (Oelze, 1992). Although the site of ALA synthesis is clearly one important regulatory site for oxygen and light, there may be other sites too, and little is known about the mechanism of action of light and oxygen or even whether they act directly or indirectly. It appears that BChl *c* synthesis competes with biomass synthesis for some common substrate such as glutamate (Oelze, 1992) so that when biomass levels are high, BChl *c* levels are low. It was further suggested that coproporphyrinogen excretion might be a valve to eliminate excess precursors of BChl *c* when a decrease in chlorosome production would lead to their accumulation (Oelze, 1992).

The regulation of the protein components of the chlorosomes may also be affected by oxygen. The BChl *c* is thought to be associated with a low molecular weight (5.7 kDa) protein. This protein is not synthesized as part of a large polypeptide precursor that is posttranslationally cleaved into functional fragments (Theroux et al., 1990). The authors isolated the gene encoding this protein, showing it to be a discrete gene (*csmA*) whose expression is regulated by oxygen either transcriptionally or posttranscriptionally. Transcriptional regulation would involve induction of message synthesis by anaerobiosis. Posttranscriptional regulation would require oxygen-dependent digestion of the *csmA* messages (Theroux et al., 1990).

A greater understanding of regulation of pigment synthesis requires isolation of key enzymes in the C_5 biosynthetic pathway and study of their regulation. Regulation of expression of the chlorosomal genes will also elucidate the possible multiple roles of oxygen in regulating the synthesis and assembly of the entire photosynthetic apparatus. The use of pigment mutants (Pierson et al., 1984b) could enhance the understanding of the role of pigments in the assembly of the photosynthetic apparatus.

F. Physical and Chemical Factors Affecting Growth and Distribution in the Environment

1. Temperature

Many aspects of thermophily have been studied in *C. aurantiacus* and only a few references are cited here. Optimal activity of several enzymes is between 45 °C and 70 °C. Isolated enzyme activities are sometimes lower than activities measured in cells. An amylase has been described with optimum activity at 71 °C (Ratanakhanokchai et al., 1992).

The photochemical reaction center of *Cf. aurantiacus* has thermal stability (Pierson et al., 1983; Nozawa and Madigan, 1991), a fact that has made it applicable to the study of energy-requiring transport phenomena in membranes from thermophilic anaerobic bacteria. The reconstituted membranes containing the thermostable reaction centers can develop a proton motive force in the presence of light under anaerobic conditions (Speelmans et al., 1993). The special pair band within the reaction center appears to be more sensitive to thermal denaturation than the accessory pigment band (Pierson et al., 1983; Nozawa and Madigan, 1991).

Membrane phenomena at high temperatures are dependent not only on thermal stability of proteins but on the stability of the inherent membrane structure which is influenced by lipid phase transitions. Oelze and Fuller (1983) determined the temperature characteristics of growth and the membrane-bound enzyme activities of NADH oxidase, succinate 2,6-dichlorophenolindophenol reductase, ATPase, and light-induced proton extrusion. Enzyme activities were maximal at 65–70 °C but membrane phenomena, such as proton extrusion, appeared to be significantly altered at temperatures above 60 °C. An apparent lipid phase transition occurred at suboptimal temperatures (near 40 °C in cells grown at 50 °C) which could contribute to a decrease in photosynthetic efficiency.

The presence of the polyamine, *sym*-homospermidine may contribute to thermal stability of some components in cells of *Cf. aurantiacus* (Norgaard et al., 1983), although this role remains to be confirmed.

2. Salinity

Marine and hypersaline *Chloroflexus*-like organisms occur at salinities ranging from 3.5% (Mack and

Pierson, 1988) to 15% (Pierson et al., 1994). The organisms of the latter habitat, when studied in mixed culture, had an optimum salinity for growth of 10% and did not grow at salinities as high as 15% even though they are exposed to such high salinities at least transiently in nature.

3. Radiation

a. Ultraviolet Radiation

Cf. aurantiacus is surprisingly resistant to ultraviolet radiation (Pierson et al., 1984b, 1993; Pierson, 1994). Cultures were grown under anoxic conditions in the light in the presence of continuous UV-C radiation with near normal growth rates but depressed yields (Pierson et al., 1993). *Cf. aurantiacus* grew very well in a continuous UV-C irradiance of 0.01 W m^{-2} , a level that was lethal to *E. coli* (Pierson et al., 1993). Although nothing is yet known of the mechanisms of UV resistance in *Cf. aurantiacus*, such tolerance may represent a relict of specific adaptations to growth in shallow mat communities early in the Precambrian prior to the existence of oxygen and a protective ozone layer (Pierson, 1994; Pierson et al., 1993).

b. Visible and Near Infrared Radiation

As a phototroph *Cf. aurantiacus* is dependent on light to sustain its primary growth in the natural environment of hot spring microbial mats. With carotenoids, BChl *c* and *a* as important photosynthetic pigments, these cells seem well-adapted to using much of the visible and NIR parts of the spectrum. By using a fiber optic probe to measure spectral irradiance within the microbial mats (Pierson et al., 1990), it has been possible to demonstrate which wavelengths are available to sustain photosynthesis at a given depth in the mat community where *Chloroflexus* cells may be found and to show which wavelengths are attenuated by specific layers of bacteria including *Chloroflexus*. In most mat habitats wavelengths below 600 nm are attenuated just below the surface leaving primarily red and NIR wavelengths penetrating to the depths at which *Cf. aurantiacus* and other *Chloroflexus*-like organisms are found (see Figs. 7 and 8 in Chapter 5 by Castenholz and Pierson). Consequently in the hot spring environment it appears that *Chloroflexus* must rely on the absorption bands at 740, 805, and 865 nm

from BChl *c* and *a* to sustain phototrophic growth.

The marine and hypersaline *Chloroflexus*-like organisms are also often found in microbial mats at depths which are exposed to irradiances containing only red and NIR wavelengths (Pierson et al., 1994).

When *Chloroflexus*-like organisms are in planktonic habitats, they are usually found fairly deep in anoxic zones where all NIR is eliminated. Consequently the photosynthetic activity of members of the Chloroflexaceae there will be dependent on the visible spectrum.

G. Motility and Tactic Responses

All of the filamentous bacteria discussed in this chapter appear to be capable of slow gliding motility, but few quantitative data are available. *Chloroflexus aurantiacus* and the broader filaments of *Heliobacterium oregonensis* (F-2 and F-1, respectively, Pierson and Castenholz, 1971) moved at apparently maximum rates of $0.04 \mu\text{m s}^{-1}$ and $0.4 \mu\text{m s}^{-1}$, respectively, on agar in a uniform light field. *Heliobacterium* displays a clumping phenomenon similar to that of many gliding filamentous cyanobacteria (see Pierson et al., 1984a). In the even broader filament type of *Oscillochloris chrysea*, gliding rates of $7 \mu\text{m s}^{-1}$ were recorded (Gorlenko, 1989a). This is a very rapid rate even for fast gliding species of the cyanobacterial genus, *Oscillatoria*.

Tactic behavior has also been observed in many field populations of *Chloroflexus* and *Chloroflexus*-like organisms, but no rigorous tests of the nature of the stimulus have been made. *Chloroflexus*-like organisms are known to migrate to the surface of hot spring mats in darkness (Doemel and Brock, 1974) and this behavior has been attributed to positive aerotaxis. Similar behavioral responses may occur in *Heliobacterium* and the red filamentous bacteria of many Yellowstone hot springs (Boomer et al., 1990; Pierson et al., unpublished). On the other hand, populations of *Chloroflexus*-like filaments in hypersaline mats appear to remain in anoxic underzones below both the sedentary and vertically migrating cyanobacterial populations (Garcia-Pichel et al., 1994).

H. Associations with Other Organisms

The little that is known about intimate associations with other organisms comes from studies of photo- or chemo-heterotrophic *Chloroflexus* and the

photoautotrophic cyanobacteria of hot springs. These are discussed in Chapter 5 by Castenholz and Pierson.

Acknowledgment

We thank Kat Menear for preparation of the manuscript.

Summary

Phototrophic sulfur bacteria often form mass developments in aquatic environments, either planktonic or benthic, where anoxic layers containing reduced sulfur compounds are exposed to light. This chapter summarizes a number of reports from the literature, collecting the information on the abundance of these bacteria as well as on their contribution to primary production. From the point of view of population dynamics, the abundance of these organisms is the consequence of a certain balance between growth and losses. Both specific growth rates, and specific rates of loss through several processes are analyzed in several environments, in an attempt to generalize on the growth status of blooms of phototrophic sulfur bacteria. The information available indicates the existence of an upper limit for the production of these bacteria in nature, and seems to suggest the existence of an upper limit for biomass based in the balance between growth and losses.

The chapter also reviews the main variables affecting growth of phototrophic sulfur bacteria in nature, paying attention both to the in situ status of these variables and to the functional response of the organisms to each of them. All of this information is integrated in a section in which several case-studies are described, and which emphasizes the role fluctuations play on competition and coexistence between different phototrophic sulfur bacteria.

I. Introduction

Phototrophic sulfur bacteria are organisms commonly found in illuminated aquatic environments containing hydrogen sulfide. Since the first observations, made at the end of last century, their presence has been repeatedly reported in lakes and sediments all over the world, and a number of reviews has been published gathering information on several aspects of their biology (Pfenning, 1978, 1989; Van Gernerden, 1983; Van Gernerden and Beeftink, 1983; Madigan, 1988; Caumette, 1989; Drews and Imhoff, 1991).

Observations on phototrophic sulfur bacteria have been reported as early as 1888 (Pfenning and Trüper, 1992). Many of the reports constitute casual observations on their presence and abundance or short term studies. More recently, communities of phototrophic sulfur bacteria have been studied for an extended period of time, sometimes spanning several years. In these cases, a great deal of information regarding that particular environment can be found in a number of different publications. Such is the case of Lake Vechten in The Netherlands (Steenbergen, 1982; Steenbergen and Korthals, 1982; Steenbergen et al., 1987) or Lake Cisó in Spain (Guerrero et al., 1985; Van Gernerden et al., 1985;

Mas et al., 1990; Gasol et al., 1991; Pedrós-Alió and Guerrero, 1993). Of interest are also the detailed observations made by different investigators in the former Soviet Union and compiled by Gorlenko et al. (1983), as well as the extensive work carried out in Japanese lakes (Takahashi and Ichimura, 1968, 1970; Matsuyama and Shirouzu, 1978; Matsuyama, 1987) or in several different lakes in the USA (Parkin and Brock, 1980a, 1980b, 1981).

The present chapter attempts to approach the ecology of these organisms by, first, providing background information on their abundance and activity in natural environments and trying to extract general patterns from the information available and, second, by reviewing some relevant data on their physiology, which allow the interpretation of a number of situations commonly found in nature.

II. Characteristic and Vertical Structure of the Habitats

Phototrophic sulfur bacteria thrive in two different types of environments, either in stratified lakes, where they can occupy the top of the anoxic layers, or on the top millimeters of shallow aquatic sediments, where they can sometimes be detected in the anoxic zone, underlying layers of oxygenic phototrophs. Their development requires the existence of the physical structure needed to avoid vertical mixing and to allow the establishment of an illuminated anoxic compartment. In planktonic environments, this structure is provided either by thermal stratification,

Abbreviations: 3-MPA – 3-mercapto propionate; A – affinity; BChl – bacteriochlorophyll; D – dilution rate; DMDS – dimethyl disulfide; DMS – dimethyl sulfide; DMSO – dimethyl sulfoxide; DMSP – dimethyl sulfonio propionate; K_s – saturation constant; MSH – methanethiol; RuBisCO – ribulose biphosphate carboxylate; Y – yield factor; μ – specific growth rate; μ_{\max} – maximum specific growth rate

as in holomictic lakes, or by differences in density related to differences in the concentration of solutes, as in meromictic lakes. In holomictic lakes, thermal stratification develops during spring and summer when the sun warms up the surface layers, and disappears with the coming of cold weather. In meromictic lakes, stratification is permanent, lasting for more than one season and, thus, permits a more permanent community. Both thermal and chemical stratification provide a stable environment where, except for gentle variations in the vertical position of the interface which in most cases can be easily followed by the organisms, phototrophic sulfur bacteria enjoy a rather stable situation. An example of a planktonic community of phototrophic sulfur bacteria can be observed in Fig. 1 corresponding to Lake Vilar (Spain). The left panel of the figure shows vertical profiles of oxygen and hydrogen sulfide. The central panel displays the vertical distribution of purple and green bacteria. Purple sulfur bacteria are positioned forming a very narrow band (around 10 cm) at the interface, while green sulfur bacteria, with a lower biomass are found underneath. Measurements of the rates of carbon dioxide fixation and sulfide oxidation, shown in the third panel, indicate low activities at the bottom of the plate and comparably

high activities at the top and at the middle of the plate. Because biomass at the top is considerably lower, the specific activity is higher, an observation which is in agreement with a higher irradiance at the top of the plate (Guerrero et al., 1985).

Benthic communities, more often referred to as microbial mats, occur at a different scale. Figure 2 shows a vertical profile of the distribution of phototrophic sulfur bacteria in a laminated sediment in Scapa Beach (Orkney Islands), as well as vertical profiles of oxygen and hydrogen sulfide at different times of the day. Although the overall structure of the system is quite similar to the structure observed in planktonic environments, bacteria in sediments face a rather different situation. As in the case of lakes, sediments also provide the physico-chemical conditions required for the development of phototrophic sulfur bacteria. However, due to the difference in scale involved, certain characteristics differ remarkably between both environments:

a) Sediments, especially in littoral areas, are much more subject to external factors such as tidal movements. The presence of the oxic layer often depends on the activity of oxygenic phototrophs occupying the upper part of the sediment. Since

Fig. 1. Vertical profiles of oxygen, sulfide, and turbidity (left panel), irradiance and biovolumes of populations of purple and green sulfur bacteria (middle panel), and rates of CO_2 fixation and sulfide oxidation (right panel) in Lake Vilar, Spain. Measurements were performed at zenith in July, 1982. Redrawn from Guerrero et al. (1985).

Fig. 2. Vertical profiles of sulfide and oxygen at 1 p.m. (left panel) and 7 p.m. (right panel) in the bloom of *Thiocapsa roseopersicina* developing on Scapa Beach, Orkney Islands, Scotland. The middle panel shows the vertical distribution of bacteriochlorophyll *a*, the upper maximum represents the present bloom, the maximum at 8–9 mm reflects an earlier, buried, bloom. Redrawn from Van Gernerden et al. (1989a).

production of oxygen by these organisms depends on light, these environments display dramatic variations in the position of the oxic/anoxic interface. These variations expose phototrophic sulfur bacteria living there to fluctuations in the levels of oxygen and hydrogen sulfide that, no doubt, influence the metabolic profile needed to successfully colonize these environments.

b) Benthic communities of microorganisms are characterized by an extremely high population density in a relatively thin layer. Because microbial activity is much more concentrated in these sediments than in planktonic layers, the biological contribution to the chemical processes occurring at the interface is also much more important. When comparing the contribution of biological processes to the oxidation of reduced sulfur compounds in oxic/anoxic interfaces, Jørgensen (1982) draws attention to the fact that in the Black Sea where the interface spans 35 meters, the oxidation of sulfide is mainly abiotic, while in a microbial mat where the interface occupies only 50 μm , the oxidation is mediated predominantly by microorganisms.

c) The fact that microbial mats have small vertical dimensions, are rich in organic matter, and occur in exposed surfaces, makes these communities potentially unstable, as they are exposed both to erosion, and grazing by a number of different predators. Thus, their occurrence is relatively precarious, being found in many cases only during reduced periods of time, or more permanently, in areas where the existence of extreme conditions reduces the presence and the impact of invertebrate predators (Awramik, 1984).

d) The spectrum of light available to phototrophic sulfur bacteria in planktonic environments is strongly modified due to absorption by water, becoming enriched with depth in the yellow-green part of the spectrum. Sediments, on the contrary, offer a light climate much more enriched in the near infrared. These differences in light quality are likely to influence the composition of the microbial community inhabiting each environment.

As a consequence of these factors, important differences in the composition of the community of phototrophic sulfur bacteria might be expected between planktonic and benthic environments. Many

data have been gathered on their occurrence in lakes, unfortunately, the data available on microbial mats do not yet allow a generalization in that respect. However, as will be shown in the following sections, the physiological characteristics of some organisms make them good candidates to occupy the sediment niche.

III. Distribution and Abundance of Phototrophic Sulfur Bacteria in Nature

Somehow, most of the literature available describes the occurrence of phototrophic sulfur bacteria in lakes and, only recently, detailed descriptions of benthic systems have been published. Many old reports contain little information besides the mentioning of the organisms, and some estimates of their abundance, based on total counts under the microscope. More recent reports also give information on the type of Bchl as well as their concentrations. Information on the major carotenoids, although extremely interesting from an ecological and taxonomic point of view, is seldom provided although, when the organisms have been identified, it can easily be deduced. After going through a rather exhaustive examination of the literature, we made a selection of the cases in which, besides a report on the occurrence of a certain organism, estimates of its abundance were also provided. The information, for both planktonic and benthic environments, has been summarized in Table 1.

A. Planktonic Environments

The systems described are representative for all sorts of planktonic environments, and display a wide range of different physico-chemical variables. Habitats for phototrophic sulfur bacteria can be found ranging from freshwater, to marine or even hypersaline environments. Some of these have a karstic origin, while others are close to the sea shore and thus exposed to intrusions of sea water. From a preliminary examination of the cases listed in Table 1, no clear regularities can be readily deduced.

The depth at which phototrophic sulfur bacteria occur in lakes is a function of the depth of the oxic/anoxic interface. In most cases, the latter is a consequence of the morphometry of the water body, its exposure to wind, the degree of thermal stability and the surface to volume ratio (Hutchinson, 1957).

The depth of the interface is likely to affect both the quantity and the quality of the light reaching the bacterial layer. Thus, certain organisms might be better adapted to the light climates predominant at higher depths, while others are better suited for growth closer to the surface. Since carotenoids are the main photosynthetic pigments responsible for light harvesting in planktonic environments, the different organisms listed in Table 1 were grouped according to their carotenoids. Their distribution with depth is represented in Fig. 3, in which the upper panel shows the occurrences reported of each carotenoid, and the lower panel displays their actual distribution with depth. In the case of purple sulfur bacteria, okenone seems to be the most frequent (36 cases), spirilloxanthin, lycopenal and rhodopinal occurring in a much lower number of cases (10, 7 and 4, respectively). In the case of purple bacteria, no clear pattern seems to emerge, except perhaps for the presence of lycopenal- and rhodopinal- containing organisms closer to the surface. However, the small number of cases involved does not allow to reach any firm conclusion. Within the green sulfur bacteria, a pattern which has already been reported and explained by Montesinos et al. (1983) emerges clearly. Green sulfur bacteria containing isorenieratene (brown-colored species) are usually found at deeper layers (average 14 m) than their chlorobactene containing counterparts (average 6 m).

The maximum abundance at which phototrophic sulfur bacteria are found in planktonic environments varies within several orders of magnitude. In Table 1 maximum abundance have been expressed either as the concentration of organisms or as the concentration of photopigments, in which BChl *a* and *b* correspond to purple sulfur bacteria and *c*, *d* and *e*, to green sulfur bacteria. In order to better visualize how often these bacteria are found at a certain abundance, the frequency distribution of the abundance has been plotted in Fig. 4. In the upper panel, apart from Mahoney Lake (British Columbia, Canada) in which population densities reach $4 \times 10^8 \text{ cells}\cdot\text{ml}^{-1}$, 50% of the cases lay in the interval between 2.4×10^4 and $4 \times 10^6 \text{ cells}\cdot\text{ml}^{-1}$. The lower panel shows the distribution of BChl which ranges from approximately 10 to $1000 \mu\text{g}\cdot\text{l}^{-1}$, with 50% of the cases being between 35 and $451 \mu\text{g}\cdot\text{l}^{-1}$. In some cases, abundance was available as the amount of BChl per square meter (Table 2). In some cases values between 1000 and $2000 \text{ mg BChl } a\cdot\text{m}^{-2}$ have been observed. These values, as will be discussed in section VII, are close

Table 1. Summary of the distribution and abundance of phototrophic sulfur bacteria in natural environments. Data have been sorted by lakes. Only reports giving an estimate of the abundance have been included

Based on literature data presented in Table 1.

to the theoretical maximum for the biomass of phototrophic sulfur bacteria.

B. Benthic Environments

Most of the cases collected in Table 1 describing the presence of phototrophic sulfur bacteria in benthic environments correspond to sandy sediments close to the seashore, either beaches or tidal flats. The presence of these organisms has also been described in other benthic microbial communities such as those occurring in hypersaline lagoons like Laguna Figueroa (Stolz, 1983, 1990) or Laguna Guerrero Negro (Javor and Castenholz, 1981, 1984; Jørgensen and Des Marais, 1986b; D'Amelio et al, 1989), or in hot springs (Castenholz, 1984, 1988; Madigan, 1984).

Due to the rapid extinction of light in the sediments, development of phototrophic sulfur bacteria is usually limited to the upper 5 millimeters. The predominant organism in most systems seems to be *Thiocapsa roseopersicina* which can reach between 10^6 and 10^7

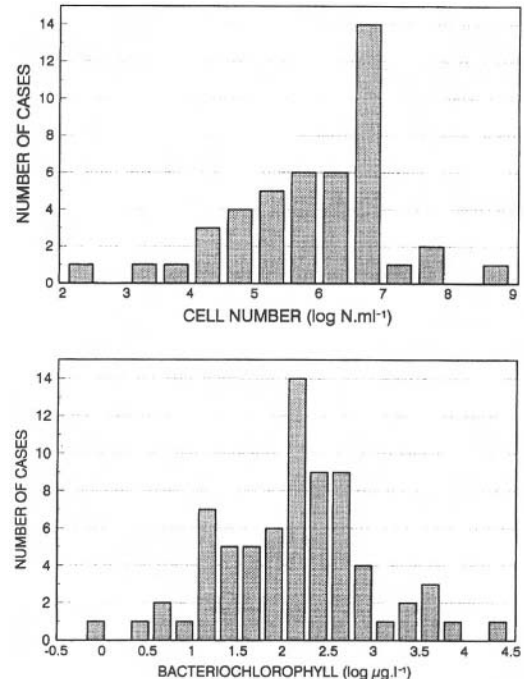

Fig. 4. Frequency distribution of cell number (upper panel) and bacteriochlorophyll concentration (lower panel) in blooms of phototrophic sulfur bacteria. Based on literature data presented in Table 1.

cells·cm⁻³. Since these values correspond to most probable number viable counts, the actual numbers might be somewhat higher. Concentrations of bacteriochlorophyll lay in most cases between 100 and 500 $\mu\text{g}\cdot\text{cm}^{-3}$. However, the maximum concentration found might depend to some extent on the resolution of the sampling, with finer resolution allowing for the detection of more narrow and concentrated layers.

IV. Contribution of Phototrophic Sulfur Bacteria to Primary Production

Besides the abundances mentioned in the previous section, some studies also provide data on CO₂ fixation. In some cases, the data have been integrated and are provided per square meter on a daily basis. In very few instances, the contribution to primary productivity is available on a yearly basis. The available rates ($\mu\text{g C}\cdot\text{m}^{-3}\cdot\text{d}^{-1}$) are shown in the upper panel of Fig. 5. Although the maximum value of 5750 $\mu\text{g C}\cdot\text{m}^{-3}\cdot\text{d}^{-1}$ measured by Wetzel (1973) in Smith's Hole constitutes the highest measure reported

until now, the distribution in Fig. 5 seems to indicate that maximum rates usually are much lower, approximately between 50 and 500 $\mu\text{g C}\cdot\text{m}^{-3}\cdot\text{d}^{-1}$.

In order to have a better idea of the extent to which phototrophic sulfur bacteria contribute to the carbon cycle of their environments, the values available on their total annual production have been compiled in Table 3. The data indicate that phototrophic sulfur bacteria indeed can play a very active role as primary producers in some environments. However, since the occurrence of these organisms in anoxic layers containing hydrogen sulfide probably restricts the role of aerobic grazers, it is not clear whether the carbon they fix will have any impact on the overall trophic structure of their environments. Furthermore, measurements of the content of stable carbon and sulfur isotopes in consumers of several meromictic lakes containing abundant populations of phototrophic sulfur bacteria seem to rule out the hypothesis of a food web based mainly on bacterial primary production (Fry, 1986).

Because photosynthetic activity depends on light, and in situ irradiances decrease with depth and with the concentration of algae in the surface layers, production by phototrophic sulfur bacteria will be high both in shallow lakes (Lake Cisó, Smith Hole) and in lakes where, although deeper, contain little algae (Fayetteville Green Lake). A good correlation seems to exist between the fraction (in %) of the total primary production due to phototrophic sulfur bacteria, and the amount of light reaching the anoxic

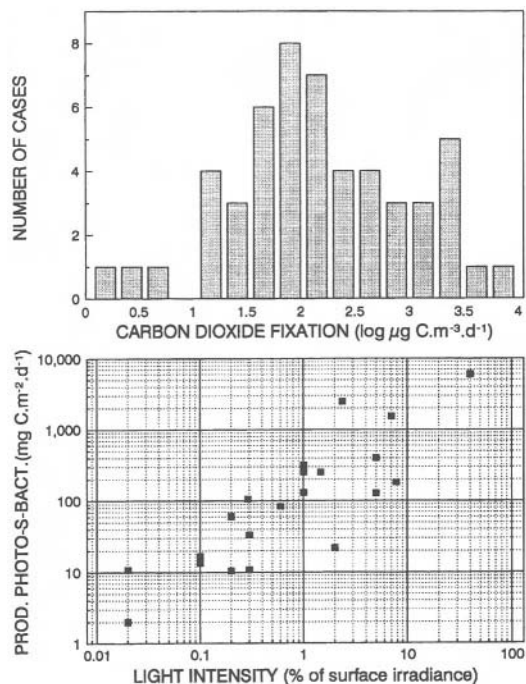

Fig. 5. Frequency distribution of the rate of CO_2 fixation in blooms of phototrophic sulfur bacteria (upper panel) and the productivity of these organisms in relation to the light intensity in % of the surface irradiance reaching the depth of the bloom (lower panel). Based on literature data presented in Table 1.

layers (Parkin and Brock, 1980a). A similar correlation can be established between the total amount of CO_2 fixed through anoxygenic photosynthesis by these organisms (per square meter and per day) and the amount of light (expressed as % of the surface irradiance) reaching the layer of phototrophic bacteria (Montesinos and Van Gemerden, 1986)(Fig. 5, lower panel). The good correlation observed suggests that light is indeed the main factor controlling primary production in blooms of phototrophic sulfur bacteria. Extrapolation of a regression line to 100% of surface irradiance actually indicates the existence of an upper limit for the production of phototrophic sulfur bacteria of approximately $10^4 \text{ mg C}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$.

This relationship, however, does not necessarily indicate that phototrophic bacteria are limited by light in all the cases included in the graph, it only indicates the existence of an otherwise obvious stoichiometry between light absorption and carbon dioxide fixation.

V. Growth Rates in Nature

In situ specific growth rates of phototrophic sulfur bacteria have been determined following two different approaches. In one of them, estimates are based on measurements of carbon dioxide fixation which are converted into specific growth rates using the following equation (Tilzer, 1984):

$$\mu = \ln\left(1 + \frac{P}{B}\right) \quad (1)$$

in which P is the rate of carbon dioxide fixation and B is the biomass expressed as carbon. When measurements are carried out at different depths within the lake, estimates of μ obtained using this approach constitute a good indication of how the organism responds to the specific set of environmental conditions prevailing at each depth. Since this procedure is based on the assumption that all carbon fixed results in growth, it tends to overestimate the growth rate of organisms which synthesize storage compounds.

Production-based estimates of the specific growth rates described in the literature are rather close to the

maximum specific growth rates measured in the laboratory (0.050–0.150 h⁻¹). Thus, Montesinos (1987) found a specific growth rate of 0.074 h⁻¹ at the top of the bacterial layer in Lake Cisó where, although biomass was rather low, light irradiance was 850 $\mu\text{E}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$. Similar measurements carried out also in Lake Cisó (Garcia-Cantizano, 1992) give specific growth rates between 0.094 and 0.144 h⁻¹. The much lower values reported for bacteria in the hypolimnion of Zaca Lake (0.0030–0.0005 h⁻¹) (Folt et al., 1989) can be attributed to the poor light conditions prevailing or, as the authors suggest, to the failure to locate the layer of maximum activity at the top of the bacterial plate.

A second approach for measuring growth rates in situ requires a detailed follow up of the biomass levels during an extended period of time, together with a careful analysis of the main loss processes such as sedimentation or predation which can effectively decrease population levels (Tilzer, 1984; Mas et al., 1990). This kind of studies assume that net biomass changes occur due to the combined effect of growth and a number of different loss processes. The overall growth balance is described by the following equation:

$$\frac{dB}{dt} = \left(\mu - \sum_{i=0}^n k_i \right) \cdot B \quad (2)$$

in which k_i are the specific loss rates of the n different factors taken into account. The measurement of both growth and losses requires samples spaced by at least several days, and vertical movement of the interface and the microorganisms during this interval can occur. Therefore, it is extremely difficult to carry out this kind of study for different layers within the bacterial plate, and measurements usually refer to the population as a whole.

Specific growth rate estimates based on the analysis of population dynamics are much lower than their production based counterparts. The analysis of the dynamics of phototrophic sulfur bacteria in Lake Cisó reveals that during most of the time loss rates are unimportant (0.025 and 0.015 d^{-1}) and that population growth rates are also very low (0.063 and 0.037 d^{-1}), compensating for what little losses occur and maintaining a constantly high biomass (1–2 $\text{g BChl } a \cdot \text{m}^{-2}$) (Mas et al., 1990). High population growth rates are only observed when biomass levels decline after periods of intense washout which occurs approximately once a year, during late winter/early spring. Recovery of the initial biomass levels occurs before summer in a pattern which can be observed periodically during several years (Fig. 6, upper panel). In a similar study Montesinos and Esteve (1984) estimated population growth rates from the increase in total biomass during summer stratification in four Spanish lakes. The data obtained (0.008, 0.012, 0.019 and 0.024 d^{-1}) were somewhat lower, probably because the negative effect of loss processes had not been taken into account.

Considering the facts that the maximum values found (0.063 d^{-1}) are about 40 times lower than the maximum rates at which the organisms can grow ($\approx 2.4 \text{ d}^{-1}$) and that carbon dioxide fixation based estimates give values close to the maximum growth rates of the organisms, it appears that only a fraction of the population is growing at a certain moment. Measurement of the specific rates of CO_2 fixation at different depths within the bacterial plate certainly indicate that the bacteria in the top few centimeters of the plate are growing (Van Gernerden et al., 1985; Montesinos, 1987) while the cells in the remainder of the plate stay in a non-active yet viable state.

Determinations of photosynthetic activity and specific growth rates in microbial mats have been

Fig. 6. Integrated values of BChl a in $\text{g} \cdot \text{m}^{-2}$ in Lake Cisó, Spain (upper panel). Growth, indicated for each year by an vertical arrow, is apparent only after the population density has been decreased during the winter months. During the summer, losses are balanced by growth resulting in rather constant population densities. A similar phenomenon can be observed when the population of purple sulfur bacteria on Scapa Beach, Orkney Islands, Scotland, has been removed artificially. Within a week the population density is restored. Redrawn from Mas et al (1990, upper panel) and Van Gernerden et al. (1989b, lower panel).

hampered by the technical problems involved. Some attempts have been made to measure photosynthetic rates in sediment slurries (Pierson et al., 1987), but besides showing that photosynthesis in the lower layers was saturated at lower irradiances than in the upper layers, interpretation of the results is difficult. Using a completely different approach Van Gernerden et al. (1989a) scrapped the upper layer of a *Thiocapsa* mat in the beach of Scapa Bay, and followed the recolonization of the exposed surface with time (Fig. 6, lower panel). The results indicate that growth went on at a specific rate of 0.306 d^{-1} , leveling up at a biomass of approximately 2 g of BChl $a \cdot \text{m}^{-2}$.

VI. Loss Processes

From a dynamic point of view, population levels are the consequence of an equilibrium between growth and losses. In planktonic environments losses by bacterial death, predation and sedimentation seem to play a prominent role, which in a few cases has been quantified. In benthic environments identical or similar processes are likely to occur although the studies carried out so far do not provide any quantitative data on their influence on the different populations of bacteria.

A. Death

Loss of activity and subsequent death can occur in populations of phototrophic sulfur bacteria exposed to adverse conditions during extended periods of time. One of the factors often summoned is exposure to oxygen (Dickman and Artuz, 1978; Folt et al., 1989), which is lethal for all green sulfur bacteria as well as for some of the large-celled Chromatiaceae. In stratified planktonic environments, exposure to oxygen occurs only during mixing. In contrast in benthic communities, in which the oxic/anoxic interface fluctuates, organisms experience a daily exposure to oxygen.

Leaving aside the deleterious effects of oxygen, the main cause of viability loss is insufficient supply of energy. When irradiance falls below a certain threshold level, phototrophic sulfur bacteria are unable to gather enough energy to fuel vital processes such as turnover of macromolecules, osmotic regulation or control of their internal pH. As a consequence, the organisms lose viability, and eventually die. Observations carried out in the hypolimnion of Lake Cisó show that, while cells in the top and peak of the bacterial plate are 100% viable, viability at the bottom of the plate decreases rapidly with depth (Van Gernerden et al., 1985). The decrease of viability is actually a function of the time the organisms have been in the dark. Given that the loss of viability occurs exponentially with depth at a rate of -0.0142 cm^{-1} , and assuming that these bacteria were sinking at a rate of approximately $1 \text{ cm} \cdot \text{d}^{-1}$ (Pedrós-Alió et al., 1989), a death rate of -0.014 d^{-1} can be calculated. This value compares well with the maximum decomposition rates of -0.016 d^{-1} estimated for *Chromatium* (Mas et al., 1990).

B. Predation

Since phototrophic sulfur bacteria live in anoxic environments containing hydrogen sulfide, and this compound is toxic for most of the potential predators, it is generally assumed that predation does not play a very important role as a loss process. Yet, the presence of crustaceans or rotifers on top of the oxic/anoxic interface feeding on the phototrophic bacteria underneath, has been repeatedly reported (See Table 3). In several cases the existence of grazing was suggested by the red color of the zooplankton which was placed right on top of the bacterial layer. In some cases, the existence of grazing was confirmed either through experiments involving uptake of radioactively labeled bacteria (Takahashi and Ichimura, 1968; Sorokin, 1970; Matsuyama and Shirouzu, 1978) or analyzing the gut content of the predators (Caumette et al., 1983). None of these studies, however, provided any indication of the actual impact of this feeding on dynamics of the microbial community.

A quantitative study carried out in Crawford Lake (Mazumder and Dickman, 1989) showed feeding rates for the major predator, *Daphnia*, of 0.3 – 1.6% of the prey population per hour. Specific loss rates calculated per hour range between -0.003 and -0.016 h^{-1} . Extrapolation of these rates to a 24 h period would yield values between -0.072 and -0.384 d^{-1} . In a more recent study, Massana et al. (1994) determined the impact of predation on the microbial community of Lake Cisó during a bloom of *Daphnia pulex*. Their results clearly indicate that *Daphnia* feeds mainly on the microaerophilic protist *Cryptomonas phaseolus* and only marginally on phototrophic bacteria due to the presence of hydrogen sulfide which somehow limits the vertical distribution of *Daphnia* to the oxic layers. Even though phototrophic bacteria constituted only a small percentage of the diet of this organism, estimated loss rates for *Chromatium* and *Amoebobacter* were -0.092 d^{-1} and -0.069 d^{-1} , respectively. These values are high compared to previously observed population growth rates in the same lake (Mas et al., 1990) but could explain the specific rates of biomass decrease (-0.100 d^{-1} and -0.041 d^{-1}) observed during the period of the bloom (Massana et al., 1994). The study of the composition of stable sulfur and carbon isotopes in the different trophic components of several meromictic lakes containing phototrophic sulfur

bacteria indicates that these organisms do not contribute substantially to the carbon and energy flow of those systems, again suggesting a marginal role as a food source for the zooplankton living there.

While the vertical distribution of macroscopic zooplankton is severely limited to the oxic layers, several groups of ciliates have been described which are well adapted to life in anoxic environments. These organisms have been found in coexistence with phototrophic sulfur bacteria (Dyer et al., 1986) and can be considered as potential predators (Table 4). Indications of grazing by ciliates on phototrophic sulfur bacteria come from the early work of Sorokin and Donate (1975), who observed the existence of red digestive vacuoles in several ciliates. More recently, Finlay et al. (1991) studied the anaerobic ciliates present in Lake Arcas-2 and estimated, on theoretical grounds, a consumption of approximately 6% of the prey biomass per day (equivalent to -0.062 d^{-1}). In a similar study carried out in Lake Cisó (Massana and Pedrós-Alió, 1994) a much lower impact (0.1% of the prey per day) was found, as a consequence of the low numbers of ciliates present in that environment. The specific loss rate calculated from the feeding rates (-0.001 d^{-1}) is too low to have any effect on the population dynamics of the prey.

The ability to prey on phototrophic sulfur bacteria is not limited to eukaryotic organisms and, in fact, a couple of prokaryotic organisms have been described (Guerrero et al., 1986) which seem to attack purple sulfur bacteria, forming lytic plaques (Esteve et al., 1992). One of them, an epibiont named *Vampirococcus*, attaches to the surface of the prey where it carries out its division. Electron micrographs suggest that during the process the cytoplasm of the infected cell undergoes major degradation (Esteve et al., 1983). The second type described, *Daptobacter*, enters the cytoplasm of the prey and divides inside. As in the previous case, the prey is killed. The presence of epibionts has been detected in several blooms of phototrophic sulfur bacteria in which they can infect a considerable fraction of the population (15–94%) (Table 4). In the upper parts of the bacterial plate where cells are active and viability is high, the percentage of infected cells is very low, virtually zero. In the layers below, where no light is available and viability actually decreases with depth, the percentage of infected cells increases (Guerrero et al., 1986). This seems to suggest that these bacteria are not operative at infecting healthy active individuals, but rather attack cells which are somehow

impaired due to prolonged exposure to a limited energy supply. Thus, because they are preying on the non-reproductive part of the population, their impact on population dynamics is likely to be small. A different hypothesis has been put forward by Clarke et al. (1993) for the epibiont they found in Arcas-2. Since the organism does not form lytic plaques and attaches to healthy cells, they suggest that it actually grows heterotrophically on the organic carbon excreted by the phototrophs.

C. Sedimentation in Planktonic Environments

Sedimentation is one of the main mechanisms through which planktonic organisms are removed from the water column. The extent to which sedimentation affects population levels depends in fact on the sinking speed (v) of the organism which, according to Stoke's Law

$$v = \frac{2}{9} \cdot g \cdot r^2 \cdot (\rho_{\text{Cell}} - \rho_{\text{H}_2\text{O}}) \cdot \frac{1}{\eta} \quad (3)$$

is a function of its size (r) (expressed as the radius of a sphere equivalent in volume to the cell), the difference between the density of the cell (ρ_{Cell}) and the density of the surrounding water ($\rho_{\text{H}_2\text{O}}$), and the viscosity of water (η).

Field measurements carried out during several months on the volume and density of the two main phototrophic sulfur bacteria present in Lake Cisó (Pedrós-Alió et al., 1989) allowed for calculations of the range of sinking speeds these organisms can experience. In the case of *Chromatium*, density remained rather constant between 1.13 and 1.16 $\text{pg} \cdot \mu\text{m}^{-3}$ while cell volumes ranged between 31 and 58 μm^3 . *Amoebobacter* (referred to as *Lamprocystis* in the paper) changed its density between 1.07 and 1.13 $\text{pg} \cdot \mu\text{m}^{-3}$ and its volume (in this case the volume of multicellular aggregates) between 31 and 97 μm^3 . Because sinking speeds, density, and viscosity of the water are affected by temperature, calculations were performed at the maximum and minimum temperatures (4 and 20 °C) measured in the lake. The calculations predicted maximum sinking speeds of 11.5 $\text{cm} \cdot \text{d}^{-1}$ for *Amoebobacter* and 18.4 $\text{cm} \cdot \text{d}^{-1}$ for *Chromatium*, while minimum sinking speeds were 1.6 and 6 $\text{cm} \cdot \text{d}^{-1}$ respectively. Actual measurements of the sinking speeds of the two organisms using sedimentation traps during a two year period (Pedrós-Alió et al., 1989) gave values of less than 1 $\text{cm} \cdot \text{d}^{-1}$, lower than the minimum predicted by Stokes' Law.

Sedimentation did occur at higher rates during certain periods, but never exceeded 10 cm·d⁻¹. Sedimentation loss rates determined during the same period (Mas et al., 1990) gave maximum values of -0.0149 d⁻¹ for *Chromatium* and -0.0150 d⁻¹ for *Amoebobacter*. Similar measurements carried out in Lake Vechten (Steenbergen et al., 1987) gave higher sinking speeds (16–27 cm·d⁻¹) corresponding to a rather high specific loss rate of -0.22 d⁻¹.

Formation of large aggregates would actually increase theoretical sinking speeds by several orders of magnitude. It is a rather common observation that

field samples containing dense populations of phototrophic sulfur bacteria form macroscopic aggregates when exposed to oxygen, which subsequently sediment to the bottom of the container in a few minutes. Thus, oxygenation of the layers where the populations of purple sulfur bacteria reside might bring up a similar phenomenon which would result in a rapid clearing of the water column. In the case of organisms containing gas vesicles, aggregate formation might constitute a mechanism to increase the speed at which they can position themselves at their optimal depth. For individual cells possessing

flagella, the tendency to sink can be easily overcome through swimming. The swimming speeds reported by *Chromatium* range between 20 and 30 $\mu\text{m}\cdot\text{s}^{-1}$ (Matsuyama, 1987; Mitchell et al., 1991), meaning that individual cells could move between 170 and 260 $\text{cm}\cdot\text{d}^{-1}$. These values probably constitute an overestimation due to the random component of bacterial movement; however it indicates clearly that motile purple sulfur bacteria can easily overcome their tendency to sink.

VII. Growth Balance, Maximum Biomass and Production in Phototrophic Communities

In both the studies carried out in Lake Cisó (Mas et al., 1990) and in Scapa Beach (Van Gernerden et al., 1989a), apparent growth slows down to a virtual stop at between 1 and 2 g of BChl $\text{a}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$. This observation, together with the systematic finding of lower integrated values of BChl in other systems (see Table 2), strongly suggests that these values actually constitute an upper limit for the biomass of phototrophic sulfur bacteria in nature.

The existence of an upper limit for the biomass of phototrophic sulfur bacteria can be predicted on theoretical grounds from the existence of an upper limit for phototrophic production discussed in section IV. Steady levels of biomass indicate that population growth rates match loss rates. An educated guess of the loss rates of phototrophic sulfur bacteria, based on the estimates reported in the previous section, is $\approx -0.1 \text{ d}^{-1}$ (corresponding to a half live time, in the absence of growth, of approximately one week). Maximum production based on Fig. 5 is 10 $\text{g C}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$. Substituting the values for μ and production in equation 1, results in an apparent upper limit for biomass of 95 $\text{g C}\cdot\text{m}^{-2}$. Considering that the carbon content of the dry weight is approximately 50% (Van Gernerden, 1968; Göbel, 1978) and that the average content of BChl is approximately 2% of the dry weight (Takahashi and Ichimura, 1968), maximum levels of integrated BChl turn out to be approximately 4 $\text{g BChl}\cdot\text{m}^{-2}$. This value could be somewhat higher in environments, either planktonic or benthic, subject to lower loss rates. On the contrary, environments where loss rates are higher, or where bacteria are not close to the surface and thus, irradiance is not 100%, will only be able to support much lower biomass levels.

VIII. Environmental Factors Affecting Growth and Survival of Phototrophic Sulfur Bacteria

A. Light

1. In situ Light Climate

Development of phototrophic sulfur bacteria in nature requires the presence of light. At the same time, due to their anaerobic nature, these organisms are usually constrained to live in the anoxic parts of lakes or sediments, at depths where light penetration is severely hampered and irradiance is actually very low, on the order of a few $\mu\text{Einstein}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$. On top of that, the spectral composition of this light is dramatically modified due to specific absorption of certain wavelengths by water itself, and very often by populations of algae or other phototrophic bacteria positioned above. In planktonic systems the infrared and UV part of the spectrum are rapidly attenuated due to absorption and scattering, while in sediments, infrared radiation penetrates deeper. This phenomenon is clearly illustrated in Fig. 7, using data from Lake Kinneret (upper panel) (Dubinsky and Berman, 1979) and from some sediments in San Francisco Bay (lower panel) (Jørgensen and Des Marais, 1986a). While in Lake Kinneret, as depth increases light is enriched in a narrow band around 550 nm, in the sediment, at a depth of 1 mm, most of the light consists of wavelengths above 850 nm. Similar data available for several other lakes and sediments and collected in Table 5 indicate a similar behavior. The higher percent of infrared light penetrating in sediments seems to be a consequence of both a high loss of blue wavelengths during the reflection in the particles of sediment and absorption by oxygenic phototrophs and little losses in the near infrared due to negligible absorption by water (Jørgensen and Des Marais, 1986a, 1988). The consequence of this differential absorption of light in lakes and in sediments is that, while organisms living in lakes have to rely mainly on their carotenoids for light harvesting, organisms in mats are probably forced to use the infrared light which is absorbed mainly by their BChl. Although it is not clear whether some organisms are better adapted than others to grow under either set of conditions, the composition of the light spectrum is a factor which will certainly have to be taken into account in order to explain the dominance of certain organisms in mats and in sediments. Thus, while okenone seems to be very

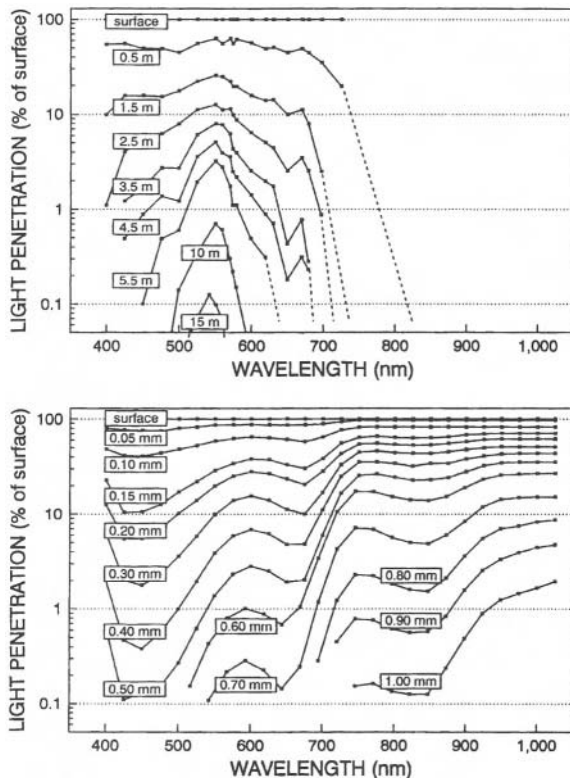

Fig. 7. Penetration of light of different wavelengths in a lake and in a sediment. The upper panel shows the spectral composition of light at increasing depths in Lake Kinneret, the dotted lines are based on patterns observed in various lakes. Depth horizons exceeding 10 m receive light of a very narrow wavelength range (500–600 nm). The lower panel shows the penetration of light in sediment of San Francisco Bay. Compared to lakes, light penetrates much less, and the spectral composition is shifted to the red part of the spectrum. Redrawn from Dubinsky and Berman, 1979 (upper panel) and Jørgensen and Des Marais, 1986 (lower panel).

abundant in aquatic environments (63% of the cases) benthic systems seem to be almost exclusively colonized by *Thiocapsa roseopersicina*, which contains spirilloxanthin. We have not been able to find any reference in the literature describing a benthic system populated by organisms containing okenone. It is, therefore, tempting to speculate on the existence of a relation between the type of carotenoid and the spectrum of the light to which the bacteria are exposed.

The adaptive role of carotenoids to grow at the light spectrum prevailing in certain planktonic environments has been well documented in Chlorobiaceae. Brown species of Chlorobiaceae contain isorenieratene and are predominant in deep bacterial plates overlaid by algae. On the contrary, green

Chlorobiaceae are selected in systems in which the layer of Chlorobiaceae is overlaid by a layer of Chromatiaceae. This phenomenon is explained by the absorption spectra of both carotenoids. Isorenieratene-containing bacteria absorb in the 500–550 nm band, which are the predominant wavelengths at higher depths. Chlorobactene, on the contrary, absorbs around 450 nm, which are precisely the wavelengths available after filtering by absorption of a plate of purple sulfur bacteria close to the surface (Montesinos et al., 1983).

2. Physiological Responses to Light Limitation

The specific growth rate of phototrophic organisms changes as a function of light irradiance according to a saturation curve whose mathematical description is still a matter of discussion (Jassby and Platt, 1973; Iwakuma and Yasuno, 1983). Despite the model used, the curve is characterized by two parameters, μ_{\max} which gives the maximum specific growth rate the organisms can achieve when light is saturating, and α , which is the initial slope of the μ vs. irradiance curve and corresponds to the maximum photosynthetic efficiency of the organisms under the experimental conditions used. Sometimes, instead of α the parameter I_k is used, which is in fact equivalent to μ_{\max}/α , and which corresponds to the irradiance at which the organism would reach μ_{\max} if the initial slope α were maintained all the way to saturation. I_k provides a rough indication of the irradiance below which growth is light limited. Because phototrophic organisms do have to invest energy into maintenance processes, even when growth does not occur, the growth vs. irradiance curve does not go through the origin, intersecting the irradiance axis at a certain irradiance. This irradiance, at which $\mu=0$, gives an indication of the total amount of energy the organisms must spend in maintenance. Extrapolation of the curve towards the μ axis yields a negative value (usually referred to as μ_e), which is actually correlated to the maintenance threshold and gives an idea of the extent to which growth of the organism is slowed down due to allocation of energy to maintenance processes.

While the adaptation to limiting irradiances has been extensively studied in phytoplankton, little is known about phototrophic sulfur bacteria. In general, they seem able to adapt their light harvesting systems by increasing their specific content of pigments (Broch-Due et al., 1978). Recent observations indicate

that the increase in the specific content of pigments actually results in an increase in the photosynthetic efficiency (α) of the organism and do not have a significant effect on μ_{\max} (O. Sánchez, personal communication). The extent to which this increase in the specific content of pigments occurs, depends in fact on the organisms. As can be seen in Table 6, green sulfur bacteria have high specific contents of BChl with maximum values of 915 and an average content of 214 $\mu\text{g BChl}\cdot\text{mg}^{-1}$ protein, while purple sulfur bacteria have much lower contents (maximum 85, average 41 $\mu\text{g BChl}\cdot\text{mg}^{-1}$ protein). Similar differences are found in μ_c , with green sulfur bacteria having values of μ_c around -0.001 h^{-1} and purple sulfur bacteria around -0.01 h^{-1} (see Table 7), ten times higher, indicating greater maintenance expenses. As a rule, green sulfur bacteria seem to be better adapted than purple sulfur bacteria to grow at low irradiances thanks to their higher light harvesting capacity together with their lower maintenance requirements. This is actually consistent with the

fact that they are found at higher depths where light irradiance is likely to be very low, and also with the rather common mention of their presence right under the layers of purple sulfur bacteria when coexisting in the same habitat.

B. Electron Donors

By definition, anoxygenic phototrophic bacteria do not produce oxygen in photosynthesis because they lack Photosystem II and, consequently, are unable to use water as an electron donor. Instead these organisms use reduced forms of sulfur or hydrogen gas in the reduction of carbon dioxide. In addition, a limited number of small organic molecules may serve the same purpose or may be directly photoassimilated.

Chemolithotrophy, namely the oxidation of reduced sulfur compounds as sources of energy, has also been observed in several Chromatiaceae.

1. Potential Photosynthetic Electron Donors for Purple and Green Sulfur Bacteria

Virtually all reduced inorganic forms of sulfur are used as electron donors by various purple and green sulfur bacteria. The one most commonly used in media to grow these organisms is sulfide (H_2S , HS^- , S^{2-}). As first demonstrated by Van Niel (1931), the oxidation of sulfide is stoichiometrically linked to the reduction of carbon dioxide. As a rule, sulfide oxidation results in the formation of zero-valent sulfur ('elemental sulfur', S^0), which is further

oxidized to sulfate. In these equations, $\langle\text{CH}_2\text{O}\rangle$ represents the simplified over-all composition of cell material at the level of carbohydrate.

The capacities of sulfide oxidation, intracellular or extracellular S^0 deposition, oxidation of S^0 to sulfate, and photopigmentation, are used to differentiate the major groups of anoxygenic phototrophic bacteria from each other. Members of the family Chromatiaceae deposit S^0 as refractile globules inside the cells, whereas those belonging to the family Ectothiorhodospiraceae form extracellular sulfur. Also green sulfur bacteria (family Chlorobiaceae) deposit S^0 outside the cells.

In the purple sulfur bacteria, S^0 appears not to be present in the form of S_8 rings, but rather in a more easily accessible form, presumably as long-chain polysulfides or polythionates. Because of these uncertainties, the term 'zero-valent sulfur' is to be preferred over 'elemental sulfur' (Steudel, 1989; Steudel et al., 1990). Chromatiaceae, like Chlorobiaceae, are able to oxidize extracellular S^0 , but growth on flower of sulfur usually is slower than on soluble sulfur species.

Among the Chromatiaceae, the utilization of thiosulfate is not uncommon, in the green sulfur bacteria this ability is restricted to the forma *thiosulfatophilum* of *Chlorobium limicola* and *Cb. vibrioforme*. In the Chromatiaceae, as well as in *Cb. vibrioforme* f. *thiosulfatophilum*, thiosulfate oxidation results in the formation of S^0 . It has been shown that in the Chromatiaceae S^0 is exclusively derived from the outer S atom (sulfane group) with the oxidation state -2 (Trüper and Pfennig, 1966).

The stoichiometry of thiosulfate oxidation, with CO_2 as carbon source, can be described as shown in the equations:

The simultaneous formation of thiosulfate and S^0 from sulfide was reported to occur in *Cb. limicola* f. *thiosulfatophilum* (Schedel, 1978; Trüper, 1984) and *Cb. vibrioforme* f. *thiosulfatophilum* (Trüper, 1984). Low concentrations of $S_2O_3^{2-}$ were also detected after sulfide incubation of *Cm. vinosum* (Steudel et al., 1990). In *Chromatium*, the final oxidation product of all inorganic sulfur compounds is sulfate, with

SO_3^{2-} as intermediate.

Tetrathionate ($S_4O_6^{2-}$) appears not to be an important electron donor for phototrophic sulfur bacteria. However, $S_4O_6^{2-}$ is readily reduced abiotically to form $S_2O_3^{2-}$ according to

in which sulfide acts as the electron donor. The formation of tetrathionate in cultures of *Rhodomicrobium vannielii* was shown to follow this route (Hansen, 1974).

Polysulfides (S_x^{2-}) may be formed in abiotic reactions between S^0 and HS^- , and are stable at elevated pH values. The utilization of S_3^{2-} has been demonstrated for a few purple and green sulfur bacteria (Visscher and Van Gernerden, 1988; Steudel et al., 1990; Visscher et al., 1990).

In addition to reduced sulfur species, hydrogen is an electron donor for many phototrophic bacteria. This ability was first described in 1935 by Roelofsen. In the Chlorobiaceae, hydrogen utilization occurs in the majority of strains, however, due to the lack of assimilatory sulfate reduction, a reduced sulfur source is required during growth on H_2 (Lippert and Pfennig, 1969).

For a few purple sulfur bacteria, utilization of dimethyl sulfide (DMS, $(CH_3)_2S$) as electron donor has been demonstrated. *Thiocystis* sp. was reported to grow slowly in the simultaneous presence of H_2S and DMS; products formed were dimethylsulfoxide (DMSO, $(CH_3)_2S=O$) and methane (Zeyer et al., 1987). In contrast, *Thiocapsa roseopersicina* showed rapid growth on DMS as sole electron donor with DMSO as oxidation product. Also, DMS and sulfide were oxidized simultaneously, yielding DMSO and S^0 , subsequently the latter was oxidized to sulfate (Visscher and Van Gernerden, 1991b).

Recently, biological CO_2 fixation in the light, in the absence of oxygen, occurring concomitantly with the oxidation of ferrous iron, was reported (Widdel et al., 1993). The organisms responsible were found to resemble *Rhodomicrobium vannielii*, *Rhodopseudomonas palustris*, and *Thiodictyon* sp., however, the latter isolate did not oxidize sulfide. The stoichiometry observed was found to be in agreement with

Since the midpoint potential of the reaction center of purple non-sulfur bacteria and that of the purple sulfur bacteria are similar (Dutton and Prince, 1978), growth of the latter with ferrous iron should be possible as well. However, Fe^{II} and S^{2-} readily react to form FeS , but ferrous iron might act as electron donor in the absence of sulfide.

A detailed consideration of sulfur chemistry, sulfur compounds and their role as photosynthetic electron donors is given in Chapter 39.

2. Abundance of Electron Donors in Nature

The most important and selective environmental factors for the development of phototrophic sulfur bacteria are (1) the lack of oxygen, (2) the availability of light, and (3) the presence of reduced sulfur compounds. There is general agreement that in nature sulfide is an important electron donor for purple and green sulfur bacteria. For obvious reasons, the profiles of oxygen and sulfide show diel fluctuations. Sediment ecosystems often become completely anoxic during the night with sulfide reaching the surface layers (De Wit et al., 1989; Revsbech et al., 1989; Van Gernerden, 1990). In stratified lakes fluctuations occur at the depth horizon of blooms of anoxygenic phototrophic sulfur bacteria (Van Gernerden, 1985; Jørgensen et al., 1979).

As a rule, an overlap is observed in the profiles of sulfide and oxygen. In a comparison between three systems, Jørgensen (1982) mentioned the large differences in the vertical dimension of the oxygen-sulfide interface in different systems. In the Black Sea, sulfide and oxygen coexisted over 35 m depth or more (Jørgensen et al., 1991), in Solar Lake, over 10 cm, and in a *Beggiatoa*-dominated mat, over no more than 50 μm . The integrated sulfide oxidation rate over the whole column was of the same order of magnitude for all three systems (10–30 $\text{mmol}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$). However, the peak rates varied over many orders of magnitude, and were 0.8 $\mu\text{mol}\cdot\text{l}^{-1}\cdot\text{d}^{-1}$ in the Black Sea, 250 $\mu\text{mol}\cdot\text{l}^{-1}\cdot\text{d}^{-1}$ in Solar Lake, and 250 000 $\mu\text{mol}\cdot\text{l}^{-1}\cdot\text{d}^{-1}$ in the microbial mat. The residence time of sulfide in the peak layer was calculated to be 5 d, 10–20 min, and 0.6 s, respectively. Consequently, the ratio between the biological and the chemical oxidation rate may vary considerably. It was concluded that the biological contribution to sulfide oxidation in the Black Sea was negligible, thus confirming earlier data of Sorokin (1964, 1972), amounted 30–50% in Solar Lake, and

was 100% in the *Beggiatoa*-dominated mat (Jørgensen, 1982). The abiotic oxidation of S^{2-} by oxygen in seawater has been reported to result in the formation of $\text{S}_2\text{O}_3^{2-}$, with minor amounts of SO_3^{2-} (Chen and Gupta, 1972). In water devoid of O_2 , S^{2-} oxidation may be attributed to a direct reaction with MnO_2 (Millero, 1991).

Except for the situation in hydrothermal vents, sulfide is generated principally by dissimilatory sulfate reduction: in marine sediments the contribution of sulfate-reducing bacteria to sulfide production has been estimated to be close to 100% (Jørgensen, 1977).

In addition to sulfide, a wide range of inorganic and organic sulfur species has been reported to occur in habitats colonized by sulfur bacteria. In microbial mats, relatively high concentrations of 'elemental' sulfur, polysulfides (S_x^0), and the iron sulfides FeS and FeS_2 (pyrite) have been reported, while the concentrations of thiosulfate and polythionates ($\text{S}_3\text{O}_6^{2-}$, $\text{S}_4\text{O}_6^{2-}$, $\text{S}_5\text{O}_6^{2-}$) were found to be much lower (Van Gernerden et al., 1989b; Visscher et al., 1990; Visscher and Van Gernerden, 1993). High concentrations of polysulfides are often found in salt marsh sediments and microbial mats (Jørgensen et al., 1979; Aizenshtat et al., 1983; Lord and Church, 1983; Luther et al., 1986; Luther and Church, 1988).

For stratified freshwater lakes and sediments, sulfur speciation is less well documented, except for the occurrence of sulfide in the hypolimnion. The explanation probably lies in the much lower sulfate content of freshwater lakes.

Organic sulfur compounds may be formed abiotically in reactions between inorganic polysulfides and organic molecules. Relatively low molecular weight organic S-compounds result as well from the microbially mediated breakdown of protein and dimethyl-sulfoniopropionate (DMSP, $(\text{CH}_3)_2\text{-S-CH}_2\text{-CH}_2\text{-COOH}$) (Kiene and Taylor, 1988a; Kiene et al., 1990). When degraded, sulfur-containing amino acids (cysteine, methionine) yield methanethiol (MSH, $\text{CH}_3\text{-SH}$), dimethyl sulfide (DMS, $\text{CH}_3\text{-S-CH}_3$), and dimethyl disulfide (DMDS, $\text{CH}_3\text{-S-S-CH}_3$). DMSP, which is present in many strains of marine phytoplankton (Keller et al., 1989) and presumably acts as an osmolyte (Reed, 1983), yields DMS and acrylate ($\text{CH}_2=\text{CH}_2\text{COOH}$), or 3-mercaptopropionate (3-MPA, $\text{HS-CH}_2\text{-CH}_2\text{-COOH}$) and MSH upon bacterial degradation (Kiene and Visscher, 1987; Kiene and Taylor, 1988b; Kiene et al., 1990). Recently, evidence was obtained for DMSP-lyase activity in

axenic cultures of the phytoplanktonic species *Phaeocystis* sp. (Stefels and Van Boekel, 1993) and *Emiliania huxleyi* (J. Stefels, pers. comm.), indicating that oceanic DMS formation not necessarily is mediated by bacteria. DMSP is also formed by the dominant cyanobacterium in mature microbial mats, *Microcoleus chthonoplastes*. Upon a down-shift in salinity, mimicking severe rainfall, 50% of the cellular DMSP was excreted (Visscher and Van Gernerden, 1991a), which likely resulted in the formation of DMS.

Potential DMS consumers are sulfate-reducing bacteria and methanogens (Kiene and Visscher, 1987), colorless sulfur bacteria (Smith and Kelly, 1988; Visscher et al., 1991), and phototrophs (Zeyer et al., 1987; Visscher and Van Gernerden, 1991b).

3. Substrate Affinities of Purple and Green Sulfur Bacteria

The scavenging capacity of organisms for a given substrate can be ranked from low to high by comparing their growth affinity for that substrate. The specific growth rate (μ) of microbes depends on the concentration (s) of the growth-rate limiting substrate. With non-inhibitory substrates the relation between μ and s is adequately described by the Monod equation, being :

$$\mu = \mu_{\max} \cdot \frac{s}{K_s + s} \quad (8)$$

in which μ_{\max} is the maximum specific growth rate and K_s is the saturation constant equal to the substrate concentration at which $\mu = 1/2\mu_{\max}$. Plotting μ versus s results in a saturating type of curve, the steeper the initial slope the higher the affinity of the organism for the substrate involved. Since K_s is a function of μ_{\max} , the magnitude of the affinity (usually cannot directly be deduced from the saturation constant (Healey, 1980; Zevenboom, 1980; Van Gernerden, 1984). Under constant environmental conditions, the organism with the highest affinity can be expected to outcompete all others utilizing the same substrate. With the assumption that substrate concentrations in nature are low (in any case much lower than K_s), affinity can be described mathematically as $A_{s \rightarrow 0} = \mu_{\max}/(K_s + s)$, being the initial slope of the Monod curve.

It appears that the affinity for sulfide of purple and green sulfur bacteria is related to the location of sulfur deposition. Chlorobiaceae and Ectothiorhodo-

spiraceae, depositing S^0 extracellularly, invariably exhibit higher affinities for sulfide than Chromatiaceae, which store S^0 inside the cells (Table 8). *Rhodobacter capsulatus*, a purple nonsulfur bacterium depositing S^0 extracellularly (Hansen and Van Gernerden, 1972), also has a high sulfide affinity (Van Gernerden, 1984). Likewise, colorless sulfur bacteria have high sulfide and thiosulfate affinities (Beudeker et al., 1982; Visscher et al., 1992). It has been postulated that in organisms having a high affinity for sulfide, the primary acceptor for the electrons released in the oxidation of sulfide is situated at the outside of the cell membrane, whereas for organisms depositing S^0 intracellularly, the primary acceptor is located at the inside of the membrane. Active transport of sulfide across the membrane, only being necessary in organisms depositing S^0 intracellularly, might then be the limiting step (Van Gernerden, 1984). At present there are no exceptions to the rule, but conclusive evidence to support this hypothesis is still lacking.

In a few organisms, affinities have been estimated for different sulfur substrates (Table 9). *Cm. vinosum* and *T. roseopersicina* displayed similar affinities for S^{2-} and S_3^{2-} . If the undissociated forms would have to pass the membrane by passive diffusion, one would expect that the larger trisulfide molecule enters the cell at a lower rate than hydrogen sulfide, resulting in a lower affinity for the former. These results thus suggests that both sulfur species are translocated by active transport. In *Cb. limicola* f. *thiosulfatophilum* the affinities for S^{2-} and S_3^{2-} differed sixfold. For yet unknown reasons, all three organisms showed a lower μ_{\max} on S_3^{2-} .

Few data are available on the utilization of other substrates than the ones the organisms were grown on. It was reported that in *Cm. vinosum* and *T. roseopersicina*, S_3^{2-} oxidation by S^{2-} -grown cells proceeds without lag (Steudel et al., 1990; Visscher et al., 1990). In contrast, *de novo* protein synthesis was required for the utilization of polysulfide by *Cb. limicola* (Visscher and Van Gernerden, 1988). Acetate-grown *Chromatium* cells oxidize sulfide without lag, which is explained by the presence of Calvin cycle enzymes in these cells (see section VIII.D).

Purple sulfur bacteria appear to be able to oxidize different substrates simultaneously, e.g. S^{2-} and S_3^{2-} (*Thiocapsa*), acetate and sulfide (*Chromatium*), or S^{2-} and DMS (*Thiocapsa*) (Visscher and Van Gernerden, 1991b). In the green sulfur bacterium

Cb. limicola, S_3^{2-} oxidation ceased upon the addition of S^{2-} , concomitantly S_3^{2-} was resynthesized. The amount of S^{2-} added was insufficient to explain the formation of S_3^{2-} from S^{2-} and S^0 , and it was hypothesized that the initial oxidation of S_3^{2-} resulted in the formation of S_2^{2-} (Visscher and Van Gernerden, 1988). The inhibition of S_3^{2-} oxidation by S^{2-} suggests a common transport system.

For other reasons, in green sulfur bacteria acetate assimilation and sulfide oxidation proceed synchronously. These organisms fix CO_2 via the reversed TCA cycle (Ormerod and Sirevåg, 1983; and see Chapter 40). The first step in acetate assimilation is a reductive carboxylation which involves the participation of reduced ferredoxin. For the formation of the latter, sulfide is required.

4. Reduced Sulfur Compounds as Sources of Energy

Chemolithotrophy is the type of metabolism in which energy requirements are fulfilled by the respiration of an externally supplied inorganic compound. When occurring, these substrates usually are respired aerobically, i.e. with oxygen. Chemolithotrophy certainly is not a common characteristic of anoxygenic phototrophic sulfur bacteria. Green sulfur bacteria are obligate phototrophs, but among the Chromatiaceae several species have been shown to possess a chemolithotrophic metabolism. Experiments in batch cultures have revealed this capacity in several, but not all, strains of *Thiocapsa roseopersicina*, *Amoebobacter roseus*, *Thiocystis violacea*, *Chromatium vinosum*, *Cm. minus*, *Cm. violascens*, *Cm. gracile*, and *Thiorhodovibrio winogradskyi* (Pfennig, 1970; Bogorov, 1974; Gorlenko, 1974; Kondratieva et., 1976; Kämpf and Pfennig, 1980, 1986a,b; De Wit and Van Gernerden, 1987, 1990a,b; Overmann and Pfennig, 1992). Some species only grow at low pO_2 , while others can do so at full atmospheric oxygen tension. All large-celled Chromatiaceae and a few small-celled species fail to grow in the presence of even low concentrations of oxygen (Kämpf and Pfennig, 1980). However, even species having the ability to grow chemotrophically appear to have a preference for phototrophy. Experimental evidence to support this hypothesis will be presented in section IX. Chlorobiaceae are unable to grow chemotrophically (Kämpf and Pfennig, 1980).

When incubated in the continuous presence of low to moderately high concentrations of oxygen, purple

sulfur bacteria eventually become completely colorless (De Wit and Van Gernerden, 1987; Overmann and Pfennig, 1992). During chemotrophic growth (aerobic respiration of sulfide or thiosulfate), the yield is much lower than during phototrophic growth. The protein concentration in phototrophic cultures of *Thiocapsa roseopersicina* strain M1, when subjected to a shift from anoxic to oxic ($52 \mu\text{mol}\cdot\text{l}^{-1}$) conditions, decreased substantially; concomitantly, the cells became completely colorless. Approximately 61 % of the thiosulfate was respired to provide energy and 39% resulted in the synthesis of cellular material (De Wit and Van Gernerden, 1987). The chemotrophic yield of phototrophic purple bacteria thus appeared to be somewhat higher than reported for colorless sulfur bacteria (Kelly, 1982).

Shift experiments as described above, were also carried out in media containing equimolar concentrations of $S_2O_3^{2-}$ and acetate (Overmann and Pfennig, 1992). Under these conditions, the protein concentration during chemotrophic growth of *T. roseopersicina* strain 6311 was 47% compared to full phototrophic growth, and the corresponding values for *Amoebobacter roseus* strain 6611 and *Thiocystis violacea* strain 2711 were 67% and 52%, respectively (Overmann and Pfennig, 1992). These organisms are unable to respire acetate. The higher yields of these organisms under chemotrophic conditions, compared to *T. roseopersicina* strain M1 are not to be explained by strain differences, but rather illustrate that much energy is required for the fixation of CO_2 .

C. Oxygen

The impact of oxygen on growth and metabolism of anoxygenic phototrophic bacteria has been studied for a long time. The metabolism of the phototrophic purple and green sulfur bacteria is inhibited by oxygen in one way or another. These organisms thrive in the anoxic parts of sediments and freshwater ponds and lakes, provided light is available. For some species (green sulfur bacteria, large-celled Chromatiaceae) oxygen is lethal, while other species survive and may grow at relatively low concentrations of oxygen. Although the general statement that 'photosynthesis of anoxygenic phototrophic bacteria is dependent on oxygen-deficient conditions' (Drews and Imhoff, 1991) suggests otherwise, some species continue to photosynthesize in the presence of elevated concentrations of O_2 , and a few are even capable of carrying out Chemolithotrophy, in which a reduced

sulfur species is oxidized aerobically to provide energy.

Oxygen, at relatively low partial pressure, specifically inhibits the synthesis of photopigments; this has not only been observed in purple non-sulfur bacteria (Cohen-Bazire et al., 1957), but in purple sulfur bacteria as well (Hurlbert, 1967). The lower limit for complete repression is not exactly known, and may well be different for different organisms. In *Chromatium vinosum*, reduced rates of BChl synthesis were observed at O_2 concentrations below $10 \mu\text{mol}\cdot\text{l}^{-1}$ (Kämpf and Pfennig, 1986a). Also, *Thiocapsa roseopersicina* and *Thiocystis violacea* were reported to contain low levels of BChl and carotenoids at 'low' oxygen concentrations (Bogorov, 1974; Kämpf and Pfennig, 1980). The latter two species are ranked as the most tolerant members of the Chromatiaceae to perform anoxygenic photosynthesis in the presence of oxygen (Kondratieva et al., 1976; Kondratieva, 1979; Kämpf and Pfennig, 1980; Madigan, 1988).

D. Carbon Sources

Carbon dioxide is commonly used as the sole source of carbon in media for growing purple and green sulfur bacteria. The stoichiometry of the reduction of CO_2 and the oxidation of S^{2-} and $S_2O_3^{2-}$ was shown in Equations 4 and 5, respectively.

In the Chromatiaceae, the main route of CO_2 fixation is the Calvin cycle. Additional CO_2 -fixing reactions have been reported (Fuller, 1978; Sahl and Trüper, 1977), but these do not seem to contribute substantially to the net conversion of CO_2 to cell material (Madigan, 1988). In the green sulfur bacteria, carbon dioxide is fixed through the reductive TCA cycle (Ormerod and Sirevåg, 1983). This metabolic route of CO_2 fixation is energetically less energy-demanding, which may, at least in part, explain why green sulfur bacteria are selectively enriched at low light intensities. Autotrophic growth of Chlorobiaceae depends on the presence of a reduced form of sulfur, such as sulfide, since these organisms lack the possibility of the reduction of SO_4^{2-} for assimilatory purposes.

Organic compounds are also assimilated by purple and green sulfur bacteria. In this respect, Chlorobiaceae show little versatility (Trüper, 1981). Except for acetate and pyruvate, for which the simultaneous presence of CO_2 and a reduced sulfur species (S^{2-} , $S_2O_3^{2-}$) is required for assimilation, no organic

compounds stimulate growth. The Chromatiaceae show a large variation in the extent to what, and under what conditions, organic compounds are used as substrates for growth. The large-celled species (such as *Chromatium okenii*, *Cm. weissei*, *Thiospirillum jenense*, and a few others), are nutritionally rather restricted. Their photo-assimilation is limited to acetate and pyruvate. In addition, like the green sulfur bacteria, these organisms are unable to reduce sulfate for assimilatory purposes, and thus rely on the presence of sulfide. The small-celled Chromatiaceae, on the other hand, possess the assimilatory sulfate reduction route, and, in addition, have a much larger range of organic compounds that can be assimilated (Trüper, 1981).

Ribulose biphosphate carboxylase (RuBisCO), being the key enzyme of the Calvin cycle, is most active during photoautotrophic growth. During photoheterotrophic growth the Calvin cycle enzymes are under metabolic control; in *Cm. vinosum* the synthesis of RuBisCO is repressed by 50–90% under photoheterotrophic conditions (Fuller, 1978). It was suggested that the considerable activity of the Calvin cycle enzymes still present under these conditions might play a role in the disposal of excess reducing power (Hurlbert and Lascelles, 1963). Under constant environmental conditions, lowering the cellular content of RuBisCO and other enzymes may be an effective adaptation, since the Calvin cycle is largely superfluous during growth on acetate. However, under fluctuating conditions, which are characteristic for most of the habitats of the phototrophic sulfur bacteria, such an 'adaptation' could be a serious drawback and might result in a reduced reactivity upon a shift from acetate assimilation to CO_2 -fixation. However, acetate-grown *Chromatium* cells oxidize sulfide at similar specific rate as sulfide-grown cells. It thus appears that the organism has an overcapacity with respect to the Calvin-cycle enzymes. A similar overcapacity with respect to the content of BChl is discussed in section IX.C.

IX. Case Studies

The competitive position of (a group of) organisms cannot be judged from their own characteristics, but requires comparison with data of other organisms under ecologically relevant conditions. A few illustrative examples are discussed below.

A. Competition Among Purple Sulfur Bacteria

In aquatic environments, particularly in fresh-water lakes and ponds, blooms of large-celled *Chromatium* species (*Cm. okenii*, *Cm. weissii*) occur frequently. In such blooms, small-celled *Chromatium* species (*Cm. vinosum*, *Cm. minutissimum*) usually are present as well. If large-celled and small-celled species comprise different ecophysiological groups, it is of interest to know what parameters are of decisive importance for bloom formation.

Large-celled *Chromatium* species grow slowly (have a relatively low μ_{\max}), require vitamin B₁₂, and were reported to grow best in dim light and dark-light cycles (Pfennig, 1965; Pfennig and Trüper, 1992). Small-celled *Chromatium* species usually do not require B₁₂ and, as a rule, are cultivated under continuous illumination (Table 10). Although the discovery of the B₁₂ requirement was a breakthrough in the cultivation of the large *Chromatium* species (Pfennig, 1965; Pfennig and Lippert, 1966), it probably is not a factor of decisive importance in the competition between these species. Similarly, once pure cultures were available, most large-celled species were found to be culturable at higher light intensities.

In a study on the competition between the small-celled *Cm. vinosum* and the large-celled *Cm. weissii*, attempts to grow the organisms together in sulfide-limited chemostats in the light invariably resulted in *Cm. weissii* being outcompeted by *Cm. vinosum*, irrespective of the dilution rate employed. This is to be expected in view of their respective affinities for sulfide (see Table 8). However, when continuous illumination was replaced by a light-dark regimen, the two organisms coexisted, which could be explained by taking into consideration that, in addition to the growth parameters μ_{\max} and K_s , the temporary storage of glycogen and S⁰ are important factors (Van Gernerden, 1974).

The affinity for sulfide is calculated from μ_{\max} and

K_s data obtained in chemostats. Under these conditions, the concentration of sulfide permanently is in the μmolar range. In nature, substrate concentrations are not constant, but rather show diel fluctuations (Jørgensen et al., 1983; Revsbech and Ward, 1984; Van Gernerden et al., 1985; Nicholson et al., 1987; Pierson et al., 1987; De Wit et al., 1989; Lassen et al., 1992; Van Gernerden, 1993). Due to decreased oxidation rates and ongoing production rates, sulfide concentrations increase during nights, and decrease during the day. All purple sulfur bacteria analyzed so far exhibit a higher sulfide oxidation capacity than that required for growth. As a result, storage compounds accumulate intracellularly during periods in which excess substrate is available (See Chapter 45). It has been established for *Cm. vinosum* that the potential rate of electron-donor oxidation is virtually identical at all specific growth rates. Consequently, the storage capacity is maximal at low growth rates (Van Gernerden and Beeftink, 1978; Beeftink and Van Gernerden, 1979). Likewise, in *Cm. weissii* the maximum rates of electron-donor oxidation and CO₂-fixation exceed the maximum specific growth rate (Van Gernerden, 1974). The fact that slow or non-growing phototrophic bacteria have high reactivities would have little ecological meaning, unless substrate concentrations fluctuate.

Secondly, the maximum rate of sulfide oxidation of *Cm. vinosum* is approximately half that of *Cm. weissii*. This is not related to differences in the rate of CO₂ fixation, which is similar in the two organisms, but rather to the fact that the large-celled *Cm. weissii* preferentially oxidizes sulfide to S⁰, whereas in the small-celled *Cm. vinosum* a larger fraction of the sulfide is directly oxidized to sulfate. Under fluctuating sulfide concentration this phenomenon could counteract a high sulfide affinity.

Sulfide is not oxidized in the dark. Applying a dark-light regimen, in combination with a constant sulfide supply, thus mimicking the environmental

Table 10. Comparison of general characteristics of large-celled and small-celled Chromatiaceae

	Large-celled Species (e.g. <i>Chromatium okenii</i>)	Small-celled Species (e.g. <i>Chromatium vinosum</i>)
Cell dimensions	4.5–6 × 8–15 μm	2.0 × 2.5–6 μm
Assimilatory SO ₄ ²⁻ reduction	lacking	present
Organic substrates	acetate, pyruvate	many
Vitamin B ₁₂ requirement	yes	no
Light intensity	2–6 $\mu\text{Ein}\cdot\text{m}^{-2}\cdot\text{sec}^{-1}$	4–40 $\mu\text{Ein}\cdot\text{m}^{-2}\cdot\text{sec}^{-1}$
Light regimen	daylight, light–dark	continuous
Specific growth rate	$\approx 0.04\text{ h}^{-1}$ ($t_d \approx 17\text{ h}$)	$\approx 0.12\text{ h}^{-1}$ ($t_d \approx 5\text{ h}$)

conditions, results in a slow increase in the concentration of sulfide during the dark periods. Co-culturing *Cm. weissei* and *Cm. vinosum* under these conditions showed that in the early hours of the illumination period, a large fraction of the accumulated sulfide was oxidized by *Cm. weissei*, resulting in the intracellular storage of S^0 and glycogen. During the remainder of the light periods, in which the sulfide concentration was extremely low, most of the incoming sulfide was oxidized by *Cm. vinosum* due to its higher affinity. During these periods, *Cm. weissei* was growing predominantly at the expense of the previously stored S^0 and glycogen. Stable coexistence between *Cm. weissei* and *Cm. vinosum* was observed at different light-dark regimens, in which longer nights resulted in a more pronounced dominance of the large *Cm. weissei* (Van Gernerden, 1974).

The co-existence of the two *Chromatium* species under fluctuating conditions thus can be explained on the basis of (1) a higher growth response of the small-celled species at all sulfide concentrations, (2) a similar maximal rate of CO_2 fixation in both organisms, and (3) a faster storage of S^0 in *Cm. weissei* upon a temporary excess of sulfide.

A high sulfide affinity also appears to be of crucial importance for organisms lacking the ability to use sulfate as sulfur source for assimilatory purposes. However, the lack of assimilatory sulfate reduction, as observed in the large-celled species, is fully compensated by the extensive storage of sulfur, thus providing the organisms with a suitable source of sulfur for the synthesis of structural cell components.

Although μ_{max} and K_s data from many more strains are required before a general conclusion can be reached, this example illustrates that the environmental fluctuations in an organism's habitat should be taken into consideration before conclusions can be drawn on the (dis)advantage of a certain characteristic.

B. Competition Between Purple and Green Sulfur Bacteria

Purple sulfur bacteria and green sulfur bacteria have very similar nutritional requirements. It is, therefore, not surprising that these organisms can be grown in media of similar composition. Green sulfur bacteria, being obligate anaerobic phototrophs, have been isolated from marine environments, but seldom develop profusely. An exception is found in the

multi-layered microbial mats of Great Sippewissett Salt Marsh, Cape Cod, USA (Nicholson et al., 1987; Pierson et al., 1987). In these systems, a layer of green sulfur bacteria developed underneath two distinct layers of purple sulfur bacteria which presumably prevented the downward diffusion of oxygen. No oxygen data were reported, but circumstantial evidence showed the layer of green sulfur bacteria to be permanently anoxic.

Green sulfur bacteria frequently bloom in freshwater lakes, often as mixed populations with purple sulfur bacteria. It is of interest to know what conditions are in favor of such a co-existence.

Numerous chemostat studies have shown that co-culturing of organisms with different substrate affinities, results in the competitive exclusion of the organism with the lower affinity. However, stable co-cultures of *Chlorobium limicola* f. *thiosulfatophilum* DSM 249 and *Chromatium vinosum* DSM 185 were obtained in sulfide-limited continuous cultures, despite the higher sulfide affinity of *Chlorobium* (see Table 8). With increasing dilution rates, the population density of *Chromatium* increased in proportion (Van Gernerden and Beeftink, 1981).

On theoretical grounds, stable coexistence of two competing organisms is feasible. One possibility is that there are at least two mutual substrates, and that the competing organisms have complementary μ -s relationships on these substrates (Taylor and Williams, 1975; Yoon et al., 1977; Gottschal, 1986). In the case of *Chlorobium* / *Chromatium*, sulfide obviously is one of the substrates for which *Chlorobium* has the better affinity. It has been suggested that S^0 acted as the second substrate (Van Gernerden and Beeftink, 1981). Extracellular S^0 , produced by green sulfur bacteria, can be used equally well by purple and green sulfur bacteria. S^0 is a powerful electron donor because it represents six out of the eight electrons released in the oxidation of sulfide to sulfate. However, the hypothesis of S^0 as second substrate had to be abandoned because of the following pure culture studies.

In continuous cultures, the population density (x) depends on the concentration of the substrate in the inflowing medium ($S_{Reservoir}$), and can be mathematically described as $x = Y \cdot (S_{Reservoir} - s)$, in which Y is the yield factor. The concentration of the left-over substrate is mathematically described as $s = K_s \cdot D / (\mu_{max} - D)$, in which K_s and μ_{max} are the kinetic growth parameters (see section VIII.B.3) and D is the dilution rate. Under steady-state conditions, μ equals D . Thus,

in contrast to x , the concentration of s is independent of $S_{\text{Reservoir}}$. However, a prerequisite is that the left-over substrate is dispersed in the medium. Consequently, in a culture of *Chromatium*, the mathematical description of s given above, is not expected to hold for the concentration of intracellular S^0 . Indeed, raising the $S_{\text{Reservoir}}$ in *Chromatium* cultures, not only resulted in increased cell densities, but also in increased concentrations of S^0 . As was to be expected, the specific content of S^0 (S^0/x) remained constant. Unanticipated, however, similar phenomena were observed in *Chlorobium* cultures. These data indicate that the S^0 produced by one individual is not detected by other individuals. For *Chromatium* this is not surprising, the observations in *Chlorobium* may be explained by the fact that S^0 somehow remains attached to the cell by which it is produced. The mechanistic explanation could be the presence of appendages as observed in other *Chlorobium* strains (Cohen-Bazire, 1963). The ecological implication of these findings is that the term 'extracellular sulfur' should be interpreted carefully, and should not be read as being fully available to other cells. Thus, it is unlikely that, in the coexistence of *Chromatium* and *Chlorobium*, extracellular S^0 acted as the second substrate (Van Gernerden, 1986).

This intriguing problem was solved by the finding that, in pure cultures of *Chlorobium*, polysulfides (S_3^{2-}) were formed abiotically (Visscher and Van Gernerden, 1988; Visscher et al., 1990). The polysulfide affinities of *Chlorobium* and *Chromatium* were very similar; however in *Chlorobium*, the utilization of polysulfide was inhibited by hydrogen sulfide, and, in addition, polysulfide oxidation required *de novo* protein synthesis (Visscher and Van Gernerden, 1988). In contrast, *Chromatium*, oxidized polysulfide and sulfide simultaneously, and polysulfide utilization occurred without lag (Steudel et al., 1990).

The balanced coexistence between *Chromatium* and *Chlorobium* observed in the laboratory thus can be explained on the basis of (1) a higher sulfide affinity of *Chlorobium*, (2) the formation of polysulfide from the abiotic reaction between H_2S , present in μmolar concentrations, and S^0 produced by *Chlorobium*, (3) the occurrence of sulfide and polysulfide as mutual substrates for *Chromatium* and *Chlorobium*, and (4) the fact that in *Chlorobium* the utilization of polysulfide required induction, in contrast to the oxidation of polysulfide by *Chromatium* (Van Gernerden, 1987). These interactions are

visualized in Fig. 8. The relationships between the specific growth rate and the concentration of sulfide and polysulfide for each of the organisms are shown in Fig. 9.

The phenomena discussed above, in combination with the differences in absorption spectra of green and purple sulfur bacteria, could offer a clue to the co-existence of these phototrophic bacteria in natural environments. Unfortunately, data on polysulfide concentrations in lakes harboring both Chromatiaceae and Chlorobiaceae presently are lacking.

C. Competition Between Purple and Colorless Sulfur Bacteria

Under constant environmental conditions, chemotrophically growing purple sulfur bacteria appear to have little chance in the competition for sulfide and thiosulfate with genuine colorless sulfur bacteria. The kinetic parameters μ_{max} and K_s for *Thiocapsa roseopersicina* M1 and *Thiobacillus thioparus* T5 for growth on reduced sulfur compounds are shown in Table 11. Accordingly, the sulfide affinity of *Thiobacillus* is 47-fold higher than that of *Thiocapsa*, and the same is true for thiosulfate. However, purple sulfur bacteria compete best when growing photo-trophically, and appear to have several other options

Fig. 8. Schematic representation of the interactions between *Chromatium* and *Chlorobium* during the competition for reduced sulfur compounds. See text for explanation. Redrawn from Van Gernerden, 1987.

Table 11. Comparison of kinetic growth parameters of *Thiocapsa roseopersicina* strain M1 and *Thiobacillus thioparus* strain T5 on reduced sulfur compounds and CO₂. Both organisms were isolated from a microbial mat

then chemotrophic growth. Important features are (1) the possibility to migrate, (2) the ability to photosynthesize in the presence of oxygen, and (3) the ambient concentration of oxygen.

Migration away from oxic zones is a successful strategy to avoid inhibition of photopigment synthesis. Since in most ecosystems, sulfide and oxygen have complementary profiles with little overlap, photosynthesis can continue, provided sufficient light is available in the deeper layers. Particularly in sediment ecosystems, having small vertical dimensions compared to stratified lakes, migration can be considered an effective mechanisms.

It was observed in marine coastal sediments that in the early morning the purple sulfur bacteria rapidly moved away from the surface layers once the overlying cyanobacteria started to produce oxygen (Jørgensen, 1982). It was reported by Sorokin (1970) that in the stratified Lake Belovod (Russia), the maximum population density of motile purple sulfur bacteria (*Chromatium okenii*, Pfennig and Trüper, 1992) was at 6 m depth at 6 a.m., and at 13 m depth at 12 a.m., at each time coinciding with the oxygen/sulfide interface. Vertical migration over such long distances could not be observed in Wintergreen Lake (USA) and have been doubted to occur on the basis of maximum swimming rates (Caldwell and Tiedje, 1975). Vertical migration over a distance of 35 cm has been reported for *Chromatium minus* in Lake Cisó (Spain), but, in the same lake, no migration could be observed for the gas-vacuolated *Amoeba-*

bacter M3 (Pedrós-Alió and Sala, 1990). In Rotsee (Switzerland), the gas-vacuolated *Thiopedia rosea* was reported to migrate over 1 m distances (Kohler et al., 1984), and in Lake Holmsjön (Finland), *Chromatium* sp. migrated downwards during the day and upwards during the night, the total distance being 30 cm (Lindholm et al., 1985). Thus, vacuolated or motile phototrophic sulfur bacteria appear to be able to position themselves in the chemocline, probably as a response to the prevailing sulfide and/or oxygen concentrations.

In the second place, cessation of photopigment synthesis does not necessarily imply cessation of photosynthesis. The Calvin-cycle enzymes of *Thiocapsa roseopersicina* are not repressed in the presence of oxygen (Kondratieva et al., 1976). It has been suggested that the organism would shift from phototrophy to chemotrophy when conditions become oxic (Madigan, 1988). However, although pigment synthesis does not occur in the presence of oxygen, pigments already present do not become inoperative, as illustrated below.

During phototrophy, electron donors are exclusively used for the synthesis of cell material. In contrast, during chemotrophy approximately two thirds of the pool of electron donors is oxidized to provide for the energy metabolism, and only one third results in the synthesis of cell material (see section VIII.B.4). Consequently, a judgment of the energy metabolism of *Thiocapsa* is facilitated by yield estimates. This purple sulfur bacterium

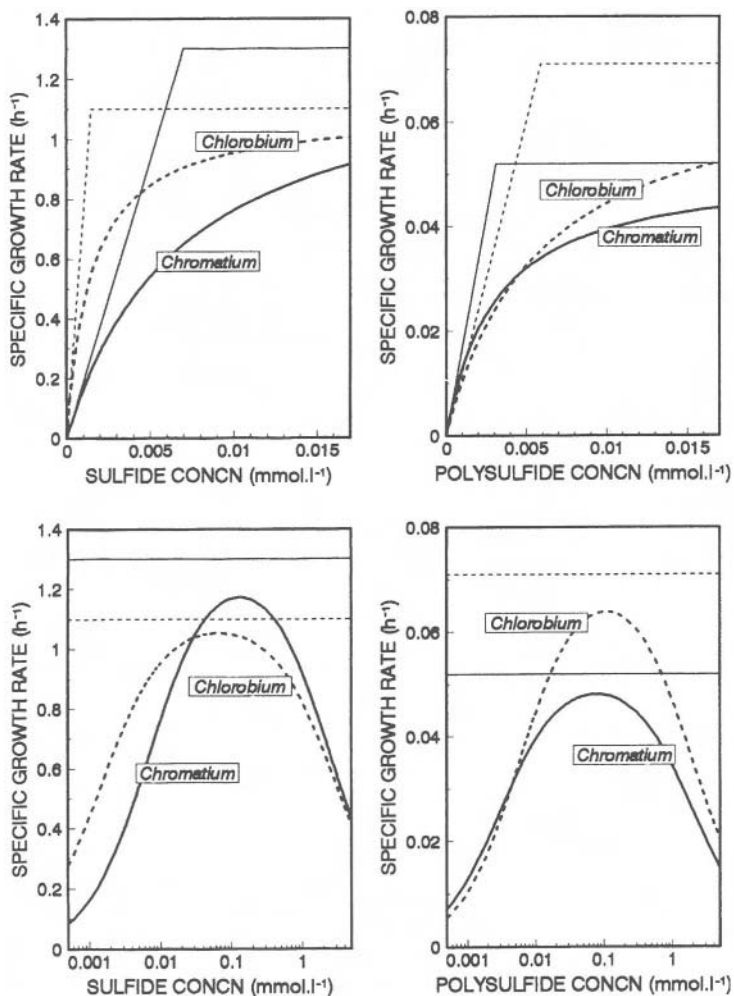

Fig. 9. Relationship between the specific rate of growth (μ) of *Chromatium vinosum* strain DSM 185 and *Chlorobium limicola* f. *thiosulfatophilum* strain DSM 249 and the concentration of sulfide (S^{2-}) (left panels) and polysulfide (S_3^{2-}) (right panels). Top panels show the specific growth rates at very low substrate concentrations (linear scale) to demonstrate the effect of affinity, the lower panels demonstrate the inhibitory effect of the substrate at higher concentrations (log scale). Based on data presented in Table 8, and calculated using the equation $\mu = \mu_{\max} \cdot s / ((K_s + s) \cdot (1 + s/K_i))$ (Haldane equation).

frequently is found as the dominant anoxygenic phototroph in microbial mats, being daily exposed to oxygen. It was observed that the yield of *T. roseopersicina*, when incubated in illuminated continuous cultures exposed to a regime of 21 h oxic/ 3 h anoxic, was virtually identical to that observed during continuously anoxic conditions. In other words, the cells were still growing phototrophically during the 21 h oxic periods, despite the fact that synthesis of photopigments only occurred during the 3 h anoxic periods (De Wit and Van Gemerden, 1990). The content of BChl *a* varied from 4 to 7 $\mu\text{g}\cdot\text{mg}^{-1}$ protein, whereas during continuously anoxic

conditions the BChl content typically is 30 $\mu\text{g}\cdot\text{mg}^{-1}$ protein. Apparently, *Thiocapsa* has a 4–7 fold higher BChl content than needed (De Wit and Van Gemerden, 1990). Such an excess capacity would not have any ecological relevance if the environmental conditions would allow the synthesis of photopigments at all times, but is of great advantage under fluctuating conditions. Despite the fact that no synthesis of photopigments occurs for prolonged periods of time, it enables *Thiocapsa* to grow phototrophically in the presence of oxygen. Conceivably, this capacity is functional as well during strongly fluctuating light intensities, due to the passing by of clouds.

Applying a regimen of 1 h anoxic/23 oxic, resulted in a BChl content varying between 0.8 and 2.5 $\mu\text{g}\cdot\text{mg}^{-1}$ protein, which is too low to allow for full phototrophic growth. However, even under these conditions *Thiocapsa* did not shift to full chemotrophy, since the yield was observed to be higher than during full chemotrophy, but lower than during full phototrophy, indicating that growth was the result of a mixed photo-chemotrophic metabolism (Schaub and Van Gernerden, 1993).

In natural environments, illumination usually coincides with the presence of oxygen, and darkness with anoxic conditions. Incubation of *Thiocapsa* at regimen in which illumination was provided during oxic periods only and not during anoxic periods, resulted in photopigment synthesis in the dark. It was calculated that ample energy was provided by the concomitant degradation of glycogen, which had been synthesized during the previous oxic/light period (De Wit and Van Gernerden, 1990). These phenomena are particularly relevant to immobile benthic organisms unable to migrate.

In the third place, it is of importance to evaluate the oxygen conditions at the depth horizon where sulfide oxidation takes place. The analogy between the three systems analyzed by Jørgensen (1982), is the prevailing low oxygen concentration at the site of maximal sulfide oxidation. As judged from the profiles of oxygen and sulfide in a microbial mat on the Frisian Island of Texel (The Netherlands), in which purple sulfur bacteria and colorless sulfur bacteria were most abundant in the same depth layer (Visscher et al., 1992), sulfide oxidation also primarily took place at low oxygen concentrations. At first sight, the much higher sulfide affinities of colorless sulfur bacteria compared to purple sulfur bacteria, seem to contradict the observed coexistence of *Thiocapsa* and *Thiobacillus*.

It has been demonstrated in chemostat experiments with pure cultures of *Thiobacillus thioparus* T5, that, in the presence of excess O_2 , sulfide virtually completely is oxidized to sulfate. During oxygen shortage, the concentration of sulfide still remained below the detection limit; however various other reduced forms of sulfur, notably S^0 and $\text{S}_2\text{O}_3^{2-}$, were excreted into the medium. Under severe oxygen-limiting conditions, the concentration of sulfide in the culture was $\leq 1 \mu\text{mol}\cdot\text{l}^{-1}$, but from the 7.1 $\text{mmol}\cdot\text{l}^{-1}$ sulfide supplied, only 1.87 $\text{mmol}\cdot\text{l}^{-1}$ was oxidized to sulfate, the remaining being present as reduced sulfur intermediates (Van den Ende and Van Gernerden, 1993). *Thiocapsa*, once introduced in such a

Thiobacillus culture, thus is provided with ample substrates to grow. Although oxygen is supplied continuously, its concentration in the mixed culture is lowered to undetectable levels by *Thiobacillus*, and thus, pigment synthesis in *Thiocapsa* is not inhibited. The result is co-existence of the colorless sulfur bacterium and the phototrophic sulfur bacterium, each growing in its own preferred mode (F. P. van den Ende and A. Laverman, personal communication).

It may be argued that in the example described above, the two organisms did not actually compete for mutual substrates, since *Thiobacillus* oxidized all sulfide and *Thiocapsa* grew on the products formed thereof. However, the fraction of a mutual substrate utilized by each population not only depends on their respective affinities, but as well on the population densities. Potentially, *Thiocapsa* might have been able to claim part of the sulfide as a result of its growth on the other sulfur species. Since the formation of these were the result of the activities of *Thiobacillus*, *Thiocapsa* will not be able to outcompete the colorless sulfur bacterium (Van Gernerden, 1993). In a similar fashion, purple sulfur bacteria might profit from their chemotrophic potential in the competition with colorless sulfur bacteria (Kuenen, 1989). This mass effect also may play a role in the competition between autotrophic and heterotrophic nitrifying bacteria (Kuenen, 1989; Tiedje et al., 1982).

In conclusion, colorless sulfur bacteria and purple sulfur bacteria can coexist under conditions of oxygen limitation, provided of course, that the penetration of light is sufficient to allow for phototrophic growth. Since in most stratified ecosystems sulfide predominantly is oxidized in the oxygen-sulfide interface, it is anticipated that in many systems these different types of sulfur bacteria are able to thrive in the same depth layers.

X. Concluding Remarks

A proper understanding of the ecology of phototrophic sulfur bacteria requires a careful description of both bacterial populations and their environment. This understanding, however, is often hampered by the nature of the information available. As van Niel pointed out (1955):

Unfortunately, the relationships between the characteristics of an environment and the flora and fauna found therein must often be deduced from

observations made at the time when the organisms are already present in large numbers. This is not always a satisfactory guide to an interpretation of ecological factors, because at such time the environment may have been considerably modified by the activities of the organisms themselves.

Underlying this statement is the idea that bacterial communities cannot be considered static systems and that a one time description of a fully developed environment actually says very little. What is actually relevant in order to understand how phototrophic sulfur bacteria bloom and decay is the analysis of the conditions, both biotic and abiotic, which regulate their growth, as well as the set of factors determining their removal from the system.

Since natural communities are complex and environmental conditions are often unpredictable, the study of their ecology can benefit from laboratory experiments using model systems. Although these models constitute extremely simplified versions of nature and the information they provide must be used cautiously, they constitute a unique tool for the testing of hypotheses both on the interaction between organisms, and on the interaction between the organisms and their environment. The successful development of a laboratory system, however, requires a detailed knowledge of the environmental conditions to which the organisms are exposed. Thus, it would be extremely helpful if field studies, in which so much time and effort is invested, provided such information.

From the analysis of the different case studies, it seems apparent that study of the ecology of phototrophic sulfur bacteria (actually the ecology of any organism) must contemplate the existence of fluctuations. There is a rather general agreement on the importance of fluctuations and a considerable body of supportive evidence has been gathered along the years. To assess which kind of physiological adaptations are better suited to deal with such fluctuations is the task of the experimental ecophysiologicalist.

Acknowledgments

Summary

It is apparent that very few species of anoxygenic phototrophs occur or grow at high temperatures, particularly when compared to species numbers for thermophilic Archaea and non-photosynthetic Bacteria. *Chloroflexus* spp. are the most thermotolerant (up to ~70 °C), but none are in the hyperthermophilic category.

Recognizing that there may be some endemic populations of anoxygenic phototrophic bacteria that have not been dispersed among geographically disparate geothermal sites, the major factors affecting the distribution of these bacteria are temperature, pH, and concentration of sulfide. Oxygen may have an effect on the vertical distribution and the diel vertical migration of some species within mats. Facultative aerobic metabolism appears to be a property of many of the anoxygenic phototrophs (but not *Chlorobium* or *Heliobacillus*) in these dynamic habitats. Light quantity and quality are affected by the diversity of pigmentation within the vertically stratified communities and adaptation to low photon fluence rates is a necessity for many species.

I. Introduction

A. Definition of Thermophily

The terms thermophily and thermotolerance in phototrophic prokaryotes should encompass a different range of temperatures than those used to define thermophily in non-phototrophic organisms, both archaeobacteria (Archaea) and eubacteria (Bacteria). Some contemporary biologists have proposed a high temperature environment for the origin of life and support this in part by pointing to the existence of living hyperthermophilic 'bacteria' that, according to parsimonious 16S rRNA sequence analyses, branch early in both eubacterial and archaeobacterial phylogenetic 'trees.' Chlorophyll-based photosynthesis occurs only in branches of the eubacterial tree (which includes chloroplasts). Phototrophic bacteria do not exist above 73–74 °C, a relatively low temperature when compared to extreme hyperthermophilic non-phototrophic prokaryotes, such as *Thermotoga* and *Aquifex* which branch off early (Olsen et al., 1994). Thus, if chlorophyll-based photosynthesis has a monophyletic origin and appeared early (as indicated by the *Chloroflexus* branch) it did not evolve at extreme temperatures (i.e. >75 °C) unless subsequent loss of caldoactive photosynthesis has occurred through extinctions. Diversity in the upper temperature range for photosynthesis (63–73 °C) is limited, although it is possible that many genotypes (or species) of the highest temperature form of the cyanobacterium *Synechococcus* sp. exist. A relatively large number of species, genera, and higher categories of phototrophic bacteria inhabit waters between 53 and 63 °C. In addition, the highest temperature phototrophs known today (i.e. *Synechococcus* sp. and *Chloroflexus aurantiacus*) have not adapted fully to the upper several degrees of their temperature range (Meeks and Castenholz, 1971; Pierson and Castenholz, 1974a; Castenholz and Schneider, 1993). It is likely, therefore, that the origins of thermophilic cyanobacteria, at least, were at low or moderate temperatures and that evolutionary expansion occurred slowly and selectively up the temperature gradient.

Abbreviations: Cb. – *Chlorobium*; Cf. – *Chloroflexus*; Cm. – *Chromatium*; Hc. – *Heliobacillus*; HTF – high temperature form; LTF – low temperature form; MTF – moderate temperature form; O. – *Oscillatoria*; YNP – Yellowstone National Park

In contrast to at least 20 species of morphologically distinct cyanobacteria known in the 53–63 °C range (e.g. Castenholz, 1969) the anoxygenic phototrophic bacteria have few known thermophilic species. Only *Chloroflexus aurantiacus* (including some distinct genotypes) and at least one other species of *Chloroflexus* thrive at temperatures above 57 °C. In the range of 50–57 °C habitats, only one known species of the green sulfur bacteria, one purple bacterium, one *Heliothrix* species, one *Helio-*bacterium, and an undescribed filamentous 'purple bacterium' are known.

In the context of phototrophs, then, we will use the term high temperature forms (HTFs) for those able to grow above 63 °C and moderate temperature forms (MTFs) for those that have upper limits below 63 °C but above 53 °C. Low temperature forms (LTFs) (upper growth limits between 43 and 53 °C) include many species with growth temperature optima well below this range. Thus, for the purposes of this discussion, those that are not able to exceed 52 °C will not be regarded as thermophiles.

B. Summary of Thermophilic Anoxygenic Phototrophs

1. Chloroflexus

Although it is now known that *Chloroflexus*-like organisms reach their greatest biomass in marine and hypersaline microbial mats (see Chapter 3 by Pierson and Castenholz), *Chloroflexus* was first discovered in hot springs, and the type species, Cf. *aurantiacus*, has been the only species studied extensively by physiologists, biochemists, and phylogenists. It grows best as a photoheterotroph, but some strains are capable of aerobic chemoheterotrophic or anaerobic photoautotrophic growth as well (see Chapter 3 by Pierson and Castenholz).

Chloroflexus aurantiacus, with at least a few genotypes (see Weller et al., 1992), occurs worldwide in hot springs of alkaline pH down to about pH 6.2 (Pierson and Castenholz, 1974a; Castenholz, 1984b, 1988; Table 1). Species determinations have not been made from populations in most hot spring areas, so with the limitation of only morphology, pigmentation, and temperature tolerance comparisons, all will be referred to simply as *Chloroflexus*. Recently Hanada et al. (1993) have isolated a new species of *Chloroflexus* from Japanese hot springs. Although quite similar to Cf. *aurantiacus* physio-

logically, a fairly large separation on the basis of 16S rRNA nucleotide sequences and DNA-DNA hybridizations (9–14%) is indicated.

In western North America (Castenholz, 1984b) in Yunnan, China (Yun, 1986), and presumably in other parts of Asia and in Africa, *Chloroflexus* populations are most prominent as distinct orange to salmon colored ‘undermats’ lying directly below a top layer of cyanobacteria (Fig. 1). Although less conspicuous, *Chloroflexus* is also invariably intermingled with the topmat species. These two-parted microbial mats may extend upwards in the thermal stream to the upper temperature limit of the cyanobacterial provider. This may be up to about 68–69 °C in North American and Asian springs where a high temperature form (HTF) of *Synechococcus* extends upward to a constant or mean temperature of ~ 73°C (Fig. 2). *Chloroflexus* mixed with *Synechococcus* may extend in low numbers up to this temperature as well. In some areas (e.g. New Zealand, Iceland, Europe) *Chloroflexus* and cyanobacteria are not as conspicuously separated into undermat and topmat, and extend upward only to 63–64 °C, the highest growth temperature for the cyanobacteria of these areas. Since all of the above populations of *Chloroflexus* are growing as heterotrophs (photo- or chemo-) they are dependent on immediate or upstream reduced carbon, the sources of which are ultimately the photoautotrophic cyanobacteria. No diazotrophic strains of *Chloroflexus* are known, in contrast to all other known anoxygenic phototrophs (Heda and Madigan, 1986).

Chloroflexus strains are also capable of a slow sulfide-dependent photoautotrophy (Castenholz, 1973a; Madigan and Brock, 1975; Giovannoni et al., 1987), and in sulfide-rich springs, mats or biofilms of *Chloroflexus* extend up the temperature gradient beyond that of the cyanobacteria to about 66 °C (Table 1). Thus, mats lacking cyanobacteria exist and are either orange, salmon-colored, or green, depending primarily on the presence (orange) or absence (green) of O₂ (Fig. 3). In culture, *Cf. aurantiacus* (from 2 sources) also has the same upper temperature limit of ~ 66°C, even as a photoheterotroph, and it is possible that field populations above ~ 68°C intermingled with the cyanobacterium *Synechococcus* are incapable of phototrophic growth, and are thus relegated to chemoheterotrophy (Castenholz, unpublished observations).

Fig. 1. (See also Color Plate 1A) Section through a microbial mat consisting of a top cover of the cyanobacterium *Synechococcus* underlaid by *Chloroflexus*. The cut is about 15 cm across and the water temperature ~60 °C. This is the source of *Chloroflexus aurantiacus*, strain OK-70-fl, Kahneeta Hot Springs, Oregon.

Fig. 2. (See also Color Plate 1B) Upper limits of *Chloroflexus* as a distinct undermat at ~68 °C. The outflow from the spring is at about 73 °C, and the siliceous sinter is dominated by *Synechococcus* until the edges cool to about 68 °C where the *Chloroflexus* undermat accretes (more orange on photograph). Buffalo Spring, White Creek drainage, YNP.

2. Heliothrix and Possibly Related Filamentous Phototrophs

On the basis of 5S and 16S rRNA sequence comparisons (Pierson et al., 1985; Weller et al., 1992), *Heliothrix oregonensis* falls within the same

Fig. 3. (See also Color Plate 1C) *Chloroflexus* as a photoautotroph (orange-red streamers) growing at a temperature of ~64–62 °C on primary sulfide in Badstofuhver, Hveragerdi, Iceland. The sulfide is quite depleted by about 62 °C, at which point the green mat of the cyanobacterium, *Chlorogloeopsis* ‘high temperature form’ (formerly referred to as *Mastigocladus* ‘HTF’) appears (see Castenholz, 1973a).

cluster branch as *Chloroflexus* (see Chapter 3 by Pierson and Castenholz). The very apparent difference between the two is that *Heliothrix* does not possess chlorosomes, and therefore lacks the major light harvesting pigments of *Chloroflexus* (i.e. bacteriochlorophyll *c*, *d*, or *e*). BChl *a*, the sole chlorophyll, occurs in the cytoplasmic membrane only; the orange color is a result of carotenoids, primarily *oxo-γ* and *OH-γ* carotenes and an *OH-γ* carotene glycoside. The undescribed reddish filamentous phototroph of Yellowstone, distinguished from *Heliothrix* by having ‘internal’ lamellar thylakoids, also possesses only BChl *a* (see Chapter 3 by Pierson and Castenholz and Castenholz, 1984b).

Heliothrix oregonensis has been studied in Oregon hot springs (Pierson et al., 1984). It is in all known cases a photoheterotroph, tolerates and possibly requires O_2 , and shows a field distribution and photoheterotrophic activity up to a temperature between 56 and 60 °C (Table 1, see also Fig. 4). *Heliothrix* is a wider diameter filament than *Chloroflexus* (~1.5 vs. 0.5–1.0 μm) and glides at a faster rate (~0.2 vs. 0.02 $\mu\text{m/s}$).

Fig. 4. (See also Color Plate 1D) *Heliothrix oregonensis* as an aerotolerant mat above a deep green cyanobacterial layer in a non-sulfidic Kahneeta hot spring (Oregon); temperature ~50 °C.

3. Chlorobium

The only thermophilic green sulfur bacterium known is *Chlorobium tepidum*, (Wahlund et al., 1991). It is barely a moderate temperature form (MTF), growing only up to about 55–56 °C in the few hot springs to which it is relegated and up to ~53 °C in the two culture isolates tested (Table 1). It is known from only a few springs in the Rotorua region of New Zealand (Castenholz et al., 1990, see Fig. 5). In culture, *Cb. tepidum* required at least 1 mM sulfide for growth and tolerated up to about 4 mM. Thiosulfate (2–8 mM) greatly stimulated growth and could be used as the sole photoreductant (Wahlund et al., 1991). A pH range for growth of 5.9–7.2 reflected the pH range of the source stream (strain TLS). *Cb. tepidum*, like most other anoxygenic bacteria, is capable of nitrogen fixation (Wahlund and Madigan, 1993).

The characteristic that most distinguishes *C. tepidum* from other species of *Chlorobium* is its thermophily. A few other features, such as large amounts of unique wax esters (Shiea et al., 1991) also help to distinguish this species. Its ‘preference’ for thiosulfate as an electron donor in photosynthesis, however, indicates a closeness to other thiosulfate-utilizing species of *Chlorobium*, such as *Cb. limicola*, and 16S rRNA sequence data confirm this (Wahlund et al., 1991).

4. Chromatium

Cm. tepidum (Madigan, 1986) is the only purple sulfur bacterium known to be thermophilic, at least

Table 1. Characteristics of Field Populations of Thermophilic Anoxygenic Phototrophs

Genus	Color of Field Populations	Principal Mode of Growth	Field Temperature Limits (°C)	Field pH Limits	Primary Sulfide in bathing water	O ₂ in bathing water	Comments	Representative Springs
<i>Chloroflexus</i>	orange-salmon	photoheterotroph (& chemoheterotroph)	~35–69(73)	6.0–~10	low or absent	+	With cyanobacteria &/or distinct bands underneath.	Worldwide
	orange-salmon	photoautotroph	< 66	6.2–>9.0	low-moderate > 0.02 mM	+	Upstream of cyanobacteria or above cyanobacteria (inverted).	esp. YNP, Iceland, New Zealand
	dull green	photoautotroph	< 66	6.2–~7.0	moderate ~0.02–0.1 mM	absent	Upstream of cyanobacteria; independent, laminated mat.	Mammoth Springs, (YNP), & (formerly) Steamboat Springs, Nevada
<i>Heliothrix</i>	orange	photoheterotroph	~35–~57	~8.0–8.5	low or absent	+	Distinct layer above cyanobacteria or mixed.	Western USA (incl. Oregon & YNP)
<i>Chlorobium</i>	dull green	photoautotroph	< 56	~4.3–~6.2	high (0.3–1.8mM)	absent	'Pure' unlaminated mat upstream of other phototrophs.	Rotorua region, New Zealand
<i>Chromatium</i>	red to pink	photoautotroph	< 58	6.2–~7.0	moderate > 0.02 mM	absent	Red-pink top cover with undermat of <i>Chloroflexus</i> upstream of cyanobacteria.	Mammoth Springs, (YNP), Thermopolis, Wyoming.
	red to pink	photoautotroph	< 58	~7.5–>8.5	low or absent	+	Distinct pink to red band under cyanobacteria in sulfate-rich springs.	Western USA
'Purple non-sulfur bacteria'	unknown	photoheterotroph	< 47(?)	4.8–>8.5	?	+	Unknown as distinct populations.	Probably most springs < 45° C
<i>Heliothrix</i>	unknown (dull brown-green)	photoheterotroph	≈ 53(?)	~7.5–8.2(?)	?	+	Unknown as distinct population (probably in strictly anoxic zone).	Hunter's Hot Springs, Oregon
Anoxygenic cyanobacteria								
<i>Oscillatoria 'amphigranulata'</i>	olive green	photoautotroph	< 57	5.9–9.2	low to high: 5 μM–3 mM	+ or absent	Distinct mat upstream of others, less sulfide-tolerant cyanobacteria.	North Island, New Zealand
<i>Spirulina labyrinthiformis</i>	deep blue-green	photoautotroph	< 52	6.2–~7.0	moderate: ~0.02–0.1 mM	+ or absent	Distinct blue-green band near 45–51° C sources.	Mammoth Springs, (YNP)

Fig. 5. (See also Color Plate 2A) *Chlorobium tepidum* mat (green cover) in highly sulfidic 'Travelodge Stream', Rotorua, New Zealand. The temperature is 45 °C in the foreground, with a pH usually in the range of 5.3–6.2 (see Castenholz et al., 1990).

capable of growth above 50 °C (optimum 48–50 °C). Halophilic species of *Ectothiorhodospira* have mildly thermophilic tendencies, often with optima for growth up to 47 °C, but with upper limits of 50 °C or lower (e.g. Raymond and Sistrom, 1969; Imhoff and Trüper, 1981). Although several genotypes of *Chromatium tepidum* may exist, the general phenotypic characteristics of this species appear to be the same or very similar wherever it occurs. It is known from several hot spring complexes in western North America where it is often abundant up to temperatures of 57–58 °C (Table 1). In culture as well it shows no growth above 57 °C or below 34 °C, and thus would be classified as a moderate temperature form (MTF). It is known primarily as an 'undermat' form, presumably depending on biogenic sulfide, but in a few areas forms a surface mat when primary sulfide is abundant.

The diagnostic characteristics of *Cm. tepidum* are the higher temperature tolerance and optima for growth, rhodovibrin as the major carotenoid (in addition to spirilloxanthin), and the light-harvesting bacteriochlorophyll *a*/protein complex with a major absorption maximum at 918 nm in addition to 800 and 855 nm (Garcia et al., 1986).

5. Purple 'Non-Sulfur' Bacteria

At present, purple 'non-sulfur' bacteria have not been isolated in culture with growth temperature limits above 47 °C (see Resnick and Madigan, 1989; Stadtwald-Demchick et al., 1990 a,b). These few species will be regarded here as mildly thermophilic or thermotolerant species of *Rhodopseudomonas* (*Rp. cryptolactis*) and *Rhodospirillum* (*Rs. centenum*). Little is known of their ecology except the nature of the hot spring pools from which they were isolated (Table 1). *Rhodospirillum centenum*, however produces high heat- and desiccation-resistant cysts which presumably explains the recovery of this species from thermal waters of 55 °C. Most earlier described species of the purple 'non-sulfur' bacteria in culture have temperature optima of 30–35 °C and only two species have optima as high as 40–42 °C (Imhoff and Trüper, 1989). N₂ fixation by several mildly thermophilic 'non-sulfur' purple bacteria has been demonstrated, indicating that this may be a means for enriching the mat environment with fixed nitrogen (Resnick and Madigan, 1989; Stadtwald-Demchick et al., 1990a,b).

Other studies of hot spring species composition and temperature limits have recovered purple 'non-sulfur' bacteria from temperatures exceeding 50 °C, perhaps up to 60 °C (Gorlenko et al., 1985, 1987). These studies have not demonstrated growth in the 50–60 °C range, since recovery was determined by plate dilutions and growth at lower temperatures (Yurkov et al., 1991). Using undiluted inoculum from hot springs of western N. America, enrichments for purple 'non-sulfur' bacteria, invariably resulted in success at 40 °C, sometimes at 45 °C, but never at 50 or 55 °C (Castenholz, unpublished data).

The purple 'non-sulfur' bacteria are infamous in being present almost everywhere (as revealed by selective/enrichment cultures). However, as in most other habitats, no identifiable, discrete populations of these organisms are apparent at any temperature in hot spring mats. Purple phototrophic bacteria of various types are represented in three phylogenetic branches of the Proteobacteria where extreme thermophily has not yet been found. The purple 'sulfur' bacterium, *Chromatium tepidum*, of the gamma branch may represent the highest temperature-tolerant thermophile of the Proteobacteria.

6. *Heliobacteria*

Heliobacteria, in general, are known as soil inhabitants and have been isolated mostly from dried soil samples, including those from rice paddies of southeastern Asia (Madigan, 1992). Essentially nothing is known of the ecology of this group of Gram positive-related bacteria. *Heliobacillus* sp., which appears quite similar morphologically to *Hc. mobilis* (Beer-Romero and Gest, 1987) has regularly become the dominant or sole phototroph in enrichments from wet (30–50 °C) inoculum from Hunter's Hot Springs (Lakeview, Oregon). Enrichments arose under incandescent lamps at 40–50 °C, although at 40–45 °C purple 'non-sulfur' bacteria sometimes arose instead (Castenholz, unpublished data). The original pyruvate-containing HAMP medium (Beer-Romero and Gest, 1987) usually 'selected' for this thermophilic *Heliobacillus*. Growth of the 45 °C enrichment culture continued when transferred to 50 or 53 °C but not at 55 or 60 °C. The abundance of *Heliobacillus* in Hunter's Hot Springs has not been estimated (Table 1). Several thermophilic heliobacteria have been isolated in pure culture from Yellowstone hot springs and Icelandic soils (Kimble and Madigan, 1994). These organisms grow up to 56 °C and have recently been described as a new species of the genus *Heliobacterium*, *Heliobacterium modesticaldum*, the species epithet meaning 'moderately hot' (Kimble et al., 1995). *Heliobacterium modesticaldum* appears similar to the isolates from Hunter's Hot Springs.

7. Anoxygenic Cyanobacteria

All known cyanobacteria retain the ability to perform oxygenic photosynthesis when environmental sulfide is low or absent. In addition to several non-thermophiles, anoxygenic photosynthesis with sulfide as the electron donor is known in some thermophilic or semi-thermophilic species of *Oscillatoria* (e.g. *O. cf. limnetica*: Cohen et al., 1986; *O. cf. amphigranulata*: Castenholz and Utkilen, 1984; *O. cf. boryana*: Castenholz et al., 1991) and also in *Spirulina cf. labyrinthiformis* (Castenholz, 1977). Not all cyanobacteria are capable of living in the presence of sulfide. Some that are incapable of anoxygenic photosynthesis are completely inhibited; some are merely tolerant and continue oxygenic photosynthesis; still others apparently perform both types

simultaneously (see Cohen et al., 1986). The competent species are generally anoxygenic only when free sulfide is over a critical level; H₂S is more effective than HS⁻ (Howsley and Pearson, 1979), the latter proportionately greater at higher pH's. In a warm sulfide-rich pool in New Zealand, it was concluded that sulfide-dependent anoxygenic photosynthesis of benthic *Oscillatoria boryana* generally began each day; as light intensity increased the sulfide surrounding the cells was depleted to ~50 μM, at which point oxygenic photosynthesis resumed (Castenholz et al., 1991).

It is known that Photosystem II is inhibited by sulfide in many cyanobacteria capable of anoxygenic photosynthesis. It is merely conjecture, however, that the ability of PS I to accept electrons derived from sulfide represents a primitive ability inherited from the photosystem-flavocytochrome complex of green sulfur bacteria (see Blankenship, 1985). Nevertheless, PS I of cyanobacteria and the photosystem of green sulfur bacteria are similar in several respects, most specifically in having iron sulfur clusters as early acceptors in the reaction centers (see Blankenship, 1992).

The thermophilic, facultatively anoxygenic cyanobacteria are limited to temperatures below 57 °C. This temperature represents the upper limit for growth of *O. cf. amphigranulata* in sulfide-rich to low sulfide springs of New Zealand with pH ranges of 5.9–9.2, and also in cultures with no sulfide (Castenholz, 1976; Castenholz and Utkilen, 1984; see Fig. 6). *Spirulina labyrinthiformis* in hot springs of Yellowstone National Park is limited to temperatures below 51 °C under any conditions (Castenholz, 1977).

II. Chemical and Geographical Diversity of Thermal Habitats

Photosynthetic prokaryotes are limited to waters with pH levels above about 4.3. Very few species tolerate levels below 6, however. Thus, even slightly acidic springs have few photosynthetic components that are not eukaryotic.

Above the pH level of 6, however, springs with waters of great chemical diversity exist (e.g. Table 2; White et al., 1963; Castenholz, 1969; Brock, 1978). The largest number of springs or clusters of host

Fig. 6. (See also Color Plate 2B) Facultatively anoxygenic *Oscillatoria* cf. *amphigranulata* in small sulfidic spring WH-1 (Cirque-1), Whakarewarera, New Zealand. Temperature at the grey-green edge of the cyanobacterium was $\sim 56^{\circ}\text{C}$. *Thiobacillus*-like whitish-yellow streamers occurred upstream to about 68°C (see Castenholz, 1976).

springs are in areas of contemporary or geologically recent volcanism. Most of these have inorganic solute values well over 1000 and below 3000 mg/l, as compared to surface waters with mean values of ~ 150 mg/l (Table 2). Saline hot springs exist, but most of these are not associated with volcanism, but rather with regions of ancient salt deposits or oil field brines. Numerous hot springs also exist in areas of active tectonism and deep faulting. These, non-volcanic types usually have a lower solute content than those associated with volcanism (Table 2).

Neutral to alkaline springs associated with volcanism occur in many regions, most prominently in western North and South America, and much of the remainder of the Pacific rim, including Kamchatka, Japan, Indonesia, and New Zealand (Waring et al., 1965). Other large clusters exist in Mediterranean Europe, the Azores, Iceland, portions of central and eastern Africa, and many other smaller island groups worldwide. Although each volcanic area appears to have a characteristic chemistry as exemplified by differing concentrations and relative proportions of various ions, most of the extensive volcanic geothermal areas have chemical overlap with other geographically remote volcanic areas, so that endemism in species composition, if indeed it exists, may be a result of local speciation and poor dispersal capabilities of some types of microorganisms.

The same overlap of chemistry occurs in the more scattered, and smaller spring clusters associated with

tectonism (e.g. White et al., 1963; Waring et al., 1965). Some of these springs which drain limestone or dolomitic bedrocks are very similar to each other chemically in the relatively few regions where they occur (Table 2).

Although endemism appears to exist among thermophilic cyanobacteria, including the species known to be capable of anoxygenic photosynthesis, so little is known about the distribution of anoxygenic purple, green, and chloroflexean bacteria, that it would be premature to discuss this except in the context of the next section, the summaries of selected hot spring habitats.

III. Principal Habitats of Thermophilic Anoxygenic Phototrophs and the Environmental Requirements: Case Studies

A. Non-Sulfidic Springs of Yellowstone and Oregon: Photoheterotrophic *Chloroflexus* and Other Filamentous Anoxygenic Phototrophs

The ecology of *Chloroflexus* in two principal non-sulfidic hot springs will be summarized. These are Hunter's Hot Springs of south central Oregon and Octopus and nearby springs in the Lower Geyser Basin of Yellowstone National Park (YNP). Both of these spring systems are alkaline (pH ~ 8.0 – 8.5), but with obvious differences in ion content (Table 2). Nevertheless, the cyanobacterium *Synechococcus* cf. *lividus* occupies the substrate up to a relatively constant temperature of 73 – 74°C in both systems. Free sulfide is very low or undetectable at this point in the outflow and *Chloroflexus aurantiacus* may be found associated with *Synechococcus* up to that temperature, and in crude culture up to about 70°C . However, in these and other similar springs, a recognizable orange to yellowish undermat of *Chloroflexus* does not develop except below a mean temperature of 68 – 69°C (Table 1).

In these and most of the North American springs, the visually abrupt transition below ~ 68 – 69°C , from the top cover of photoautotrophic *Synechococcus* to photoheterotrophic *Chloroflexus*, is obvious, i.e. from the 0.5–1.5 mm thick green to yellowish-green cyanobacterium cover to the distinctly orange to salmon-colored underlayer of *Chloroflexus* (Fig. 1). Only the uppermost few millimeters (or less) of most mats receive enough irradiance to drive phototrophic

Table 2. Partial chemical composition of selected hot springs (mg/l)

growth, at least this is true in Hunter's Hot Springs, Oregon (Fig. 7). By a depth of 1 mm in this representative *Synechococcus* and *Chloroflexus* mat, all wavelengths below 550 nm were absorbed and only 0.01–0.001 of longer wavelength visible irradiance remained. The *Synechococcus* top layer (of unbound unicells) was only about 0.5 mm thick; at 1.0 mm depth, there was almost complete absorption by BChl *c* (740 nm) and approximately 0.05–0.1 of incident infrared irradiance remained (Fig. 7). In similar mats, topped by *Oscillatoria* cf. *terebriiformis* in Hunter's Hot Springs (below 55 °C) (Richardson and Castenholz, 1987) and by *Synechococcus* sp. in Octopus Spring, microelectrode data of daytime O₂ profiles (Revsbech and Ward, 1984 a,b) showed that during most midday periods, O₂ diffuses throughout the active mixed and undermat *Chloroflexus* layer at levels often greatly exceeding saturation. Since characteristic BChl *c* and BChl *a* bands are still evident, and in the laboratory, *Chloroflexus* requires anoxic or at least microoxic conditions for the synthesis of these pigments, it is likely that the consistent anoxic conditions of nighttime are necessary for the synthesis of bacteriochlorophyll. With photopigments present in *Chloroflexus* during the oxic daytime period, photoheterotrophy probably predominates over aerobic chemoheterotrophy, since culture experiments have shown that light suppresses aerobic respiration when bacteriochlorophyll is present. Both modes apparently share the same electron transport system (see Pierson and Castenholz, 1974b, 1992).

Since anoxygenic photoautotrophy is generally excluded in these two spring systems because of the lack of sulfide or other suitable reductants, photo- or chemo-heterotrophy is a necessity for *Chloroflexus*. A direct supply of reduced carbon from *Synechococcus* or other cyanobacteria is possible but organic acids from 'intermediate' organisms, such as acetate or butyrate fermenters, may be the sources of carbon. Although Bateson and Ward (1988) gave evidence for glycolate as a main release compound of *Synechococcus* in Octopus Spring, presumably during conditions promoting photorespiration, Teiser and Castenholz have evidence that a great variety and quantity of low molecular weight compounds are released by strains of thermophilic *Synechococcus* (Teiser, 1993). These have been identified in axenic strains from Hunter's Hot Springs (Oregon), West Thumb (YNP), and Hunter Hot Springs (Montana).

Fig. 7. Downwelling spectral irradiance profile through a hot spring microbial mat composed of cyanobacteria (*Synechococcus* cf. *lividus*) and *Chloroflexus aurantiacus*. The vertical core was taken at about 60 °C from Hunter's Hot Springs, Oregon, and methods were those of Pierson et al. (1990). The top spectrum is the incident solar irradiance at the surface of the mat. The other spectra were at 1.0 mm depth increments within the mat. Arrows indicate specific attenuation of irradiance due to pigments: a = phycoerythrin; b = Chl *a*; c = BChl *c*; d & e = BChl *a*. Note that all wavelengths shorter than 550 nm are severely attenuated at a depth of 1.0 mm. The wavelengths that penetrate deeper are in yellow, red and near infrared portions of the spectrum.

They include succinate, beta-hydroxybutyrate, acetate, adonitol, and fructose as major release products; most of these can also be used by *Chloroflexus* for anaerobic phototrophic growth (Teiser, 1993).

The realization that *Chloroflexus aurantiacus* could grow entirely on products of *Synechococcus* came many years ago when dual cultures of the two organisms were first grown routinely on autotrophic agar medium (see Pierson and Castenholz, 1974a).

Hunter's Hot Springs, Oregon, differs dramatically from Octopus Spring, Yellowstone in the high concentration of sulfate (~2.7 mM – Oregon vs. 0.24 mM – Octopus; Table 2). This results in much biogenic sulfide production below about 58 °C in Hunter's Hot Springs which results in large populations of *Chromatium tepidum* also below this temperature, under a top cover of the cyanobacterium *Oscillatoria* cf. *terebriiformis*. *Chloroflexus aurantiacus* is also present and in this situation may use photoautotrophy to some extent.

It is now known that more than one genotype of thermophilic *Chloroflexus* occurs, at least in Octopus Spring (Weller et al., 1992; Ruff-Roberts et al.,

1994). However, at this point phenotypic differences have not been determined. Other *Chloroflexus*-like, organisms also occur in these two spring systems in Oregon and Yellowstone. *Heliothrix oregonensis* occurs below about 56° C in Hunter's Hot Springs and in Octopus Spring (unpublished observations). This aerotolerant, highly motile organism tends to form surface tufts, which may represent an aerotactic response. It can be fairly accurately recognized in the field and by microscopy (see section B.2). The greatest development of *Heliothrix*, however, is in summer, in unshaded springs of the Kahneeta group in eastern Oregon (Fig. 4; Pierson et al., 1984; Castenholz, 1984 a,b). In several of these small stable springs, a brilliant orange 'puffy' cover of *Heliothrix* forms on top of a dark green cyanobacterial mat (Fig. 4). It is assumed that its aerotolerance, low content of BChl *a*, and extremely high content of presumably photoprotective carotenoids, allow or promote its vertical position in these springs. Nevertheless, *Heliothrix* is known as a photoheterotroph only, and is presumably dependent on the cyanobacteria beneath it for reduced carbon.

Thick translucent mats of filamentous cyanobacteria (e.g. *Phormidium* spp.) occur in some hot springs in the Lower and Midway geyser regions of Yellowstone National Park. The *Chloroflexus* layer may occur as deep as 1.5 cm in the mat, followed even deeper by the undescribed red, filamentous bacterium containing thylakoids and BChl *a* (Castenholz, 1984b; see Chapter 3 by Pierson and Castenholz). It has been shown that primarily near infrared wavelengths are transmitted to the depths occupied by these organisms (Jørgensen et al., 1992)

B. Sulfidic Hot Springs with Photoautotrophic Chloroflexus

The most prominent mats of photoautotrophic *Chloroflexus* known are in Yellowstone National Park, Iceland, and New Zealand. The first two of these will be discussed.

In the Upper Terraces of Mammoth Hot Springs, hot springs emerge at 73–75 °C and at various temperatures below this. In all the source waters there is primary sulfide of about 30–130 μM and a pH of 6.2–6.8, depending on the spring. Prominent dull green mats of *Chloroflexus* occur in slow flowing springs that emerge in the range of 51–66 °C (Castenholz, 1977; Ward et al., 1989, 1992).

Photoautotrophic strains of *Chloroflexus* from these springs are obligate phototrophs, and although autotrophic in the field, grow best as photoheterotrophs in organic medium in the laboratory (Giovannoni et al., 1987). The conditions which dictate the dominance of photoautotrophic *Chloroflexus*, rich in BChl *c*, are waters with significant concentrations of primary sulfide bathing the substrate or mat ($\geq 30 \mu\text{M}$), pH levels above 6.2, and temperatures between 52 and 66 °C. These sulfide levels exclude all known species of cyanobacteria in North America that would otherwise grow at temperatures above about 52 °C. The fact that sulfide in these springs is lost by gaseous diffusion, by abiological oxidation, and by biological usage soon after the waters emerge, limits the mats of *Chloroflexus* to sites near the sources of the few, small, low volume springs that discharge within this narrow temperature range (see Castenholz, 1977). These waters are anoxic at the sources and over most of the photoautotrophic mat (Giovannoni et al., 1987).

A remarkable aspect of some of the stable, green *Chloroflexus* mats is that they develop laminations as they accrete. However, the orange to brownish colored underlaminae also appear to be composed of *Chloroflexus* (Giovannoni et al., 1987; Ward et al., 1989, 1992). It is possible that the uppermost bands of this 'discolored' undermat are supported as photoheterotrophs by the top layer of photoautotrophic *Chloroflexus*. Although unknown, there is no requirement that these be different strains. A depth profile of downwelling spectral irradiance revealed only the absorption bands of pigments typical of *Chloroflexus* (Fig. 8).

Orange to salmon-colored photoautotrophic mats of *Chloroflexus* occur within the same temperature range as the dull green-colored mats in larger volume, higher temperature springs of the Mammoth terraces (Castenholz, 1973a,1977). These springs contain similar sulfide concentrations as the lower temperature springs, but by the point in the shallow outflow (< 1 cm) that temperature has dropped to 66 °C (the absolute upper limit for autotrophic growth of *Chloroflexus*), much of the sulfide has disappeared and some O₂ has been acquired, O₂ limits the synthesis of bacteriochlorophylls in *Cf. aurantiacus* even more than does high light intensity, (e.g. Sprague et al., 1981; Oelze, 1992). The orange to salmon-colored mats of *Chloroflexus* which occur upstream of all cyanobacteria appear to be reliable indicators of at

Fig. 8. Downwelling spectral irradiance profile through a hot spring microbial mat composed of 'green' *Chloroflexus* (see Giovannoni et al., 1987). The mat was collected from 'New Pit Spring', Mammoth Springs (YNP) at about 57 °C, and methods were those of Pierson et al., 1990. The top spectrum is the incident solar irradiance at the surface of the mat. The other spectra were at depths within the mat of 0.125, 0.5, 1.0, 2.0, 3.0, and 4.5 mm. Arrows indicate specific attenuation due to pigments: a = BChl c; b & c = BChl a. As in Fig. 2, only red and near infrared wavelengths penetrate deeply into the mat.

least micro-oxic conditions.

Chloroflexus mats of a similar salmon or orange color, upstream of the cyanobacteria, are prominent in a few other geothermal regions as well; particularly in sulfidic springs of Iceland and New Zealand (Castenholz, 1973a, 1976; Table 1). Since many of these springs have sources near 100 °C, the orange *Chloroflexus* mats do not develop near the sources, but considerable distances downstream. Nevertheless, in many of these volcanic springs of alkaline pH, substantial sulfide exists even at 66 °C (Fig. 3). Although photoautotrophic *Chloroflexus* usually forms mats well upstream of cyanobacteria in these springs, there are some notable examples in Iceland where *Chloroflexus* forms the top layer of mat with an undermat of cyanobacteria (Fig. 9). It was shown by Jørgensen and Nelson (1988) that oxygenic photosynthesis by sulfide-sensitive cyanobacteria occurred below ~61 °C in a 0.5 mm thick band 0.8 mm below the top of the *Chloroflexus*. The sulfide concentration at the surface of the *Chloroflexus* was ~60 μM, but by a depth of 0.8 mm within the mat the sulfide had decreased sufficiently for oxygenic

Fig. 9. (See also Color Plate 2C) Inverted *Chloroflexus* mat at about 61–62 °C in Ystihver Stream, Húsavík, North Iceland. The primary sulfide which supports the photoautotrophic *Chloroflexus* is lowered within the mat, so that an underlayer of oxygenic cyanobacteria (*Chlorogloeopsis* 'high temperature form') occurs at about 1 mm below the *Chloroflexus* (see Jørgensen and Nelson, 1988).

photosynthesis, presumably because of the photosynthetic use of sulfide by the top layer of *Chloroflexus*.

C. Chlorobium in Acidic, Sulfide-rich Hot Springs of New Zealand

High sulfide (0.3–1.8 mM) with moderate temperature (55–40 °C) and pH levels between ~4.3 and 6.2 is a combination that supports *Chlorobium tepidum* as the sole phototroph, at least in hot springs in New Zealand (Castenholz, 1988; Castenholz et al., 1990). The same conditions are unknown elsewhere (at least to these authors). This photoautotroph forms unlaminated slime covers on solid substrates in the few springs with the above combination of conditions (Fig. 5). There are, of course, no cyanobacteria at this temperature range in waters with a high sulfide content and this low a pH. *Chloroflexus* is also excluded, presumably by the low pH. Even in the Rotorua/Rotoiti region of the central volcanic region of the North Island, most sulfide-rich hot springs are either too acidic (< pH 4.3) or too alkaline

(continuously over ~pH 6.2) to allow *Chlorobium tepidum* to predominate. Since the pH optimum of *Cb. tepidum* isolates is about 6.8–7.0 (Wahlund et al., 1991), the *Chlorobium* dominance in these springs is probably a result of merely a high tolerance of low pH rather than a reflection of its optimum. The restricted conditions for *Chlorobium* dominance relegate these mats to a few small natural springs in the Sulphur Point region of Rotorua, Whakarewarewa, and the south shore of western Lake Rotoiti (Castenholz et al., 1990). One spring with substantial discharge is Manupairua on Lake Rotoiti. The principal spring of study, however, was 'Travelodge Spring' which issued from a geothermal well of the Rotorua Travelodge at Sulphur Point in Rotorua (Fig. 5). In 1990, four years after the initial study, this spring had changed to the extent that little of the formerly extensive *Chlorobium* mat remained.

The *Chlorobium* mat, as originally described, was slightly yellow-green on the surface due to a thin (0.1–0.2 mm) dusting of elemental sulfur mixed with cells. Dislodging this layer with turbulence from a syringe revealed a deep green densely packed, slimy mass of *Chlorobium* which appeared microscopically to consist of one uniform cell type that corresponded to *Chlorobium*. This dense compaction of cells was about 3 mm thick over a 1–2 mm thick transition layer 'stained' black by metal sulfides (see Ward et al., 1989 for color photograph of vertical section). Photosynthetic usage of sulfide occurred to a depth of about 1.0 mm, at which point only about 0.001 % of the downward irradiance remained (Castenholz et al., 1990). Some species of *Chlorobium* are known for their ability to grow at lower photon fluence rates than any other phototrophic organism (see Overmann et al., 1991, 1992). Sulfide was also generated rapidly within the *Chlorobium* mat, at least in darkness, which may indicate anaerobic fermentation of elemental sulfur by *Chlorobium* (e.g. Paschinger et al., 1974), rather than activity by non-photosynthetic sulfur- or sulfate-reducing bacteria.

It appears that *Chlorobium tepidum* mats occur only in a restricted area of New Zealand. However, it is possible, or even probable, that a similar combination of chemical and physical conditions occurs in other volcanic regions. Therefore, an interesting question is: if such conditions exist will *Chlorobium tepidum* be there or is this non-spore forming organism an example of microbial endem-

ism, where descent from *Chlorobium limicola* occurred over the several million year history of geothermal activity and geographic isolation in New Zealand?

D. *Chromatium* in North American Hot Springs

Chromatium tepidum, the only known thermophilic purple sulfur bacterium, appears to be distributed through many hot springs of North America, and possibly the world (see Madigan, 1986, 1988). It is known from various hot springs of eastern Oregon, northern Nevada and California, New Mexico, northwestern Wyoming (e.g. Thermopolis Springs, Thermopolis; and Mammoth Springs, Yellowstone National Park) (Fig. 10). Species or strains of *Chromatium* somewhat similar to *Cm. tepidum* occur in other hot springs, but there has not yet been a demonstration of growth in these above 51 °C. Such is the *Chromatium* isolated from hot springs of the Rotorua region of New Zealand (M. Madigan, personal comm.).

In a few small springs in the Mammoth area *Cm. tepidum* is the sole photoautotroph where sulfide occurs in emerging spring sources with a temperature in the mid 50s, and where pH is above 6.2 (Madigan, 1984, 1986, 1988; Madigan et al., 1989). Springs with primary sulfide at levels sufficient to support *Chromatium* over the appropriate pH and temperature range are not common, but the undermat habitat of numerous hot springs supports *Chromatium* with biogenic sulfide. High biological production of sulfide, however, depends on water and sediments with a high concentration of sulfate (see Table 2).

In some small springs in the Upper Terraces of Mammoth Hot Springs (YNP) appropriate conditions exist to support photoautotrophic *Chromatium* (see Ward et al., 1988 for color figure). The physical and chemical constraints are very restrictive and probably fairly constant (Tables 1 and 2). Primary sulfide bathing the substrate must exceed ~25 μM, the pH must exceed ~6.2, and the temperature must be between ~50 and 56 °C. Below pH 6.2, *Chlorobium tepidum* would not be expected, however, even if inoculum existed in the region. *Chlorobium tepidum*, in culture, requires at least 1 mM sulfide (Wahlund et al., 1991), which is rare in the Mammoth Springs. Below ~51 °C the facultatively anoxygenic cyanobacterium, *Spirulina* cf. *labyrinthiformis*, predom-

Fig. 10. (See also Color Plate 3A) Exposed *Chromatium tepidum* in a nighttime view of a 45–48 °C mat of Hunter's Hot Springs, Oregon. In daytime the *Chromatium* forms an underlayer beneath the brownish-red cyanobacterium *Oscillatoria terebriformis*, which descends below the *Chromatium* at night (see Richardson and Castenholz, 1987).

Fig. 11. (See also Color Plate 3B) Daytime view of the same area as Fig. 10., with *O. terebriformis* forming the mat surface, but with *Chromatium* swarming into the water in the can which is open at both ends, but which had been darkened by a top lid a few hours earlier.

inates in these springs, particularly when sulfide is in the range of 30– ~100 μM (Castenholz, 1977; see part E. below). Temperatures above 56 °C are out of the range of *Chromatium tepidum* and within the optimum range of photoautotrophic *Chloroflexus*. However, there is still an unidentifiable element that dictates the dominance of *Chromatium*. Why, for example, does not the photoautotrophic *Chloroflexus* predominate on the temperature range of ~ 45–56 °C? The upper half of this range, at least, is well within the optimal temperature range of the autotrophic *Chloroflexus* isolates. However, *Chloroflexus* grows very slowly as a sulfide supported photoautotroph, so perhaps the potentially more rapid growth rate of *Chromatium* allows its dominance. It is notable that even in these few springs with *Cm. tepidum* as the photoautotroph, there is still an undermat of *Chloroflexus*, presumably persisting as a photo- or chemo-heterotroph as it would under a top cover of photoautotrophic cyanobacteria.

Since undermat *Chromatium*, subsisting on biogenic sulfide, and perhaps organic acids from associated mat microorganisms, is common in several North American hot springs rich in sulfate, it is difficult to single out any one system. However, waters of Hunter's Hot Springs, Oregon, contains about 2.6 mM sulfate at the sources (Table 2) and a soft organic mat is produced with abundant *Chromatium* below about 55 °C under a top cover of the cyanobacterium *Oscillatoria cf. terebriformis*.

Cm. tepidum is very conspicuous at night in these

springs since it swarms upward to the surface of the mat after dusk, at the same time that the *Oscillatoria terebriformis* makes its dusk decent into the soft mat material (see Jørgensen et al., 1992; Richardson and Castenholz, 1987; see Figs. 10 and 11). It is probable (but from still inconclusive data) that the *Chromatium* (which is laden with elemental sulfur from the incomplete, daytime, photosynthetic oxidation of sulfide) ascends to the surface at night in a positive aerotactic response. During darkness it oxidizes its 'internal' sulfur and/or environmental sulfide as a chemolithotroph and uses CO_2 as a chemoautotroph in the micro-oxic environment of the mat surface/water interface (Jue, 1990; Jue and Castenholz, unpublished data; see Figs. 10 and 11). The *Chromatium* descends into the mat again with light (using an undetermined tactic response) as the *O. terebriformis* ascends to the mat surface (see Jørgensen et al., 1992). The *Chromatium* then resumes anoxygenic photosynthesis, using the near IR radiation (which penetrates through the surface cover of cyanobacteria) and the free sulfide present beneath the cyanobacterial layer in daytime (see Richardson and Castenholz, 1987; Revsbech and Ward, 1984a). These mass nighttime movements are known also in non-thermophilic *Chromatium* (Jørgensen, 1982; Sorokin, 1970). Chemolithotrophy is known in several purple sulfur bacteria (e.g. de Wit and van Gemerden, 1987, 1990; Kämpf and Pfennig, 1986), but results were negative in the isolates of *Cm. tepidum* as described by Madigan (1986).

E. Anoxygenic Cyanobacteria in Hot Springs

The two best known examples of hot spring systems with anoxygenic cyanobacteria are sulfidic, alkaline springs of the Rotorua area of New Zealand and the neutral pH, sulfidic springs of the Mammoth Terraces of Yellowstone National Park.

The alkaline springs of New Zealand are unusual in that high sulfide levels are common (up to 3 mM), and at levels above $\sim 5 \mu\text{M}$ *Oscillatoria* cf. *amphigranulata* and, rarely, *Synechococcus* sp. are the sole cyanobacteria present in the thermophilic range. Throughout the natural distribution of *O. amphigranulata* this species forms coherent mats up to its maximum growth temperature of 56 °C (Castenholz, 1976; Fig. 6). At high sulfide concentrations (1.0–1.5 mM) in culture, *O. amphigranulata* photosynthesizes anoxygenically, but at lower sulfide concentrations (0.3–0.6 mM) and high photon fluence rates, part of the photosynthetic activity could be ascribed to oxygenic photosynthesis (Castenholz and Utkilen, 1984). Several strains of this species were isolated from different hot springs, and capacity for anoxygenic photosynthesis varied in a predictable manner with the sulfide concentration characteristics of the springs of origin (Garcia-Pichel and Castenholz, 1990).

The *O. amphigranulata* springs of New Zealand are recognized by the dull olive-green mats which can be demonstrated, in all cases, to terminate upstream at the fairly constant 56–57 °C point. These mats are sometimes preceded upstream by delicate white streamers of *Thiobacillus*-like chemolithotrophs (Fig. 6). In New Zealand springs with little or no primary sulfide, oxygenic, sulfide-intolerant cyanobacteria form brighter green mats up to a constant temperature of 63–64 °C (see Castenholz, 1976).

In contrast, the Mammoth Springs of YNP have a much lower sulfide content, but the toxicity level may be as high because of the lower pH of 6.2–6.8 (e.g. Howsley and Pearson, 1979). *Spirulina* cf. *labyrinthiformis* forms nearly monotypic dark blue-green mats wherever springs issue at about 45–51 °C with sulfide levels of 30–100 μM (Castenholz, 1977). Although this species can hardly be regarded as a thermophile with an upper limit of only 51 °C, in the Yellowstone springs area there is apparently no cyanobacterium that grows at a higher temperature in the presence of sulfide above $\sim 25 \mu\text{M}$. As in the case of *O. amphigranulata*, *S. labyrinthiformis* is

capable of strictly anoxygenic photosynthesis but only when sustained by sulfide of ~ 0.5 –1.0 mM, levels higher than in the springs of origin (Castenholz, 1977).

Summary

During the last 15 years, more than 20 strains of aerobic bacteria which possess bacteriochlorophyll (BChl) *a* have been found. They are distinguished from typical anaerobic (anoxygenic) phototrophs in that they synthesize BChl only under aerobic conditions and cannot grow without O₂ or other oxidants, even in the light. In some species, photosynthetic activities have been demonstrated. Reaction centers and light-harvesting complexes isolated from some species were shown to be similar to those of typical purple photosynthetic bacteria. The regulatory mechanism of synthesis of pigments and proteins of the photosynthetic apparatus are apparently opposite with respect to O₂ tension to that of typical anoxygenic phototrophs. The low content of BChl, unique composition of carotenoids and presence of non-photosynthetic carotenoids in most strains are other marked characteristics of these aerobic bacteria. Phylogenetically, they are not classified into single group. Species so far described are distributed rather widely within the α -subclass of Proteobacteria (purple

bacteria) in which most of the purple nonsulfur bacteria as well as many non-photosynthetic bacteria are included. Apparently, these aerobic BChl-containing bacteria represent an evolutionary transient phase from anaerobic phototrophs to aerobic non-phototrophs. However, some characteristic features distinct from anaerobic phototrophs suggest that most of them are in a evolutionary stable state.

I. Introduction

It has long been known that bacteriochlorophylls (BChls) are present in prokaryotes which perform anoxygenic photosynthesis under anaerobic-light conditions. Although some bacteria, such as species of *Rhodobacter*, are known to synthesize BChl *a* under semiaerobic conditions, their photosynthetic activities and BChl content are higher under anaerobic conditions. In 1978, however, bacteriochlorophyll *a* (BChl *a*) was detected in three strains of obligate aerobic bacteria (Sato, 1978; Harashima et al, 1978). Since then, more than 20 strains of aerobic bacteria which contain BChl *a* have been reported (Shiba et al, 1979a; Nishimura et al., 1981; Shiba and Simidu, 1982; Urakami and Komagata, 1984; Shiba and Abe, 1987; Evans et al., 1990; Shiba et al., 1991; Yurkov and Gorlenko, 1990,1991,1992; Yurkov et al., 1992; Fuerst et al., 1993; Yurkov and Van Gemerden, 1993b; Wakao et al., 1993). These bacteria were distinguished from 'typical' photosynthetic bacteria in the following points: (1) They are, in principle, obligate aerobes and cannot grow under anaerobic conditions, even in the light. (2) BChl synthesis occurs under aerobic conditions, not under anaerobic conditions.

The BChl content of these aerobic bacteria are, however, significantly lower than those of 'typical' photosynthetic bacteria (Table 1). Thus, the first question may be whether all of these aerobic BChl-containing strains have significant photosynthetic activity or not. In this article, all aerobic bacteria in which BChl has been found are described as aerobic anoxygenic phototrophs without evidence for their phototrophy or photosynthetic activity, since these properties have not been confirmed in most strains. Photosynthetic activities such as photo-stimulated CO₂ incorporation, photo-stimulated growth and photooxidation of cytochromes have been demonstrated only in a few species (Harashima et al., 1982; Shiba, 1984; Takamiya and Okamura, 1984;

Harashima et al, 1987). Phototrophy and/or the advantage of photosynthesis to other non-phototrophic aerobic bacteria have not yet been assessed in their natural habitats. The second question concerns the in vivo state of BChl. All strains so far described seem to have a photosynthetic apparatus similar to that of typical purple photosynthetic bacteria. In some species, reaction centers and antenna complexes of a purple bacterial type have been isolated. In *Roseobacter (Ro.) denitrificans* (formerly *Erythrobacter* sp. strain OCh 114), which is the species investigated most extensively among aerobic anoxygenic phototrophs, the gene structure coding for the photosynthetic apparatus was also shown to be similar to those of typical purple bacteria. However, it is possible in some species that the genetic organization of the photosynthetic apparatus is incomplete compared with those of typical purple bacteria. Regulatory systems for synthesis of BChl and the photosynthetic apparatus, which must be different from those of anaerobic phototrophs, are still unclear. A third question concerns the phylogenetic position of aerobic anoxygenic phototrophs. Phylogenetic studies based on ribosomal RNA indicated that the strains of aerobic anoxygenic phototrophs so far studied are distributed among the α -subclass of Proteobacteria (purple bacteria) in which most of the 'purple nonsulfur bacteria' as well as many non-phototrophic aerobes are included. One may consider, therefore, that each aerobic anoxygenic phototroph is on a transient phase in evolution from an anaerobic purple bacterium to an aerobic non-phototrophic bacterium. In this chapter, available data are presented to discuss the above questions, although the data are still insufficient and are confined to limited species.

II. Habitats and Culture

A. Habitats

Aerobic anoxygenic phototrophs so far described are all chemoheterotrophs and have been isolated mainly from aquatic environments, except for some

strains of facultative methylotrophs. Shiba et al. (1979b, 1991) have isolated *Erythrobacter*, *Roseobacter* and some other strains from the surface of sea weeds, coastal sands, cyanobacterial mat and water in high tidal zone. Occupation of 20 to 50% of the total aerobic heterotrophs by aerobic BChl-containing bacteria was observed in some tropical high-tidal zones (Shiba et al., 1991). However, isolation from sea water is, so far, unsuccessful (Shiba et al., 1979b). The marine bacterial group seem to contain many other species which have not yet been characterized (Shiba et al., 1991; Yurkov and Van Gernerden, 1993b). From fresh water, *Porphyrobacter*, *Acidiphilium*, *Erythromicrobium* and *Roseococcus* have been isolated (Fuerst et al., 1992; Yurkov and Gorlenko, 1990, 1991, 1992; Wakao et al., 1993). Species of the latter two genera were isolated from cyanobacterial mat formed downstream of alkaline hot springs. *Porphyrobacter*, which is phylogenetically close to *Erythrobacter*, was isolated from eutrophic fresh water. Facultative methylotrophic strains which were

once classified as *Protomonas* and, later, included into *Methylobacterium*, are isolates from various sources such as foods, soils, leaf surfaces, etc. (Urakami and Komagata, 1984; Bousfield and Green, 1985). Although one may suppose that phototrophy would be advantageous in oligotrophic environments, most strains of aerobic BChl-containing bacteria have been found in rather eutrophic environments like many species of purple nonsulfur bacteria. Among them, however, species of *Acidiphilium* require relatively low concentration of nutrients (Wakao et al., 1993). Thus, it is possible that unknown oligotrophic strains are present in various environments. So far, all strains described are mesophilic as are typical purple nonsulfur bacteria.

B. Isolation and Culture

As stated above, most aerobic anoxygenic phototrophs grow under aerobic, mesophilic and eutrophic conditions. Therefore, isolation was also performed

Table 2. Composition of the medium for growth of *Roseobacter* (Shioi, 1986)

Ingredient	Concentration (g/liter)
I. Basal salts	
NaCl ^a	20.0
MgCl ₂ ·6H ₂ O ^a	5.0
Na ₂ SO ₄ ^a	2.0
KCl ^a	0.5
CaCl ₂ ·2H ₂ O ^a	0.5
NaHCO ₃	0.2
Ferric citrate ^b	0.1
II. Organic substrates	
Yeast extract (Difco)	2.0
Polypeptone	1.0
Casaminio acids	1.0
Glycerol	1.0 ml

All of the ingredients are mixed and autoclaved for 15 min at 1.0 kg·cm⁻² after adjusting the pH to 7.5 with NaOH. The precipitate formed does not affect the bacterial growth.

^a Can be stocked together as five strength solution.

^b Added as solution (10 mg/ml); store in refrigerator.

aerobically at 20 to 30 °C on agar plates containing rather rich media. In the case of marine bacteria, media such as PPES-II, which are rich in peptones and yeast extract, have been used (Shiba et al., 1979b; Shioi, 1986, Table 2). Since BChl formation is inhibited by light as described below, the culture is kept in the dark or in some cases under intermittent light. Light is not necessary for growth in all strains so far investigated. However, optimum condition for growth and/or BChl-formation have not yet been established in most strains. Thus, it is possible that the very low content (or lack) of BChl in some aerobic phototrophs does not necessarily reflect the nature of the strain in its habitat. The isolated pigmented colonies were enriched and examined for the presence of BChl and the inability to grow under anaerobic conditions in the light. Batch cultures are usually grown on a shaker or in a bubbled bottle. The aeration rate should be controlled (depending on the strains) for the maximal formation of BChl, since saturated oxygen does not necessarily give a maximum yield of BChl (Shiba, 1987). Light conditions should also be surveyed for the yield of BChl, since the BChl-containing *Rhizobium* is known to synthesize BChl only under intermittent light (Evans et al., 1990; see Chapter by Fleishman et al.) and the BChl content of some species of *Methylobacterium* varies significantly by the interval of the

intermittent light (Sato and Shimizu, 1979; see below).

III. Photosynthetic Apparatus

A. Reaction Center

The presence of reaction centers (RCs) in aerobic BChl-containing heterotrophs was first discovered in *Ro. denitrificans* and *Erythrobacter (E.) longus* by Harashima et al. (1982) using light induced absorption changes and an absorption spectrum of iridic chloride-oxidized membranes; the results were similar to those obtained with typical purple photosynthetic bacteria. Later, similar absorption changes were observed in *Methylobacterium (M.) rhodesianum* (formerly *Protaminobacter ruber*), *M. radiotolerans* (*Pseudomonas radiora*), and *Rhizobium* strain BTail (Takamiya and Okamura, 1984; Nishimura et al., 1989; Evans et al., 1990).

Purified RC complexes have been obtained only from *Ro. denitrificans* (Shimada et al., 1985; Takamiya et al., 1987). The absorption spectrum and the photo-induced absorption changes of purified RCs were almost identical to those of typical purple bacteria which have the cytochrome subunit (Fig. 1).

Fig. 1. Absorption and reduction-oxidation difference spectra (inset) of the RC of *Roseobacter denitrificans* (from Shimada et al., 1985).

The composition of cofactors in this preparation was also the same as that in purple bacterial RCs; 4 BChls, 2 bacteriopheophytins, 4 *c*-type hemes and 2 ubiquinones-10. The estimated midpoint potential (E_m) of the primary acceptor (Q_A), -44 mV, and its independence of pH, were also very similar to those of typical purple bacteria (Takamiya et al., 1987). The polypeptide composition was also similar to those of typical purple bacteria; L, M, and H polypeptides were present along with cytochrome subunits of apparent molecular mass of 26, 30, 32 and 42 kDa, respectively. Recently, primary structures of the L and M subunits were deduced by analysis of the nucleotide sequence of a gene cluster (*puf* operon) that contained the genes for the subunits of the RC, as well as those for the two subunits of the B870 light-harvesting complex (LH I) (Liebetanz et al., 1991). The gene structure was essentially the same as those of typical purple bacteria and the amino acid sequence homology of the subunits showed very high values, especially with those of *Rhodobacter* species (up to 70%). These results suggested close relationships between aerobic anoxygenic phototrophs and anaerobic purple photosynthetic bacteria. From *E. longus* only a trace amount of RC could be obtained, which contained three subunits; probably H, M and L (Shimada et al., 1985). The lack of cytochrome in the RC of this species was supported by the absorption difference spectra of RC-LH I complex and the light induced absorption change of the membranes (Matsuura and Shimada, 1990).

Unlike RC, a pigment-protein complex presumed as RC-LH I complex could be obtained rather easily from some species. A minor absorption band around 800 nm and a shoulder around 750 nm in this complex suggested the presence of a RC of the purple bacterial type in *M. radiotolerans* and *Erythromicrobium (Em.) ramosum* (Nishimura et al., 1989; Yurkov et al., 1992). From the RC-LH I complex of *M. radiotolerans*, the four presumed subunits of RC, i.e., L, M, H and the cytochrome subunit, were clearly resolved by SDS-polyacrylamide gel electrophoresis. The mobilities of these proteins were also very similar to those of the corresponding proteins in the RC of typical purple bacteria. The presence of a purple bacterial-type RC was also suggested in many other aerobic anoxygenic phototrophs from the absorption spectra of membranes or cells which showed the same profile as that of the RC-LH I complex, probably due to a lack of the peripheral antenna (LH II) in these species.

It may be noteworthy that the cytochrome subunit of RC has been found from at least two species of aerobic anoxygenic phototrophs, since these types of RCs have been found from relatively anaerobic species of purple bacteria and are rather rare in facultative species of purple bacteria such as *Rhodobacter* species (Matsuura and Shimada, 1990). Although the role of the cytochrome subunit of RC in purple bacteria is not necessarily understood, the presence of this subunit in aerobic anoxygenic phototrophs might give a clue for the elucidation of its significance.

B. Light-Harvesting System

The in vivo absorption spectra of BChl of all aerobic anoxygenic phototrophs so far described showed red-shifted spectra of BChl as in typical purple bacteria; this indicates that almost all BChl molecules are bound to pigment proteins, as in typical purple bacteria. As stated above, most strains were suggested to have a RC-LH I complex of the purple bacterial type. Thus, in terms of the photosynthetic apparatus, all aerobic anoxygenic phototrophs seem to have the ability to perform photosynthesis despite the low content of BChl. Antenna complexes have been obtained from *E. longus*, *M. radiotolerans* and *Ro. denitrificans* (Shimada et al., 1985; Nishimura et al., 1989; Figs 2 and 3). RC-LH I type complexes were obtained from all of these species as from all typical

Fig. 2. Absorption spectra of membranes (dotted line), RC-LH I complex (solid line) and 'non-photosynthetic' carotenoids (broken line) of *Erythrobacter longus* (from Shimada et al., 1985).

Fig. 3. Absorption spectra of membranes (dotted line), RC-LH I complex (broken line) and B806 (LH II) complex (solid line) of *Roseobacter denitrificans* (from Shimada et al., 1985).

purple bacteria indicating a close similarity between the light-harvesting systems of the two groups of anoxygenic phototrophs. In *E. longus* and *M. radiotolerans*, there seem to be no pigment proteins other than the RC-LH I type complex (Fig. 2). The absorption spectra of cells or membranes of the *Methylobacterium* species, *Porphyrobacter neustonensis*, *Em. ursincola*, *Roseococcus thiosulfatophilus* and the *Acidiphilium* species indicated that these organisms also lack an LH II-type complex as in *E. longus*. The lack of LH II in these species is apparently consistent with the hypothesis that aerobic anoxygenic phototrophs are on an evolutionary line to abandon photosynthesis (Woese et al., 1984), although some typical purple bacteria such as *Rhodospirillum rubrum* also lack LH II.

Thus, the presence of an LH II type complex seems to be somewhat rare in aerobic anoxygenic phototrophs. In vivo absorption spectra of some *Erythromicrobium* species and *Erythrobacter* sp. strain OCh 175 showed absorption bands other than those of the RC-LH I complex, indicating the presence of LH II type complexes in these species (Shiba and Abe, 1987; Yurkov and Gorlenko, 1990, 1992; Fig. 4). Species of *Roseobacter* also have another pigment protein in addition to the RC-LH I type complex. The pigment protein isolated from *Ro. denitrificans* showed only one peak at 806 nm in the near infrared region at room temperature (Fig. 3). Although an additional spectral component around 815 nm was resolved at 77 K, no similar antenna complexes have been found in typical purple bacteria (Shimada et al., 1992). In spite of its unique spectral nature, the *Ro. denitrificans* B806 complex is considered to

Fig. 4. Absorption spectra of intact cells of *Erythrobacter* sp. strain OCh 175 (from Shiba and Abe, 1987).

correspond to the peripheral antenna (LH II) of typical purple bacteria, since it contained no RC and showed a Raman spectrum similar to LH II complexes of purple bacteria and transferred energy to the RC-LH I complex with high efficiency as described below (Hayashi et al., 1986; Shimada et al., 1990b). Whether the unique spectral characteristics of its B806 complex is correlated with the aerobic nature of *Roseobacter*, is not clear.

The apparent size of the antenna complexes and their constituent polypeptides of aerobic anoxygenic phototrophs so far examined were also similar to those of typical purple bacteria. Two polypeptides with apparent molecular masses of 5 to 7 kDa seemed to be the main protein components (Shimada et al., 1985; Nishimura et al., 1989). The deduced amino acid sequence of the two small polypeptides coded upstream of the RC components in the *puf* operon of *Ro. denitrificans* showed characteristic features of LH I polypeptides of typical purple bacteria (Liebetanz et al., 1991).

Efficiency of the light harvesting system of aerobic anoxygenic phototrophs has been investigated in only a few species. LH II (B806) complex of *Ro. denitrificans* showed no spectral components at longer than 820 nm which suggests low efficiency of excitation energy transfer to the LH I (B870) complex due to small spectral overlapping between the two antenna complexes. However, the transfer occurred within 6 ps, indicating a highly efficient light-harvesting system of this bacterium (Shimada et al.,

Fig. 5. Absorption and fluorescence excitation spectra of membranes and RC-LH I complex of *Erythrobacter longus*; (A) Absorption (solid line) and fluorescence excitation (broken line) spectra of membranes. (B) Absorption (solid line) and fluorescence excitation spectra (broken line) of RC-LH I complex. (C) Fluorescence excitation spectra of RC-LH I complex (solid line) and the membranes (broken line) depicted in the same scale (from Noguchi et al., 1990).

1990a). Energy transfer from carotenoids to BChl in this bacterium also occurred with high efficiency (Shimada et al., 1990b). The high efficiency of excitation energy transfer from carotenoids to BChl was also demonstrated in the RC-LHI complex of *E. longus* in spite of its unique composition of carotenoids (Noguchi et al., 1992; Fig. 5a). Thus, efficiency of the light-harvesting system of aerobic anoxygenic phototrophs is not necessarily low in spite of its low BChl content.

It may be remarkable that many species of aerobic anoxygenic phototrophs show higher ratios of carotenoid content to BChl than those of typical purple bacteria. It was suggested that only some carotenoids are bound to the light-harvesting complex or to RC in *E. longus* (Fig. 2). Excitation spectra for BChl fluorescence of membranes confirmed that the rest 'excess' carotenoids are not functioning as light-harvesting pigments (Fig. 5). In *M. radiotolerans*, a significant part of the carotenoid pool was not bound to the photosynthetic apparatus (Nishimura et al., 1989). Since such 'non-photosynthetic' carotenoids have not been found in typical purple bacteria, one of the roles of these carotenoids is likely to be concerned with protection from oxygen toxicity. As described below, these 'non-photosynthetic' carotenoids are highly polar and are structurally distinct from the carotenoids which are bound to the antenna complexes as light-harvesting pigments.

C. Membrane Structure

Aerobic anoxygenic phototrophs contain significantly lower amounts of BChl than typical purple bacteria which usually develop intracytoplasmic membranes coincidentally with BChl synthesis. Despite the low content of BChl, 'chromatophore-like' structures have been observed in *Ro. denitrificans*, *M. rhodesianum*, *Em. sibiricum* and *Rhizobium* strain BTAi1 (Harashima et al., 1982; Sato and Shimizu, 1979; Yurkov et al., 1991; Evans et al., 1990). In *Ro. denitrificans* and *M. rhodesianum*, these vesicular intracytoplasmic membranes, though poorly developed, can be observed in cells of relatively high BChl-content but not in cells of low BChl content (Harashima et al., 1982; Sato and Shimizu, 1979; Iba et al., 1988). These results suggest that the photosynthetic apparatus in these aerobes are mainly localized in the specific structure of membranes and the synthesis of such structures are regulated coincidentally with BChl synthesis as in typical purple bacteria.

IV. Pigments and Other Components

A. Bacteriochlorophyll

The only bacteriochlorophyll found in aerobic anoxygenic phototrophs thus far is BChl *a*. The esterified alcohol in all cases has been phytol

(Harashima and Takamiya, 1989; Shiba and Abe, 1987; Wakao et al., 1993). The reason that only BChl *a* has been found may be that BChl *a* is the most stable among the six chemical species of BChl in aerobic environments. However, there seems to be no reason for phytol as the exclusive esterified moiety, since some facultative purple bacteria such as *Rhodospirillum rubrum* have geranylgeraniol in place of phytol. It may thus be possible that aerobic bacteria containing BChl a_{gg} will be found in the future.

B. Carotenoids

The carotenoid composition of most aerobic anoxygenic phototrophs seems to be different from those of typical purple bacteria, as they probably have 'non-photosynthetic' carotenoids. In *E. longus*, more than 70% of total carotenoids do not function as light-harvesting pigments (Noguchi et al., 1992). These carotenoids were shown not to be bound to RC nor to the LH I complex, which is the sole antenna

complex of this bacterium (Shimada, unpubl.; Harashima, 1989). The major components of these 'non-photosynthetic' carotenoids in *E. longus* have been shown to be novel sulfate-containing carotenoids, for example, erythroanthin sulfate (Fig. 6) and caloxanthin sulfate (Takaichi et al., 1991a). Carotenoids bound to the RC-LH I complex of *E. longus* are less polar species: Among them, bacteriorubixanthinal is a novel carotenoid containing a cross-conjugated aldehyde group and a tertiary methoxy group which are unique to purple bacteria. This carotenoid also has an ionone ring which is rarely found in purple bacteria (Takaichi et al., 1988; Fig. 6). Zeaxanthin and other hydroxyl derivatives of β -carotene, which are common carotenoids of oxygenic phototrophs, are also major carotenoids in the pigment protein complex of *E. longus* (Takaichi et al., 1990; Fig. 6). It should be noted that spirilloxanthin, which is unique to purple bacteria, was also found in this RC-LH I complex, although the amount was small. Thus, in *E. longus*, three

Fig. 6. Structure of characteristic carotenoids of aerobic anoxygenic phototrophs; (A) Erythroanthin sulfate from *Erythrobacter longus* (B) Zeaxanthin from *E. longus* (C) Bacteriorubixanthinal from *E. longus* (D) Spirilloxanthin from *E. longus* (E) Diglucoosyl C₃₀-carotenoid from *Methylobacterium rhodinum*.

classes of carotenoids were found; bicyclic, monocyclic and acyclic carotenoids (Fig. 6). Almost the same carotenoid composition has been postulated in *Em. ramosum* (Yurkov et al., 1993). The complex composition of carotenoids in *E. longus* seems to be consistent with its intermediary nature between typical purple bacteria and aerobic organisms. Elucidation of the gene organization for carotenoid synthesis in *E. longus* might give clues to the reason of such complex composition.

In species of *Methylobacterium*, two classes of carotenoids seem to be present. In *M. radiotolerans*, spirilloxanthin is the dominant species in the RC-LH I complex and a few polar carotenoids containing a carboxyl group constitute the 'non-photosynthetic' carotenoid group. Interestingly, the latter is suggested to be localized in the outer membrane (Saito et al., unpubl.). One of the major carotenoids of *M. rhodinum* (formerly *Pseudomonas rhodos*) was indicated to be a diglycosyl ester of C₃₀ carotenedioate (Kleinig et al., 1979; Fig. 6). The same carotenoid and its deglycosylated form also have been postulated to be the major carotenoids in *Roseococcus thiosulfatophilus* (Yurkov et al., 1994). In *M. rhodesianum*, a major carotenoid was also suggested to have a sugar moiety and a carbonyl group (Sato et al., 1982). The highly polar nature of these carotenoids suggests that they are 'non-photosynthetic' carotenoids which are not bound to the photosynthetic apparatus of these aerobes.

The carotenoid composition of *Roseobacter* is somewhat different from other aerobic anoxygenic phototrophs, since it lacks 'non-photosynthetic' carotenoids. The dominant carotenoid species is spheroidenone which is also the dominant species in semi-aerobically grown cells of some typical purple bacteria such as *Rhodobacter (Rb.) sphaeroides* (Shimada et al., 1985, 1990a; Harashima and Nakada, 1982). In this respect, *Roseobacter* seems to have closer relationships with typical purple bacteria than other aerobic anoxygenic phototrophs. It should be noted that reduction of a significant part of spheroidenone to 3,4-dihydrospheroidenone upon illumination in *Ro. denitrificans* was observed under anaerobic conditions (Takaichi et al., 1991b; see below).

C. Quinones and Lipids

Information on quinone composition is so far limited to *Roseobacter*, *Erythrobacter* and *Methylo-*

bacterium. The dominant chemical species in all strains of these genera was ubiquinone-10 (Shiba and Simidu, 1982; Nishimura et al., 1983; Shiba, 1991; Urakami and Komagata, 1984). Except for small amounts of ubiquinone homologues, no other quinones, such as menaquinone and rhodoquinone, were found in these organisms. This seems to be consistent with the quinone composition of facultative purple bacteria in the alpha-subclass of Proteobacteria.

Cellular fatty acid composition has been studied in *Porphyrobacter* as well as in the above three genera. In all strains in the four genera, octadecenoic acid (C_{18:1}) was the dominant fatty acid (Urakami and Komagata, 1984; Urakami and Komagata, 1988; Shiba, 1991; Fuerst et al., 1993). The dominance is especially high in BChl-containing strains of *Methylobacterium*. It may be noted that significant amounts of triterpenoids have been found in some strains of *Methylobacterium*, although this was not the case in *Erythrobacter* (Urakami and Komagata, 1986, 1988).

V. Photosynthetic Activity and Electron Transfer System

A. Evidence for Photosynthetic Activity

The first question after the discovery of BChl-containing aerobic bacteria was whether the BChl molecules were functionally active or not. The first observation indicating photosynthetic activity was the reversible photo-oxidation of cytochromes and the reversible photobleaching of BChl in the presumed RC in *Ro. denitrificans* (Harashima et al., 1982). Photo-inhibition of respiration in *E. longus* and *Ro. denitrificans*, which suggested the operation of a photosynthetic electron transport system, was also observed in the same study. Similar activities were also demonstrated in *M. rhodesianum* (Takamiya and Okamura, 1984). Later, the photo-induced absorbance change of RC was also observed in *M. radiotolerans* and *Rhizobium* strain BTAil (Nishimura et al., 1989; Evans et al., 1990). Photo-inhibition of respiration has also been observed in *Acidiphilium rubrum* (Wakao et al., 1993).

Except for these observations, studies on photosynthetic activity of BChl-containing aerobic bacteria have been confined to *Ro. denitrificans* and *M. rhodesianum*. Shiba (1984) observed light-

stimulated CO_2 uptake and increases in cellular ATP pools in *Ro. denitrificans* (Fig. 7). He also observed the positive effect of light on survival under conditions of starvation. Also, light-dependent ATP formation in membrane preparations was demonstrated in the above two species (Takamiya and Okamura, 1984; Okamura et al., 1986). It should be noted that the light-stimulated activities were observed only in the presence of O_2 or, in *Ro. denitrificans*, auxiliary oxidants as described below. Light-stimulated growth of *Ro. denitrificans* was demonstrated by Harashima et al. (1987); dark grown cells which had accumulated significant amounts of BChl subsequently showed a higher growth rate in the light than did control cells kept in the dark. Also, this activity was prominent in the presence of sufficient O_2 (Fig. 8). Recently, similar light-stimulated growth was observed in *Em. hydrolyticum* (Yurkov and Van Gernerden, 1993a). In spite of these photosynthetic activities, however, no autotrophic growth supported by H_2 and CO_2 has been observed in these bacteria in the light or in darkness.

B. Effect of O_2 and Auxiliary Oxidants

As stated above, aerobic conditions are necessary, in

Fig. 7. Light-stimulated uptake of CO_2 by *Roseobacter denitrificans* in aerobic condition. Open circles, in the light; Closed circles, in the dark (from Shiba, 1984).

principle, for photosynthetic activities of these aerobes. Okamura et al. (1985) observed that light-induced oxidation of cytochromes as well as that of RC disappeared under anaerobic conditions both in membrane preparations and in intact cells of *Ro. denitrificans* (Fig. 9). Since these activities were recovered by aeration, the inactivation was considered to be caused by the over-reduction of the electron transfer system. In this respect, the higher midpoint potential (E_m) of the primary acceptor (Q_A) of the RC (+35 mV at pH 7) in aerobic phototrophs compared to that of typical purple bacteria, has been noted (Harashima and Takamiya, 1989). In *M. rhodesianum*, also, the high E_m was considered to be one of the reasons of the inactivation of photosynthetic activities under anaerobic conditions. In *Ro. denitrificans*, Harashima et al. (1982) observed the photo-reduction of a significant portion (up to 35%) of the predominant carotenoid, spheroidenone, under anaerobic conditions. This phenomenon was considered to be due to excess reducing power accumulated under anaerobic conditions. (Harashima and Takamiya, 1989; Takaichi et al., 1991b).

In 1988, Arata et al. (1988) and Shioi et al. (1988) reported that *Ro. denitrificans* could grow anaerobically in the presence of trimethylamine N-oxide (TMAO) or nitrate. Arata et al. (1988) and Takamiya et al. (1988) also observed reversible photo-oxidation of cytochrome *c* and light-driven proton translocation

Fig. 8. Oxygen requirement for the light-stimulated growth of *Roseobacter denitrificans*. The bacterium was aerobically grown in the dark for 24 h and then either semi-aerobically (S) or microaerobically (M). Closed symbols, values in the dark; open symbols, values in the light (from Harashima et al., 1987)

Fig. 9. Flash-induced oxidation of cytochrome *c* in *Roseobacter denitrificans*. (a) Under aerobic condition (b) under anaerobic condition (c) anaerobic condition in the presence of 3 mM KNO_3 (d) same as (c) + 3 mM KCN (from Arata et al., 1988).

under anaerobic condition in the presence of these oxidants (Fig. 9). These observations clearly indicated that these oxidants can be utilized as electron acceptors in *Ro. denitrificans*. Since only a small accumulation of BChl was observed in cells grown anaerobically with these auxiliary oxidants, light-stimulated growth was not observed under anaerobic conditions. However, when BChl had been accumulated previously by growth under aerobic-dark condition and, further, the corresponding reductase had been induced by either oxidants, light-stimulated growth could be observed in the presence of high concentration of the oxidant (Harashima and Takamiya, 1989).

C. Electron Transfer System

As described above, most strains of aerobic anoxygenic phototrophs seem to have purple bacterial-type RCs. The operation of this type of RC in the light has also been indicated in some of these aerobic bacteria. Therefore, one may consider that electron transfer systems similar to those of facultative purple bacteria are also functioning in aerobic anoxygenic phototrophs. However, not much is known about the electron transfer systems of aerobic anoxygenic phototrophs, especially about light-driven electron transfer. Although participation of *c*-type

cytochromes in light-driven electron transport was indicated by light-induced absorption changes in *Ro. denitrificans*, *E. longus* and *M. rhodesianum*, involvement of the bc_1 -type complex in the system is not clear. Involvement of the bc_1 complex in the respiratory electron transfer system of *Ro. denitrificans* has been suggested by the effect of antimycin on electron transport (Takamiya, 1989). Also, inhibition of electron transfer to the auxiliary oxidants by antimycin or myxothiazol suggested the participation of bc_1 complex in the anaerobic respiratory systems. In *Ro. denitrificans*, cytochrome *c*-551, which was shown to be homologous with cytochrome c_2 of purple bacteria (Okamura et al., 1987), was oxidized by illumination on the one hand, and was oxidized by O_2 or some auxiliary oxidants on the other hand. These results indicated that the bc_1 complex also participated in a light-driven electron transport system in this bacterium (Takamiya et al., 1988). The cytochrome subunit of the RC of *Ro. denitrificans*, *c*-554, was also shown to be a component of the photosynthetic electron transport system as the direct electron donor to the light-oxidized BChl (Matsuura and Shimada, 1990). As stated above, this bacterium has dissimilatory reductases for the auxiliary oxidants. One of them, nitrite reductase, was revealed to be a cytochrome cd_1 -type reductase which could accept electrons from

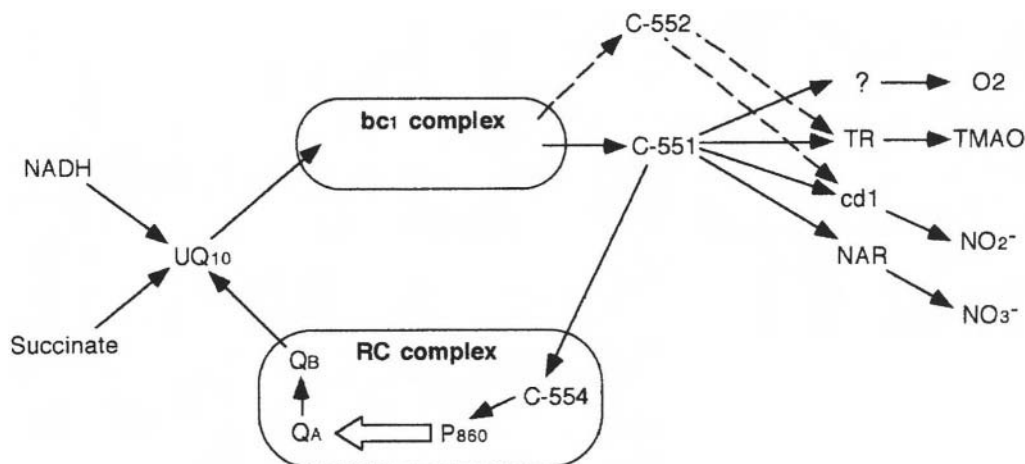

Fig. 10. A tentative scheme for the electron transfer system in *Ro. denitrificans* (from Takamiya, 1989).

cytochrome *c*-551 and also from another *c*-type cytochrome, *c*-552 (Doi and Shioi, 1989; Takamiya et al., 1993). The *in vivo* function of *c*-552 is, however, not clearly understood. Although the nature of cytochrome oxidase is still unclear, a tentative scheme for the electron transfer system in *Ro. denitrificans* is shown in Fig. 10.

From *E. longus*, an *aa₃*-type cytochrome oxidase as well as two cytochromes *c* (*c*-549 and *c*-550) have been isolated (Fukumori et al., 1987). However, presence of the *bc₁* complex in this bacterium is unclear and, consequently, little is known about the components participating in the photosynthetic electron transport system in this bacterium. In *Methylobacterium*, an *aa₃*-type cytochrome oxidase has also been obtained from a strain of *M. extorquens* (formerly *Pseudomonas* AM1) (Fukumori et al., 1985). Although an outline of the respiratory chain in this bacterium has been elucidated (Fukumori and Yamanaka, 1987), the organization of the presumed photosynthetic electron transport system is totally unknown.

The anaerobic respiratory system for the dissimilatory reduction of the auxiliary oxidants in *Ro. denitrificans* is somewhat different from those in some strains of *Rhodobacter* which are also known to utilize some auxiliary oxidants. Dimethylsulfoxide, which is a common oxidant in *Rhodobacter* strains, was not reduced by *Ro. denitrificans*. Also, denitrification from nitrate or nitrite yield nitrous oxide (N₂O), indicating the absence of nitrous oxide reductase in *Ro. denitrificans* (Arata et al., 1988; Shioi et al., 1988).

VI. Regulation of Pigment Synthesis

A. Effect of Oxygen

Aerobic anoxygenic phototrophs can synthesize and accumulate BChl which is then integrated into the photosynthetic apparatus, though the amounts are significantly lower than those in the typical purple bacteria. The fundamental difference between aerobic anoxygenic phototrophs and typical purple photosynthetic bacteria is the requirement for O₂. Aerobic anoxygenic phototrophs can grow and synthesize BChl as well as the photosynthetic apparatus only under aerobic conditions. Under anaerobic conditions, no synthesis of BChl nor growth occurs, except in the case of *Ro. denitrificans* which can grow using auxiliary oxidants and can thus synthesize a small amount of photosynthetic apparatus anaerobically (Takamiya et al., 1992). In *E. longus*, BChl content was significantly reduced in semi-aerobic conditions compared with that of aerobic conditions, while the growth rate was only slightly decreased in the same growth conditions. This suggests that O₂ tension itself stimulated the synthesis of BChl in this bacterium (Harashima et al., 1980). In *Ro. denitrificans*, on the other hand, it was suggested that O₂ itself was not stimulative for BChl synthesis, since BChl content was almost constant down to an O₂ tension below which respiratory activity dropped significantly (Shiba, 1987; Sato et al., 1989). In typical purple bacteria, some facultative species are known to synthesize the photosynthetic apparatus under semi-aerobic conditions (Shioi and Doi, 1990).

However, these species synthesize the photosynthetic apparatus also under anaerobic conditions and show significant photosynthetic activity in the light as do the obligately anaerobic strains. Thus, the effect of O_2 on the synthesis of BChl and the photosynthetic apparatus in aerobic anoxygenic phototrophs is almost opposite to that of typical purple bacteria.

In aerobic anoxygenic phototrophs which have 'non-photosynthetic' carotenoids, it has been known that the content of carotenoids is rather insensitive to oxygen tension (Harashima et al., 1980). This can be explained by constitutive synthesis of the 'non-photosynthetic' species of carotenoids. On the other hand, the synthesis of the carotenoid species which are bound to the LH and RC complexes seems to be regulated, more or less, by O_2 tension. In *E. longus* the amount of 'photosynthetic' carotenoids was roughly equal to that of BChl in various growth conditions. However, the composition of the carotenoid species varied significantly depending on aeration rate (Shimada et al., unpubl; Harashima, 1989). Whether the regulatory mechanism for the synthesis of these 'photosynthetic' carotenoids is the same with that of BChl is unclear.

Nothing is known so far about the regulatory mechanism for the synthesis of BChl and/or the photosynthetic apparatus by O_2 in aerobic anoxygenic phototrophs. The absence of the *puf Q* gene in the *puf* operon of *Ro. denitrificans* might be concerned with the lack of anaerobic synthesis of BChl (Liebetanz et al., 1991). Elucidation of the regulatory mechanism of the synthesis of pigments and proteins for the

photosynthetic apparatus in typical purple bacteria (see Chapter 58 by Bauer) will likely lead to elucidation of the role of O_2 in the synthesis of pigments and photosynthetic apparatus in aerobic anoxygenic phototrophs.

B. Effect of Light

It has been known that high light depresses the pigment content of typical purple photosynthetic bacteria. This light effect was explained by the degradation of BChl and not the repression of BChl synthesis (Biel, 1986). In aerobic anoxygenic phototrophs, continuous light also clearly repressed accumulation of BChl, while many species could synthesize BChl in continuous dark in the presence of O_2 (Harashima et al., 1987; Shioi and Doi, 1988; Sato et al., 1989). In some species, however, maximal synthesis of BChl occurred under intermittent light. In *Rhizobium* BTAi 1, BChl accumulation could be observed only under intermittent light (Evans et al., 1990; see Chapter 7 by Fleischman et al.). In *M. rhodesianum*, the synthesis of BChl depended on the light/dark condition in each growth phase (Sato and Shimizu, 1979; Sato et al., 1985b; Fig. 11). These results suggest that, in some species of aerobic phototrophs, light is not exclusively repressive but has a role of positive effector for BChl synthesis.

In *M. rhodesianum*, two isozymes for synthesis of 5-aminolevulinic acid (ALA) have been found (Sato et al., 1985a). These enzymes synthesize ALA from glycine and succinyl-CoA and, thus, are called ALA

No.	Growth conditions and cultivation time (hrs)					BChl. formed (n moles/ml culture)	
	20	40	60	80	100		
1						0.284	[30.5]
2						0.964	[32.4]
3						0.240	[31.6]
4						0.022	[31.6]
5						0.016	[31.6]

Fig. 11. Effect of light on BChl-formation in *Methylobacterium rhodesianum*. Open bar, illuminated period; Closed bar, dark period (from Sato and Shimizu, 1979). The values in brackets represent the OD_{660} of the culture [see Sato and Shimizu (1979) for details of how growth was measured].

synthases. One of them was shown to be constitutive, while the other was shown to be inducible by the conditions under which BChl synthesis occurs. This result suggests that BChl synthesis in this bacterium is regulated by de novo synthesis of the ALA synthase isozyme. In *Ro. denitrificans*, an ALA synthase which is similar to that of *Rb. sphaeroides* has been found (Shioi and Doi, 1988). However, participation of this enzyme in the regulatory mechanism of BChl synthesis in this bacterium is not clear.

In *Ro. denitrificans*, Iba and Takamiya (1989) investigated the action spectrum of the inhibitory effect of light on BChl accumulation. They found that wavelengths between 400 to 500 nm were most effective and those in the near-infrared region were less effective. This blue light effect was also observed in the aerobic growth of a typical purple bacterium, *Rb. sphaeroides*. Since this effect of blue light on BChl accumulation was also observed in the anaerobic culture of *Ro. denitrificans* in the presence of TMAO, Takamiya et al. (1992) suggested the effect of light on BChl accumulation is not stimulation of oxidative degradation of BChl or its precursor, but is a regulatory effect on the biosynthesis of BChl. The stable nature of BChl integrated in the photosynthetic apparatus in the presence of light and O₂ also supported the absence of photochemical degradation of BChl.

C. Other Factors

In some species of aerobic anoxygenic phototrophs other factors are known to affect the synthesis of pigments. In the marine bacterium, *E. longus*, low salinity caused a significant reduction of BChl content without severely affecting growth (Sato et al., 1989). In *Porphyrobacter neustonensis*, reduction of BChl content in richer growth media has been observed (Fuerst et al., 1993). However, the mechanisms of these inhibitions remains to be investigated. An inhibitor of BChl synthesis, α, α' -dipyridyl, also inhibited the formation of intracytoplasmic membranes in *Ro. denitrificans*, suggesting that BChl synthesis accompanied the synthesis of other components of the photosynthetic apparatus as in typical purple bacteria (Iba et al., 1988).

The reasons why aerobic anoxygenic phototrophs show lower specific BChl contents than typical purple bacteria is not known (see Table I). Similarly, the reasons for the significant difference in BChl content among species of aerobic anoxygenic phototrophs is

not known. It is possible, however, that the cultural conditions adopted for each species was not optimal for BChl formation. In addition, there may be unknown critical factors required for BChl formation in species which accumulate only a small amount of BChl in the growth condition currently adopted.

VII. Evolution and Taxonomy

A. Phylogeny Based on Ribosomal RNA Sequence

At present, up to 20 species and 8 genera are described as BChl-containing aerobic bacteria which are referred as aerobic anoxygenic phototrophs in this chapter (Table 1). More than half of the 20 species are newly described ones and others are newly recognized ones as the BChl-containing species. As seen in the fact that these descriptions have been made continually during these 15 years, further discovery of new species of aerobic anoxygenic phototrophs will continue in the future.

Phylogenetically, all species of aerobic anoxygenic phototrophs for which data on their ribosomal RNA sequence are available have been shown to belong to the α -subclass of Proteobacteria (Woese et al., 1984; Komagata, 1989; Fuerst et al., 1993). This seems to be consistent with the similarity of their photosynthetic apparatus to those of purple nonsulfur bacteria which belong mostly to the same subclass. In the α -subclass, aerobic anoxygenic phototrophs showed rather wide distribution as represented in Fig. 12 (see also Yurkov et al., 1994; Nishimura et al., 1994). This indicates that they are not necessarily closely related to each other. The phylogenetic diversity of them seems also to be consistent with their heterogeneity with respect to pigments and photosynthetic apparatus, such as carotenoid composition, the presence of 'non-photosynthetic' carotenoids and the possession of a cytochrome subunit in the RC.

B. Consideration on the Origin of Aerobic Anoxygenic Phototrophs

Based on phylogenetic studies and the heterogeneity of photosynthetic apparatus, it may be reasonable to assume that aerobic anoxygenic phototrophs were branched from some independent lines of purple photosynthetic bacteria. Furthermore, it seems that

Fig. 12. A phylogenetic tree of α -subgroup of Proteobacteria based on 5S rRNAs from representative species (from Komagata, 1989). * phototrophic purple photosynthetic bacteria; ** aerobic phototrophic bacterium.

each branching is not necessarily a recent event, since each of the aerobic anoxygenic phototrophs shows significant differences from its presumed purple bacteria relative in carotenoid composition and antenna organization, for example. Although *Ro. denitrificans* seems to be closely related to *Rhodobacter* in terms of ribosomal RNA sequence, primary structure of a *c*-type cytochrome and the dominant carotenoid species, they still differ in the possession of a cytochrome subunit in the RC and in the spectral characteristics of LH II, in addition to the response to O_2 . *E. longus* and *Porphyrobacter*, which are closely related to each other, have no extant purple bacteria relatives in their apparently isolated phylogenetic group (Fuerst et al., 1993). Thus, it is probable that at least some species of aerobic anoxygenic phototrophs are in a 'stable state' in the evolutionary process. The abundance of aerobic anoxygenic phototrophs in some habitats supports their ecological and evolutionary stability.

Based on their reduced BChl content, one may consider that aerobic anoxygenic phototrophs are in a transient phase of evolving from purple photosynthetic bacteria to non-photosynthetic aerobes (Woese et al., 1984). However, the reason for the small content of BChl is not known. In spite of the small content of BChl, photosynthetic activities have been clearly shown in some species suggesting that they have an almost complete set of 'photosynthetic' genes. Therefore, the smaller amount of BChl compared with those of typical purple bacteria does not necessarily mean that the loss of the 'photo-

synthetic' genes in aerobic phototrophs has occurred. It is possible, however, that some 'non-phototrophic' aerobic bacteria, which are closely related to phototrophs, still have the photosynthetic genes or their relicts. Search for such strains by suitable nucleic acid probes may contribute to our understanding of evolutionary processes in prokaryotes.

Recently, occurrence of lateral transfer of photosynthetic genes has been postulated in some cases (Blankenship, 1992; Nagashima et al., 1993). It is also possible to consider that aerobic anoxygenic phototrophs originated by incorporation of a photosynthetic gene cluster into 'non-photosynthetic' aerobes. However, the heterogeneous nature of the photosynthetic apparatus of aerobic anoxygenic phototrophs described above suggests that the origin of such photosynthetic genes are also heterogeneous. It seems unlikely that lateral gene transfers occurred in many independent lines although such possibility in some cases cannot be ruled out.

C. Perspectives

As described above, accumulated data are still not enough to discuss extensively the phylogeny and evolution of aerobic anoxygenic phototrophs. Especially, data on the structure and sequence of 'photosynthetic' genes are lacking except for that of *Ro. denitrificans*. This may be due to a lack of suitable probes for the genes. However, recent progress of gene manipulation will make it possible to search and sequence 'photosynthetic' genes in

other aerobic anoxygenic phototrophs and, possibly, in some 'non-photosynthetic' bacteria. Thus, further studies are needed to approach the origin of aerobic anoxygenic phototrophs as well as the origin of non-photosynthetic aerobes.

Thus far, species of aerobic anoxygenic phototrophs are confined to the alpha-subclass of Proteobacteria. However, it may not be unreasonable to expect the occurrence of aerobic anoxygenic phototrophs in other taxa, such as the γ -subclass. If they are present in other classes than Proteobacteria, the possibility of lateral gene transfer should be, then, taken into consideration, as in the case of *Chloroflexus* (Blankenship, 1992). Further investigation of new species may reveal a phylogenetically and ecologically wider distribution of aerobic anoxygenic phototrophs than is presently known.

And finally, it should be mentioned that nomenclature of the aerobic anoxygenic phototrophs is not consistent. Recently, Gest (1993) proposed a term for aerobic anoxygenic phototrophs, 'quasi-photosynthetic bacteria,' to distinguish them from typical anoxygenic photosynthetic bacteria. Another expression, 'paraphotosynthetic' by Madigan, was also referred to in the article. Currently, this group of bacteria is called by at least three names: 'aerobic photosynthetic bacteria,' a primary designation (Shiba, 1989); 'aerobic anoxygenic phototroph,' used in this book; and 'aerobic BChl-containing bacteria.' Thus, agreement in the nomenclature of these organisms may be an important future subject in this field.

Summary

The Green Revolution has allowed food production in many developing countries to keep pace with population growth. But the use of chemical fertilizers as a source of fixed nitrogen is expensive and creates environmental problems. The United States Agency for International Development sponsored a collaboration between U. S. and Indian scientists to develop sources of biologically-fixed nitrogen fertilizers. This effort led to the discovery that photosynthetic rhizobia are found in nitrogen-fixing nodules located on the stems of *Aeschynomene*, a legume used as a green manure in rice fields. Such rhizobia now have been isolated from *Aeschynomene* nodules and soils throughout the world. Photosynthetic rhizobia which nodulate a different genus, *Lotononis*, have been discovered recently.

The rhizobium has the photosynthetic properties of aerobic anoxygenic phototrophs. It will grow, produce the photosynthetic system and perform photosynthetic electron transport only under aerobic conditions. It can fix nitrogen in *explanta* culture and grow in the absence of any other source of fixed nitrogen. Phylogenetic studies based on 16S rRNA sequences and numerical taxonomy suggest that all of the *Aeschynomene* isolates are closely related to each other and form a cluster with *Bradyrhizobium* and *Rhodopseudomonas palustris* in the alpha-2 subdivision of the class *Proteobacteria*.

Formation of the photosynthetic system is triggered by visible and far-red light, and is suppressed by visible light. The photosynthetic system of the stem nodule endophytes probably provides energy for nitrogen fixation, diminishing competition between carbon and nitrogen fixation and allowing for more efficient plant growth.

I. Introduction

A. Symbiosis Between Plants and Rhizobia

1. Rhizobiaceae

The Rhizobiaceae are a family of Gram-negative bacteria, most of whose members form symbiotic associations with plants. Members of four currently-recognized genera form nitrogen-fixing nodules on leguminous plants. Photosynthetic bacteria may have been ancestors of the Rhizobiaceae (Woese, 1987). Phylogenetic studies based on DNA-rRNA homology (Jarvis et al., 1986) and 16S rRNA sequences (Yanagi and Yamasato, 1993) indicate that species of the genus *Bradyrhizobium* (which nodulate soybeans) form a cluster on the *Rhodopseudomonas palustris* branch of the alpha-2 subdivision of the class *Proteobacteria*. *Bradyrhizobium* and *Rp. palustris* are much more distantly related to the other Rhizobiaceae and *Rhodopseudomonas* genera.

2. The Symbiotic System

The legume nodule is a complex structure established through an elaborate exchange of chemical signals between the bacteria and the plant (Verma, 1992; Fisher and Long, 1992; Long and Staskawicz, 1993). Its function is to allow the resident rhizobia to fix nitrogen for export to the plant in return for fixed carbon. The rhizobia invade the roots, ultimately entering plant cells where they differentiate to form bacteroids, the endosymbiotic form of the rhizobia. Generally sucrose, formed photosynthetically in the leaves, is translocated to the root nodules, where it is converted to dicarboxylic acids such as malate. The bacteroids use the dicarboxylic acids as substrates for oxidative phosphorylation and as the source of the electrons required for the reduction of dinitrogen to ammonia. The ammonia nitrogen is incorporated into organic molecules such as amides and ureides which are fed to the plant by way of the xylem. Nitrogen fixation is energetically expensive, requiring at least 8 moles of ATP per mole of NH_3 formed, as well as 4 equivalents of electrons from low-potential donors. As much as half of the photosynthate produced by legumes may be allocated to nitrogen fixation.

Abbreviations: A. – *Aeschynomene*; B. – *Bradyrhizobium*; Rp. – *Rhodopseudomonas*; Rs. – *Rhodospirillum*; rRNA – ribosomal RNA

3. Stem Nodulated Legumes and Their Agricultural Significance

Most members of the Rhizobiaceae genera *Rhizobium*, *Sinorhizobium* and *Bradyrhizobium* nodulate only the roots of plants. Members of a fourth genus, *Azorhizobium*, form nitrogen-fixing nodules on both the roots and stems of the tropical legume *Sesbania rostrata* (Dreyfus and Dommergues, 1981; Dreyfus et al., 1988). Nodules are found on above-ground parts of other plants as well, including plants of the genera *Aeschynomene* (Arora, 1954; Alazard, 1985) and *Neptunia* (Schaeede, 1940). Occasionally other plants possessing aerial nodules are reported (Walter and Bien, 1989; Yatazawa et al., 1987), and under appropriate conditions nodules may form on the lower stems of such familiar legumes as field bean (Fyson and Sprent, 1980), soybean (Eaglesham and Ayanaba, 1984) and peanut (Nambiar et al., 1982). Such nodules are most frequently found on tropical legumes, where they form under flooded conditions. The nodules are usually formed on adventitious roots or their primordia. The circumstances under which it is appropriate to refer to them as stem rather than root nodules has been discussed by Ladha et al. (1992).

Sesbania and *Aeschynomene* have been of particular interest in rice-growing regions because they are flood-tolerant and so can serve as green manures—sources of biologically-fixed fertilizer nitrogen—for rice fields. When these plants are grown in flooded rice fields, the nodules on their stems can fix nitrogen even though their roots are submerged. The plants are then plowed into the fields before rice is planted, and release their fixed nitrogen into the soil. The use of green manures is of vital importance in developing countries. Most of the rice in these areas is grown by farmers who do not have convenient access to expensive chemical nitrogen fertilizers produced by the petroleum-consuming Haber-Bosch process. The expense of such fertilizers is certain to increase in the future. In addition, biological nitrogen fertilizers generate much less water and air pollution than do chemical nitrogen fertilizers.

Stem-nodulated legumes and the rhizobia that nodulate them have received special attention in India (Subba Rao et al., 1991), the Philippines (Ladha et al, 1990) and Senegal (Alazard, 1985). All aspects of stem nodulation and its applications have been reviewed recently by Ladha et al. (1992), and the symbiosis between *Azorhizobium caulinodans* and

Sesbania rostrata has been discussed in detail by de Bruijn (1988).

B. Discovery of Bacteriochlorophyll-Containing Rhizobium Species.

1. Species That Nodulate *Aeschynomene*

In the 1980's the United States Agency for International Development sponsored a collaborative effort between scientists from India and the United States, the Indo-US Science and Technology Initiative. One of its objectives was the development of biological nitrogen fertilizers. N. S. Subba Rao, of the Indian Agricultural Research Institute, had noticed that stem nodules of *A. indica* plants growing in northern India appeared to contain unusual endophytes (Subba Rao, 1988). Under USAID STI sponsorship, he brought a collection of fixed nodules to the Charles F. Kettering Research Laboratory, where the late Harry Calvert examined them with the electron microscope. Minocher Reporter and others at the Kettering Laboratory pointed out that coccoid endophytes within some of the nodules contained chromatophore-like membranous vesicles (Evans et al., 1990), and suggested that they might be photosynthetic bacteria. Endophytes subsequently separated from stem nodules collected throughout southern India by Subba Rao and S. Shanmugasundaram, of Madurai Kamaraj University, were shown to contain bacteriochlorophyll and photosynthetic reaction centers (Fleischman et al., 1988, 1991).

Efforts to culture photosynthetic bacteria from the Indian nodules by anaerobic incubation in the light were unsuccessful. However, earlier, A. R. J. Eaglesham of the Boyce Thompson Institute had isolated a strain of rhizobium, designated BTAi 1, from a nodule which had formed on the stem of an *A. indica* plant growing in unsterilized sand obtained from West Virginia (Eaglesham and Szalay, 1983). The rhizobium had been examined in detail and found to have properties of both *Rhizobium* and *Bradyrhizobium* (Stowers and Eaglesham, 1983). Experiments with BTAi 1 revealed that it could form the photosynthetic system but only when grown aerobically under cyclic illumination (e. g., 16 h light/8 h dark) in the presence of specific carbon sources (Evans et al., 1990). The properties of BTAi 1 have been reviewed by Eaglesham et al. (1990).

Lorquin et al. (1993) found that of 126 strains of

rhizobia isolated in Senegal from stem nodules of *Aeschynomene* plants belonging to three cross-inoculation groups, 83 could synthesize bacteriochlorophyll under appropriate conditions. Bacteriochlorophyll-containing rhizobia could nodulate plants belonging to two of the cross-inoculation groups. The bacteria were described as light pink, dark pink or orange.

Several hundred strains of bacteriochlorophyll-containing rhizobia have now been isolated. J. K. Ladha of the International Rice Research Institute has isolated such strains from nine *Aeschynomene* species growing in the Philippines (Ladha et al., 1990; Ladha and So, 1994) and demonstrated that most form bacteriochlorophyll-containing stem nodule bacteroids. We have isolated strains in India from a tenth species (D. Fleischman, S. Shanmugasundaram, G. Gopalan and F. Schwelitz, unpublished). Peter van Berkum of the U. S. Department of Agriculture has obtained isolates that nodulate *A. indica* from soil samples collected on five continents, from sites as diverse as Maryland soybean fields and Zimbabwe *Aeschynomene* groves (Van Berkum et al., 1995). The isolates vary widely in color and colony morphology; some form pigment constitutively. Van Berkum et al. (1995) further report that bacteriochlorophyll was formed by 38 of the 79 strains of *A. indica*-nodulating rhizobia they isolated. Both pigmented and nonpigmented strains nodulated stems and formed nitrogen-fixing symbioses. DNA from all of the pigmented isolates tested, and from 3 of 5 nonpigmented isolates, hybridized with a DNA probe containing the genes for the photosynthetic apparatus of *Rhodospseudomonas capsulatus*.

2. Species That Nodulate Other Plants

Thus far, the only rhizobia reported to contain bacteriochlorophyll have been isolated from stem or root nodules of *Aeschynomene* species. Attempts to induce formation of bacteriochlorophyll in other rhizobia, including strains isolated from stem nodules of *Sesbania rostrata* and root nodules of *A. americana* (Evans et al., 1990; Ladha and So, 1994) and from stem nodules of *Sesbania procumbens* and *Neptunia* (S. Shanmugasundaram and D. Fleischman, unpublished) have been unsuccessful. However, W. Heumann, of Friedrich-Alexander Universität in Erlangen-Nürnberg, Germany, has found that rhizobia which form effective nodules on the hypocotyl and root, but not the stem, of *Lotononis bainesii* contain bacteriochlorophyll (personal communication). The

absorption spectrum of the cells includes far-red absorption bands characteristic of the bacteriochlorophyll proteins of typical photosynthetic bacteria. Their chromosomal guanosine + cytosine content is 72.1% and their plasmid GC content is 65.3%, values much higher than those previously found in *Rhizobiaceae*. The *Lotononis* rhizobia appear to be rather distant taxonomically from the *Aeschynomene* stem nodule rhizobia. Their principal carotenoid is a C₄₀ carotenoid acid.

Liesack and Stackebrandt (1992) have attempted to determine the diversity of the bacterial population in an Australian soil sample, not by isolating bacteria, but by using the polymerase chain reaction to amplify 16S ribosomal RNA genes collected directly from the soil. They found a surprising number of sequences that were highly homologous to the 16S rRNA of BTAi 1. Their observations, together with those of Heumann, suggest that photosynthetic rhizobia may not be an isolated occurrence, but may in fact be quite widespread.

II. Relationship of Bacteriochlorophyll-containing *Rhizobium* Species to Other Bacteria

A. Relationship Based on 16S Ribosomal RNA Sequences

The unusual nature of the presence of a photosynthetic system in a rhizobium led to the proposal that BTAi 1 be placed in a new genus, to be named *Photorhizobium* (Eaglesham et al., 1990). BTAi 1, the first isolated *Rhizobium* shown to possess a photosynthetic system, would be the type strain and named *Photorhizobium thompsonianum*.

Young et al. (1991) provided the first direct information about the relationship of BTAi 1 to other bacteria. Using the polymerase chain reaction, they determined partial 16S rRNA sequences of BTAi 1 and 12 bacteria in the alpha subdivision of the *Proteobacteria*. The BTAi 1 sequence examined differed by a single base from the corresponding sequence of *Bradyrhizobium japonicum* USDA 110, and by only 6 bases from that of *Rhodospseudomonas palustris*. The sequences obtained from members of the *Rhizobium* genus were quite different. Young et al. (1991) pointed out that the diversity within the whole *Bradyrhizobium/Rhodospseudomonas*/BTAi 1 cluster was no greater than that to be expected within a single genus.

Shortly afterward, the International Subcommittee for the Taxonomy of *Rhizobium* and *Agrobacterium* proposed minimal standards for the description of new genera and species of root- and stem-nodulating bacteria (Graham et al., 1991). They recommended the use of both phylogenetic and phenotypic traits, using a relatively large number of strains. Two recently completed studies performed with bacteriochlorophyll-containing rhizobia have made substantial progress toward meeting the Committee's criteria.

Wong et al. (1994) have determined nearly complete 16S rRNA sequences of several strains of bacteriochlorophyll-containing rhizobia isolated from stem nodules of *Aeschynomene* species growing in widely separated geographical areas and belonging to two cross-inoculation groups, along with those of two *Bradyrhizobium* strains. Rhizobia belonging to the same cross-inoculation group will nodulate the same population of host species. The 16S rRNA sequences of all of the bacteriochlorophyll-containing strains were highly similar. It was concluded that the photosynthetic rhizobia form a group 'within a distinctly branched alpha-2 cluster' which also includes several *B. japonicum* strains and, branching somewhat more deeply, *Rp. palustris*. But the cluster clearly contained bacteria belonging to genera other than *Bradyrhizobium* and *Rhodopseudomonas*. These authors concur that resolution of the taxonomic question will require both molecular sequence data and more detailed phenotypic data.

B. Relationship Based on Phenotype

Ladha and So (1994) have performed a multivariate statistical analysis of 150 phenotypic features of 52 strains of bacteriochlorophyll-containing rhizobia along with reference strains of *Rhizobium*, *Bradyrhizobium* and *Azorhizobium*. They conclude that the bacteriochlorophyll-containing rhizobia isolated from *Aeschynomene* nodules belong to a cluster that is separate from those of *Bradyrhizobium*, *Rhizobium* and *Azorhizobium*. Differences between cross-inoculation groups were apparent. Based on the phenotypic characteristics examined, the bacteriochlorophyll-containing rhizobia were distinguished from *Bradyrhizobium* at a similarity level which is borderline for intrageneric differences. They were also clearly distinguishable from rhizobia that could form effective stem and root nodules on *Aeschynomene* but that could not form bacteriochlorophyll. The latter had the properties of slow-growing rhizobia.

The bacteriochlorophyll-containing isolates formed bacteriochlorophyll only aerobically under intermittent light. They were diazotrophic, i. e. they could fix nitrogen *ex planta*, and grow in the absence of any other source of fixed nitrogen. Alazard (1990) had made a similar observation with other isolates.

It appears that further study will be necessary before it can be decided whether the bacteriochlorophyll-containing rhizobia belong in a separate genus or should be included within *Bradyrhizobium*. The issue is complicated by wide phylogenetic diversity within the *Bradyrhizobium* and *Rhodopseudomonas* genera and close phylogenetic similarity between members of these genera and other bacteria which are quite different phenotypically. Willems and Collins (1992), for example, report that there is a close genealogical relationship between *Bradyrhizobium*, *Blastobacter denitrificans* and *Afipia* (the agent which causes cat scratch disease).

The available evidence does suggest that the bacteriochlorophyll-containing rhizobia, *Bradyrhizobium* and *Rp. palustris* diverged from a common photosynthetic ancestor which is not shared by the other genera of Rhizobiaceae.

III. Characteristics of *Aeschynomene Rhizobium* BTAi 1 Grown *ex planta*

A. Utilization of Carbon Sources

Stowers and Eaglesham (1983) first described the capacity of BTAi 1 to utilize various carbon sources. Twenty different carbon sources were tested at a concentration of 1% (w/v). Growth was observed with sucrose and lactose, which is a characteristic associated with fast-growing rhizobia. Growth was not obtained with malate at the 1% level but growth is observed with this carbon source at lower concentrations (Evans et al., 1990). Both succinate and malate were shown to influence the oxygen-sparing effect of light (Wettlaufer and Hardy, 1992).

Growth was not obtained when CO₂ was employed as the sole carbon source (Eaglesham et al., 1990) in the light. BTAi 1 was one of 52 strains of bacteriochlorophyll-containing rhizobia surveyed for growth on 30 different carbon sources (Ladha and So, 1994). Galactose, gluconate, glucose, glycerol, malate, mannitol and mannose were utilized by all of the strains tested.

B. Regulation of Bacteriochlorophyll Accumulation

Evans et al. (1990) reported that BTAi 1 would form bacteriochlorophyll *ex planta* only if the medium contained an appropriate carbon source. Glutamate (A. R. J. Eaglesham, personal communication), malate, fructose and succinate allow bacteriochlorophyll formation. Little bacteriochlorophyll is formed with mannitol as the carbon source. The presence of arabinose, even added concomitantly with a dicarboxylic acid, suppresses bacteriochlorophyll formation.

When BTAi 1 cultures are grown in the presence of malate under cyclic illumination from tungsten lamps, bacteriochlorophyll accumulation begins only at the end of exponential growth (Fig. 1). Perhaps the photosynthetic system is formed when the carbon source becomes depleted in order to provide an alternate energy source to allow the bacteria to survive. Such behavior would explain the observation (Eaglesham et al., 1990) that illumination does not affect the growth rate of BTAi 1 cultures. Exponentially-growing cultures do not have the photosynthetic system. When glutamate is the carbon source, bacteriochlorophyll forms early in exponential

phase (unpublished). Glutamate seems to be a poor carbon source. When cells are grown on glutamate they respire more slowly than in the presence of malate (Wettlaufer and Hardy, 1992) and grow more slowly (unpublished). Perhaps cells experience carbon limitation even in the presence of glutamate and this event triggers bacteriochlorophyll synthesis.

Illumination does slow the decline of viable cells after the exogenous carbon source had been utilized (Eaglesham et al., 1990). At this stage the photosynthetic system will have formed. Shiba (1984) has reported that illumination prolongs the viability of the aerobic photosynthetic bacterium *Roseobacter denitrificans* (formerly *Erythrobacter* OCH 114), and suggested that it forms the photosynthetic system to allow it to survive in the absence of energy-yielding substrates.

Evans et al. (1990) found that BTAi 1 would accumulate bacteriochlorophyll only if the cultures were grown under cyclic illumination, but not in continuous light or continuous darkness. Wettlaufer and Hardy (1993) report that bacteriochlorophyll will accumulate in the dark after cultures have been exposed to light for at least 30 minutes. They found that the action spectrum for initiation of bacteriochlorophyll accumulation included a blue component.

Fig. 1. Growth and bacteriochlorophyll accumulation of BTAi 1 cells. Cultures were grown under cyclic white illumination with malate (1.5 g l^{-1}) as the carbon source.

Fig. 2. Absorption spectrum of membranes from BTAi 1 cells grown in continuous red light with glutamate (1.5 g l^{-1}) as the carbon source.

We find that it also contains a far-red component (unpublished). As Wettlaufer and Hardy point out, the photoreceptor cannot be the photosynthetic light harvesting system. Light of wavelength beyond 830 nm is ineffective in inducing pigment accumulation, while the photosynthetic bacteriochlorophyll protein has a strong absorption band near 870 nm (Fig. 2). The best candidate may be a tetrapyrrole, perhaps bacteriochlorin.

Visible light inhibits bacteriochlorophyll accumulation in *Roseobacter denitrificans* (Iba and Takamiya, 1989). BTAi 1 behaves similarly (unpublished). Bacteriochlorophyll can accumulate in continuous light (Fig. 2), but only if wavelengths below 650 nm are excluded.

In summary, bacteriochlorophyll accumulation can be initiated by visible or far-red light at the end of exponential growth, but is inhibited by visible light. The conditions necessary for formation of the photosynthetic system *ex planta* are those expected within stem nodules: a dicarboxylic acid as carbon source and illumination with cyclic light (day/night) filtered through chloroplasts and leghemoglobin, which will transmit far-red light but absorb visible light.

C. The Photosynthetic System

The absorption spectrum of BTAi 1 (Evans et al., 1990; Fig. 2) resembles that of a typical purple nonsulfur bacterium or aerobic anoxygenic phototroph (Shimada, Chapter 6, this volume). The

bacteriochlorophyll content of BTAi 1 cells is typically about $0.4 \text{ nmol} \cdot \text{mg}^{-1}$ (dry weight), a value similar to that found in the aerobic anoxygenic phototrophs. The major far-red absorption band of the light-harvesting bacteriochlorophyll protein is narrow, comparable to that of *Rhodospirillum rubrum*. Perhaps, like *Rs. rubrum*, BTAi 1 has only a single form of light-harvesting bacteriochlorophyll protein. Wettlaufer and Hardy (1992) found that light suppresses oxygen uptake by BTAi 1 cells growing on several carbon sources. Such behavior is expected of photosynthetic bacteria. The action spectrum of the effect was similar to the absorption spectrum of the photosynthetic light-harvesting system; light absorbed by the carotenoids was less effective than light absorbed by bacteriochlorophyll.

BTAi 1 membranes contain photochemically-active photosynthetic reaction centers (Evans et al., 1990). The difference spectrum and kinetics of the reversible light-induced absorbance changes resemble those of typical purple photosynthetic bacteria. The photosynthetic unit of BTAi 1 contains about 80 bacteriochlorophyll molecules, implying that these bacteria have a low bacteriochlorophyll content because they have few reaction centers, not because of a small photosynthetic unit size (Evans et al., 1990).

The inability of bacteriochlorophyll-containing rhizobia to grow photosynthetically in the absence of oxygen has been perplexing. In part this may be because their low bacteriochlorophyll content results in inefficient light capture. The growth of the aerobic anoxygenic phototroph *Roseobacter denitrificans*, for example, is stimulated by very intense illumination (Harashima et al., 1987). But in this bacterium electron transport does not occur under anaerobic conditions (Okamura et al., 1985). To determine whether this is true of BTAi 1, D. Kramer and A. Kanazawa (unpublished) used a sensitive kinetic spectrophotometer (Kramer et al., 1990) to measure flash-induced electron transfer in intact BTAi 1 cells both in the presence and absence of oxygen. Light-induced electron transfer could be detected only under aerobic conditions. A sensitive kinetic fluorimeter was then used to measure light-induced fluorescence yield changes under aerobic and anaerobic conditions. The fluorescence induction kinetics indicated that the quinone pool of BTAi 1 cells becomes completely reduced within seconds after oxygen has been depleted. Light-induced electron transport is no longer possible, since there

are no (or at most no more than one) available electron acceptors. Kramer and Kanazawa were also able to observe the cytochrome bc_1 complex in membranes of BTAi 1.

The photosynthetic system of BTAi 1 thus seems to be quite similar to those of the aerobic anoxygenic phototrophs, both in composition and function.

D. Carbon Dioxide Uptake and Nitrogen Fixation

Experiments on the effect of light on CO_2 uptake with the bacteriochlorophyll-containing rhizobia have been carried out with BTAi 1. Uptake of CO_2 by BTAi 1 was stimulated severalfold under light for those cells grown under conditions which elicited bacteriochlorophyll formation versus cells grown under conditions which inhibited pigment development (Hungria et al., 1990). $^{14}\text{CO}_2$ uptake by BTAi 1 was sensitive to inhibitors of photosystem 2, but the sites of inhibition may have been the bacterial reaction center and cytochrome bc_1 complex. It seems unlikely that BTAi 1 contains an oxygen-evolving photosystem. The uncoupler NH_4Cl inhibited both $^{14}\text{CO}_2$ uptake and light-decreased O_2 uptake. However this

strain could not be grown in medium lacking a carbon source (Hungria et al., 1990).

Increases of 10- to 30-fold by light have been observed in the rate of CO_2 fixation by *A. scabra* nodules (Hungria et al., 1992). Undoubtedly some of the increased rate of CO_2 fixation was a consequence of the presence of chloroplasts in the stem nodule, but the greater response of *A. scabra* stem nodules as compared to *S. rostrata* stem nodules correlated with the photosynthetic capacity of the *Aeschynomene* endophyte.

Eaglesham et al. (1990) found that cells grown for two days under cyclic illumination had 2–5 times as much N_2 -fixing activity (assayed by acetylene reduction) as dark-grown cells. There was no immediate effect of light on the rate of N_2 fixation.

E. Ultrastructure

In general, cells of BTAi 1 grown in pure culture display fairly typical Gram-negative bacterial ultrastructure (Fig. 3a). They possess an outer membrane separated from the inner membrane, in the case of BTAi 1, by a rather pronounced periplasmic space. The cytoplasm is relatively featureless,

Fig. 3. (a). Transmission electron micrograph of a cell of BTAi 1 from a lag/early exponential phase culture showing typical Gram-negative ultrastructure. Apart from the fibrillar nucleoid with osmiophilic spheroids, the cytoplasm is relatively featureless. (b) TEM of a cell from a late exponential phase culture. Large intracytoplasmic photosynthetic vesicles are now found in the cytoplasm (large arrow). These vesicles are not free entities in the cytoplasm but rather represent a highly invaginated and convoluted inner membrane. Inner membrane invaginations are noticeable (small arrow).

containing only ribosomes and occasional poly- β -hydroxybutyrate granules. The nucleoid has a distinct fibrillar appearance. In some cells large osmiophilic spheroids are associated with the nucleoid. Conditions (described earlier) which trigger development of the photosynthetic system lead to changes in ultrastructure. In cells from late log phase cultures, one or more large photosynthetic vesicles can be found in the cytoplasm and undulations and invaginations of the inner membrane are common (Fig. 3b). The photosynthetic vesicles apparently arise from these invaginations of the inner membrane. During vesicle formation, a granular and relatively electron dense material accumulates in the periplasmic space and is eventually included in the vesicle. Although in cross-section the vesicles appear to be independent entities in the bacterial cytoplasm, observations from multiple and serial sectioning suggests that the vesicles remain attached at some point to the inner membrane. The vesicles therefore represent a complex, highly convoluted extension of the periplasmic space.

IV. Characteristics of Photosynthetic *Rhizobium* in the Symbiotic System

A. Gross Morphology of the *Aeschynomene* Stem Nodule

Depending on their location on the stem, *Aeschynomene* stem nodules are spherical or ellipsoidal in shape. The ellipsoidal forms are found more commonly on upper stems. The nodule consists of an inner infected bacterial region surrounded by a region of host cortex (Fig. 4). The bacterial region in effective nodules is colored pinkish-red due to the presence of leghemoglobin. The host cortical tissue contains chloroplasts and is therefore green.

B. Ultrastructure of the Symbiont

1. Comparison to Other Rhizobia

In mature nodules, the ultrastructure of photosynthetic rhizobial bacteroids is quite unlike that of bacteroids

Fig. 4. Light micrograph of an upper stem nodule from *Aeschynomene indica*. Bacterial Region, B; host cortex, H; Stem Tissue, S.

Fig. 5. Transmission electron micrograph of a stem nodule of *Aeschynomene indica* showing dual nodule occupancy (i.e., nodule is inhabited by two different rhizobial strains. In the natural habitat, 10–15% of leguminous nodules display dual nodule occupancy). The differences between regular rhizobial symbiosomes, RS, and photosynthetic rhizobial symbiosomes, PS, is striking. Note the extensive system of intracytoplasmic vesicular lamellae in the photosynthetic bacteroids, a feature absent in the regular bacteroids.

of regular nonphotosynthetic rhizobia. This is clearly visible in the electron micrograph of a nodule with dual nodule occupancy in which one of the occupants has the appearance of a regular rhizobium and the other a photosynthetic strain (Fig. 5). The bacteroids can be considered intracellular but not, however, intracytoplasmic. When the bacteria break through the wall during cell invasion, they do not continue on to penetrate the cell membrane. Rather, host cell membrane is laid down around the invading bacterial cells, isolating them from the cytoplasm. The resulting large cytoplasmic vesicles are known as symbiosomes. In mature nodule cells containing regular nonphotosynthetic rhizobia, each symbiosome consists of one or more irregular or pleiomorphic bacteroids (Sprent and Sprent, 1990). The bacteroids are embedded in a matrix of bacterially-produced polysaccharide. Bacteroids and polysaccharide are enclosed in the host-derived peribacteroid, or, symbiosome membrane.

Apart from their pleiomorphic shapes, the non-photosynthetic rhizobial bacteroids have a relatively featureless cytoplasm except for the often pronounced deposition of poly- β -hydroxybutyrate bodies.

In mature nodule cells containing photosynthetic rhizobia, each symbiosome contains one large

spherical bacteroid. Each bacteroid possesses a distinct array of cytoplasmic vesicles which are interpreted as photosynthetic apparatus. A lamellate septum is often also found in the bacteroid cytoplasm.

2. Comparison to Other Photosynthetic Bacteria

In sharp contrast to the above, photosynthetic rhizobia, both in culture and in symbiosis, show remarkable ultrastructural similarities to free-living photosynthetic bacteria. The pronounced periplasmic space, the intracytoplasmic membrane system and the distinct fibrillar nucleoid containing large osmiophilic spheroids seen in cultured BTAi 1 are almost identical to the ultrastructural features demonstrated by *Rhodospseudomonas palustris* when grown semiaerobically in the dark (Tauschel and Drews, 1968). The intracytoplasmic array of vesicular membranes seen in the symbiotic bacteroids are highly reminiscent of a similar membrane system found in anaerobic illuminated cultures of *Rhodospirillum rubrum* (Drews, 1960). From our own observations it is apparent that the intracytoplasmic membrane system in BTAi 1 develops as a complex and highly convoluted invagination of the inner membrane, in a manner identical to that described

for *R. rubrum* (Oelze and Drews, 1973). In symbiosis, BTAi 1 forms large spherical bacteroids, a cellular shape very rarely found in other rhizobia but which occurs commonly in *Rhodopseudomonas* spp. We have found that BTAi 1 reproduces by asymmetrical division or 'budding' (unpublished), a feature it has again in common with *Rhodopseudomonas* spp. but which has never been reported for any other rhizobia.

C. Photosynthetic System of the Symbiont

1. Pigments and Electron Transport

Bacteroids isolated from *Aeschynomene* stem nodules usually contain bacteriochlorophyll (Fleischman et al., 1991; Ladha et al., 1990). The absorption spectrum of bacteroids isolated from *A. indica* stem nodules collected in India resembles that of free-living BTAi 1 (unpublished). They possess photochemically-active photosynthetic reaction centers whose spectrum and electron transfer kinetics resemble those of BTAi 1. A comparison of the absorption and fluorescence emission spectra of these bacteroids suggests that excitation energy transfer from the carotenoids to the bacteriochlorophyll is not very efficient (Fleischman et al., 1991). Wettlaufer and Hardy (1992) have concluded that light absorbed by the carotenoids of free-living BTAi 1 cells also drives photochemistry inefficiently.

2. Influence of Light on Nitrogen Fixation

Aeschynomene stem nodule bacteroids possess a photosynthetic system. Its most plausible function is to provide energy for nitrogen fixation rather than for carbon fixation. Conventional root nodule bacteroids consume photosynthate to generate the ATP and reductant needed for dinitrogen reduction. It would be futile for bacteroids to use photosynthetically-derived ATP and reductant to fix carbon, only to degrade it again to generate ATP and reductant for nitrogen fixation. The use of the bacteroid photosynthetic system to produce ATP and reductant directly within the cells where dinitrogen is reduced is more efficient than carbon fixation in leaf chloroplasts, translocation of the photosynthate to the nodules and its reoxidation in the bacteroids. More energy is required to form photosynthate than can be regained during its catabolism. In addition, the bacteroid photosynthetic system can use light in the 800–900 nm region which is not absorbed by

chloroplasts. Although some chloroplast-generated photosynthate would still be needed as an electron source, photosynthetic nitrogen fixation in the bacteroids might decrease competition between carbon and nitrogen fixation substantially.

Plant cells in the stem nodule cortex contain chloroplasts. Eardley and Eaglesham (1985) have suggested that the stem nodule is an autonomous system, since it contains both nitrogen-fixing bacteroids and the chloroplasts needed to generate fixed carbon and O₂. They found that stem nodules indeed continued to fix nitrogen after defoliation of the plants. Illumination of stem nodules accelerated acetylene reduction (the standard assay for N₂ fixation), an effect they attributed to O₂ evolution by the chloroplasts.

In order to separate the effects of light on the chloroplasts and the bacteroids, Evans et al. (1990) examined the effect of far-red light on acetylene reduction by stem nodules.

Nodule-containing stem sections were illuminated through filters which transmitted light of wavelengths between 730 and 950 nm. Such light will drive electron transport in the bacteroids but not in the chloroplasts. The illumination consistently accelerated acetylene reduction. It appeared that acetylene reduction continued at a constant rate far longer in illuminated nodules than in nonilluminated ones. Perhaps illuminated bacteroids consume substrates more slowly, a corollary of the oxygen-sparing effect observed by Wettlaufer and Hardy (1992) in free-living cells. But the nodule behavior was quite variable, so measurements with a much larger number of stem sections will be necessary before conclusions about the effect of light can be made with confidence.

D. Mechanism of Infection Leading to the Symbiosis

1. Infection Methods

Legumes are infected by rhizobia in one of three ways. In 'root hair' infection, which is found in the most widely studied group of leguminous hosts (legume crops), the bacteria enter the plant by penetrating the wall of a root hair (reviewed by Bauer, 1981). Once inside the hair, a tubular structure made of host cell wall material is laid down around the advancing bacteria. This structure, the infection thread, is continuously laid down around the rhizobia as they make their way toward the host cortex.

In 'wound' or 'crack entry' infection, bacteria gain access to the cortical cells of the host plant *via* ruptures in the epidermis caused by the emergence of lateral or adventitious roots (Chandler, Date and Roughly, 1982). In 'epidermal' infection, rhizobia arrive in the cortex by penetrating the middle lamella between healthy epidermal cells (Faria, Hay and Sprent, 1988)

2. Nodule Development

Once inside the cortex, infection of cortical cells must occur to allow nodule development. This can happen in at least three ways (Sprent and Sprent, 1990). Firstly, each cell in the nodule is infected by bacteria being released from branches of the infection thread. Secondly, a certain number of nodule cells become infected by bacteria released from the infection thread. The infected cells then enlarge and undergo successive divisions to form a mature nodule. In the third scenario, no infection threads are formed. Some host cells simply become infected by some rhizobia entering through the cell wall. These infected cells then divide repeatedly to form the mature nodule. Nodules in *Aeschynomene* form by this third method.

3. What is the Infection Mechanism in *Aeschynomene*?

The method by which *Aeschynomene* becomes infected by the photosynthetic rhizobia is still unclear. Arora (1954) showed that root and stem nodules form in the vicinity of emerging lateral and adventitious roots, concluding that some form of wound entry was being used. In a later study, Yatazawa and Yoshida (1979) claimed that there are two types of stem nodules, which they designated lower and upper stem nodules. They agree with Arora that wound entry was the probable infection mechanism. However, they found no lateral roots in association with the upper stem nodules and surmised that some other form of infection may be taking place in the upper stem. In the absence of emerging roots in the vicinity of upper stem nodules, we concur with the conclusions of Yatazawa and Yoshida. We have noticed, however, that the upper stem of *Aeschynomene* is sparsely populated with small glandular hairs of sub-epidermal origin (unpublished). It may be that some form of hair infection is occurring or else perhaps a special case of wound infection where the shaft of the glandular hair pierces the epidermis.

V. Conclusions

A. Role of the Rhizobial Photosynthetic System

The effect of far-red light on acetylene reduction by stem nodule bacteroids (Evans et al., 1990) is consistent with the hypothesis that the bacteroid photosynthetic system furnishes energy for nitrogen fixation, and so decreases the demand of the bacteroids for photosynthate. Since photosynthate availability often limits nitrogen fixation, this process may allow increased nitrogen fixation and plant growth.

The photosynthetic system of free-living cells may allow them to survive when the nutrient supply is limited. Adebayo et al. (1989) have found substantial populations of stem-nodulating rhizobia on the surfaces of leaves. Ladha et al. (1992) have suggested that the stems may be inoculated when rain washes these bacteria down the stems. An aerobic phototroph having a limited number of photosynthetic reaction centers should be ideally adapted for survival in such an aerobic, brightly-lighted, nutrient-limited environment.

B. Future Research Directions

Highest priority should be given to determining whether the bacteroid photosynthetic system really makes a substantial contribution to nitrogen fixation and plant growth. If it does, the symbiotic association could be optimized by selection of the most effective symbiotic partners for a given region. Such studies could lead to the development of exceptionally effective green manures. Symbiosis with photosynthetic rhizobia might be extended to other legumes, including *Sesbania*.

The mechanism by which the photosynthetic rhizobia regulate the development of the photosynthetic system is especially intriguing. A comparable process occurs in cyanobacteria (Chang et al., 1992). It seems likely that the bacteria contain a light sensor which can regulate gene expression. Many bacteria contain 'two component' regulatory systems in which an environmental sensor conveys a signal, perhaps by phosphorylation, to a second component which regulates gene expression (Gilles-Gonzalez et al., 1991). The photoreceptor that initiates bacteriochlorophyll accumulation may be one of these. A bacterium having the machinery necessary for the regulation of gene expression by light presents

fascinating experimental possibilities.

Biological systems which can be manipulated by light have been extraordinarily useful research subjects. Photosynthesis research has yielded insights about electron transport and its coupling to phosphorylation that could scarcely have emerged from study of oxidative phosphorylation. Similarly, study of the visual system has provided the most detailed understanding of how G-protein-coupled hormone receptors work. Stem nodules, in which the development and function of the symbiotic partners can be manipulated by light, could provide a similar system for the study of symbiotic nitrogen fixation.

Acknowledgments

We thank Peter van Berkum, John Fuerst, W. Heumann, David Kramer and J. K. Ladha for permission to cite unpublished data. We also thank James Rogers for the light micrograph of an *Aeschynomene* upper stem nodule.

Summary

The current status of our knowledge on the structures and biosynthesis of the bacteriochlorophylls from photosynthetic bacteria is reviewed. While the structural chemistry of the bacteriochlorophylls is well established, not much is known about the biosynthesis of the chromophores. Except for the early biosynthetic steps the current insight rests mainly with mutant studies performed in the sixties. For the bacteriochlorophylls of the sulfur and non sulfur bacteria certain assumptions can be made about the biosynthesis on the basis of analogy to chemical reactions.

I. Introduction

Bacteriochlorophylls (BChls) are the central photopigments of the photosynthetic bacteria. As such they function as antenna pigments in the light harvesting complexes and as accessory and special pair chlorophylls in the reaction center. Chemically, all chlorophylls (Chls) are derivatives of the parent compound porphyrin (1). All Chls have in common the isocyclic pentanone ring V, a central magnesium ion, and a propionic ester group at C17. The

nomenclature of these compounds has been standardized (IUPAC, 1987; Smith 1994) and the IUPAC system is used throughout this paper. Figure 1 shows as an example the numbering scheme for porphyrin (Fig. 1.1) and Chl *a* (Fig 1.2). We have however retained the use of the trivial names BChl *c*, *d*, *e* for the antenna Chls from green sulfur and non sulfur bacteria to prevent the use of confusing long systematic names. These names are actually misleading since the pigments are chlorins not bacteriochlorins. In recent years a number of reviews

Fig. 1. Numbering scheme for porphyrin (1) and Chl *a* (2).

have been published on the structure and biosynthesis of the Chls (Rüdiger and Schoch, 1988, 1989, 1991; Beale and Weinstein, 1990; 1991; Leeper, 1991; Scheer, 1991; Smith, 1991; Senge, 1992a,b, 1993). Due to restricted space we have cited mostly leading references for the older literature and have concentrated more on giving complete literature references to papers with newer results. An entire special issue of *Photosynthesis Research* (Olson et al., 1994) was recently devoted to Green and Heliobacteria.

II. Structural Chemistry of the Bacteriochlorophylls

A. Bacteriochlorophylls *a*, *b*, and *g*

Bacteriochlorophyll *a* (Fig. 2.3) and *b* (Fig. 2.4) are the most widely distributed Chls found in photosynthetic bacteria, and their purple color results from the fact that the parent porphyrin macrocycle is 'reduced' not only in ring IV [as is the case in Chl *a* (2)], but also in ring II (Fig. 2). Therefore they are often termed 'tetrahydroporphyrins' or bacteriochlorins. Besides this difference in the degree of reduction another structural difference relative to Chl *a* is the presence of an acetyl group at C3 instead of a vinyl group. BChl *a* serves in most purple

bacteria (*Rhodospirales*) as the sole antenna and reaction center pigment. In the green sulfur bacteria it functions in the same roles while its Mg-free derivative, bacteriopheophytin (BPheo) *a* (Fig. 2.5), serves as an accessory pigment in the photosynthetic reaction center. The structure elucidation for the Chls and BChls *a* and *b* has been reviewed by Brockmann (1978). Recently, a high precision crystal structure was published for a BChl *a* derivative, Bacteriopheophorbide (BPhide) *a* (Barkigia et al., 1989; Barkigia and Gottfried, 1994). BChl *b* (Fig. 2.4) is found in *Rhodospseudomonas viridis*, *Rhodospseudomonas sulfoviridis*, *Thiocapsa pennigii*, *Ectothiorhodospira halochloris*, and *Ec. abdelmaleki* (Scheer, 1991) and is distinguished from BChl *a* by possessing an ethylidene group at C8 instead of an ethyl (Brockmann and Kleber, 1970; Scheer et al., 1974). Due to the ethylidene group the degree of reduction in BChl *b* can also be formulated as that of a dihydroporphyrin, since a simple migration of the ring II ethylidene double bond into ring II proper would actually yield a macrocycle at the same reduction level as Chl *a* (Fig. 1.2).

BChls generally show a higher variability in their esterifying alcohol than do the Chls. They often contain phytol, which is the most widely found esterifying alcohol (Fig. 3). However, BChl *a* from *Rhodospirillum rubrum* contains geranylgeraniol, while the BPheo *a* of the reaction center is esterified with phytol. BChl *b* from *Ec. halochloris* and *Ec. abdelmalekii* was found to contain $\Delta^2,10$ -phytadienol and smaller amounts of phytol and a trienol (Rüdiger and Schoch, 1988).

BChl *g* (Fig. 4.6) is closely related to BChl *b* and possesses a vinyl at the 8-position instead of an acetyl group (Brockmann and Lipinsky, 1983) (Fig. 4). BChl *g* is found in *Heliobacterium chlorum* and contains farnesol as the esterifying alcohol (Michalski et al., 1987). It functions both as the antenna and reaction center pigment in the *Heliobacteria*. Two special derivatives have been proposed to function in the reaction center of photosynthetic bacteria besides BChl *a* and *b* and their pheophytins. These are BChl *g'* (Fig. 4.7), the 13^2 -S-epimer of BChl *g* (Fig. 4.6) (Kobayashi et al., 1991) and 8¹-hydroxy Chl *a* (Fig. 4.8) (van de Meet et al., 1991). However, these compounds can be easily formed from the more abundant BChl *g*—the *a'* pigment by simple epimerization and the 8¹-hydroxy-Chl *a* by isomerization and oxidation in ring II of BChl *g*. Thus

Abbreviations: ALA – 5-Aminolevulinic acid; BChl – bacteriochlorophyll; BPheo – bacteriopheophytin; BPhide – bacteriopheophorbide; *Cb.* – *Chlorobium*; *Cf.* – *Chloroflexus*; Chl – chlorophyll; Chlide – chlorophyllide; *Cm.* – *Chromatium*; *EC.* – *Ectothiorhodospira*; Pheo – pheophytin; Phide – pheophorbide; Proto – protoporphyrin; *Rb.* – *Rhodobacter*; RNAase – Ribonuclease; SAM – S-adenosylmethionine

further studies are needed to clarify the situation.

B. Bacteriochlorophylls c, d, e, and f

The BChls *c* (Fig.5.9), *d* (Fig.5.10) and *e* (Fig.5.11) present a complex mixture of photosynthetic pigments (Fig. 5). In contrast to the other Chls they can occur

as more than one defined compound within a given organism (Holt et al., 1966). They function as antenna pigments in the green, brown, or red sulfur bacteria (*Chlorobiaceae*) and in Chloroflexaceae (Pfennig, 1977). Originally these pigments were named 'Chlorobium chlorophylls' (Holt, 1966), a term still found sometimes in the Russian literature. In contrast

to BChl *a* and BChl *b*, these pigments have only one reduced pyrrole ring and are, therefore chlorins like Chl *a* or Chl *b*. The gross chemical structure of the BChls *c* (Fig. 5.9) and *d* (Fig. 5.10) and their similarity to the plant chlorophylls was established by Holt and coworkers (Holt et al., 1966) while subsequently their stereochemistry (Brockmann, 1976; Brockmann

and Tacke-Karimadian, 1979; Smith and Goff, 1985; Smith, 1991) and absolute structure (Smith et al., 1982, 1983) could be established. BChl *e* (Fig. 5.11) was first isolated during the seventies (Gloe et al., 1975) and subsequently its structure elucidated (Risch et al., 1978; Simpson and Smith, 1988). Recently the conformational flexibility of the macrocycles in Chls

has come under active scrutiny (Barkigia et al., 1988; Senge, 1992b; Senge et al., 1994).

All these Chls have in common that they lack the 13^2 -carbomethoxy group and bear at the 3-position a α -hydroxyethyl group. BChl *c* (Fig. 5.9) and *e* (Fig. 5.11) are distinguished from BChl *d* (Fig. 5.10) by an additional methyl group at C20. BChl *e* also has the meso (Fig. 5.12) methyl group as well as an aldehyde group at C7 and thus is similar to Chl *b*. The name BChl *f* has been assigned to a generic structure of a BChl *e* derivative without the C20 methyl group (analogous to BChl *c-d*), though this series of pigments has not yet been found in nature (Risch et al., 1988). All three Chls occur in nature as so called homologous mixtures. The single components of these mixtures are distinguished by the substituents at C8 and C12, the stereochemistry at C3¹ (R- or S-configuration) and the nature of the esterified alcohol at C17³. On account of the various combinatory possibilities a large variety of different derivatives is possible. BChl *c* (Fig. 5.9) most often is found with an ethyl group at C8, as is the case in most natural tetrapyrroles. In *Chlorobium* strains, smaller amounts of pigments with a C8 n-propyl, iso-butyl or even neo-pentyl groups are found. The substituent at C12 is either ethyl or methyl in BChl *c* and *d*. So far BChl *e* has been isolated only with an ethyl group at C12. In most cases the esterified alcohol is farnesol (in *Chlorobium*) or stearyl (in *Cf. aurantiacus*). Smaller amounts of other esterifying alcohols have been found in many cases (Caple et al., 1978). A recent example is a strain of *Cb. limicola* which produced BChl *c* esterified with six different alcohols (farnesol, geranylgeraniol, phytol, octadec-9-en-1-ol, hexadecanol, and octadecanol) (Fig. 3) (Fages et al., 1990).

III. Biosynthesis of the Bacteriochlorophylls

A. Formation of 5-Aminolevulinic Acid

All tetrapyrroles are built up in a complex sequence from small biosynthetic precursors. The first intermediate which is common to all tetrapyrroles is 5-aminolevulinic acid (ALA) (Fig. 6.18). Depending on the organism two biosynthetic pathways leading to the formation of ALA are known (Fig. 6). The ALA-synthase pathway was first found in *Rhodobacter sphaeroides* (formerly called *Rhodospseudomonas sphaeroides*) (Kikuchi et al., 1958) and serves

in animals as the pathway for the formation of heme (see Chapter 9 by Beale). Because of the pioneering studies by Shemin on animals, this pathway is also called the Shemin-pathway. It involves the formation of ALA (Fig. 6.18) by condensation of succinyl-CoA (Fig. 6.16) and glycine (Fig. 6.17), catalyzed by the pyridoxal-dependent enzyme, ALA-synthase. Glycine is first bound as a Schiff-base to the pyridoxalphosphate cofactor, on which a succinate is transferred via succinyl-CoA. Subsequently CO₂ is split off and ALA is released from the enzyme. The other pathway, the so called C₅-pathway, was first found in plants and algae. This pathway involves the conversion of glutamate (Fig. 6.12) into ALA. First glutamate is bound by a glutamate-tRNA-synthase to a tRNA^{Glu}. This activated compound (Fig. 6.13) is utilized by a NADPH dependent hydrogenase for the formation of glutamate-1-semialdehyde (Fig. 6.14). The enzyme-bound aldehyde is then converted by a pyridoxalphosphate dependent aminotransferase into ALA (Jahn et al., 1992).

Which pathway is utilized in a given organism can be determined by feeding radioactive precursors. For example, feeding 1-[¹⁴C]-glutamate as substrate and isolation of labeled ALA indicates the operation of the C₅-pathway. Similarly, addition of ribonuclease (RNAase), which degrades the glutamyl-tRNA^{Glu}, resulting in unlabeled ALA indicates the C₅-pathway. On the other hand the ALA-synthase pathway is operating if 2-[¹⁴C]-glycine is incorporated in ALA in the presence of an RNAase. Such experiments have been performed e.g. for *Rhodospseudomonas palustris* indicating the ALA synthase route (Andersen et al., 1983).

Similar labeling experiments with ¹³C-enriched precursors allow a direct analysis of the final tetrapyrrole of a given biosynthetic pathway. After isolation of (e.g.) the BChls they can then be investigated by ¹³C-NMR for specifically enriched positions. Such experiments were performed for BChl *a* in *Rb. sphaeroides* (Oh-hama et al., 1985) again indicating the ALA synthase route. The methoxyl of the isocyclic ring methyl ester was derived from the C2 carbon of glycine, presumably via methionine. In *Cm. vinosum* the C₅-pathway was found (Oh-hama et al., 1986). Figure 7 shows the labeling pattern found for the macrocycle atoms of BChl *a* (Fig. 7.19) and *c* (Fig. 7.20). Comparative analyses of various organisms showed a large variability in the two pathways found in photosynthetic bacteria. The C₅-pathway is widely distributed and presumably is the

Fig. 6. Scheme of the two biosynthetic pathways for ALA found in photosynthetic bacteria. The distribution of specifically labeled C-atoms (from labeling experiments) is indicated by symbols (● C1 from glutamate; ■ C2 from glycine).

Fig. 7. Labeling of the macrocycle atoms in BChl *a* from C5 of ALA (19) and in BChl *c* from methionine (20).

phylogenetic oldest biosynthetic pathway for Chls. It is found in the green sulfur bacteria, e.g. in *Chloroflexus*. The ALA-synthase pathway is found in the non-sulfur purple bacteria. A detailed analysis of the pathway distribution has been performed by Avissar et al. (1989) and a detailed description of the two pathways has been given by Beale and Weinstein (1991) and by Beale in Chapter 9.

B. Intermediate Steps to Protoporphyrin

The next biosynthetic step is catalyzed by the enzyme ALA-dehydratase. It involves the condensation of two ALA molecules, and by splitting off of two water molecules, leads to the formation of the first pyrrole, porphobilinogen. Besides detailed studies on the biosynthesis of heme in animals, this enzyme has been well studied in *Rb. sphaeroides* (van Heyningen and Shemin, 1971; Jordan and Seehra, 1980). A detailed description of the enzymes and mechanisms involved in the steps to Proto has been given by Leeper (1991) and by Beale in Chapter 9.

With the exception of the variability in ALA biosynthesis discussed above, there has been little progress in understanding BChl biosynthesis since early experiments using *Chlorella* and *Rb. sphaeroides* mutants were published. This work has been extensively reviewed (Jones, 1978). Not much is known about the intermediate steps in biosynthesis up to Proto. It can however be assumed that the biosynthesis of the BChl utilizes the same intermediates as were found in the biosynthesis of heme

(Fig. 8). The enzymes hydroxymethylbilane synthase and uroporphyrinogen III synthase catalyze the formation of uroporphyrinogen III from four molecules of porphobilinogen. This is the first biosynthetic intermediate containing a tetrapyrrole macrocycle. The uroporphyrinogen III decarboxylase then stepwise decarboxylates the four acetate residues, eventually leading to the formation of coproporphyrinogen III, which is converted by oxidative decarboxylations of the propionate residues at ring I and II to give the vinyls in protoporphyrinogen. The enzyme protoporphyrinogen oxidase oxidizes this intermediate by removal of 6 hydrogen atoms (2 NH, and the four H at C5, C10, C15, and C20) to Proto, the first tetrapyrrole with a conjugated ring system. While in higher plants dioxygen is required for the aromatization and is the source of the keto-oxygen in the isocyclic ring (Walker et al. 1989), this reaction occurs in photosynthetic bacteria anaerobically (Tait, 1972). The electron acceptor in photosynthetic bacteria has not been determined, yet. The biosynthesis of all known tetrapyrroles uses the same intermediates up to uroporphyrinogen III. After this, branching occurs, leading to the formation of the different tetrapyrroles (heme, chlorophylls, corrins, and factor F430).

C. Formation of Bacteriochlorophyll a, b and g

Since the early studies on *Rb. sphaeroides* in the sixties (reviewed in Jones, 1978) not much progress has been made with elucidation of the steps after Proto. The most important results were obtained by experiments with photosynthetic mutants with blocks in the BChl biosynthesis. (Protoporphyrinato monomethyl ester)magnesium (Fig. 9.21), several metal-free derivatives, Phide a, 3¹-hydroxy-3²-hydro-Chlide a (Fig. 9.25) and -BChlide a (Fig. 9.26) and BChlide a (Fig. 9.27) have all been isolated after excretion from the mutants. Fig. 9 shows the currently accepted pathway from (protoporphyrinato monomethyl ester)magnesium to BChl a (Fig. 9.3) and this sequence is almost exclusively based on these mutant studies.

The first step is the incorporation of magnesium into Proto which is catalyzed by a magnesium chelatase. The product of this reaction is then converted by the enzyme S-adenosylmethionine: Mg-protoporphyrin-O-methyl transferase. After formation of the isocyclic ring a vinyl group is hydrated to (3¹,3²-didehydro-13²-carbomethoxy-phytoporphyrin-

Fig. 8. Scheme of the putative intermediate steps in BChl biosynthesis between porphobilinogen and Proto.

ato)magnesium (Fig. 9.23) (= monovinylprotoporphyrillide in biochemical usage). This is followed by the reduction of ring IV to Chlide a (Fig. 9.24), hydration of the vinyl group at C3 to 3¹-hydroxy-3²-hydro-Chlide a (Fig. 9.25), reduction of a second pyrrole ring II (Fig. 9.26) and formation of BChlide a (Fig. 9.27) which is then esterified with an alcohol to give BChl a (Fig. 9.3).

A possible alternate pathway has also been proposed (Pudek and Richards, 1975) on account of the fact that an *Rb. sphaeroides* mutant has been shown to excrete a protein-pigment complex containing 3-desacetyl-3-vinyl-BPhide a. This suggests that reduction of chlorin to bacteriochlorin can take place before, or after hydration of the 3-vinyl in Chlide a, to 3¹-hydroxy-3²-hydro-Chlide a (Fig. 9.25). Interestingly, BChl g (Fig. 9.6) possesses a 3-vinyl in place of the 3-acetyl found in BChl a, and thus would by necessity, require 3-vinyl precursors for its biosynthesis. These contradicting results indicate that the results from the mutant studies have only limited use in elucidating the exact biosynthetic pathway. The determination of the

Fig. 9. Currently accepted biosynthetic pathway to BChl *a*.

individual biosynthetic steps has been hampered by the fact that it is extremely difficult to develop active, cell-free systems for enzymatic and labeling studies. Some indications for the individual steps can however be delineated from analogies with chemical syntheses in situ.

A recent analysis of mutant strains of *Rb. capsulatus* with blocks in its BChl *a* biosynthesis at different

steps of the magnesium branch showed that (3¹,3²,8¹,8²-tetrahydro-13²-carbomethoxy-phytoporphyrinato)magnesium (divinyl-protoChlide) and (3¹,3²-didehydro-13²-carbomethoxy-phytoporphyrinato)magnesium (monovinyl-protoChlide), 3-devinyl-3-hydroxyethyl-Chlide *a*, and BChlide *a* were all bound to a 32 kDa protein, which was identified as the outer membrane porin protein (Bollivar and

Bauer, 1992). For a wild-type *Rb. capsulatus* the excretion of coproporphyrin bound to a protein with the same N-terminal sequence was reported by Biel (1991). No information is yet available on formation, excretion, or specificity of these complexes. The protein accumulated also in cells grown in high-oxygen conditions, indicating that it is not involved in regulation of tetrapyrrole biosynthesis. Recent years have seen an increase in studies on the molecular biology of the BChl biosynthesis (Bauer et al., 1993; Bollivar et al., 1994a,b,c). This is the topic of the Chapter 50 by Alberti et al.

Using (2R,3R)-ALA-2,3-T₂-2,3-¹⁴C₂, Emery and Akhtar (1985) have shown that the 8-ethyl group in BChl *a* in *Rb. sphaeroides* is formed by addition of hydrogen to the si-face of the corresponding double bond, resulting in an overall, formal, *trans*-addition. Chemical studies on model compounds have shown (Smith and Simpson, 1987; Simpson and Smith, 1988), that a formal reduction of the vinyl group to ethyl is possible by an initial reduction of the double bond in the corresponding pyrrole ring (Fig. 10.29) and subsequent migration of the double bond, resulting in the ethylidene derivative (Fig. 10.30) and subsequent migration of the double bond leads, then, to the unsaturated ethyl compound (Fig. 10.31). A similar mechanism might be involved in the formation of the ethylidene group in BChl *b*. On the basis of observations on photoisomerism reactions of BPheo derived from BChl *g* of *Heliobacterium chlorum*, Michalski et al. (1987) have also suggested

that all Chls are biosynthesized from a common intermediate bearing an ethylidene group as is present in BChl *b* (Fig. 2.4) and BChl *g* (Fig. 4.6).

The biosynthesis of phytol, which is esterified with the C17 propionic ester group, proceeds coupled to the biosynthesis of the chromophore (Brown and Lascelles, 1972). Starting with the specific C₅-precursor of the isoprenoid pathway, isopentenyl-diphosphate, geranylgeraniol diphosphate is formed, which is then esterified with the chromophore. The use of labeled ALA showed that the oxygen atoms of the ester groups at C17 and C13 both are derived from the carboxylate oxygen of ALA (Ajaz et al., 1985; Akhtar et al., 1984; Emery and Akhtar, 1987). This means that the ester groups in BChl *a* are formed by attack of the carboxylate groups of the chromophore on activated isoprenyl (and for C13, methyl) moieties. For Chl *a* it is known that first geranylgeraniol is bound by a chlorophyll synthetase to the pigment. Subsequently three double bonds are reduced in the side chain to give phytyl (Rüdiger and Schoch, 1988). The different esterified alcohols found in the BChls *c*, *d*, and *e* show, however, that the situation is much more complicated for the BChls.

The biosynthesis of BChl *b* (Fig. 2.4) presumably proceeds similarly to that of BChl *a* as far as the 3¹-hydroxy-3²-hydro-Chlide *a* (Fig. 9.25) step. Reduction of a double bond in ring II, as shown in Fig. 10, leads to the formation of the respective 3-hydroxyethyl-8-vinylbacteriochlorin, which after migration of the double bond yields 3-hydroxyethyl-

Fig. 10. Pathways for vinyl reduction in Chl and BChl biosynthesis, and possible route to formation of ring II ethylidene substituents in BChl *b* and BChl *g* biosynthesis.

8-ethylidenebacteriochlorin. Subsequent oxidation of the hydroxyethyl group to acetyl and esterification of the C17 acid with an isoprenoid alcohol would then yield BChl *b*. As of yet no studies on the biosynthesis of BChl *g* have been reported. It can be assumed that it follows in its biosynthesis that of BChl *a* up to Chlide *a* and that the branch point involves reduction of the Chlide *a* ring II double bond to give a vinyl bacteriochlorin (Fig. 10.29). Subsequent rearrangement of the double bond would yield an ethylidene compound analogous to (Fig. 10.30), followed by esterification with farnesol.

D. Biosynthesis of Bacteriochlorophyll c, d, and e

Similar to the situation found with BChl *a* and *b*, detailed information on the biosynthesis of the BChls *c* (Fig. 5.9), *d* (Fig. 5.10), and *e* (Fig. 5.11) is only available for the initial and ultimate steps. As described above, ALA is formed via the C₅-pathway in the green sulfur bacteria (*Chlorobium*) and the green nonsulfur bacteria (*Chloroflexus*). Detailed labeling experiments have been described for *Cb. limicola* (Andersen et al., 1983), *Cf. aurantiacus* (Swanson and Smith, 1990; Oh-hama et al., 1991), *Prosthecochloris aestuarii* (Oh-hama et al., 1986b) and *Cb. vibrioforme* (Smith and Huster, 1987; Smith and Bobe, 1987; Huster and Smith, 1990; Bobe et al., 1990). A discussion of the different results has been given by Smith (1991). No results are available on the biosynthesis of the reaction center pigments BChl *a* and *b*, which occur together with the BChls *c*, *d*, and *e* in these bacteria. A number of inhibition experiments have been performed recently. Earlier inhibition studies (see Jones, 1978) indicated a biosynthetic pathway closely resembling that of BChl *a* on the basis that intermediates similar to those of the BChl *a* biosynthesis were found. However, these results can also be reinterpreted in terms of total inhibition of BChl *c* biosynthesis very early in the pathway such that the metabolites being excreted into the medium were simply intermediates of normal BChl *a* biosynthesis. This problem could be partially overcome with the finding that anaesthetic gases, like N₂O, ethylene, and acetylene, inhibit BChl *d* (antenna pigment) formation but not that of BChl *a* (reaction center pigment) in *Cb. vibrioforme* (Ormerod et al., 1990). (Protoporphyrinato monomethyl ester)magnesium (Fig. 9.21) was found to accumulate under these conditions, suggesting that

the biosynthetic pathway of BChl *a* and *d* branch prior to isocyclic ring formation. Another possibility might be different compartmentalization of the biosynthetic enzymes for both pigment types and/or interference of the inhibitors with chlorosome formation. Inhibition experiments with gabaculine also supported the operation of the C₅-pathway in *Cf. aurantiacus* (Kern and Klemme, 1989). For *Chlorobium* it was shown that cell extracts have RNA-dependent ALA formation from glutamate as describe above (Rieble et al., 1989).

Labeling experiments with ¹³C-labeled precursors showed that all of the 'extra' carbon atoms in the side chains of the BChl *c* are derived from methionine (Fig. 7, formula 20) (Kenner et al., 1978; Smith and Huster, 1987; Huster and Smith, 1990). A lower level incorporation of porphobilinogen was also found.

Enzymatic studies are still lacking, due to the problems described above. However some insight into the biosynthesis can be obtained from analogy with chemical reactions. Not much is known with certainty about the latter stages in the biosynthesis of the BChls *c*, *d*, and *e*, so much of what follows should be regarded as conjecture rather than substantiated fact. For the biosynthesis of the different alkyl substituents at C8 two different pathways are feasible (Fig. 11) (Smith, 1991) which, by successive methylation and reduction of the side groups lead to the different homologues. The ethyl group at C8 can be formed analogous to that in BChl *a* (Fig. 10), i. e. by dehydrative decarboxylation of the propionate (Fig. 10.31) and subsequent reduction of the vinyl group (Fig. 11, steps 33 → 34). A methylation of the α -methyl group of the propionate by SAM and subsequent vinylation and reduction presents a possible scheme for the formation of the propyl homologue (Fig. 11, steps 35 → 37). Repetition of this sequence would lead to the isobutyl homologue (Fig. 11.40). Biosynthesis of the neopentyl group via this 'propionate alkylation pathway' would however involve a rather cumbersome concomitant decarboxylation and methylation of (Fig. 11.38) to (Fig. 11.44). The presumed more likely 'vinyl alkylation' pathway is shown as path B in Fig. 11. Starting with the 8-vinyl derivative (Fig. 11.33) a direct methylation with SAM would yield a carbocation which after deprotonation to the corresponding alkene (Fig. 11.36) and subsequent reduction would yield the propyl homologue (Fig. 11.37). Repetition of this process would give the corresponding isobutyl and neopentyl homologue (Fig. 11.41). A first indication

Fig. 11. Scheme of the propionate (A) and vinyl (B) alkylation pathway as a possible biosynthetic route for R⁸ homologation in the Bchl *c*, *d*, and *e*. Note that direct decarboxylation of intermediates (35) and (38) can lead directly to (37) and (40), respectively.

for the existence of this pathway was given by the identification of the rearranged homologue (Fig. 11.43) in small quantity from *Cb. vibrioforme* (Goff, 1984). The formation of this derivative can only be explained by a rearrangement of the carbocation which precedes the formation of the neopentyl homologue. Deprotonation of the tertiary carbocation

(Fig. 11.42) and reduction yields then the isolated 1,2-dimethylpropyl homologue (Fig. 11.43).

The biosynthesis of the C₁₂ homologues can be explained by a decarboxylation of the C₁₂ acetic acid group (Fig. 12). This step occurs in the other Chls before the vinyl reduction of the C₈ group and thus constitutes a possible early branch point in the

biosynthesis of the chlorophylls. After decarboxylation the methylene group (Fig. 12.46) can be methylated by SAM to give an ethyl group (Fig. 12.47). This is corroborated by model studies on the oxidation of C12 ethyl to acetyl in BPheo *d* (Senge et al., 1991) and labeling experiments which show the direct incorporation of the $^{13}\text{CD}_3$ -methyl group of SAM at this position (Kenner et al., 1978).

The BChls *c* and *d* are found with both possible stereochemical configurations at the C3-hydroxyethyl group (Fig. 5). The distribution of the different homologues shows that the predominant isomer depends on the size of the substituent at C8. If the residue at C8 is small (e.g. ethyl) the R-configuration is predominant. The S-configuration is preferred if the C8 substituent is large (e.g. neopentyl). This has been interpreted in terms of remote control of induced stereochemistry by the bulk of the C8 substituent, possibly involving rotamers of the presumed 2-vinyl precursor (Smith et al., 1983b). This requires that the formation of the different C8 homologues occurs prior to the introduction of the hydroxy group at C-3¹ (presumably by hydration of the respective vinylogous precursor).

The question occurs as to why the green sulfur bacteria produce only one BChl *a* or *b* but a multitude of different homologues of the antenna BChls *c*, *d*,

and *e*. Investigation of the absorption spectra of BChl *c*, *d*, and *e* in nonpolar solvents revealed a strong dependence of the absorption maxima from the size of the substituent at C8 (Smith et al., 1983c). Similar results were observed in living cells. Since the light harvesting complex of the bacteria constitutes of oligomeric BChls and a protein backbone it is possible that modification of the homologue composition allows a variation of the wavelengths region in which light is absorbed. When the oligomer is small, the bathochromic shift (monomer to oligomer) in the optical spectrum of the antenna system is small, and *vice versa* for large oligomers. Thus, the size of the antenna aggregate is controlled indirectly by the size of the C8 substituent and directly by the chirality of the C3¹-center, because a major interaction holding the oligomer together involves the central magnesium ion of one BChl and the oxygen of the 3-(1-hydroxyethyl) group of another. Under low light intensities an activation of the corresponding methylating enzymes leads to modification of the absorption spectrum. Alkylation in newly developing cells causes a red shift in the antenna system which in better light utilization because of better penetration of low energy light through the medium, and because existing bacteria in the medium absorb at higher energy (Smith and

Fig. 12. Possible mechanism for the biosynthetic transformation of the 12-acetic side chain into 12-ethyl, mediated by SAM.

Bobe, 1987; Bobe et al., 1990). Dilution of the bacterial suspension results in a termination of the alkylation process and a decrease in the content of *n*-propyl and isobutyl containing pigments relative to 8-ethyl. Thus this adaptation process is reversible.

A similar adaptation to environmental conditions has been observed for the BChl *d* producing strain *Cb. vibrioforme* (Broch-Due and Ormerod, 1978). Under low light intensities this bacterium slowly converts BChl *d* to BChl *c* (Smith and Bobe, 1987; Bobe et al., 1990). This *meso*-alkylation shifts the absorption maxima another 20 nm into the red spectral region. The C20 methyl group is also derived from methionine via SAM.

IV. Degradation of the Bacteriochlorophylls

Besides the many unsolved questions concerning the biosynthesis of the BChls, the degradation of these pigments remains unsolved, too. So far it is known that the first steps in the catabolic pathway are connected to loss of magnesium, removal of the esterified alcohol at C17³ and to oxidation reactions at ring V (Haidl et al., 1985). The enzymes of these steps remain unknown. For heme it is known that the ring system is broken up at a *meso*-bridge and then subsequently degraded (Brown et al., 1991). From model compounds it is known that C20-substituted BChls *c* undergo photochemical ring opening reactions at the C20 *meso*-bridge (Brockmann and Belter, 1979; Brown et al., 1980; Struck et al., 1990). The methyl group activates the molecule for such reactions and it was believed that introduction of a *meso*-substituent might be an essential part of Chl breakdown (Rüdiger and Schoch, 1989). Recent reports on Chl degradation show however that in plants the ring opening reaction occurs at the C5 *meso*-bridge (Kräutler et al., 1991; Engel et al., 1991). Thus the situation remains unclear for the BChls.

Both the catabolic and anabolic pathway remain largely unknown. Due to their easy cultivation and simple physiology, photosynthetic bacteria remain the premier objects for studies on photosynthesis. Thus they also serve as models for studying the photosynthesis in higher organisms. Therefore a more detailed analysis of their biochemistry is of central importance. A renewed effort with a combination of chemical, biological, and physiological methods might reveal more fascinating facets about these interesting compounds.

Summary

Anoxygenic phototrophs are capable of synthesizing all three major types of tetrapyrroles: hemes, chlorophylls, and corrins. These molecules are derived from a common, branched biosynthetic pathway. Facultative aerobes in the α -proteobacterial group (purple nonsulfur bacteria), which includes the genera *Rhodobacter*, *Rhodopseudomonas*, and *Rhodospirillum*, have been used extensively as model systems for studying tetrapyrrole biosynthesis, and much is known about the biosynthetic pathway and the physical and regulatory properties of the enzymes in these organisms. Strictly anaerobic phototrophic species have been less thoroughly studied, but they are known to derive their tetrapyrroles from metabolic precursors that differ from those used by the facultative aerobes. This chapter describes the structures and biosynthesis of tetrapyrrole precursors, hemes, and related molecules.

I. Introduction

A. The Tetrapyrroles of Anoxygenic Phototrophic Bacteria

Tetrapyrroles are ubiquitous molecules that play essential roles in energy metabolism. The tetrapyrrole family includes hemes, chlorophylls, and structurally related compounds. In the anoxygenic phototrophs, tetrapyrroles are used in the fundamental roles of light absorption and electron transfer through which these organisms achieve phototrophy.

The anoxygenic phototrophs are versatile tetrapyrrole synthesizers: along with the ability to produce hemes and chlorophylls, a property which they share with plants, algae, and cyanobacteria, some of these organisms are capable of forming the corrin nucleus of coenzyme B₁₂. Moreover, these procaryotes contain several heme types that are not found in eucaryotic organisms. This chapter is concerned specifically with the structures and biosynthesis of hemes in anoxygenic phototrophs. However, inasmuch as all tetrapyrroles share a common biosynthetic pathway, much of the material covered here is applicable to the biosynthesis of other tetrapyrrole end products.

B. Outline of the General Tetrapyrrole Biosynthetic Pathway

All biological tetrapyrroles can be arranged as products of a single, branched biosynthetic pathway (Fig. 1). The biosynthetic steps from early precursors to protoporphyrin-based hemes constitute the major, common portion of the pathway, and other steps leading to specific groups of products can be considered to be branches off the common pathway. The pathway is a highly conserved one and, with few exceptions, the biosynthetic intermediates and enzyme-catalyzed reactions are very similar or identical in all organisms where they have been studied. The existence of a branched pathway with several categories of end products indicates the need for complex regulation to ensure that the products are synthesized in appropriate proportions in response

Abbreviations: ALA – δ -aminolevulinic acid; BChl – bacteriochlorophyll; *Cb.* – *Chlorobium*; *Cf.* – *Chloroflexus*; *Cm.* – *Chromatium*; *E. coli* – *Escherichia coli*; gabaculine – 3-amino-2,3-dihydrobenzoic acid; GSA – L-glutamate-1-semialdehyde; PBG – porphobilinogen; *Rb.* – *Rhodobacter*; *Rc.* – *Rhodocyclus*; RNase A – Ribonuclease A; *Rp.* – *Rhodospseudomonas*; *Rs.* – *Rhodospirillum*

to changing environmental and growth conditions.

Many major discoveries in the area of tetrapyrrole biosynthesis have been made using one group of anoxygenic phototrophs, the α -proteobacteria (nonsulfur purple bacteria), as model systems. For example, *Rhodobacter sphaeroides* and *Rhodospirillum rubrum* were among the first organisms of any kind to yield in vitro enzyme activities for early steps of the pathway. Compared to the α -proteobacteria, other groups of anoxygenic phototrophs are much less well characterized with respect to their tetrapyrrole biosynthetic capabilities. It is important to be aware of the different extent of knowledge about tetrapyrrole biosynthesis in the different groups of organisms and to avoid premature generalizations, since, as will be described below, there are some major differences in the actual biosynthetic steps used by the different organisms for producing the same end product.

Anoxygenic phototrophs, like other phototrophic organisms, are able to regulate the content and composition of their tetrapyrroles, especially those which are components of their photosynthetic apparatus, in response to environmental signals such as light intensity and spectral composition, nutritional status, and O₂ tension. Several of these topics are covered in Chapter 52 by Biel. In the present chapter, discussion of regulation will be primarily concerned with the regulatory properties of individual biosynthetic enzymes.

II. The Early Common Steps

A. Biosynthesis of ALA

δ -Aminolevulinic acid (ALA) can be considered to be the first universal, committed tetrapyrrole precursor (Fig. 1). Discussion of ALA formation is complicated by the fact that two different biosynthetic routes to ALA exist. The α -proteobacteria include the facultative phototrophic genera *Rhodospseudomonas*, *Rhodobacter* and *Rhodospirillum*, obligately aerobic bacteriochlorophyll-(BChl)-containing phototrophs that have been placed in the *Erythrobacter* and *Methylobacterium* groups, and non-chlorophyllic relatives such as *Agrobacterium*, *Rhizobium*, *Azorhizobium*, and *Bradyrhizobium*. These organisms, as well as eucaryotes that do not contain plastids (e.g., animals, yeasts, fungi), form ALA from glycine and succinate (Fig. 2). Plants, algae, and most groups

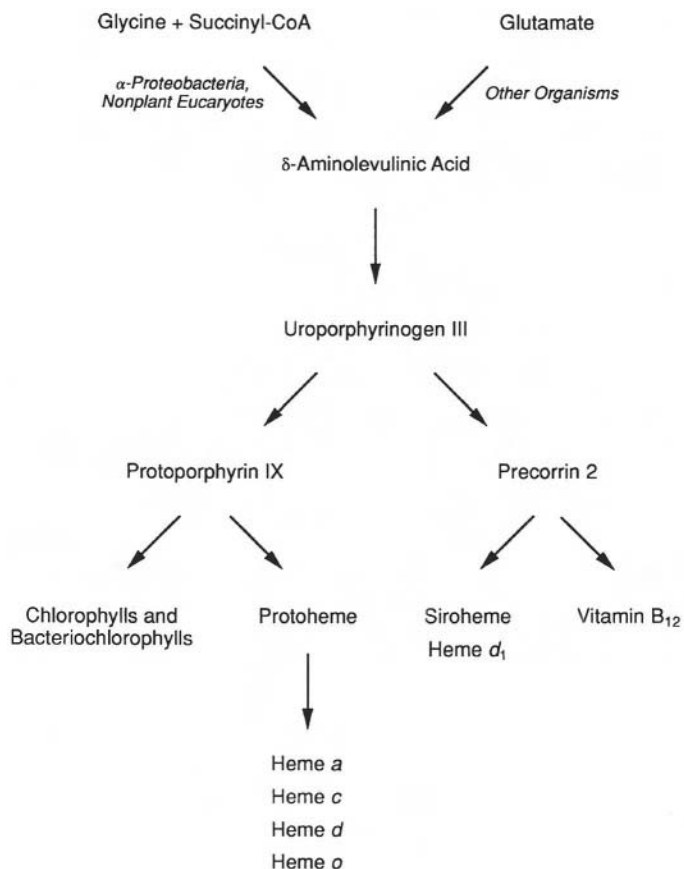

Fig. 1. Outline of tetrapyrrole biosynthesis.

of bacteria, including cyanobacteria, the strictly anaerobic phototrophs (green sulfur bacteria, green nonsulfur bacteria, and heliobacteria), and archaeobacteria, form ALA by a different route (Fig. 3), wherein glutamate, rather than glycine and succinate, provides the C and N atoms.

1. The Glycine/Succinyl-CoA Route

Rb. sphaeroides and *Rs. rubrum* were among the first organisms of any kind to yield in vitro ALA-forming activity (Gibson, 1958; Kikuchi et al., 1958; Sawyer and Smith, 1958). ALA is formed in these cells by the condensation of succinyl-CoA and glycine, mediated by the pyridoxal phosphate-requiring enzyme, ALA synthase (succinyl-CoA:glycine C-succinyltransferase (decarboxylating) EC 2.3.1.37) (Fig. 2). In the reaction, the carboxyl carbon of glycine is lost as CO_2 and the remainder is incorporated into the ALA.

ALA synthase has been highly purified from *Rb.*

sphaeroides (Warnick and Burnham, 1971; Fanica-Gaignier and Clement-Metral, 1973b; Nandi and Shemin, 1977). The native enzyme has an apparent molecular weight of 80,000 to 100,000 and is a homodimer consisting of two 41,000–45,000 molecular weight subunits. A native molecular weight of 61,000–65,000 was derived for ALA synthase from *Rhodospseudomonas palustris* (Viale et al., 1987a). One mole of pyridoxal-phosphate is bound per subunit of the *Rb. sphaeroides* ALA synthase (Davies and Neuberger, 1979b), but the relatively loose binding (the apparent K_m was calculated to be 3–5 μM), and the fact that pyridoxal-phosphate protects an essential thiol group, suggest that the cofactor is not bound covalently as a Schiff base, but instead may be complexed with a cysteine thiol. The existence of two distinct ALA synthases, called Fraction I and Fraction II, has been demonstrated in *Rb. sphaeroides* (Tuboi et al., 1970a,b; Fanica-Gaignier and Clement-Metral, 1973a,b). Fraction I and Fraction II are both repressed under high O_2

Fig. 2. ALA biosynthesis from glycine and succinyl CoA catalyzed by ALA synthase.

tension. Reduction of O₂ tension induces Fraction I, and induction of Fraction II requires both low O₂ tension and light (Tuboi et al., 1970). It has been reported that one form of ALA synthase is cytoplasmic and is functionally associated with dark metabolism, and the other is found in the chromatophores, is specifically induced in the light, and is functionally associated with photometabolism (Fanica-Gaignier and Clement-Metral, 1973a). The two enzyme forms may be encoded by different genes (see below).

The ALA synthase reaction mechanism has been extensively studied. Product inhibition studies with the *Rb. sphaeroides* enzyme indicate a bi-bi reaction sequence in which glycine binds first and ALA is released last (Fanica-Gaignier and Clement-Metral, 1973c). During the reaction, the glycine α -proton having the *pro-R* configuration is specifically removed and the *pro-S* proton occupies the *pro-S* position at C-5 of ALA (Zaman et al., 1973; Abboud et al., 1974). The retention of only one glycine α -proton in

the product, and its stereospecific position in the product, indicate that the reaction of pyridoxal-bound glycine carbanion with succinyl-CoA precedes decarboxylation, i.e., that enzyme-bound α -amino- β -ketoacid is an intermediate, and that the decarboxylation step occurs before the final product is released from the enzyme, which means that ALA synthase is a decarboxylase as well as a condensing enzyme. In the absence of succinyl-CoA, the enzyme catalyzes the exchange of the glycine *pro-R* α -proton with the solvent (Laghai and Jordan, 1976), and in the absence of either substrate, the enzyme catalyzes exchange of one of the C-5 protons of ALA with the solvent (Laghai and Jordan, 1977). Protoheme, a powerful allosteric inhibitor (see below), has little effect on the exchange reaction with glycine but does affect the exchange reaction with ALA.

Genes that encode ALA synthase have been cloned and sequenced from *Rhodobacter capsulatus* (Biel et al., 1988; Hornberger et al., 1990) and *Rb. sphaeroides* (Tai et al., 1988; Neidle and Kaplan,

Fig. 3. ALA biosynthesis from glutamate via the tRNA-dependent five-carbon pathway. The intermediate, GSA, is shown in linear, hydrated, and cyclic forms, which probably coexist as an equilibrium mixture in solution.

1993a). Whereas *Rb. capsulatus* contains a single ALA synthase-encoding gene, *hemA*, *Rb. sphaeroides* contains two such genes, *hemA* and *hemT*, which respectively are located on the large and small chromosomes of these cells (Neidle and Kaplan, 1993b). The *Rb. capsulatus hemA* sequence predicts a 401 amino acid, 44,100 molecular weight peptide. The *Rb. sphaeroides hemA* and *hemT* genes encode peptides that are 53% identical to each other, and each contains 407 amino acids. The *Rb. capsulatus* and *Rb. sphaeroides* HemA peptides are 76% identical. These bacterial ALA synthase peptides are also significantly similar to ALA synthase peptides from other bacterial and eucaryotic species. Interestingly, there is detectable similarity to the peptide sequences of two other enzymes that catalyze similar condensation reactions, 7-keto-8-amino-pelargonic acid synthase (BioF) and 2-amino-3-ketobutyrate coenzyme A ligase (EC 2.3.1.29) (Neidle and Kaplan, 1993a). It has been proposed (Tai et al., 1988), but not directly proven, that the *hemA* and *hemT* gene products correspond to the two types of *Rb. sphaeroides* ALA synthase discussed above.

As might be expected for an enzyme that catalyzes the first committed step of tetrapyrrole biosynthesis, ALA synthase is highly regulated. Regulation is exerted at both the enzyme (allosteric activity modulation) and gene expression (transcriptional control) levels. *Rb. sphaeroides* ALA synthase is reversibly inhibited by protoheme at physiologically relevant concentrations (Burnham and Lascelles, 1963; Yubisui and Yoneyama, 1972). Greater than 50% inhibition was caused by $1 \mu\text{M}$ protoheme, and nearly complete inhibition was achieved at $10 \mu\text{M}$ protoheme. The inhibition appeared to be competitive with glycine. Unnatural protoheme analogs such as hemothene, deuteroheme, and dimethylprotoheme also inhibited at concentrations comparable to that of protoheme (Yubisui and Yoneyama, 1972). Other physiological tetrapyrroles such as protoporphyrin IX and Mg-protoporphyrin IX inhibited at higher concentrations (Burnham and Lascelles, 1963; Yubisui and Yoneyama, 1972), but it is doubtful that these tetrapyrroles ever reach inhibitory concentrations in vivo.

Rb. sphaeroides ALA synthase is also inhibited by

ATP and inorganic pyrophosphate at physiologically relevant concentrations; purified enzyme was inhibited 60–88% by 1 mM ATP (Fanica-Gaignier and Clement-Metral, 1971; 1973c). The inhibition was competitive with glycine. It has been noted that exogenous ATP inhibits BChl formation in *Rb. sphaeroides*, and the suggestion was made that ATP may be a general repressor of the tetrapyrrole biosynthesis in this species (Fanica-Gaignier and Clement-Metral, 1971).

In addition to the inhibitory responses noted above, *Rb. sphaeroides* ALA synthase activity has been shown to be influenced by certain thiol-rich compounds. Initially, it was reported that fresh cell extracts from phototrophically-grown cells had low ALA synthase activity and that activity spontaneously increased upon preliminary purification (Kikuchi et al., 1958) or exposure of the extract to air (Marriott et al., 1970). It was suggested that activation requires the oxidation of some unidentified inhibitor. Disulfide-containing compounds, such as cystine, oxidized glutathione, and lipoic acid, were shown to activate ALA synthase in vitro (Tuboi and Hayasaka, 1972). Later, trisulfides such as cystine trisulfide and the mixed trisulfide of glutathione and cystine, but not disulfides, were reported to activate the enzyme (Sandy et al., 1975) and to supplant air activation (Davies and Neuberger, 1979a). In contrast to the activating effect of O₂ on ALA synthase in vitro, exposure of whole cells to O₂ reduces the level of extractable ALA synthase. Cellular levels of trisulfide compounds were found to decrease upon oxygenation, and the decrease was proposed to be responsible for the decrease in extractable active ALA synthase upon oxygenation of the cells. Finally, proteinaceous activators, such as cystathionase (EC 4.4.1.1) (Inoue et al., 1979; Oyama and Tuboi, 1979) and reduced thioredoxin (Clement-Metral, 1979) were shown to activate ALA synthase. It remains to be determined whether the influence of the sulfhydryl environment on ALA synthase activity is of importance in the control of BChl formation by O₂ tension.

Rb. sphaeroides and *Rs. rubrum* cells accumulate significantly more BChl when grown at low light intensity than at high intensity (Cohen-Bazire et al., 1957; Arnheim and Oelze, 1983; Oelze and Arnheim, 1983). It seems probable that the influence of light intensity on BChl content is an indirect one, perhaps mediated by effects of light on BChl stability (Biel, 1986) or on the rate of ALA synthesis via feedback inhibition, cellular ATP concentration, and/or thiol

oxidation/reduction state. However, there has been one unconfirmed report that light directly inhibits *Rb. sphaeroides* ALA synthase in vitro (Oelze, 1986).

Relatively little is known about the regulation of the expression of ALA synthase-encoding genes. These genes are not located within the major photosynthetic gene clusters (Hornberger et al., 1990). ALA synthase is induced upon transfer of dark-grown, aerobic *Rb. sphaeroides* cells to anaerobic, light conditions (Kikuchi et al., 1958). Exogenous protoheme inhibits this induction (Goto et al., 1967). Oxygen completely blocks BChl formation in *Rb. sphaeroides* (Cohen-Bazire et al., 1957). Oxygenation of anaerobically-grown *Rb. sphaeroides* (Lascelles, 1960) and *Rp. palustris* (Viale et al., 1987b) cells diminished the level of extractable ALA synthase by approximately 70%. *Rb. capsulatus hemA-lacZ* fusion expression was inhibited by factors of 2–3 by high O₂ tension. The relatively small effect of O₂ on ALA synthase levels and the fusion expression suggests that transcriptional regulation of *hemA* is not a major factor in O₂-mediated control of tetrapyrrole biosynthesis in this species (Wright et al., 1991). In *Rb. sphaeroides*, disruption of both ALA synthase-encoding genes, *hemA* and *hemT*, was required to produce ALA auxotrophy (Neidle and Kaplan, 1993b). However, disruption of either *hemA* or *hemT* alone was sufficient to cause decreased cellular contents of BChl, carotenoids, and light-harvesting BChl-proteins, as well as lowered levels of *puc* and *puf* transcripts. Somewhat paradoxically, *hemT* transcripts could not be detected in wild-type cells that had an intact, expressible *hemA* gene, although *hemT* transcripts were present in *hemA* mutant cells (Neidle and Kaplan, 1993a). In wild-type and *hemT* mutants, the *hemA* transcript level was 3 times higher under phototrophic conditions than during aerobic conditions.

In contrast to facultative aerobes such as *Rb. sphaeroides* and *Rb. capsulatus* which form BChl only in the absence of O₂, several obligately aerobic BChl-containing species have been described (see Chapters 6 and 7). These include the marine species *Erythrobacter longus* (Harashima et al., 1978) and *Roseobacter denitrificans*. OCh114 (Harashima et al., 1980), the methylotrophs *Methylobacterium (Protomonas) ruber* (Sato, 1978) and *M. (Pseudomonas) radiora* (Nishimura et al., 1981), and a BChl-containing *Bradyrhizobium*-like organism, strain BTAi 1 (Evans et al., 1990). These organisms are all members of the α -proteobacterial group (Kawasaki

et al., 1993) and all form ALA via the ALA synthase route (Sato et al., 1981; Shioi and Doi, 1988). Whereas O_2 prevents BChl synthesis in the facultatively aerobic species, the obligate aerobes require O_2 for BChl synthesis as well as growth (Chapters 6 and 7). In the methylotrophs, BChl is formed in the dark, but not under continuous illumination. After a shift from light to dark, the ALA synthase level increased in parallel with the rate of BChl synthesis (Sato et al., 1985). However, detectable ALA synthase activity was present in light-grown cells, even though BChl was not formed. The cells contain two ALA synthase isoenzymes, one of which is constitutive and the other is induced in the dark (Sato et al., 1985). Although the marine *Erythrobacter* species, like the methylotrophs, synthesize BChl only in the dark, the ALA synthase level does not correlate with BChl synthesis, and is actually higher in the light than in the dark (Shioi and Doi, 1988).

2. The Five-Carbon Pathway

Until the early 1970s, the only known route of ALA formation was *via* condensation of succinyl-CoA and glycine. The first evidence indicating an alternative biosynthetic route was the preferential incorporation of ^{14}C from exogenous five-carbon precursors, such as glutamate, and poorer incorporation of ^{14}C from glycine and succinate, into ALA by greening intact plant tissues that had been treated with the ALA analog, levulinic acid, which causes ALA to accumulate *in vivo* by inhibiting porphobilinogen (PBG) synthase (Beale and Castelfranco, 1974a, 1974b; Meller et al., 1975). Degradation studies indicated that the glutamate carbon skeleton was incorporated intact into ALA (Beale et al., 1975; Meller et al., 1975). Shortly after the initial reports on the plant studies appeared, similar results were reported for cyanobacteria (Meller and Harel, 1978; Avissar, 1980; Kipe-Nolt and Stevens, 1980). Later, incorporation of glutamate into ALA or BChl was shown to occur in the anoxygenic phototrophs *Chromatium vinosum* (Oh-hama et al., 1986a), *Prosthecochloris aestuarii* (Oh-hama et al., 1986b), *Chlorobium vibrioforme* (Andersen et al., 1983; Smith and Huster, 1987), and *Chloroflexus aurantiacus* (Swanson and Smith, 1990; Oh-hama et al., 1991).

Particulate-free cell extracts capable of converting glutamate to ALA were first obtained from plants (Gough and Kannangara, 1977) and algae (Wang et al., 1984; Weinstein and Beale, 1985a; Mayer et al.,

1987; Breu and Dörnemann, 1988). Later, active cell-free preparations were obtained from cyanobacteria (Rieble and Beale, 1988; O'Neill et al., 1988) and the prochlorophyte *Prochlorothrix hollandica* (Rieble and Beale, 1988). Similar or identical reaction mechanisms appear to operate in all cases, and reaction components from some heterologous sources can be mixed to reconstitute activity in fractionated systems.

In a survey of ALA biosynthetic routes in anoxygenic phototrophs, *in vitro* RNA-dependent conversion of glutamate to ALA was measured in extracts of a green sulfur bacterium (*Cb. vibrioforme*), a green nonsulfur bacterium (*Cf. aurantiacus*), a Heliobacterium (*Heliospirillum* sp.), a phototrophic β -proteobacterium (*Rhodocyclus gelatinosus*), and a phototrophic γ -proteobacterium (*Cm. vinosum*) (Avissar et al., 1989). In contrast, ALA synthase-catalyzed condensation of glycine and succinyl-CoA was detected only in extracts from members of the α -proteobacterial group (*Rs. rubrum*, *Rb. sphaeroides*). Thus the five-carbon ALA biosynthetic route is the predominant one in anoxygenic phototrophs.

The currently accepted model for the transformation of glutamate to ALA requires three enzyme-catalyzed reactions (Fig. 3). In the first, glutamate is activated by ligation to tRNA in a reaction identical to the charging reaction in protein biosynthesis. Like aminoacyl-tRNA formation in general, this reaction requires ATP and Mg^{2+} . Next, the tRNA-bound glutamate is converted to a reduced form in a reaction that requires a reduced pyridine nucleotide. The product of this reduction has been characterized as glutamate-1-semialdehyde (GSA) (Hooper et al., 1988), the hydrated hemiacetal form of GSA (Hooper et al., 1988), or a cyclized form of GSA (Jordan et al., 1993). Finally, the positions of the nitrogen and oxo atoms of the reduced five-carbon intermediate are interchanged to form ALA. Consistent with this reaction model, the ALA-forming systems extracted from plants (Bruyant and Kannangara, 1987), algae (Weinstein et al., 1987), and cyanobacteria (Rieble and Beale, 1991) have been separated into four macromolecular components, all of which must be present to catalyze *in vitro* ALA formation from glutamate. Three of these components are enzymes and the fourth is a low molecular weight RNA.

Most of the available information on the five-carbon pathway has been derived from plants, algae, cyanobacteria, and three nonphotosynthetic bacteria

that have well understood genetic systems, *Escherichia coli*, *Salmonella typhimurium*, and *Bacillus subtilis*. However, one anoxygenic phototroph, *Cb. vibrioforme*, has been examined in some detail: the overall properties of in vitro ALA formation have been described (Rieble et al., 1989) and a *Cb. vibrioforme* gene that encodes a key enzyme has been cloned (Avissar and Beale, 1990), expressed in *E. coli*, and sequenced (Majumdar et al., 1991). The results indicate that the *Cb. vibrioforme* system is similar to those that have been examined in more detail from other organisms that use the five-carbon pathway.

a. tRNA^{Glu}

ALA formation in extracts of organisms that form ALA from glutamate is blocked by preincubation with ribonuclease (RNase) A (Kannangara et al., 1984; Breu and Dörnemann, 1988; Huang et al., 1984; Weinstein and Beale, 1985b; Avissar et al., 1989; Rieble et al., 1989). Addition of the RNase inhibitor, RNasin, plus low molecular weight RNA from the same species restores activity. In all species that have been examined, the RNA required for ALA formation is tRNA^{Glu(UUC)} (Schön et al., 1986; Schneegurt and Beale, 1988). The same tRNA is used for both ALA and protein synthesis. The first anticodon base of tRNA^{Glu} from *E. coli* cells and barley chloroplasts is highly modified, to 5-methylaminomethyl-2-thiouridine (Schön et al., 1986). In *E. coli*, modification of this base is important for efficient charging with glutamate by glutamyl-tRNA synthetase (Sylvers et al., 1993). It has been proposed that the modified base may have regulatory significance, because oxidation of the 5-methylaminomethyl-2-thiouridine with I₂ inactivated the tRNA for both glutamate acceptance and ALA synthesis, and subsequent reduction with thiosulfate reactivated it (Kannangara et al., 1988). However, treatment of the tRNA derived from dark-grown barley leaves with thiosulfate did not increase its activity.

b. Glutamyl-tRNA Synthetase

The same glutamyl-tRNA synthetase (EC 6.1.1.17) is used to charge tRNA^{Glu} for both protein and ALA synthesis (Bruyant and Kannangara, 1987; Rieble and Beale, 1991). Glutamyl-tRNA synthetase from *E. coli* (Lapointe and Söll, 1972) and *B. subtilis*

(Proulx et al., 1983) is a monomeric enzyme of 56,000 and 63,000 molecular weight, respectively, and is encoded by the *gltX* gene. These enzymes co-purify with a 46,000 molecular weight regulatory peptide. Glutamyl-tRNA synthetase from *E. coli* and *B. subtilis* contains a tightly-bound Zn²⁺ atom that is required for native conformation and catalytic activity (Liu et al., 1993). The aminoacylation reaction requires ATP and Mg²⁺. Although *Chlamydomonas reinhardtii* glutamyl-tRNA synthetase is inhibited by heme under some conditions (Chang et al., 1990), and the *Scenedesmus obliquus* enzyme is inhibited by protochlorophyllide (Dörnemann et al., 1989), the *Synechocystis* sp. PCC 6803 glutamyl-tRNA synthetase is insensitive to heme or protochlorophyllide at physiologically relevant concentrations (Rieble and Beale, 1991). Moreover, it was determined that *Synechocystis* sp. PCC 6803 tRNA^{Glu} was always fully acylated in vivo, and that the cellular content of tRNA^{Glu} was a constant fraction of the total cellular tRNA population under growth conditions in which chlorophyll content was modulated over a 10-fold range (O'Neill and Söll, 1990). It therefore seems unlikely that either glutamyl-tRNA synthetase or tRNA^{Glu} has a regulatory role in tetrapyrrole biosynthesis.

c. Glutamyl-tRNA Reductase

Glutamyl-tRNA reductase catalyzes NADPH-linked reduction of tRNA-activated glutamate to GSA, which is the first committed step unique to ALA formation from glutamate. For technical reasons, glutamyl-tRNA reductase is usually measured in coupled enzyme assays where the substrate is generated in vitro from glutamate plus tRNA, and/or the product is converted *in situ* to ALA by GSA aminotransferase. However, glutamyl-tRNA reductase is physically separable from the other enzyme components by affinity chromatography (Weinstein et al., 1987; Rieble and Beale, 1991). Affinity-purified glutamyl-tRNA reductase is active in GSA formation from glutamyl-tRNA in the absence of glutamyl-tRNA synthetase and GSA aminotransferase (Rieble and Beale, 1991). However, there is some evidence that glutamyl-tRNA synthetase and glutamyl-tRNA reductase may form an association. In the presence of glutamyl-tRNA, *C. reinhardtii* glutamyl-tRNA synthetase and glutamyl-tRNA reductase form a complex that migrates as a single entity on glycerol gradient centrifugation (Jahn, 1992). A complex

between the two enzymes may facilitate the channeling of glutamyl-tRNA toward ALA biosynthesis and competition with the protein synthesizing apparatus for glutamyl-tRNA.

Affinity-purified glutamyl-tRNA reductase from *Synechocystis* sp. PCC 6803 and *Chlorella vulgaris* requires a divalent metal such as Mg^{2+} , Mn^{2+} , or Ca^{2+} for activity, with optimum activity occurring at 15 mM Mg^{2+} (Mayer et al., 1993b).

It is of interest that glutamyl-tRNA reductase from a given source can use, as substrate, glutamyl-tRNA from some, but not other, sources. For example, the barley and *C. vulgaris* enzymes can use plant and algal, but not *E. coli*, yeast, or animal glutamyl-tRNA (Kannangara et al., 1984; Weinstein et al., 1986). On the other hand, the reductases from *C. reinhardtii* and *Cb. vibrioforme* can use *E. coli* glutamyl-tRNA (Huang and Wang, 1986; Rieble et al., 1989).

Native glutamyl-tRNA reductase isolated from different sources appears to have widely divergent physical properties. The *C. reinhardtii* enzyme was reported to be a monomer with a molecular weight of 130,000 (Chen et al., 1990). In contrast, *E. coli* appears to contain two different glutamyl-tRNA reductases with molecular weights of 45,000 and 85,000 (Jahn et al., 1991). *B. subtilis* glutamyl-tRNA reductase migrated as an oligomer with an apparent molecular weight of 230,000 (Schröder et al., 1992).

Glutamyl-tRNA reductase is encoded by the *hemA* gene in organisms that use the five-carbon pathway. Mutation of the *E. coli hemA* gene results in a deficiency of glutamyl-tRNA reductase (Avisar and Beale, 1989a). The tRNA substrate specificity of glutamyl-tRNA reductase in complemented *hemA* strains of *E. coli* resembled that of the species from which the complementing DNA was derived, which indicates that the *hemA* gene encodes a structural component of glutamyl-tRNA reductase (Avisar and Beale, 1990; Majumdar et al., 1991). The glutamyl-tRNA reductase-encoding *hemA* gene from most sources encodes a peptide with a molecular weight of approximately 45,000, although the *B. subtilis* gene product is somewhat larger at 50,800 molecular weight (Petricek et al., 1990). The *Cb. vibrioforme* predicted Hema peptide has a molecular weight of 46,174 and is 30% identical to that of *B. subtilis* (Majumdar et al., 1991).

Glutamyl-tRNA reductase from many sources is allosterically inhibited by physiologically relevant concentrations of protoheme. The *Cb. vibrioforme*

enzyme was inhibited 50% by 0.2 μM protoheme (Rieble et al., 1989). Protoheme inhibition is likely to be significant in regulating the rate of ALA formation in response to the cellular demand for end-product tetrapyrroles. The sensitivity of *C. vulgaris* glutamyl-tRNA reductase to protoheme inhibition is increased several fold by physiologically relevant concentrations of GSH (Weinstein et al., 1993).

d. GSA

GSA has been chemically synthesized by several methods for use as a substrate for the enzyme-catalyzed conversion to ALA (Kannangara and Gough, 1978; Houen et al., 1983; Gough et al., 1989). Material identical to chemically synthesized GSA accumulates in greening leaves (Wang et al., 1981; Kannangara and Schouboe, 1985) and algal extracts (Breu and Dörnemann, 1988) that have been treated with 3-amino-2,3-dihydrobenzoic acid (gabaculine), a mechanism-based suicide inhibitor of ω -aminotransferases (see below) that blocks chlorophyll synthesis.

Jordan et al. (1993) have investigated the structure of GSA in aqueous solution by NMR and mass spectroscopy and concluded that it exists as the cyclic ester between the γ -carboxyl group and the hydrated aldehyde group, rather than the free aldehyde (Fig. 3). The cyclic structure does not contain free aldehyde or carboxylic acid functions, and is more compatible with previously reported properties of the chemically synthesized product (stability in aqueous solution, heat stability) than the free α -aminoaldehyde. The cyclic compound, and not GSA, was proposed to be the product of glutamyl-tRNA reductase and the substrate of GSA aminotransferase. It is likely that the cyclic and linear forms of GSA coexist in solution in an equilibrium ratio, analogously to the aldose sugars.

e. GSA Aminotransferase

GSA aminotransferase (EC 5.4.3.8) catalyzes the conversion of GSA to ALA. Enzymes capable of converting chemically synthesized GSA to ALA have been purified from several plant, algal, and bacterial sources. The transamination reaction requires no added substrate other than GSA. The enzyme contains bound pyridoxal-phosphate (Avisar and Beale, 1989b; Bull et al., 1990). GSA

aminotransferase is inhibited by the mechanism-based suicide substrate analog gabaculine (Kannan-gara and Schouboe, 1985; Avissar and Beale, 1989b). Gabaculine reacts with enzyme-bound pyridoxal-phosphate to irreversibly form a secondary amine. Gabaculine-treated *C. vulgaris* GSA aminotransferase can be reactivated by gel filtration (to remove gabaculine-pyridoxal-phosphate adducts and excess gabaculine) followed by incubation with pyridoxal-phosphate (Avissar and Beale, 1989b).

A proposed reaction mechanism for GSA aminotransferase involves transfer of NH_2 from enzyme-pyridoxamine-phosphate to the terminal aldehyde carbon of GSA to form enzyme-pyridoxal-phosphate and 4,5-diaminovaleric acid, followed by transfer of the NH_2 at the 4-position of the intermediate back to the cofactor, thereby forming ALA and regenerating the pyridoxamine-phosphate form of the cofactor. Implicit in this mechanism is that the N atom of ALA is derived from a different precursor molecule than the C atoms. This prediction was tested by the use of a mixture of ^{13}C - and ^{15}N -labeled glutamate molecules as substrate for conversion to ALA by algal cell extracts. When the heavy isotope labels were present on separate substrate molecules, a significant proportion of the ALA product molecules contained two heavy atoms, indicating that the conversion occurs by intermolecular nitrogen transfer (Mau and Wang, 1988; Mayer et al., 1993a). This result supports the proposed reaction mechanism and indicates that the enzyme catalyzes two aminotransferase reactions, rather than an aminomutase reaction, even though the substrate and product have the same atomic composition.

Native GSA aminotransferase from *Synechocystis* sp. PCC 6803 has a molecular weight of 99,000 (Rieble and Beale, 1991b). Purified aminotransferase from *Synechococcus* sp. PCC 6301 has a molecular weight of 46,000 on denaturing SDS-PAGE (Grimm et al., 1989). Therefore, the native enzyme appears to be a homodimer, like other members of the aspartate aminotransferase enzyme family.

The GSA aminotransferase-encoding *hemL* gene (called *gsa* in plants and algae) has been cloned and sequenced from several plants, algae, and bacteria. These genes encode highly conserved peptides that have predicted molecular weights of approximately 46,000 and have recognizable similarity to other members of the aspartate aminotransferase enzyme family (Elliott et al., 1990; Matters and Beale, 1994). All *hemL/gsa*-encoded peptides have a conserved

putative active site containing an essential lysine, which is at position 265 in the *Synechococcus* sp. PCC 6301 enzyme (Grimm et al., 1991a). It is believed that the pyridoxal-phosphate cofactor binds to this lysine. Mutagenesis of this lysine inactivates the enzyme (Grimm et al., 1992; Ilag and Jahn, 1992). A *Synechococcus* sp. PCC 6301 mutant that was selected for resistance to gabaculine has a GSA aminotransferase with a lower specific activity than the wild-type enzyme. The mutation that confers gabaculine resistance is $\text{M}_{248}^{\text{F}}$ (Grimm et al., 1991b). Most, but not all GSA aminotransferases contain a methionine at this position (Matters and Beale, 1994).

B. Formation of the Tetrapyrrole Skeleton from ALA

1. Conversion of ALA to PBG

Formation of the first pyrrole in the pathway, PBG (Fig. 4), by asymmetric condensation of two ALA molecules is catalyzed by the enzyme PBG synthase (ALA dehydratase) (EC 4.2.1.24). PBG synthase from all sources examined, including plants and *Rb. sphaeroides*, has an octameric structure with native molecular weights ranging from 250,000 to 320,000 (Nandi and Shemin, 1968; Shibata and Ochiai, 1977; Huault et al., 1987; Jordan, 1991). An interesting difference among PBG synthase enzymes from different sources is the metal requirement: the animal, yeast, and *E. coli* enzymes require Zn^{2+} for activity (Jordan, 1991; Spencer and Jordan, 1993), the plant enzyme requires Mg^{2+} (Shibata and Ochiai, 1977; Liedgens et al., 1983), and the *Rb. sphaeroides* enzyme requires K^+ (Burnham and Lascelles, 1963; Nandi and Shemin, 1968). A comparative study concluded that PBG synthase from all sources has tightly-bound Zn^{2+} , but that a second, weaker metal-binding site binds Zn^{2+} in the animal, yeast, and *E. coli* enzymes and Mg^{2+} in the plant enzyme (Mitchell and Jaffe, 1993). The *E. coli* and plant enzymes were proposed to have a third metal-binding site which stimulates activity approximately two-fold when Mg^{2+} is bound (Mitchell and Jaffe, 1993). The *hemB* gene that encodes PBG synthase has been cloned from *Rb. sphaeroides* and expressed in *E. coli* (Delaunay et al., 1991). The expressed gene product has a molecular weight of 39,000.

Single turnover experiments with PBG synthase from *Rb. sphaeroides* have established that in the reaction, the first bound ALA molecule is the one

Fig. 4. Transformation of ALA to uroporphyrinogen III. Eight ALA molecules are shown in the approximate positions that their atoms occupy in the intermediates and final product. The conventional Fischer scheme for designating the pyrrole rings, peripheral pyrrole carbon atoms, and bridge carbons of tetrapyrroles is shown for uroporphyrinogen III.

that contributes the propionic acid side chain of the product (Jordan and Seehra, 1980). The fact that the *pro-S* hydrogen atom that is derived from the C₅ hydrogens of ALA is stereospecifically retained in the product indicates that during the in the formation of PBG, removal of hydrogen to form the aromatic pyrrole ring must occur on the enzyme (Abboud and Akhtar, 1976).

Some evidence exists for a regulatory role of PBG synthase in *Rb. capsulatus*. A *bchH* mutant strain of *Rb. capsulatus* cannot form BChl and accumulates

protoporphyrin IX when grown anaerobically. Oxygen inhibited the protoporphyrin IX accumulation (Biel, 1992; Chapter 52). Exogenous PBG, but not ALA, overcame the O₂ inhibition. The results were interpreted to indicate that O₂ regulates the conversion of ALA to PBG.

2. Conversion of PBG to Uroporphyrinogen III

Uroporphyrinogen III, the last common precursor of all end-product tetrapyrroles, is synthesized from

PBG by the sequential action of two enzymes, hydroxymethylbilane synthase and uroporphyrinogen III synthase (Fig. 4).

a. Hydroxymethylbilane Synthase

Hydroxymethylbilane synthase (PBG deaminase) (EC 4.1.3.8) condenses four PBG molecules to form the first tetrapyrrole, uroporphyrinogen. The initial product of enzymic catalysis is the linear tetrapyrrole, hydroxymethylbilane (preuroporphyrinogen), which, in the absence of uroporphyrinogen III synthase, spontaneously cyclizes to form uroporphyrinogen I. Biosynthesis of the biologically relevant isomer, uroporphyrinogen III, requires the action of uroporphyrinogen III synthase during or immediately after release of hydroxymethylbilane from PBG deaminase.

Hydroxymethylbilane synthase from most sources is a monomer of approximately 40,000 molecular weight, and the enzyme does not require metal ions or other cofactors for activity (Jordan, 1991). The *Rp. palustris* enzyme was reported to have a native molecular weight of 74,000, and it may be a dimer (Kotler et al., 1987). The *hemC* gene, which encodes hydroxymethylbilane synthase, has been cloned from several bacteria including *E. coli* (Thomas and Jordan, 1986) and *Cb. vibrioforme* (Majumdar et al., 1991; Moberg and Avissar, 1994), and the *E. coli* enzyme has been crystallized and its structure determined by X-ray crystallography (Louie et al., 1992).

Hydroxymethylbilane synthase from *Rb. sphaeroides* and *Euglena gracilis* was used to establish that the order of assembly of the four PBG units is ABCD, as they appear in uroporphyrinogen (Fig. 4) (Jordan and Seehra, 1979; Battersby et al., 1979a). The nascent monopyrrole- through tetrapyrrole-enzyme complexes are bound *via* a dipyrrole cofactor (Battersby et al., 1979b; Scott et al., 1980; Jordan and Berry, 1981; Battersby et al., 1983; Hart et al., 1987; Jordan and Warren, 1987; Warren and Jordan, 1988). In hydroxymethylbilane synthase from *E. coli*, the dipyrrole cofactor is attached to a cysteine residue (C₂₄₂ of the *E. coli* enzyme) after formation of the apoprotein, and it remains permanently attached to the enzyme, while the link between the cofactor and the nascent oligopyrrole chain is severed after the hexapyrrole stage is reached, which releases a tetrapyrrole and prepares the enzyme to accept new substrate molecules.

C. Uroporphyrinogen III Synthase

Hydroxymethylbilane is unstable in solution and it rapidly cyclizes to uroporphyrinogen I, a physiologically nonproductive end product. Uroporphyrinogen III synthase (EC 4.2.1.75) catalyzes closure of the tetrapyrrole macrocycle with inversion of ring D to form the type III product. The mechanism of ring inversion has been the subject of intensive investigation and is now generally believed to involve a *spiro* intermediate (Crockett et al., 1991, Stark et al., 1993). Uroporphyrinogen III synthase has been purified from several sources including *E. coli* (Jordan et al., 1988). The native enzyme from all sources is a monomer of approximately 29,000 molecular weight and contains no reversibly-bound cofactors or metal ions. The *hemD* gene, which encodes uroporphyrinogen III synthase, has been cloned from *E. coli*, sequenced, and overexpressed (Alwan et al., 1989; Sasarman et al., 1987; Jordan et al., 1988, Crockett et al., 1991). The *Cb. vibrioforme hemD* gene has been cloned and expressed in *E. coli* (Moberg and Avissar, 1994).

Hydroxymethylbilane synthase and uroporphyrinogen III synthase may form a complex that facilitates transfer of hydroxymethylbilane between the two enzymes. The presence of *E. gracilis* uroporphyrinogen III synthase influences the K_m of *E. gracilis* hydroxymethylbilane synthase for PBG (Battersby et al., 1979c). The sedimentation velocity of wheat germ hydroxymethylbilane synthase is also influenced by the presence of wheat germ uroporphyrinogen III synthase (Higuchi and Bogorad, 1975). The presence of *Rb. sphaeroides* uroporphyrinogen III synthase was reported to facilitate release of the tetrapyrrole product from hydroxymethylbilane synthase (Rosé et al., 1988).

D. The Branch from Uroporphyrinogen III to Reduced Hemes and Corrinoids

Siroheme (Fig. 5) is the prosthetic group of the assimilatory nitrite and sulfite reductases (ferredoxin-nitrite reductase, EC 1.7.7.1; NAD(P)H-nitrite reductase, EC 1.6.6.4; ferredoxin-sulfite reductase, EC 1.8.7.1; and NAD(P)H-sulfite reductase, EC 1.8.1.2) that are required for full reduction of highly oxidized forms of nitrogen and sulfur to NH_4^+ and S^{2-} (Siegel, 1978). Heme d_1 (Fig. 5) is another reduced heme that is a prosthetic group of the cytochrome *cd*₁

Fig. 5. Hemes of anoxygenic phototrophs. Siroheme is labeled according to the Fischer scheme.

type of dissimilatory nitrite reductase (EC 1.9.3.2), and is present in many bacteria. Interestingly, *Rb. sphaeroides* f. sp. *denitrificans* has an entirely different dissimilatory nitrite reductase that does not contain a tetrapyrrole prosthetic group (Michalski and Nicholas, 1985).

It is not clear how prevalent siroheme and heme d_1 prosthetic groups are in anoxygenic phototrophs, but siroheme-containing enzymes are likely to be present at least in those facultative and obligately aerobic species that must obtain their nitrogen and sulfur nutrients from oxygen-rich environments. In any case, many anoxygenic phototrophs are capable of coenzyme B_{12} biosynthesis, the initial step of which is shared with that of siroheme.

Formally, siroheme can be derived from uropor-

phyrinogen III by: (a) methylation of the tetrapyrrole ring at positions 1 and 3 to form precorrin 2; (b) oxidation of precorrin 2 to the tetrahydroporphyrin, sirohydrochlorin, by removal of two electrons; (c) chelation of Fe^{2+} . The alternative fate for precorrin 2 is conversion to corrins (coenzyme B_{12} nucleus) (Fig. 1).

Chemical arguments suggest that the order of the steps of siroheme formation from uroporphyrinogen III is probably that given above: first methylation, then oxidation, and finally Fe^{2+} chelation. Methylation of rings A and B of uroporphyrinogen III to produce precorrin 2 effectively limits subsequent oxidation beyond the tetrahydroporphyrin (dihydrochlorin) state. Oxidation of precorrin 2 to sirohydrochlorin produces a compound that has the aromaticity and

metal-binding properties necessary for efficient chelation of Fe^{2+} . Heme d_1 could be formed from siroheme by the replacement of the propionate groups on rings A and B with oxygen atoms, decarboxylation of the acetate groups on rings C and D to methyl groups, and the oxidation of the 7-propionate to an acrylate group (Wu and Chang, 1987). The methyl groups at positions 1 and 3 of heme d_1 are in the same configuration as those of siroheme and, like the methyl groups of siroheme (see below), they are derived from *S*-adenosyl-L-methionine (Yap-Bondoc et al., 1990).

The methyl groups of siroheme were shown to be derived from methionine in *E. coli* cells (Siegel et al., 1977), and precorrin 2 is formed in vitro from *S*-adenosyl-L-methionine and uroporphyrinogen III in a reaction catalyzed by uroporphyrinogen methyltransferase (Warren et al., 1990). On the basis of the structure of a singly-methylated (1-methyl) product isolated from *Clostridium tetanomorphum* (Deeg et al., 1977), and the incorporation of 1-methyl-uroporphyrinogen III into cobyrinic acid by extracts of *Propionibacterium shermanii* (Brunt et al., 1989), the order of methylation was deduced to be first at the 1-position, and then at the 3-position. In *Pseudomonas denitrificans*, uroporphyrinogen methyltransferase is encoded by the *cobA* gene (Crouzet et al., 1990). A somewhat different methyltransferase is encoded by the *cysG* gene in *E. coli* (Warren et al., 1990) and *S. typhimurium* (Goldman and Roth, 1993). It is of interest that *cysG* is the only known genetic locus specifically associated with siroheme synthesis in enteric bacteria. *cysG* encodes a 52,000 molecular weight peptide. Its COOH-terminal region is similar to the smaller, 29,200 molecular weight peptide encoded by the *cobA* gene. Because *cysG* is the only known gene of *S. typhimurium* that is involved in siroheme synthesis, and because only a portion of its encoded peptide is similar to the smaller *cobA* product, the CysG protein may be a multifunctional enzyme that catalyzes all steps of the conversion of uroporphyrinogen III to siroheme in the enteric bacteria (Goldman and Roth, 1993). In any case, it appears that Fe^{2+} insertion into sirohydrochlorin is not catalyzed by the ferrochelatase that is responsible for protoheme formation (Powell et al., 1973; Hansson and Wachenfeldt, 1993). That enzyme is encoded by the *hemH* gene in *E. coli* (previously known as *visA*) (Frustaci and O'Brian, 1993), *B. subtilis* (Hansson and Hederstedt, 1992), and *Bradyrhizobium japonicum* (Frustaci and O'Brian, 1992) (see below).

E. The Branch from Uroporphyrinogen III to Protoporphyrin IX

1. Decarboxylation of Uroporphyrinogen III to Form Coproporphyrin III

Uroporphyrinogen decarboxylase (EC 4.1.1.37) catalyzes the decarboxylation of all four of the acetate residues on uroporphyrinogen to yield coproporphyrinogen, which contains methyls in their place. At physiological substrate concentrations, the decarboxylations occur in a specific sequence, beginning at ring D and proceeding clockwise around the macrocycle (Luo and Lim, 1993). At higher substrate concentrations, the decarboxylation sequence becomes random (Luo and Lim, 1993; Jones and Jordan, 1993). No metal requirements were detected. A stereochemical analysis of the reaction indicated that the decarboxylations proceed with retention of configuration about the α -carbon atoms, i.e., the lost carboxyl groups are replaced with solvent hydrogens in the same orientation (Barnard and Akhtar, 1975).

Uroporphyrinogen decarboxylase has been purified to homogeneity from *Rb. sphaeroides*, and the native enzyme was characterized as a 41,000 molecular weight monomer (Jones and Jordan, 1993). The enzyme from *Rp. palustris* was also reported to be a monomer, with a molecular weight of 46,000 (Koopman et al., 1986). The gene that encodes uroporphyrinogen decarboxylase has been cloned from several eucaryotes including yeast and mammals, as well as *B. subtilis*, in which it has been identified with the *hemE* locus (Hansson and Hederstedt, 1992). *B. subtilis hemE* encodes a 40,347 molecular weight peptide.

2. Oxidative Decarboxylation of Coproporphyrinogen III to Form Protoporphyrin IX

Coproporphyrinogen oxidase (EC 1.3.3.3) oxidatively decarboxylates the propionate groups at positions 2 and 4 of coproporphyrinogen III to vinyls, thereby producing protoporphyrinogen IX. The enzyme is specific for the III isomer of coproporphyrinogen over the nonphysiological I isomer, although chemically synthesized coproporphyrinogen IV is also decarboxylated by the enzyme (Mombelli et al., 1976). Evidence indicating that the 2-propionate is converted before the 4-propionate includes characterization of a 2-monovinyl intermediate in rat liver

preparations (Elder et al., 1978) and the preferential action of the *E. gracilis* enzyme on the chemically synthesized 2-monovinyl porphyrin compared to the ring 4-monovinyl porphyrin (Cavaleiro et al., 1974).

In obligately aerobic organisms, coproporphyrinogen oxidase is an O₂-requiring reaction. Extracts of anaerobically-grown *Rb. sphaeroides* cells can carry out the reaction anaerobically in the presence of ATP, oxidized pyridine nucleotide, and methionine (Tait, 1972). Similar requirements were reported for anaerobic extracts of yeast (Poulson and Polglase, 1974) and *B. japonicum* (Keithly and Nadler, 1983). Involvement of *S*-adenosyl-L-methionine in the reaction is indicated by its inhibition by *S*-adenosyl-L-homocysteine (Tait, 1972).

Seehra et al. (1983) have studied the anaerobic as well as the aerobic coproporphyrinogen oxidase reactions in extracts of *Rb. sphaeroides*. The oxidative decarboxylations proceed with specific loss of the pro-*S*- β -protons of the propionate groups and retention of the pro-*R* protons. A reaction mechanism was proposed involving pyrrolic N-assisted removal of single protons as hydride ions from the β -carbons of the propionate groups. The α -protons of the propionate groups do not appear to be involved: In the reaction catalyzed by an avian blood extract, both of the α -protons of both propionate groups were retained on the terminal carbon atoms of the protoporphyrinogen vinyl groups (Zaman and Akhtar, 1978).

Yeast coproporphyrinogen oxidase is a 70,000 molecular weight homodimer that contains two molecules of Fe (Camadro et al., 1986). A yeast gene (*HEM13*) encoding coproporphyrinogen oxidase has been cloned and sequenced (Zagorec et al., 1988), and a soybean nuclear gene that encodes a 43,000 molecular weight protein complements a yeast *HEM13* mutant (Madsen et al., 1993). The deduced soybean gene product is 50% similar to the yeast *HEM13* gene product. An *Rb. sphaeroides* gene has been cloned and sequenced that, when overexpressed in *E. coli*, causes increased coproporphyrinogen oxidase activity (Coomber et al., 1992). The *Rb. sphaeroides* gene product has a predicted molecular weight of 34,000 and is 44% identical to the yeast *HEM13* product. Because *Rb. sphaeroides* cells in which this gene was disrupted were unable to form BChl under anaerobic inducing conditions, but were able to grow aerobically, it was proposed that in *Rb. sphaeroides*, the gene product is an anaerobic coproporphyrinogen oxidase dedicated to BChl

synthesis. However, it was not reported whether O₂ was required for activity of the recombinant coproporphyrinogen oxidase obtained from *E. coli* cells expressing the *Rb. sphaeroides* gene.

The *E. coli hemF* gene has been cloned by complementation of a yeast *HEM13* mutant (Troup et al., 1994). *E. coli hemF* encodes a 34,300 molecular weight peptide that is 43% identical to the yeast *HEM13* product. *S. typhimurium* contains two genes, *hemF* and *hemN*, either of which can support aerobic heme synthesis (Xu et al., 1992). The *hemF* gene encodes a peptide with a predicted molecular weight of 34,400 that is 44% identical to the yeast *HEM13* product and 90% identical to the *E. coli hemF* product (Xu and Elliott, 1993). Because *hemN* mutants accumulated coproporphyrinogen III and were auxotrophic for protoheme when grown anaerobically, the authors suggested that the *hemN* product is an anaerobic coproporphyrinogen oxidase. The predicted *S. typhimurium hemN* product is a 52,800 molecular weight peptide that is 38% identical to the *Rb. sphaeroides hemF* product but has little if any similarity to the *S. typhimurium hemF* product (Xu and Elliott, 1994). Interestingly, the predicted amino acid sequence of the *Rb. sphaeroides hemF* and *S. typhimurium hemN* products are significantly similar (35% identity) to a portion of the *Rhizobium phaseoli* and *R. leguminosarum nifD* gene product, which is the α -subunit of nitrogenase.

3. Oxidation of Protoporphyrinogen IX to Form Protoporphyrin IX

Protoporphyrinogen oxidase (EC 1.3.3.4) catalyzes the removal of six electrons from the tetrapyrrole macrocycle to form protoporphyrin IX, the last biosynthetic step that is common to hemes and chlorophylls. In obligately aerobic organisms, O₂ is the electron acceptor and is required for enzyme activity. In contrast, the *Rb. sphaeroides* protoporphyrinogen oxidase cannot use O₂ directly as an oxidant, but instead, protoporphyrinogen IX oxidation is coupled to the respiratory electron transport chain (Jacobs and Jacobs, 1981). The same is true for the protoporphyrinogen oxidase reaction in anaerobic *E. coli* cells, which is coupled to the reduction of nitrate or fumarate (Jacobs and Jacobs, 1976).

There is an interesting stereochemistry in the removal of the four meso hydrogens from protoporphyrinogen IX. In the transformation of PBG to protoporphyrinogen IX, the meso-bridge methylene

carbon atoms are derived from the aminomethyl carbon (C_{11}) of PBG (see Fig. 4). If the protoheme was formed from PBG that was labeled nonstereospecifically with ^3H at C_{11} , then all four meso positions of the porphyrin moiety were equally labeled with ^3H (Jones et al., 1984). However, if the PBG was labeled specifically in the *pro-S* hydrogen at C_{11} , then the product contained ^3H only at the β -meso position (the one between rings B and C). Given the fact that the incorporation of the four PBG groups into the original tetrapyrrole, hydroxymethylbilane, is an oligomerization that probably involves a single reaction mechanism, and given that cyclization of the hydroxymethylbilane to form the porphyrinogen macrocycle does not seem to cause loss of label from the γ and δ meso methylene hydrogens, it seems likely that the C_{11} *pro-S* hydrogen of PBG will be found on the same face of the porphyrinogen at all four meso positions. Therefore, the hydrogen that is removed from the β -meso position must be removed from the opposite face of the molecule than the ones that are removed from the α , γ , and δ meso positions. It was hypothesized that three of the meso hydrogens are lost by an oxidation process occurring on one face of the molecule, and that the fourth proton is lost from the other face by a tautomerization reaction (Jones et al., 1984). Confirmation of this hypothesis will require determination of whether the uroporphyrinogen III synthase reaction affects the stereochemistry of the γ and δ meso methylene hydrogens.

In eucaryotic organisms, protoporphyrinogen oxidase is a mitochondrial or chloroplast membrane-associated protein that has an apparent molecular weight of 210,000 and is composed of 36,000 molecular weight subunits (Jacobs and Jacobs, 1987). The *Rb. sphaeroides* enzyme is also associated with membranes (Jacobs and Jacobs, 1981). Detergent-solubilized protoporphyrinogen oxidase from the anaerobe *D. gigas* was reported to have a native molecular weight of 148,000 and to contain three dissimilar subunits of 12,000, 18,500, and 57,000 molecular weight (Klemm and Barton, 1987). In contrast to the above enzymes, the *B. subtilis* protoporphyrinogen oxidase is soluble (Dailey et al., 1994).

In *S. typhimurium*, the *hemG* gene was suggested to encode protoporphyrinogen oxidase, on the basis of the accumulation of protoporphyrin IX (as well as coproporphyrin III and uroporphyrin III) in *hemG* mutants (Xu et al., 1992). In *B. subtilis*, mutations at

the *hemY* locus caused accumulation of either coproporphyrinogen III alone or both coproporphyrinogen III and protoporphyrinogen IX (Hansson and Hederstedt, 1992). It was originally proposed that the *B. subtilis hemY* product, which at 51,400 molecular weight is significantly larger than the *S. typhimurium* HemF and the 37,600 molecular weight yeast coproporphyrinogen oxidase that is encoded by the *HEM13* gene, may be a bifunctional enzyme that has both coproporphyrinogen oxidase and protoporphyrinogen oxidase activities (Hansson and Hederstedt, 1992). More recently, however, the *B. subtilis hemY* gene was expressed in *E. coli* and its product was determined to have protoporphyrinogen oxidase activity, but not coproporphyrinogen oxidase activity (Dailey et al., 1994). It was suggested that the *B. subtilis* gene designation be changed from *hemY* to *hemG*, to correspond with the protoporphyrinogen oxidase-encoding gene of *S. typhimurium*.

The *E. coli hemG* gene has been cloned, sequenced and expressed (Sasarman et al., 1993). The cloned gene complements a protoporphyrinogen oxidase-deficient *E. coli* mutant and the expressed *hemG* product has protoporphyrinogen oxidase activity. *E. coli hemG* encodes a 21,202 molecular weight membrane-associated peptide that is considerably smaller than the protoporphyrinogen oxidase peptides from barley, *B. subtilis*, yeast and mouse liver, which have molecular weights of 36,000, 51,400, 56,000 and 65,000, respectively.

F. Chelation of Iron to Form Protoheme

The last step of protoheme formation, insertion of Fe^{2+} into protoporphyrin IX, is catalyzed by ferrochelatase (protoheme ferrolyase, EC 4.99.1.1). In addition to its physiological substrates, ferrochelatase can use Zn^{2+} and Co^{2+} as the metal substrate and deuteroporphyrin IX, mesoporphyrin IX, and hematoporphyrin IX as the porphyrin substrate. Ferrochelatase from most sources, including *Rb. sphaeroides*, is an intrinsic membrane protein that requires detergents or chaotropic agents for solubilization (Dailey, 1982). An apparent exception is the *B. subtilis* ferrochelatase, which was reported to be a soluble enzyme (Hansson and Hederstedt, 1992). Detergent-solubilized ferrochelatase from *Rb. sphaeroides* is a 115,000 molecular weight monomer (Dailey, 1982). No chromophoric prosthetic groups were detected. Mg-protoporphyrin IX is a powerful inhibitor of *Rb. sphaeroides* ferrochelatase: It inhibits

by 50% at 4 μM and nearly completely at 80 μM (Jones and Jones, 1970). However, it is uncertain whether the intracellular free Mg-protoporphyrin IX ever reaches inhibitory concentrations.

The *hemH* gene, which encodes ferrochelatase, has been cloned and sequenced from yeast and several animal sources, as well as from *E. coli* (Miyamoto et al., 1991; Frustaci and O'Brian, 1993), *S. typhimurium* (Xu et al., 1992), *B. japonicum* (Frustaci and O'Brian, 1992), and *B. subtilis* (Hansson and Hederstedt, 1992). The molecular weights of the encoded polypeptides from these bacterial genes range from 34,000 to 38,000 and are somewhat smaller than the polypeptides encoded by the animal and yeast genes.

G. Biosynthesis of Other Protoporphyrin IX-Based Hemes

1. Protoheme Ligation to Apoproteins to Form Heme c

All phototrophic organisms contain one or more types of cytochrome *c* which function as components of the photosynthetic and respiratory electron transport chains (Meyer and Cusanovich, 1989). Heme *c* is the covalently bound prosthetic group of *c*-type cytochromes (Fig. 5). Apocytochromes *c* incorporate protoheme by enzyme-catalyzed ligation of the vinyl groups to cysteine residues on the protein. A specific ligating enzyme, named cytochrome *c* heme lyase, has been described in yeast and *Neurospora crassa* (Taniuchi et al., 1983; Nicholson et al., 1987). In these eucaryotic cells, heme lyase is localized in the inner mitochondrial membrane (Nargang et al., 1988; Enosawa and Ohashi, 1986) and ligation requires reduced (ferro)protoheme as a substrate (Nicholson and Neupert, 1989). Genes for cytochrome *c* heme lyase have been cloned and sequenced from yeast (*CYC3*) and *N. crassa* (*cyt-2*) (Dumont et al., 1987; Drygas et al., 1989). Although the two encoded peptides are 32% identical, the yeast peptide is considerably smaller than the *N. crassa* peptide (molecular weights of 29,600 and 38,000, respectively). A second yeast heme lyase, cytochrome-*c*₁-heme lyase, is responsible for assembly of cytochrome *c*₁ (Zollner et al., 1992). This protein is encoded by the *CYT2* gene, which has been cloned and sequenced. The two yeast heme lyases are 35% identical. The yeast results suggest that each *c*-type cytochrome may require a different, specific heme lyase for its formation.

In gram-negative bacteria, *c*-type cytochromes are located in the periplasmic space. *Rb. sphaeroides* and *Rb. capsulatus* contain at least five distinct cytochromes *c* (Meyer and Cusanovich, 1989). In *Rb. capsulatus*, several genes have been identified that are necessary for the biogenesis of all cytochromes *c* but are not required for synthesis and secretion of apocytochrome *c* into the periplasmic space (Davidson et al., 1987; Biel and Biel, 1990; Beckman et al., 1992). One group of these genes, *helA*, *helB*, and *helC*, are similar to a class of transporter proteins and their products may be involved in exporting protoheme to the periplasmic space (Beckman et al., 1992). The products of two other genes, *ccl1* and *ccl2*, have no recognizable similarity to yeast heme lyases, but they do have similarity to mitochondrial and chloroplast open reading frames with unassigned function. The specific roles of *ccl1* and *ccl2* in cytochrome *c* formation have not been identified. The topic of heme attachment to cytochrome apoproteins is covered in more detail by Kranz and Beckman in Chapter 33.

2. Terminal Oxidase Hemes

Cytochrome oxidase (EC 1.9.3.1) of the *aa*₃ type is present in many obligate and facultative aerobic bacteria including *B. subtilis*, *Rb. sphaeroides* (Sasaki et al., 1970; Gennis et al., 1982; Garcia-Horsman et al., 1994; Chapter 44), and the BChl-containing obligate aerobe *Erythrobacter longus* (Fukumori et al., 1987). The heme *a* prosthetic group of cytochrome oxidase (Fig. 5) is formed from protoheme by ligation of a farnesyl group to the 2-vinyl group and oxidation or oxygenation of the 8-methyl group to a formyl group. The precursor status of protoheme has been shown in *B. subtilis*. Strains that are defective in enzymes that catalyze the later steps of protoheme formation (uroporphyrinogen decarboxylase, coproporphyrinogen oxidase, protoporphyrinogen oxidase, and ferrochelatase) could not form heme *a* unless protoheme was added to the medium, even though the same cells could form siroheme, presumably using a different ferrochelatase for its biosynthesis (Hansson and Wachenfeldt, 1993).

Cytochrome *o* is an O₂-reducing terminal oxidase present in many facultative aerobes including *E. coli* and the phototrophs *Rb. capsulatus* (Zannoni et al., 1976), *Rhodospseudomonas viridis* (Kämpf et al., 1987), *Rp. palustris*, and *Rb. sphaeroides* (which also contains cytochrome *aa*₃) (Sasaki et al., 1970;

Anraku and Gennis, 1987; Garcia-Horsman et al., 1994). Heme *o*, the prosthetic group of cytochrome *o*, has the structure of a possible heme *a* precursor in which the 2-farnesyl group has been added but the 8-methyl group has not been converted to a formyl group (Wu et al., 1992). The *cyoE* gene of *E. coli*, when overexpressed, caused conversion of protoheme to heme *o* in vivo (Saiki et al., 1992), and the overexpressed *cyoE* gene product catalyzed in vitro condensation of ferrous protoheme and farnesylpyrophosphate to form heme *o* (Saiki et al., 1993). Two *B. subtilis* genes, *ctaA* and *ctaB*, are required for heme *a* synthesis (Svensson et al., 1993). The *ctaB* gene complements *E. coli cyoE* mutants. *B. subtilis ctaA* mutants accumulate heme *o* instead of heme *a*. *B. subtilis ctaB* mutants accumulate neither heme *o* nor heme *a*. Interestingly, the *B. subtilis ctaA* gene, when expressed in *E. coli*, caused the accumulation of heme *a*, even though *E. coli* normally does not produce this heme. These results indicate that *ctaB* and *ctaA* encode a farnesyltransferase and a methyl oxidase or oxygenase, respectively. The results also suggest that farnesylation precedes formyl group formation in heme *a* biosynthesis.

A third type of O₂-reducing terminal oxidase, cytochrome *d*, is present in some facultative aerobes including *E. coli* (Gennis, 1987; Garcia-Horsman et al., 1994) and *Rp. viridis* (Kämpf et al., 1987). Heme *d*, the prosthetic group of cytochrome *d*, has a dihydroxychlorin macrocycle structure (Fig. 5) (Sotiriou and Chang, 1988) that differs greatly from the sirohydrochlorin structure of heme *d*. Although the active form of heme *d* is believed to be the free dihydroxyl form shown in Fig. 5, the 6-hydroxyl group forms a lactone with the 6-propionate under some isolation conditions. In addition to its presence in cytochrome *d*, heme *d* is also found as the prosthetic group of *E. coli* catalase (EC 1.11.1.6) type HP11. However, heme *d* from these two sources is subtly different: while the two ring C hydroxyl groups of the cytochrome *d* prosthetic group are in the relative *trans* configuration (Timkovich et al., 1985), the hydroxyls are *cis* in the catalase HP11 heme *d* (Chiu et al., 1989). The absolute configurations of the hydroxyl groups have not been determined for either type of heme *d*. It can be deduced from the structure of heme *d* that it is derived from protoporphyrin IX or protoheme by hydroxylation. It was proposed (Timkovich and Bondoc, 1990) and later reported (Loewen et al., 1993) that *E. coli* catalase HP11 catalyzes the formation of its own heme *d* prosthetic

group from protoheme. It is not known whether a similar autologous conversion occurs for the prosthetic group of cytochrome *d*.

Acknowledgments

The author thanks Y. J. Avissar and D. W. Bollivar for critically reading the manuscript and making helpful suggestions. Research grant support from the National Science Foundation, the Department of Energy, and the U. S. Department of Agriculture is gratefully acknowledged.

Summary

Differences in profiles of polar lipids and quinones distinguish major groups of phototrophic prokaryotes. Also the fatty acid composition of representative species of purple sulfur bacteria, purple nonsulfur bacteria, green sulfur bacteria, *Chloroflexus aurantiacus* and *Heliobacterium* and *Heliobacillus* species are significantly different. Phospholipids, and specifically PG, are present in all phototrophic bacteria. The presence of ornithine lipids and the sulfolipid SQDG has been clearly established only in purple nonsulfur bacteria. Various glycolipids are major components in *Chloroflexus* and green sulfur bacteria and are also common in Chromatiaceae, but absent from Ectothiorhodospiraceae and *Heliobacterium*; occasionally, they occur in purple nonsulfur bacteria. The presence of MGDG has only been established for green sulfur bacteria. The specific distribution of major quinones in anoxygenic phototrophic bacteria and the variety of hopanoid triterpene structures found in these bacteria are considered in this chapter. A major part of the chapter is concerned with polar lipids of *Rhodobacter* species because they have been most intensively studied in this chapter. Also biosynthesis, lipid transfer activities, and incorporation of lipids into different membrane fractions are discussed. Special attention is paid to the influence of growth conditions on lipid and fatty acid composition and to possible differences in the composition of cellular membrane fractions (CM, ICM, OM).

I. Introduction

Lipids are important structural components of all biological membranes. They are essential for the formation of bilayer structures and for a number of membrane associated processes. The term 'lipids' is not clearly defined on the basis of a chemical structure, but lipids are characterized as a group of molecules which have only limited solubility in water and are more readily dissolved in organic solvents. Structurally and functionally completely different molecules are known as lipids (Ratledge and Wilkinson, 1988). In this chapter we will discuss *polar* lipids (including phospholipids, glycolipids, sulfolipids, aminolipids) and *apolar* lipids (including quinones and hopanoids). Some representative structures of lipids, quinones and hopanoids are shown in Fig. 1. Fatty acids will also be treated separately, although they are rarely present in the

free form but constitute a molecular part of polar lipids and other membrane lipids. Carotenoids, bacteriochlorophylls and complex lipids such as lipid A and lipoproteins typical of Gram-negative bacteria are not considered in this chapter; the reader is referred to Chapter 8 by Senge and Smith.

Phototrophic purple bacteria have three distinct types of membranes, the cytoplasmic membrane (CM), the intracytoplasmic membranes (ICM, also called chromatophores) and the outer membrane (OM), which is characteristic of all Gram-negative bacteria. The green bacteria lack intracytoplasmic membranes, but have chlorosomes that are bound by a lipid membrane, which is proposed to be a lipid unilayer (Staehelin et al., 1980). Though bacterial membranes differ in composition and function, various kinds of lipids and fatty acids are principal constituents. Together with integral membrane proteins, lipids form the continuum of the cytoplasmic membrane that separates the internal space of the bacterial cells from the external one. The functional unit of CM, ICM and OM is a bilayer with the head groups of polar lipids facing the inner and outer surface of this bilayer and the fatty acid tails touching each other in the membrane interior. In this way a hydrophobic interior and a hydrophilic membrane surface can be formed. The integrity of the cytoplasmic membrane bilayer is crucial for energy generation of the cells, for maintenance of gradients of a variety of solutes and the success of transport processes and thus for the survival of each single cell.

A second property important to membrane function

is the mobility of the membrane components, which significantly influences reaction kinetics within the membrane. Both bilayer stability and membrane fluidity are influenced by the composition of lipid headgroups, fatty acid structure, lipid-lipid and lipid-protein interactions, as well as external parameters such as temperature, pressure, salinity, pH and others. In order to maintain the functional integrity of their membranes, bacteria have developed mechanisms to

adapt their membrane composition to varying environmental conditions. Therefore, the qualitative and quantitative lipid composition of the membranes of a specific bacterium is not constant but varies with growth conditions and also with the growth phase. Nevertheless, specific compositions of lipids, fatty acids and quinones are characteristic properties of numerous bacterial species and can be valuable tools in species identification and taxonomy. However,

Fig. 1. Continued. Hopanoids.

whenever possible, standardized media and culture conditions have to be used for this purpose.

Indeed, lipids, fatty acids and quinones have been analyzed in recent years in a great number of bacteria. Their composition varies greatly among different bacteria and is used to differentiate bacterial groups and even closely related bacterial species. As would be expected from the great heterogeneity of anoxygenic phototrophic bacteria derived from physiological, structural as well as genetic information, the composition of lipids, fatty acids and quinones shows great variation among these bacteria.

This chapter will not give a comprehensive overview on the relevant literature of lipids, fatty acids and quinones of phototrophic bacteria. It rather presents a quite personal view of this topic and primarily will discuss the distribution of lipid

components among the species and groups of anoxygenic phototrophic bacteria. A comprehensive review and a detailed compilation of early data on lipids and fatty acids of phototrophic bacteria can be found in Kenyon (1978).

II. Polar Lipids and Fatty Acids

A. Polar Lipids

Great variation occurs in the polar lipid structures of different phototrophic bacteria. However, analytical procedures employed often do not give precise information on their exact chemical structure, which therefore, is still unknown for a number of lipids of phototrophic bacteria. This applies in particular to

some glycolipids and aminolipids.

Though the polar lipid composition under standard cultivation conditions is a stable property, the qualitative and quantitative composition may change with the growth conditions much more than that of quinones, but in general less than that of fatty acids. From the data available it is obvious that major groups of phototrophic bacteria can be differentiated on the basis of their polar lipid composition (Table 1). Qualitative and quantitative differences between *Heliobacterium chlorum*, *Chloroflexus aurantiacus*, green sulfur bacteria, Chromatiaceae, Ectothiorhodospiraceae and purple nonsulfur bacteria are depicted in respect to their content of different phospholipids, glycolipids, sulfolipids and aminolipids. Relative proportions of glycolipids are high in Chlorobiaceae and Chloroflexaceae, but considerable lower in Chromatiaceae, which have higher proportions of phospholipids. Phospholipids are clearly dominant in purple nonsulfur bacteria and glycolipids are absent from the majority of these bacteria as they are from

Ectothiorhodospiraceae and *Hb. chlorum*.

1. Ectothiorhodospiraceae

The lipid composition of all Ectothiorhodospiraceae is characterized by the predominance of PG, PC and CL and minor but varying amounts of PE (Asselineau and Trüper, 1982; Imhoff et al., 1982). All species contain small to trace amounts of lyso-PE, and also PA, lyso-PC, and unidentified phospholipids have been found in some species. Glycolipids as found in Chromatiaceae, purple nonsulfur bacteria and green sulfur bacteria and ornithine lipids as known from purple nonsulfur bacteria, are absent in *Ectothiorhodospira* species (Asselineau and Trüper, 1982; Imhoff et al., 1982; Thiemann and Imhoff, 1991). In strains of *Ectothiorhodospira halophila*, both PG and CL separated into two distinct spots on two-dimensional TLC plates and were significantly different in their fatty acid composition (Thiemann and Imhoff, 1991). Nothing is known about

^a Data from references cited in the text.

differences of localization and function of these two fatty acid variants in *Ec. halophila*.

2. Chromatiaceae

The phospholipids, PG, PE and CL are major components of Chromatiaceae species, none of which is clearly predominant. Also lyso-PE could be detected in the investigated species (Imhoff et al., 1982; Steiner et al., 1969; Takacs and Holt, 1971). Additional aminophospholipids were found in *Thiocapsa roseopersicina* and *Thiocystis gelatinosa*, but not in *Chromatium vinosum*, *Chromatium minus* and *Chromatium warmingii* (Imhoff et al., 1982). PC was absent from these species.

Several glycolipids were found in almost all Chromatiaceae (Imhoff et al., 1982; Imhoff, unpublished results). The number of glycolipid components and their chromatographic properties varied with the species. One of these glycolipids, which was characterized from *Chromatium vinosum*, had similar chromatographic and staining properties to MGDG but was shown to lack galactose and to be a monoglucosyldiglyceride (Steiner et al., 1969). Galactose was also absent from hydrolyzed total lipid extracts, proving the absence of galactolipids from this species. This glycolipid may be present in other species of the Chromatiaceae as well (Imhoff et al., 1982; Imhoff, 1988; Imhoff, unpublished results). Two other glycolipids from *Chromatium vinosum* have been described as mannosyl, glucosyldiglyceride and as dimannosyl, glucosyl-diglyceride (Steiner et al., 1969). Whether these also occur in other Chromatiaceae is not known. Glycolipids from *Thiocapsa roseopersicina* were found to contain glucose and rhamnose (Takacs and Holt, 1971). SQDG has so far not been identified in Chromatiaceae species, although glycolipids with similar chromatographic properties were present (Imhoff et al., 1982).

3. Purple Nonsulfur Bacteria

The polar lipid composition of purple nonsulfur bacteria shows the greatest diversity of all groups of phototrophic bacteria. In many cases polar lipid compositions are characteristic of the species. Phospholipids are predominant in all species, ornithine lipids and other aminolipids are characteristic for these bacteria, whereas glycolipids are not common, but present in some species in smaller proportions (Kenyon, 1978; Imhoff et al., 1982;

Imhoff, 1988). Among the lipids most commonly distributed in these bacteria are PG, PE, OA and CL, while PC and SQDG characteristically are present in some species but absent from others. Glycolipids with chromatographic properties similar to MGDG only occasionally have been found. The presence of such a glycolipid in *Rs. molischianum* reported by Constantopoulos and Bloch (1967) could not be verified later (Imhoff et al., 1982), but lipids with similar chromatographic properties have been found in *Rs. salexigens* and *Rp. sulfoviridis* (Imhoff, unpublished results). Their exact chemical structure is unknown.

a. Sulfolipids

Sulfolipids have obtained much interest because it was thought that they may play a functional role in photosynthesis. The first evidence of SQDG, the 'plant type sulfolipid', in an anoxygenic phototrophic bacterium was obtained for *Rs. rubrum* (Benson et al., 1959). Later this sulfolipid was found in *Rm. vannielii* at very low proportions of only 0.01% of cell dry weight (Park and Berger, 1967) and in *Rb. sphaeroides* containing 2–4% of this sulfolipid (Wood et al., 1965; Radunz, 1969; Russell and Harwood, 1979). Its presence in *Rb. capsulatus* at low proportions (Russell and Harwood, 1979) could not be reproduced by others (Wood et al., 1965; Imhoff et al., 1982; Imhoff, 1991). On the basis of incorporation of label from radioactive sulfur sources, however, Sulfolipids were found in several other species including *Rb. capsulatus* at very low proportions (Imhoff, 1984b). Significant amounts of the plant type sulfolipid have been found in *Rp. marina*, *Rs. salexigens* and some *Rhodobacter* species (Tables 1 and 2) (Imhoff et al., 1982; Imhoff, 1984b). The identity of the head group of the sulfolipid from *Rb. sphaeroides* with that from spinach leaves was demonstrated by identical fragmentation pattern in fast atom bombardment mass spectrometry (Gage et al., 1992).

During studies with radioactively labelled sulfur sources, several sulfolipids were detected in purple nonsulfur bacteria (Imhoff, 1984b). Sulfate as well as reduced sulfur compounds (thiosulfate and cysteine) served as sulfur sources for the sulfolipids in these species. The relative proportions of the sulfolipid in *Rb. sulfidophilus* were not significantly influenced by the sulfur source, but reduced sulfur sources inhibited the incorporation of label from ^{35}S -

sulfate (Imhoff, 1984b). This indicates the preference of reduced sulfur compounds over sulfate as a source of sulfur for this sulfolipid. Sulfolipids in high proportions were also found in *Rp. sulfoviridis* and *Rb. adriaticus*, which are unable to assimilate sulfate and depend on reduced sulfur sources. Both species incorporated sulfur from the reduced sulfur sources into their sulfolipids (Imhoff, 1984b). The major sulfolipids of *Rp. viridis* and *Rp. sulfoviridis* had R_f -values different from SQDG (Imhoff, 1984b).

b. Ornithine lipids

Many Gram-negative bacteria have ornithine lipids with amide-linked hydroxy fatty acids that show some structural similarity to the lipid A of lipopolysaccharides and may fulfill some of its functions (Wilkinson et al., 1982). Ornithine lipids have been found in *Rs. rubrum*, *Rp. palustris*, *Rubrivivax gelatinosa*, *Rp. viridis*, *Rm. vannielii* and others (Brooks and Benson, 1972; DePinto, 1967; Gorchein, 1968; Russell and Harwood, 1979; Wood et al., 1965). Apparently ornithine lipids are generally present in and characteristic for purple nonsulfur bacteria (Imhoff et al., 1982). The presence of ornithine-PG in several purple nonsulfur bacteria, claimed by Wood et al. (1965), was not confirmed later (Imhoff et al., 1982; Imhoff, 1991). A lipid that could be ornithine-PG according to chromatographic and staining properties, but was not clearly identified, was found in *Rm. vannielii* and *Rhodopila globiformis* (Imhoff et al., 1982). Ornithine-PG has been identified in *Rm. vannielii* (Park and Berger, 1967).

The ornithine lipid from *Rb. sphaeroides* has been shown to be an ester of N-acylornithine with a long-chain fatty acid residue forming an amide bond with the α -amino group of ornithine and an alcohol residue esterified to its carboxyl group (Gorchein, 1968). Another ornithine amide was identified in *Rs. rubrum* with a long chain fatty acid esterified to the hydroxyl group of a 3-hydroxy fatty acid, which in turn forms an amide bond with the α -amino group of ornithine (Brooks and Benson, 1972). Either of these compounds or a mixture of them may be present in other species of purple nonsulfur bacteria.

4. Polar Lipids of Rhodobacter Species

Most reports on composition and metabolism of phospholipids deal with one or the other species of the genus *Rhodobacter*, in particular with *Rb.*

sphaeroides. Polar lipids of *Rb. sphaeroides* and *Rb. capsulatus* have been investigated repeatedly (Wood et al., 1965; Russell and Harwood, 1979; Marinetti and Cattieu, 1981; Gorchein, 1968; Imhoff et al., 1982) and also the polar lipid composition of *Rb. sulfidophilus* has been reported (Imhoff et al., 1982). A comparison of polar lipid and fatty acid compositions of the six described *Rhodobacter* species on the basis of 21 strains has been undertaken recently (Imhoff, 1991). All strains were grown under identical conditions anaerobically in the light at their respective optimum salinity. Each of the investigated species revealed a specific polar lipid composition (Table 2).

There is a general agreement upon the presence of PC, PG and PE and the absence of SQDG and CL in whole cell lipid extracts from *Rb. capsulatus* (see Kenyon, 1978), though the results of Russell and Harwood (1979) imply the presence of CL and SQDG in one strain (NCIB 8253) of this species. An aminolipid, which is most probably identical to the ornithine amide from *Rb. sphaeroides*, has not been reported in earlier literature, but has been regularly found later (Russell and Harwood, 1979; Imhoff et al., 1982; Imhoff, 1991). The presence of ornithine-PG postulated by Wood et al. (1965) could not be verified.

In *Rb. sphaeroides*, the presence of SQDG, CL and ornithine amide in addition to PC, PG and PE is generally agreed on. The ornithine lipid of this species has been characterized (see above) and may be common to all *Rhodobacter* species. It was named ornithine lipid 1 (OL1, Imhoff et al., 1982) and later aminolipid (AL, Imhoff, 1991). The analysis of the lipids of *Rb. sphaeroides* by Marinetti and Cattieu (1981) revealed the presence of three nitrogen bases, ethanolamine, ornithine and an unidentified amino-compound with chromatographic mobility as 1-amino-3-propanol. These authors concluded that an unknown aminolipid 'is a fatty acid amide of ornithine and of 1-aminopropanol or some other diamino compound'. Although the structure of this lipid needs to be established, it may well be that depending on the species and the growth conditions, much more structural variability among the aminolipids of purple nonsulfur bacteria exists than hitherto known.

During studies on cell-cycle specific accumulation of phospholipids into the intracytoplasmic membrane, an unknown phospholipid, later identified as N-acylphosphatidylserine (NAPS) was detected in *Rb. sphaeroides* strain M29-5 (Cain et al., 1981; Donohue

Table 2. Major polar lipids of *Rhodobacter* species^a

et al., 1982a). An unknown phospholipid with similar properties to NAPS was also detected in *Rb. sphaeroides* strain NCIB 8253 (Onishi and Niederman, 1982). This lipid represented between 20–45% of the total cellular phospholipids in several strains of *Rb. sphaeroides* (except two wild type strains) and *Rb. capsulatus* grown either photoheterotrophically or chemoheterotrophically in Tris supplemented culture media (Donohue et al., 1982b). Its accumulation at the expense of PE ceased immediately upon the removal of Tris (Donohue et al., 1982b). Together with the other phospholipids, the accumulated NAPS was distributed to all membrane systems of the cell. Small levels (1.0 to 2.0%) of NAPS also were present in *Rs. rubrum* and *Rp. palustris* (Donohue et al., 1982b). From the labeling pattern observed in pulse-chase experiments it was concluded that NAPS is neither a product of the direct acylation of PS nor an obligate precursor in the PS biosynthesis, but is probably a metabolite of an undescribed branch of phospholipid biosynthesis (Cain et al., 1982; 1983).

a. Biosynthesis and Lipid Transfer Activities

Biosynthesis of PE and PG in *Rb. sphaeroides* apparently proceeds as in *E. coli* with CDP-diglyceride as intermediate reacting either with sn-glycerol-3-phosphate or L-serine to yield PG (via phosphatidylglycerophosphate) or PE (via PS), respectively (Cain et al., 1983). Enzymatic activities that transfer fatty acids from acyl-ACP to glycerol-3-phosphate forming lyso-PA and PA have been found in a particulate fraction from *Rb. sphaeroides* grown phototrophically (Lueking and Goldfine, 1975). In pulse-chase experiments with (2-³H)glycerol, PA was the earliest identifiable glycerol-containing intermediate and was considered to be the product of the sn-glycerol-3-phosphate acyltransferase activity (Cain et al., 1983). PA labeling decreased with the increase in PS label, followed by accumulation of

label in PE concomitant with a decrease in that of PS. After treatment of the cells with 50 μ M hydroxylamine, a known inhibitor of PS decarboxylase of *E. coli* (Raetz and Kennedy, 1972), an accumulation of label in PS at the expense of that in PE was observed. Both the transient labeling of PS and the accumulation of label in PS in the presence of hydroxylamine emphasize the precursor-product relationship between these two phospholipids (Cain et al., 1983). Synthesis of PC by successive methylation of PE has been demonstrated by studies with methyl-¹⁴C-methionine that yielded label in phosphatidyl-N-methylethanolamine, phosphatidyl-N,N-dimethylethanolamine and PC (Gorchein et al., 1968a).

Apparently lipids are synthesized in the CM or in distinct domains thereof and transferred from the location of biosynthesis to other membranes. Intracytoplasmic membranes of *Rb. sphaeroides* grown under photoheterotrophic conditions are considered to originate from the cytoplasmic membrane (Gorchein et al., 1968b; Drews and Oelze, 1981; Kaplan and Arntzen, 1982; Niederman and Gibson, 1978). When non-pigmented cells of *Rb. sphaeroides* double-labeled with ³²P and methyl-¹⁴C-methionine were allowed to adapt to semi-anaerobic growth conditions to induce the development of intracytoplasmic membranes, lipids of the cytoplasmic membrane became incorporated into the ICM (Gorchein et al., 1968b). Thus, a complete de novo biosynthesis of ICM of *Rb. sphaeroides* was ruled out and it was concluded that the ICM and their lipids originate from the cytoplasmic membrane (Gorchein et al., 1968b). These findings were substantiated later by further detailed studies. Enzymes of phospholipid biosynthesis mainly were found located within the CM of *Rb. sphaeroides* (Cooper and Lueking, 1984; Cain et al., 1984; Radcliffe and Niederman, 1984; Radcliffe et al., 1985). A separation of the membranes from *Rb.*

sphaeroides strain NCIB 8253 by density gradient centrifugation verified the localization of enzyme activities catalyzing the first steps of phospholipid biosynthesis in membrane fractions of the cells (Radcliffe et al., 1985). Both in chemoheterotrophically and in photoheterotrophically grown cells, the majority of the activity of phosphatidyl-glycerophosphate synthase (EC 2.7.8.5.) was found in the CM and was distributed uniformly over this membrane (Radcliffe et al., 1985; 1989). Phosphatidylserine (PS) synthase activity (EC 2.7.8.8), however, was associated with a lower membrane fraction present in photo- and chemotrophically grown cells and located at the position of ICM of phototrophically grown cells. The authors suggested that PS synthase is localized in distinct domains of the cytoplasmic membrane, which after cell disruption and separation by density gradient centrifugation, form a band together with the ICM fraction (Radcliffe et al., 1985, 1989).

Phospholipid transfer activities have been detected in *Rb. sphaeroides* cells grown chemotrophically and phototrophically (Tai and Kaplan, 1984; 1985). The cellular distribution of these activities was similar under both conditions and the total cellular activity was directly related to the growth rate (Tai and Kaplan, 1985). Activities were found to be membrane-associated as well as in soluble cell fractions (15% membrane-associated, 32% periplasmic, 53% cytoplasmic at medium light intensity). Cells grown anaerobically at low light intensity, characterized by large amounts of ICM, had the highest membrane-associated transfer activity, whereas aerobically grown cells (lacking ICM) only showed minor activities of the membrane-associated enzyme, indicating that this activity could be involved in ICM biogenesis (Tai and Kaplan, 1985). Soluble transfer activity was low under low light conditions, but much higher under high light conditions (91.4% of total transfer activity) (Tai and Kaplan, 1985). Both cytoplasmic and periplasmic phospholipid transfer activities had different preferences for their substrates. The cytoplasmic transfer activities showed a clear preference for PG over PE and PC, while the periplasmic activity transferred phospholipids without a specific preference (Tai and Kaplan, 1985).

b. Incorporation of Lipids into ICM

During the normal cell cycle lipid incorporation into ICM apparently occurs only within a limited time

interval in close relation to the division of the cells, which does, however, not reflect cyclic changes in lipid biosynthesis but rather transfer of lipids into the growing ICM from other 'places of the cell' (Lueking et al., 1978; Fraley et al., 1979; Cain et al., 1981). The discontinuous increase of net accumulation of phospholipids into intracytoplasmic membranes was in strong contrast to the continuous insertion of proteins and pigments into this membrane (Lueking et al., 1978). It was found in experiments with synchronously dividing cells of *Rb. sphaeroides* that the protein/phospholipid ratio of purified intracytoplasmic membrane preparations underwent cyclic changes of 35–40% during the normal cell division cycle (Lueking et al., 1978). This ratio increased to a maximum value in membranes shortly before cell division and decreased to a basic value with the cell division, indicating that phospholipids are only accumulated into the intracytoplasmic membrane at the time of cell division.

Similar cell-cycle specific fluctuations in the composition of intracytoplasmic membranes were also observed in synchronous cultures of phototrophically grown *Rs. rubrum* (Myers and Collins, 1986). Furthermore, in starvation-synchronized cells of this species that were grown under aerobic conditions and had no intracytoplasmic membranes, cell cycle specific changes in the protein/phospholipid ratio were found in the cytoplasmic membrane but not in the outer membrane (Myers and Collins, 1987). Asynchronous cultures, however, had a constant protein/phospholipid ratio.

In contrast to the discontinuous incorporation of phospholipids into ICM coupled to cell-division in synchronously dividing cells of *Rb. sphaeroides* (Lueking et al., 1978; Cain et al., 1981), a continuous incorporation of phospholipids into ICM was demonstrated under conditions which induce ICM formation and transiently repress cell division (Radcliffe et al., 1985).

5. Green Sulfur Bacteria

All Chlorobiaceae contain considerable amounts of glycolipids, the major part of which (more than 80%) is associated with the chlorosomes. Phospholipids dominate in the cytoplasmic membrane (Cruden and Stanier, 1970). On a molar basis chlorosomes have 1–3 moles of sugar per mol of phosphate, whereas membranes contain only 1 mol of sugar per 5–12 moles of phosphate.

First Constantopoulos and Bloch (1967) described glycosyl glycerides in the phototrophic green bacterium '*Chloropseudomonas ethylica*' (later found to be a mixed culture) as monogalactosyl diglyceride (MGDG) and glycolipid II (containing galactose, rhamnose and a third unidentified sugar). Cruden and Stanier (1970) substantiated these findings with pure cultures of *Chlorobium limicola* (strain 1230) and *Chlorobium limicola f. thiosulf.* (strains 6130 and 6230). They separated membranes and chlorosomes and found monogalactosyl diglyceride associated with the chlorosomes and the glycolipid II with the membranes. It has been suggested later that MGDG is specifically associated with the chlorosomes and forms a monolayer covering its cytoplasmic boundary (Staehelin et al., 1980). As a consequence of this model the cellular content of MGDG in green sulfur bacteria would be expected to vary with their content of chlorosomes and BChl. However, no such correlation could be found in cells of *Chlorobium vibrioforme f. thiosulf.* (strain NCIB 8327)* (Holo et al., 1985). These authors found the specific content of MGDG to be approximately constant and independent of light intensity and BChl content. Furthermore, the ratio of MGDG to BChl was higher in whole cells than in the chlorosomes and it was suggested that the chlorosomes are not the only site of MGDG in green sulfur bacteria (Holo et al., 1985).

Though only two glycolipids have been detected in green sulfur bacteria using the diphenylamine spray reagent (Constantopoulos and Bloch, 1967; Cruden and Stanier, 1970), later work has shown that this reagent gives no color reaction with several other glycolipids of these bacteria. At least five different glycolipids could be found in *Cb. vibrioforme f. thiosulf.* (strain 8327) and in *Cb. limicola f. thiosulf.* (strains 6230 and 6430) by using 1-naphtol, periodate-Schiff, and anisaldehyde spray reagents (Bias, 1985). Two of these were identical to MGDG and glycolipid II. Two others have been described as lipid 1 and lipid 2 from *Cb. vibrioforme f. thiosulf.* (strain 8327) and *Cb. limicola f. thiosulf.*

(strains 6230 and 2230) by Knudsen et al. (1982). Lipid 1 demonstrates R_f -values similar to PI, but contains no phosphate, stains positive with ninhydrin and shows characteristic color reactions with 1-naphtol, anisaldehyde and periodate-Schiff reagents (Bias, 1985). This aminolipid was characterized from the membrane fraction of *Cb. limicola f. thiosulf.* strain 6230 and shown to be a tertiary or secondary amide containing one mole of myristic acid but no phosphorus or known amino acid (Olson et al., 1983; 1984). Jensen et al. (1991) purified this aminolipid and characterized it by TLC, IR-Spectroscopy, $^1\text{H-NMR}$, $^{13}\text{C-NMR}$, plasma desorption mass spectrometry and fast atom bombardment mass spectrometry. They revealed the lipid 1 to be an aminoglycosphingolipid which in contrast to previous reports (Olson et al., 1983), does not fluoresce in the pure state. The carbohydrate component was identified as neuraminic acid and the main fatty acid as myristic acid.

By proton NMR studies it was confirmed that only one mole of fatty acid is present per mole of aminolipid. As a possible structure the authors propose the neuraminic acid to be attached to the sphingosine backbone with the myristic acid linked to the sphingosine by an amide bond. The aminoglycosphingolipid of *Chlorobium* was exclusively found in the cytoplasmic membrane but not in the chlorosomes (Olson et al., 1983, 1984; Jensen et al., 1991). It was therefore speculated that this lipid might operate as a membrane anchor for the hydrophilic BChl *a* protein (Low and Slatid, 1988; Ferguson and Williams, 1988), that forms a two-dimensional crystal between the plasma membrane and the chlorosomes of *Chlorobium* (Olson, 1980; see also discussion of the Fenna–Matthews–Olson [FMO] protein in Chapter 20 by Blankenship et al.).

Lipid 2 moves somehow similar to DGDG on one-dimensional thin layer plates. The negative results of staining reactions with molybdate and choline reagents exclude this lipid to be PC. Lipid 2 also is diphenylamine and ninhydrin negative, but shows characteristic colorations with 1-naphtol, periodate-Schiff and anisaldehyde reagents. Its characteristic but atypical staining reactions demonstrate the unusual nature of this lipid (Bias, 1985). Knudsen et al. (1982) report on the presence of mannose and of two unidentified sugars in this lipid.

In addition, one or two minor glycolipids with chromatographic properties somehow similar to SQDG are present in *Chlorobium*. Because of its

* This strain was isolated by June Lascelles and was deposited in the NCIB as *Chlorobium limicola f. thiosulf.* However, its identity is uncertain and it is more likely to belong to *Chlorobium vibrioforme f. thiosulf.* (Norbert Pfennig, personal communication). This strain can be obtained from the DSM as a strain of *Chlorobium vibrioforme*. We are using the name *Cb. vibrioforme f. thiosulf.* in this chapter, though most of the literature refers to it as *Chlorobium limicola f. thiosulf.*!

similar R_f -values to the plant type SQDG, its negative staining reactions with ninhydrin, molybdate and diphenylamine reagents, and its positive reaction with the 1-naphtol, one of these lipids was suggested to be SQDG (Kenyon and Gray, 1974; Knudsen et al., 1982). However, comparison of the R_f -values of authentic SQDG from spinach with those of the glycolipids from *Cb. vibrioforme f. thiosulf.* 8327 under identical two-dimensional TLC conditions, showed slight differences (Bias, 1985). In addition, the color reactions with periodate Schiff and anisaldehyde-sulfuric acid reagents of the *Chlorobium* lipids were different from those of the spinach SQDG (Bias, 1985). The absence of SQDG in *Cb. vibrioforme f. thiosulf.* (strain 8327) and in *Cb. limicola f. thiosulf.* (strains 6230 and 6430) was further substantiated by culture experiments with radioactively labelled sulfur isotopes in cysteine and thiosulfate (labelled in sulfane or sulfone sulfur). All polar lipids inclusive of the SQDG-like glycolipid were present in the lipid extracts of cells from these experiments. Although growing cells did incorporate labelled sulfur from both substrates, no radioactivity could be found in the polar lipid fraction and in particular in the glycolipid chromatographically similar to SQDG (Bias, 1985).

CL and PG have been commonly identified as phospholipids of green sulfur bacteria. PE has been found in some cases, but not in others. Olson et al. (1983) working with *Cb. limicola f. thiosulf.* (strain 6230) mention that high proportions of PE in lipid extracts from whole cells were correlated with the presence of a colorless, motile contaminant in the cultures, though very low levels of PE were also found in the absence of the contaminant. PE has been identified in pure cultures of *Cb. vibrioforme f. thiosulf.* (strain 8327) and *Cb. limicola f. thiosulf.* (strains 6230 and 6430) (Knudsen et al., 1982; Bias, 1985; Imhoff, 1988). PE was absent from *Cb. vibrioforme* (6030, not thiosulfate-utilizing) and from *Pelodictyon luteolum* (Imhoff, 1988). Though data were not presented, the absence of PE from strains of *Pelodictyon luteolum*, *Cb. phaeobacteroides*, *Cb. phaeovibrioides*, *Cb. limicola*, *Cb. vibrioforme* and *Cb. vibrioforme f. thiosulf.* have been reported (Kenyon and Gray, 1974). In contrast to other reports these authors did not find PE in *Cb. limicola f. thiosulf.* strain 6230.

It may be concluded that the polar lipid composition of green sulfur bacteria is characterized by the presence of PG, CL, MGDG, glycolipid II, lipid 2

and the aminoglycosphingolipid (lipid 1). It also appears that PE, despite the discrepancies mentioned above, is present in *Cb. limicola f. thiosulf.* and *Cb. vibrioforme f. thiosulf.*, but may be absent in other green sulfur bacteria. PC, PI and sulfolipids are absent from Chlorobiaceae.

6. *Chloroflexus aurantiacus*

Chloroflexus aurantiacus also contains large proportions of glycolipids (Kenyon and Gray 1974; Knudsen et al., 1982; Imhoff 1988). Glycolipid II, lipid 1 (aminoglycosphingolipid) and lipid 2 as described for *Chlorobium* species were absent (Jensen et al., 1991; Imhoff, 1988). Instead two glycolipids have been found with R_f -values and staining behavior similar to MGDG and DGDG, respectively (Kenyon and Gray, 1974). Both of these lipids contain galactose and another sugar. The DGDG-like lipid contains galactose and glucose in equal amounts and is different from the lipid 2 of Chlorobiaceae by staining with 1-naphtol, although its R_f -value is similar to this lipid (Knudsen et al., 1982; Imhoff, 1988). Similar to the situation in Chlorobiaceae, the presence of SQDG has been postulated on the basis of negative results in staining with molybdate and ninhydrin and its R_f -value, but is doubtful. The lipid with a similar R_f -value to SQDG does not show the intense red color typical for SQDG by staining with 1-naphtol and 40% sulfuric acid (Imhoff, 1988).

Cf. aurantiacus appears to be the only phototrophic bacterium that contains PI as major phospholipid (Kenyon and Gray, 1974). Analysis of phospholipids in several strains of *Cf. aurantiacus* indicated the presence of PG and PI whereas PE and PS were absent (Kenyon and Gray, 1974; Knudsen et al., 1982; Imhoff, 1988). In contrast to other reports, CL has been tentatively identified in *Cf. aurantiacus* strain OK-70-fl, by R_f -value and positive staining reaction with molybdate reagent (Imhoff 1988).

Similar to the findings with green sulfur bacteria, also chlorosomes from *Chloroflexus* are enriched in glycolipids relative to the cell membranes. The chlorosomes of *Cf. aurantiacus* contain phosphate and sugar in nearly equal molarity, whereas its membranes have four times the amount of phosphate compared to sugars (Schmidt, 1980). In *Chloroflexus* cells grown aerobically in the dark, chlorosomes and BChl are absent, whereas substantial amounts of the lipid similar to MGDG are detectable (Sprague et al., 1981; Holo et al., 1985). The specific cellular content

of this lipid was approximately constant and independent of light intensity and BChl content (Holo et al. 1985). This suggests that this lipid, similar to the MGDG of green sulfur bacteria, is enriched in but not exclusively bound to the chlorosomes.

7. *Heliobacterium chlorum*

The lipid composition of *Hb. chlorum* is completely different from that of the green sulfur and nonsulfur bacteria. Glycolipids are absent and among the phospholipids present, CL, PE and PG are dominant. Lyso-PE and three further unidentified aminolipids are present in smaller amounts (Imhoff, 1988).

B. Fatty Acids

Fatty acids of most phototrophic bacteria are mainly saturated and mono-unsaturated straight chain C-16 and C-18 fatty acids. Small amounts of C-14 and C-20 fatty acids are present in many phototrophic purple bacteria and also C-15, C-17 and C-19 fatty acids may occur in traces or small proportions. Branched-chain fatty acids represent a major fraction of the cellular lipids only in *Heliobacterium* species and related bacteria. 3-OH fatty acids are known as constituents of the lipopolysaccharides and are present in all phototrophic purple bacteria and in Chlorobiaceae. Also C-17 and/or C-19 cyclopropane fatty acids are present in many species. Altogether, there are significant differences in the fatty acid composition of the major groups of anoxygenic phototrophic bacteria represented by the purple sulfur bacteria, purple nonsulfur bacteria, green sulfur bacteria, *Chloroflexus* sp. and heliobacteria.

Fatty acids are most susceptible to dynamic changes during growth and to variations with growth conditions and media compositions. This is certainly the reason for greatly varying fatty acid compositions found by different research groups. It is therefore important to use standardized media composition and growth conditions whenever the fatty acid composition of different strains and species is to be compared. In this respect surveys of a large number of strains yield valuable data if attention has been paid to standardization of the methods. Such surveys have been published on purple nonsulfur bacteria (Kato et al., 1985; Urakami and Komagata, 1988). A congruent set of data was also obtained with more than 20 strains of all known *Rhodobacter* species (Imhoff, 1991).

1. Purple Sulfur Bacteria

All Chromatiaceae examined have well balanced proportions of 16:0, 16:1 and 18:1, with 18:1 as the major but not dominant component (Table 3).

Under all culture conditions major fatty acids of *Ectothiorhodospira* species were 18:1 and 16:0 (Asselineau and Trüper, 1982; Imhoff and Thiemann, 1991). These results are in accordance with previously described observations on *EC. halophila* SL1 (see Kenyon, 1978). 18:0 and 16:1 were found as minor components in *EC. mobilis* and the species requiring low salt concentrations. The content of 16:1 was even lower in *EC. halophila* and other extremely halophilic *Ectothiorhodospira* species (Table 3). Various proportions of 19cyc were present in all *Ectothiorhodospira* species. The presence of branched-chain fatty acids in *Ec. mobilis* found by Oyewole and Holt (1976) could not be verified by others (Asselineau and Trüper, 1982; Imhoff and Thiemann, 1991, Imhoff, unpublished).

3-OH-14:0 is the only hydroxy fatty acid of Chromatiaceae analyzed so far (Meissner et al., 1988a). 3-hydroxy fatty acids of *Ectothiorhodospira* species are 3-OH-10:0 and 3-OH-12:0 (*Ec. vacuolata* and *EC. shaposhnikovii*), 3-OH-10:0 (*Ec. mobilis*) and 3-OH-10:0, 3-OH-12:0, 3-OH-14:0 and 3-oxo-14:0 in *Ec. halophila* (Zahr et al., 1992; Meissner et al., 1988b).

2. Purple Nonsulfur Bacteria

The fatty acid composition of all purple nonsulfur bacteria is characterized by C-16 and C-18 straight-chain saturated and monounsaturated fatty acids, with minor amounts of C-14 fatty acids present in most species. Also C-15 and C-17 fatty acids may be present in trace amounts (Kato et al., 1985; Urakami and Komagata, 1988; Kenyon, 1978; Imhoff, 1988, 1991). Gradual differences in the proportions of 18:1, 16:1, 16:0 and 18:0 allow the distinction of several groups of species (Tables 4 and 5).

In contrast to all other purple nonsulfur bacteria, in species of the genera *Rhodocyclus*, *Rhodoferax* and *Rubrivivax* (β -subgroup of the Proteobacteria) C-16 fatty acids are present in higher proportions than C-18 fatty acids. 16:1 is the major component and also proportions of 16:0 are higher than those of 18:1 (Table 4b). Species of the genus *Rhodospirillum*, as shown in Table 4a, contain 18:1 as major but not dominant component (approx. 45–55%) and a total

Table 3. Major fatty acids of representative phototrophic purple sulfur bacteria

of approx. 50% C-16 fatty acids. The clear predominance of 18:1 is characteristic of species of *Rhodobacter*, *Rhodospseudomonas*, *Rhodopila* and *Rhodomicrobium* with 18:1 generally representing more than 70% and in some species (*Rm. vannielii*, *Rp. blastica*) reaching 90% or more. Species of the genus *Rhodobacter* can be distinguished on the basis of differences in their fatty acid pattern (Table 5). Cyclopropane fatty acids have been found in several species. They are usually present in quite small proportions that may increase considerably in stationary phase or under unfavorable growth conditions.

3-OH-10:0 is the dominant 3-hydroxy fatty acid in *Rhodocyclus* and *Rubrivivax* species, while 3-OH-8:0 predominates in *Rhodoferax fermentans* (Drews et al., 1978; Hiraishi et al., 1991). Major-3-hydroxy fatty acids of *Rhodobacter* species are 3-

OH-10:0 and 3-OH-14:0, C-14 and C-16 chains are dominant in other purple nonsulfur bacteria either single or both together. 3-OH-14:0 and 3-OH-18:0 are present in *Rhodopila globiformis* (Drews et al., 1978; Urakami and Komagata, 1988; see also Imhoff and Trüper, 1989). 3-OH-18:0 and also 3-OH-12:0 occasionally have been found in other purple nonsulfur bacteria.

3. Green Sulfur Bacteria

Green sulfur bacteria contain straight-chain, saturated and monounsaturated fatty acids in the range of C-12 to C-18, with large amounts of 14:0, 16:0 and C 16:1 and small to trace amounts of 18:0, 14:1 and 18:1 (Kenyon and Gray, 1974; Knudsen et al., 1982). In comparison to purple bacteria, Chlorobiaceae have a relative higher ratio of saturated to unsaturated fatty

acids. The large amounts of 14:0 are characteristic for green sulfur bacteria (Table 6). This fatty acid was found as major component of the aminoglycosphingolipid from *Chlorobium* (Olson et al., 1983; Jensen et al., 1991). 17cyc was present in all strains examined though significant amounts were only found in strains of *Cb. limicola f. thiosulf.* and *Pelodictyon luteolum* (Kenyon and Gray, 1974; Knudsen et al., 1982). Hydroxy fatty acids (3-OH-14:0; 3-OH-16:0) were found in whole cells and phenol-water extracted phases (Knudsen et al., 1982). Whole cells and chlorosomes from *Cb. limicola f. thiosulf.* had a largely similar fatty acid composition apart from a lower content of 14:0 in chlorosomes (Schmitz, 1967). In the thermophilic *Chlorobium* species *Cb. tepidum* (Wahlund et al., 1991), C-16 and C-18 fatty acids were predominant (Shiea et al., 1991). Similar to *Chloroflexus aurantiacus*, *Cb. tepidum* also contained large amounts of wax esters, predominantly of C-30 and C-32 chain length (Shiea et al., 1991).

4. *Chloroflexus aurantiacus*

The thermophilic nature of *Cf. aurantiacus* certainly influences its fatty acid composition. Although mesophilic strains of *Chloroflexus* have been observed (Pirovarova and Gorlenko, 1977), nothing is known about their lipid and fatty acid composition. The

fatty acid composition of *Cf. aurantiacus* is characterized by the presence of 16:0, 18:0 and 18:1 as major components. Significant amounts of 16:0, 17:0, 17:1, 19:0, 20:0 and 20:1 were present in all strains investigated (Kenyon and Gray, 1974; Knudsen et al., 1982). In addition, fatty alcohols and wax esters (2.5–3.0% of cell dry weight) were present (Knudsen et al., 1982). The chain length of these saturated and monounsaturated wax esters was from C-28 to C-38, those of C-34 and C-36 being predominant (Knudsen et al., 1982). The results of the two research groups showed major differences in the proportions of various fatty acids (Table 7). These differences may be due to differences in growth temperature (45 °C by Kenyon and Gray, 1974 and 52 °C by Knudsen et al., 1982), but also due to different media composition. In particular the elevated proportion of 18:1 and the lower one of 16:0 at the higher temperature (Knudsen et al., 1982) resemble temperature-dependent changes observed in *Ectothiorhodospira* species (Imhoff and Thiemann, 1991) and could indicate similar temperature dependent adaptation phenomena in the two bacteria. Two different media have been used in the work of Knudsen et al. (1982), but it is not clear whether cells taken for fatty acid analysis were grown in the synthetic medium or not. Although these authors do not discuss discrepancies to the earlier work in regard

to the presence of 18:2, it could well be that the presence of complex nutrients led to the incorporation of 18:2 in one of the studies (Kenyon and Gray, 1974), but that *Chloroflexus* is unable to synthesize this fatty acid. This would explain the failure of Knudsen et al. (1982) to detect 18:2 in *Cf. aurantiacus* strains that presumably were grown in a synthetic medium.

5. *Heliobacterium* and *Heliobacillus* Species

Fatty acids from *Heliobacterium chlorum*, *Heliobacterium gestii* and *Heliobacillus mobilis* revealed significant differences to all other anoxygenic phototrophic bacteria (Beck et al., 1990). This group of bacteria is related to the Gram-positive bacteria according to 16SrRNA sequence similarities (Woese et al., 1985). Characteristic features of their fatty acid composition are the high content of branched-chain fatty acids (iso 13:0, anteiso 14:1, anteiso 14:0, iso 15:0, iso 16:1) and the dominance of 16:1 (Beck et al., 1990); 18:0 and 16:0 were minor components (Table 8).

C. Influence of Growth Conditions on Lipid and Fatty Acid Composition

Growth conditions may have considerable influence on the polar lipid and fatty acid composition of phototrophic bacteria. However, detailed studies on the influence of growth conditions have rarely been undertaken. Differences in lipid and fatty acid compositions obtained for the same species or even the same strain may be the result of different conditions applied to cultivate the bacteria much more than variations in analytical methods. In particular, variation of proportions of individual lipids and the detection of some minor constituents may depend upon the cultivation methods. However, little emphasis is given to this aspect in the literature and often media and growth conditions are reported insufficiently to evaluate the results in this respect.

The presence of Tris (20 mM) in media of *Rb. sphaeroides* and its effect on synthesis and proportions of N-acylphosphatidylserine (NAPS) well demonstrate the effect of minor changes in culture media on lipid proportions quite well. Very minor levels of 1–2% of NAPS increased to more than 40% of total

^aData from Beck et al. (1990); nd – not detected

lipids in the presence of Tris (Cain et al., 1981; Donohue et al., 1982a; 1982b). In respect to the findings with *Rb. sphaeroides* it is of interest that *Ectothiorhodospira halophila* has been cultivated in media containing 20 mM Tris-HCl by Raymond and Siström (1969) and that these authors found a ninhydrin-positive phospholipid in addition to PE that could be NAPS (see Kenyon, 1978). This lipid was never found in our studies, in which media without Tris were used. It needs to be established whether the effect of Tris on the lipid composition of *Ec. halophila* is similar to that of *Rb. sphaeroides*.

Also phosphate concentrations of the media are important, because phospholipids may be replaced by other phosphate-free lipids under conditions of phosphate limitation. It has been shown recently that the proportions of the sulfolipid in *Rb. sphaeroides* increased under phosphate limiting growth conditions. Phosphate limitation caused reduced growth of mutants deficient in sulfolipid biosynthesis, but not of wild type cells (Benning et al., 1993), indicating a clear advantage of the sulfolipid under these conditions. Different concentrations of phosphate in growth media could be of relevance in explaining discrepancies in the literature in regard to sulfolipid presence within some purple nonsulfur bacteria.

Also complex nutrients that contain lipid components or precursor molecules must have an impact on the lipids and fatty acids incorporated into the bacterial membranes. For example, cells of *Rs. rubrum* contained PC when peptone was present in the medium but PC was absent when yeast extract was substituted for peptone as complex nutrient source (see Kenyon, 1978). The formation of PI may depend on the supplementation with inositol, which is present in yeast extract. Therefore, it was necessary to assure synthesis of PI in *Cf. aurantiacus* also in synthetic medium lacking yeast extract (Knudsen et al., 1982).

The growth phase also has significant influence on the fatty acid composition. Proportions of cyclopropane fatty acids are known to increase in stationary phase cells. In particular proportions of 19cyc increased at the expense of 18:1 in stationary phase cells of *Ec. mobilis* and other *Ectothiorhodospira* species (Oyewole and Holt, 1976; Imhoff and Thiemann, 1991; Imhoff, unpublished results). Proportions of 19cyc may be as high as 25–33% in stationary phase cells of *Ec. mobilis* 8113 (Oyewole and Holt, 1976) and as low as 2–3% in exponentially growing cells of *Ec. mobilis* 9903 (Ditandy and Imhoff, 1993).

Apart from this, an increase in temperature caused a decrease of C-18 and of unsaturated fatty acids in *Ec. mobilis* (strain 9903), while the contents of C-16 and saturated fatty acids increased (Imhoff and Thiemann, 1991; Table 3). These effects were principally due to changes of 16:0 and 18:1 and were regarded as mechanisms to regulate membrane fluidity and bilayer stability of the membranes in response to temperature changes (Imhoff and Thiemann, 1991).

1. Phototrophic Versus Chemotrophic Growth and Lipids of Cell Fractions

a. Lipids From Cell Fractions

Many investigations have attempted the analysis of differences in lipid and fatty acid composition of membrane fractions. The failure to detect such differences may be due to the fact that clear separation of CM, ICM and OM is difficult to achieve, and that significant differences in overall composition may not exist. Polar lipid compositions apparently were very similar in CM and ICM of *Rb. sphaeroides* (Gorchein, 1968b), and ICM and whole cell lipids from *Chromatium vinosum* (Haverkate et al., 1965)

and *Thiocapsa roseopersicina* (Takacs and Holt, 1971). The analysis of pure fractions of CM, ICM and OM from *Ec. mobilis* (strain 9903) revealed no significant qualitative and quantitative differences in polar lipid and fatty acid composition between CM and ICM, though both were not identical and showed minor quantitative variations (e.g. content of C-14 and C-16 fatty acids) (Ditandy and Imhoff, 1993). Differences were, however, noted between OM and other membrane fractions. Lyso-PE was specifically and exclusively found in the OM fraction of *Ec. mobilis*, which also had higher proportions of CL compared to the other membrane fractions. Also in *Rs. rubrum*, relative proportions of individual phospholipids were similar in CM and OM fractions, though lyso-PE was specifically associated with the outer membrane fraction (Oelze et al., 1975). 18:1 was the major fatty acid of all membrane fractions from *Ec. mobilis*, although its proportion was significantly lower in OM, which in turn had higher proportions of all shorter chain and saturated fatty acids (14:0, 16:0, 18:0, 20:0) (Ditandy and Imhoff, 1993). The proportions of saturated fatty acids, in particular those of 14:0, were higher in the OM fraction of *Rhodospirillum rubrum* grown aerobically (chemoheterotrophically), whereas the CM fraction had higher amounts of 16:1 and 18:1 (Collins and Niederman, 1976; Oelze et al., 1975). Very similar trends were reported for OM fractions from *Rb. capsulatus* (Flamman and Weckesser, 1984), *Rp. palustris* (Weckesser et al., 1973) and *Cm. vinosum* (Hurlbert et al., 1974). It was concluded that this trend could be a general phenomenon in Gram-negative bacteria (Ditandy and Imhoff, 1993).

b. Phototrophic Versus Chemotrophic Growth

Because major differences between ICM and other cellular membranes were not observed, it was not surprising that no significant changes in qualitative and quantitative phospholipid compositions were observed in cells of *Rb. sphaeroides* grown aerobically or phototrophically at high light intensities (Onishi and Niederman, 1982). In phototrophically grown cells, the phospholipid composition was dependent upon the incident light intensity (Onishi and Niederman, 1982).

Nevertheless, relative proportions of PC, PG and PE of *Rb. capsulatus* were found to be different in cells grown phototrophically or chemotrophically (Steiner et al., 1970), although no significant

differences in the polar lipid composition between CM and ICM were reported. Russell and Harwood (1979) found increasing proportions of PG in cells of *Rb. sphaeroides*, *Rb. capsulatus* and *Rs. rubrum* when cells were transferred from chemotrophic to phototrophic growth conditions. Proportions of PE (and in *Rb. sphaeroides* also PC) decreased concomitantly.

Kato et al. (1985) and Urakami and Komagata (1988) analyzed fatty acids from a number of strains and species of purple nonsulfur bacteria grown aerobically in the dark and anaerobically in the light. The cellular fatty acid composition was not much different in cells grown phototrophically or chemotrophically, but the results from Urakami and Komagata (1988) were different from those of Kato et al. (1985), although they came from the same lab. In the case of disagreement between the two papers results from Urakami and Komagata (1988) were included in Table 4. Similar findings have been made earlier with *Rs. rubrum* (Oelze et al., 1970; Brooks and Benson, 1972) and *Rb. sphaeroides* (Scheuerbrandt and Bloch, 1962). Differences in fatty acid composition were noted, however, by some other authors. The cellular content of saturated fatty acids was found to be lower in chemotrophically grown cells of *Rubrivivax gelatinosus*, *Rs. rubrum* and *Rp. palustris* (Hands and Bartley, 1962; Wood et al., 1965).

2. The Influence of Salt Concentration

Ectothiorhodospira species represent a group of halophilic phototrophic bacteria with a characteristic dependence on saline and alkaline growth conditions (Imhoff, 1989). Certain strains of the extremely halophilic *Ec. halophila* are the most halophilic eubacteria known and are able to grow in saturated salt solutions. Comparative analyses of salinity-dependent lipid composition of slightly, moderately, and extremely halophilic *Ectothiorhodospira* strains revealed strong effects on their lipid composition. Most significant salt-dependent changes were observed in the proportions of PG, CL and PE. These changes reflect phenomena of salinity-dependent PG/PE antagonism known from other Gram-negative eubacteria; increasing the salinity promotes the biosynthesis of PG relative to that of PE, CL and PC. Upon dilution stress responses were reversed and corresponded in a strong increase of PE synthesis (Thiemann and Imhoff, 1991). Significant increases

in the proportions of PG and concomitant decreases in those of PE and CL resulted in a considerable increase of the excess negative charges with increasing salinity (Imhoff et al., 1991; Thiemann and Imhoff, 1991). This effect was most dramatic in the slightly halophilic *Ec. mobilis* (strain BN 9903) and quantitatively less significant in moderately and extremely halophilic strains of *Ec. halophila* (strains BN 9626 and BN 9630) which had, however, an overall higher percentage of negative charges of their lipids.

The most important aspect of structural adaptation of lipid composition upon increasing medium salinity was assumed to be the stabilization of the membrane bilayer. The portions of PC and PG, which are both regarded as lipids supporting the bilayer structure, steadily increased with salinity in all three *Ectothiorhodospira* strains and were expected to counterbalance the bilayer destabilizing effects of the increasing ionic strength (Thiemann and Imhoff, 1991).

Of crucial importance for integrity of the bilayer and its proper fluidity also are changes of the fatty acid composition. The salt concentration had strong influences on the fatty acid composition in *Ectothiorhodospira* species. Minimum values of C-16 and saturated fatty acids and maximum values of C-18 and unsaturated fatty acids were found at or close to the salt optimum. Similar changes and correlations with minima of C-16 and saturated fatty acids at the salt optima also were found in *Rb. adriaticus*, *Rp. marina* and *Chromatium purpuratum* (Imhoff and Thiemann, 1991). Despite the fact that the species-specific proportions of major fatty acids in these bacteria were significantly different, in principal similar changes occurred in respect to changing salt concentrations, when related to their growth optima. It was concluded that the underlying mechanisms were the same in all of these purple bacteria and that the data obtained were of relevance to the fatty acid composition of Gram-negative bacteria in general.

III. Apolar Lipids

A. Quinones

The characteristic feature of all quinones is their ability to function as redox carriers in electron transport processes within the membranes. While

the important role of Q in photosynthetic electron transport is well recognized, the functions of RQ and MK are much less studied. Their crucial role in electron transport processes is discussed in other chapters of this book (see Chapters 14 and 44 by Vermeglio et al. and Zannoni, respectively). The chemical structure of quinones contains two elements, the quinoid ring system and an isoprenoid side chain. Variation occurs in both of these elements. According to the quinone ring structure we distinguish between menaquinones, ubiquinones and rhodoquinones. Variation of the side chain is obtained by the chain length (number of isoprenoid units) and in some cases by specific modifications of its chemical structure.

The presence of quinones with defined structures of ring system and side chain apparently is a characteristic feature of bacterial species and can be used for taxonomic classification. Also different species of the same genus are expected to have identical quinone composition. Minor variations of growth conditions have no or only small influence on the quinone composition. However, depending on the quinone composition and on their different functions in respiratory and photosynthetic electron transport, changes may be expected during adaptation of the more versatile species from aerobic dark to anaerobic light conditions.

1. Purple Nonsulfur Bacteria

The older literature on quinones in phototrophic purple bacteria has been reviewed by Collins and Jones (1981) and reveals scattered and sometimes conflicting results, which varied in particular regarding the presence of menaquinones and the determination of the predominant chain length of some species. More recently several investigations on the quinone composition of phototrophic purple bacteria have been published and give a quite comprehensive view of quinone occurrence in this group (Hiraishi and Hoshino, 1984; Hiraishi et al., 1984; Imhoff, 1984a; Kato et al., 1985). Available data are summarized in Tables 9 and 10.

All known purple nonsulfur bacteria contain ubiquinones. Some species have ubiquinones as sole quinone component and lack menaquinones and rhodoquinones. Others contain ubiquinone and rhodoquinone, ubiquinone and menaquinone or ubiquinone, menaquinone and rhodoquinone. Rhodoquinones, which were first discovered in *Rs*.

^a Data from Hiraishi and Hoshino, 1984; Hiraishi et al., 1984; Hiraishi et al., 1991; Imhoff, 1984a; Kato et al., 1985.

¹ *Rhodocyclus gelatinosus* (formerly *Rhodopseudomonas gelatinosa*) has been transferred to *Rubrivivax gelatinosus* (Willems et al., 1991)

rubrum (Glover and Threlfall, 1962) also were found in several other purple nonsulfur bacteria. RQ-8 dominates in *Rhodospirillum photometricum*, RQ-9 and RQ-10 in *Rhodopila globiformis*, RQ-10 in *Rs. rubrum*, *Rhodopseudomonas acidophila*, and *Rhodomicrobium vannielii* (Hiraishi and Hoshino, 1984; Imhoff, 1984a). In *Rs. rubrum* also epoxy derivatives of Q-10 have been found (Friis et al., 1967), although it was not clear whether these occur naturally or are formed during extraction and purification procedures.

Species grouped according to their quinone ring systems can be further differentiated on the basis of

the isoprenoid chain length of their predominant quinone components. Regardless of the quinone ring structure, the side chains of the major components in an individual species normally are of the same length, though exceptions do exist. In the majority of the species quinones with one specific chain length predominate over all others with 90–99% of the total amount. In most, but not all cases the major component has the longest side chain. In general, the analogue with one isoprenoid unit less can be found in amounts of less than 10% and others in very low amounts or traces, with relative concentrations decreasing with the chain length. Only high-

^aData from Hale et al., 1983; Hiraishi, 1989; Imhoff, 1984a; Imhoff, 1988.

sensitivity mass spectrometry of ubiquinones from *Rs. rubrum* revealed the presence of Q-1 through Q-10 with extremely low levels even of Q-1 through Q-4 (Daves et al., 1967).

2. Purple Sulfur Bacteria

Much less information is available on quinones in other groups of phototrophic bacteria. From the data available it may be concluded that all Chromatiaceae species uniformly have Q-8 and MK-8 (Imhoff, 1984a), though more species have to be analyzed. Among Ectothiorhodospiraceae differences occur between species with low and high salt requirements (Imhoff, 1984a; Table 10).

3. Green Sulfur Bacteria

Quite a few reports deal with the quinones of green sulfur bacteria. The presence of MK-7 and 1'-oxo-MK-7 (also called chlorobiumquinone) was found to be highly specific for *Cb. limicola f. thiosulf.* (Frydman and Rappaport, 1963; Redfean and Powls, 1968; Powls et al., 1968). MK-7 and chlorobiumquinone were later found in strains of *Cb. vibrioforme* (strain 6030), *Cb. vibrioforme f. thiosulf.* (strain 8327) and *Pelodictyon luteolum* (strain 2530) (Imhoff, 1988). These components may be characteristic for all species of the green sulfur bacteria but more species have to be analyzed to prove this.

4. Chloroflexus aurantiacus

Chloroflexus aurantiacus has menaquinone (MK-10) as the only quinone component but lacks Q, RQ and chlorobiumquinone (Hale et al., 1983; Imhoff, 1988).

5. Heliobacterium chlorum

The presence of menaquinones (MK-9 being the major component) but the absence of ubiquinones, rholoquinones and chlorobiumquinone in *Heliobacterium chlorum* has been demonstrated (Imhoff, 1988; Hiraishi, 1989).

B. Hopanoids

Hopanoid triterpenes are present in many bacteria. They are structural analogues and putative phylogenetic precursors of the eukaryotic sterols, which are generally absent from prokaryotes. They possess a quasi-planar, rigid, amphiphilic structure similar to that of sterols and therefore also may be functional equivalents in bacteria (Rohmer et al., 1979; Ourisson et al., 1987). Major components always were C₃₅ bacteriohopanepolyols with bacteriohopanetetrol as the most common one (Rohmer et al., 1984). In addition, the C₃₀ hopanoids diploptene and diplopterol were found in almost all hopanoid-containing bacteria. Their biosynthesis is completely independent

from molecular oxygen since no oxidation step is required as in sterol biosynthesis. Therefore hopanoid biosynthesis is possible under anoxic conditions and evolution of the biosynthetic pathways could have occurred in strictly anaerobic bacteria. Hopanoids are formed by direct cyclization of squalene by a squalene cyclase resulting in the formation of pentacyclic triterpenoids (Ourisson et al., 1987). Some squalene analogues that act as inhibitors of squalene cyclases were growth inhibitory to hopanoid producing bacteria (including *Rm. vannielii*, *Rp. acidophila* and *Rp. palustris*) at concentrations in the μM range, whereas hopanoid non-producers were not affected (Flesch and Rohmer, 1987). These results demonstrate the importance of hopanoids for life and survival of their producers.

Hopanoids were not detected (less than $10 \mu\text{g/g}$ dry weight) in the phototrophic green and purple bacteria *Chromatium vinosum* (strain D), *Thiocapsa roseopersicina* (strain 6311), *Amoebobacter roseus* (strain 6611), *Thiocystis violacea* (strain 2311), *Ectothiorhodospira mobilis* (strain 8115), *Ectothiorhodospira shaposhnikovii* (strain Moskau N1) and *Chlorobium limicola* f. *thiosulf.* (strain 6230) (Rohmer et al., 1984).

The first triterpene (paluol) in a phototrophic purple bacterium was found in *Rp. palustris* (Jensen, 1962). From inhibitor studies it had been concluded that sterols may occur in this bacterium (Aaronson, 1964). This author found that benzmalecene and triparanol inhibited growth of *Rp. palustris* and that ergosterol, squalene and oleic acid overcame this inhibition. In a screening of purple nonsulfur bacteria for squalene and hopanoid components, squalene was found only in *Rubrivivax gelatinosus* and hop-22(29)-ene and hopan-22-ol in *Rp. palustris* and *Rp. rutila* (Urakami and Komagata, 1988). Other authors found hopanoids in several purple nonsulfur bacteria, including *Rs. rubrum*, *Rb. sphaeroides*, *Rp. palustris*, *Rp. acidophila* and *Rm. vannielii* (Rohmer et al., 1984; Ourisson et al., 1987). The principal fraction was represented by bacteriohopanepolyols present in these species in amounts from 1.4–4.8 mg/g dry weight. Lower amounts (below 0.3 mg/g dry weight) of diploptene and diplopterol were also found. Diplopterol was absent from two strains of *Rp. acidophila* (Rohmer et al., 1984). The highest content of bacteriohopanepolyols were found in *Rm. vannielii* (Rohmer et al., 1984).

The structural variety of the triterpenoid components is great. For example, in cells from *Rhodo-*

microbium vannielii grown phototrophically 16 different hopanoids and fernens have been isolated (Howard et al., 1984). In this report **3 β -hydroxy-21-methylhopane**, 29-hydroxy-3,21 dimethylhopane and hop-22(29)-ene (diploptene) were identified as principal components (Howard et al., 1984). Further components were hop-21 (22)-en-3-one, 22-hydroxyhopan-3-one, and other minor components, some of which, however, may be isolation artifacts (Ourisson et al., 1987). The presence of 22-hydroxyhopan-3-one could not be confirmed by Neunlist et al. (1985), though reference material was available and sensitivity was at the microgram level. These authors recognized derivatives of bacteriohopanetetrol with an amino group in their side chain and linked to aminoacyl residues as the major hopanoids of *Rm. vannielii* (Neunlist et al., 1985). 35-aminobacteriohopane-32,33,34-triol and N-tryptophanyl and N-ornithyl derivatives thereof were identified and represented the first hopanoids known to contain an amino group in the side chain. Bacteriohopane-aminotriol and free aminopolyols also have been found in *Rp. palustris* (Ourisson et al., 1987). The first evidence of the triterpenoid tetrahymanol in a prokaryote has recently been obtained in *Rp. palustris* (Kleemann et al., 1990). Furthermore, nucleoside analogues, 30-(5'-adenosyl)-hopanes, were isolated and identified from *Rp. acidophila* (Neunlist et al., 1988). Another new hopanoid has been described from *Rs. rubrum* as a derivative of bacteriohopanetetrol having an glucuronopyranosyl residue linked alpha-glycosidically to the hydroxyl group of C₃₅ (Lopitz et al., 1992). In addition to the principal structural variation in different bacteria, a strong dependence of the relative levels of different triterpenes on growth conditions was revealed in *Rs. rubrum* (Barrow and Chuck, 1990).

Summary

The purple bacteria—being spread in the different subdivisions of the *Proteobacteria*—have a Gram-negative cell wall organization. Satisfactory matching of lipopolysaccharide composition, in particular of the conservative lipid A but also of the core-regions, with genetic studies confirms in many cases the phylogenetic relationship between distinct species of purple bacteria and their nonphototrophic relatives. The deep phylogenetical separation between the green sulfur bacteria (Chlorobiaceae) and the green non-sulfur bacteria (Chloroflexaceae) finds also a remarkable confirmation in the analyses of cell wall composition: The cell wall of Chlorobiaceae is typically Gram-negative with A1 γ -type peptidoglycan and lipopolysaccharide, whereas that of *Chloroflexus aurantiacus* has characteristic properties in common with the Gram-positive cell wall type.

The different lipid A types (lipid A_{GlcN}, lipid A_{Hyb}, lipid A_{DAG}) found in purple bacteria have proven to be either highly toxic (*Rubrivivax gelatinosus*) or to exhibit little (*Rhodocyclus tenuis*) or no toxicity (*Rhodobacter capsulatus*, *Rhodobacter sphaeroides*, *Rhodopseudomonas viridis*). A comparison of their structure-endotoxic activity relationships may contribute to the knowledge of the structural requirements for exhibiting endotoxic activity as well as of the fate and site of action of endotoxin in the higher organism.

The complete three-dimensional structure of the porin of *Rhodobacter capsulatus* 37b4 (and recently also that of *Rhodopseudomonas blastica* DSM 2131) has been identified at atomic resolution by X-ray diffraction of crystals. The functional complex is a trimer built up by three identical subunits each forming a pore. Each subunit consists of an antiparallel 16-stranded β -barrel twisted in the usual right-handed manner. The strands are connected mainly by short loops. Among the longer loops, the largest one runs into the inside of the barrel and narrows the channel, defining the pore size. A strong charge-gradient exists within the pore. The porin of *Rhodobacter capsulatus* is assumingly a paradigm for the hydrophilic pores presently considered as nonspecific of the outer membrane of *Proteobacteria*.

I. Introduction

In this chapter the cell wall and the external layers of the anoxygenic phototrophic bacteria will be discussed. We will focus on more recent data; for respective earlier reviews see Weckesser et al. (1978), Weckesser et al. (1979), Mayer et al. (1985), and Mayer et al. (1990a). The cell walls of the oxygenic cyanobacteria (Weckesser and Jürgens, 1988; Jürgens and Weckesser, 1990), phylogenetically quite distant from the anoxygenic phototrophic bacteria, are not considered here.

A brief characterization of the cell wall and its constituents will be given first, then the various phylogenetic groups of anoxygenic phototrophic

bacteria and of some of their nonphototrophic relatives will be discussed. Separate sections will be devoted to the contribution of their LPS's to endotoxin research, to the structure of their porins, and to the so far limited knowledge of their external surface layers.

II. Definition, Function, and Constituents of the Cell Wall

The term cell envelope comprises all layers surrounding the cytoplasm (Fig. 1): the cytoplasmic membrane, the cell wall (peptidoglycan plus outer membrane) and the external layers (capsule and slime materials, S-layers). The function of the cell wall may be summarized very briefly: The peptidoglycan (murein sacculus) contributes to the formation and maintenance of size and shape of the cell, it withstands the osmotic pressure of the protoplast. In the Gram-negative cell wall type, the outer membrane represents an effective permeability barrier in controlling the permeation of substrate and antibiotics as well as the export of substances. In addition, the outer membrane carries the molecules responsible for the serological O-specificity of the respective cells and their phage-receptors. With the exception of *Chloroflexus aurantiacus*, anoxygenic phototrophic bacteria are Gram-negative. The macro-

molecular constituents of the Gram-negative wall type are peptidoglycan of the A1 γ -type, and the outer membrane constituents LPS (O-antigen, endotoxin), lipoprotein, porin and other proteins, and phospholipids.

The external layers, often being lost during growth under laboratory conditions, protect the cell from generally unfavorable conditions such as dryness or mechanical stress. Compounds often found as the most external layers are acidic polysaccharides of the more or less amorphous capsule or slime layers, or the regular arranged proteins or glycoproteins of the (surface) S-layers (Beveridge and Graham, 1991; Messner and Sleytr, 1992). The S-layers may serve as protective coats, molecular sieves and/or ion traps.

III. Phylogenetic Relevance of Cell Wall Constituents

A. Phylogenetic Considerations

The anoxygenic phototrophic bacteria are spread throughout the phylogenetic tree of Bacteria,

phototrophic and nonphototrophic phenotypes are intermixed in many cases, in particular within the *Proteobacteria* (Woese, 1987; Stackebrandt et al., 1988a,b; Olsen and Woese, 1993). Restriction to only phototrophic bacteria in this article would bring about neglect of their intimate nonphototrophic relatives. Consequently, some nonphototrophic *Proteobacteria* will also be discussed briefly.

B. Major Groups of Anoxygenic Phototrophic Bacteria and Their Cell Wall Composition

1. *Proteobacteria*: Purple Bacteria and Relatives

As far as studied, the anoxygenic phototrophic *Proteobacteria* have a Gram-negative cell wall organization with lipoprotein likely bound to A1 γ -type peptidoglycan, as revealed for *Rhodobacter sphaeroides* and *Rhodobacter capsulatus* (Drews et al., 1978; Bräutigam et al., 1988; Woitzik et al., 1989), *Rhodospirillum rubrum* (Newton, 1968), *Chromatium tepidum*, *Thiocystis violacea* (Meissner et al., 1988a) and *Ectothiorhodospira vacuolata* (Meissner et al., 1988b). Baumgardner et al. (1980)

described in *Rhodobacter sphaeroides* ATCC 17023 two different outer membrane proteins (app. M_r 8,000 and 10,000, respectively). They were suggested to be equivalents to the free and peptidoglycan-bound form, respectively, of the *Escherichia coli* lipoprotein. The rigid layer of both *Rb. sphaeroides* ATCC 17023 and *Rb. capsulatus* 37b4, however, did not react with antisera against lipoprotein of *E. coli* K12 (Drews et al., 1978; Woitzik et al., 1989). Antisera against heat-killed cells of *Rb. capsulatus*, *Rp. viridis* and *Rp. palustris* also showed little or no serological cross-reactivity with lipoprotein of *Escherichia coli* (Drews et al., 1978). In the peptidoglycan of *Rp. viridis*, *Rp. sulfoviridis*, and *Rp. palustris* there is a partial lack of N-acetyl substitution of the D-GlcN residues, rendering this peptidoglycan lysozyme-resistant (Schmelzer et al., 1982).

In general, *Proteobacteria* have LPS's in their outer membrane. From a phylogenetic point of view—aside from peptidoglycan—the composition of their lipid A regions is particularly of interest (Fig. 2). It is the most conserved domain of the heteropolymer; the core-structure is less conserved but in some cases also valuable as a taxonomical criterion. The O-chains are highly variable and confer the serological O-specificity to a given strain (Framberg et al., 1974; Drews et al., 1978; Weckesser et al., 1979), but they are absent in many species.

In the following, the purple bacteria and some of their nonphototrophic relatives will be discussed according to their grouping into the α , β , and γ subdivisions of *Proteobacteria* (Table 1; Woese et al., 1984 a,b; Woese et al., 1985; Woese, 1987;

Stackebrandt et al., 1988a). The δ subdivision does not include phototrophic species. The analytical data are compiled in Table 1. For the definition of lipid A_{GlcN} , lipid A_{Hyb} , lipid A_{DAG} , and 'mixed' lipid A, see Section IV ('Lipid A') and Fig. 6.

a. α Subdivision

Subgroup α -1: Among the subgroup α -1, *Rhodospirillum rubrum*, *Rhodospirillum molischianum*, and *Rhodopila globiformis* have been investigated for the composition of their LPS's (Pietsch et al., 1990). *Rs. rubrum* and *Rs. molischianum* have lipid A_{GlcN} , while the lipid A of *Rhodopila globiformis*, more distantly related to *Rs. rubrum* and *Rs. molischianum*, contains in addition, DAG. It also contains the rare 3-OH-19:0, possibly in its iso- or anteiso-branched form. It is not yet clear whether we are dealing here with a lipid A_{Hyb} type or 'mixed' lipid A, or whether the GlcN found in the lipid A fraction is part of the polysaccharide. The latter would indicate the presence of lipid A_{DAG} in *Rhodopila globiformis*, otherwise found mainly in subgroup α -2 of *Proteobacteria*. The moderately halophilic *Rhodospirillum salexigens*, belonging also to the α subdivision (cited in Evers et al., 1986) lacks LPS (Evers et al., 1986), and therefore neither β -hydroxy fatty acids nor Kdo were found in hot phenol-water extracts and in whole cells. However, an outermost protein layer of hexagonally arranged subunits was observed in *Rs. salexigens* (Golecki and Drews, 1980). The protein (app. M_r = 68,000) forming the outermost layer had a high excess of acidic over basic amino

Fig. 2. Structure makeup of enterobacterial lipopolysaccharide (Rietschel et al., 1987, modified).

acids, which is in accord with its low isoelectric point of 4.4 (Evers et al., 1984). A thin, apparently outer membrane but no peptidoglycan layer was seen in ultrathin sections. Although peptidoglycan was described as a major constituent of a cell envelope fraction (Tadros et al., 1982), whole cells of *Rs. salexigens* were found to have a very low peptidoglycan content (0.17 μmol muramic acid/mg cell dry weight), which is apparently not sufficient to form a complete sacculus structure (Evers et al., 1986). A polysaccharide consisting of D-GlcN and a 2-amino-2-deoxy-pentose (likely ribosamine) was extracted into the water phase of phenol water extracts of whole cells. Removal of the cell surface layer exposed six proteins to labeling with radioactive iodine catalyzed by lactoperoxidase. They were suggested to be constituents of an outer membrane of *Rs. salexigens* (Evers, 1984; Evers et al., 1986). The cell wall of *Rs. mediosalinum* (Kompanseva and Gorlenko, 1985) shows a fine structure typical of Gram-negative bacteria, but chemical data are not yet available. An outermost layer of hexagonal subunits and a thick capsule were also observed.

Subgroup α -2: The finding of lipid A_{DAG} in *Rhodopseudomonas palustris*, *Rhodopseudomonas viridis*, *Rhodopseudomonas sulfoviridis*, *Nitrobacter winogradskyi*, *Pseudomonas diminuta*, and *Phenylobacterium immobile* (Fig. 3 A) supports their common phylogenetic grouping (Mayer et al., 1983, 1984; Mayer, 1984; Mayer and Weckesser, 1984; Weckesser and Mayer, 1987). They all exhibit amide-bound 3-OH-14:0. The close relationship between *Rp. palustris* and *Nitrobacter winogradskyi* is additionally expressed by the common presence of L,D-Hep in the core-region, which is absent in other members of the subgroup α -2. It should be noted that lipid A_{DAG} is not uniformly distributed in all members of the subgroup α -2. It is found neither in *Rhodomicrobium vannielii* nor in *Rp. acidophila* and especially not in species of Rhizobiaceae (Weibgen et al., 1993). Lipid A_{GlcN} of *Rm. vannielii* and *Rp. acidophila* contain nonphosphorylated β -1,6-linked D-GlcN disaccharides, carrying D-Man as a non-acylated substituent at C'-4.

Recently, long-chained *n*-2-hydroxylated fatty acids, a new characteristic class of lipid A components, were detected in α -2 subgroup species (Hollingsworth and Carlson, 1989). In a comparative study, 27-OH-28:0 was found in lipid A of almost all species of the subgroup α -2 (Bhat et al., 1991). The

distribution of 27-OH-28:0 and higher homologues was restricted to this subgroup; strains of the β and γ subdivisions, including also the enterobacterial LPS's, were devoid of this unusual fatty acid. The long-chained fatty acids are usually ester-bound to ester- or mostly amide-linked 3-OH-fatty acids. The diesters reach chain lengths which allow them to stretch through the entire outer membrane. Their functional OH-group at the penultimate position of the hydrocarbon chain may interact with components of the hydrophilic part of the inner leaflet of the outer membrane, thus, possibly contributing to membrane stabilization. Long-chained *n*-2-hydroxylated fatty acids are found in both, D-GlcN- or DAG-containing lipid A's. They have also been detected in the LPS of methane-utilizing (methanotrophic) bacteria (Bowman et al., 1991).

The polysaccharide moiety also allows to distinguish between the species of the subgroup α -2. The O-antigens of *Rp. palustris* strains have a core structure with Kdo and L,D-Hep, while those of *Rp. viridis* and *Rp. sulfoviridis* lack heptoses (Weckesser et al., 1979; Ahamed et al., 1982). The O-chains of *Rp. palustris* and *Rp. viridis* are complex and reveal a ladder-like pattern on DOC-PAGE, indicating possible S-layers in *Rp. palustris* (Krauss et al., 1988a).

Subgroup α -3: Most studies on the cell wall of anoxygenic phototrophic bacteria were performed with species of the subgroup α -3. Both *Rhodobacter capsulatus* 37b4 and *Rhodobacter sphaeroides* ATCC 17023 have lipid A_{GlcN} (see chapter A, 'Lipid A'). Both also share a rare variation in their fatty acid composition: The amide-bound 3-OH-14:0 is partly (*Rb. sphaeroides* ATCC 17023) or almost entirely (*Rb. capsulatus* 37b4; *Roseobacter denitrificans*) replaced by 3-oxo-14:0 (Salimath et al., 1983; Qureshi et al., 1988; 1983; Krauss et al. 1989). Both have ester-linked 3-OH-10:0, and this was recognized to be due to a highly specific acyltransferase (Williamson et al., 1991). Comparable fatty acid patterns have been found in nonphototrophic species of this cluster (Fig. 3A) such as *Paracoccus denitrificans* and *Thiobacillus versutus* (Wilkinson et al., 1986; Mayer et al., 1990a,b).

In all the species mentioned, the core region contains Kdo but no heptoses. It is worth mentioning that in a comparative study (Krauss et al., 1988b) Neu5Ac was found as a constituent of LPS only in the α -3 group, in particular only in *Rhodobacter*

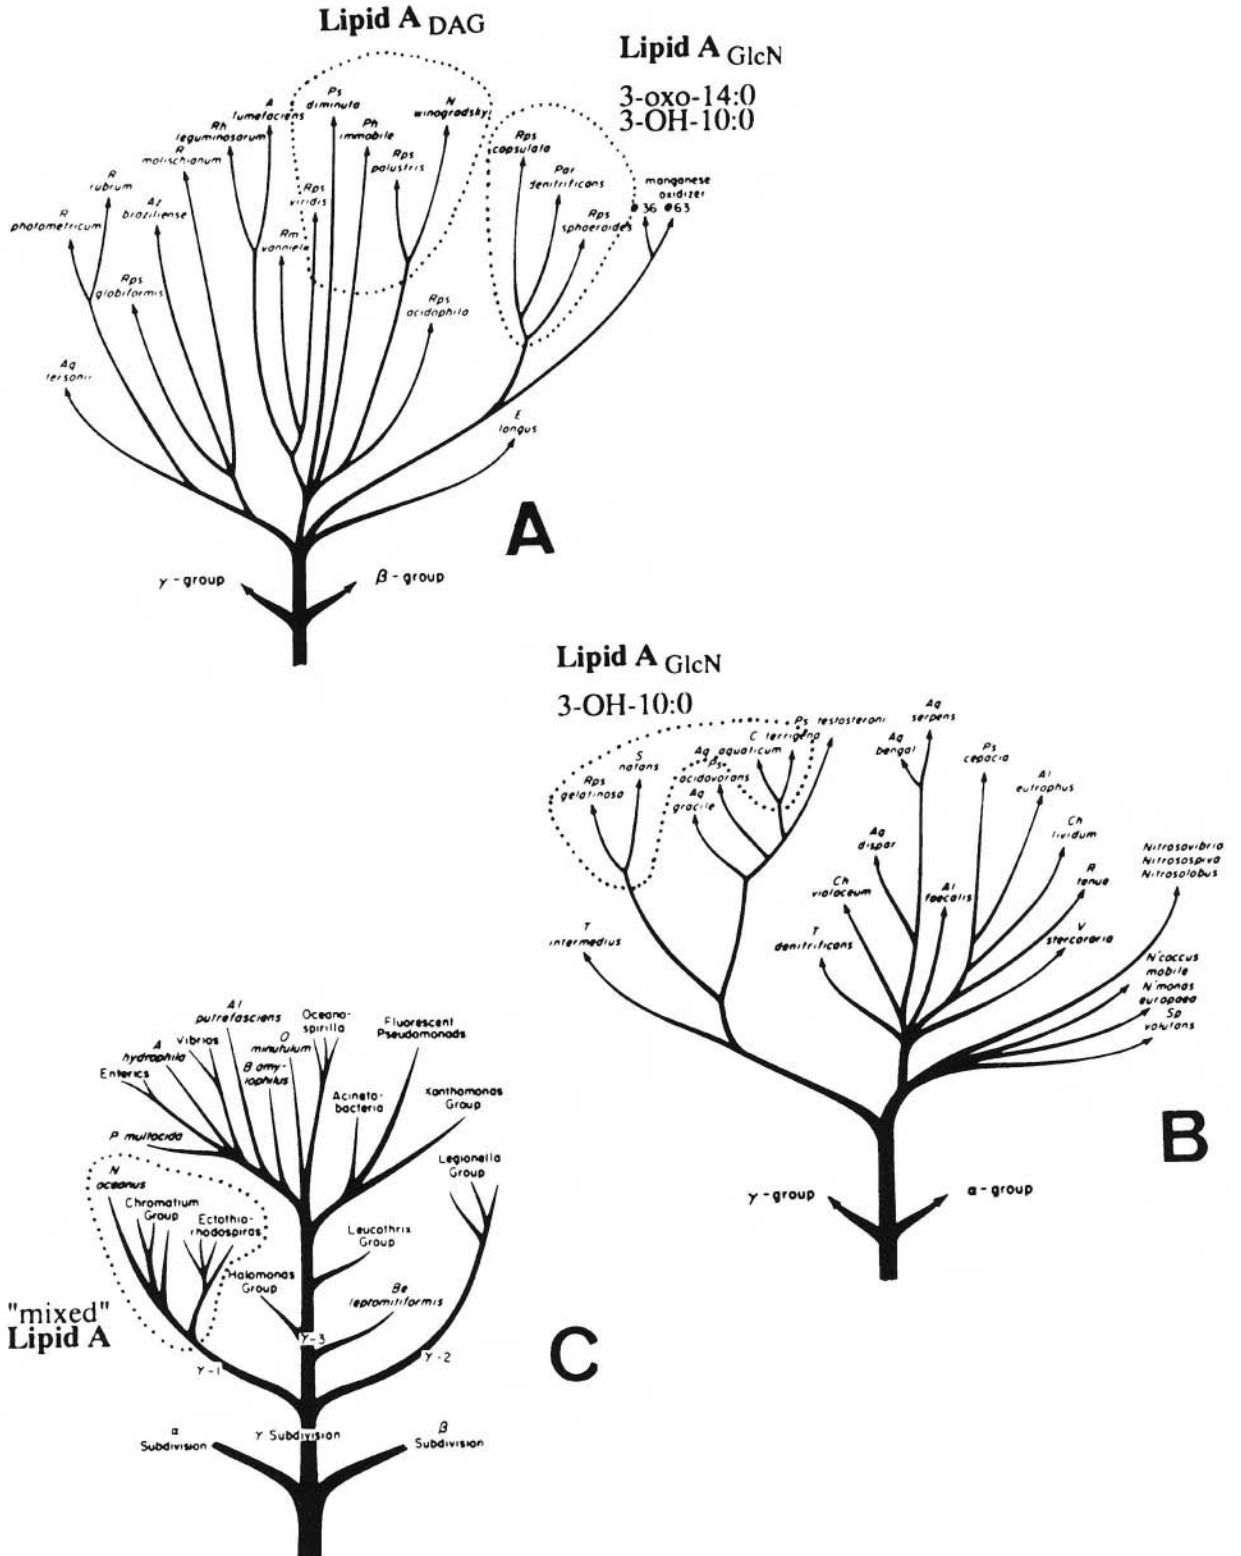

Fig. 3. Comparison of lipid A types and 16S rRNA catalogue data of the (A) α , (B) β , and (C) γ subdivisions of *Proteobacteria* (Mayer et al., 1989, modified). Note that 3-OH-10:0 is exclusively ester-linked in (A) and both amide- and ester-linked in (B).

species (*Rb. capsulatus*, *Rb. sphaeroides*, *Rb. sulfidophilus*, *Rb. veldkampii*).

Outer membrane lipoprotein with a fatty acid pattern of 18:1, 18:0, and 16:0 was isolated from *Rb. sphaeroides* ATCC 17023 (Woitzik et al., 1989). In accordance with lipoprotein of *Escherichia coli*, a major part of 18:1 is amide-bound and lysine possibly represents the C-terminal amino acid. In another study (Baumgardner et al., 1980), two different outer membrane proteins (app. M_r 8,000 and 10,000, respectively) in the same strain were suggested to be equivalents of the lipoprotein of *E. coli*, the app. M_r 8,000 protein to the free and the app. M_r 10,000 protein to the peptidoglycan-bound form of lipoprotein. The rigid layer of both *Rb. sphaeroides* ATCC 17023 and *Rb. capsulatus* 37b4 did not react with antisera against lipoprotein of *E. coli* K12 (Drews et al., 1978; Woitzik et al., 1989).

b. β Subdivision

Subgroup β -1: Lipid A_{GlcN} of *Rubrivivax* (*Rhodocyclus*) *gelatinosus* also resembles that of enterobacterial lipid A_{GlcN} (see Section IV 'Lipid A') in having a bisphosphorylated lipid A glcN. Characteristic are the amide- and ester-linked 3-OH-10:0 fatty acids, ester-bound are also 12:0 and 16:0 (Fig. 4). *Sphaerotilus natans*, closely related to *Rubrivivax*

gelatinosus (Fig. 3B), has high structural similarities: also here 3-OH-10:0 is both amide- and ester-linked (Masoud et al., 1991a). All *Rubrivivax gelatinosus* strains studied so far have R-type LPS's (Krauss et al., 1988a) with D,D-Hep as the only heptose.

Subgroup β -2: Lipid A_{GlcN} of *Rhodocyclus tenuis* 2761 carries a third, unsubstituted D-GlcN unit in its backbone structure (see Section IV 'Lipid A'). In further contrast to *Rubrivivax gelatinosus*, the phosphate moieties at C-1 and C-4' are substituted with D-Araf and 4-amino-L-arabinose (4-AA), respectively. Lipid A_{GlcN} from *Rhodocyclus purpureus* is similar to that of *Rc. tenuis* in also containing these two sugars (Weckesser et al., 1983). The ester-bound fatty acids of both *Rc. purpureus* and *Rc. tenuis* are 14:0 and 16:0.

In contrast to *Rubrivivax gelatinosus*, both *Rc. tenuis* and *Rc. purpureus* have L,D-Hep (in some cases together with D,D-Hep) and O-chains with typical repeating units as indicated by a ladder-like pattern on DOC-PAGE (Fig. 4; Krauss et al., 1988a).

c. γ Subdivision

Among the Chromatiaceae, five species (*Chromatium vinosum*, *Chromatium tepidum*, *Thiocapsa roseopersicina*, *Thiocapsa pfennigii*, *Thiocystis*

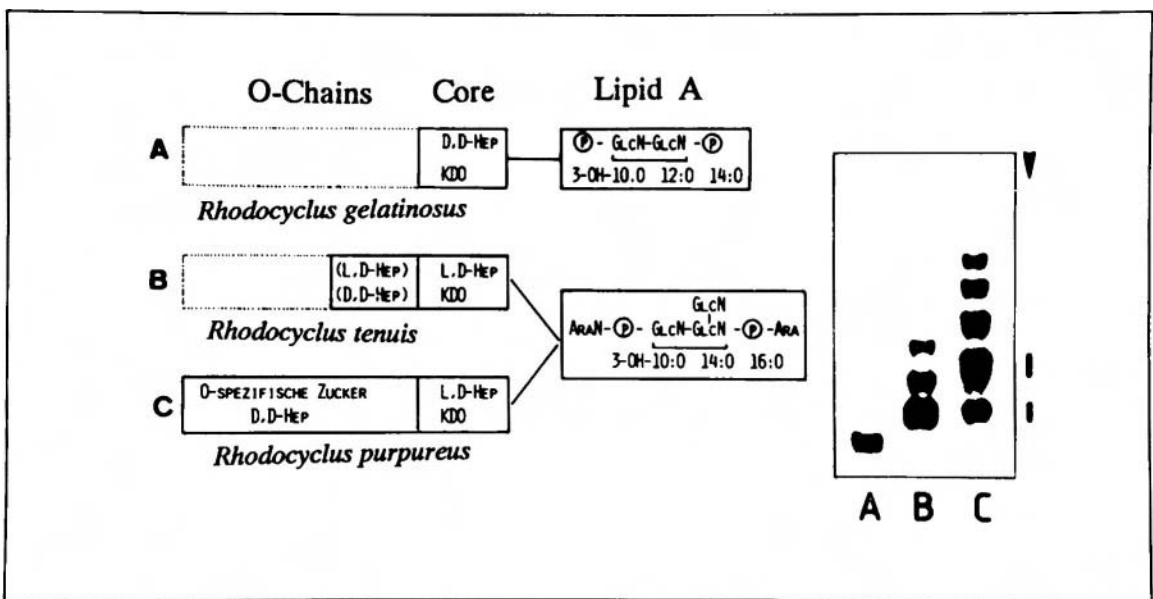

Fig. 4. Structural regions with their characteristic constituents, and DOC-PAGE of LPS's from *Rubrivivax* (*Rhodocyclus*) *gelatinosus* (short), *Rhodocyclus tenuis* (middle), and *Rhodocyclus purpureus* (long); in parenthesis are given the lengths of the sugar chains of the respective LPS's. Taken from Weckesser and Mayer (1987).

violacea) have been investigated for their LPS composition (Hurlbert et al., 1976; Hurlbert and Hurlbert, 1977; Meissner et al., 1988c). The so far incomplete data reflect the close phylogenetic relationship within the Chromatiaceae (Fig. 3C). Lipid A_{GlcN} from all of these species has uniformly a phosphate-free backbone with D-GlcN as the only amino sugar (only traces of DAG were found), and contain terminally-bound, nonacylated D-Man, probably attached to the C-4' position, but proven so far only for *Cm. vinosum* lipid A (Hurlbert et al., 1976). They all have amide-bound 3-OH-14:0 and 12:0 as the major ester-bound fatty acid. Other common characteristics are a core structure with D,D-Hep, as well as long O-chains, built up by repeating units as first demonstrated for a phototrophic bacterium by Hurlbert and Hurlbert (1977) using SDS-PAGE.

Several features in LPS composition have confirmed the separation of the Ectothiorhodospiraceae from the Chromatiaceae, as examined for the moderate halophilic species *Ectothiorhodospira vacuolata*, *Ectothiorhodospira mobilis*, *Ectothiorhodospira shaposhnikovii* and for the extreme halophilic *Ectothiorhodospira halophila* (Meissner et al., 1988d; Zahr et al., 1992). None of the species of Ectothiorhodospiraceae contain D-Man in their lipid A. The lipid A's from the Ectothiorhodospiraceae are phosphate-containing and have both D-GlcN and DAG with the diamino sugar being found in at least similar amounts as D-GlcN, revealing lipid A_{Hyb} or 'mixed' lipid A. In *Ec. halophila*, DAG is strongly dominating over D-GlcN, indicating the presence of lipid A_{DAG}. Lipid A_{DAG} has been found so far mostly within the subgroup α -2. Amide-bound 3-OH-14:0, as found with Chromatiaceae, is absent from the Ectothiorhodospiraceae. Within the Ectothiorhodospiraceae, the three moderately halophilic species can be differentiated from *Ec. halophila* by their LPS fatty acid spectra (Zahr et al., 1992). The similarities between the less moderately halophilic species confirm the data of 16S rRNA analyses (Stackebrandt et al. 1988b), revealing particular genome similarities between *Ec. shaposhnikovii*, *Ec. mobilis* and *Ec. vacuolata*. The finding of 3-oxo-14:0 in *Ec. halophila* is remarkable. This fatty acid has been found so far only in the species of the subgroup α -3 and in *Vibrio anguillarum* (cited in Mayer et al. 1990b). Also notable is the amide-linkage of 3-OH-10:0. It has been found elsewhere only in *Rhodocyclus* (Tharanathan et al.

1985) and in some *Aquaspirillum* species (Rau et al., 1993) belonging to the β subdivision of *Proteobacteria*.

Like the Chromatiaceae, the LPS's of all of the Ectothiorhodospiraceae species studied so far have D,D-Hep as the only heptose and Kdo in their core, but the Ectothiorhodospiraceae are lacking typical O-chains with repeating units.

2. Green Sulfur Bacteria (Chlorobiaceae)

Among the green sulfur bacteria (Chlorobiaceae), only *Chlorobium vibrioforme* f. *thiosulfatophilum* NCIB 8327 has been studied for its cell wall composition. Peptidoglycan with m-A₂pm of the A1 γ -type was present (Jürgens et al., 1987), and LPS is found in their outer membrane (Meissner et al., 1987). The latter has a phosphate-containing lipid A_{GlcN} with D-GlcN (and only traces of DAG). It is free of D-Man, a fact which clearly differentiates lipid A_{GlcN} of Chlorobiaceae from that of Chromatiaceae. The fatty acid spectrum is very characteristic by having three different amide-bound β -hydroxy fatty acids (3-OH-14:0, 3-OH-16:0, iso-branched 3-OH-18) but no ester-bound fatty acids. The polysaccharide moiety has a core region with Kdo and heptoses (L,D-Hep and D,D-Hep). On DOC-PAGE no ladder-like pattern was seen, indicating an R-type LPS (Table 1).

3. Green Non-Sulfur Bacteria (Chloroflexaceae)

The deep phylogenetic separation of the thermophilic green-nonsulfur bacterium *Chloroflexus aurantiacus* from the Chlorobiaceae is remarkably confirmed by cell wall analyses, although both contain the characteristic chlorosome structures (Fig. 5): Firstly, *Cf. aurantiacus*, although staining Gram-negatively (the peptidoglycan layer is thin), has partly phosphorylated muramic acid in which m-A₂pm is completely replaced by L-Orn (Jürgens et al., 1987). Secondly, a large polysaccharide of complex composition is likely covalently linked to muramic acid-6-phosphate via phosphodiester bridges in this peptidoglycan. Thirdly, peptidoglycan-bound protein or lipoprotein was not found here. Fourthly, LPS is absent, no β -hydroxy fatty acids, nor Kdo or heptoses were found in hot phenol-water extracts of cells of *Cf. aurantiacus* (Meissner et al., 1988e). In addition, an outer membrane is not seen in ultrathin sections. These properties are characteristic of Gram-positive

CHLOROSOMES		
	CHLOROBIAEAE (<i>Chlorobium vibrioforme</i>)	CHLOROFLEXACEAE (<i>Chloroflexus aurantiacus</i>)
LPS:	KDO Hep	D-GlcN 3-OH-14:0 3-OH-16:0 3-OH-18:0
Peptidoglycan:	m-A ₂ pm (Lipo)protein	L-Orn and MurN-6-P Complex polysaccharide

Fig. 5. Cell wall composition of Chlorobiaceae (Gram-negative type) and Chloroflexaceae (Gram-positive type). Taken from Stackebrandt et al. (1988b).

bacteria. It deserves mention that the cell wall of the nonphototrophic gliding bacterium *Herpetosiphon aurantiacus*, which together with *Cf. aurantiacus* belongs to the same phylum of eubacteria (Woese, 1987) and which shows clear, but not close, affinities with *Cf. aurantiacus* (Gibson et al., 1985), also was found to have characteristics of the Gram-positive cell wall organization comparable to those of *Cf. aurantiacus* (Jürgens et al., 1989).

4. Heliobacteriaceae

The cell wall of heliobacteria has properties reminiscent of the Gram-positive cell wall type (Madigan, 1992). *Heliobacterium chlorum* contains L,L- instead of m-A₂pm in its peptidoglycan, and glycine forms the interpeptide bridges according to preliminary studies (as stated in Beer-Romero et al., 1988). Both properties are found with Gram-positive but not with Gram-negative bacteria. Correspondingly, LPS was absent from both hot phenol-water or phenol-chloroform-petroleum ether (PCP) extracts of several species of heliobacteria (Beck et al., 1990). Instead, a polysaccharide was extractable by hot phenol-water. The walls of heliobacteria are unusually fragile and penicillin-sensitive, the reason for this is so far not known.

IV. Structure of Lipopolysaccharide (LPS)

A. Lipid A

The backbone amino sugar of lipid A in anoxygenic phototrophs can vary (Fig. 6), as first detected by Roppel et al. (1975) in *Rhodospseudomonas viridis*: 'Lipid A_{GlcN}' has D-GlcN as the only amino sugar,

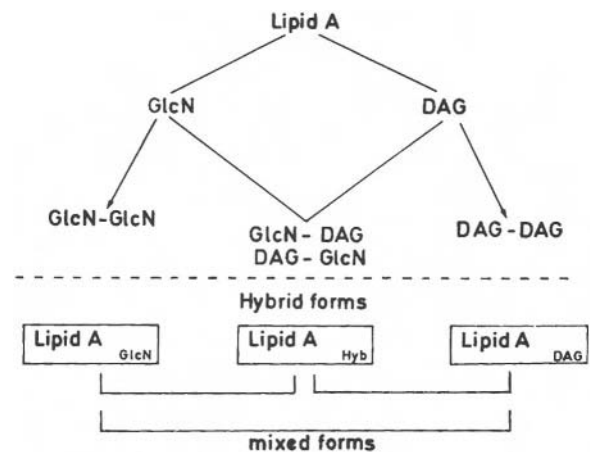

Fig. 6. Definition of lipid A_{GlcN}, lipid A_{Hyb}, lipid A_{DAG}, and 'mixed' lipid.

'lipid A_{Hyb}' (hybrid lipid A) has D-GlcN and DAG in the backbone (Moran et al., 1991), and 'lipid A_{DAG}' has exclusively DAG (Weckesser and Mayer, 1988). 'Mixed lipid A' indicates the concomitant occurrence of lipid A_{GlcN} and lipid A_{DAG} and sometimes also of hybrid forms in one and the same strain (Moran et al., 1991; Rietschel et al., 1992). Although lipid A_{Hyb} is likely present in distinct anoxygenic phototrophic bacteria, there is so far only a single proof for it, namely in *Rhodospirillum salinarum* (Heike Rau, unpublished data). The explanation for the structural variability in the backbone structure results probably from the reported lack of specificity of the lipid A synthetase (Raetz, 1992) as pointed out by Weckesser and Mayer (1988), and secondary processing of lipid A structure.

Lipid A_{GlcN} from *Rhodobacter sphaeroides* and *Rhodobacter capsulatus*: Lipid A_{GlcN} of both of these species (Fig. 7C and D) is structurally similar to enterobacterial lipid A_{GlcN} (Fig. 7A), which results also in a complete serological cross-reactivity (H. M. Kuhn, unpublished; Mayer et al., 1992). They all share a bisphosphorylated D-GlcN-β(1,6)D-GlcN backbone (Strittmatter et al., 1983; Krauss et al., 1989). In *Rb. sphaeroides* the phosphate groups are unsubstituted and 3-OH-10:0 is ester-linked at both the C-3 and C-3' positions. The acyloxyacyl group [(either 3-O-(*cis* Δ⁷-14:1)-10:0 or 3-O(14:0)14:0)] and the 3-oxo-14:0 or 3-OH-14:0 occupy the 2'- and 2-positions, respectively (Qureshi et al., 1988). In free lipid A, the hydroxyl groups at C-4 and C-6' are free (Salimath et al., 1983).

In contrast to *Rb. sphaeroides*, both amino groups

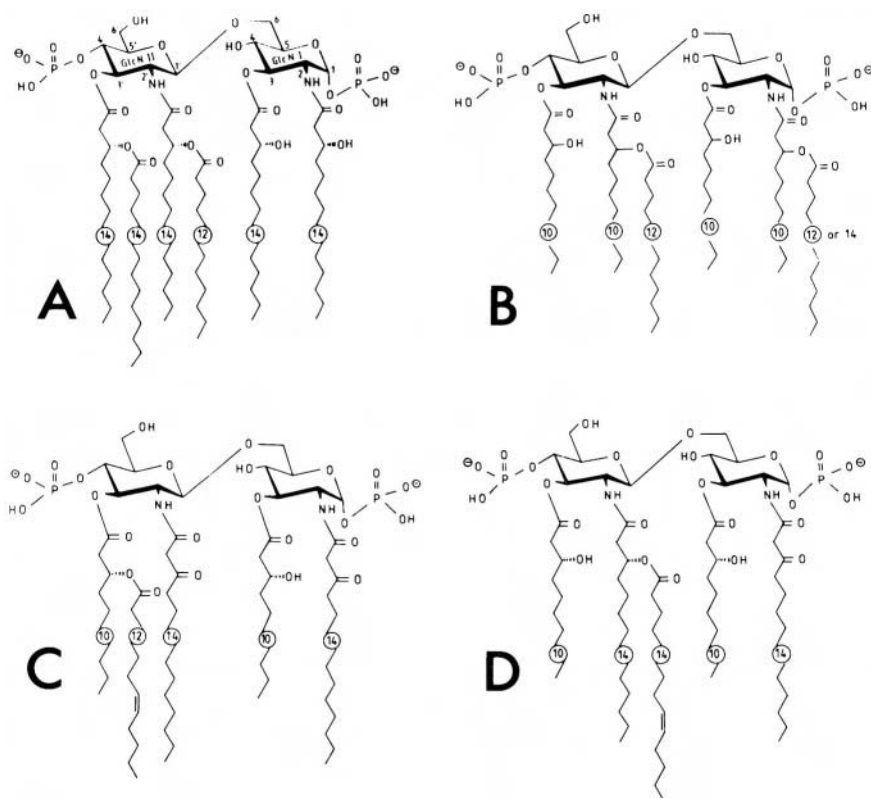

Fig. 7. Structures of toxic lipid A_{GlcN} from (A) *Escherichia coli* and (B) *Rubrivivax gelatinosus*, and of nontoxic lipid A_{GlcN} from (C) *Rhodobacter capsulatus* and (D) *Rhodobacter sphaeroides* (Weckesser and Mayer, 1988). Toxic forms with asymmetrical (A) and symmetrical (B) distribution of fatty acyl groups.

of the D-GlcN backbone are almost entirely substituted in *Rb. capsulatus* by 3-oxo-14:0, but like in *Rb. sphaeroides*, 3-OH-10:0 occupies both C-3 and C-3', the 3-OH-10:0 at C-3' being substituted with *cis* Δ^5 -12:1 (T. Merkofer, unpublished diploma work), forming the diester 3-O(*cis* Δ^5 -12:1)-10:0. In *Rb. capsulatus* 37b4 lipid A_{GlcN} , the C-4' and C-1 positions are partially substituted by ethanolamine and ethanolamine phosphate, respectively. Interestingly, lipid A_{GlcN} from *Rb. capsulatus* and *Rb. sphaeroides* are almost completely nontoxic (see next paragraph).

Lipid A_{GlcN} from *Rubrivivax (Rhodocyclus) gelatinosus*: The highly toxic lipid A_{GlcN} from *Ru. gelatinosus* (Galanos et al., 1977) is also structurally very similar to enterobacterial lipid A_{GlcN} but the six fatty acids are symmetrically distributed over both D-GlcN residues (Fig. 7B). The bisphosphorylated D-GlcN- β (1,6)D-GlcN backbone is in some strains substituted at the phosphate groups at C-1 and C-4' by ethanolamine (Masoud et al., 1990). The amino

groups of D-GlcN are occupied by 3-OH-10:0, which in turn are substituted by 12:0 and 14:0 forming acyloxyacyl residues. Unsubstituted 3-OH-10:0 residues occupy the C-3 and C-3' positions.

Lipid A_{GlcN} from *Rhodocyclus tenuis*: The backbone of this lipid A_{GlcN} is the commonly found β -D-GlcN-(1,6)D-GlcN disaccharide, but at least in *Rc. tenuis* 2761, the C-4 position is substituted by a third, non O- or N-acylated D-GlcN. The positions C-1 and C-4' are substituted by the rare D-Araf and by 4-AAP, respectively. The amino groups of both backbone D-GlcN units are substituted by 3-OH-10:0. In further contrast to *Ru. gelatinosus*, C-3 and C-3' are occupied by 14:0 and 16:0. In cultures grown at lower temperature (14 or 20 °C) the ratio of unsaturated/saturated fatty acids increased significantly (Masoud et al., 1990).

Lipid A_{GlcN} from *Rhodocyclus vannielii*: This lipid A_{GlcN} has also a β -D-GlcN-(1,6)D-GlcN backbone which, however, is not phosphorylated (Holst et al., 1983). Instead, the OH-group at C-1 is free, that of

C-4' carries partially D-Man. A comparison of photo- and chemotrophically grown *Rm. vannielii* cells revealed no significant difference in fatty acid composition except for the presence of an additional palmitic acid in chemotrophically grown cells (Rózalski and Kotelko, 1985). The amino group of the reducing GlcN is substituted by 3-OH-16:0.

Lipid A_{DAG} from *Rhodopseudomonas viridis*: A first structural proposal of this lipid A_{DAG} has been published (Roppel et al., 1975; Mayer et al., 1989). The backbone consists of nonphosphorylated DAG substituted by amide-linked 3-OH-14-OH. Although a monosaccharide backbone structure was proposed, it is very likely that we are dealing here also with a disaccharidic backbone of the diamino sugar similar to that of lipid A_{DAG} from *Pseudomonas diminuta* (Kasai et al., 1987). The only ester-linked fatty acids in lipid A_{DAG} of *Rp. viridis* (see Section III B, 1a) are the long-chained fatty acids such as 27-OH-28:0 and 28-OH-29:0. They are linked to the amide-linked 3-OH-14:0 (M. Busch and H. Mayer, unpublished data).

B. Polysaccharide Moiety

There are only a few structural studies available on the polysaccharide moieties of LPS's of phototrophic bacteria. One example is the core region of the LPS of *Rubrivivax gelatinosus* Dr2. It contains one residue of Kdo ketosidically linked to C-6' of the non-reducing D-GlcN of lipid A_{GlcN} (Masoud et al., 1991b). The Kdo unit is substituted at C-4 by an α -1,4-linked D-GalA disaccharide and at C-5 by a single unit of D,D-Hep partially substituted at C-7 by phosphate (Fig. 8). *Ru. gelatinosus* strains are lacking ADP-D,D-Hep-6-epimerase (Masoud et al., 1991b), which in Enterobacteriaceae converts ADP-D,D-Hep to ADP-L,D-Hep.

Rhodocylus tenuis strains have a common core composed of a branched trisaccharide of L,D-Hep and Kdo comparable to the inner core of enterobacterial LPS's, but there are strain-specific variations in the substituents (Fig. 8). They all share the D-manno-configuration (D-Man, L,D- and D,D-Hep) and are assumed to be transferred to the 4-position of the heptose unit of the L,D-heptosyl-Kdo-disaccharide by related or even identical transferases (Radziejewska-Lebrecht et al., 1981). Both, the core trisaccharide and the strain-specific regions are partially phosphorylated.

With the Neu5Ac-containing S- and R-type LPS's

of *Rb. capsulatus* a structural investigation of the core or the core-adjacent region was performed (Krauss et al., 1992). With the deep R-type LPS of strain Sp 18 which lacks the outer core region, the nonreducing terminal position of Neu5Ac was determined. In the R- and S-type LPS's of strains Kb-1 and 37b4, however, Neu5Ac is chain-linked. A trisaccharide of D-Gal- α (1,6)D-Glc- β (1,7)Neu5Ac was proven in the core-oligosaccharide of strain 37b4. It represented the first demonstration of a 7-substituted Neu5Ac in nature (Carfield and Schauer, 1982).

The structure of the oligosaccharide moiety of the *Rb. sphaeroides* ATCC 17023 O-antigen has been elucidated by Salimath et al. (1984). It is a L-Thr-containing 1,4-linked trisaccharide of α -linked D-GlcA disaccharide units linked to the 4-position of Kdo. Phosphorylation of Kdo at C-8 contributes further to this high accumulation of negative charges. L-Threonine is linked to the carboxylic group of D-GlcA by its amino group (Fig. 8). The linkage between core and lipid A_{GlcN} is by a single 1,4-substituted unit of Kdo attached by a 2,6'-linkage to lipid A_{GlcN}. Together with the knowledge of the respective lipid A_{GlcN} (see Section IV 'Lipid A'), the complete structure of the *Rhodobacter sphaeroides* ATCC 17023 LPS is thus known.

V. Contribution of the Lipopolysaccharides (LPS) of Purple Bacteria to Endotoxin Research

The different structural variants of lipid A found in anoxygenic phototrophic bacteria (for some structures see Fig. 7) can be nontoxic, as first observed with *Rhodobacter capsulatus* 37b4 (Weckesser et al., 1972; Strittmatter et al., 1983), or highly toxic, as in case of *Rubrivivax gelatinosus* 29/1 (Galanos et al., 1977). A comparison of their structure-endotoxic activities relationship has been undertaken in order to elucidate the structural requirements of lipid A for exhibiting endotoxic activity. For recent publications on the mechanism of endotoxic action including the activation of monocytes by the LPS-binding protein (LBP) via the LBP-LPS-complex, and the CD-14-receptor of monocytes, cytokine release including the tumor necrosis factor (TNF) as the prime mediator of endotoxic activity, and other cytokines see Mathison et al. (1992), Rock and Lowry (1991), and Schumann (1990).

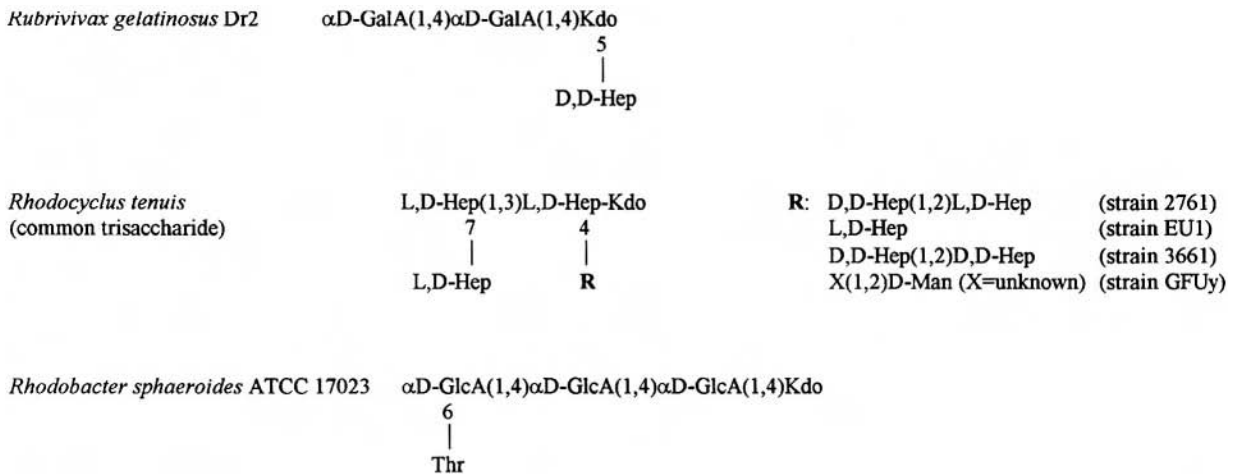

Fig. 8. Examples of core structures of LPS's from purple bacteria (according to Holst and Brade, 1992).

The nontoxic variants comprise two different groups, the first one (*Rb. capsulatus* 37b4, *Rb. sphaeroides* ATCC 17023) possessing a backbone structure comparable to enterobacterial lipid A_{GlcN}. The affinity of nontoxic lipid A_{GlcN} of *Rb. capsulatus* 37b4 and *Rb. sphaeroides* ATCC 17023 to LBP is only 1/100 and 1/40, respectively, of that of lipid A_{GlcN} of *Salmonella* sp. (Mayer et al., 1992). Lipopolysaccharide of *Rb. capsulatus* 37b4 induces mononuclear cell-derived interleukin-1 and interleukin-6 only at very high concentrations, and does not induce TNF activity. The *Rb. capsulatus* 37b4 LPS or the lipid A precursor Ia, or synthetic lipid A precursor ('compound 406') can act as endotoxin antagonists not only for lethality but virtually for all endotoxic activities (Loppnow et al., 1990; Loppnow et al., 1992). The mechanism of the antagonism is still unknown, but a strong inhibition of cytokine-induction by toxic LPS specimens from various bacteria was observed in co-incubation experiments in vitro (Loppnow et al., 1990).

Considering cytokine and especially TNF release as a measure of endotoxic activity, *Rb. sphaeroides* lipid A_{GlcN} has been recognized to specifically inhibit in vitro the biological action of toxic LPS's, including blocking the stimulatory effect of toxic LPS for β 2 integrin CD11b/CD18 expression on neutrophils in a variety of human and mouse cell types (Golenbock et al., 1991; Lynn et al., 1991; Lynn and Golenbock, 1992). The LPS of *Rb. sphaeroides* ATCC 17023 (Strittmatter et al., 1983) was used to serve as an

antagonist in the activation of macrophages by toxic lipid A_{GlcN} by studies on competitive binding to the receptor sites on the macrophage. Its purified bisphosphoryl lipid A_{GlcN} was shown to block the induction of TNF by toxic Re-type LPS of *Escherichia coli* in macrophage cell lines; it does not activate B-lymphocytes and does not induce cytokines in macrophages (Takayama et al., 1989). Lipid A from *Rb. sphaeroides* ATCC 17023 also did not stimulate the murine pre-B cell line 70Z/3 to synthesize surface immunoglobulin or mRNA (Kirkland et al., 1991). It was, however, able to block specifically *Escherichia coli* LPS-induced activation of 70Z/3 cells. Kirkland et al. (1991) conclude that lipid A from *Rb. sphaeroides* ATCC 17023 may antagonistically compete with the toxic LPS for lipid A receptors on the 70Z/3 cell, but this is not a generally accepted hypothesis.

In vivo tolerance to endotoxin-shock in rats by lipid A_{GlcN} from *Rb. sphaeroides* was recently described by Carpati et al. (1993). Qureshi et al. (1993) reported lipid A of *Rb. sphaeroides* to induce corticosteroids. Chemical reduction of 3-oxo-14:0 and Δ^7 -14:1 did not render the *Rb. sphaeroides* ATCC 17023 lipid A_{GlcN} toxic, which indicated that the lacking endotoxic activity is not due to the presence of 3-oxo and unsaturated fatty acids (Qureshi et al., 1991). The authors concluded that the lack of endotoxic activity may be either due to the presence of only five (instead of six in toxic lipid A_{GlcN}) fatty acyl groups or to the presence of unusually short

ester-linked 3-OH-10:0 coexisting with much longer amide-linked fatty acids (3-oxo-14:0) at positions 3 and 3' and the higher variation in size of the fatty acids (Qureshi et al., 1993). Since lipid A_{GlcN} from both *Rb. capsulatus* 37b4 and *Rb. sphaeroides* ATCC 17023 express complete serological cross-reactivity with enterobacterial lipid A_{GlcN} using polyclonal (Galanos et al., 1977) and defined monoclonal antibodies against various lipid A_{GlcN} with known epitope specificities (Mayer et al., 1992; Kuhn et al., 1992), the lack of toxicity should be caused by structural differences residing in the hydrophobic (fatty acid) part. For discussion of a lamellar supramolecular structure in the nontoxic lipid A, *versus* an inverted structure in toxic lipid A's, see below.

The other group of nontoxic lipid A is represented by phosphate-free lipid A_{DAG} or lipid A_{Hyb} (see Section IV A), thus, having profound modifications in the hydrophilic part of lipid A. Lipid A_{DAG} from *Rp. viridis* does not cross-react with either of the other lipid A_{GlcN} variations mentioned.

Recent studies have indicated that the sole replacement of D-GlcN by DAG in a toxic lipid A, while keeping all other structural parameters identical does not lead to a decrease in lethality (Moran et al., 1991). Variation in the phosphate substitution pattern of the backbone disaccharide is accompanied by reduced lethality (Takada and Kotani, 1992), although it seems that the endotoxic activities are (partly) retained by an exchange of one of the backbone phosphate groups by D-GlcA as in *Pseudomonas vesicularis* (Arata et al., 1992), and as recently documented also by D-GalA in *Rs. fulvum* (Heike Rau, unpublished results). Using X-ray diffraction with synchrotron radiation as well as by Fourier Transform (FT) infrared spectroscopy with toxic (*Rv. gelatinosus*, *Salmonella* sp.) and nontoxic (*Rb. capsulatus*, *Rp. viridis*) LPS's, it was found that differences in the primary lipid A structure led to differences in their supramolecular aggregation. The toxic lipid A_{GlcN} variants have a strong tendency to form inverted, the nontoxic lipid A_{GlcN} variants as well as the nontoxic lipid A_{DAG} from *Rp. viridis*, however, lamellar structures even at low temperature (Brandenburg et al., 1993). As opposed to the toxic properties (lethality, pyrogenicity, cytokine induction), the anticomplementary activity is most pronounced for compounds with lamellar structure. These findings may indicate that receptor molecules such as CD-14 or distinct proteins with high affinity

for LPS/lipid A complexes with LPS-binding protein (LBP) or bactericidal permeability increasing protein (BPI) (Gazzano-Santoro et al., 1992), may react preferentially with lipid A having inverted structures.

VI. Porin

A. Porins in Anoxygenic Phototrophic Bacteria

Porins are proteins of the outer membrane which form large water-filled channels which allow for diffusion of hydrophilic molecules into the periplasmic space (Nikaido, 1992). Among phototrophic bacteria, biochemical and functional characterizations of porins were performed with *Rhodobacter sphaeroides* ATCC 17023, *Rhodobacter capsulatus* strains St. Louis and 37b4 and *Rhodobacter blastica* DSM 2131 (Weckesser et al., 1984; Flammann and Weckesser, 1984; Benz et al., 1987; Woitzik et al., 1990; Butz et al., 1993). A major outer membrane protein (42 kDa) was described in *Chromatium vinosum* but not investigated for porin-function (Lane and Hurlbert, 1980a,b). The same is true for the major outer membrane proteins (app. Mr 43,000 and 14,000, respectively) of *Rhodospirillum rubrum* FR 1 (Oelze et al., 1975).

In contrast to porin from e.g. *Escherichia coli*, the oligomeric forms of the porins from both *Rb. sphaeroides* and *Rb. capsulatus* form monomeric porin upon treatment with 10 mM EDTA at 30 °C for 20 min (Weckesser et al., 1984; Flammann and Weckesser, 1984; Woitzik et al., 1990). The monomers chromatofocused revealing an isoelectrical point of about 4.0. With the oligomer, a single channel conductance of 3.15 nS in 1 M KCl was determined after reconstitution into artificial lipid bilayer membranes (Benz et al., 1987; Woitzik et al., 1990). The value was essentially in agreement with the pore diameter of the porin of *Rb. capsulatus* St. Louis, as determined by the liposome swelling assay (Flammann and Weckesser, 1984). The native porin of *Rb. sphaeroides* 2.4.1 (ATCC 17023) has been reported to be composed of heterologous subunits, an app. Mr 47,000 subunit and additional polypeptides of smaller molecular masses. The N-terminal alanine was found to be blocked due to bound fatty acids (Baumgardner et al., 1980; Deal and Kaplan, 1983a,b). Polyclonal antibodies against the major outer membrane protein of *Rb. sphaeroides* 2.4.1 (ATCC 17023), suggested to be a portion of the porin structure, reacted with

outer membrane preparations of various *Rb. sphaeroides* and one *Rs. rubrum* strain, but not with those of *Rb. capsulatus* and *Paracoccus denitrificans* (Deal and Kaplan, 1983c). No serological cross-reaction was obtained with porins from *Rb. capsulatus* and *Rb. sphaeroides* (Woitzik et al., 1989).

The export of the porin of *Rb. capsulatus* 37b4 was studied with the use of an uncoupler of the electron transport chain, radioactive labeling and immunoprecipitation (Woitzik et al., 1989). A protease-sensitive preform porin was accumulated in the cells in the presence of the uncoupler; the exported form was resistant to the enzyme. A 32 kDa protein associated with tetrapyrrole intermediates in the bacteriochlorophyll *a* biosynthetic pathway was found to be identical to the porin of *Rb. capsulatus* in biochemical and serological features (Bollivar and Bauer, 1992). It was discussed by the authors that the intermediates excreted by the cell become non-specifically lodged within the porin complex.

B. Structure of Porins

The porin of *Rhodobacter capsulatus* 37b4 was first crystallized by Nestel et al. (1989), showing at that time an X-ray diffraction to 3.2 Å resolution and a trigonal R3 space group. The resolution was later on increased up to 1.8 Å (Kreusch et al., 1991; Weiss and Schulz, 1992). Recently, the structure of porin from *Rhodopseudomonas blastica* was also elucidated to atomic resolution (Fig. 9A). The primary structure of the porin from *Rb. capsulatus* 37b4 was determined after trypsin, CNBr and Asp-N protease cleavage (Schiltz et al., 1991). The peptides obtained were aligned to a total length of 301 residues with an Mr of 31,536. A high excess of 34 Asp and 17 Glu (16.9%) over 10 Lys, 7 Arg, and 2 His (6.3%) confirmed the low isoelectric point of 3.9. The sequence was used as the basis for the interpretation of the electron density map derived from X-ray diffraction of porin crystals (Weiss et al., 1991a,b). Using the above mentioned techniques, the complete three-dimensional structure of the *Rb. capsulatus* 37b4 porin was elucidated (Weiss et al., 1991a,b). The functional complex is a trimer of three identical subunits each forming a separate pore. The three pores merge on the cell external surface side. Each monomer is a 16-stranded β-barrel (Fig. 9B). The β-strands are all antiparallel, the barrel is twisted in a right-handed manner, all strands are connected to their direct neighbors. Three of the 15 connecting loops contain

short α helices. The barrel rim, orientated to the external surface side, contains quite irregularly folded chain segments (no loop is shorter than 3 residues) and is called the 'rough side'. The largest connecting loop contains 43 residues and is between the fifth and the sixth β-strand at the rough side of the barrel. It runs into the inside of the barrel where it narrows the channel at the approximately half height and defines the pore size. In contrast, the lower rim of the barrel at the periplasmic space side of the pore is formed by 7 β-strand loops, 5 of them with short two-residue loops and 2 with three or more residue loops in a rather regular way. It is therefore called the 'smooth side'. The smooth side contains the N- and C-termini of the porin protein. Within the pore, 12 negatively charged amino acids (Asp and Glu) are localized at the large 43 residue loop. Opposite to them in this area, at the other inside of the pore, are located 6 positively charged amino acids (Arg, His, Lys), producing a strong charge-gradient across the pore (Fig. 9 C and D).

Thus, the trimer contains 3 distinct functional channels separated from each other by walls with an axial length of about 20 Å. If one divides one subunit at the barrel equator one observes only 7 negative and 7 positive charges in the lower half whereas there are as many as 44 negative and 12 positive charges in the upper half. The large excess of negative charges in the upper half is obvious and therefore the channel is electrostatically asymmetric along the axis. Around the equatorial circumference of the trimer there are non-polar side chains contacting the non-polar inner-part of the membrane, whereas the side-chains lining the channel are polar.

VII. External Envelope Layers

A. Capsules and Slimes

In *Rhodobacter capsulatus* St. Louis, capsule and slime polysaccharides with different chemical compositions and which differed in sugar composition from the respective O-chains of LPS were found (Omar et al., 1983a,b,c). The capsule was found to be strongly attached to the lipoprotein-peptidoglycan forming an unusually firm capsule polysaccharide-protein-peptidoglycan complex, insoluble in boiling sodium dodecyl sulfate and hot phenol-water (Bräutigam et al., 1988). The assumed capsule polysaccharide-protein bond was sensitive to

hydrofluoric or hydrochloric acid, and to alkaline hydrolysis. Digestion of the complex with pronase solubilized the capsule polysaccharide moiety with a characteristic amino acid pattern (Gly, Glu, Ser and Ala) remaining associated with it. On treatment of the protein-peptidoglycan moiety with lysozyme, the protein with peptidoglycan residues bound to it was solubilized. In the phage-resistant mutant *Rb. capsulatus* St. Louis RC1⁻, in which the capsule polysaccharide is present in a free form, the same protein was obtained by lysozyme digestion without preceding acid treatment. The capsule-free *Rb. capsulatus* 37b4 contained the protein-peptidoglycan complex but not the capsule polysaccharide moiety.

B. S-Layers

Surface (S)-layers are planar arrays of proteinaceous or glycoproteinaceous subunits which can be aligned as regular (crystalline) layers on the cell surface. They are found in many taxonomic groups of both Bacteria and Archaea species, but can be lost on cultivation under laboratory conditions. Amongst anoxygenic phototrophic bacteria, they were found in strains of the Chromatiaceae (*Chromatium okenii*, *Cm. weissei*, *Cm. warmingii*, *Cm. buderi*, *Cm. gracile*, *Thiocapsa floridana*, *Amoebobacter* sp.), and in the Ectothiorhodospiraceae (the moderate halophilic *Ectothiorhodospira mobilis* and the extremely halophilic *Ectothiorhodospira halochloris*). Layers, especially those of hexagonal symmetry, are widely distributed in nonsulfur purple bacteria of the subgroups α -1 (*Rhodospirillum rubrum*, *Rhodospirillum molischianum*, likely also in *Rhodospirillum salexigens*) and in the subgroup α -2 (*Rhodopseudomonas palustris*, *Rhodopseudomonas acidophila*). They have been at least tentatively identified in the green bacteria (*Pelodictyon* sp., *Chlorochromatium aggregatum*), as summarized by Messner and Sleytr (1992). The DOC-PAGE pattern of LPS preparations can provide valuable hints for the presence of S-layers as exemplified with a number of anoxygenic phototrophic bacteria (Krauss et al., 1988a). Detailed structural studies on S-layers from phototrophic bacteria, however, are to our knowledge not yet available.

VIII. Concluding Remarks

It has been urgently requested to use chemotaxonomic

or other phenotypic characteristics for proving or disproving the validity of relatedness of species based on nucleic acid sequence analyses (Murray et al., 1990). The analyses of cell wall macromolecules of anoxygenic phototrophic bacteria generally confirm ribosomal RNA sequencing investigations. One impressive example is the confirmation of the disparate phylogeny of the green sulfur and the green non-sulfur bacteria by their completely different cell wall organization. The cell wall of the thermophilic *Chloroflexus aurantiacus* may represent a character phylogenetically more ancient than the Gram-negative cell wall organization of the purple and the green sulfur bacteria, or the cyanobacteria.

A particularly attractive feature of phototrophic *Proteobacteria* and green-sulfur bacteria for comparative cell wall studies is their polyphyletic origin. Thus, they can be used as model organisms for study of the cell wall chemistry of nonphototrophic bacteria as well. The relatedness is especially expressed and confirmed within the α subdivision of *Proteobacteria*. Matching of lipid A composition and phylogenetic position of species is recognizable for most of the phototrophic bacteria studied so far, confirming in particular the phylogenetic relationship existing between phototrophic bacteria and their nonphototrophic relatives. Since bacterial photosynthesis is considered to have developed relatively early in evolution, it is not surprising that some of the LPS's of recent phototrophic bacteria may represent analogues of biosynthetic precursors or variants of the R-core and lipid A of more developed nonphototrophic species as discussed with examples by Mayer (1984) and Weckesser and Mayer (1988).

The spectrum of lipid A structural variants found with phototrophic bacteria (including the cyanobacteria), with a high variability of their biological properties, forms a reservoir of naturally occurring lipid A variants. This is of pharmacological and even actual clinical interest. Structural analyses of nontoxic and toxic lipid A's can contribute to answers concerning structure and endotoxic activity, in particular to the differentiation between the wanted biological properties of LPS, such as increase in unspecific resistance, and undesired properties, such as toxicity or endotoxic shock. The interest is focused today on those lipid A's which show highly reduced toxicity, for their possible use as endotoxin antagonists; in this regard lipopolysaccharide of *Rhodobacter sphaeroides* has recently become commercially available (List Biological Laboratories,

Fig. 9. (See also Color Plate 4.) Structure representations of porins from *Rhodopseudomonas blastica* and *Rhodobacter capsulatus*: (A) Space-filling model of the porin from *Rp. blastica* DSM 2131 as established at 2.0 Å resolution (Kreusch et al., 1994). The view is perpendicular to the membrane plane, the three pore eyelets are clearly visible. Hydrogens are not considered in this model. (B) Secondary structure of one subunit of the major porin from *Rb. capsulatus* 37b4 as viewed from the threefold symmetry axis. The external medium is at the top, the periplasm at the bottom. The 16 β -strands are given by blue arrows and the 3 short α -helices by orange helices. The long 43-residue loop inserting into the barrel is obvious. The interface part of the barrel is rather low while the membrane-facing part is high. The 'rough' barrel end at the top and the 'smooth' barrel end at the bottom can be visualized clearly.

*Fig. 9. Continued (See also Color Plate 5.) (C) Color-coded projection of one subunit from the *Rb. capsulatus* 37b4 porin onto the membrane plane. Aromatic side chains are yellow; positively and negatively charged side chains are red and dark blue, respectively. The interface and the threefold symmetry axis are at the bottom. Obviously, the rim of the pore eyelet is lined by positively charged side chains protruding from the interface area of the barrel juxtaposed to negatively charged side chains from the 43-residue loop running into the barrel interior. Most likely these charges form an electric field that facilitates permeation of polar solutes and hinders nonpolar ones. (D) Detail of the construction of the pore eyelet of the *Rb. capsulatus* porin. The amino acid residues are given in the usual color code, the fixed water molecules by crosses and the calcium ions by balls. Hydrogen bonds are indicated by dashed lines. 'Fixation' of the water molecules means that they are clearly visible in the X-ray structure analysis at the high resolution of 1.8 Å. This implies that water molecules are accommodated at the water positions most of the time. Still, these water molecules can move away. It should be noted that there is a defined network of hydrogen bonded water molecules at the eyelet leaving a rather small nonstructured cross-section in the center.*

Inc., Campbell, CA, USA).

Knowledge of the structure of the porin of *Rhodobacter capsulatus* 37b4 at atomic resolution was achieved by X-ray diffraction studies. The main properties of the *Rb. capsulatus* 37b4 porin have been used to predict those of the OmpF and PhoE porins of *Escherichia coli* (Welte et al., 1991), which were later essentially confirmed (Cowan et al., 1992), indicating that the porin from *Rb. capsulatus* 37b4 can be used as a model for the non-specific hydrophilic pores of the outer membrane of species of *Proteobacteria*. Thus, anoxygenic phototrophic bacteria have been proven to be useful as model organisms for cell wall studies contributing to a number of questions of general biological interest.

Summary

Photosynthetic Proteobacteria are used as model systems for many fields of modern biological research. The exciting results increased the progress considerably: Transduction of light energy into an electrochemical gradient of protons and electron- and proton-translocation in reaction centers and other membrane bound complexes has been studied on the molecular and atomic level with purple bacteria. Theories on the phylogeny of the energy metabolism have been stimulated and supported by 16S rRNA evolutionary analyses and biochemical investigations. Facultative purple bacteria have also been used to study cell and membrane differentiation. In this chapter it will be shown that most members of the anaerobic, anoxygenic photosynthetic bacteria develop a continuous system of cytoplasmic (CM)-intracytoplasmic membranes (ICM). The ICM is organized in characteristic, species-specific patterns of vesicles, tubules, thylakoid-like membrane sacs or highly organized membrane stacks. This development is strictly regulated by external growth factors like oxygen tension and light intensity. The ICM is formed under low oxygen tension by invaginations of the CM. At high oxygen tension and high light intensities the formation of ICM is suppressed. Although CM and ICM

form a membrane continuum, they are not homogenous in their composition. Membrane fractions differ in buoyancy density (lipid/protein ratio), pigment content, and biochemical activities. The photochemical apparatus is concentrated in the ICM and the enzymes of the respiratory chain and transport systems in the CM, respectively. Functional complexes of the photosynthetic apparatus have been visualized by freeze-fracture electron microscopy. Photochemical reaction centers are surrounded by oligomers of the core antenna complexes (B870) in stoichiometric ratios. The working hypothesis that core particle and ubiquinone-cytochrome bc_1 complexes form supramolecular structures in the membrane and that the dense population of membranes with proteins limits the free lateral mobility of proteinous complexes in the fluid-crystalline phase of the CM and ICM, is a challenge for future research on protein-protein interactions in membranes. Another interesting observation is the characteristic size and structure of ICM in the form of vesicles, tubules or stacks of flat membrane sacs. It has been proposed but not proved that distinct proteins are morphogenetic factors.

The morphogenesis of the photosynthetic apparatus is mainly regulated on the transcriptional level, but the signal chains, from sensing the external oxygen-partial pressure or light intensity to activation of transcription, is known only in parts, and an interesting field for future research. Targeting and translocation of pigment-binding proteins to and across the membrane is proposed to be supported by chaperonene and membrane-bound assembling proteins. Exchange or deletion of highly conserved amino acid positions in the pigment-binding proteins resulted in an inhibition of stable insertion and assembly. The cofactors bacteriochlorophyll, carotenoids and cytochromes are important factors in the assembling process. A blockade of their biosynthesis inhibits formation of stable complexes. Biosynthesis of the photosynthetic apparatus is presumably regulated via a signal chain and many activators which initiate transcription of supraoperonal DNA structures. Since no large precursor pools for phospholipids, membrane proteins, pigments, hemes and quinones have been observed, the process of membrane synthesis and differentiation must be highly coordinated. It is a challenge for future research to analyze and discover this process on transcriptional and posttranscriptional levels.

I. Introduction

Most of the anoxygenic photosynthetic purple bacteria have in addition to the cytoplasmic membrane (CM), which encloses the protoplast, intracytoplasmic membranes (ICM), which have a characteristic organization and function (Oelze and Drews, 1972; Collins and Remsen, 1991). The third type of membranes, the outer membrane, is a part of the cell wall of Gram-negative bacteria and has been described in Chapter 11 by Weckesser et al. ICMs are characteristic of but not restricted to phototrophic proteobacteria. Obligate methylotrophic bacteria and nitrifying bacteria also contain ICMs (Drews, 1992). Obviously, ICMs have developed during evolution as a functional adaptation to environmental conditions and as a process of functional differentiation of membrane-bound energy-transducing systems.

Structure, function and biogenesis of the CM-ICM system has been studied extensively in *Rhodospirillum rubrum*, *Rhodobacter capsulatus*, and other facultative photosynthetic bacteria, which grow under chemotrophic and phototrophic conditions as well (Fig. 1). These bacteria are excellent models to study membrane biosynthesis and differentiation under well defined external growth conditions. The major components of the ICM are the membrane-bound complexes of the photosynthetic apparatus.

The reader of this chapter will be introduced by the classical static view of electron microscopy, which, along with biochemical studies, opened the field of modern research on photosynthetic bacteria about forty years ago. Electron microscopical studies of thin sections from cells cultivated under defined conditions showed very early that formation of ICM and bacteriochlorophyll (BChl) and increase of photophosphorylating activity run parallel as a dynamic process. Quantitative freeze-fracture electron microscopy opens the interior of membranes and exposes the integral membrane particles, showing the asymmetry of the fracture halves of the lipid layer and distinct size classes of particles which have

Abbreviations: BChl – bacteriochlorophyll; CM – cytoplasmic membrane; EF–exoplasmic fracture face; ICM–intracytoplasmic membrane; LH – light-harvesting; PF – plasmic fracture face; *Rb.* – *Rhodobacter*; RC – reaction center; *Rc.* – *Rhodocyclus*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*

Fig. 1. Scheme of structure and arrangement of intracytoplasmic membranes (ICM) bearing the photosynthetic apparatus. 1) Vesicle type, realized in *Rhodospirillum rubrum* (see also Fig. 12), *Rhodobacter capsulatus* (Figs. 7, 8, 15), *Chromatium vinosum* (Figs. 5, 6), *Thiocapsa roseopersicina* and other species. 2) ICM consisting of tubuli in *Thiocapsa pfennigii* and some other bacteria. 3) ICM are flat thylakoid-like membranes organized in regular stacks, present in *Rhodospirillum molischianum*, *Ectothiorhodospira shaposhnikovii* (Fig. 4) and other species. 4) Large thylakoids, partially stacked and irregularly arranged, are presented in *Rhodopseudomonas palustris* (Fig. 13) and *Rhodopseudomonas viridis* (Reproduced from G. Drews and J. F. Imhoff, 1991).

Fig. 2. Scheme of the photosynthetic apparatus in the intracytoplasmic membrane of *Rhodobacter capsulatus* and related bacteria. The reaction center (RC), consisting of subunits M, L and H, is surrounded by the light-harvesting complex LH I (B870) forming the core complex. The core complexes are connected by LH II (B800–850) antenna complexes. B870 has 2 mol BChl per monomer and B800–850 3 mol BChl per monomer (1α -, 1β -polypeptide). All LH complexes form oligomers (\approx hexamers, octamers). *Rb. capsulatus*, *Rb. sphaeroides* and *Rhodospirillum rubrum* have no tetra-heme cytochrome unit bound to RC. The electrons are shuttled by cytochrome c_2 from the ubiquinone-cytochrome bc_1 complex to RC. The functional subunits of the respiratory chain, such as NADH dehydrogenase and the terminal oxidases, which are present in CM and ICM, have been omitted for clarity.

been identified as pigment protein complexes. High-resolution electron microscopy of isolated defined complexes confirmed and extended results from freeze-fracture electron microscopy. Today many of the functional complexes of CM and ICM have been isolated, the primary structure of their proteins determined by protein or DNA sequencing, and the structure, topography and organization (Fig. 2) analyzed to different levels. The most exciting work on biosynthesis and assembly of membranous functional complexes and their regulation is in an

early state. The first results will be reported at the end of this chapter.

II. Structure and Supramolecular Organization of Cytoplasmic and Intracytoplasmic Membranes

A. Ultrastructure

The outer membrane of the cell wall is characterized in ultrathin sections as a typical double track layer

Fig. 3. Invaginations (➤) of the cytoplasmic membrane (CM) to form intracytoplasmic membranes (ICM) demonstrating the continuity of both membranes. a) Ultrathin section of *Rhodobacter capsulatus*. b) Freeze-fracture micrograph of the plasmic fracture face (PF) of the cytoplasmic membrane of *Rhodospirillum rubrum* (reproduced from Golecki and Drews, 1980). Arrow in the upper right corner of the freeze-fracture micrograph indicates, as in all following freeze-fracture pictures, the direction of shadowing. Bars represent 100 nm.

Fig. 4. Ultrathin section of *Ectothiorhodospira shaposhnikovii* exposing several lamellar stacks of ICM. Cell wall (CW). Bar represents 200 nm.

with two electron-dense lines separated by an electron transparent middle zone (Figs. 3, 4; see also Figs. 8, 15). The thickness of the outer membrane is approximately 8 nm.

In this report we only want to mention a connection of the outer membrane with the cytoplasmic membrane by adhesion sites which could be detected in ultrathin sections of some purple bacteria (Golecki, unpublished results). The adhesion sites described for *Escherichia coli* and *Salmonella typhimurium* (Bayer, 1968; Mühlradt et al., 1974) have been interpreted to be export sites of newly synthesized lipopolysaccharides into the outer membrane. In respect to the presence of lipopolysaccharides in the outer membrane of purple bacteria (Weckesser et al., 1979), these adhesion sites may have the same function as in enteric bacteria.

The CM underlying the cell wall surrounds the protoplast and represents a selective barrier to the environment. In ultrathin sections the CM presents the same ultrastructure of a double track layer (7–8 nm of thickness) as the outer membrane (Figs. 3, 4; see also Figs. 8, 15). In some micrographs the CM

appears to be separated from the cell wall by an electron transparent periplasmic space. This seems to be an artifact because the periplasmic space is a densely populated space and not empty. In the CM the components of the respiratory chain, other energy transducing complexes and transport systems are localized, whereas the photosynthetic activities generally are housed in the ICM (Fig. 2)(Bowyer et al., 1985). Most phototrophically grown purple bacteria form ICM that carry out photosynthetic activities. The continuity of the CM and ICM has been demonstrated in several facultative phototrophic bacteria (Drews and Giesbrecht, 1963; Cohen-Bazire and Kunisawa, 1963; Boatman 1964; Holt and Marr 1965a; Tauschel and Drews, 1967).

The ICM is formed by invagination of the CM (Fig. 3)(Drews and Giesbrecht, 1963; Hickman and Frenkel, 1965; Tauschel and Drews, 1967). In spite of the morphological continuity and possible morphogenetic relationships, both membrane types present clear differences in chemical and structural composition, physical properties, function and kinetics of biosynthesis (Section II.B–D).

Fig. 5. Negative stained preparation of intracytoplasmic membranes of *Chromatium vinosum* isolated by a mild procedure. Large parts of the ICM vesicles are still connected to each other (▶). Bar represents 200 nm (Reproduced from Hurlbert et al., 1974; courtesy of J.R. Golecki).

Fig. 6. Negatively stained ICM vesicles (= chromatophores) of *Chromatium vinosum* after French press isolation. The connections between the vesicles are interrupted. Bar represents 200 nm (Reproduced from Hurlbert et al., 1974; courtesy of J.R. Golecki).

Fig. 7. Ultrathin section of a spheroplast preparation of *Rhodobacter capsulatus* exposing the transition of tubular into vesicular ICM types (▶). The sample was taken early after induction of membrane differentiation. Bar represents 100 nm (Reproduced from Dierstein et al., 1981; courtesy of J.R. Golecki).

Fig. 8. Ultrathin sections of *Rhodobacter capsulatus*. (a) grown at high light conditions exhibiting only a small number of ICM vesicles. (b) grown at low light conditions with numerous ICM of vesicular type. Bars represent 200 nm.

Among the numerous members of the purple bacteria, several types of ICM have been discovered (Fig. 1; Bachofen and Wiemken, 1986; Sprague and Varga, 1986). The ICMs consist of a network of vesicles (Figs. 5, 6, 7, 8; see also Figs. 12, 15), tubules (single or arranged in bundles), thylakoid-like flat lamellae sometimes forming grana-like stacks (Fig. 4; see also Fig. 13), or irregular non-stacked membranes (Oelze and Drews, 1972). The ICM are connected to each other (Fig. 5), at least during their morphogenesis, and form a large membrane continuum together with the cytoplasmic membrane (Holt and Marr, 1965a; Hurlbert et al., 1974; Dierstein et al., 1981).

During isolation procedures, the small tubular connections between the ICM vesicles or lamellae are interrupted and single ICM vesicles are obtained, which have been described as ‘chromatophores’ (Fig. 6). Due to the process of invagination during morphogenesis, the interior of the ICM structures is an extra-cytoplasmic space. Therefore the intra-membrane components of the ICMs are oriented inversely (see Figs. 12 and 15) in comparison to

cytoplasmic membranes (Hochman et al., 1975; Michels and Konings, 1978). The extension of ICM is dependent on several external factors like oxygen tension, light intensity, and some other growth factors (Holt and Marr, 1965 b).

Under strictly aerobic, chemotrophic growth conditions, purple bacteria generally exhibit no ICM. One exception is *Rhodobacter capsulatus* which forms a few polar tubular ICMs even under high oxygen tensions (Lampe and Drews, 1972; Lampe et al., 1972; Dierstein et al., 1981; Fig. 7).

Turning to phototrophic growth conditions (i.e. anaerobic in the light) the formation of ICM is induced (Figs. 3, 7). In the early stages of ICM differentiation (i.e. 1 to 4 h after the shift to phototrophic growth conditions) in *Rb. sphaeroides*, the newly formed ICM often has the form of flat sheets or broad tubules with a high lipid-to-protein ratio as indicated by the low particle number per membrane area (Chory et al., 1984). Later on during the adaptation the broad tubules or flat sheets became more rounded and reduced in size. When at the end of the adaptation period the cells were growing photosynthetically, the ICM is composed of small vesicles (40 to 70 nm in diameter) seen in photosynthetically grown control cells. Similar observations were obtained with *Rb. capsulatus* after the shift from chemotrophic to phototrophic growth conditions (Dierstein et al., 1981; Kaufmann et al., 1982; Fig. 7). The amount of ICM produced under anaerobic conditions depends on light intensity (Cohen-Bazire and Kunisawa, 1963; Holt and Marr, 1965 b; Golecki et al., 1980; Reidl et al., 1983, 1985): Under high-light conditions only a few vesicles are detectable at the periphery of the protoplast in cells of *Rs. rubrum* and *Rb. capsulatus* (Fig. 8a). Under low light conditions, however, the bacteria contain a much higher number of vesicles filling most of the cytoplasmic space (Fig. 8b). Cells of *Rb. capsulatus* grown at low light conditions (7 W m^{-2}) contained 1150 ICM vesicles per cell, which is 6.3 fold more than in cells grown at high light intensities (2000 W m^{-2}) (Golecki et al., 1980).

Due to an increase of the number of vesicles under low light conditions the total surface area of ICM per cell is enlarged to approximately $6 \mu\text{m}^2$; this represents an area 2.7-fold larger than the area of the whole CM. Concomitant with the enlargement of the ICM area in low light grown cells, the BChl content as well as the size and concentration of photosynthetic units increases (a photosynthetic unit is one photochemical

reaction center (RC) plus surrounding antenna pigment-protein complexes and is calculated as mol total BChl per mol RC).

In contrast to most nonsulfur purple bacteria, which adapt from chemotrophic to phototrophic growth conditions by forming photosynthetically active ICMs, cells of *Rubrivivax gelatinosus*, *Rhodocyclus purpureus*, and, in particular, *Rhodocyclus tenuis*, exhibit only occasional small single tubular intrusions of the CM (De Boer, 1969). This lack of ICM is compensated by a larger area of CM (Wakim et al., 1978) and higher density of photosynthetic units.

Occasionally ICMs with non-photosynthetic activities have been described for purple bacteria. These mesosomes, also described for other non-photosynthetic bacteria, were defined as sac-like invaginations of the cytoplasmic membrane (Reavely and Burge, 1972). They were thought to be involved in cell processes like replication and segregation of the chromosomes and in cell division. However, modern electron microscopic preparation techniques (Ebersold et al., 1981; Dubochet et al., 1983) gave evidence that classical mesosomes are artifacts of the preparation technique. Another type of ICM with a myelin-like configuration was observed in cells of *Rs. rubrum* after long-term anaerobic dark growth (Schön and Ladwig, 1970; Uffen et al., 1971). It was suggested that these myelin-like deposits resulted from the degradation of photosynthetically active membranes (chromatophores).

B. Membrane Architecture Shown by Freeze-Fracture Electron Microscopy

Much information about the supramolecular organization of photosynthetic membrane systems in purple bacteria has been obtained by freeze-fracture studies. This method exposes the internal architecture of the membranes on two complementary fracture faces (i.e. the plasmic and exoplasmic fracture face [PF and EF, respectively]) by splitting the membranes along their hydrophobic middle zone. Therefore membrane components like proteins or pigment-protein complexes become visible as so-called intramembrane particles of different size. The number of the particles per membrane area is an indication of the numerous biochemical activities of the membrane (Figs. 9, 10, 11).

Participation of the CM in the ICM-forming process has been demonstrated by freeze-fracture for several purple bacteria. In chemotrophically (dark)

Fig. 9. Plasmic fracture face (PF) of the cytoplasmic membrane of *Rhodobacter sphaeroides* grown under chemotrophic conditions aerobically in the dark. A high population of homogeneously distributed intramembrane particles is visible on the PF of the cytoplasmic membrane. Bar represents 200 nm.

Fig. 11. Freeze-fracture micrograph of *Rhodospirillum rubrum* exposing numerous invaginations (↖) on the EF of the CM after induction of ICM formation by shifting to photosynthetic growth. Bar represent 200 nm (Reproduced from Golecki and Oelze, 1975).

Fig. 10. Freeze-fracture micrographs of *Rhodocyclus tenuis* exposing the exoplasmic fracture face (EF) of the cytoplasmic membrane. (a) Under chemotrophic growth conditions the cytoplasmic membrane is covered only by a small number of intramembrane particles. The exoplasmic fracture face (EF) of the outer membrane (OM) is also exposed. (b) Under phototrophic growth conditions photosynthetically active complexes are incorporated in a high number into the exoplasmic leaflet of the CM. Bars represent 200 nm (Reproduced from Wakim et al., 1978; courtesy J.R. Golecki).

grown cells of *Rs. rubrum*, *Rb. sphaeroides*, *Rc. tenuis* and *Rb. capsulatus* (Golecki and Oelze, 1975, 1980; Wakim et al., 1978; Golecki et al., 1979) the plasmic fracture face (PF) is usually densely covered with intramembrane particles of varying sizes (Fig. 9; see also Fig. 13), while the exoplasmic fracture face (EF) (Fig. 10a) of the CM is sparsely covered with large particles. Apart from some minor differences in the number and size of the intramembrane particles among the different strains, the fracture faces of chemotrophically grown purple bacteria are not distinguishable from those of other bacteria like *E. coli* (Fig. 9). Clear differences become visible when chemotrophically grown cells are transferred to phototrophic growth conditions (Fig. 10, 11). Among the different members of photosynthetic bacteria a great variation was demonstrated concerning the participation of the CM in the formation of photosynthetically active structural components (Golecki and Oelze, 1980).

Cells of the facultative purple bacteria *Rhodocyclus tenuis*, *Rubrivivax gelatinosus* and *Rc. purpureus* are distinguished from other phototrophic bacteria by their poorly developed ICM. They contain only small single tubular intrusions of the CM. This lack of ICM system is compensated by a larger area of CM and a higher density and diameter of intramembrane particles in the CM of phototrophic compared with chemotrophic cells. The extension of the CM area results from incorporation of photosynthetic units in the existing electron transport system of chemotrophic cells (Wakim et al., 1978; Wakim and Oelze, 1980). Cells of *Rhodocyclus* species have a lower diameter

than most other purple bacteria. The incorporation of the photosynthetic apparatus is not accompanied by invaginations but by extension of CM. In a comparative study by freeze-fracture electron microscopy, Golecki and Oelze (1980) demonstrated the striking difference in intramembrane particle patterns between the ICM-forming species *Rhodospirillum rubrum* and *Rhodobacter sphaeroides* and the CM extension-type represented by *Rhodocyclus tenuis*.

The number and size of intramembrane particles in the CM of *Rs. rubrum* and *Rb. sphaeroides* remain relatively constant under various culture conditions, but in the CM of *Rhodocyclus tenuis* the particle size and number change strongly upon induction of the photosynthetic apparatus. The newly formed photosynthetic units are placed in the outer leaflet of the CM. On the EF of the CM the number of intramembrane particles increases by a factor 6.9 after transfer to phototrophic conditions, whereas the particle number on the PF is nearly constant under both conditions. The increased number of particles on the EF was mainly the result of an increased occurrence of particles with diameters of ≥ 10 nm (Fig. 10b).

In *Rs. rubrum*, however, the number of particles on the EF of the CM stayed nearly constant, but on the PF the particle number increased from 4,700 to 6,200 particles per μm^2 after transfer to phototrophic conditions. The increase in number was largely caused by an enhanced occurrence of 10 nm particles.

Invaginations of the CM to form the ICM could be demonstrated as indentations and protuberances (Fig. 11) on both complementary fracture faces of the CM (Golecki and Oelze, 1975). Before the first invaginations could be observed, BChl was detected in the cells. The synthesis of BChl before forming ICM indicates that BChl and BChl-binding proteins become incorporated into the CM during the initial phase of adaptation. In a second phase, the BChl content increased and invaginations of the CM occurred and increased in number. In a later stage the number of invaginations and the cellular BChl content do not increase in the same rate. In *Rs. rubrum* the particular involvement of the CM in the process of BChl incorporation and ICM formation could be demonstrated by particle size histograms of freeze-fractured cells (Golecki and Oelze, 1980). After transfer to phototrophic conditions, the number of 10 nm particles increased on the PF of the CM by 33%. The 10 nm class is the predominant class of particles

Fig. 12. ICM vesicles of *Rhodospirillum rubrum* exposing regularly arranged intramembrane particles of approx. 10 nm in diameter. (a) on the plasmic fracture face of the ICM and (b) on the outer surface of frozen-etched ICM vesicles. Bar represent 100 nm.

visible on the plasmic fracture faces of ICM vesicles (Fig. 12). These 10 nm particles could be extracted with lauryl dimethylamine oxide from ICM vesicles concomitant with the extraction of reaction centers (Oelze and Golecki, 1975).

In *Rb. sphaeroides* the number of particles of both fracture faces of the CM stayed nearly constant after transfer to phototrophic conditions. The mean diameter appeared to be slightly increased under phototrophic conditions. Particles in CM and ICM of phototrophically grown cells were of similar diameter (7.0 – 8.0 nm). In cells of *Rb. sphaeroides* invaginations were demonstrated on fracture faces of the CM under phototrophic and under chemotrophic conditions at low oxygen tension.

In *Rb. capsulatus* (Golecki et al., 1979) the particle number on the PF of the CM increased about 20–55%; after the induction of BChl synthesis the 9.5 nm particle class dominates under all conditions. The distribution of particles on the fracture faces of the CM is homogenous. The same was observed in other purple bacteria.

The CM of photosynthetically grown cells of *Rhodopseudomonas palustris*, however, is spatially differentiated into regions of extremely high particle density and areas of lower particle densities (Varga and Staehelin, 1983). Areas with a higher particle

Fig. 13. *Rhodospseudomonas palustris* exposing plasmic fracture faces of the cytoplasmic membrane and of the lamellar arranged ICM membranes. Bar represents 200 nm.

density correspond to the adhesion sites between CM and ICM. The stacked ICM of *Rp. palustris* occupied the same areas of high particle density as detected on the CM (Fig. 13). This implies that the CM too is differentiated for photosynthesis in these regions. On the respective fracture faces of the ICM stacks, changes in particle size distribution could be demonstrated in response to changes in the light intensity supporting growth. When light intensity was decreased from 8500 to 100 lx, the average particle diameter on the PF of stacked ICM and CM increased in size. Four prominent particle classes of 7.5, 10.0, 12.5, and 15.0 nm were measured. When light intensity decreased, the portion of larger particles increased, suggesting that after lowering the light intensity subunits of discrete size are being added to the core particle. The smaller particles (7.5–10.0 nm), which are the most prevalent at high light conditions, were interpreted to represent the core particles formed by reaction center and light-harvesting I (LH I) complexes (Figs. 13, 14). The larger particles (10.0–15.0 nm), only seen in appreciable amounts in low-light cells, were proposed to be formed by adding light-harvesting II (LH II) complexes in defined portions to the core particles

Fig. 14. Freeze-fracture micrograph of a liposome with incorporated reaction center-LH I core complexes of *Rhodobacter capsulatus*. Bar represents 200 nm.

(Fig. 2). The arrangement of the LH I and LH II complexes around the reaction centers results in a six-fold axis of symmetry.

The influence of different light intensities on the size and number of intramembrane particles on the fracture faces of ICM was demonstrated also for *Rb. sphaeroides* (Yen et al., 1984) and *Rb. capsulatus* (Golecki et al., 1979, 1980). An increasing size of intramembrane particles on the PF of the ICM concomitant with decreasing light intensities was shown also for *Rb. sphaeroides* (Yen et al., 1984). This is similar to *Rp. palustris*, where the RC and LH I complexes are in a fixed stoichiometry while the number of LH II complexes vary inversely as a function of light intensity.

Different particle sizes of the LH I-core complexes in purple bacteria containing either BChl *a* or BChl *b*, were explained by a different polypeptide composition (Meckenstock et al., 1992). The number of LH polypeptides per reaction center was calculated to be 36 in BChl *b*-containing bacteria compared to 24 in BChl *a*-containing bacteria. The size of the BChl *a*-containing LH I-core complex was believed to be smaller. This is in good agreement with the RC-to-RC distance of 10.2 and 10.0 nm for the BChl *a*-containing core complexes of *Rp. marina* (Meckenstock et al., 1992) and *Rs. rubrum* (Oelze and Golecki, 1974), respectively, compared with RC-to-RC distances of 13.0 nm for the BChl *b*-containing bacterium *Rhodospseudomonas viridis* (Stark et al., 1984).

The intramembrane particles of the photosynthetic apparatus showed a hexagonal lattice in several BChl *b*-containing (Giesbrecht and Drews, 1966; Miller, 1979; Wehrli and Kübler, 1980; Engelhardt et al.,

1983) and also some BChl *a*-containing (Oelze and Golecki, 1975, Meyer et al., 1981; Merckenstock et al., 1992) purple bacteria. The ordered arrangement was shown by freeze-fracturing (Fig. 12), negative staining, and shadow casting. From the concomitant disappearance of 10 nm particles and RC it was concluded that the 10 nm particles of *Rs. rubrum* are formed by the reaction center and LH I complexes.

Generally the particle density (= particle number per defined membrane area) on fracture faces of photosynthetic ICMs is higher than the particle density on the respective fracture faces of the CM (Lommen and Takemoto, 1978 a; Golecki et al., 1979; Golecki and Oelze, 1980; Varga and Staehelin, 1983). In *Rb. capsulatus*, a decrease in light intensity leads to an increase in the number of particles in the ICM (Golecki et al., 1980), whereas in *Rp. palustris*, the particle number decreases with reduction of light intensity while particle size increases (Varga and Staehelin, 1983).

The analysis of freeze-fractured or negative stained preparations of ICMs with image processing methods like Fourier filtration techniques increased the resolution and gave new information about the supramolecular organization of the RC-LH I core complexes. This was demonstrated with *Rp. viridis* (Miller, 1979, 1982; Wehrli and Kübler, 1980; Stark et al., 1984) and some other BChl *b*-containing species (Engelhardt et al., 1983) and the BChl *a*-containing *Rhodospseudomonas marina* (Meckenstock et al., 1992).

A combination of image analysis and immunoelectron microscopy with monoclonal antibodies against the H-polypeptide of the reaction center (Stark et al., 1986) leads to the following model of the photosynthetic unit of *Rp. viridis*: the reaction center is surrounded by 12 LH complexes. The H-polypeptide is located in the central core with an asymmetrical lateral distribution on the CM surface. The LH units are arranged in a ring of 24 transmembrane α -helices. It is speculated that each of these α -helices belong to a B1015- α or B1015- β polypeptide and their N-termini are located on the plasmic surface.

C. Identification and Organization of Membrane Particles

Immunoelectron microscopical methods using specific antibodies against defined components of the photosynthetic apparatus were applied to get

information on the topography of defined components of the photosynthetic apparatus in the ICM (Valkirs and Feher, 1982; Collins and Remsen, 1984; Crook et al., 1986). The ATPase was demonstrated on the surface of the CM of *Rb. sphaeroides* (Reed and Raveed, 1972) and *Rs. rubrum* (Löw and Afzelius, 1964) as knob-like particles of 9 nm in diameter. Labeling with ferritin-conjugated antibodies against H, L and M proteins of the RC demonstrated the asymmetrical distribution of the reaction center across the *Rb. sphaeroides* membrane (Reed et al., 1975; Valkirs and Feher, 1982). The H and M subunits were labeled at both the cytoplasmic and periplasmic surface of the ICM, whereas the L subunit was labeled only at the periplasmic surface of the membrane. These data in combination with iodination experiments indicated very early that RC complexes span the membrane. Using gold-labeled antibodies against the LH complex of *Rb. sphaeroides*, the presence of LH antigens on the PF of the chromatophore membrane was demonstrated (Collins and Remsen, 1984).

The asymmetrical distribution of RC and light-harvesting proteins on cytoplasmic and periplasmic surfaces has been demonstrated for *Rp. viridis* (Jay et al., 1983). A cytoplasmic location of the reaction center cytochrome, H, M and L-chain and of the light-harvesting polypeptides α , β and gamma was observed on isolated ICM vesicles by the use of ferritin-conjugated antibodies in combination with surface-specific iodination and protease treatment. In addition, an exoplasmic location of polypeptide H was noted.

Subchromatophore particles with photosynthetic activity were detected in Triton X-100 treated preparations of *Rhodospseudomonas* sp. (Garcia et al., 1968). The particle had an outer diameter of 13.5 nm and showed an inner core which was 6.0 nm in diameter. A pure fraction of native photoreceptor units isolated from ICMs of *Rp. viridis* could be shown in negative stained preparations (Jay et al., 1984, Stark et al., 1984). The isolated photoreceptor unit presented the same symmetry and dimensions as the particles in the intact ICM.

Defined membrane particles, for example RC + LH I core complexes, have been incorporated into liposomes to study size and structure (Fig. 14). Pigment-protein complexes from *Rp. palustris* were inserted into phospholipid liposomes (Varga and Staehelin, 1985). In freeze-fracture preparations of the liposomes the different particles could be

classified in distinct size classes which could be related to specific components of the photosynthetic apparatus. The following correlations were observed: 5 nm particles represent free RC or LH I tetramers; 7.5 nm particles LH I or LH II octamers (or both); 10 nm particles RC-LH I core complexes (1 RC plus 12 LH I)(Fig. 14) or large LH II oligomers (or both), and large particles of 12.5 and 15 nm LH II associated with the RC-LH I core complex (Varga and Staehelin, 1985). The purified reaction centers of *Rs. rubrum* presented after incorporation into liposome membranes in freeze-fracture preparations, slightly smaller (9–11 nm) particles than in native chromatophores (Meyer et al., 1981). The functional interaction and the lateral topography of photosynthetically active components were examined by combined electron microscopic and functional test methods with reconstituted complexes of the photosynthetic apparatus (Baciou et al., 1991; Takemoto et al., 1985; Crielaard et al., 1989). Reaction centers from *Rp. viridis* reconstituted into liposomes were frozen for freeze-fracturing at temperatures between, above, and below the phase transition temperatures of the lipids forming the liposomes (Baciou et al., 1991). It was shown that the phase transition affects the thermodynamic parameters associated with the electron-transfer process in the reaction center.

Isolated chromatophores of *Rb. capsulatus* and *Rb. sphaeroides* were fused with liposomes. The fused chromatophores were examined electron microscopically after freeze-fracturing and the kinetics of excitonic energy transfer were studied. It was shown that lipid dilution lowered efficiencies of energy transfer between the LH I complex and the reaction center in *Rb. capsulatus* (Takemoto et al., 1985), and in a decrease of cytochrome *b*-561 reduction (Snozzi and Crofts, 1984) and a slightly reduced absorption due to the LH I complex (Theiler and Niederman, 1991) in *Rb. sphaeroides*.

D. The Influence of Proteins on the Structure of Intracytoplasmic Membranes

The different morphological types of ICM (Fig. 1) were investigated with respect to a possible morphogenetic effect of defined components of the photosynthetic apparatus on the ICM formation. In the carotenoid- and LH II-less mutant strain R 26 of *Rb. sphaeroides* (Lommen and Takemoto, 1978 b) both vesicular and large lamellar ICM has been observed instead of small regular vesicles normally

seen in the wild type. According to experiments with several mutants of *Rb. sphaeroides* having defects in the LH II-complex it was supposed that incorporation of the α and β polypeptides of the LH II-complex is essential for molding and maturation of the ICM (Hunter et al., 1988; Kiley et al., 1988). In these mutants the ICM consists mainly of long tubes spanning the cell in the longitudinal axis. It was suggested that in absence of the LH II-complex the ICM was arrested at a tubular stage.

However, the LH II-deficient mutant 19 of *Rb. sphaeroides* exhibited in ultrathin sections not only regularly shaped ICM vesicles (average diameter of 43 nm), but also long tubes of ICM with diameters of 60–95 nm (Golecki et al., 1989, 1991). Freeze-fracture preparations revealed that these tubes were densely covered with intramembrane particles regularly arranged in rows. Therefore these tubes do not represent lipid-enriched ICM-invaginations as discussed for other mutants of *Rb. sphaeroides* with

Fig. 15. Ultrathin section of *Rhodobacter capsulatus* mutant A1 a⁺, lacking the LH II complex. The cells contain ICM vesicles of larger diameter (mean diameter = 72 ± 9 nm) than wild type. Bar represents 200 nm. Inset: ICM vesicles of *Rb. capsulatus* A1 a⁺ exposing intramembrane particles on the PF. OM, outer membrane. Freeze-fracture preparation. Bar represents 100 nm.

similar tubular ICM (Kiley et al., 1988). Phototrophic and RC positive, but LH I and/or LH II negative mutants of *Rb. capsulatus* (Dörge et al., 1990; Stiehle et al., 1990) still retain vesicular ICM (Golecki et al., 1989, 1991; Golecki unpublished results; Fig. 15). *Rs. rubrum*, which does not contain the LH II complex, forms regularly shaped ICM vesicles with diameters ranging from 60 to 100 nm. It is remarkable that all ICM vesicles from LH II-lacking purple bacteria are larger than vesicles from bacteria with LH II besides the core complex (Figs. 8, 15). A defined LH II deletion mutant (Δ *pucBACDE*) of *Rb. capsulatus* contains vesicles of irregular size but no tubules (Golecki and Drews, unpublished).

III. Biosynthesis of Membranes and the Assembly of the Functional Complexes of the Photosynthetic Apparatus

A. Coordinated Biosynthesis of Phospholipids, Proteins and Pigments during Membrane Formation

The major lipid compounds of CM and ICM membranes are the phospholipids phosphatidyl ethanolamine, phosphatidyl choline, phosphatidyl serine, diphosphatidyl glycerol, phosphatidyl inositol and ornithine lipids, which are esters of C16:0, C16:1, C18:0, C18:1; fatty acids (Kenyon, 1978 and see also Chapter 10 on quinones and lipids by Imhoff). Glycolipids appear to be absent in nonsulfur purple bacteria; they were found in Chromatiaceae and green sulfur bacteria. Sulfolipids (sulfoquinovosyl-diacylglycerol) are present in many photosynthetic bacteria (Imhoff et al., 1982; and see also Chapter 10 by Imhoff and Imhoff). Hopanoid pentacyclic triterpenoids were found in purple nonsulfur bacteria but not in purple sulfur bacteria (Rohmer et al., 1984; Neunlist et al., 1988; Urakami and Komagata, 1988). Ubiquinone-10 is the major mobile electron carrier in the membrane. Ubiquinone-9, menaquinone-8, 9 or 10, and rhodoquinone-10 have been found occasionally (Urakami and Komagata, 1988; and see also Chapter 10 by Imhoff and Imhoff).

The phospholipid biosynthetic enzymes, i.e. CDP-diglyceride synthetase, phosphatidylglycerophosphate synthetase, phosphatidylglycerophosphate phosphatase, phosphatidylserine (PS) synthase, PS decarboxylase, and S-adenosyl-L-methionine: phosphatidylethanolamine N-methyltransferase, were

detected in the soluble fraction of cells of *Rb. sphaeroides* while CDP-diglyceride synthetase, phosphatidylglycerophosphate synthase, and PS decarboxylase was localized in the CM (Cain et al., 1984). The pathway for synthesis of phosphatidylethanolamine and phosphatidylglycerol in purple bacteria seems to be the same as in other eubacteria (Cain et al., 1984). A phospholipid transfer protein and an acyl carrier protein have been isolated and purified (Tai and Kaplan, 1984; Cooper et al., 1987).

Kaplan's group has shown that phospholipids are synthesized at the CM and from there transferred to the ICM just prior to cell division (Lueking et al., 1978; Cain et al., 1984). Proteins and pigments, however, are inserted into the CM and ICM continuously throughout the cell cycle (Fraley et al., 1977, 1979; Kaplan et al., 1983; Myers and Collins, 1987). As a consequence, the protein/phospholipid ratio and the specific density and fluidity of the membrane fluctuate with the cell cycle. The discontinuous accumulation of cellular phospholipids during synchronous growth is directly attributable to observed changes in the rate of phospholipid synthesis (Fraley et al., 1979). The number of photosynthetic units per membrane area can vary by nearly a factor of two over the course of the cell cycle (Kaplan et al., 1983). Under constant growth conditions the average size and density of intramembrane particles remains unchanged during the cell cycle (Yen et al., 1984). The cell-cycle-dependent fluctuation in membrane composition, shown for *Rb. sphaeroides*, has been likewise confirmed for CM preparations of *Rs. rubrum* (Myers and Collins, 1987).

Shifts of light intensity or oxygen tension do not change significantly the patterns of phospholipids and fatty acids in the membrane fractions of non-synchronized cells (Kaufmann et al., 1982; Onishi and Niederman, 1982; Campbell and Lueking, 1983).

B. Characteristics of Membrane Fractions

Several membrane fractions have been isolated by sucrose density gradient centrifugation from various purple bacteria induced to form the photosynthetic apparatus. These membrane fractions differ in specific density and composition. Components of the respiratory chain, photosynthetic apparatus, transport systems, penicillin-binding proteins, and other functional units and phospholipids are present in variable but different amounts in the different membrane fractions (Hurlbert et al., 1974; Barrett et

Table 1. Composition of membrane fractions isolated from chemotrophically and phototrophically grown cells of *Rhodobacter capsulatus*

Abbreviations: Cyt – cytochrome; DH – dehydrogenase; RC – reaction center; UQ – ubiquinone

al., 1978; Dierstein et al., 1981; Garcia et al., 1981; Inamine and Niederman, 1982; Kaufmann et al., 1982; Inamine et al., 1984). Penicillin-binding proteins have been found exclusively in the CM (Shepherd et al., 1981). Table 1 illustrates the compositional heterogeneity of membrane fractions isolated from cells of *Rb. capsulatus* grown chemotrophically and phototrophically, respectively. A generalization is not possible, because data are available from few species only.

The isolated 'light' membrane fraction consists of small membrane pieces (Lampe et al., 1972; Kaufmann et al., 1982). The concentration of bacteriochlorophyll-protein complexes is low and the ratio of reaction center plus light-harvesting complex I (LHI) : LHII is much higher than in the 'heavy' fraction (Reilly and Niederman, 1986). The transfer of excitation energy from LHII to LHI is not coupled efficiently. Rates of photophosphorylation and photoreduction of *b*-type cytochromes are low (Hunter et al., 1979; Garcia et al., 1981; Kaufmann et al., 1982). Barrett et al. (1978) found cytochrome *c* and NADH-cytochrome *c* reductase activity enriched in the light fraction. The light fraction seems to be identical with the CM or those parts of the CM where the insertion of photosynthetic units is initiated (Reilly and Niederman, 1986).

The low activities of oxidative phosphorylation, NADH oxidation, cytochrome oxidase and other enzymes of electron transport chains in the light fraction seems to be caused by harsh treatment of cells during disruption and isolation. The separation of CM from ICM and outer membrane is a difficult task, especially when phototrophically grown cells are used (Oelze and Drews, 1972; Hurlbert et al., 1974; Kaplan and Arntzen, 1982). Small pieces of CM, formed during cell disruption, do not form vesicles. Washing of membranes reduces the level of soluble cytochrome c_2 and of enzyme constituents loosely bound to the membrane. Even when CM is isolated under mild and controlled conditions it remains difficult to quantify light-driven and respiratory coupled functions because CM vesicles are at best 70% right-side out, while ICM vesicles can be 100% inside out with a higher content of cytochrome c_2 than CM vesicles (Lommen and Takemoto, 1978; Michels and Konings, 1978; Garcia et al., 1987). Moreover, apparent activity of cytochrome oxidase and amount of oxidase protein, detected by immunoelectrophoresis, do not follow the same kinetics when cells are shifted from

phototrophic to chemotrophic growth conditions (Hüdig and Drews, 1985; Hüdig et al., 1987). Enzymatic activity and synthesis of membrane bound components seem to be regulated differently.

The light membrane fractions of *Chromatium vinosum* and *Ectothiorhodospira mobilis* contained the highest BChl content and were not contaminated with cell wall constituents (Hurlbert et al., 1974; Ditandi and Imhoff, 1993). Obviously the photosynthetic apparatus of both species is extended to the CM, which may be caused by the obligately or primarily phototrophic way of life in these species. The fractions of highest density are enriched in cell wall constituents.

The heavy membrane fraction of facultative phototrophic bacteria consists of ICM vesicles (i.e. chromatophores) which are enriched in the photosynthetic apparatus (Fig. 6). Chromatophores catalyze light-driven proton translocation into the vesicles and photophosphorylation by the H^+ -ATPase (Frenkel, 1954; Lampe and Drews, 1972; Lampe et al., 1972).

The morphological continuity of the CM-ICM system has been described in Section II.A of this chapter (Figs. 3, 5). The continuity of the membranes implies that ICM vesicles have an inverted orientation after isolation; they have an inside-out orientation, while protoplasts and CM vesicles should have right-side out orientation. This can be shown by localization of the F_1 part of ATPase on the outer surface of ICM vesicles and on the inner surface of CM vesicles. Light-induced proton translocation is directed into the ICM vesicles but from the cytoplasm to the periplasmic space in whole cells and spheroplasts. Likewise, light-driven amino acid transport is directed oppositely in chromatophores and CM vesicles, (Michels and Konings, 1978). Opposite membrane asymmetry of the CM and ICM was also detected by freeze-fracture electron microscopy (see Section II.B).

Since membranes are fluid-crystalline structures it cannot be excluded that the connections between ICM vesicles or lamellae and CM and ICM are transient. From the heterogeneity of membrane fractions it can be inferred that a barrier must exist between membranous domains which inhibits or slows down free lateral diffusion of phospholipids and proteins in the membrane continuum (Lavergne and Joliot, 1991).

C. The Formation of Intracytoplasmic Membranes

Rhodospirillum rubrum and *Rhodobacter sphaeroides* are facultative photosynthetic bacteria which do not contain either BChl or ICM vesicles when cultivated under strictly aerobic conditions in the dark. Upon induction of the photosynthetic apparatus by lowering the oxygen tension or shifting to anaerobic light conditions, invaginations of the CM and BChl synthesis appear simultaneously (Cohen-Bazire and Kunisawa, 1963; Drews and Giesbrecht, 1963; Peters and Cellarius, 1972; Golecki and Oelze, 1975). The formation of ICM by invaginations of the CM was also visualized by immunochemical means (Crook et al., 1986). A shift of newly incorporated radioactivity from CM into the ICM fraction was demonstrated by pulse-chase experiments (Oelze and Drews, 1969).

It was suggested that an 'upper pigmented band' (light membrane fraction) represents peripheral regions of immature ICM invaginations (Niedermaier et al., 1979; Inamine and Niedermaier, 1982; Inamine et al., 1984). This fraction was found to be enriched in *b*- and *c*-type cytochromes, in succinate-cytochrome *c* oxidoreductase and in reaction center (Bowyer et al., 1985; Reilly and Niedermaier, 1986). The incorporation of newly synthesized proteins into this membrane fraction was demonstrated in pulse-chase experiments (Niedermaier et al., 1979, 1981).

The H-subunit of RC, present in the membrane fraction of aerobically grown cells of *Rb. sphaeroides* (Chory et al., 1984) and *Rb. capsulatus* (N. Cortez, unpublished), was proposed to function as a structure to initiate assembly of the core complex (RC + LHI). A rapid shift from aerobic, chemotrophic growth to anaerobiosis in the presence of light in *Rb. sphaeroides* results in an immediate cessation of cell growth, and of protein, DNA and phospholipid accumulation. But the synthesis of phosphatidylcholine begins midway through the lag period and well before the resumption of total phospholipid synthesis. Small indentations within the CM appear early in the lag phase and seem to be converted into discrete ICM invaginations and mature ICM vesicles. It was speculated that specific regulatory sites of phospholipid synthesis at the level of phosphatidylethanolamine methyltransferase and acyl carrier protein, besides H-subunit and other proteins, are locally enriched where indentations in the

membrane are formed as initiation sites for assembly of pigment-proteins and invaginations of the CM or ICM (Chory et al., 1984). Throughout the cell cycle the level of LH complex II remains low in the light membrane fraction. It was shown by pulse-labeling with [³⁵S] methionine that the incorporation of proteins into the light membrane fraction was much higher than in the heavy membrane fraction. Pulse-chase experiments showed a shift of radioactivity from the light into the heavy membrane fraction. These results were interpreted as support of the idea that core complexes of the photosynthetic apparatus were incorporated preferentially into sites of membrane growth initiation which were visualized as small indentations of the CM (Chory et al., 1984; Reilly and Niedermaier, 1986). Later, when the indentation became CM invaginations and ICM vesicles, light-harvesting complexes II were incorporated and due to a higher density, these vesicles were isolated with the heavy membrane fraction.

The molecular mechanism of this local membrane growth and differentiation resembles the budding process at the plasma membrane of eukaryotic cells during assembly of enveloped viruses. In this process host membrane proteins are displaced by virus proteins which serve as anchor proteins for virus assembly.

The insertion of pigment- or redox carrier-binding proteins of the photosynthetic apparatus into the membrane lowers the fluidity of the membrane. This might be a signal to transfer phospholipids to ICM. New ICM vesicles are formed not only by invagination of CM but also by incorporation of new photosynthetic units into buds of preexistent ICM vesicles or thylakoids (Drews and Giesbrecht, 1963; Oelze and Drews, 1969, 1972; Hurlbert et al., 1974; Dierstein et al., 1981) or flat membranes (thylakoids) which appears as branching of membranes in *Rp. palustris* (Tauschel and Drews, 1967).

D. The Influence of Oxygen Tension and Light Intensity on Membrane Differentiation

The external signals of oxygen partial pressure and light intensity are the major factors which determine membrane differentiation and formation of the photosynthetic apparatus (Lascelles, 1959; Cohen-Bazire and Kunisawa, 1963; Biedermann et al., 1967; Marrs and Gest, 1973; Dierstein and Drews, 1975; Drews 1978, 1988, 1991; Schumacher and Drews, 1979; Arnheim and Oelze, 1983a,b; Donohue and

Kaplan, 1986; Kiley and Kaplan, 1987; Oelze, 1988; Reidl et al., 1983, 1985; Chory et al., 1984; Klug et al., 1985, 1991; Lee and Kaplan, 1992 a,b). In addition, temperature and substrate composition and concentration influence the morphogenesis of the photosynthetic apparatus (Kaiser and Oelze, 1980a,b; Grether-Beck and Oelze, 1987; Gardiner et al., 1992).

Lowering the oxygen tension in a dark culture of facultative phototrophic bacteria induces the formation of the photosynthetic apparatus. The threshold value of oxygen partial pressure which is critical for triggering the morphogenetic process is different in the species which have been examined. Cells of *Rs. rubrum* and *Rb. sphaeroides* are free of ICM and BChl when cultivated in air saturated culture medium. The threshold value for these species is relatively sharp at about 5 mm Hg = 666 Pa = 6.66 mbar oxygen partial pressure (Biedermann et al., 1967).

Cultures of *Rb. capsulatus* always contain small amounts of BChl and some polar tubular ICM, even when grown at 500 kPa pO_2 (Lampe et al., 1972; Fig. 7). The BChl concentration increases strongly when in chemotrophically grown cells of *Rb. capsulatus* the oxygen tension is lowered below 1 kPa (Dierstein and Drews, 1974, 1975). In other species, like *Rb. sulfidophilus* (Doi et al., 1991) or *Rs. centenum* (Yildiz et al., 1991) changes in oxygen tension are much less effective on the formation of the photosynthetic apparatus.

Lowering of the oxygen tension below the threshold value stimulates, in species responsive to oxygen, not only synthesis of the photosynthetic apparatus but also formation of ICM. Both processes are light-independent and have been observed even in anaerobic dark cultures of *Rb. capsulatus* (Madigan et al., 1982). Activities of respiratory enzymes are higher in cells grown chemotrophically than phototrophically (King and Drews, 1975; Drews and Oelze, 1981; Cox et al., 1983; Hüdig et al., 1987). Thus, variation of oxygen tension has an opposite effect on synthesis of components of the photosynthetic versus respiratory apparatus. Oxygen stimulates synthesis and/or activity of NADH-dehydrogenase and cytochrome *c* oxidases, but the redox components of electron transport, which are active for respiratory and light-driven electron transport, like the bc_1 -complex, cytochrome c_2 and the ubiquinone pool, are regulated differently (Kaufmann et al., 1982; Garcia et al., 1987).

BChl synthesis is regulated on the level of key

enzymes, i.e. the aminolevulinic acid synthase and Mg-chelatase, the branching point of tetrapyrrole synthesis to heme and BChl synthesis, respectively (Lascelles, 1959, 1978; Gorchein, 1973). Transcriptional and posttranscriptional regulatory processes are involved (see Chapters 9 by Beale and 52 by Biel).

When cells of facultative phototrophic bacteria are shifted from anaerobic light to aerobic dark conditions, the synthesis of pigments, pigment-binding proteins of the photosynthetic apparatus and formation of ICM are immediately suppressed (Marrs and Gest, 1973; Drews et al., 1987). The components of the photosynthetic apparatus are not degraded but remain in the ICM. Instead of these components, structures of the respiratory apparatus and other housekeeping components are incorporated into the CM. Hence the relative concentration of photosynthetic structures in the membrane gradually dilutes out. Since phototrophically grown cells of *Rs. rubrum* and *Rb. capsulatus* and other facultative phototrophic bacteria have under all growth conditions a potentially active respiratory system, they continue to grow after shift from phototrophic to chemotrophic conditions. Growth and membrane differentiation are separately regulated (Marrs and Gest, 1973; Baccarini-Melandri and Zannoni, 1978; Zannoni et al., 1978; Arnheim and Oelze, 1983a,b; Oelze and Arnheim, 1983; Drews et al., 1987; Kiley and Kaplan, 1988).

In all phototrophic organisms light is the energy source for growth and also an external factor which determines morphogenesis. The quantum efficiency of light on growth has been studied in chemostat cultures (Göbel, 1978) and the influence of light on growth and morphogenesis by Oelze's group (Arnheim and Oelze, 1983a; Grether-Beck and Oelze, 1987). Changes of light intensity modify the composition and activity of the photosynthetic apparatus. Lowering of light intensity under anaerobiosis increases the BChl content of cells and membranes and the ratio of the pigment-binding proteins of LH II/RC + LH I (Cohen-Bazire et al., 1957; Cohen-Bazire and Kunisawa, 1963; Drews and Giesbrecht, 1963; Lien and Gest, 1973; Schumacher and Drews, 1979; Golecki et al., 1980; Reidl et al., 1985; Garcia et al., 1987; Oelze, 1988 and Fig. 2). Cells exposed to a downshift in light intensity adapt to a new energy level of light irradiation. In cells of *Rb. capsulatus* and *Rb. sphaeroides* this process takes about 2–3 generations.

During adaptation, the growth rate is lowered due to energy limitation. The amount of ICM vesicles and the number of photosynthetic units per cell increase (Fig. 8, Table 1). The size of the photosynthetic unit (mol BChl/mol RC) increases due to the relative increase of the peripheral LH complex II (Reidl et al., 1985). In species like *Rs. rubrum* and *Rp. viridis*, which have one light-harvesting complex only, the number of photosynthetic units and the ICM increase (Oelze et al., 1969). In species like *Rp. palustris*, *Rp. acidophila* and *Cm. vinosum*, which contain different types of peripheral LH complexes, the development of single species of LH complexes is differently regulated by light intensity, oxygen tension and temperature (Firsow and Drews, 1977; Mechler and Oelze, 1978 a,b,c; Hayashi et al., 1982; Cogdell et al., 1983; Evans et al., 1990; Deinum et al., 1991; Gardiner et al., 1992; Takaichi et al., 1992). The primary acceptor for light energy transduction is the pigment system of the photosynthetic apparatus. The sensor for light effecting morphogenesis is unknown. Blue light seems to inhibit BChl synthesis (Drews and Jaeger, 1963; Oelze, 1986; Takamiya et al., 1992).

Variation of light intensity influences not only the synthesis of pigment-proteins of the photosynthetic apparatus, but also the concentration of redox carriers. The molar ratios of ubiquinone and cytochromes c_2 , c_1 , b -561 and b -566 per reaction center were three to five fold higher in membranes from high-light than from low-light grown cells (Table 1; Garcia et al., 1987) and the photochemical and respiratory activities change accordingly (Table 1; Reidl et al., 1983, 1985; Garcia et al., 1987; Hüdig et al., 1987).

Membrane differentiation is regulated on different levels, transcriptionally and posttranscriptionally, which has been reviewed by Kiley and Kaplan (1988) and Sganga and Bauer (1992) and detailed in several chapters of this volume.

E. Assembly of the Photosynthetic Apparatus

The complexes of the photosynthetic and of the respiratory apparatuses are multicomponent, supramolecular integral membrane-bound structures. From several complexes we have detailed information on the primary structure of proteins, localization and orientation of the bound cofactors, and organization and topography of the complex in the membrane (see Chapters 18, 23, 37 and 38, by Cogdell and Zuber, Roy et al., Gromet-Elhanon, and Jackson, respec-

tively). The organization of proteins and cofactors has been optimized during evolution to an efficient communication between the cofactors within the complex and redox carriers in the lipid layer of the membrane (cofactors e.g. quinones). Furthermore, the complexes have to interact with ions, substrates, or redox carriers on the cytoplasmic and periplasmic side of the membrane, respectively. Excitation energy or electrons have to be efficiently translocated. All these functions and the formation of a membrane potential and an electrochemical gradient of protons across the membrane are dependent on the correct assembly of subunits resulting in a functional organization and a correct orientation of the complexes and cofactors in the membrane. All immunochemical, ultrastructural, and biochemical studies have confirmed that complexes are uniformly oriented when synthesized in native membranes, but they may be more or less randomly oriented when incorporated in liposomes (Tadros et al., 1987; Crielgaard et al., 1989; Güner et al., 1991; Brunisholz and Zuber, 1992).

F. Targeting and Insertion of Proteins into the Membrane

Targeting of proteins to the membrane surface is the first important step of the assembly process which is initiated by distinct signals, the signal sequences on the so-called targeting protein (Saier et al., 1989; Müller and MacFarlane, 1994). Signal sequences of proteins which are translocated across the membrane are cleaved off after translocation. Proteins which are inserted into the CM generally have non-cleavable signal sequences. These non-cleavable signal sequences are difficult to identify because they are not split off and the sequence is not well defined (Saier et al., 1989). The N-terminal region of the LHI polypeptide α of *Rb. capsulatus* has some features in common with typical signal sequences, i.e. two positively charged amino acids at the end of the N-terminus followed by a short sequence of hydrophobic amino acids and two other positively charged amino acids immediately before the central hydrophobic membrane spanning domain of the polypeptide. Exchange of four positively charged with four negatively charged amino acids on the N-terminal domain of the α subunit inhibits a stable insertion of α and β proteins into the membrane and the assembly of the LHI complex (Dörge et al., 1990; Stiehle et al., 1990). Interestingly, the β polypeptide

of the LHI complex, which has a net negative charge in its N-terminal region and no similarity to a signal sequence, is inserted earlier into the membrane than the LHI α polypeptide. Moreover, the β polypeptide inserts in the absence of α but does not remain stably integrated as it does in presence of α (Richter and Drews, 1991). LHI α in absence of β is also integrated into the membrane (A. Meryandini, personal communication). Site-directed mutagenesis of other highly conserved amino acids in the N-terminal region of the α and β LHI polypeptides interfered with stable formation of a light-harvesting complex I, indicating that the N-termini of the LHI polypeptides contains important topogenic information (Dörge et al., 1990; Richter et al., 1991, 1992).

Intensive studies on insertion and translocation of proteins into and across the CM of *Escherichia coli* have shown that the process is generally *sec*-dependent (Müller and MacFarlane, 1994). Sec A, Sec B and Sec Y are proteins which support targeting (Sec B+A) or translocation (Sec Y) of proteins across the CM of *E. coli* (Müller and MacFarlane, 1994). Sec A- and Sec B-activities for protein export have not been found in cells of *Rb. capsulatus*, but proteins similar in function are present (Müller et al., unpublished). In vitro experiments using a cell-free homologous system of *Rb. capsulatus* have shown that the incorporation of LHI α and β and of the H-protein of the RC into the ICM fraction is more efficient in the presence than in absence or posttranslationally addition of membranes (Troschel and Müller, 1990; Troschel et al., 1992). A low salt extract from ICM-vesicles contains one or more proteins which support targeting and translocation of precytochrome c_2 and LHI $\alpha\beta$ (Wieseler and Müller, 1993; A. Meryandini, unpublished). These experiments suggest but do not prove that targeting and insertion of LH and RC proteins are cotranslational processes. They indicate that the competence of these proteins for insertion is diminished when membranes are added posttranslationally (Troschel and Müller, 1990). LHI α and β polypeptides seem to interact before insertion. In absence of DnaK, LHI α and β were not synthesized in a cell-free translation system. When GroEL was removed from the system, the LHI proteins were not stably inserted into the membrane (A. Meryandini and G. Drews unpublished).

LH-proteins of purple bacteria are very small, (about 50 residues) and they span the membrane only once (Drews, 1985). The translocation of the

M13 coat protein and some other small proteins is Sec A or Sec Y independent (Kuhn and Troschel, 1992). The translocation of leader peptidase became Sec A independent when the protein was shortened (Andersson and von Heijne, 1993). This, and the failure to detect Sec functions in *Rb. capsulatus*, suggest that all topogenic information necessary for targeting and insertion already exist in the primary structure of LH proteins. However, several observations support the idea that protein targeting and membrane insertion in *Rb. capsulatus* is assisted by a system of proteins. Trypsin-treatment of ICM interfered with integration of LHI α and β and the H-subunit of the RC into ICM (Troschel et al., 1992; Troschel and Müller, unpublished) indicating that proteins exposed on the membrane surface assist targeting and insertion. LHI α polypeptide is not stably inserted into membranes in the absence of LHI β , although its N-terminus has a positive net charge, suggesting that α and β bind to each other before or during targeting. This could be shown recently in a cell-free translation system of *Rb. capsulatus* (A. Meryandini and G. Drews, unpublished). The N-terminal region of LHI β has a negative net charge which interferes with the negative charge of the phospholipid head groups on the membrane surface during targeting. A surface exposed membrane protein could overcome this problem and act as a receptor for targeting and insertion. Gene products which are not identical with the pigment-binding proteins have been identified which are essential for correct and stable assembly (Tichy et al., 1989, 1991; Drews, 1992). Others which may have a more general function for insertion and assembly of proteins in the membranes of phototrophic bacteria are yet to be detected. LHI α becomes phosphorylated during or after incorporation into the membrane of *Rb. capsulatus* (Cortez et al., 1992; Garcia et al., 1994).

G. Translocation and Assembly of Antenna-Pigment-Proteins

The N-terminal regions of LH α and β and RC proteins M and L of several species become exposed on the cytoplasmic side of the membrane after insertion and translocation (Tadros et al., 1987; Brunisholz and Zuber, 1992). Translocation of the hydrophobic α -helical region of these proteins across the membrane depends on the proton motive force. Addition of uncouplers completely inhibits trans-

location (Dierstein and Drews, 1986). The sequence of steps in the assembly of the LH-complexes is not known. The binding of BChl and carotenoids to the proteins of the LH-complexes seems to be an early step that influences the conformation of proteins and therefore assembly. In mutant strains blocked at different stages of BChl synthesis, LHI α , LHI β , and LHII β proteins are incorporated into the membrane, as shown by pulse experiments, but disappear during the chase period (Klug et al., 1986; Brand and Drews, unpublished). The *pufQ* gene product seems to be of importance for assembly of BChl and proteins (see Chapters 57, 58 and 59 by Beatty, Bauer, and Klug, respectively). LHII α polypeptide, however, remains stable in the membrane when BChl is absent. The steps of BChl synthesis, catalyzed by Mg-chelatase and methyl-transferase, seem to be membrane bound (Gorchein, 1973). The pool of unbound BChl in the membrane and whole cells is very small (Beck and Drews, 1982). Precursors of BChl can be accumulated in mutant strains. They are excreted as free precursors or nonspecifically bound to proteins (Drews et al., 1971; Bolivar and Bauer, 1992). They do not form LH complexes. However, pseudo complexes may be formed by interaction with other LH proteins in the absence of the specific ones (Tadros et al., 1989). The LH-complexes in the membrane are oligomers of the basic α - β -pigment-subunit. This has been shown by molecular mass determination of isolated complexes in lipid micelles or in crystals using different methods (Shiozawa et al., 1982; Guthrie et al., 1992; Kleinekofort et al., 1992) and by in vitro resolution and reconstitution of isolated complexes (see Chapter 16 by Zuber and Cogdell). The monomeric subunits differ from oligomers in their spectroscopic properties (van Grondelle et al., 1992).

Besides BChl, the carotenoids are a morphogenetic factor for LHII complexes. Carotenoid-less mutants of *Rb. capsulatus* are unable to form the stable, wild-type LHII complex (Kaufmann et al., 1984; Zsebo and Hearst, 1984; Dörge et al., 1987; Lang and Hunter, 1994).

Within the transmembrane α -helical segment of both α and β antenna polypeptides a strong conserved histidine residue, serving as a fifth ligand for BChl, is positioned. Other conserved amino acids in a distance of approximately one helix turn [Ala-X-X-X-His-X-X-X-Leu (Trp, Tyr, Phe)] (His + 4 and His - 4) are candidates to interact and stabilize the position of BChl in the periplasmic bilayer half of the membrane (Brunisholz and Zuber, 1992). Exchange

of histidine or one of the conserved amino acids in position ± 4 for another amino acid impair or inhibit not only BChl binding but also formation of the LHI complex and stable insertion of α and β polypeptides (Bylina et al., 1988; M. Brand, G. Drews, unpublished). Interestingly, an exchange of Ala-34 and His-38 of LHI β does not impair the assembly of LHI or alter the wild type in vivo absorption spectrum. Deletion of the highly conserved His-20 in LHI β did not inhibit LHI formation but resulted in a broadening of the absorption peak in one membrane fraction (M. Brand, G. Drews, unpublished). Pulse chase experiments have shown that inhibition of BChl binding to α or β polypeptides by mutation of amino acids very often impairs insertion and translocation of the mutated and of the partner protein (Klug et al., 1986; M. Brand, G. Drews, unpublished). These multiple effects of mutations in amino acid positions are possibly caused by changes in conformation and topogenic signals of proteins and, therefore, influence targeting, translocation and assembly.

The interpretation of results of the influence of pigments on the synthesis and assembly of pigment-binding proteins is conflicting in the literature. The light-harvesting chlorophyll-binding protein of chloroplast thylakoid membranes was stably incorporated into the CM of *E. coli* after addition of a bacterial signal peptide, although chlorophyll was not present (Kohorn and Auchincloss, 1991). In eukaryotic systems, the chlorophyll apoprotein expression and accumulation was found to be influenced by the level of chlorophyll (Eichacker et al., 1992; Herrin et al., 1992).

The LHII complex of *Rb. capsulatus* contains, besides the α and β polypeptides, a third protein, called γ which does not bind BChl. It can be removed from the membrane by an alkaline wash (Tadros et al., 1990) or by trypsin treatment (Feick and Drews, 1978) and is not necessary for the function of LHII (Tadros et al., 1990). Deletion of *pucE*, the gene coding for the gamma protein, and of *pucD*, a gene of unknown function, affects the formation and stability of LHII (Tichy et al., 1991). Cells which are suppressed in transcription of *pucD*, and *E*, form less LHII than in the wild type and the absorption maximum at 800 nm decreased (Tichy et al., 1991). It has been shown that the gamma protein stabilizes the LHII complex strongly (C. Kortlüke, F. Weber, G. Drews, unpublished). The gene product of *pucC* is essential for expression of the *puc* operon and for synthesis and assembly of LHII proteins (Tichy et

al., 1991; LeBlanc and Beatty, 1993). The function of PucC is unknown but it is neither a structural component of LHII nor a protein which assists targeting and assembly. Presumably it contributes to regulation of gene expression (Tichy et al., 1991); under control of the T7 promoter and a strong Shine-Dalgarno sequence, *pucC* was overexpressed in *E. coli* (C. Kortlüke, unpublished).

Phosphorylation of BChl-binding proteins and other membrane proteins have been observed in several eukaryotic and prokaryotic photosynthetic organisms (Bennet, 1977; Owens and Ohad, 1982; Holuigue et al., 1985; Holmes and Allen, 1988; Pairoba and Vallejos, 1989; Harrison et al., 1991; Cortez et al., 1992). The intensity of phosphorylation of LHI α of *Rb. capsulatus* was found to be redox-controlled which indicates that phosphorylation and dephosphorylation regulate the organization and function of the antenna system (Cortez et al., 1992). The LHI α protein is phosphorylated presumably by a Ser/Thr kinase after insertion into the membrane (Garcia et al., 1994; M. Brand, unpublished).

I. Assembly of Other Membrane-Bound Complexes

RC, like LHII of *Rb. capsulatus*, contains a third subunit, called the H-subunit, which does not bind pigments (see Chapter 23 by Lancaster et al.). The gene for the H subunit is located some 35 kb upstream from the *puf*-operon (coding for RC-M and RC-L) in the *puhA* locus (Youvan et al., 1984; Sockett et al., 1989). Deletion of the *puhA* gene results in a photosynthetically incompetent mutant strain of *Rb. sphaeroides* which synthesizes only trace amounts of RC and no LHI complex, although *puf* mRNA is synthesized. It was speculated that the H subunit is necessary for either insertion of RC M and RC L polypeptides into the ICM or for stabilization of RC complexes (Sockett et al., 1989). Since the H subunit is present in membranes of chemotrophically grown cells, it was proposed that the H subunit directs M and L subunits to the proper site and facilitates assembly (Sockett et al., 1989). The effect of a deletion in *puhA* on the expression of *pufB* may be due to an inhibition of the expression of the open reading frame F1696. An insertion mutation in F1696 affects a 67% reduction in LHI in *Rb. capsulatus* (Bauer et al., 1991). The primary structure of F1696 is very similar to that of *pucC* (Bauer et al., 1991; Tichy et al., 1991) These proteins may have a similar

function in activation of gene expression. Until now there is no direct evidence for proteins (chaperones), besides GroEL, which keep the pigment-binding proteins of the LH- and RC-complexes in an unfolded state after translation and before insertion, or which assist targeting, translocation, and assembly in the membrane.

The ubiquinol:cytochrome *c* oxidoreductase, an ubiquitous proton pump, comprises three catalytic subunits, a two-heme Cyt *b*, a cytochrome *c*, and a Rieske 2Fe-2S protein (see Chapter 35 by Gray and Daldal). The Rieske subunit from *Rb. sphaeroides* has been expressed in *Escherichia coli* and also in a strain of *Rb. sphaeroides* lacking the other subunits of the *bc*₁ complex. The Rieske subunit forms a Rieske-like iron-sulfur cluster and assembles in the CM showing the characteristic EPR signal (van Doren et al., 1993). The data are consistent with models in which the Rieske subunit is bound to the membrane and assembled via a single membrane-spanning α helix and independently of the other subunits of the *bc*₁ complex (van Doren et al., 1993). Otherwise the apoproteins for cytochromes *b* and *c*₁ are stably assembled in the ICM of *Rb. capsulatus* mutants containing no Rieske subunit. The two-protein subcomplex was functional with intact Q_i and Q_o sites (Davidson et al., 1992). These data indicate that synthesis, cofactor binding and assembly of subunits of the *bc*₁ complex seem to be relatively independent from each other. Specific factors for targeting and incorporation of the subunits into the membrane are not known.

Cytochrome *c*₂ is a soluble periplasmic redox carrier involved in both aerobic and photosynthetic electron transport in *Rhodobacter* (see Chapter 34 by Meyer and Donohue). The N-terminal sequence of 21 amino acids is absent in the mature polypeptide and contains all of the features of a typical signal peptide (Brandner et al., 1991). The signal peptidase and cleaving of the signal sequence has been demonstrated in an in vitro system in *Rb. capsulatus* (Wieseler et al., 1992). Translocation of pre-cytochrome *c*₂ across the ICM requires the proton-motive force and proceeds at a higher efficiency when cell-free membranes are present cotranslationally. Peripheral membrane proteins, which can be removed from the membrane by low-salt treatment, support translocation. Deletion of the signal peptide does not prevent export, heme attachment, or function of cytochrome *c*₂ (Brandner and Donohue, 1994). The extract of peripheral proteins does not contain

activities that in vitro could replace the *E. coli* transport factors Sec A and Sec B (Wieseler and Müller, 1993). From *cycA-phoA* translational fusion experiments it was concluded that cytochrome c_2 export does not require heme attachment as was shown for Cyt *c* import into mitochondria (Brandner et al., 1991). Heme is covalently attached to two cysteines in the Cyt c_2 polypeptide via thioether linkages. His-19 and Met-100 are noncovalent axial ligands to the iron in the porphyrin ring. Heme can be attached to the Cyt *a* apoprotein which lacks as many as 94 C-terminal amino acids, including Met-100 (Brandner et al., 1991).

Acknowledgments

The work of the authors described in this article was supported by Deutsche Forschungsgemeinschaft, Land Baden-Württemberg, and Fonds der Chemischen Industrie. We thank Ms Kerstin Jakobs and Brunhilde Schmidt for typing the manuscript.

Summary

Although belonging to evolutionary distantly related groups, cells of members of the Chlorobiaceae and the Chloroflexaceae exhibit structurally and functionally comparable substructures. While the photochemical reaction center complex plus a light-harvesting unit are housed in the peripheral cytoplasmic membrane (CM) system, an accessory light-harvesting unit is localized in specialized structures, the chlorosomes, underlying the CM. In this chapter, the present knowledge on the fine structure of chlorosomes and the CM is reviewed. After a description of methods commonly employed to isolate chlorosomes and CM, data of chemical analyses of both subcellular fractions are detailed. In spite of considerable similarities in the overall ultrastructural and

functional properties, the chemical composition reveals significant differences between chlorosomes and CM, when isolated from *Chlorobium* and *Chloroflexus*, respectively. The same holds true with respect to the supramolecular organization, particularly of chlorosomes and elements involved in their connection to the CM. Since the photosynthetic apparatus of green bacteria is composed of two different moieties, i.e. the chlorosomes and the CM-bound unit, the important questions arise how these different units are synthesized, how the synthesis of individual constituents is controlled and how the syntheses of chlorosomes and the CM-bound units are coordinated. In the present contribution these problems are approached on the basis of the pigments characteristic of both units. In addition, the knowledge on polypeptide formation is presented. These data are combined with the respective changes in number and size of chlorosomes. In spite of a considerable amount of detailed information available as yet, it is finally concluded that considerable research efforts are still required in order to understand the development of the biologically unique type of photosynthetic apparatus characteristic of the green bacteria.

I. Introduction

Early studies on the ultrastructure of several members of the purple phototrophic bacteria revealed the presence of an intracytoplasmic membrane continuum, which upon cell breakage formed closed vesicles. These vesicles contained the entire photosynthetic apparatus and were named chromatophores according to their pigmentation (Oelze and Drews, 1972). Any attempts to identify similar structures within cells of the green bacteria, however, remained unsuccessful. Instead, Cohen-Bazire (1963) was able to show that thin sections of cells of *Chlorobium limicola* and *Cb. thiosulfatophilum* exhibit the presence of oblong inclusion bodies adjacent to the CM. These structures surrounded by a thin layer were named *Chlorobium* vesicles. Subsequently, similar structures containing high amounts of bacteriochlorophyll (BChl) could be isolated from homogenates of these and related organisms. On this basis, it was proposed that, in members of the green bacteria, *Chlorobium* vesicles were the major sites of the photosynthetic apparatus (Cohen-Bazire, 1963) including the photochemical reaction centers (Fowler et al., 1971). The latter suggestion, however, was not supported by subsequent investigations. Instead, it could be shown that the photochemical reaction center, containing BChl *a*, was localized in the CM, while *Chlorobium* vesicles house accessory light-harvesting BChl units (Boyce et al., 1976; Olson et al., 1976; Olson 1980).

In 1974 it became apparent that *Chlorobium* vesicles were formed not only by members of the Chlorobiaceae but also by the distantly related and newly discovered *Chloroflexus aurantiacus* (Pierson and Castenholz, 1974a,b). Therefore, it was proposed to more generally name such vesicles chlorosomes (= green bodies) (Staelin et al., 1978). In this contribution we will compile the present knowledge on the structure and composition as well as on the development of the photosynthetic apparatus of green bacteria comprising the chlorosomal and the CM-bound units.

II. Ultrastructure

A. Membranes

The CM of green bacteria is visualized by electron microscopy of ultrathin sections of cells as a double track layer underlying the cell wall. This membrane with a thickness of approximately 8 nm represents the outer layer of the protoplast (Fig. 1). The periplasmic space becomes visible in thin sections as an electron transparent space localized between the CM and the cell wall. In freeze-fracture electron micrographs of chemoorganotrophically grown *Cf. aurantiacus* (Sprague et al., 1981b) the CM exposes the well known architecture of other bacteria (Golecki and Oelze, 1980) that is to say, a plasmic fracture face (PF) densely covered with intramembrane particles of different size and an exoplasmic fracture face (EF) sparsely covered with larger particles. However, in phototrophically grown cells of both *Cb. limicola* and *Cb. tepidum*, distinct areas enriched in larger intramembrane particles (> 9 nm) were demonstrated on both fracture faces of the CM (Fig. 2

Abbreviations: ALA – 5-aminolevulinic acid; BChl – bacteriochlorophyll; *Cb.* – *Chlorobium*; *Cf.* – *Chloroflexus*; CM – cytoplasmic membrane; CW – cell wall; D – dilution rate; EF – exoplasmic fracture face; MGDG – monogalactosyl diglyceride; Pa – Pascal; PF – plasmic fracture face; SDS-PAGE – sodium dodecyl sulphate polyacrylamide gel electrophoresis

Fig. 1. Ultrathin sections of *Chlorobium vibrioforme* strain 6230 exhibiting the cytoplasmic membrane (CM) with underlying chlorosomes (C) as well as the cell wall (CW) including the outer membrane (OM) and the peptidoglycan (P) layer. Bar represents 200 nm. Sections in (a) longitudinal (reproduced from Staehelin et al., 1980, with permission) and (b) horizontal axis of the cell; (c) chlorosomes at higher magnification presenting the baseplate (◄) between the chlorosome and the CM as an electron dense layer, L = chlorosome envelope.

and Staehelin et al, 1980). These areas of the CM are localized at the presumptive sites of chlorosome attachment. The larger particles were interpreted as structural equivalents of the photosynthetic units.

Both fracture faces of the CM of phototrophically grown cells of *Chloroflexus* and *Chlorobium* exhibit, in addition, characteristic chlorosomes (Fig. 3 and Staehelin et al., 1978). Because of the close association of chlorosomes and the CM, the fracture plane can be deflected very often from the CM into the underlying chlorosome.

In *Chloronema* (Dubinina and Gorlenko, 1975), *Oscillochloris* (Sprague and Fuller, 1991) and in some mesophilic *Chloroflexus*-like organisms from marine environments, the CM forms invaginations studded with chlorosomes (Larsen et al., 1991). Internal membranes originally described as mesosomes (Cohen-Bazire et al., 1964) may be the results of artificial preparation conditions as demonstrated with several other bacterial species (Ebersold et al., 1981). Additional artifacts may be the lipid bilayer structures, which can be identified on freeze-fracture preparations of the thermophilic *Cf. aurantiacus* strain J-10-fl as large flattened vesicles without detectable substructure (Staehelin et al., 1978). It appears likely that these vesicles arise in the CM by phase separation induced by a shift-down in temperature.

Fig. 2. Freeze-fracture micrograph of *Chlorobium tepidum* exposing the plasmic fracture face (PF) of the cytoplasmic membrane (CM). The membrane fracture face reveals the presence of elongated patches of mostly larger (> 9 nm) intramembrane particles corresponding to the attachment sites of the underlying chlorosomes. Some of these patches have been outlined (black dots). Arrow in the upper right corner indicates direction of shadowing. Bar represents 200 nm.

Fig. 3. Freeze-fracture micrograph of *Chlorobium tepidum* showing the exoplasmic fracture face (EF) of the cytoplasmic membrane with associated chlorosomes. The crystalline baseplate (➔) exhibits striations with a periodicity of 6 nm. The ridges of the baseplate make an angle of 40–60° with the longitudinal axis of the chlorosome. Each ridge possesses a regular, globular substructure with a periodicity of approximately 3.5 nm. In addition some rod elements (◻➔) of 10 nm in diameter are visible in the core of the chlorosome. Inset: baseplate at higher magnification. Arrow in the upper right corner indicates direction of shadowing. Bar represents 200 nm.

In the filamentous cells of *Chloroflexus*, the CMs of two neighbouring cells are connected by 10–30 microplasmadesmata, which can be identified within the central area of the septum (Staehelin et al., 1978).

Cell envelopes of Gram-negative bacteria are composed of the CM and the peptidoglycan layer as well as the outer membrane of the cell wall. All of these structural elements can be identified on ultrathin sections of *Chlorobium* strains (Fig. 1). However, in *Cf. aurantiacus* it is difficult to identify an outer membrane or a defined peptidoglycan layer. These morphological findings, together with biochemical data such as the lack of both lipoprotein and lipopolysaccharides and the presence of L-ornithine in the peptidoglycan, revealed that *Chloroflexus* forms a cell wall resembling that of Gram-positive rather than that of Gram-negative bacteria (Jürgens et al., 1987.)

B. Chlorosomes

Chlorosomes are elliptical structures, which are arranged in a single layer underlying the CM (Figs. 1a, 1b, 8). Usually chlorosomes are not detectable within the cytoplasm of the cells. As mentioned above, however, *Oscillochloris* and some mesophilic *Chloroflexus*-like organisms (Larsen et al., 1991) were reported to form internal foldings of the CM with aligned chlorosomes.

On the average, chlorosomes exhibit lengths of about 70–260 nm and widths of 30–100 nm. With chlorosomes from *Cb. limicola* widths of 40–100 nm and lengths of 70–260 nm have been determined. The chlorosomes of *Cf. aurantiacus* seem to be smaller. They exhibit an average length of 106 ± 24 nm and a width of 32 ± 10 nm. The height of the latter chlorosomes is 10–20 nm (Golecki and Oelze, 1987). The lengths and widths of chlorosomes of other members of the green bacteria are generally within the same range: for '*Chloropseudomonas ethylicum*': 130–150 nm and 30–50 nm (Holt et al., 1966), *Cb. thiosulfatophilum*: 100–150 nm and 30–40 nm (Cohen-Bazire et al., 1964), *Chloroherpeton thalassium*: 140 nm and 33 nm (Gibson et al., 1984), *Cb. tepidum*: 100–180 nm and 40–60 nm (Wahlund et al., 1991), *Cb. vibrioforme*, *Pelodictyon luteolum* and *Pelodictyonphaeum*: 70–150 nm and 30–80 nm (Puchkova et al., 1975). However, external conditions may have a significant influence on the size and, thus, the volume of chlorosomes (Broch-Due et al., 1978; Golecki and Oelze, 1987). A more detailed description of the effects of external factors on the size and development of chlorosomes will be given in Section V-B of this chapter.

As yet, detailed studies on the ultrastructure of chlorosomes have been performed only with cells of either *Cb. limicola* or *Cf. aurantiacus*. In these studies, freeze-fracture electron microscopy has been employed to obtain insights into the internal architecture and organization of chlorosomes and the underlying membrane (Staehelin et al., 1978 and 1980; Sprague et al., 1981a,b; Golecki and Oelze, 1987). The results revealed that the chlorosomes of *Chloroflexus* and *Chlorobium* exhibit essentially the same ultrastructure with the following comparable elements; i.) a distinct area within the CM referred to as the membrane attachment site, ii.) a highly ordered baseplate between the chlorosome core and the CM, iii.) internal rod elements in the core of chlorosomes,

iv.) an envelope forming the cytoplasmic boundary of the chlorosome.

As mentioned above, in *Chlorobium*, the attachment sites are visible as distinct oblong areas on the plasmic (PF) and exoplasmic (EF) fracture faces of the CM enriched in larger intramembrane particles (> 9 nm) in a non-crystalline order (Fig. 2). The size of these non-crystalline ordered particles is larger than the average size of the other particles on the respective fracture face of the CM. In *Cf. aurantiacus*, on the other hand, the attachment site presents a highly ordered array of particles. The periodicity of the lattice is 6 nm with an orientation perpendicular to the long axis of the chlorosome (Staehelin et al., 1980).

According to the original definition, the baseplate connects the chlorosome to the CM (Staehelin et al., 1980). In ultrathin sections, the baseplate appears as an electron dense layer of 5–6 nm thickness (Figs. 1 and 8). The supramolecular architecture of the baseplate, however, is detectable only with freeze-fracture preparations. The baseplates of *Cb. limicola*

and *Cb. tepidum* are detectable on the exoplasmic fracture-face of the CM as elliptical, striated plate-like structures exhibiting a crystalline substructure (Fig. 3 and Staehelin et al., 1980). The ridges of the baseplate lattice (6 nm distance) form an angle of 40° to 60° with the longitudinal axis of the plate. Each ridge exhibits a fine granular substructure with a periodicity of 3.3–3.5 nm. Baseplates are nearly as large as complete chlorosomes. In *Chloroflexus*, baseplates exhibit a crystalline arrangement with fine striations of 6 nm periodicity (Fig. 4d, Staehelin et al., 1978; Sprague et al., 1981a,b). In contrast to *Chlorobium*, these striations are oriented at right angles to the longitudinal axis of the baseplate. With *Chloroflexus* an average baseplate size of $3,200 \pm 800 \text{ nm}^2$ was determined (Golecki and Oelze, 1987).

The cores of *Chlorobium* and *Chloroflexus* chlorosomes are filled with a variable number of closely packed rod-shaped elements with diameters of 10 and 5.2 nm, respectively (Fig. 4 and Staehelin et al., 1978 and 1980). The rod elements are embedded in an unetchable matrix, oriented longitudinally to

Fig. 4. Freeze-fracture micrographs of cells of *Chloroflexus aurantiacus*. The fracture faces of the CM show baseplates (\blackrightarrow) and chlorosomes (\blacktriangleright) with fractures along the cytoplasmic face of the envelope layer. (a) Exoplasmic fracture face (EF) exhibiting small chlorosomes (Table 1, culture 1C); (b) EF exhibiting long chlorosomes (Table 1, culture 2C); (c) plasmic fracture face (PF) exhibiting the rod elements ($\square\rightarrow$) of chlorosomes; (d) baseplate with a lattice order with a periodicity of 6 nm. Arrow in the upper right corner indicates direction of shadowing. Bar represents 200 nm.

the long axis and spanning the full length of the chlorosomes (Stahelin et al., 1980). In *Chlorobium* the presence of 10 to 30 rod elements per chlorosome was described. In *Chloroflexus*, however, the number of rod elements seems to vary in a wider range as a response to changes in external growth factors and, thus, to changes in BChl *c* contents (Sprague et al., 1981 a; Golecki and Oelze, 1987).

On their plasmic sides, chlorosomes are bounded by a layer which exhibits a thickness of 2–3 nm (Fig. 1). This boundary appears as a single electron dense layer in ultrathin sections.

III. Chemical Composition

A. Isolation of Chlorosomes and Membranes

1. Chlorosomes

Pierson and Castenholz (1978) compiled the methods employed to isolate subcellular fractions from green bacteria. Since then a number of improvements have been developed. However, differences in isolation procedures have yielded chlorosome preparations of different composition. This in turn, may be considered as one of the primary reasons for the formulation of controversial hypotheses on the functional architecture of chlorosomes. Basic principles of the most commonly used methods are detailed below.

Feick et al. (1982) suspended washed cells of *Cf. aurantiacus* in Tris-hydrochloride buffer (1 g wet weight per 5 ml, 10 mM, pH 8.0) and passed the suspension three times through a precooled French pressure cell (138 MPa). After a low spin centrifugation, the homogenate was centrifuged for 90 min at $180,000 \times g$. The pellet, containing more than 95% of the total cellular BChl, was treated with sodium iodide and the dipolar detergent Deriphat (N-lauryl- β -iminodipropionate) in order to detach chlorosomes from CM fragments. Subsequent centrifugation yielded a supernatant (referred to as supernatant I) and a floating pellet, which was enriched in chlorosomes. The floating pellet was withdrawn and dialysed against buffer. After addition of the dipolar detergent Miranol, the material was separated by sucrose gradient centrifugation. Chlorosomes banded at 27% (w/w) of sucrose. Gradient centrifugation was repeated if contaminations of CM-bound BChl *a* absorbing at 866 nm were observed. Alternatively, the whole membrane pellet of the first high spin

centrifugation was directly treated with Miranol and separated by sucrose centrifugation.

Chlorosomes isolated by the method of Feick et al. (1982) contained BChl *c* and small, yet constant, amounts of BChl *a* in a ratio of 25: 1.

Gerola and Olson (1986) published a widely accepted method to isolate chlorosomes from *Cb. limicola* f. *thiosulphatophilum* by sucrose density gradient centrifugation. This method has subsequently been used to successfully isolate chlorosomes from *Cf. aurantiacus* as well. The procedure includes the chaotropic agent NaSCN in the presence of ascorbate rather than of detergents. NaSCN was shown to stabilize *Chlorobium* chlorosomes, which are much more fragile than those of *Cf. aurantiacus*. Stable chlorosomes from *Chlorobium* isolated by the Gerola/Olson-method contain BChls *c* and *a* at a ratio of approximately 90.

Chlorosomes completely free of any detectable amounts of BChl *a* were isolated from *Cf. aurantiacus* by Griebenow and Holzwarth (1989) (Fig. 5). After sonication of cell suspensions, chlorosomes were isolated from homogenates by a combination of native gel electrophoresis and gel filtration (i.e. gel-electrophoretic filtration) in the presence of the Li salt of the detergent dodecyl sulfate. In addition, it turned out that *Chloroflexus* chlorosomes obtained by the Gerola/Olson-method can be purified from residual amounts of BChl *a* by treatment with sodium dodecyl sulfate (Olson et al., 1990).

2. Membranes

All of the relevant methods employed as yet to isolate membrane fractions from cell homogenates of green bacteria include sucrose gradient centri-

Fig. 5. Negative staining preparation of isolated chlorosomes from *Chloroflexus aurantiacus*. The intact chlorosomes present the typical oblong shape. Bar represents 200 nm.

fugation. According to Schmidt (1980), CM from *Cf. aurantiacus* band at a density corresponding to 40–45% (w/w) of sucrose. CM from *Cb. limicola* f. *thiosulfatophilum*, on the other hand, bands at 35%. Interestingly, CM fractions from *Cf. aurantiacus* were reported to exhibit flat, irregular pieces, while fractions from *Chlorobium* appear as vesicular and regular structures.

Probably the purest CM preparations depleted of any detectable amounts of the chlorosomal BChl *c* were isolated by Feick et al. (1982). These membranes were purified from supernatant I (mentioned above in context of chlorosome isolation) by sucrose density gradient centrifugation in the presence of sodium iodide and the detergent Deriphath.

B. Composition of Chlorosomes and Membranes

Cell breakage as well as isolation procedures may affect severely the structure and composition of subcellular structures. Thus, when evaluating results of biochemical analyses, it should be kept in mind not only that essential constituents might have been lost or decomposed, but also that other cellular constituents may have become attached during the isolation of subcellular fractions. Moreover, these artifacts may affect comparable fractions from different organisms to different extents. An example for the latter is given by chlorosomes from *Chlorobium* species, which appear much more fragile than chlorosomes from *Chloroflexus*.

1. Chlorosomes

a. Pigments

Chlorophylls. BChls are the most prominent constituents of chlorosomes. Depending on the bacterial species, the chlorosomes house the majority of BChls *c*, *d* or *e*. These different types of magnesium tetrapyrroles can be further subdivided into different homologues. In the cases of BChls *e* and *d*, respectively, at least eight and six homologues are known. These homologues are characterized on the basis of different substituents at the chlorine nucleus. In addition, there are indications that the most common farnesyl ester side chains of BChls *c* and *d* may be substituted to a minor extent by several other alcohols (Smith et al., 1983; Bobe et al., 1990; Otte et al., 1993).

It should also be noted that different basic types of BChl may be formed by one organism as a response

to changes in culture conditions. This latter effect has been observed with *Cb. vibrioforme* f. *thiosulfatophilum*, which synthesizes BChl *c* instead of BChl *d* when adapting from high to low light conditions (Broch-Due and Ormerod, 1978; Huster and Smith, 1990). It has been suggested that methylation of BChl *d* to BChl *c* increases the hydrophobicity, giving rise to a higher degree of packing of antenna BChl molecules in the chlorosome (Bobe et al., 1990). On this basis it is not surprising that, recently, Otte et al. (1993) reported on the presence of significant amounts of BChl *c* together with BChl *d* in chlorosomes of *Cb. vibrioforme*.

BChl *c* of chlorosomes of *Cf. aurantiacus* (strain OK-70-fl) was identified as a mixture of at least ten derivatives. In contrast to BChl *c* homologues of *Chlorobium*, the BChls of *Cf. aurantiacus* differ on the basis of five different esterifying alcohol side chains, each of which has two epimeric forms (either 2aR, 7S, 8S or 2aS, 7S, 8S, Fages et al., 1990). In addition, *Cf. aurantiacus* strain J-10-fl synthesizes small amounts of BChl *d* (Bobe et al., 1990).

As mentioned above, minor amounts of BChl *a* have been reported for chlorosomes from various Chlorobiaceae as well as from *Cf. aurantiacus*. However, while a BChl *a* polypeptide complex with an absorption peak at 794 nm apparently forms an integral part of chlorosomes of *Chlorobium*, a comparable BChl *a* complex absorbing at 790 nm can be removed from chlorosome preparations from *Cf. aurantiacus* (Griebenow and Holzwarth, 1989; Gerola and Olson, 1986).

Carotenoids. Schmidt (1980) analyzed the carotenoid composition of *Cb. limicola* f. *thiosulfatophilum* and *Cf. aurantiacus*. Most of the carotenoids synthesized by both species were localized in the chlorosome fraction. Specific carotenoid contents of chlorosomes from both species were 19 and 33 μg per mg of protein, respectively. About 80% of the total carotenoids of *Cf. aurantiacus* are composed of almost equal amounts of β - and γ -carotene. In addition, minor amounts of lycopene, 4-oxo- γ or β -carotene as well as hydroxy- γ -carotene and its glucoside were identified. The predominant carotenoids of *Chlorobium* chlorosomes are chlorobactene (69%) and neurosporene (21%).

b. Lipids

Glycolipids are the major lipids of chlorosomes of Chlorobiaceae and Chloroflexaceae (Cruden and Stanier, 1970; Schmidt, 1980). Chlorosomes from

Chlorobium preferentially contain monogalactoside diglyceride (MGDG), while those of *Cf. aurantiacus* contain digalactosyl diglyceride as well (Holo et al., 1985).

c. Polypeptides

Chlorosomes isolated from different members of the green bacteria contain significant amounts of protein (Schmidt, 1980; Feick and Fuller, 1984; Holo et al., 1985). *Chloroflexus* chlorosomes were shown by SDS-PAGE to comprise four major polypeptides of 18, 11, 5.8 and 3.7 kDa (Feick and Fuller, 1984). The 5.8 kDa polypeptide belongs to the baseplate, which, depending on the isolation method employed, may co-purify with chlorosomes. Amino acid analysis of the 3.7 kDa polypeptide revealed a mass of 5,592 Da. Therefore, in the following and in the literature, this polypeptide is referred to as 5.6 kDa polypeptide (Zuber and Brunisholz, 1991). In spite of the large body of results obtained on the structure and molecular genetics of the 5.6 kDa polypeptide, it was claimed that this polypeptide was a degradation product (Griebenow et al., 1990). This claim, however, was not supported by subsequent investigations (Eckhardt et al., 1990; Niedermeier et al., 1992; Wullink et al., 1991). Nevertheless, it gave rise to the development of, until then, unknown concepts on the organization of photosynthetic antenna systems (see Chapter 20 by Blankenship et al.).

A 6.3 kDa polypeptide with 30% sequence homology to the 5.6 kDa polypeptide of *Cf. aurantiacus* was isolated from different species of green sulfur bacteria (Wagner-Huber et al., 1988). In addition, a second polypeptide of 7.5 kDa molecular mass and an amino acid sequence significantly different from the 6.3 kDa polypeptide, was isolated from chlorosomes of *Cb. limicola* (Gerola et al., 1988). The sequence homology of this 7.5 kDa polypeptide with the 5.6 kDa *Chloroflexus* polypeptide was only 17% (Gerola et al., 1988). Lack of cross reactivity of antisera to chlorosome peptides from *Chloroflexus* with chlorosome polypeptides from various green sulfur bacteria support the low degree of homology described on the basis of the amino acid sequence (Stolz et al., 1990).

2. Membranes

The chemical composition of CM isolated from *Cf. aurantiacus* and *Cb. limicola* f. *thiosulfatophilum*

was compared by Schmidt (1980). Interestingly, CM from *Cf. aurantiacus* contained significantly lower amounts of gluco- and phospholipids than those from *Chlorobium*. With respect to the cellular composition and distribution of carotenoids it is interesting to note that typical carotenoids of both species are present as glucosides, while chlorosomes contain the corresponding carotenoids in a non-glucosylated form. Moreover, while membranes from *Cf. aurantiacus* exhibited both NADH-oxidase and succinate-dehydrogenase activities, the latter activity could not be detected in preparations from *Chlorobium*.

All species of green bacteria synthesize a CM-bound moiety of the photosynthetic apparatus characterized by the presence of BChl *a* as the major tetrapyrrole pigment. In *Cf. aurantiacus*, this BChl *a* is associated with both light-harvesting antenna units and photochemical reaction center complexes with absorption properties very similar to the corresponding complexes of purple bacteria. However, reaction centers from *Cf. aurantiacus* are composed of two polypeptides, which do not show any amino acid sequence homology to known reaction center polypeptides from purple bacteria (Shiozawa et al., 1987). This difference is supported on the basis of the pigment composition of reaction centers, which, in *Cf. aurantiacus*, contains the primary electron donor BChl *a* dimer (P 865), an additional BChl *a*, three bacteriopheophytins *a* and two menaquinones (Pierson and Thornber, 1983; Blankenship and Fuller, 1986).

The CM-bound antenna complex of *Cf. aurantiacus*, designated B808-866 (Feick and Fuller, 1984), contains BChl, carotene and two different polypeptides (Zuber and Brunisholz, 1991; Wechsler et al., 1991). This complex resembles that of purple bacteria not only on the basis of spectral properties (Vasmel et al., 1986) but also on the homology of the two polypeptides. The proportion of light-harvesting BChl *a* per reaction center was shown to stay fairly constant at (20–25): 1 (Feick et al., 1982; Feick and Fuller, 1984).

Since *Cf. aurantiacus* is a facultatively phototrophic organism, it is able to perform a respiratory energy metabolism. Constituents of the respiratory chain are assembled together with the photochemical electron transport chain in the CM. However, when growing strictly chemotrophically, i.e. aerobically in the dark, the photosynthetic apparatus is missing in membranes from *Cf. aurantiacus* (Foster et al., 1986).

The latter applies not only to BChl complexes but also to cytochromes like the high potential cytochrome *c*-554, which is assumed to function as electron donor to the reaction center. Nevertheless, membranes isolated from chemotrophically grown cells contain at least three *c*-type and one *b*-type cytochromes in addition to menaquinone (Wynn et al., 1987). According to Zannoni and Fuller (1988) aerobic cells of *Cf. aurantiacus* exhibit a branched electron transport chain from NADH to two different terminal oxidases as based on their different sensitivities toward KCN and CO (see also Chapter 44 by Zannoni).

The CM-bound moiety of the photosynthetic apparatus of green sulfur bacteria exhibits a high degree of relatedness to photosystem I of plants. The presence of a quinone pool, of photo-reducible cytochrome *b* and of photo-oxidizable cytochrome *c* suggests participation of a cytochrome *bc* complex in photochemical electron transport (Hurt and Hauska, 1984). The analysis of a recently isolated reaction center complex from *Chlorobium* revealed the presence of about 40 molecules of BChl *a* and about four cytochromes *c*-553 per primary donor, P840 (Feiler et al., 1992). It has been suggested that the primary electron donor BChl P840 is associated with a chlorophyll-like primary acceptor as well as with a set of acceptors comprising a ubiquinone-type compound and three FeS centers (Nitschke et al., 1990). Recently, the primary acceptor, originally designated BChl₆₆₃, has been identified as an isomeric form of chlorophyll *a* (van de Meent et al., 1992).

IV. Supramolecular Organization of Chlorosomes

A. Chlorosome Envelope

As mentioned above, results of freeze-fracture studies suggest that a single layered envelope with a thickness of 2–5 nm forms the cytoplasmic boundary of chlorosomes. This together with the localization of MDGD in chlorosomes has led to the hypothesis that the chlorosome envelope is composed of a monolayer of galactolipids (Staehelin et al., 1980). Indeed, the presence of galactose moieties pointing to the cytoplasmic outside of the envelope was demonstrated by the agglutination of isolated chlorosomes from *Cb. limicola* and *Cf. aurantiacus* with Ricinus lectin (Holo et al., 1985). Agglutination was enhanced

after trypsin treatment of chlorosomes, suggesting in situ masking of galactose moieties by protein. The presence of a lipid monolayer with polar groups on the outside infers that the core of chlorosomes is largely hydrophobic. A detailed study on the localization of polypeptides in chlorosomes from *Cf. aurantiacus* gave rise to a hypothetical model structure, in which the 18 and the 11 kDa polypeptides are constituents of the envelope (Feick and Fuller, 1984). Immunogold-labeling electron microscopy performed subsequently showed, however, that each of the three antisera raised against the 18, the 11, or the 5.6 kDa polypeptides of *Chloroflexus* chlorosomes reacted with isolated chlorosomes (Wullink et al., 1991). Consequently, the 5.6 kDa polypeptide is now considered a constituent of the envelope as well.

B. Chlorosome Core

Originally, it was proposed that the rod elements of the chlorosome core were composed of regularly arranged antenna BChl *c*-polypeptide complexes (Feick and Fuller, 1984). However, through numerous studies, performed more recently, the hypothesis has been developed that the proper arrangement of BChl *c* molecules within the chlorosome does not require the presence of polypeptides (Holzwarth et al., 1990, 1992; Matsuura and Olson, 1990; Matsuura et al., 1993; see Chapter 20 by Blankenship et al.).

C. Baseplate

It is assumed that the baseplates of *Chloroflexus* chlorosomes contain the chlorosome-specific BChl *a*-polypeptide complex of 5.8 kDa (Sprague and Fuller, 1991). (This complex should not be confused with the 5.6 kDa polypeptide believed to be localized in the chlorosome envelope). As mentioned above, the baseplate BChl *a*-polypeptide usually co-purifies with chlorosomes. It can, however, be detached from chlorosome preparations without impairing their structure and function.

Chlorosomes from different members of the green sulfur bacteria, like *Cb. limicola* f. *thiosulfatophilum*, *Cb. vibrioforme*, *Cb. phaeobacteroides* and *Prosthecochloris aestuarii*, contain small but significant amounts of BChl *a* with an absorption peak near 800 nm (Gerola and Olson, 1986; Otte et al., 1991). This chlorosomal BChl *a* seems to be involved in energy transfer from the pool of major antenna pigments in the chlorosome to the CM-bound moiety of the

photosynthetic apparatus. In contrast to chlorosomes of *Cf. aurantiacus*, however, the chlorosomal BChl *a* of Chlorobiaceae absorbing near 800 nm appears to be functionally connected to a second type of BChl *a*-protein complex. This complex, with an absorption peak at 809 nm, is commonly referred to as the 'water soluble BChl *a*-protein'. Originally, this water soluble complex was postulated to form the baseplate of green sulfur bacteria (Staehelin et al., 1980). However, in more recent models, BChl *a* moieties of chlorosomes rather than the water soluble BChl *a*-complexes of Chlorobiaceae are referred to as baseplates because of their functional similarities to BChl *a* (790 nm) complexes of baseplates of *Cf. aurantiacus* (Otte et al., 1991).

V. Development of the Photosynthetic Apparatus

A. Control of Bacteriochlorophyll Synthesis

Most of the BChl *a* of green bacteria is localized in the CM and most of the BChls *c*, *d* or *e* in chlorosomes. Therefore, formation of these different BChl species can be used, in a first approximation, to follow the formation of the two structurally as well as functionally defined units of the photosynthetic apparatus. Moreover, the ratio of BChl *a/c* is a basis for estimating the ratio of the CM-bound to the chlorosomal moieties of the photosynthetic apparatus of *Cf. aurantiacus*.

For obvious reasons, light may be considered the physiologically most relevant external factor involved in the control of the development of the photosynthetic apparatus. However, factors like oxygen or the proper supply of substrates and cofactors may become important, too. In the following, the effects of these physiological factors are detailed as well as those of physiologically probably less important inhibitors.

1. Light

The first studies on the regulation of BChl synthesis in green bacteria were performed with '*Chloropseudomonas ethylicum*' strain 2-K, which was later identified as *Prosthecochloris aestuarii* (Holt et al., 1966; Trüper and Pfennig, 1978). These cultures increased their specific BChl *c* contents by a factor of 5–8 when illumination was increased from about 0.1 to 110 klx. (Interestingly, the specific growth rate of

the culture was hardly affected by this variation in light energy supply). A comparable, however less pronounced effect, was observed by Broch-Due et al. (1978) upon analyzing light dependent changes in BChl *d* contents of *Cb. limicola*. Apparently, BChl *a* contents stayed largely constant under the various conditions tested by Broch-Due et al. (1978). As described above, *Cb. limicola* and *Cb. vibrioforme* were shown to eventually shift from BChl *d* to BChl *c* formation when adapting to conditions of low illumination (Broch-Due and Ormerod, 1978; Bobe et al., 1990). These shifts are believed to increase the packing of BChl within the chlorosome. Obviously, synthesis and the proper packing of an enormous amount of light-harvesting antenna BChl enables members of the Chlorobiaceae to grow at extremely low illumination. This conclusion is supported by the fact that a strain of *Cb. phaeobacteroides* (containing BChl *e*) could be isolated from a level of the Black Sea as deep as 80 m (Overmann et al., 1992).

The first more systematic analysis of the control of BChl *a* and *c* synthesis in *Cf. aurantiacus* was performed by Pierson and Castenholz (1974b). When illumination was increased from 0.25 to 54 klx, specific BChl *c* contents decreased in a negatively exponential fashion from 23.42 to 0.63 (μg per mg dry weight of cells), while specific BChl *a* contents decreased from 2.27 to 0.78. Thus the molar ratio of BChl *c/a* decreased from 10.3 to 0.8. These results show that specific BChl contents vary in inverse proportion with variations in illumination. However, BChl *c* contents are subjected to a significantly higher degree of variation than are BChl *a* contents.

Schmidt et al. (1980), analyzing effects of different illuminations at the level of isolated chlorosomes, showed that a decrease in illumination from 2 to 0.4 klx caused an increase in the specific BChl *c* content of chlorosomes from 69 to 348 (μg per mg of protein), while the carotenoid content stayed almost constant at about 30 μg per mg of protein. Consequently, chlorosomes from highly illuminated cells exhibited a three-times higher ratio of carotenoid to BChl *c* than chlorosomes from cells grown at low illumination. The functional implications of these observations are not as yet understood.

All of the results mentioned above were obtained with batch cultures of *Cf. aurantiacus* grown in a complex medium. Therefore, to avoid the possibility of uncontrolled culture conditions in studying phenomena of control, the effects of light were studied

with serine-limited chemostat cultures of *Cf. aurantiacus* (Oelze, 1992). Increasing illumination from 5 to 25 klx caused decreases in specific steady state contents of both BChls *a* and *c*. Since, however, BChl *c* formation was more affected by the shift-up in illumination, the molar ratio of BChl *c/a* decreased from 9.5 to 6.

Studies performed with members of the non-sulfur purple bacteria on the control of BChl synthesis gave rise to the hypothesis that external factors, like light and oxygen, exert their controlling effects at the level of the initial reaction of tetrapyrrole synthesis, i.e. the formation of 5-aminolevulinic acid (ALA). To confirm this hypothesis in *Cf. aurantiacus*, serine-limited chemostat cultures adapted to 50 klx were supplied with 10 mM ALA (Oelze, 1992). This resulted in an increase of the initially low specific BChl *c* content by a factor of four (Fig. 6). The effect was less pronounced at the level of BChl *a*, so that the steady state molar ratio of BChl *c/a* increased from 5 to 12. This means that, in spite of high illumination (50 klx), addition of ALA to the culture resulted in a BChl *c/a* ratio which is typical of low-light cells (see also, Pierson and Castenholz, 1974b). As expected, addition of 10 mM of the growth limiting substrate, serine, increased the steady state biomass level. However, addition of serine stimulated the level of BChl *c* to a much lesser extent than did the addition of ALA.

2. Oxygen

In contrast to members of the green sulfur bacteria, *Cf. aurantiacus* can grow not only anaerobically in the light (i. e. phototrophically) but also with aeration in the dark (i.e., chemoheterotrophically) (Madigan and Brock, 1977; Foster et al., 1986). Under these latter conditions, the photosynthetic apparatus is not required. Nevertheless, the organisms still synthesized BChl when growing with low aeration. Vigorous aeration, adjusting the dissolved oxygen concentration to about 180 μM , is required to completely repress BChl synthesis. On the other hand, when the dissolved oxygen was adjusted to concentrations in the range of 1 to 50 μM , BChl was still synthesized in the dark (Foster et al., 1986). Importantly, during the first phase of adaptation from high to low aeration, BChl *a* was synthesized at a higher rate than BChl *c*. This result was in contrast to a previous observation (Fuller and Redlinger, 1985). It appears possible, however, that this discrepancy may result from the

Fig. 6. Dependence of cell protein levels and tetrapyrrole formation by *Chloroflexus aurantiacus* on ALA (10 mM) or on increasing the serine supply from 5 to 15 mM. Serine-limited chemostat cultures were grown at 50 klx and a constant dilution rate of $D = 0.068 \text{ h}^{-1}$. At the times indicated, ALA was added to the culture (arrow 1), ALA supply was stopped (arrow 2), and serine supply was increased (arrow 3). BChl *a* (\times), BChl *c* (\circ). (Reproduced from Oelze, 1992 with permission).

fact that the two cited investigations were started with cultures containing different initial levels of BChl.

In the phototrophic purple bacteria, formation of accessory light-harvesting units is generally more sensitive toward oxygen than formation of the photochemical reaction center complex (Oelze, 1981). The same principle can be observed with respect to the accessory antenna BChl *c* units and the reaction center BChl *a* complex of *Cf. aurantiacus*. This was shown recently, when phototrophic chemostat cultures adapted to anaerobiosis were suddenly exposed to air (Oelze, 1992). Upon aeration the specific rates of BChl synthesis decreased from 0.086 h^{-1} to 0.052 h^{-1} for BChl *a* yet to 0.039 h^{-1} for BChl *c*. In contrast to the inhibition of BChl *c* synthesis by high illumination, the effect of oxygen

could not be compensated for by addition of ALA. Obviously, this means that oxygen affects BChl *c* synthesis not only at the level of ALA formation.

3. Supply of Nutrients

Phototrophic chemostat cultures of *Cf. aurantiacus* supplied with the complex medium of Pierson and Castenholz (1974a) showed a negatively exponential decrease in specific BChl *c* contents with increasing the growth rate, while specific BChl *a* contents decreased linearly (Oelze and Fuller, 1987). Accordingly, the molar ratio of BChl *c/a* decreased with increasing growth rate, although the external conditions of illumination were not changed. Actually, variations in illumination did not influence specific BChl contents adjusted to a given growth rate. Thus, it was concluded that the growth rate or factors constituting the growth rate, like the rate of substrate supply, were involved in the control of BChl synthesis. To further analyze the basis of these observations, the consumption of the most prominent substrates of the complex medium, i. e. amino acids, was determined (Oelze et al., 1991). This revealed a characteristic pattern of amino acid utilization by batch and chemostat cultures of *Cf. aurantiacus*. In particular, it seems important to note that consumption of Glx (representing glutamate and glutamine) was high at low growth rates and decreased with increasing growth rates. The opposite was true with respect to consumption of Asx (i.e. aspartate and asparagine). In evaluating these results, it should be remembered that *Cf. aurantiacus* employs the C5 pathway of tetrapyrrole synthesis, which is initiated by the conversion of glutamic acid into ALA (Avissar et al., 1989; Kern and Klemme, 1989). This suggests that the BChl *c/a* ratio decreased because consumption of glutamate (i. e. the precursor of BChl) decreased with increasing growth rate on complex medium as well. Again, the shortage in BChl precursors affected formation of BChl *c* to a significantly higher extent than formation of BChl *a*. Biomass production, however, was warranted under these conditions by the increased consumption of amino acids like Asx.

An explanation for the decreasing rate of Glx utilization became apparent when *Cf. aurantiacus* was grown phototrophically in glutamate-limited chemostat culture. Upon increasing the growth rate, increasing steady state amounts of glutamate became detectable in the culture fluid (Oelze and Söntgerath,

1992) suggesting the presence of a cellular uptake system with relatively low affinity for glutamate.

Serine, on the other hand, is an amino acid, which, at any growth rate tested, was almost completely taken up by *Cf. aurantiacus*. Consequently, steady state specific BChl *c* contents as well as the molar ratio of BChl *c/a* of serine-limited chemostat cultures increased with increasing growth rate.

In addition to growth substrates, vitamins have been reported to be essential for the proper formation of BChl complexes. For instance, *Cf. aurantiacus* produced significantly higher amounts of BChls *c* and *a* when grown in the presence of the vitamin solution introduced by Madigan et al. (1974) than in its absence (Oelze and Söntgerath, 1992). Very recently, BChl formation has been studied with the vitamin B₁₂-dependent strain 1230 of *Cb. limicola* (Fuhrmann et al., 1993). Cells grown in the presence of 20 µg of vitamin B₁₂ per liter exhibited, respectively, 5 and 2.4 times higher specific BChl *c* and BChl *a* contents than control cells grown in the absence of the vitamin (see Fig. 10). Slight effects of vitamin B₁₂ on BChl *d* and *a* synthesis were observed, as well, with the vitamin B₁₂-independent strain 8327 of *Cb. vibrioforme*.

4. Non-Physiological Inhibitors

Gabaculine is an inhibitor of transaminase reactions and, thus, of the initial step of tetrapyrrole formation via the C5 pathway (Kern and Klemme, 1989). When *Cf. aurantiacus* was grown in the presence of gabaculine, formation of BChl *c* was inhibited with considerably higher sensitivity than was BChl *a*, while biomass production was hardly affected by the inhibitor (Oelze, 1992). According to the site of inhibition, addition of ALA completely abolished the inhibitory effect of gabaculine (Fig. 7), which indicates that BChl *c* synthesis was stimulated to a much higher extent than BChl *a* synthesis.

Several anesthetic gases have been described to comprise a group of inhibitors of BChl synthesis in *Cb. vibrioforme* (Ormerod et al., 1990). When added to phototrophic cultures of *Cb. vibrioforme*, gases such as nitrous oxide (N₂O), ethylene, and acetylene inhibited the synthesis of the accessory BChl *d*, but not of BChl *a*. Interestingly, mutants could be isolated which, except for N₂O, were resistant to the gases mentioned above.

Fig. 7. Effects of different concentrations of ALA on phototrophic batch cultures of *Chloroflexus aurantiacus*. The organisms were grown at 25 klx in batch culture in the presence of $2 \mu\text{M}$ of gabaculine for 72 h. Cell protein concentrations, the molar ratio of BChl *c/a*, and specific contents of BChl *a* (\times), BChl *c* (\circ), and coproporphyrin are shown. (Reproduced from Oelze, 1992, with permission).

5. Conclusions

All of the results reviewed above on the control of BChl synthesis in green bacteria show that formation of the accessory BChls *c*, *d* or *e* is much more affected by controlling factors than is formation of BChl *a*. The physiological significance of this effect is evident: Formation of the central unit of the photosynthetic apparatus, i.e. the photochemical reaction center BChl *a* complex, occurs as far as possible under conditions of restricted BChl synthesis. However, the mechanisms channeling tetrapyrrole precursors into the formation of either BChl *a* or the accessory types of BChl are not as clear. In an ALA synthetase-deficient mutant of *Rhodobacter sphaeroides* it has been shown that formation of the reaction center complex becomes saturated at a much lower rate of ALA supply than formation of the accessory

light-harvesting unit (Oelze, 1983). Operation of a comparable mechanism may explain the differential stimulation of BChl *a* and BChl *c* synthesis in *Cf. aurantiacus* upon addition of ALA to cultures inhibited in BChl synthesis either by high illumination or by the presence of gabaculine. This might mean that formation of the CM-bound reaction center BChl *a* complex requires only low levels of tetrapyrrole precursors, while the resulting surplus of precursors is converted into accessory BChl *c* units. In this context it is interesting to note that, at very high supplies of ALA, cells excrete tetrapyrrole precursors into the growth medium (Oelze, 1992). This suggests that packing of BChl *c* within the cells may become limited because of limited availability of chlorosomes or of space within the chlorosomes. This in turn, leads to questions as to the coordination of BChl *c* synthesis and chlorosome formation.

B. Development of Chlorosomes

Variations in the cellular contents of BChls *c*, *d*, or *e* mean that the light-harvesting capacity of the cells is subject to variation. Since by far most, if not all, of the three types of BChl is located in chlorosomes, the question arises whether variation of the cellular levels of the chlorosomal pigments is accompanied by i.) changes in the size of the already existing chlorosomes, ii.) changes in the number of chlorosomes per unit of cell, or iii.) both changes in number and size of chlorosomes. Evidence available as yet suggest that all of the three possibilities may take place if the cells are grown with different illuminations or other factors controlling the synthesis of chlorosomal pigments (Foidl et al., 1994).

The first report on the effect of light on the photosynthetic apparatus of green bacteria suggested that regulation of the cellular BChl content of *Prosthecochloris aestuarii* (formerly *Chloropseudomonas ethylica*) was achieved by changes in numbers as well as by changes in BChl content of chlorosomes (Holt et al., 1966). As far as known, the latter change is accompanied by changes in the size of chlorosomes. A light dependent change in the size of chlorosomes was observed with *Cb. limicola*, as well (Broch-Due et al., 1978). In the latter case, however, it became apparent that chlorosome preparations isolated from cells grown at a given light intensity exhibited already considerable variations in size. Similar results were obtained with *Cf. aurantiacus* as well. More detailed

studies on this aspect performed with *Cf. aurantiacus* revealed that changes in size are largely due to changes in length as well as in height rather than to changes in the width of chlorosomes (Figs. 8, 9) (Sprague et al., 1981a; Golecki and Oelze, 1987). Yet, like other members of the green phototrophic bacteria, *Cf. aurantiacus* changes not only the size but also the cellular number of chlorosomes (Schmidt et al., 1980; Sprague et al., 1981b; Golecki and Oelze, 1987).

In contrast, Pierson and Castenholz (1974b) suggested in their early paper that the cellular BChl *c* content of *Cf. aurantiacus* was regulated by the number of chlorosomes. This suggestion was taken up by Feick et al. (1982) who concluded that cells of *Cf. aurantiacus* increased only the number of chlorosomes upon adaptation from high to low light conditions. This conclusion was based, first, on the isolation of chlorosomes exhibiting identical ratios of BChl *c/a* irrespective of the light regimen employed to grow the cultures and, secondly, on the assumption that the BChl *c/a* ratio represents the size of chlorosomes.

On the other hand, an increase in only the size of chlorosomes has been observed very recently in *Cb. phaeobacteroides* strain MN1, which showed increased BChl *e* contents after adaptation to low light (Fuhrmann et al., 1993). In addition, resting as well as chemostat cultures of *Cf. aurantiacus* supplied with ALA increased the cellular content of BChl *c* as well as the volumes of chlorosomes rather than their numbers (Figs. 4a,b, 8 and Table 1). As demonstrated in Fig. 9, these changes in volume were largely due to changes in the length of chlorosomes, while the height varied only in the range of 15 to 17 nm.

Moreover, the data compiled in Table 1 demonstrate

that both types of chlorosome development mentioned above, i.e. increases in number and/or size, may take place under appropriate conditions (Foidl et al., 1994).

In chemostat cultures growing under steady state conditions the steady state number of chlorosomes per area of membrane stayed constant (Table 1, culture 1C). This means that new chlorosomes of constant volume were steadily formed at a constant rate. In contrast, resting cells did not form any additional chlorosomes. Upon stimulation of BChl *c* synthesis by addition of ALA, however, chemostat cells and resting cultures increased the volume of chlorosomes. The possibility of an increase in the number of chlorosomes without significant changes in volume is demonstrated with cultures of comparable BChl *c/a* ratios as well as chlorosome sizes but different BChl *c* contents (cultures 1C and 2B of Table 1).

On the basis of all of the results reported above, we propose that growing cells steadily form new chlorosomes and fill them up with pigments. Under these conditions the average volume of chlorosomes stays constant. If, however, this equilibrium becomes impaired, e. g. by an increased supply of ALA, the average volume of chlorosomes increases because of enhanced BChl *c* incorporation.

C. Formation of the Photosynthetic Apparatus

The ability of *Cf. aurantiacus* to grow both phototrophically in the light and chemotrophically in the dark makes them unique organisms to study de novo formation of the photosynthetic apparatus of green bacteria. However, cultures of *Cf. aurantiacus* need not be transferred from chemotrophic to phototrophic conditions in order to synthesize the

Fig. 8. Ultrathin sections of *Chloroflexus aurantiacus* with low BChl *c* contents ($7.7 \text{ nmole} \cdot \text{mg of protein}^{-1}$) and flat chlorosomes (left) and with high BChl *c* contents ($48.5 \text{ nmole} \cdot \text{mg of protein}^{-1}$) and thick chlorosomes (right). Cell wall (CW). Bar represents 100 nm.

Fig. 9. Size histograms of baseplates of cultures of *Chloroflexus aurantiacus* grown in the presence (B) and absence (A) of ALA. Cultures 1C and 2C of Table 1 were analyzed.

photosynthetic apparatus. As is known for the photoheterotrophic purple bacteria, *Cf. aurantiacus* is also able to induce the photosynthetic apparatus when transferred from conditions of high to low aeration in the dark (Sprague et al., 1981a; Foster et al., 1986). Importantly, a comparative study of the induction of the synthesis of BChls *a* and *c* revealed that it is not possible to distinguish the effect of low oxygen from that of light (Fuller and Redlinger, 1985; Redlinger and Fuller, 1985).

Electron micrographs of cell samples from highly aerated dark cultures were reported to be free of any detectable chlorosomes (Sprague and Fuller, 1991). A more precise definition of oxygen concentrations showed that cultures adapted to darkness and dissolved oxygen concentrations near $180 \mu\text{M O}_2$ were completely depleted of both BChls *a* and *c* as well as of cytochrome *c*-554, the primary electron donor to the photochemical reaction center (Foster et al., 1986). BChls *a* and *c* as well as cytochrome *c*-554 were induced in parallel and became detectable

as early as 1 h after the oxygen concentration was reduced to a value near $50 \mu\text{M}$. In an earlier study it was reported that chlorosome polypeptides became detectable 8–12 h after induction of the photosynthetic apparatus (Fuller and Redlinger, 1985; Redlinger and Fuller, 1985). On the basis of immunological results, it was suggested that the three chlorosomal polypeptides of 18, 11, and 3.7 kDa (determined by SDS-PAGE) were transcribed and translated as precursor polyproteins of 60 and 47 kDa. While the former protein reacted with antisera against all of the three chlorosomal polypeptides, the latter reacted only with antisera against the 18 and the 11 kDa polypeptides. Both polypeptide precursors were proposed to be processed into chlorosomal polypeptides in the presence of BChl, which in turn is controlled by light or oxygen (Redlinger and Fuller, 1985). Yet, a more recent study on the molecular biology of the chlorosomal polypeptides could not identify a genetic basis for the occurrence of a precursor polyprotein (Theroux et al., 1990).

A promising system to study the development of the photosynthetic apparatus in green sulfur bacteria has recently been introduced by Fuhrmann et al. (1993). These authors reported that strain 1230 of *Cb. limicola* forms chlorosomes (Fig. 10) as well as significant amounts of BChls *a* and *c* only if supplied with vitamin B_{12} . Cells grown in the absence of the vitamin are depleted of BChls and of any detectable chlorosomes. However, when subsequently supplied with B_{12} , it takes no more than 10 h to fully develop BChls and chlorosomes.

Little is known about the coordination of the synthesis of chlorosomes and the synthesis of the CM-bound moiety of the photosynthetic apparatus. According to Redlinger and Fuller (1985) as well as to Foster et al. (1986), the antenna BChl *c*-chlorosome complex is assembled by posttranslational protein processing, while the synthesis of BChls *a* and *c*, of the reaction center BChl *a*- and the antenna BChl *a*-

Table 1. Chlorosome development upon addition of 10 mM of 5-aminolevulinic acid (ALA) to serine-limited chemostat (C) and resting batch (B) cultures of *Chloroflexus aurantiacus*. In addition, specific BChl contents of cells are given. Cultures 1 and 2 were grown in the absence and presence of ALA, respectively (Foidl et al., 1994).

complexes as well as of cytochrome *c*-554, are under coordinated control of oxygen. Coordination of the synthesis of both BChls *a* and *c*, on the one hand, and, on the other, of complexes containing BChl *a* and chlorosomes was suggested by results on the relationship between cellular BChl *a* levels and chlorosome contents of *Cf. aurantiacus*. This showed a direct proportionality of specific BChl *a* contents of cells and the percentage of CM covered with chlorosomes as well as of numbers of chlorosomes per unit of CM (Golecki and Oelze, 1987).

VI. Open Questions

All of the light-harvesting pigment units of the photosynthetic apparatus of different organisms

investigated so far are made up of BChl-polypeptide holochromes. With respect to chlorosomes of green bacteria, however, the picture emerges that these units may be active even if depleted of their typical polypeptides (see Chapter 20 by Blankenship et al.). In addition, it is possible to re-assemble structures from lipophilic fractions extracted from native chlorosomes which exhibit structural as well as functional properties of the original chlorosomes which lack polypeptides. This questions the significance of polypeptides in native chlorosomes. It has been stated, for example, that the 5.6 kDa polypeptide is required for a proper arrangement of pigment molecules within the chlorosome. Reconstitution of chlorosomal structures without participation of polypeptides, however, does not favor this interpretation.

An alternative function of chlorosomal polypeptides may be based on their participation in the process of chlorosome biogenesis. As detailed above, chlorosomes are defined structures underlying the CM membrane. Thus the question arises of how pigments and lipids become incorporated into the interior of chlorosomes. As far as is known on the basis of results obtained with other bacterial species, pigments like BChl and carotenoids, as well as lipids, are formed in close association with the CM. If this is also true with the green bacteria, then the chlorosome precursors have to be transferred from the CM into the chlorosomes. These processes might require participation of polypeptides. Alternatively, chlorosomal polypeptides might function in the final steps of the synthesis of chlorosomal constituents. At present, however, practically nothing is known about the function, composition, and intracellular localization of biosynthetic pathways leading to individual constituents of the chlorosomes.

Another closely related problem concerns the site of chlorosome biogenesis. Chlorosomes are always found attached to the CM. Currently it is assumed that the attachment site represents the site of the CM-bound unit of the photosynthetic apparatus. However, evidence available indicates that in cells adapting from high to low aeration, the CM-bound unit is formed before the chlorosomes. This could mean that components of the CM-bound unit function as targets in the early assembly of chlorosomes. If this is the case, the question arises how cells control the assembly of the CM-bound unit within defined patches. Electron micrographs suggest the presence of such patches. It is not known, however, whether all of the CM-bound units of the photosynthetic apparatus are confined to patches or whether all of the patches represent sites of chlorosome attachment.

All of the questions posed above require more detailed insights into various aspects of chlorosome biogenesis. We believe that the time is ready for these studies, which should yield new and important information on the assembly of biological structures.

Acknowledgments

The original investigations by J.O. were financially supported by the Deutsche Forschungsgemeinschaft. The authors would like to thank M.D. Kamen and M. Foidl for their critical comments on the manuscript.

Summary

Purple nonsulfur photosynthetic bacteria are probably the most versatile of all microorganisms. Besides growing photoautotrophically or photoheterotrophically, they can also develop chemotrophically in darkness under aerobic conditions. Moreover, some of these bacteria are capable of dark anaerobic respiration. The photosynthetic and respiratory chains are localized in two different regions of the membrane, the intracytoplasmic and the cytoplasmic parts, respectively. This variety in bioenergetic pathways allows the bacteria to accommodate changes in the available sources of energy and in environmental factors. A first level of regulation concerns the biosynthesis of electron transfer components. A second regulation concerns the interactions between these different processes. In this chapter, emphasis is made on the interactions and the organization of these different electron transport chains. The bacteria utilize preferentially the light as energy source. In darkness, the use of the electron acceptor with the highest redox potential allows the bacteria to recover the maximum free energy. Two different mechanisms are responsible for these interactions. First the proton motive force, delocalized on the internal membrane, exerts a thermodynamic back pressure on the first complexes of respiratory chains. Second, modulation is mediated by changes in the redox state of electron carriers involved in the different bioenergetic processes. Two distinct pools of cytochrome c_2 , a periplasmic electron carrier, have been found. A first pool, localized in the periplasmic space, is connected to the respiratory chains but can be photooxidized by the small number of reaction centers present in the cytoplasmic part of the membrane. This photooxidation inhibits the respiratory activities. The second pool is associated with the intracytoplasmic membrane. One cytochrome c_2 , two reaction centers and one cytochrome bc_1 complex are organized in a supercomplex where the electron transfer is confined. This supermolecular organization allows for a very efficient photoinduced cyclic electron transfer not limited by the diffusion of the reactants. The stability of the supercomplex depends upon different factors like the redox state of cytochrome c_2 , the pH and the presence of divalent cations. Different mechanisms for their formation are discussed.

I. Introduction

Anoxygenic photosynthetic bacteria, as with all living cells, derive energy from their environment. The universal cellular energy vector, ATP, is synthesized by three metabolic pathways: fermentation, respiration (aerobic and anaerobic) and photosynthesis. Contrary to fermentation, respiration and photosynthesis involve electron carrier chains formed by transmembrane complexes connected by lipid (quinone) and water (cytochrome) soluble diffusible components. These photosynthetic and respiratory chains catalyze electron and proton transport across the membrane and induce the formation of a transmembrane potential, the main component of the proton motive force (Junge and Jackson, 1982). This proton motive force is recognized as the central energetic intermediate that induces ATP synthesis, and indirectly participates in the translocation of ions and metabolites, motility, and other energy consuming processes. In photosynthetic bacteria, the membrane potential perturbs the absorption spectra of the light-harvesting carotenoids (Wraight et al., 1978). The identity of the carotenoid band shift induced by photosynthesis or respiration (Chance and Smith, 1955) is a strong indication that the membrane potential is delocalized on the same energy-transducing membrane where the electron transfer components coupled to these chains are located.

The large number of bacterial species with different energetic pathways is the evolutionary response to variability of the environment. Anoxygenic photosynthetic bacteria have been previously classified into three families of purple bacteria (Rhodospirillaceae, Chromatiaceae, Ectothiorhodospiraceae) and two families of green bacteria (Chlorobiaceae, Chloroflexaceae) (Trüper and Pfennig, 1981). With the advance of studies on ribosomal ribonucleic acid (rRNA), a new classification on a phylogenetic basis has been proposed (Woese, 1987). The purple bacteria and their relatives belong to a new class, the Proteobacteria (Stackebrandt et al., 1988). The α subclass of this phylum contains most of the species

of the Rhodospirillaceae (nonsulfur purple bacteria), *Rhodobacter*, *Rhodospirillum*, *Rhodopseudomonas* and the strictly aerobic *Erythrobacter* species (Harashima et al., 1989). Other members of the Rhodospirillaceae, *Rhodocyclus* and *Rubrivivax*, are found in the β subclass. Members of these two subclasses are widely distributed in aquatic environments and soils exposed to light and many of them can also develop in the presence of air. They include various aerobic and anaerobic respiratory pathways in addition to the photosynthetic chain (Ferguson et al., 1987). The purple sulfur bacteria (Chromatiaceae and Ectothiorhodospiraceae) are included in the γ subclass.

Green sulfur (Chlorobiaceae) and nonsulfur bacteria (Chloroflexaceae) are not closely related in this new classification and form two distinct phylogenetic classes (Woese, 1987). The green nonsulfur bacteria can develop photoautotrophically, photoheterotrophically or, in the dark, chemoorganotrophically while the green sulfur (Chlorobiaceae) and purple sulfur (Chromatiaceae and Ectothiorhodospiraceae) bacteria are rather strict anaerobes (Madigan, 1988). The photosynthetic electron transfer chain operates according to cyclic or linear electron flow, depending on the presence of an exogenous reductant such as reduced sulfur compounds. The growth of green and purple sulfur bacteria is primarily phototrophic. Chemotrophic growth has never been observed under any nutritional conditions for Chlorobiaceae. Some Chromatiaceae species are capable of chemoorganotrophic or chemolithotrophic growth at very low oxygen tension but the growth rates are extremely slow. This suggests that these metabolic pathways do not play an essential role in their energetic metabolism. Little is known about the organization of the electron transfer chains in green and purple sulfur bacteria.

Most of our present knowledge concerns the members of the α subclass of Proteobacteria. We will discuss in this chapter the mechanism of interactions between the different electron transfer chains and the structural and functional information on their organization. It is generally assumed that the soluble carriers, namely the quinones and cytochrome (Cyt), or protons and ions are able to diffuse over long distances, mediating a redox equilibration over large membrane areas. In this case, kinetics of electron transfer between components of the respiratory and photosynthetic chains will be essentially independent of their relative localization and of the supramolecular

Abbreviations: BChl – bacteriochlorophyll; Cyt – cytochrome; Cyt c_1 – cytochrome c_2 + cytochrome c_1 ; DCPIP – 2,6-dichlorophenolindophenol; DMSO – dimethylsulfoxide; P – primary electron donor; RC – reaction center; *Rc.* – *Rhodocyclus*; *Rb.* – *Rhodobacter*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*; *Rv.* – *Rubrivivax*; TMAO – trimethylamine-N-oxide; TMPD – *N,N,N',N'*-tetramethyl-*p*-phenylenediamine

organization of proteins within the membrane. However several lines of evidence suggest that, in some instances, diffusion of mobile carriers is restricted to membrane domains of various sizes. These domains may correspond to the association of a few protein complexes with reproducible structure and stoichiometry, in which soluble carriers are trapped (i.e. supercomplexes). Such restricted diffusion is a way to favor one electron transfer pathway relative to another.

II. The Versatile Metabolism of the Rhodospirillaceae

Contrary to mitochondria and chloroplasts which function in a highly controlled environment, photosynthetic bacteria can be found in a large number of quite different habitats. They are therefore subjected to large changes in available source of energy (light or electron donors and acceptors). These organisms have developed multiple pathways to accommodate these versatile growth conditions. Besides photosynthesis and aerobic respiration, some species of photosynthetic bacteria are able to use a variety of acceptors in anaerobic electron transfer reactions (Ferguson et al., 1987). As a consequence, the purple nonsulfur bacteria are probably the most flexible group of microorganisms in biology. This

flexibility will be discussed from examples taken essentially from *Rb. sphaeroides*, *Rb. capsulatus* and *Rp. viridis*.

Figure 1 represents the different electron transport systems which can occur in these species (Vignais et al., 1985; Ferguson et al., 1987; Jackson, 1988). Three main chains can be present: the photosynthetic chain, the aerobic respiratory electron transfer system, and the anaerobic respiratory chains with trimethylamine-*N*-oxide (TMAO), dimethyl sulfoxide (DMSO) or nitrous oxide (N_2O) as electron acceptors. In addition, some strains of a few species (two strains of *Rp. palustris*, *Roseobacter denitrificans* and *Rb. sphaeroides* forma sp. *denitrificans*) are able to perform complete denitrification, i.e. to reduce nitrate (NO_3^-) into dinitrogen (N_2) via nitrite (NO_2^-), and also probably nitric oxide (NO) and nitrous oxide (N_2O) (Satoh et al., 1976; Klemme et al., 1980; Shio et al., 1988). Each of these electron transfer chains induces a proton motive force across the same membrane. This proton motive force, created by a given chain, may influence the functioning of the electrogenic complexes of the other chains. A pool of quinone molecules, a small, lipid soluble electron carrier, serves as a turntable for these different electron transfer chains. The periplasmic soluble Cyt c_2 is also involved in many of these different bioenergetic pathways. Diffusion of these two electron carriers within the hydrophobic domain (ubiquinone) and

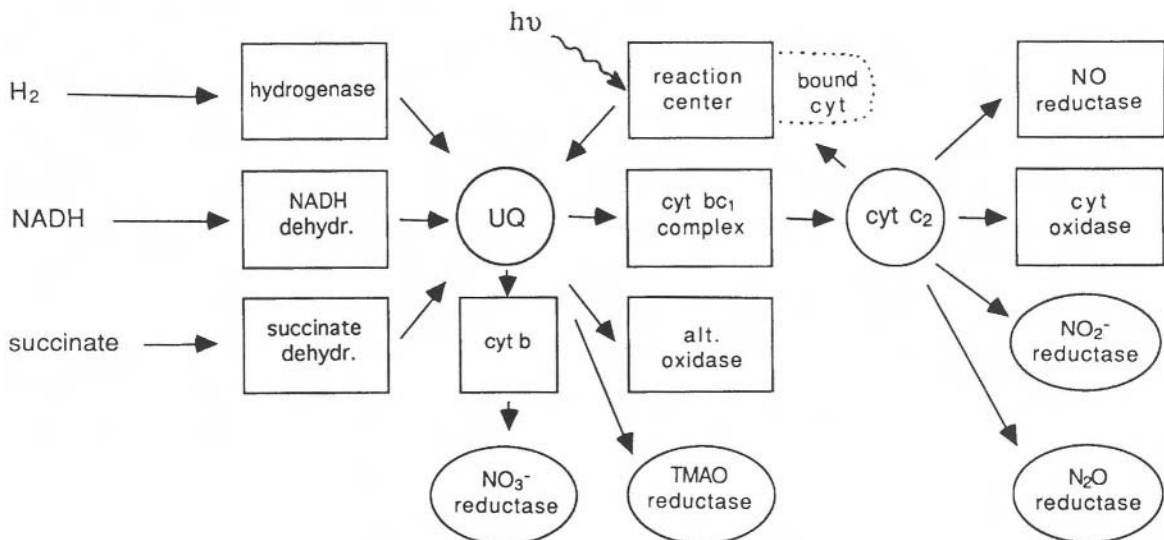

Fig. 1. The different electron transfer pathways of *Rhodobacter sphaeroides* and *Rhodobacter capsulatus*. The components in boxes are membrane proteins while the components in ovals are soluble periplasmic enzymes. The components in circles are the membranous (UQ) and periplasmic (Cyt c_2) turntables. See details in the text.

the periplasmic space (Cyt c_2) may provide interconnections between the different electron pathways. These points will be discussed in Section IV.

In general two types of antenna complexes, LH I and LH II, serve as light-harvesting complexes in Rhodospirillaceae. The LH I complex absorbs at around 870–880 nm and at around 1010 nm for bacteriochlorophyll (BChl) a - and BChl b -containing species, respectively. The LH II is only found in BChl a containing species and presents two absorption bands centered around 800 and 850 nm. Two types of reaction center (RC) can be found in Rhodospirillaceae. Most of these bacterial species contain a RC which possesses a tightly bound tetrahemic Cyt as in *Rp. viridis* (Deisenhofer et al., 1985; Deisenhofer and Michel, 1989; Bartsch, 1991). This Cyt serves as immediate electron donor to the primary donor P (Dracheva et al., 1986; Shopes et al., 1987). In this case, the cyclic electron transfer between RC and the Cyt bc_1 complex may be completed by Cyt c_2 (Garcia et al., 1993) or other soluble donors such as High Potential Iron sulfur Protein (HiPIP), Cyt c -553 or copper proteins depending on the species (Bartsch, 1991; Meyer, 1991). Other species do not have a RC bound Cyt and the cyclic electron transfer is completed by the Cyt bc_1 complex and the soluble Cyt c_2 acting as secondary donors (Dutton, 1986; Jackson, 1988; Prince, 1990).

Under dark conditions, the proton motive force is generated by the reduction of different acceptors at the expense of substrate oxidation. Input of electrons into the transfer chains is realized by membrane polypeptide complexes, namely NADH dehydrogenase, succinate dehydrogenase or hydrogenase. Two membrane proteins, both including a Cyt b , the Cyt oxidase and the ubiquinol oxidase, catalyze electron transfer from Cyt c_2 or from the ubiquinone pool, respectively, to oxygen during aerobic respiration (Zannoni and Baccharini-Melandri, 1980; Fenoll and Ramirez, 1984). In addition to oxygen, several compounds can be used as alternative electron acceptors such as DMSO, TMAO, nitrate (NO_3^-) or N_2O (Ferguson et al., 1987). These reactions are realized by soluble periplasmic enzymes (Sawada and Satoh, 1980; Urata et al., 1982; McEwan et al., 1984a).

The different electron transfer chains described in Fig. 1 are regulated at two different levels. A first level concerns control of the biosynthesis of the

enzymes and components involved in these different processes. The second level concerns short term regulation, with no change in the relative concentration of the electron transfer carriers and allows for the bacteria to utilize efficiently the available energy by selecting the most favorable pathway.

III. Regulation of the Biosynthesis of the Electron Transfer Components

Some of the electron transfer components described above are genetically controlled to adapt the bacteria to environmental changes (Kiley and Kaplan, 1988; Drews, 1991). Nevertheless, under most growth conditions the different electron transfer chains described in Fig. 1 are present. The respiratory chain is expressed even under strict anaerobic conditions and the development of the photosynthetic apparatus does not require light. The terminal reductase of DMSO/TMAO respiration is constitutive although present in low concentration. This is also true for the various enzymes involved in denitrification in the few species able to reduce nitrate (Michalski and Nicholas, 1984; Sabaty et al., 1994a).

The relative ratio between the different bioenergetic chains is regulated by light intensity, oxygen concentration and the presence of acceptors like nitrate. The highest concentration of RC and light-harvesting complexes per cell is observed at low light intensity under anaerobic conditions. When light intensity is increased, the synthesis of antennae and RCs is partly repressed. The presence of low oxygen concentration in the growth medium at a given light intensity also partially represses the synthesis of the photosynthetic chain. Therefore, high light intensity and the presence of oxygen increase the ratio between Cyt c_1 (c_2 plus c_1) and RC (Garcia et al., 1987; Verméglio et al., 1993). The synthesis of antenna and RCs is totally repressed only under dark and highly aerated cultures (Cohen-Bazire et al., 1957; Zhu and Hearst, 1986). In the case of *Rb. sphaeroides* but not for *Rb. capsulatus* or *Rs. rubrum*, these dark aerobic conditions induce the synthesis of a terminal oxidase similar to the aa_3 Cyt oxidase complex of mitochondria (Connelly et al., 1973).

In *Rb. sphaeroides denitrificans* and in *Rb. capsulatus*, a partial repression of the photosynthetic apparatus is also observed when cells are grown in the presence of nitrate or nitrous oxide (Michalski

and Nicholas, 1984; Matsuura et al., 1988; Richardson et al., 1989). Consequently the ratio between Cyt *c*₂ and RC is more than three times higher for cells grown photosynthetically in the presence than in the absence of nitrate (Matsuura et al., 1988). Under these conditions, the enzymes of the denitrification pathway are strongly expressed even at oxygen concentration as high as 37% air saturation (Sabaty et al., 1994a).

The structural genes coding for the α and β subunits of the LH I complex and the two of the RCs polypeptides, L and M, are adjacent in the genome (Williams et al., 1986; Youvan et al., 1984) and transcribed as a polycistronic message (Zhu and Kaplan, 1985; Zhu et al., 1986). All these photosynthetic genes are therefore members of a single operon, denoted *puf*, and the stoichiometry between the LH I complexes and the RC is constant whatever the growth conditions are (Aagaard and Siström, 1972). In agreement with this constant stoichiometry between the LH I complexes and RC, a supra-molecular organization between the components has been characterized for a few species (Miller, 1979; Engelhardt et al., 1983; Meckenstock et al., 1992). These results will be discussed in section V. On the other hand, the structural genes of the α and β subunits of the LH II complex are linked to the *puc* operon. The *puf* operon is regulated by oxygen at the transcriptional level while the *puc* operon is regulated by both light and oxygen. Therefore the relative amounts of LH I and LH II complexes are highly dependent upon growth conditions. The large decrease in the concentration of the photosynthetic chain components per cell induced by dark semiaerobic growth and high light intensity or the presence of nitrate, is also accompanied by a decrease in the LH II/LH I ratio (Aagaard and Siström, 1972; Michalski and Nicholas, 1984; Reidl et al., 1985).

Such regulation, since it affects the content of the complexes of the internal membrane, also induce large changes in the ultrastructure of the cells (Sprague and Varga, 1986; Drews, 1991). A relationship between the amount of photosynthetic chains and the amount of intracytoplasmic membranes (chromatophores) is observed for *Rb. sphaeroides*, *Rb. capsulatus* and *Rs. rubrum*. The amount of intracytoplasmic membrane is minimal under aerobic conditions. The cellular content in chromatophores decreases when the incident light intensity increases (Kiley and Kaplan, 1988). The addition of nitrate or oxygen in the growth medium

induces a large decrease in the number of chromatophores (Sawada and Satoh, 1980). This is shown in Fig. 2 where the ultrastructure of *Rb. sphaeroides* forma sp. *denitrificans* cells, grown in the absence or in the presence of nitrate, are compared. The induction of long tubular structures, which may impair cell division, is also observed when this species is grown in the presence of nitrate (Sabaty et al., 1994b) (Fig. 2). The formation of these tubules is correlated with the decrease in the LH II/LH I ratio observed in these growth conditions, since different mutants lacking the LH II complex have a similar ultrastructure (Hunter et al., 1988; Kiley et al., 1988).

In the case of *Rc. tenuis* or *Rubrivivax gelatinosus*, internal membranes are present as only a few irregular invaginations. When adapting from chemotrophic to phototrophic growth conditions, changes in the cellular content is achieved by modifications in the length and the diameter of the cell and in the density of particles in the cytoplasmic membrane (Drews and Oelze, 1981; see also Chapter by Drews and Golecki).

The finding that intracytoplasmic membranes are formed when the photosynthetic apparatus is induced

Fig. 2. Thin-section electron micrographs of *Rhodobacter sphaeroides* forma sp. *denitrificans*. The top and bottom panels show cells grown under photosynthetic conditions in the absence or in the presence of nitrate, respectively. Outer membrane (OM), intracytoplasmic membrane (ICM) and tubules (T) are indicated by arrows. Note that the tubules are running between two parts of a dividing cell. The bar corresponds to 200 nm.

has been taken as evidence that respiratory and photosynthetic chains are separated and localized in the cytoplasmic and in the intracytoplasmic parts of the membrane, respectively. A large number of biochemical investigations have confirmed this model. The main evidence is the following: (1) cytoplasmic membranes isolated from phototrophically grown cells of *Rb. sphaeroides* are largely depleted in BChl complexes but contained the enzymes of the respiratory activity; (2) the photosynthetic apparatus is localized in the purified intracytoplasmic membranes; (3) the segregation of these different bioenergetic activities between cytoplasmic and intracytoplasmic membranes is correlated with differences in the lipid composition of the two types of membranes (Kaufman et al., 1982).

Other arguments based on the analysis of photooxidation of Cyt c_1 are also in agreement with the intracytoplasmic and cytoplasmic parts of the membrane having different functions. In an early study, Chance and Smith (1955) noticed that oxygenation of *Rs. rubrum* cells only partly oxidized the Cyt c_2 but that its complete oxidation required continuous illumination. We have more recently shown that Cyt c_1 and RC photooxidation by continuous illumination of whole cells of *Rb. sphaeroides* strain Ga are nearly monophasic at low pH (< 7.5) over a large photon flux density range (Verméglio et al., 1993). These kinetics become clearly biphasic at high pH (> 8.5) or in the presence of divalent cations such as Mg^{++} , demonstrating the occurrence of two domains out of thermodynamic equilibrium. There are about 2 RCs per Cyt c_2 and Cyt bc_1 complex involved in the fast photooxidation phase. The slow phase corresponds essentially to Cyt c_2 photooxidation and the ratio between Cyt c_2 and RC implicated in this phase can reach 7 for cells grown semiaerobically in the dark. The relative proportion between the fast and the slow phases of Cyt c_1 photooxidation depends upon the growth conditions: the larger the number of chromatophores, the larger the amplitude of the fast phase. Moreover, only the Cyt c_2 involved in the slow phase is readily oxidized in the presence of oxygen. Therefore the slowly photooxidized Cyt c_2 is coupled to the cytoplasmic part of the membrane while the fast one is connected to the intracytoplasmic part (Verméglio et al., 1993). Similarly, two distinct pools of Cyt c_2 have been detected in *Rb. sphaeroides* forma sp. *denitrificans* whole cells (Matsuura et al., 1988). The

first pool is photooxidized by the first two flashes of a series. The relative stoichiometry of the electron transfer components involved in this reaction is similar to the one determined for the fast photooxidation of Cyt c_1 of *Rb. sphaeroides* Ga, i.e. 2 RCs, 1 Cyt c_2 and 1 Cyt bc_1 complex (Sabaty et al., 1994b). This reaction is present for cells grown both in the presence or in the absence of nitrate and is not affected by an increase of the medium viscosity (Matsuura et al., 1988). The second pool of Cyt c_2 is observed only when the denitrification pathway is induced. Its full photooxidation requires a large number of actinic flashes and their efficiency is strongly decreased in the presence of glycerol (Matsuura et al., 1988). Moreover, this second pool of Cyt c_2 is specifically oxidized by respiratory or denitrification activities (Sabaty et al., 1994b).

This series of results suggests that one pool of Cyt c_2 is tightly connected to RC and the Cyt bc_1 complex. These electron transfer components are localized in the intracytoplasmic membrane and are rapidly photooxidized whatever the conditions are. Clear cut evidence of the organization of the components involved in photosynthesis into supercomplexes will be presented in more detail in Section V. The other pool of Cyt c_2 is free to diffuse between the photosynthetic, respiratory or the denitrification chains, only at low pH or in a low viscosity medium. At high pH or when the diffusion is restricted, this Cyt c_2 is photooxidized by a small fraction of RC present in the cytoplasmic part of the membrane. A schematic representation of the organization and localization of the electron carriers is depicted in Fig. 3.

IV. Short Term Interactions Between Photosynthetic and Respiratory Activities

Short term interactions regulate electron transfer between the different chains. Photosynthesis inhibits all the other bioenergetic processes, namely respiration (Nakamura, 1937; Cotton et al., 1983), denitrification (Satoh, 1977; McEwan et al., 1982; Sabaty et al., 1993) and reduction of DMSO and TMAO (King et al., 1987). Aerobic or anaerobic respiration can only occur at a very low rate under continuous illumination.

In the dark, photosynthetic bacteria use the available acceptor which possesses the highest redox potential, i.e. the most energetically favorable. Thus

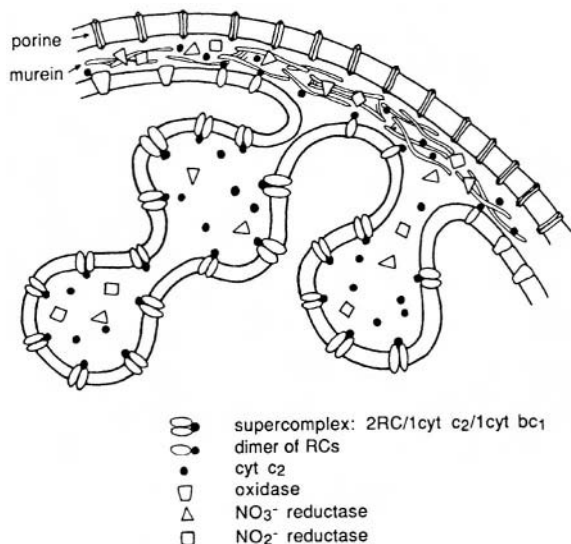

Fig. 3. Schematic representation of the organization and location of electron transfer components in *Rhodospira rubra* cells. See text for details.

O₂/H₂O ($E_m = +820$ mV) is reduced in preference to NO₃⁻/NO₂⁻ ($E_m = +420$ mV) or DMSO/DMS ($E_m = +160$ mV). This allows the bacteria to recover a free energy of 226, 146 or 92 kJ/mol when NADH is oxidized at the expense of oxygen, nitrate or DMSO reduction, respectively. These interactions between photosynthesis, aerobic respiration and denitrification are illustrated in Fig. 4. We will now discuss the mechanisms of the regulation of these bioenergetic activities.

A. Light-Inhibition of Aerobic and Anaerobic Respirations

The light inhibition of respiration has been extensively studied. In intact cells of *Rb. capsulatus*, inhibition by continuous illumination is observed whatever the oxidase, alternative oxidase, or Cyt *c* oxidase, implicated in the respiratory activity (Richaud et al., 1986). Two types of mechanism have been proposed to explain the inhibition of respiration by light. The first type is the result of thermodynamic control by the light induced proton motive force on the proton translocating complexes, i.e. the dehydrogenases and the Cyt *bc*₁ complex, involved in the electron flow (Cotton et al., 1983; Richaud et al., 1986). In the second type, changes in the redox state of electron transfer components common to the different bioenergetic chains, i.e. ubiquinone and Cyt *c*₂, play

Fig. 4. Inhibition by light of the respiratory and denitrification activities and inhibition by oxygen of the denitrification pathway. The evolution of gases (O₂) and (¹⁵N₂) was followed by a mass spectrometer for a suspension of *Rhodospira rubra* forma sp. *denitrificans* in the presence of 2 mM K¹⁵NO₃. Reduction of nitrate is effective only when all of the oxygen has been consumed by the bacteria. Light (arrow up: light on, arrow down: light off) strongly inhibits both respiration and denitrification (from Sabatay et al., 1993).

an important role in the modulation of respiration by light. Both types of mechanisms are an efficient way for the bacteria to respond rapidly to variations in environmental factors and therefore, to use the most favorable bioenergetic process.

Although non exclusive, these two types of interpretations have often been opposed. Both interpretations have important structural implications. The inhibition of respiration by the light induced membrane potential implies that both respiratory and photosynthetic electron components are localized on the same continuous internal membrane and experience the same proton motive force, but do not necessarily share redox components. Such connection between electron transfer chains is of course, mandatory in the second mechanism. Our present view is that both types of mechanism exist. Their relative contribution depends upon the type of illumination (continuous light or flash excitation) and the oxidases involved.

The involvement of the proton motive force in the control of electron transfer processes can be demonstrated by measuring the effect of uncouplers. The inhibition of respiration by continuous light is prevented by the addition of uncouplers like CCCP (Ramirez and Smith, 1968; Cotton et al., 1983; Richaud et al., 1986). The modulation of the respiratory activity by the light induced membrane potential is therefore predominant under continuous

illumination. The light induced proton motive force plays an important role in inducing a reverse electron flow between the quinone pool and NAD^+ (Knaff and Kämpf, 1987). This explanation is an extension of Mitchell's description of respiratory control in mitochondria, where the proton motive force exerts a back pressure on the proton translocating electron components and consequently, decreases the respiration rate. The proton motive force may also exert a control on the Cyt bc_1 complex involved in the respiratory activity. On the other hand, this mechanism is not operative for the terminal Cyt c oxidase. Light inhibition is prevented in the presence of exogenous electron donors like TMPD, although the light-induced membrane potential is maximal in these conditions.

Interaction between respiratory and photosynthetic chains involving common electron carriers has been observed under specific conditions. The role of the ubiquinone pool as a branching point between photosynthetic and respiratory chains has been clearly demonstrated by the light induced respiratory activity of the ubiquinol oxidase (photooxidase activity). This stimulation of the respiratory activity is observed under continuous illumination when the ubiquinone pool is reduced at the expense of artificial electron donors like TMPD or DCPIP (Zannoni et al., 1978). Interaction between photosynthetic chains and anaerobic respiratory chains at the level of ubiquinone has also been established by the effect of electron acceptors such as TMAO or NO_3^- . These acceptors provide a sink for reducing power during photosynthetic growth and maintain an optimal redox poise for the photosynthetic electron transfer components (Takamiya et al., 1988; McEwan et al., 1985). Indeed photoinduced cyclic electron transfer is maximal in a narrow range of redox potential around +50 mV (Culbert-Runquist et al., 1973; Van der Berg et al., 1983). Over-reduction of the primary electron acceptor or over-oxidation of the quinone pool will induce a decrease of the rate of electron flow (Dutton and Jackson, 1972) and consequently of the rate of ATP synthesis (Van der Berg et al., 1983).

Direct interaction at the level of electron transfer components has been demonstrated during a series of short excitation flashes (Verméglio and Carrier, 1984; Richaud et al., 1986). The respiratory activity is inhibited on each odd flash and reactivated after even flashes. This oscillatory pattern is not affected by the addition of uncouplers and has therefore been

interpreted as due to the channeling of electrons from the respiratory chain toward the photosynthetic chain at the level of Cyt c_2 or the ubiquinone pool. The oscillations in respiration have been shown to be linked only to the Cyt oxidase activity, respiration coupled to the activity of the alternative oxidase not being affected by low frequency flash excitation (Richaud et al., 1986). A single flash reduces the rate of respiration by less than 10% (Verméglio and Carrier, 1984; Richaud et al., 1986). This result is in agreement with the observation that only a small fraction of RCs, compared to Cyt c_2 , is localized in the cytoplasmic part of the membrane where the respiratory chains reside (see Section III).

Since most of the enzymes of the denitrification chain are periplasmic and coupled to Cyt c_2 (see Fig. 1), interaction at the level of this electron carrier plays an important role in the modulation of denitrification by the photosynthetic chain. This has been demonstrated in whole cells of *Rb. sphaeroides* forma sp. *denitrificans* where the inhibition by light of each step of the reduction of nitrate into dinitrogen is prevented by the addition of an exogenous electron donor, although the light induced membrane potential is maximal under these conditions (Sabaty et al., 1993).

B. Interactions Between Different Respiratory Activities

Complete inhibition of electron transport to either NO_3^- , N_2O or TMAO by oxygen is observed for whole cells of *Rb. capsulatus* and *Rb. sphaeroides* forma sp. *denitrificans* (McEwan et al., 1984b; King GF et al., 1987; Sabaty et al., 1993). As already stated, this allows the bacteria to use the available electron acceptor with the highest redox potential and therefore, to recover the maximum free energy. Contrary to what is observed for the light inhibition, the inhibition of both TMAO reduction or denitrification by oxygen is not reversed by the addition of uncouplers (McEwan et al., 1984b; King et al., 1987). This implies that inhibition by oxygen is not a consequence of a thermodynamic control exerted by the respiration induced proton motive force. The more likely hypothesis is that the different electron chains interact via some common electron carriers. Sabaty et al. (1993) have shown that the oxidation of Cyt c_1 induced by respiratory activity is responsible for the inhibition of NO_2^- and N_2O reduction. This mechanism cannot be applied to the inhibition by

oxygen of NO_3^- or TMAO reduction since Cyt c_2 and the Cyt bc_1 complex are not involved in these processes (Fig. 1). In this case the redox state of the quinone pool must be the monitoring factor. The reduction of NO_3^- or TMAO may require a large reduction of the ubiquinone pool. By oxidizing this pool, respiratory activity may inhibit the reduction of NO_3^- or TMAO. Similar modulation of the activity of the alternative oxidase by the redox state of the quinone pool has been demonstrated (Zannoni and Moore, 1990). This enzyme is not engaged until this pool is at least 25% reduced. On the other hand, a linear relationship is observed between the respiratory rate of the Cyt oxidase and the reduction level of the quinone pool (Zannoni and Moore, 1990).

Two main conclusions concerning the interactions between the different bioenergetic chains can be drawn:

(1) The light induced membrane potential exerts a thermodynamic control on the NADH dehydrogenase. During continuous illumination the ubiquinone pool is oxidized at the expense of the reduction of NAD^+ . This indirect modulation of the redox state of the ubiquinone pool explains how the respiratory activity of the alternative oxidase, the first step of denitrification and TMAO reduction, are inhibited by light, since these reactions necessitate a large reduction of this pool.

(2) Direct interactions between the different bioenergetic chains have also been clearly demonstrated at the level of Cyt c_2 and the ubiquinone pool. Oxidation of Cyt c_2 is involved in oxygen inhibition of denitrification and light inhibition of Cyt oxidase activity. The light stimulation of the alternative oxidase is mediated by the photoreduction of the ubiquinone pool. This implies diffusion of reduced quinone along the internal membrane and the photooxidation of Cyt c_2 linked to the respiratory activities by the small number of RCs present in the cytoplasmic part of the membrane.

V. Organization of the Electron Carrier Proteins into Supercomplexes

Information on the lateral organization of the photosynthetic complexes within the membrane have

been obtained for BChl b -containing species, such as *Rp. viridis* and *Ectothiorhodospira halochloris* (Miller, 1979; Engelhardt et al., 1983) and one BChl a -containing species, *Rp. marina* (Meckenstock et al., 1992). This has been possible because of three favorable circumstances: the above species possess large flat membranes, they do not possess the LH II antenna and the amount of Cyt bc_1 complex is very low. This allows electron microscopy and image processing of negatively stained membranes. A large central structure corresponding to the RC, surrounded by six smaller LHI units, has been identified. Similar hexagonal arrays of RC surrounded by LH I have also been observed by freeze fracture of chromatophores of *Rs. rubrum* (Meyer et al., 1981). In the case of mutants of *Rb. sphaeroides* lacking the LH II complexes, freeze-etching micrographs reveal a very ordered organization of the membrane complexes. Particles, which have dimensions of about $100 \times 200 \text{ \AA}$, are arrayed helically along the longitudinal axis of the tubules (Robert A Niederman, personal communication) (Fig. 5). Similar structures were observed on tubules present in the cells of *Rb. sphaeroides* forma sp. *denitrificans* grown in the presence of nitrate (Fig. 2) (Sabaty et al., 1994b). It is hoped that the biochemical characterization and image processing of negative staining micrographs will reveal the organization of the electron transfer components of this region of the membrane.

Functional analysis is the main source of information on the supramolecular organization of the electron carrier proteins within the membrane. These approaches directly address the structural properties of functional relevance, but rely heavily on models with several assumptions. In some instances, the diffusion of mobile carriers is restricted to domains of limited size. These domains could correspond to supercomplexes defined as the association of a few protein complexes in which mobile carriers are possibly trapped. Within these domains, local thermodynamic equilibration rapidly occurs (ms range) while equilibration between domains occurs over a much longer time range (several seconds). A thermodynamic approach based on the idea that a restricted diffusion of mobile electron carriers confined within isolated domains will prevent a global equilibration of the photochemically generated redox equivalents has been developed. This method has been applied to the photosynthetic electron transfer chain, including primary and secondary donors in *Rb. sphaeroides*

Fig. 5. Freeze-etching electron micrograph of the tubules present in cells of *Rhodobacter sphaeroides* mutant M_{21} lacking the LH II complex. Specific associations (possibly dimeric) between membrane particles induce a regular array. The bar represents 100 nm (Courtesy of R. Niederman).

R_{26} cells, lacking the peripheral antenna LH II (Joliot et al., 1989). The kinetics of oxidation of the primary donor (P) and Cyt c_1 have been measured under continuous illumination in the presence of myxothiazol, which blocks the reduction of the donors. In Fig. 6 is plotted the redox state of P versus that of Cyt c_1 during the course of illumination. Whatever the initial redox conditions, the [P] versus [Cyt c_1] functions measured during the course of continuous illumination are far from the equilibrium curve computed from the redox titration data (solid line). These functions are unchanged for light intensities varying from 10 to 100 photons per RC per second. These results show that the primary and secondary donors are not in thermodynamic equilibrium despite the rate of electron transfer not being limited by dark processes.

A theoretical analysis of these thermodynamic anomalies has been made assuming that components of the photosynthetic electron transfer chain are included in small isolated domains (Lavergne et al.,

Fig. 6. Percentage of reduced Cyt c_1 as a function of reduced P for a suspension of *Rhodobacter sphaeroides* R_{26} for different redox states of the cells. Open symbols: during the time course of continuous illumination. Filled symbols: after 2 min of dark adaptation. The solid line corresponds to the theoretical curve for an equilibrium constant of 70 between the primary donor P and the secondary acceptor, Cyt c_1 . The dashed lines correspond to theoretical curves computed supposing that 70% of supercomplexes involved 2RC, 1 Cyt c_2 and 1 Cyt bc_1 complex and 30% of supercomplexes involved 2RC and 1 Cyt c_2 (see insert for a schematic representation) (adapted from Joliot et al., 1989).

1989). Under continuous illumination, photons are randomly distributed among domains according to a Poisson distribution, which implies that the rates of donor oxidation differ among domains. Therefore, at a given time, the redox state of the electron transfer components is not identical in the different domains. This explains why these carriers are not in thermodynamic equilibrium during the course of illumination. By comparing the oxidation of electron donors induced by either continuous or saturating flash excitation, a structural model in which RC, Cyt c_2 and the Cyt bc_1 complex form a supercomplex has been proposed. The key features of this model are that Cyt c_2 is trapped in the supercomplex which then behaves as an isolated domain and that the contact between two RCs allows the binding of only one Cyt c_2 per dimeric RCs. This model provides a simple interpretation for the biphasic reduction of P^+ observed after flashes of short duration (Dutton et al., 1975; Overfield et al., 1979). Following a saturating flash, the two P 's of the RC dimer are

oxidized. About half of the RCs have a Cyt c_2 bound at the time the flash occurs. For this fraction of centers, P^+ is reduced in a few microseconds (μs). The reduction of the second P^+ follows a first order process ($t_{1/2}=110 \mu\text{s}$) which is essentially limited by the electron transfer from Cyt c_1 to Cyt c_2 . From the relative extents of the three different phases of P^+ reduction (few μs , 110 μs and 1 s phases), we deduced that about 70 % of the supercomplexes include 2 RC, 1 Cyt c_2 and 1 Cyt bc_1 complex (see insert of Fig. 6) while the remaining ones included only 2 RC and 1 Cyt c_2 . Dimeric association of RCs has also been suggested from the analysis of the energy transfer between antenna and RC in membranes of *Rb. sphaeroides* (Vos et al., 1988).

The model of supercomplexes has been challenged by Fernández-Velasco and Crofts (1991), who addressed the same problem in isolated chromatophores of *Rb. sphaeroides* Ga, using a different functional approach based on inhibitor titrations. These authors studied the flash induced redox changes of Cyt c_1 in the presence of subsaturating concentrations of inhibitors (myxothiazol or stigmatellin) of the quinol oxidizing site of the Cyt bc_1 complex. When 80% of the complexes are inhibited, most of Cyt c_1 can still be rapidly reduced by quinol (Fig. 7). Thus, the fraction of uninhibited complexes (20%) can catalyze the reduction of most of the oxidized Cyt c_1 . Under these conditions, uninhibited centers undergo several turnovers and thus, the half-time for Cyt c_1 reduction increases with the concentration of inhibited Cyt bc_1 complexes. The authors conclude that the oxidation of quinol is a second order process and that Cyt c_2 freely diffuses in large domains including several RCs and Cyt bc_1 complexes. These domains probably correspond to chromatophores (Fernández-Velasco and Crofts, 1991). Although these experiments do not exclude the possibility that the membrane components (RCs and Cyt bc_1 complexes) are associated in supercomplexes, they imply that Cyt c_2 is not trapped in the supercomplex.

We have used the same experimental approach to test the validity of the supercomplex model in the case of whole cells of *Rb. sphaeroides* R_{26} (Joliot et al., 1993). Following a flash excitation, we observed that subsaturating concentrations of myxothiazol decreased in the same proportion as the fraction of active Cyt bc_1 complexes and the amplitude of the fast phase of Cyt c_1 reduction, with no change in the half-time of this reaction. This behavior is opposite

Fig. 7. Kinetics of reduction of Cyt c_1 at different concentrations of stigmatellin following a single saturating excitation flash for chromatophores isolated from *Rhodobacter sphaeroides* Ga. The redox potential of the suspension was poised at 200 mV (from Fernández-Velasco and Crofts, 1991).

to that observed in isolated chromatophores and clearly supports the supercomplex model. We recently addressed the same problem in the case of *Rb. sphaeroides* Ga cells, which have a normal LH II content. In this strain, the kinetics of Cyt c_1 reduction are multiphasic, which makes their interpretation difficult. We therefore analyzed the flash induced kinetics of the carotenoid bandshift. In the absence of inhibitor, a slow increasing phase occurs in the ms range. This slow phase is associated with ubiquinol oxidation and Cyt c_1 reduction catalyzed by the Cyt bc_1 complex. Addition of subsaturating concentrations of myxothiazol decreases both the amplitude and the initial rate of the slow electrogenic phase to the same extent, with no significant change in the half-time (Fig. 8). Moreover, the same decrease in the rate and amplitude of the slow electrogenic phase is observed for saturating or subsaturating flashes. We therefore conclude that the diffusion of Cyt c_2 is strictly restricted to domains including a single Cyt bc_1 complex, in agreement with the supercomplex model proposed for the organization occurring in *Rb. sphaeroides* R_{26} cells. It must be appreciated, however, that chromatophore extraction perturbs the supercomplex structure (Fernández-Velasco and Crofts, 1991). As discussed in section III, the photosynthetic electron transfer chains organized in supercomplexes are located within the intracytoplasmic membranes (Fig. 3). Since most of the slow phase of the carotenoid

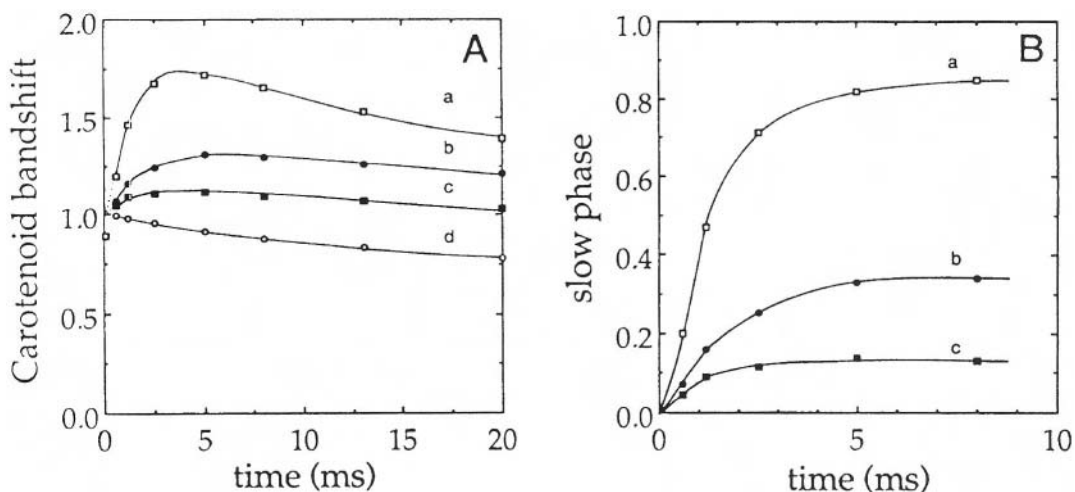

Fig. 8. Kinetics of the carotenoid bandshift in the presence of different concentrations of myxothiazol: (a) no addition (b) 0.08 μM (c) 0.12 μM and (d) 20 μM . Graph A: total absorption changes. Graph B: amplitude of the slow electrogenic phases after subtraction of the myxothiazol insensitive part and correction for the decay of the membrane potential, assuming an exponential decrease (from Verméglio et al., 1993).

bandshift corresponds to the activity involved in the supercomplexes, the small fraction of RCs and Cyt bc_1 complexes included in the cytoplasmic membrane do not give rise to a measurable electrogenic phase in the ms range.

In the case of *Rb. capsulatus*, Snozzi and Crofts (1985) have studied the dependence of the binary oscillations in the two electron gate of the acceptor side of the RC. They found that these oscillations titrated out with the midpoint potential of Cyt c_2 within chromatophores with more than 0.5 of this Cyt per RC. The binary oscillations could be observed at much lower redox potential in spheroplasts or in chromatophores with a low Cyt c_2 content. They deduced that the association of two RCs in dimers is stabilized by one molecule of reduced Cyt c_2 . The study of different mutants of *Rb. capsulatus* has also been an important source of information. Although *Rb. sphaeroides* and *Rb. capsulatus* are closely related, differences in the phenotype have appeared when deletion mutants in the Cyt c_2 have been obtained for both species. In the case of *Rb. sphaeroides*, the loss of Cyt c_2 induces a photosynthetically incompetent phenotype (Donohue et al., 1988), demonstrating that this Cyt is the sole and obligatory electron carrier between the Cyt bc_1 complex and RCs. Analysis of spontaneous revertants has shown that they accumulate a soluble Cyt c (isocyt c_2), 20 to 40% of the level of Cyt c_2 found in the wild type cells (Fitch et al., 1989; Rott et al., 1992). On the other

hand, the deletion of Cyt c_2 in *Rb. capsulatus* does not impair the photosynthetic activity (Daldal et al., 1986). Subsequent work by Jones et al. (1990) and Daldal and coworkers (Zannoni et al., 1992; Jenney and Daldal, 1993) demonstrate that connection between RC and the Cyt bc_1 complex is performed by a new Cyt denoted Cyt c_x or c_y . Mutants deleted in both Cyt c_y and Cyt c_2 are photosynthetically incompetent but regain this competence by complementation with either Cyt c_2 or Cyt c_y (Jenney and Daldal, 1993). The primary structure of Cyt c_y has been determined by sequencing of a complementary DNA fragment. Hydrophathy analyses of Cyt c_y indicate that the amino-terminal portion is hydrophobic while the carboxy-terminal is hydrophilic and equivalent to Cyt c (Jenney and Daldal, 1993). These data together with biochemical analyses strongly support the interpretation that Cyt c_y is a membrane bound c -type Cyt able to mediate electron transfer between two integral membrane proteins, the RC and the Cyt bc_1 complex. A fast electron transfer (half-time faster than 100 μs) has been observed between these different electron transfer components and the RC (Prince et al., 1986; Jones et al., 1990). This suggests that a strong association between these components occurs in the membrane, in agreement with the supercomplex model we have proposed in the case of *Rb. sphaeroides*. Strong associations between the Cyt bc_1 complex, the Cyt oxidase and a membrane bound Cyt c have already

been demonstrated in the case of *Paracoccus denitrificans* (Berry and Trumpower, 1984).

The organization into supercomplexes, in which Cyt c_2 is trapped, does not appear as a general characteristic of species of Rhodospirillaceae. As expected, the Cyt c_2 is a freely diffusing species when the stoichiometry between RCs and the Cyt bc_1 complex largely exceeds 2. This is the case for *Rs. rubrum* (Van Grondelle et al., 1976; Joliot et al., 1990) and *Rp. viridis* (Garcia et al., 1993) and in the cytoplasmic membrane of *Rb. sphaeroides* (Verméglio et al., 1993). In the case of *Rs. rubrum*, electron transfer from Cyt c_2 to the reaction center is a pure diffusional process occurring in the 100 μ s time range, which implies that no tightly bound Cyt c_2 is present in dark adapted cells. Under saturating flash excitation, about half of the photooxidized primary donors are reduced in less than 1 ms, while the remainder is reduced in tens of ms. The complex kinetics of Cyt c_2 oxidation and P^+ reduction are correctly described by a model in which RCs are associated in dimers. The affinity of Cyt c_2 for the RCs is low when it is reduced and high when oxidized. Electrostatic or steric interactions prevent the binding of two Cyt c_2 molecules on the same dimer of RC (Joliot et al., 1990). In *Rp. viridis* whole cells, the viscosity of the medium does not affect the rate of electron transfer between Cyt c_2 and high potential heme c -556 of the tetrahemic Cyt, while it greatly slows down the reduction of the photooxidized Cyt c_2 . Moreover, a full reduction of Cyt c_2 is observed in the presence of subsaturating concentrations of myxothiazol while the half time of the reaction is increased (Garcia et al., 1993). It was concluded that reduced Cyt c_2 forms a stable complex with the tetrahemic Cyt and is rereduced after photooxidation by the Cyt bc_1 complex according to a diffusion limited process.

In the future it is important to search for similar dimeric association of the RC in other species which do not possess tetrahemic Cyt and contain a low concentration of Cyt bc_1 complex. The organization between the dimeric RC, soluble (or membranous) Cyt c and the Cyt bc_1 complex must be studied for species such as *Rb. capsulatus* or *Rp. palustris* in which the ratio between Cyt bc_1 complex and RC is close to 0.5.

As discussed above, the organization of the photosynthetic chain into a supercomplex is not mandatory for its functioning. Such organization is not present in *Rp. viridis* and *Rs. rubrum* cells or in

the cytoplasmic membrane of *Rb. sphaeroides* Ga or *Rb. sphaeroides* forma sp. *denitrificans* cells. However, in conditions where the diffusion of mobile carriers is the limiting step, i.e. under rapid electron flow, the organization into a supercomplex of RC, Cyt c_2 and Cyt bc_1 complexes would allow a more efficient photoinduced cyclic electron transfer, not limited by the diffusion of the reactants. In the cytoplasmic part of the membrane, the same Cyt c_2 and Cyt bc_1 complex is involved in photosynthesis, respiratory, or denitrification activities and therefore the organization into supercomplexes is not possible. The small proportion of RC located in the cytoplasmic membrane is able to photooxidize all the Cyt c_2 involved in respiration or denitrification. This allows a rapid modulation of these bioenergetic processes by light in optimizing the rate of electron transfer of the photosynthetic pathway relative to the others.

Several questions have not yet been addressed: How are the supercomplexes formed and what are the forces involved in these associations? The PufX polypeptide is encoded by a gene located downstream of the L and M genes of RC on the *puf* operon (Zhu et al., 1986). Although the *pufX* gene is part of the polycistronic photosynthesis gene messages, no specific function has yet been described for the PufX polypeptide. This gene is not present, at least at the same position on the genome, in *Rp. viridis* and *Rs. rubrum* cells, species which do not possess supercomplex association (Laußermair and Oesterheld, 1992). Deletion of this polypeptide leads to photosynthetically incompetent mutants of *Rb. sphaeroides* (Farchaus et al., 1990) and *Rb. capsulatus* (Lilburn et al., 1992) species. The electron transfer from the RC to the Cyt bc_1 complex is impaired beyond the second flash of a series. The PufX polypeptide may play an important role in the formation of supercomplexes and therefore in the photosynthetic competence of these species (Farchaus et al., 1992; Lilburn et al., 1992). This hypothesis deserves further examination.

In *Rb. sphaeroides*, the fraction of RCs involved in supercomplexes is regulated by the relative amount of intracytoplasmic and cytoplasmic membranes. This is a long term modulation. It may also be necessary for the bacteria to adapt rapidly to environmental changes. This can be achieved by at least two different ways. We have already seen that stabilization of the association of the Cyt c_2 within the supercomplex is modulated by the redox state of Cyt c_2 and the pH or the presence of divalent cations

(Section III). This modulation occurs probably without dissociation of the interactions between the membranous complexes. Association or dissociation of these complexes involve small energy differences. Changes in phosphorylation states of membrane proteins, such as antenna complexes or RC, may play an important role in such regulation. Several membrane proteins have been found to be phosphorylated (Holuigue et al., 1985; Turner and Mann, 1986; Holmes et al., 1986). Phosphorylation and dephosphorylation of antenna has been observed in photosynthetic bacteria depending upon the redox state of the quinone pool (Holmes and Allen, 1988). Contrary to the situation in green plants and microalgae, this phenomenon is not well understood and the location and nature of the different complexes involved is still unresolved (Allen, 1992). In *Chlamydomonas* cells, it has been clearly shown that reduction of the plastoquinone pool, i.e. phosphorylation of light-harvesting complexes, induces the movement of Cyt b_6f complexes from the grana to the lamellae. This reduction also favors a strong association between the Cyt b_6f complexes and Photosystem I complexes (Wollman and Bulté, 1989). This regulates the relative contribution between linear and cyclic electron transfer. Regulation of the amount of supercomplexes, i.e. modulation between the different bioenergetic pathways in purple nonsulfur bacteria, may involve similar mechanisms of phosphorylation and migration of membrane proteins between cytoplasmic and intracytoplasmic membranes.

Summary

This chapter deals with theoretical mechanisms for electronic excitation transfer among photosynthetic pigments. General multipole expansions of intermolecular electrostatic potential energies are described in detail. We review the Golden Rule derivation of the Förster-Dexter theory for dipole-dipole and exchange transfer in the weak-coupling limit; emphasis is placed on its underlying assumptions and limitations. Extension of the Golden Rule to higher-order perturbation theory permits the description of spin-forbidden (e.g. singlet-triplet) energy transfer, as well as remote heavy-atom effects on intersystem crossing. The concepts of the density operator and density matrix are introduced. We demonstrate the need for a unified energy transfer theory that treats coherence as well as excited state population decay. The stochastic Liouville equations (SLE) are solved for the prototype case of a strongly interacting pair of chromophores, and expressions are obtained for the time-dependent anisotropy $r(t)$ in optical fluorescence and pump-probe experiments in strongly coupled systems. While time-dependent SLE solutions are required to predict anisotropy decays, evaluation of the *initial* anisotropy $r(0)$ requires only knowledge of the excitation conditions and the exciton component transition moments. Current techniques are described for the simulation of temperature dependence in Förster energy transfer rates, via the influence of electron-phonon and electron-vibration coupling on pigment absorption and fluorescence spectra.

I. Introduction

During the last ten years, many excellent reviews have addressed the theory of electronic excitation transfer and its applications to photosynthetic systems (Knox, 1975; van Grondelle, 1984; van Grondelle and Amesz, 1986; Geacintov and Breton, 1987). In the present short review, we begin by examining some of the physical assumptions underlying the well-established Golden Rule theories for dipole-dipole and exchange energy transfer in the weak-coupling limit. The latter limit holds when the intermolecular interactions are small compared to the bandwidths of the molecular electronic transitions. We then briefly consider extensions of the Golden Rule to higher-order perturbations, which can provide mechanisms for spin-forbidden (e.g. singlet-triplet) energy transfer.

The recent acquisition of femtosecond laser technology by a growing segment of the photosynthesis community has prompted intense interest in coherence effects on energy transfer, and especially about their manifestation through optical anisotropies in time-resolved fluorescence and pump-probe experiments. These topics are the subject of Section III. One of our goals is to make these calculations widely accessible to the photosynthesis community, so that others may be encouraged to tailor similar calculations to protein-pigment systems of interest. In Section IV, we review some techniques for simulation of temperature-dependent rate constants in Förster energy transfer.

While most of the chapters in this book have adopted SI units as a standard, this chapter has been written in cgs (centimeters-grams-seconds) units, because the vast majority of previous accounts of energy transfer theory have been based on these units. This is intended to facilitate comparisons of this chapter with the other sources in the literature.

II. The Weak Coupling Limit

A. Multipole Expansion of Electrostatic Interactions

The exact classical electrostatic energy of two

Abbreviations: FMO – Fenna-Matthews-Olson bacteriochlorophyll protein; RHAЕ – remote heavy atom effect; SLE – stochastic Liouville equation

molecules D and A is given by the sum of pairwise Coulomb energies,

$$V_e = \sum_i \sum_j \frac{q_i q_j}{r_{ij}} \quad (1)$$

where r_{ij} is the separation between charges q_i and q_j , and the indices i and j run over all pairs of charges (electrons and nuclei) on molecules D and A collectively. This energy may be broken up into the partial sums

$$V_e = V_{mol} + V_i \quad (2)$$

Here the molecular *self-energy*

$$V_{mol} = \sum_{i,j \in D} \frac{q_i q_j}{r_{ij}} + \sum_{i,j \in A} \frac{q_i q_j}{r_{ij}} \quad (3)$$

is summed over all pairs of charges (i,j) on molecules D and A, respectively. In the evaluation of the intermolecular *interaction energy*

$$V_i = \sum_{\substack{i \in D \\ j \in A}} \frac{q_i q_j}{r_{ij}} \quad (4)$$

the indices i,j indicate charges on molecules D and A, respectively. If the intermolecular separation R is large compared to the molecular size, so that the overlap between the respective electronic charge distributions is small, it is useful to expand the interaction energy V_i in a power series in $1/R$ (for example, see Hirschfelder and Meath, (1967)),

$$V_i = \sum_{n=1}^{\infty} V_n / R^n \quad (5)$$

In this *multipole expansion*, the coefficients V_n are given by

$$V_n = \sum_{l_D=0}^{n-1} \sum_{m=-l_D}^{l_D} \frac{(-1)^n (n-1)! Q_{l_D}^m(D) Q_{l_A}^{-m}(A)}{[(l_D - m)!(l_D + m)!(l_A - m)!(l_A + m)!]^{1/2}} \quad (6)$$

where $l_<$ is the lesser of l_D and $l_A = (n-1-l_D)$. The Q_l^m are the irreducible tensor components of the electrostatic multipole operators for the interacting molecules D, A (see, for example, Gottfried (1966)). For example, $Q_0^0(D)$ and $Q_0^0(A)$ are the total molecular charges q_D and q_A , respectively. The tensor components Q_l^m for $l=1$ are linear combinations of

Cartesian components of the electric dipole moment operators μ ,

$$\begin{aligned} Q_1^{-1}(D) &= -e \sum_i (x_i - iy_i) / \sqrt{2} = (\mu_{Dx} - i\mu_{Dy}) / \sqrt{2} \\ Q_1^0(D) &= -e \sum_i z_i = \mu_{Dz} \\ Q_1^1(D) &= e \sum_i (x_i + iy_i) / \sqrt{2} = -(\mu_{Dx} + i\mu_{Dy}) / \sqrt{2} \end{aligned} \quad (7)$$

where e is the magnitude of the electronic charge, and the z -axis points from the center of molecule D to the center of molecule A. In Eqs. (7), the sums run over all of the charges in molecule D; analogous expressions may be written for molecule A. For general $l > 0$, the irreducible tensor components for the charge distribution on molecule D may be expressed in terms of the spherical harmonic functions via

$$Q_{lp}^m(D) = -\sum_i \left(\frac{4\pi}{2l+1} \right)^{1/2} (e r_i)^l Y_{lp}^m(\theta_i, \phi_i) \quad (8)$$

and similarly for molecule A. The angles θ_i, ϕ_i are defined with respect to a right-handed Cartesian coordinate system with its origin at the center of molecule D, and with its z -axis parallel to the intermolecular axis. After substitution of explicit expressions for the spherical harmonic functions into Eq. (8), the multipole expansion of the electrostatic interaction energy (Eq. (5)) assumes the form

$$\begin{aligned} V_i &= \frac{q_D q_A}{R} + \frac{q_D (\mu_A \cdot \hat{R}) - q_A (\mu_D \cdot \hat{R})}{R^2} \\ &+ \frac{\mu_D \cdot \mu_A - 3(\mu_D \cdot \hat{R})(\mu_A \cdot \hat{R})}{R^3} \\ &+ \frac{q_D [Q_{xx}(A) + Q_{yy}(A) - 2Q_{zz}(A)]}{R^3} \\ &+ \frac{q_A [Q_{xx}(D) + Q_{yy}(D) - 2Q_{zz}(D)]}{R^3} \\ &+ \dots \end{aligned} \quad (9)$$

Here the vector \mathbf{R} points from the center of molecule D to the center of molecule A, and the quantities Q_{kl} represent Cartesian components of the molecular electric quadrupole tensor \mathbf{Q} (see, for example, Jackson (1966)). The successive terms in Eq. (9) represent the charge-charge, charge-dipole, dipole-dipole, and charge-quadrupole contributions to the total electrostatic energy. An advantage of this

multipole expansion stems from the fact that in the long-range (large- R) limit, the power series in $1/R$ converges rapidly, and can be well approximated by its leading nonzero term. In the special case where both molecules are uncharged, the terms involving q_D and q_A drop out. The lowest-order nonvanishing terms in the multipole expansion of V_i then correspond to the dipole-dipole and dipole-quadrupole interactions,

$$\begin{aligned} V_i &= \frac{\mu_D \cdot \mu_A - 3(\mu_D \cdot \hat{R})(\mu_A \cdot \hat{R})}{R^3} \\ &+ \frac{3[Q_{xx}(D)\mu_x(A) + Q_{yy}(D)\mu_y(A) - Q_{zz}(A)\mu_x(D) - Q_{zz}(A)\mu_y(D)]}{R^4} \\ &+ \frac{3[Q_{xx}(D) + Q_{yy}(D) - 2Q_{zz}(D)]\mu_z(A)}{2R^4} \\ &- \frac{3[Q_{xx}(A) + Q_{yy}(A) - 2Q_{zz}(A)]\mu_z(D)}{2R^4} \\ &+ \dots \end{aligned} \quad (10)$$

In cases where the donor and acceptor electronic charge distributions overlap appreciably, the multipole expansion of Eq. (5) remains valid. However, its utility then becomes limited by the fact that many higher-order terms may need to be included in order to accurately describe medium- to short-range interactions. In such cases, it may be simpler to proceed from the exact expression for V_e , given by Eq. (1).

B. Dipole-Dipole Energy Transfer

In the limit of weak intermolecular coupling, the probability for energy transfer from donor molecule D to acceptor molecule A is given by Dirac's Golden Rule (Gottfried, 1966),

$$P_{D \rightarrow A} = \frac{2\pi}{\hbar} \left| \langle D^* A | V_i | DA^* \rangle \right|^2 \rho(E) \quad (11)$$

where the donor and acceptor molecules are electronically excited in the initial and final states $|i\rangle = |D^* A\rangle$ and $|f\rangle = |DA^*\rangle$, respectively. The total (electronic plus nuclear) energies of the donor and acceptor in their electronic ground states are denoted ϵ_D and ϵ_A ; the corresponding quantities for the electronically excited species are ϵ_D^* and ϵ_A^* . E is the initial donor excitation energy $\epsilon_D^* - \epsilon_D$; $\rho(E)$ is the density of states isoenergetic with the initial level in the final manifold of states $|f\rangle$. Integration over all allowed combinations of initial and final donor and

acceptor energies then yields

$$P_{D \rightarrow A} = \frac{2\pi}{\hbar} \frac{1}{g_D^* g_A} \int dE \int d\epsilon_A p_A(\epsilon_A) \cdot \int d\epsilon_D^* p_D^*(\epsilon_D^*) \left| \langle D^* A | V_c | D A^* \rangle \right|^2 \quad (12)$$

Here p_D^* and p_A denote the initial energy distributions in the donor and acceptor molecules; g_D^* and g_A are the electronic state degeneracies of the excited donor and ground-state acceptor; and $E = (\epsilon_D^* - \epsilon_D) = (\epsilon_A^* - \epsilon_A)$. The electronic ground state of the isolated n -electron donor molecule may be expanded in Slater determinants of spin-orbitals u_i (e. g. Levine, 1991),

$$|D\rangle = \frac{1}{\sqrt{n!}} \begin{vmatrix} u_1(1) & u_2(1) & \dots & u_n(1) \\ u_1(2) & u_2(2) & \dots & u_n(2) \\ \dots & \dots & \dots & \dots \\ u_1(n) & u_2(n) & \dots & u_n(n) \end{vmatrix} \equiv |u_1 u_2 u_3 \dots u_n\rangle \quad (13)$$

while the excited state $|D^*\rangle$ may be similarly expanded in Slater determinants of spin-orbitals u_i^* . Analogous expressions may be written for the electronic wavefunctions of acceptor molecule A. According to Eq. (10), the leading term in the matrix element required to evaluate the transition probability for energy transfer between uncharged molecules becomes

$$\left| \langle D^* A | V_c | D A^* \rangle \right|^2 = \frac{\kappa^2}{R^6} \left| \langle D^* | \mu_D | D \rangle \right|^2 \left| \langle A | \mu_A | A^* \rangle \right|^2 \quad (14)$$

where κ^2 , the dipole-dipole orientational factor, is given by

$$\kappa^2 = [\hat{\mu}_D \cdot \hat{\mu}_A - 3(\hat{\mu}_D \cdot \hat{R})(\hat{\mu}_A \cdot \hat{R})]^2 \quad (15)$$

It may be shown (Birks, 1970) that the probability for spontaneous electric dipole emission of a photon of energy E by excited donor D^* is

$$A_D(E) = \frac{4E^3 n^3}{3\hbar^4 c^3 g_D^*} \int p_D^*(\epsilon_D^*) d\epsilon_D^* \left| \langle D^* | \mu_D | D \rangle \right|^2 \quad (16)$$

where c is the speed of light and n is the medium refractive index at the emission wavelength. Since the donor molecule's radiative lifetime is

$$\tau_0 = \frac{1}{\int A_D(E) dE} \quad (17)$$

it follows that

$$\int p_D^*(\epsilon_D^*) d\epsilon_D^* \left| \langle D^* | \mu_D | D \rangle \right|^2 = \frac{3\hbar^4 c^3 g_D^*}{4E^3 n^3 \tau_0} f_D(E) \quad (18)$$

where $f_D(E)$ is the donor emission spectrum normalized to unity. The Einstein coefficient for electric dipole absorption of a photon with energy E by the acceptor molecule A is

$$B_A(E) = \frac{2\pi}{3\hbar^2 g_A} \int p_A(\epsilon_A) d\epsilon_A \left| \langle A | \mu_A | A^* \rangle \right|^2 \quad (19)$$

This differs from the molecular absorption cross section $\sigma_A(E)$ by the factor nhE/c (Birks, 1970). Substitution of Eqs. (18) and (19) into Eq. (12), with the help of Eq. (14), then leads to

$$P_{D \rightarrow A} = \frac{9c^4 \kappa^2 \phi_D}{8\pi^4 R^6 \tau} \int d\omega f_D(\omega) \sigma_A(\omega) / \omega^4 \equiv \frac{3}{2} \frac{\kappa^2}{\tau} \left(\frac{\bar{R}_0}{R} \right)^6 \quad (20)$$

The factor of 3/2 is conventionally introduced so that when $P_{D \rightarrow A}$ is averaged over randomly oriented molecular pairs, it assumes the form $P_{D \rightarrow A} = (\bar{R}_0/R)^6 / \tau$. Here we have used the fact that the empirical fluorescence lifetime of a noninteracting donor chromophore differs from its radiative lifetime τ_0 by the factor ϕ_D , its fluorescence quantum yield; ω denotes the circular frequency $E/\hbar = 2\pi\nu$. The use of Eqs. 18 and 19 in deriving the transition probability in terms of donor fluorescence and acceptor absorption spectra implicitly assumes that donor vibrational relaxation occurs on a faster timescale than energy transfer. This is probably valid for the original situations visualized by Förster (energy transfers in dye solutions, in which the chromophores were typically separated by tens of Å). Many single-step antenna energy transfers occur within hundreds of fs (Du et al., 1993; Savikhin et al., 1993), and so this assumption may be questionable in photosynthetic systems. Donor and acceptor pigment spectra in photosynthetic antennae frequently exhibit 100–200 cm^{-1} inhomogeneous broadening. In cases where a narrow laser excitation bandwidth (e.g. $\sim 50 \text{ cm}^{-1}$ for ~ 1 ps laser pulses) excites only a subpopulation within an inhomogeneously broadened

donor spectrum, the use of the full donor pigment fluorescence spectrum in Eq. (20) appears to be inappropriate. The quantity \bar{R}_0 (which has units of length) is the *Förster parameter* that characterizes the strength of the dipole-dipole contribution to the energy transfer probability. An alternative Förster parameter, R_0 , is defined by using the donor radiative lifetime τ_0 instead of its empirical fluorescence lifetime τ in Eq. (20). Since the two Förster parameters \bar{R}_0 and R_0 then differ by the factor $\phi_D^{1/6}$, it is important to ascertain which definition of ' R_0 ' is being used when accessing values from the literature (Knox, 1975). Experimental chemical physicists have tended to use \bar{R}_0 because τ is directly measurable. In the photosynthesis community, R_0 is widely used instead. According to Eqs. (16), (19), and (20), dipole-dipole energy transfer occurs with large probability only if the $D^* \rightarrow D$ and $A \rightarrow A^*$ electronic transitions are strongly electric dipole-allowed. Since the electric dipole operators μ_D and μ_A in Eq. (14) do not operate on the electron spin functions, dipole-dipole energy transfer necessarily conserves spin on both donor and acceptor molecules. The electronic ground states of photosynthetic antenna pigments are closed-shell singlet states, so this restricts Förster energy transfer to singlet-singlet processes. The orientational factor κ^2 , which can assume values from 0 to 4, strongly influences the transition probability; its importance for energy transfer between molecules in ordered pigment systems has been discussed by Knox (1975). Since the molar decadic absorption coefficient $\epsilon(E)$ is obtained from the molecular absorption cross section $\sigma(E)$ by multiplying the former by $10^3 \ln 10 / N_{Av}$ (where N_{Av} is Avogadro's number), a working expression for the Förster parameter \bar{R}_0 is (Förster, 1959; Knox, 1975)

$$\bar{R}_0 = \left[\frac{9000c^4 \phi_D \ln 10}{8\pi n^4 N_{Av}} \int f_D(\omega) \epsilon_A(\omega) d\omega / \omega^4 \right]^{1/6} \quad (21)$$

Van Grondelle and Amesz (1986) have tabulated representative values of \bar{R}_0 , τ , and ϕ_D for energy transfers among commonly encountered pigments, including Chl *a* and *b*, BChl *a* spectral forms in purple bacteria, several carotenoids, and open tetrapyrrole chromophores found in phycocyanin and allophycocyanin antennae.

C. Exchange Mechanism for Energy Transfer

At close separations, for which the molecular electronic charge distributions overlap appreciably, many terms may contribute significantly to the power series for the interaction energy V_p and the advantages of using the multipole expansion are lost. At the same time, the magnitudes of the inter- and intramolecular interactions V_i and V_{mol} may become comparable. We therefore revert to the original expression for V_e (Eq. (1)) in the transition probability,

$$P_{D \rightarrow A} = \frac{2\pi}{\hbar} \left| \sum_{ij} \langle D^* A | \frac{q_i q_j}{r_{ij}} | DA^* \rangle \right|^2 \rho(E) \quad (22)$$

Here the summation is carried out over all pairs of charges on D and A. The matrix elements now contain the *two-electron* operators $O(ij) = 1/r_{ij}$, evaluated between initial and final electronic states. For isolated donor and acceptor molecules containing *n* and *m* electrons respectively, each of the antisymmetrized electronic states may be expanded as (linear combinations of) Slater determinants with *n!* and *m!* terms respectively (cf. Eq. (13)). However, in the presence of substantial overlap between donor and acceptor charge distributions, the electronic states of the molecule pair must be completely antisymmetrized by expanding them in terms of Slater determinants with $(n+m)!$ terms, i.e.

$$\begin{aligned} |D^* A\rangle &= |u_1 u_2 u_3 \dots u_n; v_1 v_2 v_3 \dots v_m\rangle \\ |DA^*\rangle &= |u_1 u_2 u_3 \dots u_n'; v_1 v_2 v_3 \dots v_m'\rangle \end{aligned} \quad (23)$$

The evaluation of matrix elements like those in Eq. (22) is then greatly simplified by the *Condon-Slater rules* for matrix elements of two-electron operators between determinant wavefunctions (for example, see Levine (1991)). Each spin-orbital u_k represents a product of a space function ϕ_k and a spin function σ_k , i.e. $u_k \equiv \phi_k \sigma_k$. The spin functions σ_k are either α (spin up) or β (spin down). We assume in Eqs. (23) that the ground and excited states on the donor molecule D differ by only *one* spin-orbital ($u_n \neq u_n'$), and similarly for acceptor molecule A ($v_m \neq v_m'$). In this case, application of the Condon-Slater rules for matrix elements of a two-electron

operator leads immediately to

$$\begin{aligned}
 \sum_{ij} \langle D^* A | \frac{1}{r_{ij}} | D A^* \rangle &= \langle u_n'(1) v_m'(2) | \frac{1}{r_{12}} | u_n(1) v_m(2) \rangle \\
 - \langle u_n'(2) v_m'(1) | \frac{1}{r_{12}} | u_n(1) v_m(2) \rangle \\
 &= \langle \phi_n'(1) \phi_m'(2) | \frac{1}{r_{12}} | \phi_n(1) \phi_m(2) \rangle \langle \sigma_n'(1) | \sigma_n(1) \rangle \langle \sigma_m'(2) | \sigma_m(2) \rangle \\
 - \langle \phi_n'(2) \phi_m'(1) | \frac{1}{r_{12}} | \phi_n(1) \phi_m(2) \rangle \langle \sigma_n'(1) | \sigma_n(1) \rangle \langle \sigma_n'(2) | \sigma_m(2) \rangle
 \end{aligned}
 \tag{24}$$

Here the first and second terms on the right-hand side are termed the *direct* and *exchange* contributions to the matrix element, respectively. The numbers 1,2 are dummy indices that denote the coordinates of electrons 1 and 2. The *direct* term is responsible for the Förster dipole-dipole matrix element discussed in the previous section. Its contribution to the total transition probability reduces to the Förster rate for energy transfer between uncharged molecules in the limit of large separations R when the dipole-dipole transition probability is appreciable. At smaller separations, it will also contain substantial contributions from higher-order multipole interactions (dipole-quadrupole, etc.). For the direct term, the spin-function overlaps clearly require that $\sigma_n = \sigma_n'$ and that $\sigma_m' = \sigma_m$. This implies that spin must be conserved on both donor and acceptor molecules during energy transfer, and hence that only singlet-singlet energy transfers arise from this term in antennae (since the electronic ground states of antenna pigments are singlets). The direct term can also account for excitation trapping at oxidized reaction centers ($D^* + P^+ \rightarrow D + (P^+)^*$), which frequently occurs with high efficiency. Like singlet-singlet energy transfers in antennae, this direct singlet-doublet energy transfer process is spin-allowed, because the ground and excited acceptor states P^+ and $(P^+)^*$ are both doublet states. In contrast, the *exchange* term requires that $\sigma_m' = \sigma_n$ and that $\sigma_n' = \sigma_m$. This term is therefore nonzero in antennae when (a) the electronically excited molecules D^* and A^* are both singlet states, or (b) D^* and A^* are both triplet states; it vanishes otherwise. This exchange term thus appears to provide a major mechanism for triplet-triplet energy transfer (Dexter, 1953). It may also provide a route for singlet-singlet energy transfer when Förster transfer is symmetry-forbidden, as in

energy transfers from 2^1A_g carotenoids to BChl a pigments (Frank et al., 1993). Inspection of the spatial factor in the exchange term shows that its R -dependence is dominated not so much by the factor $1/r_{12}$, but by the fact that appreciable contributions to this matrix element arise only from regions where the two-center products $\phi_n' \phi_m$, $\phi_m' \phi_n$ are large. Substantial spatial overlap between donor and acceptor orbitals is therefore a prerequisite for rapid exchange energy transfer. Two-center exchange integrals like the one in Eq. (24) exhibit exceedingly complicated R -dependence, even for the prototypical simple case where the electronic wavefunctions ϕ_m , ϕ_m' , ϕ_n , ϕ_n' are hydrogenlike atomic orbitals - not to mention porphyrin molecular orbitals (Slater, 1963). Following Dexter (1953), R -dependence in the exchange integral is often coarsely parameterized in the form $\exp(-R/L)$, where L is a constant (with dimensions of length) that is on the order of the molecular size. The spatial overlap requirement thus tends to limit the exchange mechanism to short-range energy transfers between closely situated chromophores. This situation contrasts markedly with the case of Förster transfer, where (according to Eq. (20)) an excited donor exhibits equal probabilities of intramolecular decay and nonradiative excitation transfer when $\kappa^2 = 2/3$ and $R = \bar{R}_0$. For dipole-dipole transfers between identical Chl a chromophores, \bar{R}_0 can be as large as 60–70 Å, which considerably exceeds the molecular size (Knox, 1975).

Knox and Davidovich (1979) considered the form of the spectral overlap integral appropriate for triplet-triplet exchange energy transfer. The zeroth-order chromophore electronic states $|D\rangle$, $|D^*\rangle$, $|A\rangle$, and $|A^*\rangle$ may be chosen to be eigenstates of the Born-Oppenheimer electronic Hamiltonian H_{el} , which includes all intramolecular electrostatic interactions and the electronic (but not nuclear) kinetic energies. Since H_{el} does not contain electron spin operators, these Born-Oppenheimer states will be either pure singlet or pure triplet states. Perturbation of H_{el} by the intramolecular spin-orbit coupling H_{so} mixes these zeroth-order states, so that the perturbed electronic states $|D'\rangle$, $|D'^*\rangle$, $|A'\rangle$, and $|A'^*\rangle$ are either singlet states containing small admixtures of triplet states, or vice versa. This provides one mechanism (mechanism 1) through which the otherwise spin-forbidden radiative processes of singlet-triplet absorption and phosphorescence can occur. A second mechanism (mechanism 2) is first- and/or second-order spin-orbit-vibronic coupling. If the absorption

and phosphorescence spectra are dominated by mechanism 1, the triplet-triplet exchange energy transfer rate is given by

$$P_{D \rightarrow A} = \frac{2\pi e^4}{\hbar g_D g_A} \left\langle \left| \phi'_n(2) \phi'_m(1) \right|_{r_{12}} \left| \phi_n(1) \phi_m(2) \right| \right\rangle^2 \int f_D(E) F_A(E) dE \quad (25)$$

Here $f_D(E)$ and $F_A(E)$ are the normalized donor phosphorescence and the acceptor singlet-triplet absorption spectra,

$$f_D(E) = \frac{E^{-3} A_D(E)}{\int E^{-3} A_D(E) dE} \quad (26)$$

$$F_A(E) = \frac{E^{-1} \sigma_A(E)}{\int E^{-1} \sigma_A(E) dE}$$

If, however, the spectra contain overlapping components arising from mechanism 2, these components do not contribute to the energy transfer rate; using the empirical spectra in Eq. (25) would then overestimate the rate constant.

D. Higher-Order Processes: Spin-Forbidden Energy Transfer

The Golden Rule rate in Eq. (11) only expresses the leading term in a perturbation expansion of the radiationless transition rate. Extension of this treatment to higher orders under a perturbing Hamiltonian V yields the more general result (Gottfried, 1966)

$$P_{D \rightarrow A} = \frac{2\pi}{\hbar} |T_{D \rightarrow A}|^2 \rho(E) \quad (27)$$

where the T-matrix is given to third order by

$$T_{D \rightarrow A} = \langle D^* A | V | D A^* \rangle + \sum_{D' A'} \frac{\langle D^* A | V | D' A' \rangle \langle D' A' | V | D A^* \rangle}{E_{D' A'} - E_{D A^*}}$$

$$+ \sum_{\substack{D' A' \\ D'' A''}} \frac{\langle D^* A | V | D' A' \rangle \langle D' A' | V | D'' A'' \rangle \langle D'' A'' | V | D A^* \rangle}{(E_{D' A'} - E_{D A^*})(E_{D'' A''} - E_{D A^*})} + \dots \quad (28)$$

These summations are carried out over all donor and acceptor states ($D' A'$, $D'' A''$, ...) other than the initial state $D^* A$. The perturbation V is not limited to the electrostatic interaction V_e , but may include additional perturbations such as the intra- and/or intermolecular

spin-orbit Hamiltonian H_{so} (Avouris et al., 1977; Struve, 1989). For example, two second-order terms in $T_{D \rightarrow A}$ that may contribute to the spin-forbidden singlet-triplet energy transfer process ${}^1D^* A \rightarrow D^3 A^*$ are

$$T_{D \rightarrow A}^{(2)} = \frac{\langle {}^1D^* A | H_{so} | {}^3D^* A \rangle \langle {}^3D^* A | V_e | D^3 A^* \rangle}{E_{D^3 A^*} - E_{D^* A}}$$

$$+ \frac{\langle {}^1D^* A | V_e | D^1 A^* \rangle \langle D^1 A^* | H_{so} | D^3 A^* \rangle}{E_{D^1 A^*} - E_{D^* A}} \quad (29)$$

In the first term, the donor excited singlet state ${}^1D^*$ is viewed as being coupled (through H_{so}) to a virtual donor triplet state ${}^3D^*$; the latter interacts in turn with the acceptor triplet state ${}^3A^*$ through the exchange mechanism. (As explained in Section II.C, the exchange mechanism alone cannot account for spin-forbidden energy transfer between a pure singlet state and a pure triplet state.) Such a mechanism may be relevant in cases where the acceptor molecule has no energetically accessible singlet states, but has triplet levels lying below the donor state ${}^1D^*$. In the second term, the donor excited singlet state interacts with an acceptor singlet state (e.g. by the Förster mechanism); the latter is coupled through H_{so} to an acceptor triplet state. In the presence of spin-orbit coupling, the acceptor triplet states are not pure triplets, but contain small admixtures of acceptor singlet states. Hence, these admixtures may alternatively be viewed as being coupled to the donor singlet state through the dipole-dipole interaction.

Third-order terms in the T matrix appear to be responsible for the remote heavy-atom effect (RHA), in which intramolecular singlet \rightarrow triplet intersystem crossing on a 'donor' molecule is prompted by intermolecular spin-orbit coupling, due to the presence of a heavy atom on a nearby chromophore. Such processes have recently been characterized in dimeric peptides that contain a fluorescing β -(1-naphthyl)-alanine chromophore perturbed by *p*-bromo-L-phenylalanine (Basu et al., 1993).

III. Unified Theory for Energy Transfer

A. The Density Operator and Density Matrix

We consider a quantum mechanical system whose time-dependent wavefunction $|\psi(t)\rangle$ can be expressed as a linear superimposition of orthonormal basis

states $|\chi_n\rangle$,

$$|\psi_n(t)\rangle = \sum_n c_n(t) |\chi_n\rangle \quad (30)$$

The time-dependent expectation value of a quantum mechanical observable in this state is

$$\begin{aligned} \langle A(t) \rangle &= \langle \psi(t) | \hat{A} | \psi(t) \rangle = \sum_{n,m} c_n^*(t) c_m(t) \langle \chi_n | \hat{A} | \chi_m \rangle \\ &\equiv \sum_{n,m} c_n^*(t) c_m(t) A_{nm} \end{aligned} \quad (31)$$

In this representation, all of the information concerning the state's time evolution is given by the set of time-dependent products of expansion coefficients $c_n^*(t)c_m(t)$. If we define the *density operator*

$$\rho(t) \equiv |\psi(t)\rangle\langle\psi(t)| \quad (32)$$

the matrix elements of this new operator in the basis states $|\chi_n\rangle$ will be given by

$$\begin{aligned} \rho_{nm}(t) &= \langle \chi_n | \rho(t) | \chi_m \rangle \\ &\equiv \langle \chi_n | \psi(t) \rangle \langle \psi(t) | \chi_m \rangle = c_m^*(t) c_n(t) \end{aligned} \quad (33)$$

and will thus contain the dynamic information of interest. The set of these matrix elements $\rho_{nm}(t)$ make up the *density matrix*.

Oftentimes a system is not prepared in a pure quantum mechanical state $|\psi(t)\rangle$, but in a mixture of states $|\psi_k(t)\rangle$ in such a way that the probability that the system in state k is $p_k(t)$. In this case, we may define the partial density operator

$$\rho_k = |\psi_k\rangle\langle\psi_k| \quad (34)$$

for state $|\psi_k\rangle$. The corresponding expression for the full density operator that yields the correct expressions for the expectation values and the density matrix is then given by (Cohen-Tannoudji, Diu, and Laloë, 1977)

$$\rho = \sum_k p_k \rho_k \quad (35)$$

The physical significance of the *diagonal* density matrix elements may be seen by evaluating

$$\begin{aligned} \rho_{nn} &= \sum_k p_k [\rho_k]_{nn} = \sum_k p_k \langle \chi_n | \psi_k(t) \rangle \langle \psi_k(t) | \chi_n \rangle \\ &= \sum_k p_k \left\langle \chi_n \left| \sum_m c_m^{(k)}(t) \chi_m \right. \right\rangle \left\langle \sum_{m'} c_{m'}^{(k)}(t) \chi_{m'} \left| \chi_n \right. \right\rangle \\ &= \sum_k p_k \left| c_n^{(k)}(t) \right|^2 \end{aligned} \quad (36)$$

It is clear from this that the diagonal density matrix element $\rho_{nn}(t)$ —which is nonnegative definite—is the probability that the system is in the basis state $|\chi_n\rangle$, statistically averaged over the probabilities p_k that the system is in the various superimposition states $|\psi_k(t)\rangle$. It is frequently referred to as the *population* in state $|\chi_n\rangle$. A similar calculation shows that the *off-diagonal* matrix elements are

$$\rho_{nm} = \sum_k p_k c_m^{(k)*}(t) c_n^{(k)}(t) \quad (37)$$

The complex-valued cross terms appearing in each term of this sum reflect interferences between the basis states $|\chi_n\rangle$ and $|\chi_m\rangle$. When statistically weighted by the p_k over the superimposition states $|\psi_k(t)\rangle$, these interferences may average to a nonzero value—in which case the quantum mechanical phase coherence among the basis states is at least partially maintained in the ensemble averaging. The off-diagonal matrix elements in Eq. (37) are sometimes termed *coherences*.

B. Master equations in the site and delocalized representations

The conventional master equations for the probabilities $\rho_{11}(t)$, $\rho_{22}(t)$ that electronic excitation will be found on one of two identical molecules 1 and 2 after laser pumping are given by (Förster, 1948)

$$\begin{aligned} \frac{d\rho_{11}}{dt} &= -\frac{\rho_{11}}{\tau} - F(\rho_{11} - \rho_{22}) \\ \frac{d\rho_{22}}{dt} &= -\frac{\rho_{22}}{\tau} - F(\rho_{22} - \rho_{11}) \end{aligned} \quad (38)$$

Here $1/\tau$ is the total (radiative plus nonradiative) decay rate for either of the isolated molecules, and F is the rate of excitation transfer between molecules. (In the weak-coupling limit, F is given by expressions developed in Section II.) Equations 38 predict that at long times $t \gg 1/F$, the excited state populations will

converge to the same equilibrium value, i.e. $(\rho_{11} - \rho_{22}) \rightarrow 0$.

Alternatively, the interaction energy J may be so large that it is more useful to describe the excitations in terms of the (delocalized) exciton states

$$\begin{aligned} |+\rangle &= 2^{-1/2}(|1\rangle + |2\rangle) \\ |-\rangle &= 2^{-1/2}(|1\rangle - |2\rangle) \end{aligned} \quad (39)$$

This interaction lifts the original degeneracy between the localized states $|1\rangle$ and $|2\rangle$, yielding exciton component states $|+\rangle, |-\rangle$ whose energies are separated by $2J$. In the strong coupling limit, the time-dependent probabilities ρ_{++}, ρ_{--} that the respective delocalized states are populated following laser excitation are governed by the master equations (Knox and Gülen, 1993)

$$\begin{aligned} \frac{d\rho_{++}}{dt} &= -\frac{\rho_{++}}{\tau_+} - \gamma\rho_{++} + \gamma\rho_{--} \\ \frac{d\rho_{--}}{dt} &= -\frac{\rho_{--}}{\tau_-} - \gamma'\rho_{--} + \gamma\rho_{++} \end{aligned} \quad (40)$$

Here γ and γ' are rates for upward and downward transitions between the exciton components. These must be unequal at finite temperatures, in view of the requirement that $\gamma'/\gamma = \exp(-2J/kT)$ according to detailed balancing (Rahman et al., 1979). Furthermore, the fluorescence lifetimes τ_+, τ_- of the two exciton components $|+\rangle, |-\rangle$ will be different unless the transition moments of the two chromophores 1,2 happen to be perpendicular (Chambers et al., 1974). The master equations 40 in the delocalized representation reasonably predict that at long times, the ratio ρ_{--}/ρ_{++} of equilibrium populations in the exciton states will be given by the ratio γ/γ' of upward to downward transition rates.

C. The Need for a Unified Theory

A paradox arises when one attempts to transform the master equations for the site representation in the weak coupling limit (Eqs. (38)) into those for the delocalized representation in the strong coupling limit (Eqs. (40)). In view of the transformation (Eqs. (39)) between localized and delocalized states, it follows that

$$\begin{aligned} |+\rangle\langle +| &\equiv \frac{1}{2}(|1\rangle + |2\rangle)(\langle 1| + \langle 2|) \\ &= \frac{1}{2}(|1\rangle\langle 1| + |2\rangle\langle 1| + |1\rangle\langle 2| + |2\rangle\langle 2|) \end{aligned} \quad (41)$$

The corresponding density matrix elements ρ_{kl} analogously obey

$$\rho_{++} = \frac{1}{2}(\rho_{11} + \rho_{21} + \rho_{12} + \rho_{22}) \quad (42)$$

The diagonal matrix elements ρ_{kk} give the probability that excitation resides in state $|k\rangle$. Similar equations can be written for the other density matrix elements ρ_{--}, ρ_{+-} , and ρ_{-+} in the delocalized representation in terms of the matrix elements $\rho_{11}, \rho_{21}, \rho_{12}$, and ρ_{22} in the site basis (Rahman et al., 1979),

$$\begin{aligned} \rho_{--} &= \frac{1}{2}(\rho_{11} - \rho_{21} - \rho_{12} + \rho_{22}) \\ \rho_{+-} &= \frac{1}{2}(\rho_{11} + \rho_{21} - \rho_{12} - \rho_{22}) \\ \rho_{-+} &= \frac{1}{2}(\rho_{11} - \rho_{21} + \rho_{12} - \rho_{22}) \end{aligned} \quad (43)$$

It is clear that substitution of these expressions into the strong-coupling master equations (40) *cannot* yield the weak-coupling master equations (38) in the site representation, because this would introduce cross terms (involving the off-diagonal matrix elements ρ_{12} and ρ_{21}) that are not present in the weak-coupling master equations. In a similar way, it may be shown (by using the inverse of the transformation in Eqs. 42–43) that the weak-coupling master equations (small J , large γ) do not go over into the strong-coupling master equations (large J). Hence, both theories are fundamentally incomplete, through their omission of these cross terms. According to Eq. (43), the probability that excitation resides in the delocalized state $|+\rangle$ is equal to

$$|c_+\rangle^2 = |c_1\rangle^2 + c_2^*c_1 + c_1^*c_2 + |c_2\rangle^2 \quad (44)$$

While the quantum-mechanical phases in the localized basis states $|1\rangle, |2\rangle$ automatically cancel in the computation of the absolute values-squared in the diagonal terms in Eq. (44), they do not cancel in the off-diagonal terms. This phase information will persist in the statistical averaging that yields the off-diagonal elements of the full density matrix, unless it is destroyed by dephasing processes (e.g. arising

from interactions of the electronic states with random protein motions). Hence, the cross terms are connected with coherence decay in the laser-prepared excited states.

D. The Stochastic Liouville Equations

Rahman et al. (1979) showed that the correct master equations in the delocalized representation for the excited state dynamics in a homodimer (i.e. a pair of identical chromophores) have the generic form

$$\begin{aligned} \frac{d\rho_{++}}{dt} &= -\gamma\rho_{++} + \gamma'\rho_{--} - \frac{(1+\cos\theta)\rho_{++}}{\tau_0} - \left(\frac{1}{\tau} - \frac{1}{\tau_0}\right)\rho_{++} \\ \frac{d\rho_{--}}{dt} &= -\gamma'\rho_{--} + \gamma\rho_{++} - \frac{(1-\cos\theta)\rho_{--}}{\tau_0} - \left(\frac{1}{\tau} - \frac{1}{\tau_0}\right)\rho_{--} \\ \frac{d\rho_{+-}}{dt} &= -2iJ\rho_{+-} - \left(2A + \frac{1}{\tau}\right)\rho_{+-} - (\Gamma + B - A)(\rho_{+-} - \rho_{-+}) \\ \frac{d\rho_{-+}}{dt} &= 2iJ\rho_{-+} - \left(2A + \frac{1}{\tau}\right)\rho_{-+} - (\Gamma + B - A)(\rho_{-+} - \rho_{+-}) \end{aligned} \quad (45)$$

Here the rate constants γ and γ' for upward and downward transitions between the exciton components depend on local fluctuations in the excited state energies $E_{1(2)}$; their mean is Γ . The monomer radiative and total decay rates are $1/\tau_0$ and $1/\tau$, respectively. The angle between the transition dipole moments of chromophores 1,2 is θ . The constants A and B are related to local fluctuations in the interaction J , and therefore to J^2 . In the weak coupling limit, the Förster rate for excitation transfer between the two chromophores is given by $F = A + 2J^2/(2\Gamma + 2B + 1/\tau)$. Using the relationships (Eqs. (42–43)) between the density matrices in the delocalized and site representations, these master equations can be transformed into (more complicated) master equations in the site representation. A major simplifying feature of the master equations in the delocalized representation is that the diagonal matrix elements ρ_{++}, ρ_{--} are not coupled to the off-diagonal matrix elements ρ_{+-}, ρ_{-+} .

The solutions to these master equations are readily obtained through standard Laplace transform techniques. In particular, the diagonal density matrix elements behave as

$$\begin{aligned} \rho_{++}(t) &= a_+(t)\rho_{++}(0) + b_+(t)\rho_{--}(0) \\ \rho_{--}(t) &= a_-(t)\rho_{--}(0) + b_-(t)\rho_{++}(0) \end{aligned} \quad (46)$$

with

$$a_{\pm}(t) = \frac{r_1 e^{-r_1 t} - r_2 e^{-r_2 t} + (e^{-r_1 t} - e^{-r_2 t}) \left(\gamma_{\pm} + (1 \mp \cos\theta)/\tau_0 + \left(\frac{1}{\tau} - \frac{1}{\tau_0} \right) \right)}{r_1 - r_2} \quad (47)$$

and

$$b_{\pm}(t) = \frac{\gamma_{\pm} (e^{-r_1 t} - e^{-r_2 t})}{r_1 - r_2} \quad (48)$$

Here we have set $\gamma_+ = \gamma'$ and $\gamma_- = \gamma$. The quantities r_1, r_2 (which have units of s^{-1}) are given by

$$r_{1,2} = \Gamma + \frac{1}{\tau} \pm \frac{1}{2} \sqrt{\left(\gamma - \gamma' + \frac{2\cos\theta}{\tau_0} \right)^2 + 4\gamma\gamma'} \quad (49)$$

The off-diagonal density matrix elements may be expressed as

$$\begin{aligned} \rho_{+-}(t) &= c_+(t)\rho_{+-}(0) + d_+(t)\rho_{-+}(0) \\ \rho_{-+}(t) &= c_-(t)\rho_{-+}(0) + d_-(t)\rho_{+-}(0) \end{aligned} \quad (50)$$

where

$$\begin{aligned} c_{\pm}(t) &= \frac{s_1 e^{-s_1 t} - s_2 e^{-s_2 t} + (e^{-s_1 t} - e^{-s_2 t}) \left(A + B + \Gamma + \frac{1}{\tau} \mp 2iJ \right)}{s_1 - s_2} \\ d_{\pm}(t) &= \frac{(\Gamma + B - A)(e^{-s_1 t} - e^{-s_2 t})}{s_1 - s_2} \end{aligned} \quad (51)$$

Here the roots s_1 and s_2 are given by

$$s_{1,2} = A + B + \Gamma + \frac{1}{\tau} \pm i \sqrt{4J^2 - (\Gamma + B - A)^2} \quad (52)$$

It is clear from Eqs. (46–48) and (50–51) that the time-dependent functions $a_{\pm}(t)$ and $c_{\pm}(t)$ initialize to unity at zero time. Similarly, the functions $b_{\pm}(t)$ and $d_{\pm}(t)$ initialize to zero. In general, $a_{\pm}(t)$ and $b_{\pm}(t)$ — which control the exciton level populations, cf. Eqs. (46) — are biexponential functions of time, because the numbers r_1, r_2 are always real. However, the functions $c_{\pm}(t)$ and $d_{\pm}(t)$ — which control the coherence decays according to Eqs. (50) — may display oscillatory behavior ('quantum beats'), since the numbers s_1, s_2 are complex when $4J^2 > (\Gamma + B - A)^2$.

E. Optical Anisotropy in Fluorescence and Pump-Probe Experiments

The result of an optical anisotropy experiment in many-chromophore systems such as photosynthetic antennae is directly sensitive to the presence of exciton couplings and coherence decay. Since the delocalized exciton states $|+\rangle$ and $|-\rangle$ in a homodimer are linear combinations of the localized excited states $|1\rangle$ and $|2\rangle$ (Eqs. 40), the transition moment orientations μ_+ , μ_- of the exciton transitions differ in both direction and magnitude from those in the site representation, μ_1 and μ_2 . The initial values of the density matrix elements in the delocalized representation, promptly following electric-dipole absorption of a photon with polarization \mathbf{e}_p , are given by (Rahman et al., 1979)

$$\begin{aligned}\rho_{++}(0) &= K_+ B_+ (\hat{\mathbf{e}}_p \cdot \hat{\mu}_+)^2 \\ \rho_{--}(0) &= K_- B_- (\hat{\mathbf{e}}_p \cdot \hat{\mu}_-)^2 \\ \rho_{+-}(0) = \rho_{-+}(0) &= (K_+ K_- B_+ B_-)^{1/2} (\hat{\mathbf{e}}_p \cdot \hat{\mu}_+) (\hat{\mathbf{e}}_p \cdot \hat{\mu}_-)\end{aligned}\quad (53)$$

Here K_+ , K_- are the incident light intensities at the wavelengths for absorptive transitions to the two exciton states, and B_+ , B_- are the corresponding Einstein coefficients. The fluorescence intensity subsequently emitted by the homodimer at time t with polarization \mathbf{e}_f will then be

$$\begin{aligned}I(t) &= A_+ \rho_{++}(t) (\hat{\mathbf{e}}_f \cdot \hat{\mu}_+)^2 + A_- \rho_{--}(t) (\hat{\mathbf{e}}_f \cdot \hat{\mu}_-)^2 \\ &+ (A_+ A_-)^{1/2} (\rho_{+-}(t) + \rho_{-+}(t)) (\hat{\mathbf{e}}_f \cdot \hat{\mu}_+) (\hat{\mathbf{e}}_f \cdot \hat{\mu}_-)\end{aligned}\quad (54)$$

where A_+ , A_- are the corresponding Einstein coefficients for spontaneous emission from the exciton components. According to Eq. 53, selective excitation of *one* of the exciton components (e.g. $K_+ = 0$) yields vanishing initial values $\rho_{+-}(0)$, $\rho_{-+}(0)$ of the off-diagonal density matrix elements. Since the diagonal and off-diagonal matrix elements are uncoupled in the stochastic Liouville equations in this representation, the off-diagonal elements (the coherences) then remain equal to zero at all later times. Equations (54) then imply that the total fluorescence spectrum and polarization will simply evolve as incoherent, weighted sums of the respective quantities for the two exciton components. For *spectrally broad* excitation ($K_+ = K_-$), the off-diagonal elements will initialize to large values. The resulting

interference terms in Eq. (54) can then markedly affect the fluorescence polarization, with time dependence that reflects processes responsible for the decay in ρ_{+-} and ρ_{-+} . These coherence decays may be observed in ultrafast fluorescence or pump-probe spectroscopy, since femtosecond excitation pulses are inherently spectrally broad.

In a typical fluorescence anisotropy measurement, the excitation laser is polarized along the laboratory x -axis, while the fluorescence is detected with analyzers polarized along either the x - or y -axis. The polarized fluorescence intensities emitted by a sample of randomly oriented homodimers (in which the transition moments of chromophores 1,2 are separated by the well-defined angle θ) are then obtained by combining Eqs. (46), (50), (53), and (54) :

$$\begin{aligned}I_{||} &= K_+ A_+ B_+ a_+(t) \langle (\hat{x} \cdot \hat{\mu}_+)^4 \rangle + K_- A_- B_- b_-(t) \langle (\hat{x} \cdot \hat{\mu}_-)^2 (\hat{x} \cdot \hat{\mu}_+)^2 \rangle \\ &+ K_- A_- B_- a_-(t) \langle (\hat{x} \cdot \hat{\mu}_-)^4 \rangle + K_+ A_+ B_+ b_+(t) \langle (\hat{x} \cdot \hat{\mu}_+)^2 (\hat{x} \cdot \hat{\mu}_-)^2 \rangle \\ &+ (K_+ K_- A_+ A_- B_+ B_-)^{1/2} (c_+(t) + d_+(t) + c_-(t) + d_-(t)) \langle (\hat{x} \cdot \hat{\mu}_+)^2 (\hat{x} \cdot \hat{\mu}_-)^2 \rangle\end{aligned}$$

and

$$\begin{aligned}I_{\perp} &= K_+ A_+ B_+ a_+(t) \langle (\hat{x} \cdot \hat{\mu}_+)^2 (\hat{y} \cdot \hat{\mu}_+)^2 \rangle + K_- A_- B_- b_-(t) \langle (\hat{x} \cdot \hat{\mu}_-)^2 (\hat{y} \cdot \hat{\mu}_-)^2 \rangle \\ &+ K_- A_- B_- a_-(t) \langle (\hat{x} \cdot \hat{\mu}_-)^2 (\hat{y} \cdot \hat{\mu}_+)^2 \rangle + K_+ A_+ B_+ b_+(t) \langle (\hat{x} \cdot \hat{\mu}_+)^2 (\hat{y} \cdot \hat{\mu}_-)^2 \rangle \\ &+ (K_+ K_- A_+ A_- B_+ B_-)^{1/2} (c_+(t) + d_+(t) + c_-(t) + d_-(t)) \cdot \\ &\langle (\hat{x} \cdot \hat{\mu}_+) (\hat{x} \cdot \hat{\mu}_-) (\hat{y} \cdot \hat{\mu}_+) (\hat{y} \cdot \hat{\mu}_-) \rangle\end{aligned}$$

Here the brackets $\langle \rangle$ indicate averaging over the (random) orientational distribution of homodimers. The transition moments μ_+ , μ_- in a symmetric homodimer are mutually orthogonal, regardless of the angle θ between the chromophore transition moments μ_1 , μ_2 (Chambers et al., 1974). This fact may be used in performing the required orientational averages (van Amerongen and Struve, 1993), yielding

$$\begin{aligned}I_{||}(t) &= \frac{3}{15} K_+ A_+ B_+ a_+(t) + \frac{3}{15} K_- A_- B_- a_-(t) + \\ &\frac{1}{15} K_- A_- B_- b_-(t) + \frac{1}{15} K_+ A_+ B_+ b_+(t) \\ &+ \frac{1}{15} (K_+ K_- A_+ A_- B_+ B_-)^{1/2} (c_+(t) + d_+(t) + c_-(t) + d_-(t))\end{aligned}\quad (55a)$$

and

$$\begin{aligned}
I_{\perp}(t) = & \frac{1}{15} K_{+} A_{+} B_{+} a_{+}(t) + \frac{1}{15} K_{-} A_{-} B_{-} a_{-}(t) \\
& + \frac{2}{15} K_{-} A_{+} B_{+} b_{+}(t) + \frac{2}{15} K_{+} A_{-} B_{-} b_{-}(t) \\
& - \frac{1}{30} (K_{+} K_{-} A_{+} A_{-} B_{+} B_{-})^{1/2} (c_{+}(t) + d_{+}(t) + c_{-}(t) + d_{-}(t))
\end{aligned} \quad (55b)$$

In view of the fact that $a_{\pm}(0) = c_{\pm}(0) = 1$ and $b_{\pm}(0) = d_{\pm}(0) = 0$, the fluorescence anisotropy at time $t = 0$ becomes

$$\begin{aligned}
r(0) = & \frac{I_{\parallel}(0) - I_{\perp}(0)}{I_{\parallel}(0) + 2I_{\perp}(0)} \\
= & \frac{2K_{+}A_{+}B_{+} + 2K_{-}A_{-}B_{-} + 3(K_{+}K_{-}A_{+}A_{-}B_{+}B_{-})^{1/2}}{5(K_{+}A_{+}B_{+} + K_{-}A_{-}B_{-})}
\end{aligned} \quad (56)$$

In a homodimer for which θ is the angle between transition moments μ_1 and μ_2 , the Einstein coefficients A_{\pm} and B_{\pm} for spontaneous emission and absorption are proportional to $(1 \pm \cos \theta)$. In the limit of *spectrally broad* excitation ($K_{+} = K_{-}$), in which all of the density matrix elements are 'created equal' by broadband light — the initial anisotropy therefore simplifies into

$$r(0) = \frac{7 + \cos^2 \theta}{10(1 + \cos^2 \theta)} \quad (57)$$

Hence, the initial anisotropies are bounded between 0.4 and 0.7 in the case of broadband excitation of a homodimer (Knox and Gülen, 1993). The minimum $r(0) = 0.4$ is attained when the chromophore transition moments μ_1 and μ_2 are parallel; in this case, only one of the exciton components is electric-dipole accessible from the homodimer ground state. The maximum $r(0) = 0.7$ occurs when $\theta = 90^\circ$, in which case the two perpendicular transition moments μ_+ and μ_- have equal magnitude. The initial anisotropy thus depends on the symmetry of the transition moment distribution among the exciton components that are excited. Equation 57 agrees with one obtained by Wynne and Hochstrasser (1993) using Redfield theory (1965). These results are of course strongly influenced by the excitation and detection conditions; empirical anisotropies will be 'filtered' by the excitation bandwidth and by the detector's spectral sensitivity.

It is straightforward to show from Eqs. 46–52 that

in the special case where $\theta = 90^\circ$, the anisotropy function $r(t)$ evolves as

$$r_{90}(t) = \frac{1}{10} (1 + 3e^{-2\Gamma t} + 3\xi(t)) \quad (58)$$

It may be similarly shown that for general θ ,

$$r(t) = \frac{r_{90}(t) + \frac{1}{10} (3 + e^{-2\Gamma t} - 3\xi(t)) \cos^2 \theta + \frac{2}{5} (1 - e^{-2\Gamma t}) \frac{(\gamma' - \gamma)}{2\Gamma} \cos \theta}{1 + e^{-2\Gamma t} \cos^2 \theta + (1 - e^{-2\Gamma t}) \frac{(\gamma' - \gamma)}{2\Gamma} \cos \theta} \quad (59)$$

when the excited state decay rate $1/\tau$ is small compared to A , B , Γ , and J . The function $\xi(t)$, which equals unity at zero time, is

$$\begin{aligned}
\xi(t) = & e^{-\gamma(A+B+\Gamma)t} \\
& \left[(B + \Gamma - A) \frac{\sin \sqrt{4J^2 - (B + \Gamma - A)^2} t}{\sqrt{4J^2 - (B + \Gamma - A)^2}} + \cos \sqrt{4J^2 - (B + \Gamma - A)^2} t \right]
\end{aligned}$$

In accordance with detailed balancing, the factor $(\gamma' - \gamma)/2\Gamma$ must equal $\tanh(J/kT)$. Exciton splittings $2J$ on the order of several hundred cm^{-1} are common in pigment-protein complexes, and hence this factor is significant even at room temperature. The function $\xi(t)$ exhibits sinusoidal character in the strong-coupling (large J) limit, causing the occurrence of 'quantum beats' (Knox and Gülen, 1993). In the weak-coupling limit (where $J \rightarrow 0$ and $(B + \Gamma - A) \sim \Gamma$, the argument of the square root in Eqs. (51–52) becomes negative, and $\xi(t)$ no longer contains sinusoidal terms. The third term on the right-hand side of Eq. 58 then approaches $3\exp(-2\Gamma t)$, and so this decay component in $r_{90}(t)$ corresponds to ordinary Förster energy transfer between the two chromophores. Equations 57 and 59 predict that $r(t)$ should decay rapidly from $r(0) \geq 0.4$ with lifetime $(2\Gamma)^{-1}$, and then decay more slowly from $r \sim 0.4$ with dynamics that resemble Förster kinetics in the weak-coupling limit.

It appears that the stochastic Liouville equations for N-chromophore systems ($N > 2$) are not simple extensions of the homodimer master equations (Kenkre, 1982). However, the prediction of *initial* anisotropies $r(0)$ does not require knowledge of the time-dependent density matrix, but may be obtained directly from initial conditions similar to those used in Eqs. (53–56). For example, each protein subunit in an FMO trimer from the BChl *a* baseplate antennae in green sulfur bacteria contains 7 BChl *a* chromophores. Each of the 7 monomer exciton

components becomes split into three sublevels in the trimer: a nondegenerate level polarized parallel to the threefold axis, and a doubly degenerate, mutually perpendicular pair polarized in the plane of the trimer. The Einstein absorption coefficients B_{\perp} of the two degenerate transitions are equal, while the relative magnitude B_{\parallel} of the third Einstein coefficient depends on the projection of the unsplit monomer exciton component's transition moment on the threefold axis. Uniform excitation of these three FMO trimer exciton components alone would then lead to the initial anisotropy function

$$r(0) = \frac{7 + 2x^2 + 6x}{10 + 5x^2} \quad (60)$$

where $x = B_{\parallel}/B_{\perp}$ is the ratio of parallel to perpendicular absorption coefficients. In the limit where $x \rightarrow 0$ (uniform excitation of two equally intense, mutually perpendicular transitions), $r(0) \rightarrow 0.7$. In the limit where $x \rightarrow$ large (absorption dominated by a single linearly polarized transition), $r(0) \rightarrow 0.4$. In the special case where $x = 1$ (uniform excitation of three equally intense, mutually perpendicular transitions), $r(0) = 1.0$. In the latter case, the total weighted transition moment for exciton components excited by the laser is exactly parallel to the laser polarization—with the result that the perpendicular fluorescence component $I_{\perp}(0)$ vanishes and $r(0)$ becomes unity. Hence, these three limiting cases illustrate examples of linear, planar, and spherical oscillators, respectively. In a recent pump-probe study of FMO trimers from the green sulfur bacterium *Chlorobium tepidum* (Savikhin et al., 1993), initial anisotropies $r(0)$ in excess of 0.4 were found at 796 and 821 nm. These decayed to ≤ 0.4 within ~ 100 fs. A subsequent, slower anisotropy decay occurred at both wavelengths, with lifetime 1.7–2.0 ps. These fast component decays are consistent with spectral hole-burning experiments on FMO trimers from *Prosthecochloris aestuarii* (Johnson and Small, 1991), in which the level widths of the higher-lying Q_y exciton components corresponded to a timescale of 100 fs for relaxation between exciton components. The slower (~ 2 ps) components are similar to Q_y pump-probe anisotropy decays observed under lower time resolution by Lyle and Struve (1991). Anisotropies $r(0) \sim 0.7$ have recently been observed in magnesium tetraphenylporphyrin (Galli et al., 1993). In this case, the prototype homodimer model of Rahman et al. (1979) is germane, because the two ‘chromo-

phores’ are provided by the components of a doubly degenerate excited state (in effect, an intramolecular version of the intermolecular excited state dynamics treated by Rahman et al.).

IV. Temperature Dependence of Energy Transfer

In the context of the first-order Golden Rule treatment of dipole-dipole and exchange energy transfer in the weak coupling limit, their thermal effects originate from temperature changes in the spectral overlap integral. Hence, temperature modeling of Förster rate constants has been focused on simulating the temperature dependence in pigment absorption and fluorescence spectra. Such temperature dependence is caused by electron-phonon and electron-vibrational interactions, arising from differences between nuclear mode equilibrium geometries and frequencies in the pigment's electronic ground and excited states. For definiteness, we consider a particular harmonic vibrational mode of frequency ω_s . Its coordinate equilibrium position is shifted by Δ , and its vibrational frequency changes by $\Delta\omega_s$ from ω_s to ω_s' , when a ground-state chromophore is promoted to the electronic excited state. In the special case where Δ and $\Delta\omega_s$ both vanish (zero electron-vibration coupling), the vibrational quantum number obeys the strict selection rule $\Delta v = v' - v'' = 0$ in dipole-allowed electronic transitions (Birks, 1970; Struve, 1989). All vibrational bands in the electronic spectrum then occur at the same wavelength irrespective of temperature T , and this mode contributes no T dependence to the electronic absorption spectrum. A nonzero shift Δ in equilibrium geometry exerts two major effects on the absorption spectrum. It leads to a series of nonzero Franck-Condon factors (which are proportional to vibrational band intensities) over a *progression* of wavelengths, corresponding to different vibrational state changes Δv in the electronic band spectrum. It also causes *hot bands* to appear at wavelengths longer than that of the vibrationless electronic transition. The hot band intensities are weighted by the initial thermal vibrational level populations in the electronic ground state. Similar effects arise when the ground and excited state vibrational frequencies are unequal.

A commonly used measure of electron-vibration (or electron-phonon) coupling strength is the dimensionless Huang-Rhys parameter S . If the

ground and excited state vibrational Hamiltonians are given by

$$\begin{aligned} H_g &= \frac{-\hbar^2}{2\mu} \frac{\partial^2}{\partial Q^2} + \frac{1}{2} \mu \omega_s^2 Q^2 \\ H_e &= \frac{-\hbar^2}{2\mu} \frac{\partial^2}{\partial Q^2} + \frac{1}{2} \mu (\omega_s')^2 (Q - \Delta)^2 \end{aligned} \quad (61)$$

the Huang-Rhys parameter is defined by

$$S = \frac{\frac{1}{2} \mu \omega_s'^2 \Delta^2}{\hbar \omega_s} = \frac{1}{2} \frac{\mu \omega_s'}{\hbar} \Delta^2 \quad (62)$$

The temperature-dependent single-site absorption profile for an electronic transition in which the electron-vibration (or electron-phonon) coupling is strongly dominated by a *single* mode of frequency ω_s is (Harris, Mathies, and Pollard, 1986)

$$\begin{aligned} \alpha(\omega) &= 2e^{-S \coth(\omega_s/2kT)} \cdot \\ &\int_0^\infty e^{-\gamma t/2} e^{S \coth(\omega_s/kT) \cos \omega_s t} \cos(\omega t - S \sin \omega_s t) dt \end{aligned} \quad (63)$$

Here γ is the Lorentzian broadening parameter, equal to the sum of the inverse excited state radiative and nonradiative lifetimes. This model does not consider vibrational frequency shifts $\Delta\omega_s$. The behavior of this function is illustrated at several temperatures in Fig. 1 for $S = 0.2$ and $S = 0.8$. The profiles for $S = 0.8$ exhibit the longer Franck-Condon progressions of vibrational bands, in consequence of the larger equilibrium geometry shift Δ . The relative intensities of the hot bands (which occur at lower frequencies than the 0-0 band) increase with temperature, to an extent that correlates with the magnitude of the Huang-Rhys parameter. The linewidths of the individual vibrational bands are proportional to γ . Hence, Eq. (63) concisely expresses the Franck-Condon sequence of vibrational band intensities for electronic transitions between displaced harmonic oscillators, with hot band intensities weighted by appropriate Boltzmann factors.

Realistic simulations of pigment absorption profiles require simultaneous treatment of all Franck-Condon active phonons and vibrational modes. Spectral broadening due to site inhomogeneity must also be taken into account. In a spectral hole-burning study of the antenna Chl *a* Q_y spectrum in

PSI-200 particles from spinach, Gillie et al. (1989) measured the frequencies, Huang-Rhys factors, and frequency shifts for some 41 Chl *a* vibrations. The ground state frequencies of these intramolecular modes are distributed from 262 to 1524 cm^{-1} , and exhibit small S (≤ 0.044) along with fractional frequency shifts of $\leq 3\%$. A highly Franck-Condon active phonon mode ($\omega_s = 22 \text{ cm}^{-1}$) was characterized with $S = 0.8$, arising from a large pigment-protein interaction. Hence, this phonon mode is expected to dominate the temperature dependence in the Chl *a* Q_y absorption spectrum. Jia et al. (1992) incorporated these data in a simulation of the Chl *a* temperature-dependent absorption spectrum in a full 42-mode quantum-mechanical calculation, using

$$\alpha(\omega) = \int_{-\infty}^{+\infty} e^{-\gamma t} e^{-\Gamma t^2} \langle e^{iH_e t} e^{-iH_g t} \rangle e^{-i\omega t} dt \quad (64)$$

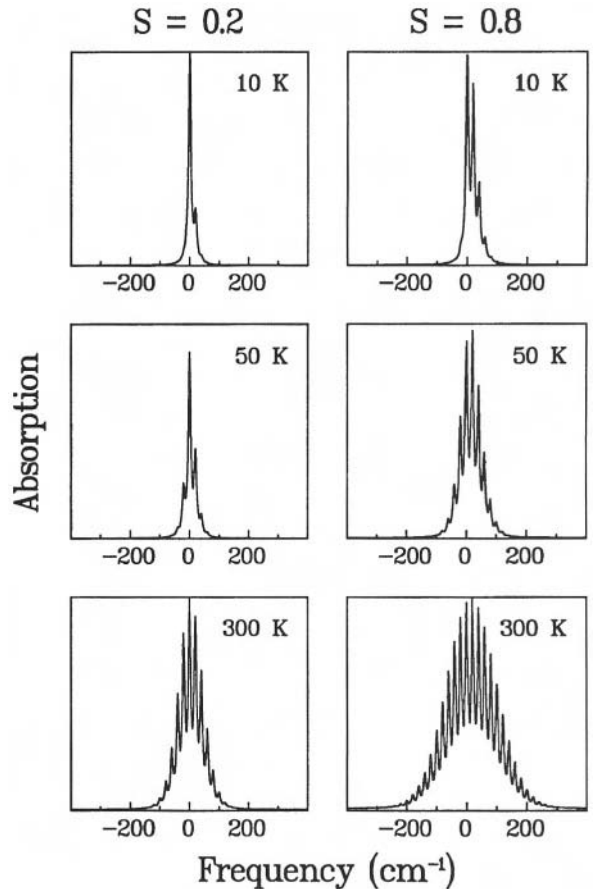

Fig. 1. Single-site absorption spectra calculated using Eq. (63) at several temperatures for a molecule with one Franck-Condon active mode of frequency 20 cm^{-1} : (a) $S = 0.2$; (b) $S = 0.8$.

Here the vibrational Hamiltonians H_e and H_g are 42-mode generalizations of Eqs. (61), and the brackets $\langle \rangle$ represent a thermal average over the phonon and vibrational levels in the ground electronic state. This integrand includes a Gaussian factor that simulates 200 cm^{-1} inhomogeneous broadening (Hayes et al., 1988). Aside from the presence of Gaussian broadening, this expression coincides with Eq. (63) in the limit where only one mode is Franck-Condon active and exhibits no frequency shift. The fluorescence spectrum required in the calculation of the Förster transition rate (cf. Eqs. 20, 21) was derived from the mirror image of the absorption spectrum (Birks, 1970), a procedure that is valid when the Franck-Condon active modes do not exhibit large frequency shifts. In view of the 200 cm^{-1} inhomogeneous broadening, the total Chl *a* absorption band fwhm in this simulation increases only by a factor of ~ 2 (from ~ 200 to $\sim 450 \text{ cm}^{-1}$) when the temperature is raised from 0 to 300 K.

An alternative formulation of the single-site absorption profile for a Franck-Condon active phonon mode at low temperature (Personov, 1983; Hayes et al., 1988) is

$$\alpha_p(\omega) = e^{-S} l_0(\omega) + \sum_{r=1}^{\infty} \frac{S^r e^{-S}}{r!} l_r(\omega - r\omega_s) \quad (65)$$

where the values of r correspond to zero-, one-, etc., phonon transitions. The r -phonon absorption profile $l_r(\omega)$ is obtained by convoluting the one-phonon profile with itself ($r - 1$) times. The coefficient $S^r \exp(-S)/r!$ is the Franck-Condon factor for the r -phonon band, which is centered at frequency $r\omega_s$. If N vibrational modes are incorporated with Huang-Rhys factors S_v and frequencies ω_v , the low-temperature single-site absorption profile becomes

$$\alpha(\omega) = \sum_{v=1}^N \sum_{t=0}^{\infty} \frac{S_v^t e^{-S_v}}{t!} \alpha_p(\omega - t\omega_v) \quad (66)$$

which is a superimposition of phonon profiles centered at the t -vibration transition frequencies $t\omega_v$ and weighted by vibrational Franck-Condon factors. At finite temperatures, hot band terms must be included with appropriate thermal and Franck-Condon weights; the Huang-Rhys factors S are superseded everywhere by a temperature-dependent parameter $S(T)$. Using a suitable choice (Hayes et

al., 1988) for the zero-phonon profile $l_0(\omega)$, T-dependent single-site absorption spectra are readily calculated. Examples of single-site Chl *a* absorption spectra evaluated using Eq. (66) are shown in Fig. 2. These must be convoluted with a site distribution function to simulate inhomogeneous broadening.

Jia et al. raised the issue of whether the site inhomogeneities of the donor and acceptor pigments (modeled using a 200 cm^{-1} Gaussian distribution) are truly uncorrelated as assumed in their model. In the absence of such correlation, the energy transfer rates are comparatively insensitive to temperature between 0 and 300 K, because the total Q_y absorption linewidth only increases by a factor of ~ 2 . However,

Fig. 2. Simulations of Chl *a* single-site absorption spectra using Eq. (66). Frequencies and Huang-Rhys factors for phonon and vibrational modes are from spectral hole-burning work of Gillie et al. (1989). Temperature are (in order of increasing fwhm) 10, 100, and 300 K.

it is possible *a priori* that some degree of correlation exists between the site inhomogeneities of donor and acceptor pigments, in such a way that the donor-acceptor energy gap ϵ exhibits a significantly narrower site distribution function than that of the empirical donor fluorescence or acceptor absorption spectrum. Such a situation would produce much stronger variation of energy transfer rates in this temperature range. Experimental temperature dependence studies of single-step energy transfer kinetics are expected to shed light on this question in the near future.

Acknowledgments

The author has benefited greatly from extensive conversations and correspondence with Drs. Robert Knox and Herbert van Amerongen. I am indebted to Dr. Tonu Pullerits for the computer algorithm and program used to calculate the spectra in Fig. 2. The Ames Laboratory is operated by Iowa State University for the U.S. Department of Energy under Contract No. W-7405-Eng-82. This work was supported by the Division of Chemical Sciences, Office of Basic Energy Sciences.

Summary

This chapter presents a comprehensive overview of what is currently known about the structure of purple bacterial antenna complexes, with special emphasis upon modeling their three-dimensional structure and intramembrane organization.

Purple bacterial antenna complexes can be grouped into two major types, the 'core' B875-type which forms a close association with the reaction centers and the 'variable' B800-850- or B800-820-type. Both these types of complex are constructed on a similar modular principle and are oligomers of α and β -apoproteins. These antenna apoproteins have been sequenced from a range of species and form a rather homologous group of proteins. The light-absorbing pigments, BChl and carotenoids, are non-covalently bound to these apoproteins.

As is described below, in a few cases these antenna complexes have been crystallized and structure determinations are under way. However, in the absence of three-dimensional structural information a great deal can be deduced by a comparison of their primary structures. The main part of this chapter illustrates the type of models for antenna structure that can be constructed by a detailed analysis of the conserved structural elements which can be seen by such an examination of the database of antenna apoprotein primary structures.

I. Structure and Function of Antenna Complexes from Purple Bacteria

A. The Purple Bacterial Photosynthetic Unit

The major light-absorbing pigments in purple bacteria are the bacteriochlorophylls (*a* and *b*) and the carotenoids. These pigments are non-covalently attached to two types of integral membrane proteins forming on the one hand the photochemical reaction centers and on the other the light-harvesting or antenna complexes (Hawthornthwaite and Cogdell, 1991; Zuber and Brunisholz, 1991). The majority of these pigments perform a light-harvesting role and serve to funnel absorbed solar radiation to a specialized few which form the reaction center. The combination of antenna complexes with a reaction center constitutes the photosynthetic unit (PSU). For

most commonly studied purple bacteria the size of the PSU is variable. Usually, however, it is in the range of between 20 and 200 BChl *a* molecules per reaction center (Aagaard and Sistrom, 1972). This arrangement of reaction centers surrounded by an antenna system ensures that each reaction center is kept well supplied with incoming solar energy and effectively increases their cross-sectional area for photon capture. The detailed structure and function of the reaction center is described in section V of this volume. The rest of this contribution will concentrate upon the antenna complexes.

B. Intracytoplasmic Membranes

In the purple bacteria the PSU is located in the intracytoplasmic membranes. Most species can survive either by respiration or photosynthesis. In the presence of oxygen, the cells tend to be unpigmented and have a smooth cell membrane. When they become anaerobic, they switch photosynthetic mode and the photosynthetic apparatus develops de novo. During this changeover, the cells

Abbreviations: *Cm.* – *Chromatium*; *Ec.* – *Ectothiorhodospira*; LDAO – lauryl dimethylamine-N-oxide; PSU – Photosynthetic unit; *Rb.* – *Rhodobacter*; *Rc* – *Rhodocyclus*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*

become highly pigmented and the cell membrane invaginates to form an extensive system of intracytoplasmic membranes. All of the newly synthesized components of the light-reaction of photosynthesis are 'housed' in and on these membranes.

The structure of these membranes varies. In some species they are present as lamellar structures, others as tubular structures and still others as vesicular invaginations (Trüper and Pfennig, 1981). What regulates which membrane shape develops is entirely unclear. Interestingly, some mutants of *Rhodobacter (Rb.) sphaeroides* which lack carotenoids and the peripheral antenna complex (B800–850) show intracytoplasmic membranes with an altered morphology. The reason for this pleotropic effect is a mystery but does show that an analysis of mutants may provide a way of unraveling this problem of the control of membrane shape. The internal architecture of the intracytoplasmic membranes is one of the major taxonomic characteristics that has been used in the recent reclassification of the purple bacteria (Imhoff et al., 1984; Trüper and Pfennig, 1981).

C. Isolation and Characterization of Antenna complexes

When BChl *a* is dissolved in an organic solvent such as 7:2 v/v acetone:methanol its near IR absorption band is at 772 nm. This is typical of monomeric BChl *a*. However, when it is non-covalently bound into a light-harvesting complex its NIR absorption band is red shifted to between 800 and 900 nm depending upon the type of complex. For BChl *b* this red shift is even larger with the in vivo NIR absorption peak in *Rhodospirillum (Rs.) rubrum*, for example, located at 1012 nm (Hawthornthwaite and Cogdell, 1991). In most species this red shift is also associated with an increase in spectral complexity, with several peaks/shoulders clearly visible in the absorption spectrum. This red-shift arises from pigment-protein and pigment-pigment interactions within the native antenna complexes and is routinely used as a way of identifying them and judging their integrity.

Some species of purple bacteria, such as *Rhodospirillum (Rs.) rubrum* and *Rp. viridis*, only have a single strong NIR absorption band, corresponding to a single antenna type (B880 or B1012 respectively) (Hawthornthwaite and Cogdell, 1991; Zuber and Brunisholz, 1991). Others, such as *Rb. sphaeroides* or *Rb. capsulatus*, contain two types of

antenna complexes (B875 which is equivalent to the B880 from *Rs. rubrum*, and B800–850). Still others, such as *Rp. acidophila* and *Rp. cryptolactis*, contain additional antenna types, for example, the B800–820 complexes. At first glance this may seem a very confusing situation, however it is now possible to draw a simplified picture which clarifies this situation.

In purple bacteria there are two major types of antenna complex (Hawthornthwaite and Cogdell, 1991; Zuber and Brunisholz, 1991). The first type is the B880 from *Rs. rubrum* or the B875 from *Rb. sphaeroides*. This forms the so-called 'core' complex and all wild-type purple bacteria contain it. The 'core' complex is closely associated with the reaction center and forms a stoichiometric complex with it (e.g. there are 24 molecules of BChl *a* per reaction center, in an intact RC-'core' antenna supramolecular complex, see Section V.C.2). In some species such as *Rp. viridis* or *Rs. marina* this supramolecular complex has been visualized by electron microscopy (Stark et al., 1984; Meckenstock et al., 1992). The antenna component forms a doughnut-like structure around the reaction center (Fig. 16). All other antenna types, such as B800–850, B800–880, B830, etc., form the so-called variable or peripheral antenna complexes. This heterogeneous class of complexes, as their names suggest, are located further away from the reaction centers than the 'core' complexes and are present in variable amounts with respect to the number of reaction centers present. The amount present depends upon a variety of environmental factors such as light-intensity, temperature, carbon source, etc.

Isolation of a purple bacterial antenna complex, since they are integral membrane proteins, begins with the solubilisation of the photosynthetic membrane with a suitable detergent (Cogdell and Hawthornthwaite, 1993). Then the individual complexes are purified from the solubilized mixture by standard methods of protein purification. The choice of the detergent is very important. It must be 'strong' enough to solubilize the antenna complexes yet 'mild' enough not to denature them. In most cases we have found that the detergent lauryl dimethylamine-N-oxide (LDAO) is the most suitable and it is also very cheap! LDAO also has the advantage that if you need the complex in a different detergent for subsequent studies then it is easily exchanged for other detergents both by dialysis and on small ion exchange columns.

We have found that for most purple bacteria the easiest procedure to purify the antenna complexes is

to initially fractionate them by sucrose gradient centrifugation. This conveniently separates them into RC-B875 and B800–850 or B800–820 complexes. They can then be further purified by DE cellulose anion exchange chromatography and molecular sieve chromatography. The integrity of the isolated antenna complexes can be easily assessed from their absorption spectra (as described above) and indeed by eye.

All of the purple antenna complexes are built upon the same modular principle (Papiz et al., 1989). The pigments are non-covalently bound to two low molecular weight (typically 5–7Kd) very hydrophobic apoproteins. These are called the α - and β -apoproteins (or polypeptides) and they aggregate to produce the native pigmented antenna complexes (see Sections V.A–D).

D. Approaches to Determine the Structure of Antenna Complexes

For most proteins with molecular masses of 20 kD and above, determination of their 3D structure requires the production of highly ordered crystals, either 2D or 3D, which can then be subjected to analysis by electron or X-ray crystallography. The antenna complexes are no exception to this, they are just difficult to crystallize since they are membrane proteins.

Several RC-B880 complexes have been crystallized as 2D arrays (Meckenstock et al., 1994; Ghosh et al., 1993). Indeed, in some cases, such as *Rp. viridis*, they naturally occur in 2D-arrays within the photosynthetic membrane, and these have been subjected to high-resolution EM and image analysis to generate low resolution ($\sim 20\text{\AA}$) maps of their structure. In recent years bacteriorhodopsin (Henderson and Unwin, 1975) and now the major Chl *a/b* protein from peas (Kühlbrandt, 1984) have been very successfully studied by an electron diffraction of 2D arrays. The methodology for this type of crystallographic analysis is now well developed, and indeed may be more generally applicable for membrane proteins than X-ray diffraction of 3D-crystals.

Table 1 lists the purple bacterial antenna complexes which have been crystallized 2D arrays. These are now actively being studied and improved, and it is hoped that they will go on to yield high-resolution structural information.

Several B800–850 complexes have been crystallized as large, single 3-D crystals (Table 2). Two in particular, the B800–850 complexes from *Rp. acidophila* strain 10050 (Papiz et al., 1989) and from *Rs. molischianum* (Michel, 1990) have been shown to diffract X-rays to high resolution. In both cases heavy atom searches have begun and it is hoped that these will soon yield the phase information needed to solve their structures. However, initial analyses of the native data sets, together with molecular weight analysis and electron microscopy, has revealed that these two complexes have different oligomeric states. The *Rp. acidophila* complex is an $\alpha_6\beta_6$ oligomer (Papiz et al., 1989) while the *Rs. molischianum* complex appears to be $\alpha_8\beta_8$ (Kleinekofort et al., 1993; Germeroth et al., 1993). It is most likely that the fundamental building block is an $\alpha_2\beta_2$ tetramer which repeats three times in *Rp. acidophila* and four times in *Rs. molischianum*.

E. Modeling the Structure of the B800–850 Complex from *Rp. acidophila* Strain 10050 Based upon Native Crystallographic Diffraction Data.

In the absence of suitable heavy atom derivatives that would allow the phases to be solved and therefore the three-dimensional structure of this antenna complex to be determined, some structural information can be obtained from the native crystallographic data. It must be emphasized, though, that this is just modelling and must be treated with caution. Figure 1 shows a slice through Patterson space calculated from the full native data set to a resolution of 3.2\AA . The section depicted is through the *a*, *b* plane. Very simply, this type of calculation takes each atom in turn, puts it at the origin of the projection, and calculates the vector between it and every other atom in the molecule. Clearly, regular structures will build up density in this type of calculation. As is described below (see section 3b) it is thought that 40–50% of the antenna apoproteins are folded up as an α -helix. The pattern seen in Fig. 1 can be interpreted by considering what type of α helical packing might be present in the complex. The density at the origin goes up and down and 'c' axis (that is at right-angles to the projection) for 22–23 \AA . If we assume that this density comes from the α -helices, then they must be lined up in the crystal almost parallel to the 'c' axis and be 44–46 \AA in length. Clearly, this is an oversimplification but it

Table 1. 2D crystals of B880 antenna complexes

Fig. 1. Section through Patterson space in the *a*, *b* plane calculated on the native diffraction data set of the B800–850 antenna complex from *Rp. acidophila* strain 10050 to a resolution of 3.2 Å. We thank Dr M. Z. Papiz for the Patterson calculations.

does allow an interesting, testable model to be developed. The rings of density progressing outwards from the origin at 10.5Å, 14.2Å and 24Å can be explained by reference to Fig. 2. If two *a*-helical rods lie next to and parallel to each other, then the distance between the center of gravity of one and the center of gravity of the other will be 10.5Å. If four parallel *a*-helical rods are arranged in a square, then the distance across the diagonal, from the center of gravity of one helix to the center of gravity of the next is 14.2Å. At

24Å in the space group R32 six peaks would be expected from the crystallographic symmetry. However, 18 peaks are seen. Hence there must be an additional non-crystallographic three-fold axis of symmetry. All these features can be accounted for by assuming that the intact antenna complex contains three bundles of four *a*-helices arranged as in Fig. 2. It will be interesting to see when the structure of this antenna complex is finally determined how accurate this model is.

Fig. 2. A model for the arrangements of the α -helices based on the Patterson calculation shown in Fig. 1. (A) 10.5 Å, distance between helices, (B) 14.2 Å, diagonal packing distances, (C) 24 Å, distance between the bundles of four helices.

II. Structure and Function of Antenna Polypeptides from Purple Bacteria. General Aspects

The antenna systems of all photosynthetic organisms surround the reaction center and form a multi-molecular unit which functions as a regulated, energy-uptake and energy-transfer system. The physical requirements of the energy transfer processes within the antenna system and to the reaction center result in the structure and organization of antenna complexes and their various pigment molecules displaying a set of general features, which may be outlined as follows (Zuber, 1987, 1993; Zuber et al., 1987; Zuber and Brunisholz, 1991):

- In the antenna system pigment molecules are highly ordered and form pigment clusters of a given size and symmetry.
- Pigment clusters in the antenna complexes are the basic units of the directed, heterogeneous transfer of energy within and between the antenna complexes (hierarchy of pigment organization).
- Directed energy transfer to the reaction center is influenced and regulated by the spatial separation of the pigment clusters (minimizing random walk).

Important to the formation of the energy transfer system of organized pigment molecules in pigment-protein complexes are specific, structural and functional interactions, that is pigment-pigment, pigment-polypeptide and polypeptide-polypeptide. Here the lipid environment of antenna complexes in the photosynthetic membrane also plays a decisive role. The structure and function of antenna polypeptides and their corresponding hierarchical organization is of fundamental importance for the organization of pigment molecules. The polypeptides form the main basis of the spectral and energy-transfer characteristics of the pigments. A large body of structural data shows that:

- Pigment molecules are bound specifically to polypeptides and form defined antenna complexes. They determine the position, distance, orientation and environment of the pigment molecules. That is their essential function.
- Polypeptides have specific association characteristics in forming oligomeric or multimeric units (pigment-protein complexes), i.e. antenna complexes (including subcomplexes) and the entire antenna system. Antenna polypeptides associate in an hierarchical order: a) formation of microdomains (subcomplexes of 2–4 polypeptides), b) formation of antenna complexes with larger pigment clusters through association of microdomains, c) formation of the entire antenna system through the association of antenna complexes.

These structural principles of pigment and polypeptide organization are particularly recognizable in the relatively simple antenna systems of purple bacteria. (See also the reviews: Thornber et al., 1983; Cogdell and Valentine, 1983; Drews, 1985; Zuber 1985a,b; Cogdell, 1986; Thornber, 1986; Zuber, 1987, 1993; Zuber et al., 1987; Zuber and Brunisholz, 1991). Characteristic of these and indicating the structural principles are: 1.) the existence of two main types of pigment-protein complexes, the core complex B870/B890 (BChl *a*), or B1020 (BChl *b*) in proximity to the reaction center, and the peripheral complex B800–850 (800–820) (see Section I this chapter) and, 2.) the existence of two main populations of BChl molecules in antenna complexes, one group having absorption bands between 820 and 860 nm (peripheral complex), or 870–1020 nm (core

complex), and a second group having absorption bands at 800 nm (peripheral complex only) (Thorner et al., 1983). Both structural/functional features come to fruition in the three-dimensional structure of the entire antenna system, that is, in the efficient transfer of energy to the reaction center. As the three-dimensional structures of polypeptides are based upon their primary structure (amino acid sequence), the primary structure of these polypeptides already contains the information which determines the structure and organization of the antenna complexes and the arrangement of the pigments in the entire antenna system.

III. Amino Acid Sequences (Primary Structure) of Antenna Polypeptides. Sequence Homologies, Structural and Functional Features

A. Isolation and Sequence Analysis of Antenna Polypeptides

In order to solubilize and isolate membrane polypeptides from the photosynthetic membrane (chromatophores) or from isolated antenna complexes, organic solvents such as chloroform (or methylene chloride)-methanol (ratio 1:1) have been used (Tonn et al., 1977). This solvent mixture plus 0.1 M ammonium acetate (with (5–10%) and without acetic acid) proved especially useful in solubilization and fractionation (gel filtration and ion exchange chromatography by stepwise elution with acetic acid) of the antenna polypeptides in purple bacteria (Brunisholz et al., 1981; Brunisholz et al., 1984a; Brunisholz et al., 1985; Theiler et al., 1984). More recently the use of reverse phase chromatography (matrix: octyl-silica or butyl-silica, solvent 50–85% acetonitrile) has proved to be very quick and effective and is now the method of choice for separating large numbers of various types of antenna polypeptides (6 and more) which are formed in some species of purple bacteria (Brunisholz and Zuber, 1987).

Although today DNA sequencing is frequently the method of choice for determining the primary structure of polypeptides (for example for the of antenna polypeptides (see Chapter 22 by Hunter), protein sequencing is also necessary in order to obtain a full understanding of the structure and function of antenna polypeptides for the following reasons:

- Identification of the sites of processing of the antenna polypeptides, e.g. sites of posttranslational cleavage of the polypeptide or modification of amino acid side chains
- Assignment of individual antenna polypeptides to particular antenna complexes
- Determination of the stoichiometry of antenna polypeptides in the antenna complex
- Determination of the position and orientation of antenna polypeptides in the photosynthetic membrane by means of enzymatic cleavage and chemical labeling
- Analysis of the relation of structure to spectral characteristics by use of chemical labels and limited proteolytic hydrolysis
- Crosslinking of antenna polypeptides

B. Comparison of Primary Structures (Amino Acid Sequences) of Antenna Polypeptides in Purple Bacteria: Derivation of Important, General Structural Elements

During the course of the past ten years, the primary structures of a great number of antenna polypeptides, both of the B870/B890 core complexes and of the peripheral B800–850 (820) complexes, were determined (Zuber and Brunisholz, 1991) (Figs. 3, 4). It was found that all antenna complexes are composed of α and β polypeptides which are of approximately the same size (40–70 amino acid residues) and which have homologous amino acid sequences (Zuber, 1985, a, b; 1987). They do differ, however, in their characteristic structural features. The polarity (Capaldi and Vaanderkooi, 1972) of these membrane polypeptides lies at 23–37%. The low degree of sequence homology, or distant phylogenetic relation, between the α and β polypeptides of about 5% is an indication of an early evolutionary separation of these polypeptides (Fig. 5A). On the other hand, a sequence homology of 13–28% between the α or β polypeptides of the core and peripheral complexes shows them to be definitely related phylogenetically (evolution of the entire antenna). Species differences of antenna polypeptides of the core and peripheral antenna complexes in

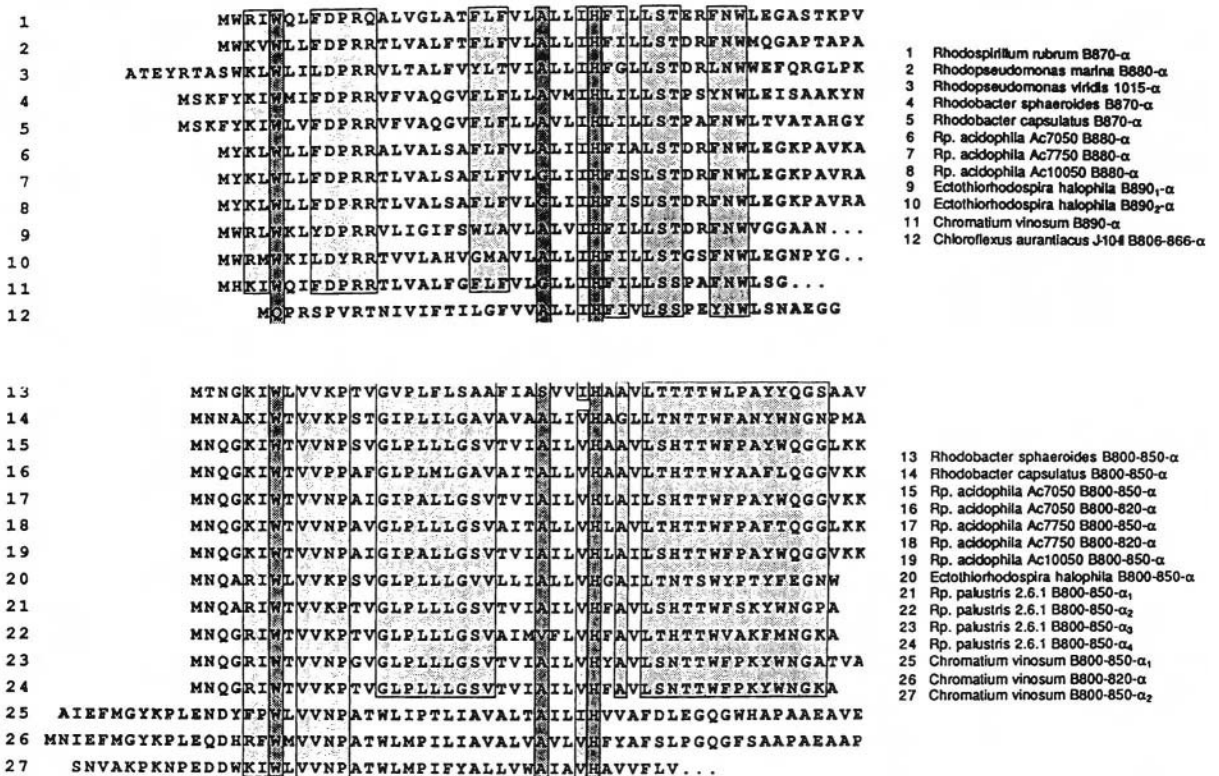

Fig. 3. Amino acid sequences of the α -antenna polypeptides of the core (1–12) and peripheral (13–27) antenna complexes of purple bacteria. Sequence homologous amino acid residues or complex specific clusters of amino acid residues with pronounced homology are shaded.

various purple bacteria mean that the degree of homologies lie between 28 and 78%. The characteristic structural features of the amino acid sequences in the antenna polypeptides are both conserved single amino acid residues and clusters of conserved amino acid residues. These are characteristic both of the α and β polypeptides and of the B870/B890 and B800–850 (820) complexes, which indicates that they play a special structural and functional role (Figs. 3, 4 and 5B). Especially striking is the large number of basic amino acid residues (Arg, Lys) in the N-terminal region of the α polypeptide chain and acidic amino acid residues (Glu, Asp) in the N-terminal region of the β polypeptide chain. A specific, electrostatic interaction of the α and β polypeptide chains in this region (ion pairs) therefore seems likely. Perhaps, however, the most important structural characteristic common to all antenna polypeptides in purple bacteria is their three-domain structure, which is found in both the linear amino acid sequence and in their three-dimensional structure (Brunisholz et al., 1984a; Zuber, 1985, a, b). We can distinguish between the

N-terminal, polar domain (α polypeptide chain: core and peripheral antennae 12–14 residues; β polypeptide chain: core antenna complex: 17–25 residues, peripheral antenna complex: 13–23 residues), the polar C-terminal domain (α polypeptide chain, core and peripheral antenna complexes: 16–20 residues, β polypeptide chain, core and peripheral antenna complexes: 5 residues, with the exception of e.g. *Rs. rubrum*, *Rp. viridis*, *Rp. acidophila*: 11/12 residues) and a central, hydrophobic domain (21–23 residues). The two polar domains lie on the surface or in the polar head region of the membrane. The primary structure in the N-terminal domain suggests that there is an amphipathic helix parallel to the membrane plane (Theiler and Zuber, 1984). The long C-terminal domain of the α polypeptide chain, especially in the case of *Rhodocyclus (Rc.) gelatinosus* (36 residues, oligo-Ala segments), has a particular sequence which indicates that this may represent a second domain spanning the membrane (Zuber and Brunisholz, 1991). In the center of the sequence of the antenna polypeptides lies the hydrophobic domain which

spans the membrane as an α helix (tilted α helix: average 30–35°) (IR (UV), CD spectra, labeling experiments) (Jay et al., 1983; Breton and Nabdryk, 1984). Proteolytic digestion and labeling experiments applied to the B870 core complex of *Rs. rubrum* showed the orientation of the antenna polypeptides (α helix) in the membrane, i.e. the location of the N-terminal domain of the α and β polypeptides at the cytoplasmic side (proteinase K, trypsin, chymotrypsin) (Wiemken et al., 1983; Brunisholz et al. 1984a, 1986). Similarly, the N-terminal regions of the L and M polypeptides of the reaction center were also localized at the cytoplasmic side. The structural role of hydrophobic or hydrophilic amino acid residues, particularly with respect to the assembly of the antenna polypeptides and the formation of the antenna complexes in the membrane, was analyzed by mutagenesis of the α and β -polypeptides (Richter et al., 1992). Redox-controlled in-vivo and in-vitro phosphorylation of the α -polypeptides of the core complex (*Rb. sphaeroides*) was found, which indicates a membrane-bound protein kinase (Cortez et al., 1992).

C. Relationship Between the Data on the Primary Structure of Antenna Polypeptides and the Function (Spectral Characteristics) of the Antenna Complexes

The three-domain structure of the antenna polypeptides also provides the framework for considering possible structural-spectral (functional) relationships, i.e. the binding, organization and environment of the BChl molecules in the three-dimensional structure of the transmembrane helix. The most conserved amino acid residue of the α and β polypeptides from the core, as well as from peripheral antenna complexes, is a His residue. This central His residue is 4 (α) or 6 (β) amino acid residues (1–2, α -helix turns) from the boundary between the hydrophobic domain and the polar C-terminal domain which extends towards the periplasmic side. This conserved His most probably forms the central binding site for BChl (central BChl), and is especially important in the energy transfer within and between the antenna complexes and to the reaction center (absorption maximum 850, 820 or 1020 nm) (Brunisholz et al.,

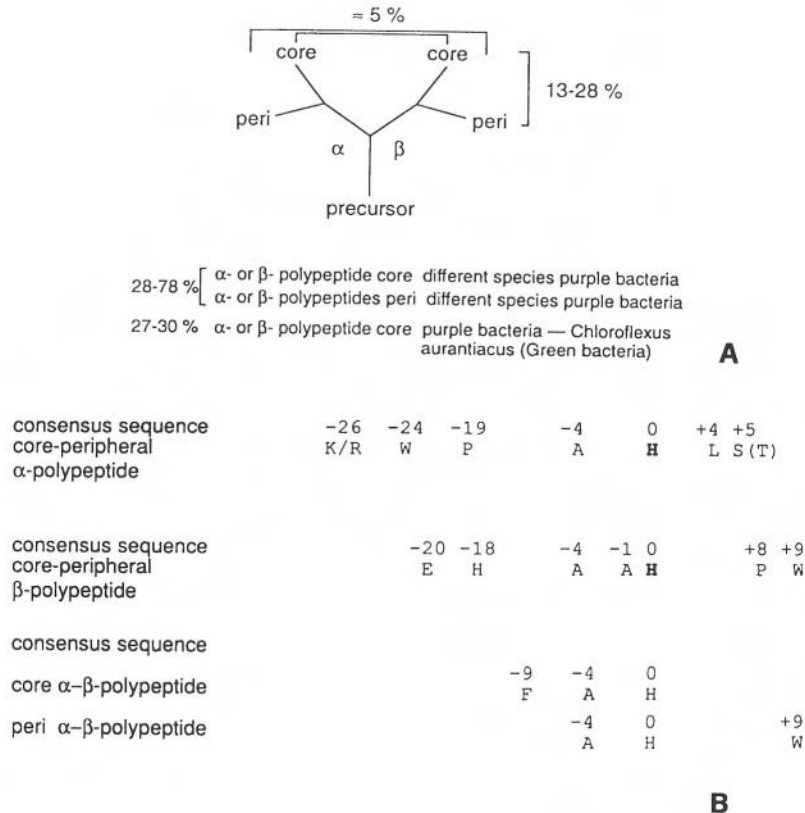

Fig. 5. A: possible phylogenetic relationship (% sequence homology) of α - and β -antenna polypeptides of purple bacteria. B: consensus sequences of the α - or β -polypeptides between the core- and peripheral antenna complexes and between the α - and β -polypeptides of the core or peripheral antenna complexes.

1981, 1984a; Theiler et al., 1984). This was confirmed by resonance-Raman spectroscopy (Robert and Lutz, 1985) and mutagenesis experiments (Bylina et al., 1986). A second, usually conserved His residue in the β chain near the N-terminal domain has been suggested to be the binding site for monomeric BChl (absorption maximum: 800 nm) (Zuber, 1985b, 1987). On the other hand, this conserved His residue is also found in the β chain of the B870/B890 antenna complexes, even though this additional BChl is absent in this core complex. Interestingly, as well resonance-Raman studies also did not find that the BChl (800 nm)-absorbing in the peripheral antenna complexes (Robert and Lutz, 1985) had an imidazole ligand. In *Rc. gelatinosus*, (B800–850, β -polypeptide), His is replaced by Gln, which could also, in principle, bind BChl (Zuber and Brunisholz, 1991). In the β chain of core antenna complex B806–866 in the green photosynthetic bacterium *Chloroflexus aurantiacus* (related phylogenetically to purple bacteria), the second conserved His residue was also

found, and the BChl bound by this His could be responsible for the absorption maximum of 806 nm (coplanar orientation of the BChl with respect to the membrane) (Wechsler et al., 1985, 1987).

The folding of the α helices, the relative organization of α and β polypeptides (heterodimers) and the order of the diverse side chains of amino acid residues in the linear polypeptide sequence create a particular micro-environment for the His residues, or BChl molecules respectively, which by means of pigment-polypeptide interactions determines the function of the BChl molecules (spectral characteristics, energy transfer). Of special interest are the conserved amino acid residues found at a certain distance from the His residues in the amino acid sequence, that is, in relation to the folded polypeptide chain of the α helix (Figs. 3, 4). These may form secondary binding sites for the of BChl molecules and could also control the specific orientation of the tetrapyrrole ring. Amino acid residues around the central His, His-4 (Ala, α and β polypeptide chains,

small hydrophobic residue) and His +4 (Leu, α polypeptide chain) seem to be of special importance here (Theiler and Zuber, 1984). The spectral characteristics of the BChl molecules bound to the central His residue are also influenced by: 1.) the totality of hydrophobic amino acid residues (Ala, Val, Ile, Leu, Phe) in the region of His ± 4 and 2.) the conserved aromatic amino acid residues (Tyr, Trp) (Brunisholz et al., 1984a): at a distance from the central His residue of His +4, +6 and +9 in the β chain of the core complex B870/B890, or His +9 in the β chain of the peripheral complex B800–850 (820) and in the α polypeptide chain of His +11 of the core complex B870/B890 and of His +9 and +14 of the peripheral complex B800–850. In the case of Trp (His +14) of the peripheral antenna complex in *Rp. acidophila* (strain 7050,7750), it was postulated that the substitution of Trp by Leu or Thr was the origin of the spectral shift of the 850 nm band of B800–850 to the 820 nm band of B800–820 (Brunisholz et al., 1984, a; Brunisholz and Zuber, 1992). This postulated functional role of aromatic amino acid residues was then demonstrated by means of site-directed mutagenesis of the B870 complex in *Rb. capsulatus* (Babst et al., 1991), through substitution of Trp (His +11, position 43) by Ala, Leu, Tyr (blue shift 8–11 nm) and the peripheral B800–850 complex in *Rb. sphaeroides* (Fowler et al., 1992) through substitution of Trp (His +13) and (His +14) by Phe, or Phe, Leu (double mutant, blue shift 11 and 24 nm, respectively). Interestingly, there is a Trp residue in the α polypeptide of the extremely long-wave length absorbing core complex B1015 of *Rp. viridis* at position His +12 (next to Trp His +11) (Brunisholz et al., 1985). This aromatic amino acid residue, and possibly the aromatic amino acid residue (Tyr) in this region in the γ polypeptide (see 3. e.), cause this large red shift. Strong (NIR)-CD signals were reported on the core antenna complexes from *Rs. rubrum*, *Rp. viridis* and *Rp. acidophila*. (biphasic, with zero crosspoint at 880 nm) (Fig. 6). In contrast, CD signals of the core complex from *Rb. sphaeroides*, *Rb. capsulatus* and *Rc. gelatinosus* are much weaker. It was suggested that these spectral differences are determined by the greater length of C-terminal domains of the β polypeptide chains and the existence of Trp, or Tyr residues, in this lengthened polypeptide chain area in *Rs. rubrum*, *Rp. viridis* and *Rp. acidophila*. (Zuber and Brunisholz, 1991). In addition, there is in the α polypeptide chain of the core complex from the first group of organisms (above) a Phe

residue in place of Leu at position His +1.

A surprising finding was made with regard to the functional role of aromatic amino acid residues when comparing the aromatic clusters of the antenna polypeptides (α , β , core antenna) with those in the L and M polypeptides of the photosynthetic reaction center (*Rp. viridis*) (that is close to the central His residues of the α , β -antenna polypeptides, or the His residues of the special pair of the L and M subunits (D helix)) (Brunisholz and Zuber, 1988, a, b). The BChl molecules, bound by His residues of both 'special pairs', show similar absorption characteristics. Proteolytic cleavage experiments (*Rs. rubrum*) showed that the N terminus of the antenna polypeptides and the L and M polypeptides of the reaction center lies on the cytoplasmic side. However, due to the identical position of the two 'special pairs' towards the periplasm and because of the differing number of transmembrane helices (the antenna polypeptides (α , β) have one helix each, the reaction center polypeptides 4 helices up to helix D), the amino acid sequences of the α and β antenna polypeptides and the D helices in the membrane of the reaction center must run antiparallel (N \rightarrow C and C \rightarrow N, respectively, Fig. 7B). A comparison of these sequences, taking account of the fact that they are antiparallel, showed an interesting structural similarity with regard to the arrangement of clusters of aromatic amino acid residues in proximity to both 'special pairs'. 8 of 11 aromatic amino acid residues in the special pair binding pocket of the reaction center are in the same position in the core antenna complex (Fig. 7A). This finding may represent a phylogenetic relationship of a primordial reaction center and the antenna system (Fig. 7B). The third polypeptide component of the B1015 complex, the γ polypeptide from *Rp. viridis*, also has these aromatic amino acid residues, which may also be close to the BChl pair and indicate that this polypeptide plays a role in terms of the large red shift of this complex. These findings indicate analogous functional roles of the aromatic amino acid residues in both of the complexes of the cooperative antenna-reaction center conjugate. An ever increasing amount of data is now being accumulated which demonstrates that the aromatic amino acid residues interact functionally with BChl molecules. A future task will be to visualize this structural situation in the three-dimensional structure of antenna complexes as well, and to understand the theoretical basis of the spectroscopic consequences of these interactions.

D. Studies on the Influence of the Environment of the BChl Molecules on their Spectral Properties: Limited Proteolysis of Isolated Peripheral Antenna Complexes

In addition to mutagenesis experiments modifying the α and β polypeptide chains of antenna complexes (see Chapter 22 by Hunter), limited proteolysis of these polypeptides in the antenna complex is a method well suited to studying the influence of the polypeptide environment on the spectral properties. Especially promising is hydrolytic cleavage of the polypeptide chain with enzymes at the C-terminus near the central BChl molecules (Brunisholz and Zuber, 1993). When the B802–858 (B800–850) complex from *Rp. acidophila* (10050) is detergent solubilized (LDAO) it is relatively stable. Such a preparation was treated with elastase and carboxypeptidase A and B, and spectral changes were analyzed in relation to the changes in amino acid sequence of the antenna polypeptides. Use of elastase resulted in a strongly decreased 858 nm absorption and a small blue shift (856 nm). This enzyme cleaved the α polypeptide

chain at the C-terminus, removing the amino acid residues Lys-Ala-Ala, and the β polypeptide chain, removing Leu-His or Trp-Leu-His. Carboxypeptidase A treatment shifted the absorption maximum from 858 nm to 853 nm, and this was connected with a strong decrease in 858 nm absorption and in the (NIR)-CD signal. In this proteolytic cleavage in the α polypeptide chain Lys-Ala-Ala and in the β polypeptide chain Trp-Leu-His are split off at the C-terminus. Limited proteolysis using carboxypeptidase A plus B resulted in a further blue shift to 837 nm of the absorption maximum and CD signal and to a further hypochromic shift (extinction coefficient of about 50 to 60%) of the 800 nm absorption. The increased spectral changes result from a further cleavage of the α polypeptide chain up to the region of Trp His +14. These findings also show the important contribution of the aromatic Trp residue to spectral characteristics of BChl (absorption, extinction and CD signal).

E. Antenna Polypeptides of Core Antenna Complexes Binding BChl b

The core antenna complexes of photosynthetic bacteria containing BChl b, e.g. *Rp. viridis*, *Ectothiorhodospira (Ec.) halochloris*, show unusual functional and structural features: 1.) an extreme red shift to 1015 – 1020 nm of the absorption maximum and 2.) a marked formation of regular 2D arrays of antenna complexes in the membrane which are clearly visible in the electron microscope (Engelhardt et al., 1983; Stark et al. 1984). These features must be due to the special structure of the antenna polypeptides. The primary structures of the α and β antenna polypeptides, which are very similar to analogous antenna polypeptides of the other purple bacteria, have additional aromatic amino acid residues at two important positions of the α and β polypeptide chains: in the α polypeptide chain Trp (His +12) and Tyr (His-9) and in the β polypeptide chain Tyr (His +1) and Tyr (His-8) (Figs. 3, 4). These may be the origin of the large red shift. But of very special significance, both structurally and functionally, is the presence of the additional γ polypeptides (Brunisholz et al, 1985; Brunisholz and Zuber, 1992). These were isolated, characterized and in part sequenced from *Rp. viridis*, *Ec. halochloris* and *Ec. abdelmalekii* (Fig. 8A.) The γ polypeptides and the α and β polypeptides are present in the B1015 complex of *Rp. viridis* in a ratio of 1:1:1. Two

are clearly closely related and show common structural features. Of great importance here is a special sequence-homologous region in the C-terminus with its structurally important Gly, Pro and the aliphatic amino acid residues (Ile, Leu), or Arg, Trp and Tyr residues. These C-terminal, aromatic amino acid residues appear to be of particular functional significance. Crucial to understanding the structural/functional role of these conserved amino acid residues is the position and orientation of γ polypeptides in the membrane and their interaction with the α and β polypeptides. It has been found that the orientation of the N-terminal region of the γ polypeptide from *Rp. viridis* is towards the cytoplasm (unpublished results). As a consequence, hydrophobic γ polypeptides most probably form a transmembrane helix reaching to the periplasmic side of the membrane. The role of the γ polypeptide could be, on the one hand, that of a linker polypeptide, which together with the BChl *b*-carrying α and β polypeptides forms the core complex. The particular structure of the BChl *b*-containing core complexes

on the membrane surface could reflect this possibility. On the other hand, the specific position of the Trp and Tyr residues at the C-terminus could, when we consider the length of the γ polypeptides (36 or 29 amino acid residues), allow interactions of these aromatic amino acid residues with Trp residues in the C-terminal domains of the α and β polypeptide chains (α : Trp His+11 and +12, and β : Trp His+4 and +9). This type of interaction could increase the functional coupling of these residues with BChl *b*- and therefore be responsible for the large red shift.

IV. Structural and Functional Variability of the Antenna Polypeptides and Pigments within the Antenna Complex

A. Variability of the BChl-Binding Sites

It was observed in some cases that BChl-binding sites of the α and β polypeptide chains vary, both in regard to type (nucleophilic amino acid side chain)

and to position. In the β polypeptide chain of the core antenna complex from *Ec. halochloris*, the central His residues is replaced by Asn (BChl b-binding site) (Wagner-Huber et al., 1988). In the β polypeptide chain of the peripheral antenna complex from *Rc. gelatinosus* (DSM 149, 151), the second His (near the cytoplasm) is substituted by Gln (Zuber and Brunisholz, 1991). In peripheral antenna complexes B800–850 of Type II from *Cm. vinosum*, *Rp. acidophila* and *Rp. palustris*, the absorption band at 800 nm is spectrally dominant (extinction, specific (IR)-CD signal) compared to absorption at 850 nm or 820 nm. The structural basis of this spectral characteristic is as yet unknown—possible alternative BChl interactions (dimeric BChl molecule) are currently being considered (Zuber and Brunisholz, 1991).

B. Variability and Multiplicity of Antenna Polypeptides. Role of the Binding Site B800

1. Core Antenna Complexes

Members of the family of Ectothiorhodospiraceae, moderately to extremely halophilic purple photosynthetic bacteria, show in their antenna systems characteristic, and quite different, spectral features compared to those seen in the Rhodospirillaceae. These must also be due to the variation in the types and organization of their antenna complexes. *Ec. halophila*, for example, is characterized by NIR absorption bands of 800, 850 and 890 nm, with the 890 nm as the dominant band (Leguijt and Hellingwerf, 1991). On the other hand, the BChl *b*-containing antenna system from *Ec. halochloris* and *Ec. abdelmalekii* has, in addition to a typical absorption maximum of 1020 nm, further absorption maxima at 800 nm and 830 nm (and a very weak one at 880 nm) (Steiner and Scheer, 1985).

How can these spectral characteristics be explained by the organization and structure of these antenna complexes, and in particular, the structure of the antenna polypeptides. In the case of *Ec. halochloris*, it was possible to isolate a fraction of antenna complexes having absorption maxima at 800 nm, 850 nm and 1020 nm (Steiner and Scheer, 1985). This fraction contains, according to its (NIR)-CD signals, at least 5 strongly interacting BChl *b*-molecules. Especially characteristic of this antenna system is the strong biphasic CD-signal with a zero crosspoint at around 800 nm (which interestingly is

also typical of the peripheral antenna complex in *Chromatium (Cm.) vinosum* (Hayashi et al., 1981)). Five polypeptides having the apparent molecular weight of 4.5, 6.0, 6.5, 15.5 and 35 kDa were identified by means of SDS-PAGE (Steiner and Scheer, 1985). As yet it has not been possible to dissociate these antenna complexes into subfractions, that is, into discrete antenna complexes with absorption maxima at 800 nm plus 830 nm and 1020 nm. In spite of this, attempts have been made to analyze the structure of diverse antenna polypeptides present, because such analysis might be expected to yield insight into the nature of these antenna complexes (Wagner-Huber et al., 1988, 1992). Using organic solvent extraction and subsequent molecular sieve and reversed phase chromatography, 2α , 2β antenna polypeptide types and a fifth, very small polypeptide were isolated from the membrane of *Ec. halochloris*. From *Ec. halophila* it was possible to isolate 3 α and 2 β antenna polypeptide types. Here, for the first time in a core antenna complex, a multiplicity of α and β antenna polypeptides was found. A marked degree of multiplicity of antenna polypeptides was also found in peripheral antenna complexes of *Cm. vinosum* (Bissig, 1989). Primary structure analysis of these *Ectothiorhodospira* polypeptides again revealed the characteristic three-domain structure which is so diagnostic of antenna polypeptides as found in the Rhodospirillaceae. The α and β polypeptides could not, unfortunately, be ascribed directly to core or peripheral antenna complexes, as these polypeptides could only be obtained from the photosynthetic membrane and not from isolated antenna complexes. However, comparison of the primary structures of diverse antenna polypeptides from *Ec. halochloris* and *Ec. halophila* did allow, upon the basis of their structural characteristics, their possible assignment to core or peripheral antenna complexes. The two types of α -polypeptides (N-terminal sequence MWR, MWK (*Ec. halochloris*) or MWRL, MWRM (*Ec. halophila*), and β -polypeptides (N-terminal sequence AND, TDI (*Ec. halochloris*) or ADEM, ADNM (*Ec. halophila*) exhibited a pronounced sequence homology to diverse antenna polypeptides of the core complexes from Rhodospirillaceae (Wagner-Huber et al., 1992). Only the α polypeptide with the N-terminal sequence MNQA (*Ec. halophila*) was clearly related to the antenna polypeptides of 'classical', peripheral complexes. But why then are there two types of α and β antenna polypeptides (α , β) types in the core complex? The proportion of α to

β antenna polypeptides, isolated from the membrane, is 1:1:1:1. On the basis of the possible structure of the core antenna complex, analogous to Rhodospirillaceae, for which a cyclical arrangement of 6 tetrameric units ($\alpha_2\beta_2$) was postulated (see V.C.), there are three possible arrangements of the α_1 and α_2 , or β_1 and β_2 antenna polypeptides, respectively:

- There are two different core antenna complexes, each having 6 $\alpha_1\beta_1$ tetramers, or $\alpha_2\beta_2$ tetramers, respectively.
- There is only one core antenna complex, having mixed α_1/α_2 , or β_1/β_2 polypeptide units ($\alpha_1\alpha_2/\beta_1\beta_2$).
- There is only one core antenna complex, for example ($\alpha_1\alpha_1$)₂, whereby the α_2 and β_2 polypeptides surrounding the core complex form the peripheral antenna complexes. It is also conceivable here that the α_1 or β_1 and α_2 or β_2 antenna polypeptides could form both the core and also the peripheral antenna complex. This would lead, in principle, to antenna complexes with mixed polypeptide units, within the entire antenna system.

The existence of an α polypeptide with the characteristic structural elements of the peripheral antenna complex in *Ec. halophila* indicates the existence of peripheral antenna complexes, possibly having absorption maxima from 800–850 nm. This does not, however, rule out the possibility that a part of the α_1 -(α_2 -), or β_1 -(β_2 -) antenna polypeptides also form peripheral antenna complexes (see above) and are located between the actual core complex B890 and the B800–850 antenna complex (heterogeneous energy transfer system).

2. Peripheral Antenna Complexes

In contrast to the classic Rhodospirillaceae (for example *Rs. rubrum*, *Rp. viridis*, *Rb. sphaeroides* and *Rb. capsulatus*) which have only one type of α and β antenna polypeptides (in a ratio of 1:1), some species of Rhodospirillaceae have peripheral antenna complexes with several types of α and β polypeptides which differ in their amino acid sequence (Zuber and Brunisholz, 1991) (Fig.3, 4, Fig. 8B). The appearance of differing types of antenna polypeptides is often

accompanied by variability in spectral characteristics, whereby the proportion of the different polypeptide types or the spectral characteristics of the antenna complexes can be changed (or regulated) through the environmental factors of light and temperature. In this sense, the diversity of antenna polypeptides is possibly of functional significance with regard to the regulatory adaptation of antenna complexes to the variable conditions of the environment. The various types of α and β polypeptides still, however, possess the characteristic features of α and β polypeptides (which allow the α or β type classification). This allows the suggestion that even given the diversity of these polypeptides the α and β polypeptides form the basis of α/β heterodimers, just as is the case in the antenna complexes of classic Rhodospirillaceae with only one type of α or β polypeptide. However, the question remains open here (as in the core complexes as well) as to whether the individual types of α or β polypeptides build specific antenna complexes or hybrid antenna complexes with differing types of α and β polypeptides. The diversity of antenna polypeptides is based on the diversity of genes (gene families) (Tadros and Waterkamp, 1989). This corresponds to the situation with other peripheral antenna complexes, for example LHC II in algae and in higher plants, e.g. Dunsmuir et al., 1983. In all these cases it is difficult, however, to clearly recognize or experimentally demonstrate the functional-adaptive reason for the diversity of polypeptides, due to the fact that the diversity of genes in these organisms today could have other origins (e.g. evolutionary reasons.)

A definite relationship between the variable pattern of antenna polypeptides and variable spectral characteristics has been demonstrated, for example with the peripheral antenna complexes in *Rp. acidophila*. *Rp. acidophila* strain 7050 changes its NIR absorption maxima and its carotenoid composition depending upon the light intensity (Heinemeyer and Schmid, 1983; Cogdell et al., 1983). Under high light (2000 lux), the core antenna complex B880 and the peripheral antenna complex B800–850 (type 1) are synthesized. Under low light conditions (200 lux), 800 nm absorption is greatly decreased, and a blue shift of 850 to 825 takes place. Under low light the B800–850 complex is replaced by a B800–820 complex. Both antenna complexes have only 1 α and 1 β polypeptide. Primary structure analysis of the α and β polypeptides of the peripheral B800–850

complex (α : 53 residues, β : 48 residues) and of the B800–820 (825) complex (α : 53 residues, β : 42 residues) revealed in the C-terminal domain a substitution of Tyr⁴⁴ Trp⁴⁵ by Phe⁴⁴-Leu⁴⁵, which most probably causes the blue shift from 850 to 820 nm (Brunisholz et al., 1987; Bissig, 1989; Brunisholz and Zuber, 1988a; Zuber and Brunisholz, 1991). An analogous amino acid substitution (Tyr⁴⁴ Trp⁴⁵ to Phe⁴⁴ Thr⁴⁵) resulting in a blue shift of 850 to 820 nm (that is, the transition from B800–850 complex to B800–820 complex) was unexpectedly observed in *Rp. acidophila* strain 7750 when the growth temperature was changed from 30 °C to temperatures below 25 °C (optimum 22 °C). (Schmidt and Brunisholz, 1986). This temperature effect (towards lower temperatures) produces the B800–820 complex (arising from the B800–850 complex having 1 type each of α and β polypeptide chain), with two different β polypeptide types. A multiplicity of antenna polypeptides, e.g. in B800–850 3 α - and 3 β -polypeptides, was found in *Rp. acidophila* (strain 10050). *Rp. palustris* also synthesizes multiple forms of antenna complexes and antenna polypeptides (Brunisholz et al., 1989, 1990). Under high light conditions, a B800–850 complex (type 1) is formed in *Rp. palustris* (strain 'French') in accordance with the absorption maxima, as in classical Rhodospirillaceae. On the other hand, the 850 nm band decreases greatly under low light conditions. Both in the high and low light forms of the peripheral antenna complex, several types of α and β polypeptides are found (a total of 7 polypeptides: 4 α and 3 β polypeptides). The α polypeptide chains differ especially in the C-terminal domain, and the β polypeptide chains in the N-terminal domain, in a number of amino acid substitutions. At the genetic level as well, a diversity of genes were isolated and sequenced from *Rp. palustris* (four sets of α and β polypeptides) (Tadros and Waterkamp, 1989). Through comparison of the DNA sequences with the protein sequences derived by protein sequencing, it was shown that in the C-terminal domain, cleavage of the polypeptide chain occurs post-translationally. The situation in *Cm. vinosum* appears to be even more complex in terms of spectral features and patterns of antenna polypeptides. Five different absorption maxima of BChl were found in *Chromatium* chromatophores: 795 nm, 805 nm, 820 nm, 850 nm, (845 nm) and 890 nm (Thorner, 1970; Hayashi et al., 1981). Here also the spectral features are dependent upon light intensity

and temperature (30–40 °C) (Mechler and Oelze, 1978). In *Cm. vinosum*, at least 10 different antenna polypeptides are synthesized independently of culture conditions (Bissig, 1989; Bissig et al., 1989). The core complex B890 contains 3 polypeptides $\alpha/\beta_1/\beta_2$ in a ratio of 2:1:1. From the peripheral antenna complex 3 α polypeptides and 4 β polypeptides were isolated and sequenced. They show the typical three-domain structure of α and β polypeptides of the peripheral antenna complex. In addition, however, they also have characteristic structural elements that differentiate them from antenna polypeptides in Rhodospirillaceae; e.g., which are located in the elongated N-terminal domain of the α -polypeptides.

V. Possible Structural Organization of Polypeptides and BChl Molecules in the Antenna Complex Derived from Primary Structure Data (Primary Structure Models): Considerations on the Three-Dimensional Structure of Antenna Complexes

A. General Structural Features of the Antenna Polypeptides Important for the 3-D Structure of Antenna Complexes

The specific structural-functional features of antenna polypeptides derived from primary structure data must ultimately be the basis of the three-dimensional structure of the antenna complexes and, finally, of the entire antenna system of purple bacteria. The following characteristic structural features of antenna polypeptides indicate that there is a specific organization of the antenna polypeptides and BChl molecules in the 3-D structure (Zuber, 1987, 1993; Zuber et al., 1987; Zuber and Brunisholz, 1991):

- Two different types of polypeptides (α , β) bind functionally different α and β BChl molecules. These polypeptides or BChl pairs form, as heterodimers, the basic structural and functional unit of the antenna complexes and the entire antenna system.
- The α and β antenna polypeptides form a homologous family and are structurally closely related. However, they do show specific amino acid clusters which clearly separate them into core and peripheral antenna complexes. We can

therefore expect to find in the three-dimensional structure a similar arrangement of these polypeptides but having a complex-specific form.

- The three-dimensional structure of the α and β polypeptides makes it likely that the central, transmembrane α helix (length 31 or 34 Å, diameter approximately 10 Å) plays an important role in the organization of antenna polypeptides in the antenna system (Fig. 9). The α -helical structure of antenna polypeptides in antenna complexes was postulated on the basis of IR, UV and CD spectra (Breton and Nabdryk, 1984) and labeling experiments (Jay et al., 1983). IR dichroism studies also showed that the α helices are tilted (on the average, at 30 to 35° away from the membrane plane) (Breton, 1986). In the tilted α helices of the α - β polypeptide heterodimers, the central BChl molecules can lie quite close together (up to 10

–15 Å) and thus be exciton-coupled (Sauer and Austin, 1978). The arrangement of the tilted helices is the basis for the tilted helices model.

- The present status of crystallographic studies indicates that the α -helices of the α - and β -polypeptides are not tilted and form a four-helix bundle of parallel helices. (Basis of the four-helix bundle model, Cogdell and Hawthornthwaite, 1993; Donnelly and Cogdell, 1993).
- Proteolytic cleavage experiments (Brunisholz et al., 1984b) and labeling experiments (Wiemken et al., 1983; Peters and Drews, 1983a; Jay et al., 1983, 1984) yielded a vertical asymmetry of the α and β polypeptide chain, with the N-terminal domain on the cytoplasmic side and the C-terminal domain on the periplasmic side. Thus the central α - β -BChl pair also lies on the periplasmic side and forms a two-dimensional energy transfer system in

Fig. 9. Transmembrane orientation of the α - and β -antenna polypeptides (example *Rs. rubrum*). 3-domain structure with polar N- and C-terminal domain and a hydrophobic central domain (α -helix). PK, TR, CH and SA: splitting points with proteinase K, Trypsin, Chymotrypsin, staph. proteinase (see further text). Fig. from Zuber, 1987.

the environment of the special pair of the reaction center, which is also located on the periplasmic side.

B. Transmembrane Helices of the α - β Heterodimer Form the Minimal Structural Unit of the Antenna Complexes and the Entire Antenna System

Data from various sources (see below V.E) indicate that the relatively small antenna polypeptides form large polypeptide aggregates and are thus the fundamental building blocks from which the functional network of the BChl molecules is assembled. It is assumed that the specific interactions of the α helices of the α and β polypeptide chains, the packing of the helices in the lipid environment, and the specific BChl polypeptide and BChl-BChl interactions are the decisive factors in the formation of the polypeptide aggregates in the antenna (Zuber, 1987, 1993; Zuber and Brunisholz, 1991;). Complementary to this, the globular structures of the N and C terminal domains on the membrane surfaces form interaction sites within and between the antenna complexes.

1. Four Tilted Helices Model

With regard to the specific aggregation of the α helices, this model predicts that a crucial role is played by the specific interactions among the amino acid side chains on the surface of the helices, helically distributed in four rows along the axis of the transmembrane helices (Fig. 10A) (Zuber, 1987; Zuber and Brunisholz, 1991). These interactions make possible an optimal packing of the tilted helices, in the formation of both α - β heterodimers and larger polypeptide assemblies in the lipid environment. Here it is important that both (α - and β -) helices possess a transverse asymmetry with more polar amino acid residues on the N-terminal (cytoplasmic) side (Fig. 11C) and more hydrophobic amino acid residues including the central BChl binding site on the C-terminal (periplasmic) side (Fig. 11P) of the helices. This leads to structural (packing), as well as functional (energy transfer) asymmetry. Polar (charged) amino acid residues on the N-terminal side can form four possible regions of interaction (hydrogen bonds) between the α helices, which results in a defined orientation of the α helices both in the α -

Fig. 10. A: Helix pair (heterodimer) of the α - and β -polypeptides tightly packed and twisted by about 30–35 °C. Fig. from Zuber, 1987. B: Possible helix-helix interaction sites between the α - and β -polypeptides in the cyclic hexamer I_L, I_U, II_L, III_L or I_U, II_U, IV_L, IV_U: possible interaction sites at the periplasmic or cytoplasmic side, respectively. Fig. from Zuber and Brunisholz, 1991. C: Model of the possible cyclic hexamer $\alpha_6\beta_6$ with tilted α -helices. Figure from Zuber and Brunisholz, 1991.

β heterodimers and between the α - β heterodimers (Fig. 10B). Over this central helical region, the α and β polypeptides associate in an hierarchical order, leading to the formation of α - β heterodimers (interaction in region I_L, I_U) and the association of the heterodimers via regions II_L, II_U (β - α), III_L, III_U (α - α) and IV_L, IV_U (β - β) to cyclic arrays, e.g. cyclic hexamers (of heterodimers = 12 polypeptides) (Fig. 10B, C). Thus, through the tilt and the sidedness of the helices, a system of specific polypeptide interaction results, with polar (charged) and hydrophobic residues on the cytoplasmic side (upper (U) level) and hydrophobic residues and BChl-BChl interactions on the periplasmic side (lower (L) level).

2. The Use of Fourier Transform Methods to Predict the α -Helical Structure of Antenna Complexes. Four Helix Bundle Model

Recently Donnelly and Cogdell (1993) used a Fourier transform method to try and predict the conformation and orientation of the conserved transmembrane

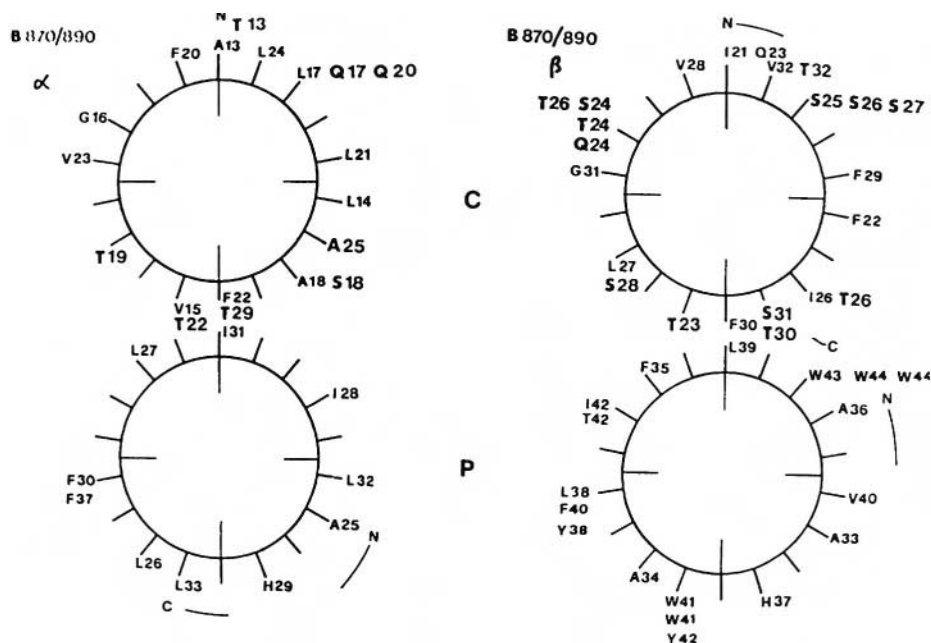

Fig. 11. Cross section of the α -helix of the α - and β -antenna polypeptides of B870/B890 at the cytoplasmic (C) and periplasmic (P) side. C: positions of the polar residues S, T, Q that form up to four specific helix-helix interaction sites. segments of the purple bacterial antenna complexes. Similar methods had been successful with bacterial reaction centers and bacteriorhodopsin (Donnelly and Cogdell, 1993) where the 'real' structures are known. The modelling was carried out on 60 antenna sequences, using primary structural information from both 'core' and 'peripheral' antenna complexes. As part of the modelling procedure the direction of the hydrophobic face of the helix was calculated with reference to the helical wheel. The data could be best reconciled by assuming a 4 helix bundle (see Fig. 12). Interestingly, the Fourier analysis suggested that the length of the helical rods was at least 30 residues, and that part way along the helix the hydrophobic face, which is to the outside, 'flips' and moves to the inside. This is just the sort of behavior that would be expected for a helix which extends from the hydrophobic regions of the membrane out into the polar head group region, and indeed into the aqueous phase.

C. Dimers of Heterodimers $\alpha_2\beta_2$: Basic Structural and Functional Units for Energy Transfer Within and Between the Cyclic Antenna Complexes

1. Cyclic Peripheral Antenna Complexes (Hexamers)

With regard to the four tilted heliced model with optimally packed and interacting peripheral antenna complexes (B800–850, B800–820) surrounding the core complexes with the reaction center, the smallest functional, active cyclical aggregate of α - β heterodimers appear to be the cyclical hexamers (Fig. 13). In the case of the peripheral complex B850–880 from *Rs. molischianum*, however, an octameric structure was postulated (Kleinekofort et al., 1992). In the case of cyclical hexamers not only are the α and β polypeptides packed into a cyclical system, but these cyclical hexamers are packed optimally in 'lakes' as well (Fig. 14). As a result of this, two types of BChl-BChl interactions are possible in the two-dimensional energy transfer system on the periplasmic side: (1) BChl α -BChl β interaction for cyclical energy transfer within the cyclical hexamers and (2) BChl β -BChl β interactions for the transfer of energy between the cyclical hexamers. Here BChl α -BChl β - as well as BChl β -BChl β - can be exciton-coupled. The important structural and

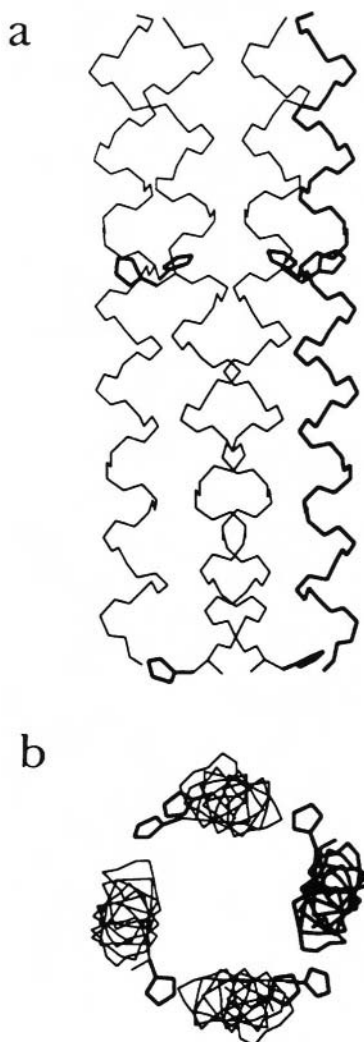

Fig. 12. A 3-D model of the $\alpha_2\beta_2$ tetrameric building block of a purple bacterial antenna complex viewed (a) from within and (b) perpendicular to the plane of the membrane. One of the α subunits and the conserved histidines is shown in bold.

functional units in the optimal packing of the hexamers are $\alpha_2\beta_2$ dimers of the heterodimer ($\alpha_2\beta_2$ units) (polypeptides, or BChl molecules) (Fig. 15). Through these $\alpha_2\beta_2$ units, the cyclical transfer of energy within hexamers is transformed to energy transfer between hexamers. With regard to the $\alpha_2\beta_2$ units, the cyclical hexamers show a three-fold symmetry. Two or three hexamers can be coupled through $\alpha_2\beta_2$ units (Fig. 15A, B).

With regard to the four helix bundle model see V.B.2 and Fig. 12.

2. Cyclic Core Antenna Complexes Close to the Reaction Center: Four Tilted Helices Model

The principle of a cyclical arrangement of the α - β heterodimers, or $\alpha_2\beta_2$ units, seems to apply not only to the peripheral complexes but also to the core complexes B870 or B890. Certain indications of this are also found in the primary structures of antenna polypeptides of peripheral and core complexes, which are sequence-homologous (structural basis for the formation of α - β -heterodimers or $\alpha_2\beta_2$ -units). On the other hand, complex-specific sequence differences may lead to the somewhat different arrangement of the $\alpha_2\beta_2$ units in the core complex surrounding the reaction center. For the various core complexes with BChl *a*, ratios of BChl to the reaction center were found of between 21:1 and 41:1 (Dawkins et al., 1988), while for the core complexes containing BChl *b*-, a ratio of 24:1 was postulated. Hypothetically, there are three possible reasons for this variability of the ratio of BChl to reaction center: (1) In the core reaction center complex the reaction center is unstable. Therefore, the ratio of BChl to the reaction center varies. (2) 24 polypeptides with 24 central BChls, bound to the central His, and a variable amount of BChls, bound to the β polypeptides, surround the reaction center (maximum 36 BChl). In the corresponding structure model (Fig. 16B), 2 hexamers (with 12 polypeptides each) would always be coupled over an $\alpha_2\beta_2$ unit (Fig. 15A). (3) 36 polypeptides with 36 central BChls, bound to the central His, surround the reaction center. The variability of BChls is caused by loss of BChl occurring during isolation or a lower BChl content of the core complex. In this structure model (Fig. 16A) 3 hexamers (with 12 polypeptides each) are coupled over 3 $\alpha_2\beta_2$ units, as in the peripheral antenna complex (Fig. 15B). This structure model (Fig. 16A) seems to be rather unlikely for BChl *a* containing core complexes. Recent electron microscopic studies indicate that in all core complexes investigated, only 24 polypeptides seem to exist (Cogdell, unpublished data). In the BChl *b*-containing complexes, however, with the additional γ polypeptide, 36 polypeptides have to be organized in the core complex (see below).

In the case of the core complex in *Rp. viridis* containing BChl *b*- with 24 BChl, circular structures having a diameter of 130 Å were found in the

Fig. 13. Model of the cyclical hexamer of the peripheral antenna complex B800-850 (B800-820). Fig. from Zuber, 1987.

Fig. 14. 'Lake' of cyclic hexamers (see Figs. 10 and 13) with six hexamers surrounding a central hexamer and densely packed by specific helix-helix interactions between the hexamers. Basis for the directed energy transfer within and between the hexamers. Circles: α -helices of the α - and β -polypeptides at the periplasmic level. Bars: BChl molecules. Fig. from Zuber and Brunisholz, 1991.

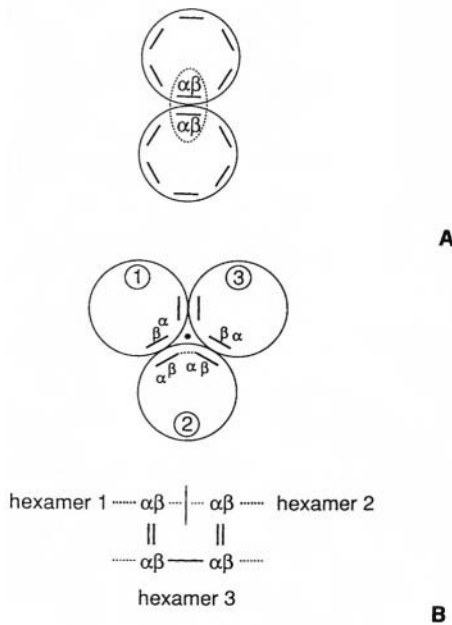

Fig. 15. A: Basic structural and functional units of $\alpha_2\beta_2$ (dimers of heterodimers) for energy transfer within and between the hexamers (two hexamers: structure model 1 (Fig. 16B) and three hexamers: structure model 2 (Fig. 16A)). B: Interaction unit between 3 hexamers via the $\alpha_2\beta_2$ unit.

photosynthetic membrane (chromatophores) with the electron microscope (Engelhardt et al., 1983; Stark et al., 1984; Jay et al., 1984; Stark et al., 1986) (Fig. 17). They appear to consist of a core region with a reaction center and a ring region (width 20 Å) of antenna complexes with 12 (Fig. 17A) or 6 (Fig. 17B) peripheral peaks. They may represent the 12 α - β heterodimers or the 6 $\alpha_2\beta_2$ units. The γ polypeptides without BChl, which exist in a ratio to the α (1) and β (1) polypeptides of 1:1:1, are not visible. There are two possible ways that the 6 $\alpha_2\beta_2$ units and the γ polypeptides (12 α , 12 β and 12 γ polypeptides) can be organized relative to the reaction center (Fig. 17):

- The $\alpha_2\beta_2$ units are organized as in the hexamer of the peripheral complex (Fig. 18 A, C; structure model Fig. 16A). Three hexamer units, including the γ polypeptides, surround the reaction center. Through this, six $\alpha_2\beta_2$ units surround the reaction center, and six γ polypeptides form a linker polypeptide complex. Interaction of the BChl of the antenna system with the special pair of the reaction center is possible.

Fig. 16. A: Cyclic arrangement of three-hexamer units surrounding a central reaction center. These three-hexamer units are also connected to 6/2 reaction centers at the periphery (photoreceptor complex). B: Cyclic arrangement of two-hexamer units surrounding a central reaction center. These two-hexamer units are also connected to 6/2 reaction centers at the periphery (photoreceptor unit). See further text.

- Six $\alpha_2\beta_2$ units, connected by two γ polypeptides each, surround the reaction center and have a different orientation compared to Fig. 18A. (Fig. 18B; structure model Fig. 16B). Through this, the β BChls of two $\alpha_2\beta_2$ units can interact between the core complexes. Interaction of BChl of the antenna complexes with the reaction center is more difficult due to the larger distance.

A B880 core complex containing BChl *a* was isolated from *Rp. marina* and characterized (molecular weight, α , β polypeptide ratio, BChl *a*: α or β polypeptide ratio) (Meckenstock et al., 1992a;

Fig. 17. Structure of the core complex surrounding the reaction center of *Rp. viridis*. Electron micrographs and Fourier processed images of tantalum/tungsten rotary shadowed, Triton X-100-treated membranes (Stark et al. 1984). A: Single membrane sheet with the plasmic surface upwards. B: Double membrane with the exoplasmic surface uppermost. Hexagonal lattice with a repeat distance of ~ 130 Å. The reaction center (diameter ~ 45 Å) is surrounded by 12 or 6 subunits on the plasmic or exoplasmic side, respectively. Scale of bar = 100 Å. Figure from Zuber, 1987.

see also Ghosh et al, 1993) (*Rs. rubrum*). The core complex consists of 24 polypeptides with 24 BChl *a* molecules, or of 6 B820 subcomplexes having 4 polypeptides each, or 4 BChl. Two-dimensional crystals reveal in the electron microscope a six-fold symmetry of the ringlike B880 complex (image processing, 20 Å resolution) (Meckenstock et al.,

1992b, 1994) (Fig. 19 A, B). They exhibit a hexagonal lattice with a lattice constant of 102 ± 3 Å. The $\alpha_2\beta_2$ units could be organized correspondingly to the structural model in Fig. 16B (6/3 hexamers = 24 polypeptides or 24 BChl) analogously, as in the core complex of *Rp. viridis*, which contains BChl *b* (Fig. 18B), but without connecting γ polypeptides, which would explain the smaller lattice constant of only 102 Å.

3. Cyclic Core Antenna Complexes Close to the Reaction Center: Four Helix Bundle Model

In this model the tetramer $\alpha_2\beta_2$ -unit should be organized similarly to the structure model in Fig. 16B for the BChl *a* containing core complexes. The bars in the cyclic hexamers (Fig. 16A, B, and Fig. 15 A) represent the external α - or β -BChl interacting with other antenna hexamers or the special pairs of the reaction center.

D. Possible Structural and Functional Organization of the Core and Peripheral Antenna Complexes in the Entire Antenna

Energy transfer to the reaction center depends on 1.) the state of the reaction centers (open and closed reaction centers) and, 2.) since the photochemical reaction is a rate limiting step, relative to the fast energy transfer processes within the antennae, on the ratio of the number of BChl *a* as final energy traps of the antenna to the special pair energy trap. Of particular importance in this respect are the structural (steric) conditions for the energy transfer from the core antenna to the special pair, which is particularly determined by the twofold symmetry of the special pair or the L and M subunits of the reaction center in relation to the six-fold symmetry of the surrounding core complex. Due to the non-central location of the special pair in the reaction center, six orientations of the special pair are possible within the cycle of the core complex (see Fig. 16).

In the case of the four tilted helices model the special pair could interact with an α - β heterodimer of the core complex in the form of an $\alpha_2\beta_2$ unit (hybrid between the α - β antenna special pair (heterodimer) and the special pair). A statistical distribution of the orientation of the special pair

Fig. 18. Possible arrangements of the antenna polypeptides of the core complex B1015 (eg. *Rp. viridis*) surrounding the reaction center. The helices represent the α -helices (three cross-sections per tilted helix) of the α -, β - and γ polypeptide. A: Possible basis for the formation of the $\alpha_2\beta_2$ -units that surround the reaction center: substitution of two $\alpha\beta$ -heterodimers by 2×2 γ polypeptides. B: Cyclic dodecamer ($\alpha_2\beta_2\gamma_2$) or ($\alpha_2\beta_2\gamma_2/6$) surrounds the reaction center. The six $\alpha_2\beta_2$ units associate primarily via the γ polypeptides and the β -BChl pair, or C: the γ polypeptides forming hexamers of linker polypeptides. Fig. from Zuber and Brunisholz, 1991.

would, in the cycle of the six α - β heterodimers of the core complex pointing to the reaction center, always result in such a single $\alpha_2\beta_2$ unit transferring energy from the antenna system to the reaction center (one nearest-neighbouring antenna lattice site; (Pearlstein, 1982,1992; Zhang et al., 1992). In the instance of the four helix bundle model this functional interaction would also take place via a BChl pair of the core complex and of the special pair.

The core-antenna complex forms in the entire antenna system large aggregates (photoreceptor units), in which, according to the structural model in Fig. 16B, 108 BChl ($12 \times 12 = 144 - 36$ BChl) interact and are in contact with the next photoreceptor unit and with 4 reaction centers ($1 + 6/2$). This situation is perhaps especially the case in the photosynthetic membrane of purple bacteria, which contain only the B880(890) or B1015 complex.

In the entire antenna system of purple bacteria with core and peripheral complexes, two different

arrangements of the peripheral antenna complex relative to the core complex and the reaction center are possible:

- The core antenna complexes and the peripheral antenna complexes are distinct entities. The peripheral antenna complexes surround the core complexes (Fig. 20). From the point of view of heterogeneous energy transfer, this arrangement should be favored above the mixed type below.
- An antenna system surrounds the reaction centers in which the core and peripheral antenna complexes are mixed.
- The entire antenna system may be made up of 10–20 photoreceptor units of the core complex with 40–80 reaction centers and > 1000–2000 BChl (see below, 0.5–1.0 μ diameter). Light intensity, or spectral conditions, determine the

Fig. 19. A: Electron micrograph of a two dimensional crystal of the B880 core complex of *Rp. marina* negatively stained with Uranyl acetate. Image processing and six fold symmetrization of image. Each B880 core complex is shown as a hexagonal ring consisting of 6 subunits. B: Electron micrograph of a two dimensional crystal. Image processing and six fold symmetrization of image of a frozen hydrated preparation. The six subunits are further divided into two identical, minor subunits, possibly $\alpha_2\beta_2$ -units. Fig. from Meckenstock et al., 1994.

size of the entire antenna and the ratio of core : peripheral antennae (up to 1:3) (Aagaard and Sistrom, 1972).

E. Comparison of the Structural Models of the Core and Peripheral Antenna Complexes with Experimental Data

The antenna models above should satisfy the following biochemical data:

- Composition and size of the isolated pigment-protein complexes, BChl content, α polypeptide:

β polypeptide ratio, BChl : antenna polypeptides ratio, BChl (antenna polypeptide): reaction center ratio (Cogdell and Valentine, 1983; Drews, 1985; Kaplan and Arntzen, 1982; Zuber, 1985a, 1987; Zuber et al., 1987; Zuber and Brunisholz, 1991; Barber, 1987; Miller et al. 1987; Ghosh et al., 1988). There is, however, disagreement with respect to the mol. weight of the B820 subunit ($\alpha\beta$ heterodimer or $\alpha_2\beta_2$ unit) (Ghosh et al., 1988; Meckenstock et al., 1992a; Jirsakova et al., 1992).

- Crosslinking experiments establishing lateral topology. In *Rb. capsulatus* (B800–850) and

Fig. 20. Possible arrangement of the peripheral antenna complexes surrounding the reaction centers (RC). Core and peripheral antenna complexes are separated. Peripheral antenna complexes (cyclic hexamers): shaded circles.

Rp. viridis (B1015), heterooligomers (α - β) and homooligomers (α - α , β - β) as crosslinking products have been identified (Peters et al., 1983, 1984; Peters and Drews, 1983b; Ludwig and Jay, 1985). In *Rb. capsulatus*, in addition to crosslinking between the α - α and β - β polypeptides of the B870 core complex, a crosslinking product between the α polypeptide of the B800–850 complex and the H subunit of the reaction center has been found (Peters et al., 1983).

- Dissociation and reassociation experiments with antenna complexes and antenna polypeptides, including the isolation and characterization of antenna subcomplexes (Miller et al., 1987; Ghosh et al., 1988; Parkes-Loach et al., 1988, 1990; Heller and Loach, 1990; Berger et al., 1992; Visschers et al., 1992).
- The structural model must also be in agreement with the following spectroscopic data (Bolt and Sauer, 1978; Sauer and Austin, 1978; Breton et al., 1981; Kramer et al., 1984; Breton and Nabedryk, 1984):
- UV, CD and IR data which show the trans-

membrane orientation. The four tilted helices model agrees with experimental data which shows a tilt of the α -helices, but the four helix bundle model does not.

- Strong CD signals suggest exciton interaction between pairs of BChl molecules.
- Linear dichroism data demonstrate that BChl Q_y transitions (850 nm) are approximately parallel to the membrane plane.
- Q_x transitions (590 nm) of BChl *a* are approximately perpendicular to the membrane plane.
- The orientations of the Q_y and Q_x transitions suggest that the porphyrin rings of BChl *a* 850 are approximately perpendicular to the membrane plane.
- On the other hand, the Q_y and Q_x transitions of BChl *a* 800 lie approximately in the plane of the membrane.

The structural models of the B800–850 complex, therefore, fit in principle (and particularly in the instance of the four helix bundle model) with a model of a minimal functional unit of the B800–850 complex of four antenna polypeptides ($\alpha_2\beta_2$) with four BChl 850, two BChl 800, established on the basis of spectroscopic data and the size of antenna polypeptides and the ratio of BChl: carotenoid: polypeptide (Kramer et al., 1984).

Fluorescence kinetic measurements (picosecond time-domain in coherent singlet excitation and trapping kinetics transfer) in the core complex of *Rs. rubrum* also suggest aggregates of four BChls, which could correspond to the $\alpha_2\beta_2$ minimal functional unit (Pullerits and Freiberg, 1992).

In contrast, on the basis of fluorescence polarization measurements and low temperature absorption spectroscopy of a subunit (B820) of the core complex and of the entire core complex of various purple bacteria, it was postulated that the B820 subunit is a dimer of interacting BChl (exciton coupling) (Visschers et al. 1991, 1993; Van Mourik et al., 1991; see also chapter by Loach and Parkes-Loach).

The structural models are also consistent with data on the size of functional domains, i.e. the cluster of connected BChl among which the excitations can be

freely transferred. With the singlet-singlet annihilation method (Van Grondelle et al., 1983; Kramer et al., 1984; Van Grondelle, 1985; Vos et al., 1986; Deinum et al., 1991) using chromatophores or isolated antenna complexes, it has been found that, e.g. at 4K, B870 (*Rb. sphaeroides*, *Rs. rubrum*) consists of clusters of 100–150 functionally connected BChl, and the peripheral B800–850 of clusters of 30 BChl 850. At 298K, energy transfer takes place within these complexes in larger lakes of >1000 BChl 870 or > 365 BChl 850, respectively. The low-temperature form of the functional domain having approximately 100 BChl would correspond to the photoreceptor unit of the core complex of the structural models above, and the 298K form would correspond to the size of the entire antenna of the structure model with at least 10 photoreceptor units (10×100 BChl = 1000 BChl). In this connection there is a finding of great importance: in two-dimensional crystals of the core antenna complex in *Rp. marina*, the giant CD spectrum, which shows a large aggregate of BChl, appears in two-dimensional crystals of a size of 0.5–1 μ . (Meckenstock et al., 1994). This would be in agreement with the structural model with an aggregate of approximately 10 photoreceptor units. Interestingly, the size of these aggregates lies within the region of the wavelength of the absorption maximum of these complexes (880 nm)—possibly an important fact with regard to the theoretical basis of the functional state of the entire antenna during energy transfer, or of the giant CD spectra.

Finally, the data from X-ray structural analyses of antenna complexes (see Fig. 1.) and from electron microscopy (see above) should be congruous with the antenna model described above.

The structure model of the core complex B820 with six α - β heterodimers derived from spectroscopic measurements does not fit the data of electron microscopy since for sterical reasons six α - β heterodimers are too small to form a core complex with the diameter of 103 Å or 140 Å (+ γ) (see also core-complex, *Rb. sphaeroides*, mutant) (Nunn et al., 1992).

F. Other Antenna Models and Related Theoretical Studies on the Energy Transfer System of Light-Harvesting Antennae of Purple Bacteria

Scherz and Parson (1986) developed a model for the structure of the antenna complexes based upon

spectroscopic data. They assumed that two heterodimers coupled to a tetramer represents the minimal unit of the B850 antenna complex. In principle, this concept agrees with the structural models described above. However, the arrangement of the tetramers ($\alpha_2\beta_2$) in the B870/B890 and B800–850 complexes is different in the four tilted helices model. There is no agreement between these structural models discussed above and the structural model of Hunter et al. (1988), which assumes there are α - β polypeptide trimers ($\alpha\beta$)₃ in the core antenna complex B875 and the peripheral complex B800–850 (see Chapter 22 by Hunter).

On the basis of the various antenna models of purple bacteria, efforts have been made to try and analyze theoretically exciton effects and electronic state energy transfer (Pearlstein, 1991). The diverse structural-functional models of antenna complexes and of the entire antenna system do not, however, allow a more detailed theoretical analysis to be performed, as they only describe structural-functional marginal conditions. In order to surmount this problem, in the future, three-dimensional structural analyses of antenna complexes will be necessary which show the exact position, orientation and spacing of BChl and carotenoid molecules.

Note Added in Proof

Since this chapter was written, the structure of the B800-850 complex from *Rp. acidophila* strain 10050 has been determined to a resolution of 2.5 Å (McDermott et al., 1995). It is an $\alpha_9\beta_9$ oligomer as shown in Fig. 21. The nine α -apoproteins are arranged in the middle with the nine β -apoproteins around the edge. The view seen in Fig. 21 looks down on this complex as it would lie in the plane of the membrane, from the cytoplasmic side, while Fig. 22 shows it from a view perpendicular to the symmetry axis. The α -helices are clearly seen. All the pigments are located within the space between the two rings of helices. The top and bottom of the structure is formed by the N- and C-termini folding over. At no point do the α - or β -apoprotein α -helices interact. The BChl *a* molecules are organized into two groups. A ring of nine monomeric 800 nm-absorbing BChl *a*'s lying flat in the plane of the membrane between the β -apoprotein α -helices. A second ring of 18 850 nm-absorbing BChl *a* molecules form a tightly coupled ensemble towards the periplasmic side of the complex.

Fig. 21. (See Color Plate 6A). Cytoplasmic view of the LH2 antenna complex from *Rhodospseudomonas acidophila*. The protein is shown in purple, with BChl molecules in green and carotenoid in yellow. For further details see McDermott et al. (1995).

Fig. 22. (See Color Plate 6B). The LH2 complex from *Rhodospseudomonas acidophila* viewed perpendicular to the symmetry axis. The periplasmic surface of the membrane is at the top and the cytoplasmic surface is at the bottom. The α helical parts of the protein are shown as purple ribbons. BChl B850 molecules are shown in red, with B800 molecules in green and carotenoids in yellow. For further details see McDermott et al. (1995).

The carotenoids connect these two rings.

It is clear that this structure was not well modeled by any of the models described in this chapter. However, it is interesting, especially since modeling the structure of membrane proteins is a very popular pastime, to describe why this is. All of the models presented in this chapter were based upon $\alpha\beta$ helix-helix interaction. This does not occur in the real structure. The real structure is dominated by pigment-pigment and pigment-protein interactions—40% by weight of the complex is pigments. It is clear that the modeling process did not and could not allow for this and, hence, the models failed.

Acknowledgments

HZ wishes to thank Mrs. E. Zollinger for the careful preparation of the manuscript. His work reported in this chapter was supported by the Swiss National Foundation (Project 3.286-0.82, 3207-0.85, 31-25179.88, 31-32071.91) and by the Eidgenössische Technische Hochschule, Zürich.

Summary

The transfer and trapping of excitation energy in photosynthetic purple bacteria, as it appears from time-resolved and steady-state spectroscopy, are discussed. As a background to the dynamics we first briefly describe the structure and organization and spectroscopy of purple bacterial antenna pigments. The concept of spectral inhomogeneous broadening and its consequences for understanding the spectroscopy and dynamics is thoroughly discussed. We start the discussion of the dynamics by describing the overall energy equilibration and trapping processes in antenna-reaction center systems of varying complexity. These processes occur on the time scale of several picoseconds to tens of picoseconds. The most conspicuous results are that excitation energy is equilibrated very rapidly, ≤ 10 ps, over the entire antenna, but transfer of the energy from the antenna to the reaction center (the special pair) is a relatively slow process (30–40 ps), both at room temperature and 77 K. The reaction center is not a perfect trap for the excitation energy; at room temperature ~25% of the energy returns

to the antenna in *Rhodospirillum rubrum*, upon selective excitation of the reaction center pigments. At low temperatures (≤ 77 K) the back transfer to the antenna is negligible. With recently available subpicosecond and femtosecond laser pulses the most fundamental steps of energy transfer has been resolved. It is shown that energy transfer between a pair of bacteriochlorophyll molecules typically occur on the timescale 0.2–0.5 ps. On this extremely short timescale it becomes necessary to also take into account various intramolecular processes, like vibrational relaxation and vibrational energy redistribution. For such very fast energy transfer processes it may be necessary to question the applicability of conventional Förster theory of electronic energy transfer. In order to test particular structural and dynamical aspects of the energy transfer and trapping, molecular biology methods are invaluable tools to introduce specific changes into the pigment-protein systems. Several examples of advanced spectroscopy on genetically modified systems are given.

I. Introduction

Photosynthetic purple bacteria are particularly well suited for studying structure-dynamics-function relationships of the primary photosynthetic processes, since these organisms have relatively simple pigment systems. A variety of well characterized light-harvesting and reaction center preparations exist, and specific mutations can be performed to introduce well defined site-selective alterations of individual amino acids. During the last approximately five years there has been a very rapid development in time resolved studies of excited state dynamics in bacterial pigment systems. Before 1985 very few studies existed, but with the advent of low pulse energy high repetition rate dye lasers there has been a virtual explosion in the number of works using picosecond transient absorption and fluorescence to study energy transfer and trapping dynamics. At present, researchers are engaged in the second step of this revolution where it is now becoming possible to study dynamics in photosynthetic systems on a sub-100 femtosecond timescale, using femtosecond lasers to generate highly stable, very short (10–100 fs) and broadly tunable pulses. Simultaneously, there has been a strong development of high resolution non-photochemical spectral hole burning techniques as an alternative to study very fast dynamics in photosynthetic pigment systems at very low temperatures. This development has now brought us to the point where we very accurately can study energy and electron transfer dynamics over a wide timescale, representing the characteristic times ranging from that of energy or electron transfer processes between individual molecules to those of

energy equilibration and overall trapping (representing a large number of individual steps).

II. Pigment-Protein Organization in LH1 and LH2

Purple photosynthetic bacteria contain bacteriochlorophyll *a* (BChl *a*) or bacteriochlorophyll *b* (BChl *b*) as the dominant pigment in the light-harvesting antenna and the reaction center (RC). Of the BChl *a*-containing bacteria many different species have been characterized, whereas for BChl *b*-containing bacteria only *Rhodopseudomonas (Rp.) viridis* has been reasonably well studied. The high-resolution crystallographic structures of *Rp. viridis* (Deisenhofer et al. 1984; Deisenhofer et al., 1986) and *Rb. sphaeroides* (Allen et al., 1987a,b; Yeates et al., 1987) reaction centers suggest that reaction centers of different purple bacteria are quite similar. The reaction center is surrounded by the LH1 core antenna, which consists of pairs of small transmembrane polypeptides (α and β) to which BChl is non-covalently attached in a 1:1 stoichiometry (Zuber and Brunisholz, 1991; Brunisholz and Zuber, 1992). Most likely, the highly conserved histidines in the α and β polypeptides are used as 5th ligand (Robert and Lutz, 1985; Zuber, 1985; Zuber and Brunisholz, 1991; Brunisholz and Zuber, 1992). The BChl *b* containing bacteria have an additional γ -polypeptide, which is not involved in pigment binding (Brunisholz et al., 1985). In vivo, the LH1-RC core has a constant number of 24 BChl per RC (12 α and 12 β), although some uncertainty and variation in this number is possible (Aagard and Sistrom, 1972; Dawkins et al. 1988; Beekman et al., 1993). Electron micrographs of membranes of *Rp. viridis* and other BChl *b*-containing species (Miller, 1982; Engelhardt et al., 1983; Stark et al., 1984; Stark et al., 1986) and,

Abbreviations: BChl – bacteriochlorophyll; *Cm.* – *Chromatium*; LH1, LH 2 – light-harvesting complex 1 or 2; *Rb.* – *Rhodobacter*; RC – reaction center; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*

recently, the BChl *a*-containing species *Rp. marina* (Meckenstock et al., 1992b) show that LH1 surrounds the RC in a circular way. The diameter of the RC-LH1 complex was estimated to be about 13 nm for the BChl *b*-containing and 10 nm for the BChl *a*-containing species; the difference is possibly due to the absence of the γ -polypeptide in the latter. A recent electron microscopy and image analysis study of purified RC-LH1 core particles of *Rhodospirillum (Rs.) molischianum* resulted in very similar structure, in which the 12 $\alpha\beta$ -pairs can be distinguished (Boonstra et al., unpublished). Ring-like structures with approximately the same dimensions have also been observed for concentrated solutions of purified LH1 (Meckenstock et al., 1992b). For the purified LH1 complex isolated from *Rb. sphaeroides* M2192 in detergent solution (octylglucoside) the ring may have collapsed and the particle appears to consist of two closely linked $(\alpha\beta)_6$ units (Boonstra et al., 1993). All these results suggest models for the organization of the α and β polypeptides in the membrane in which the minimal structural unit is a $(\alpha\beta\text{BChl}_2)$ complex (Zuber, 1985; Hunter et al., 1989; see also Chapter 16 by Zuber and Cogdell and Chapter 22 by Hunter in this volume). These minimum units form a circular structure with the centers of all BChl pigments and their Q_y -transition moments in a single plane parallel to the membrane (Breton and Vermeglio, 1982; van Grondelle, 1985). Spectroscopic measurements have shown that the RC-LH1 cores aggregate further into extended networks containing more than 10 RCs over which, at least at room temperature, the excitation can freely diffuse (Vredenberg and Duysens, 1963; Clayton, 1966; Bakker et al., 1983; Kingma et al., 1983; Vos et al., 1986; Vos et al., 1988; Deinum et al., 1989; Trissl et al., 1990; Deinum et al., 1991, 1992a). At low temperature the excitation diffusion is restricted to, possibly, a single RC-LH1 core (Vos et al., 1988; Deinum et al., 1991; van Mourik et al., 1993).

Various models have been suggested for the detailed structural organization of the α and β polypeptides of the LH1 antenna (Theiler et al., 1984a,b, Theiler and Zuber, 1984c; Hunter et al., 1989; Scherz and Rosenbach-Belkin, 1989, Scherz et al., 1990; Braun and Scherz, 1991; Zuber and Brunisholz, 1991; Brunisholz and Zuber, 1992). It is believed that pairs of α and β -polypeptides form a minimum unit which aggregates further to form the fully functional in vivo antenna. Such a minimal unit was first isolated by Loach and coworkers (Loach et

al., 1985; Miller et al., 1987; Parkes-Loach et al., 1988) and spectroscopically analyzed in detail (see section III.D). A molecular weight determination of this so-called B820 subunit by gel filtration showed that B820 had a considerably lower molecular weight than the reassociated B873 form. Similar subunits could be purified from various other photosynthetic purple bacteria (Ghosh et al., 1988; Chang et al., 1990; Heller and Loach, 1990; Meckenstock et al., 1992a; Jirsakova et al., 1992). Recently, a B820 subunit was prepared from *Rp. marina* (Meckenstock et al., 1992a) with a reported molecular mass of 33 kDa, about 1/6 of the molecular mass of purified LH1 from the same species. From these biochemical results the $(\alpha\beta)_2$ -form was considered to be the most likely aggregation form for B820 (Meckenstock et al., 1992a,b). However, a careful evaluation of all the molecular weight measurements strongly suggests that B820 arises from a single $\alpha\beta$ -pair, in agreement with the spectral properties (see Chapter 21 by Loach and Parkes-Loach).

Several species of purple bacteria contain, in addition to the LH1 core antenna, a peripheral LH2 antenna at higher excited state energy with major BChl absorption between 820 and 860 nm depending on the species, and a second major BChl *a* Q_y -transition around 800 nm (see Hawthornthwaite and Cogdell, 1991 for an overview). The ratio of LH2 to LH1/RC depends strongly on the growth conditions. For instance, in *Rb. sphaeroides* grown under low-light conditions LH2 is by far the dominant spectral species. It is now well established that some species (*Rp. palustris*, *Rp. acidophila*, *Cm. vinosum*) have the ability to change the antenna polypeptide composition (and consequently their absorption) in response to light and/or temperature (Zuber and Brunisholz, 1991; Hawthornthwaite and Cogdell, 1991; Brunisholz and Zuber, 1992). Simultaneously, they can adapt the relative amount of pigment absorbing around 800 nm. LH2 may have a complex carotenoid composition and the BChl to carotenoid ratio may vary between 1:1 and 3:1 (Thorner et al., 1983; Hawthornthwaite and Cogdell, 1991); for instance in the case of LH2 of *Rb. sphaeroides* this ratio is 2:1 (Evans et al., 1988). The LH2 protein backbone also consists of transmembrane α and β -polypeptides, which bind three BChl *a* per $\alpha\beta$ -pair.

The organization of the pigments in the LH2 of *Rb. sphaeroides* (B800–850) was extensively studied (Bolt and Sauer, 1979; Breton et al., 1981; van Grondelle et al., 1982; Kramer et al., 1984a) and

detailed arrangements of the pigments have been proposed (see below), although up to now no agreement exists about the aggregation state and minimum functional unit ($\alpha\beta$, $\alpha_2\beta_2$, etc.). A unit composed of $(\alpha\beta)_2$ containing 6 BChl *a* molecules and three carotenoids explains most of the steady-state and time-resolved spectroscopic properties of LH2 (Kramer et al., 1984a; van Grondelle, 1985). Zuber and coworkers (Zuber, 1985; Zuber and Brunisholz, 1991; Brunisholz and Zuber, 1992) have proposed the cyclic $(\alpha\beta\text{BChl } a_3)_6$ structure based on structural considerations. An electron microscopic and image analysis study of LH2 from *Rb. sphaeroides* isolated in the detergent lauryl dimethyl amine oxide (LDAO) gave similar result (Boonstra et al., 1993). Crystals of the B800–850 LH2 complex of *Rp. acidophila* suggest a trimeric $(\alpha\beta)_2$ structure as the basic unit (Hawthornthwaite et al., 1989), which are in their turn arranged in a circle, in agreement with a suggestion originally proposed by Scherz and coworkers (Scherz and Rosenbach-Belkin, 1989; Scherz et al., 1990; Braun and Scherz, 1991).

In vivo, light absorbed by LH2 is efficiently transported to the RC probably via LH1, although a mutant of *Rb. sphaeroides* lacking LH1 but containing LH2 and RCs shows trapping kinetics closely similar to those observed for the RC-LH1 species (Hess et al., 1993a). For *Rb. sphaeroides* LH2 connects cores of LH1/RC units, containing at most a few RCs (Monger and Parson, 1977; Vos et al., 1986). Recently, it was shown for *Rp. acidophila* that the LH2 antenna interconnects individual LH1/RC units. In case of a B800–820 connecting antenna, the LH1/RC units were effectively isolated (even at room temperature), while in case of a B800–850 antenna excitations were able to migrate between different LH1/RC units (Deinum et al., 1991).

III. Spectroscopy of the LH1 and LH2 Light-Harvesting Antennae

A. In vivo Spectral Properties of LH1 and LH2

The major BChl (*a* or *b*) absorption in LH1 and LH2 is strongly red-shifted relative to the absorption of BChl in organic solvents. In case of BChl *a*-containing LH1, room temperature absorption maxima are observed at about 870–880 nm, which shift even further to the red upon lowering the temperature. For some species, e.g. *Ectothiorhodospira mobilis*

(Trüper, 1968; Leguijt et al., 1992) and *Cm. tepidum* (Garcia et al., 1986), the long wavelength maximum may be above 900 nm. For each species the precise maximum depends somewhat on the particular conditions; for instance the absence (or type) of carotenoid in LH1 of *Rb. sphaeroides* may shift the absorption maximum almost 10 nm to the blue (Parkes-Loach et al., 1988; Olsen unpublished). For the BChl *b* containing species the major absorption at room temperature is around 980 nm, which sharpens and shifts to about 1035 nm upon cooling to 77 K (or 4 K).

Typically, the major LH2 absorption in purple bacteria is between 820 and 860 nm with a second peak around 800 nm. For instance, LH2 of *Rb. sphaeroides* absorbs at about 800 and 850 nm; LH2 of *Rp. acidophila* 7050, grown under dim light conditions absorbs maximally around 800 and 820 nm (Zuber and Brunisholz, 1991; Brunisholz and Zuber, 1992; Hawthornthwaite and Cogdell, 1991). The precise location of the peaks is also here sensitive to the presence and type of carotenoid. Recently, Fowler et al. (1992) succeeded in blue shifting the major absorption transition of LH2 of *Rb. sphaeroides* by site-directed mutation of the double tyrosine motif (αTyr44 , Tyr45) in the α -polypeptide. The single (αTyr44 , Tyr45 \rightarrow Phe, Tyr) and double (αTyr44 , Tyr45 \rightarrow Phe, Leu) mutants absorbed around 838 and 826 nm, respectively. This mutation was inspired by the PheLeu motive in the 800–820 complex of *Rp. acidophila* and showed that this pair of residues is indeed responsible for the spectral tuning, possibly by the formation of an H-bridge between αTyr44 residues and the *c*-2-acetyl group of one of the BChl molecules (Fowler, unpublished).

Both LH1 and LH2 are believed to have a quite similar organization of their pigments. Consequently, their spectroscopic properties are also closely related. In particular, the organization of the BChl *a* of LH2 absorbing at 820–860 nm is believed to be rather similar to that of BChl *a* of LH1, with a dimer of BChl *a* as basic structure. All BChl molecules in LH1 and LH2 have their major Q_y transitions in the plane of the membrane (Bolt and Sauer 1979, 1981; Bolt et al., 1981; Breton et al., 1981; Kramer et al., 1984a,b). Within this plane there is, however, no preferential orientation. The Q_x -transitions belonging to B870 in LH1 and B820–850 in LH2 absorb around 590 nm and are oriented perpendicular to the membrane plane (or make at most a small angle with the normal). In LH2 of *Rb. sphaeroides* the

B800:B850 ratio is 1:2, but the B800 peak is markedly sharper than the B850 peak and asymmetric in low temperature absorption spectra (Clayton and Clayton, 1981; van Grondelle et al., 1982). The B800 pigment is assumed to be 'monomeric' and is possibly not liganded to histidine (Robert and Lutz, 1985), but rather weakly attached to the LH2 structure (Clayton and Clayton, 1982; Kramer et al., 1984a; Chadwick et al., 1987). The B800 absorption shows a predominant orientation in the plane (Breton et al., 1981; Kramer et al., 1984a). Species with an increased absorption around 800 nm (e.g., *Rp. palustris*) usually exhibit complex CD, LD and polarized fluorescence excitation spectra reflecting stronger interactions between the B800 pigments (Hayashi et al., 1982a,b,c; Leguijt et al., 1992; van Mourik et al., 1992c).

B. Site Inhomogeneous Broadening in LH1 and LH2

Previously, the low temperature (<100K) spectroscopic and excitation transfer properties of the purple bacterial antenna have been described in terms of the 'two-pool' hypothesis, in which the LH1 spectrum of *Rb. sphaeroides* was proposed to be composed of a major form (B880) and a minor long-wavelength form (B896) (Borisov et al., 1982; Kramer et al., 1984b; Bergström et al., 1988a; Deinum et al., 1989; Shimada et al., 1989; Hunter et al., 1990; Reddy et al., 1992a). Fast excitation energy transfer was proposed to take place from B880 to B896, leading to strong depolarization of the fluorescence. Similarly, for LH2 of *Rb. sphaeroides* the existence of a major B850 and a minor B870 form has been forwarded (van Dorssen et al., 1988; Reddy et al., 1992a).

Recently, however, low-temperature fluorescence (van Mourik et al., 1992a; Visschers et al., 1993), time-resolved fluorescence (Timpmann et al., 1991; Pullerits et al., 1994) and absorption (van Mourik et al., 1993) and spectral hole-burning experiments (van der Laan et al., 1990; Reddy et al., 1991, 1992a,b) have demonstrated that the LH1 and LH2 absorption spectra are in fact inhomogeneously broadened. Van Mourik et al. (1992a) applied narrow-banded laser excitation on purified LH1 complexes at 4 K and measured as a function of the excitation wavelength (λ_{exc}) the position of the LH1 emission maximum (λ_{max}) and the fluorescence polarization. It was observed that λ_{max} was unchanged at 904 nm for $\lambda_{\text{exc}} \leq 886$ nm. For $\lambda_{\text{exc}} > 886$ nm, λ_{max} shifted linearly with λ_{exc} to the red and the polarization increased

from about 0.1 to close to maximal (0.5). Similar results were also obtained with purified LH2 (Visschers et al., 1993). For LH1-RC complexes and intact membranes of *Rp. viridis* the increase in fluorescence polarization in the long-wavelength part of the absorption spectrum (1050 nm) was also detectable using narrow-banded laser excitation and occurred only upon excitation in the very red edge (Monshouwer et al., unpublished).

These results are not consistent with the two-pool hypothesis but can be fully explained by assuming inhomogeneous broadening as the dominant factor in determining the shape of the LH1 and LH2 absorption spectra. Within the framework of this concept, LH1 and LH2 may be regarded as small clusters of weakly coupled BChl *a* dimers among which fast excitation energy transfer takes place. Each individual cluster is supposed to be a random sample from the total inhomogeneously broadened pigment pool. For small clusters, with efficient energy transfer leading to rapid thermalization of the excited state, the effects of site-selection depend on the cluster size only and, consequently, site-selective excitation yields information about the number of coupled BChl *a* molecules in a cluster. It was demonstrated that this model explains the observed emission polarization excitation spectrum unequivocally (van Mourik et al., 1992a). The cluster-size dependence of the inhomogeneously broadened LH1 antenna was confirmed by the correlation of the value of the excitation wavelength at which the fluorescence polarization started to increase with the LH1 cluster size (van Dorssen et al., 1988; Visschers et al., 1993).

Spectral holeburning experiments at 1.2 K have recently been reported for LH1 and LH2 of *Rb. sphaeroides* (Reddy et al., 1991, 1992a) and *Rp. acidophila* (Reddy et al., 1992b). Excitation in the middle or blue wing of the main LH1 (~875 nm) or LH2 (~850 nm) absorption bands only resulted in broad, featureless spectra, whereas excitation of the red wings of these absorption bands resulted in narrow holes (3.2 cm^{-1}), implying a 5–10 ps lifetime. Plotting burning efficiency as a function of laser frequency mapped out a profile with a width of 70 cm^{-1} peaking around 895 nm in LH1 and around 870 nm in LH2. The narrow (5–10 ps) hole was always accompanied by a rather broad feature, with a width of about $200\text{--}210 \text{ cm}^{-1}$, close to half the bandwidth of the original LH1/2 absorption band, and a strong absorption increase (anti-hole) in the blue wing. In

contrast to the 'weak coupling of dimers' model mentioned above (van Mourik et al., 1992a), the B850 results were interpreted in terms of a 'strong exciton coupling' model in which all ($\alpha\beta$ BChl₂) pairs are organized in a cyclic unit cell and strongly exciton coupled. Further (weaker) coupling was proposed to occur between the interacting cells (note that such a view has also been proposed for the spectroscopic properties of the BChl *a*-containing Fenna-Matthew-Olson (FMO) complex of green sulphur bacteria (Johnson and Small, 1989, 1991)). Within the context of this model, B896 and B870 are the lowest exciton states of the LH1 and LH2 unit cells and the 70 cm⁻¹ profile reflects the inhomogeneous linewidth. In contrast to the FMO complex, no further exciton level structure was observed on the ground state and hole-burning spectrum. The broad profile observed in the holeburning spectrum was ascribed to a special form of homogeneous broadening caused by the close spacing of the many exciton levels, the lifetime broadening of each exciton level due to fast inter-exciton level relaxation (~200 fs) and disorder (Johnson and Small, 1991; Reddy et al., 1992a,c). Alternatively, the excitation profile of the narrow hole could be related to the probability of exciting a lowest energy state in a cluster. It is of interest to note that the limiting wavelength for observing the narrow hole in LH1 and LH2 coincides with the onset wavelength of the fluorescence redshift and polarization increase observed in fluorescence site-selection experiments described above (van Mourik et al., 1992a; Monshouwer et al., unpublished). In that case the broad hole arises from a broad phonon wing accompanying the zero-phonon hole obtained at the burning wavelength (Pullerits et al., 1994; Pullerits et al., unpublished).

Holeburning experiments on LH2 complexes from various organisms have shown that the B800 absorption band is inhomogeneously broadened. The holewidth in the red edge of the band yields a linewidth that corresponds with the estimated time-constant for B800 → B850 excitation energy transfer (see below), which is 2.4 ps ($\Gamma_{\text{hom}} = 70$ GHz (van der Laan et al., 1990; Reddy et al., 1991, 1992a,b; van der Laan et al., 1993) in LH2 of *Rb. sphaeroides* between 1.2 and 30K. If the burning wavelength is tuned to the blue edge of the band the holes become progressively broader, reaching a value of 250–300 GHz upon burning at 795 nm or lower (De Caro et al., unpublished). In the case of blue excitation in LH2 of *Rp. acidiphila* a broad hole is obtained in the

red edge of the B800 band. All these features are interpreted as resulting from subpicosecond downhill energy transfer within the B800 band, consistent with steady-state fluorescence polarization measurements (Kramer et al., 1984a) and with more recent time-resolved data (Visscher et al., 1993a, 1993b; Hess et al., 1993b).

C. Stark Spectroscopy of LH1 and LH2

Stark spectroscopy of BChl *a* in films has yielded a value for the difference (between excited and ground state) dipole moment of $|\Delta\mu_A| = 1.3\text{--}2.0$ D/f (Gottfried et al., 1991), in which f is the local field correction factor. For BChl *a* in the FMO complex rather similar values were obtained, suggesting that the BChl *a* molecules in FMO behave as a set of non-interacting pigments with respect to the electric field.

For LH2 of *Rb. sphaeroides* the B800 band has $|\Delta\mu_A| = 0.8\text{--}0.9$ D/f, while the B850 band shows an unusually large $|\Delta\mu_A| = 3.4$ D/f (Gottfried et al., 1991). Stark spectra of both components have anomalous lineshapes and the spectra do not match the second derivative of the absorption spectrum (as expected for a single transition with a single value for $\Delta\mu_A$). The complex spectrum may (in part) be explained by assuming that red-shifted species are hidden under the LH2 absorption profile with enhanced charge transfer character. The amplitude of the B850 Stark spectrum shows that the BChl *a* chromophores are strongly coupled, giving rise to enhancement of $|\Delta\mu_A|$. $|\Delta\mu_A|$ for B850 is not affected by the disappearance of B800 upon lithium dodecyl sulfate (LDS) treatment. The B800 Stark effect is consistent with the idea that B800 represents weakly coupled BChl *a*, susceptible to perturbations in the external environment. Surprisingly, LH2 shows an unprecedented large decrease in fluorescence yield in an applied electric field. It was suggested that the proposed charge transfer character of (part of) the B850 absorption is responsible.

For B875, the Stark absorption and emission spectra are dominated by a strong first derivative contribution (Gottfried et al., 1991). Fitting the Stark absorption spectrum to a sum of derivative components yielded $|\Delta\mu_A| = 3.3 \pm 0.2$ D/f and in addition a very large polarizability difference. Although the Stark absorption spectrum does not hint at special red states in the B875 profile, it is still possible that the observed effects are due to overlap of transitions within the LH1 absorption band, with

different responses to the applied electric field. In comparison with the special pair of the RC ($|\Delta\mu_{\lambda}| = 7$ D/f) (Lockhart and Boxer, 1988) the Stark effect is 'weak', which may indicate that for LH1 not all of the redshift is due to an increase in electronic coupling, but rather to 'local' effects (see next section).

D. Spectral Properties of the B820 LH1 Subunit and the Nature of the Redshift

The isolation of a subunit form, B820, of LH1 of *Rs. rubrum* and *Rb. sphaeroides* (Loach et al., 1985; Miller et al., 1987; Parkes-Loach et al., 1988; Gosh et al., 1988; Chang et al., 1990; Heller and Loach, 1990; Meckenstock et al., 1992a; Jirsakova et al., 1992; Visschers et al., 1992) has added significantly to our understanding of the spectroscopy of LH1 in relation to the aggregation state. From absorption, CD and fluorescence polarization spectra it was concluded that two excitonically interacting BChl *a* molecules are responsible for the spectral properties of B820. Recent triplet-minus-singlet spectroscopy, singlet-triplet annihilation and fluorescence site-selection studies (van Mourik et al., 1991; Visschers et al., 1992, 1993a) have demonstrated that the B820 spectral properties are those of a BChl *a* dimer, with little or no interaction between different dimers. The dimer was proposed to have a head-to-tail arrangement, putting most of the oscillator strength in the red-shifted transition (Visschers et al., 1991). The high-energy component could only be observed by a small dip in the polarized excitation spectrum around 790 nm. The 'monomer' transition is located at 808 nm, which indicates that in B820 more than 2/3 of the redshift (from 777 nm) is non-excitonic. Within the B820 dimer the monomer transition dipoles are quasi-equivalent and they make a small angle of about 20° to account for the observed CD (Visschers et al., 1991; Koolhaas et al., unpublished). Low-temperature site-selected fluorescence experiments (Visschers et al., 1993) have shown that the B820 absorption band is inhomogeneously broadened and in fact behaves like a 'single state' system, as expected for a strongly coupled dimer. In addition, the major B820 absorption band is narrower with a factor of about $\sqrt{2}$ than the estimated monomer transition, which is consistent with the idea that each B820 dimer is composed of two BChl *a* monomers that are randomly selected from the total inhomogeneous distribution.

Recently, the time-resolved association of B820

into B875 using stopped flow has strongly suggested that only two B820 units are required to form B875 (van Mourik et al., 1992b). A spectroscopic intermediate could not be detected and further aggregation only marginally affected the spectrum. The CD spectrum of the reassociated B873 is, apart from the red-shift, not very different in shape and intensity from that of B820, which suggests that the interactions within the dimer have not been altered much during the aggregation. These experiments have been taken to imply that the nature of the red-shift of BChl in LH1 (and probably also in LH2) is largely non-excitonic. This is supported by low-temperature triplet-minus-singlet spectra (van Mourik et al., 1993), which appear to be red-shifted copies of the B820 triplet-minus-singlet spectrum and do not show the appearance of a strong monomer absorption band far to the blue of the original LH1 absorption.

An earlier model that was proposed to explain the *in vivo* LH1 and LH2 spectra was based on model studies, which showed that artificially prepared dimers of BPheo *a* have absorption and CD spectra that are strongly reminiscent to those of LH1 and LH2 (Scherz and Parson, 1984, 1986; Scherz and Rosenbach-Belkin, 1989; Scherz et al., 1990). On the basis of these results it has been suggested that the major species of LH1 and LH2 consists of dimers of BChl *a* in a configuration similar to that of the special pair of the bacterial RC. The red-shift would be purely excitonic. The strong CD of LH1 and in particular LH2 was ascribed to much weaker interaction between various dimers. However, also in the case of the special pair of the RC, the origin of the redshift is certainly not purely excitonic, since even the proposed high energy exciton component (Breton, 1985) is still very red-shifted relative to the absorption of BChl *a* in organic solvents. Experiments by Picorel and co-workers (Picorel et al., 1986; Gingras and Picorel, 1990) provide further evidence that this model is not correct. It was demonstrated that the cross-section for γ -radiation inactivation of the spectroscopic unit of LH1 corresponds with the size of the ($\alpha\beta$ -BChl₂) pigment-protein complex. The product of the inactivation has the size of a single polypeptide plus one molecule of BChl *a*. Despite its small size, the product formed by the radiation inactivation of LHI still has a highly red-shifted absorption spectrum.

Then what is the cause for the redshift observed in LH1 and LH2 and how is it related to the redshift of B820 upon formation of B873? In the B820 complex

a molecule of the detergent octylglucoside may occupy the position of the carotenoid (Visschers et al., 1993 b). Consequently, the interaction between the detergent molecule and BChl *a* may have some effect on the BChl *a* absorption band. As discussed earlier, Fowler et al. (Fowler et al., 1992) have shown that in LH2 of *Rb. sphaeroides* the B850 absorption band can be shifted more than 20 nm to the blue upon mutation of a Tyr pair in the α -polypeptide. Resonance Raman spectra have shown that the spectral shift upon formation of B820 and in LH2 upon mutagenesis of the Tyr pair in the α -polypeptide are accompanied by dramatic changes in the H-bonding pattern of the BChl molecules (Visschers et al., 1993b; Fowler et al., unpublished). Similar effects have been observed in LH1 (Olsen, unpublished). These observations are in line with the view that non-excitonic factors, such as charge effects (Davis, et al., 1981; Eccles and Honig, 1983), deviations in planarity of the porphyrin ring system (Gudowska-Nowak et al., 1991) or the change in dielectric constant in close environment of the pigments (Altmann et al., 1992) may largely determine the site-absorption of the pigments. Similar ideas have been put forward for the interpretation of the spectrum of the FMO-complex (Gudowska-Nowak, et al. 1991; Pearlstein, 1992; Lu and Pearlstein, 1993).

IV. Energy Transfer in LH2-Less Purple Bacteria

A. *Rhodospirillum rubrum* and *Rhodobacter sphaeroides* (LH1-RC Only Mutants)

Rs. rubrum and RC-LH1-only mutants of *Rb. sphaeroides* may be regarded as photosynthetic systems in which excitation energy transfer and trapping occur in a 'homogenous' core antenna. The original results of Vredenberg and Duysens (1963) have shown that at room temperature such systems should be viewed as 'lakes' in which many reaction centers are connected through very efficient excitation energy transfer. These ideas were further substantiated by singlet-singlet and singlet-triplet annihilation experiments (Monger and Parson, 1977; Pailotin et al., 1979; Bakker et al., 1983; van Grondelle et al., 1983; Vos et al. 1986).

The actual time required to trap an excitation by photochemically active ('open') reaction centers at

room temperature was measured to be 50–70 ps with both picosecond absorption (Nuijs et al., 1985, 1986; Sundström et al., 1986) and fluorescence (Freiberg et al., 1984, 1987; Borisov et al., 1985) techniques. In 'closed' centers (with oxidized primary electron donor), the excited state lifetime lengthens to about 200 ps, showing that even in the state P⁺ the reaction center efficiently quenches the excitations in the antenna. Picosecond absorption kinetics (Sundström et al., 1986) also displayed an additional 20–50 ps decay component, which at that time was ascribed to the equilibration of excitation density among different spectral forms in the LH1 antenna, but also may have included singlet-triplet annihilation (Freiberg et al., 1990; Valkunas et al. 1991; Timpmann et al., 1993).

1. Trapping and Detrapping of the Excitation Energy

From the functional dependence on distance, orientation and spectral parameters of energy transfer it can be expected that the rate and efficiency of trapping and detrapping (escape) of excitation energy by the reaction center is a sensitive probe of pigment organization and relative excited state energies of antenna and special pair. Earlier models based on homogeneous lattices have suggested a fast transfer rate from neighbouring LH1 to P and a high escape probability for an excitation arriving on P, as a consequence of the near degeneracy of P and LH1 and of the assumed fast transfer rate from neighboring LH1 to P (Duysens, 1979; Bakker et al., 1983; Borisov et al., 1985). On the other hand, early measurements of fluorescence excitation spectra of purple bacteria in which the reaction center absorption was well separated from the major LH1 band indicated a relatively low probability of observing the LH1 fluorescence through excitation of the reaction center, also at room temperature (Olson and Clayton, 1986; Wang and Clayton, 1971). These results were recently confirmed and extended at low temperature (Otte et al., 1993) where the escape probability was found to be <5% in all cases.

Selective picosecond excitation and probing in the red wing of the LH1 absorption band has shown that in the temperature range 100–200 K. energy is transferred to the RC with a time-constant of 35–40 ps (Bergström et al., 1989; Visscher et al., 1989), which was considered to reflect excitation transfer from (one of) the nearest neighbor(s) of the RC to P. At room temperature, a slightly shorter time constant

was estimated. The weak temperature dependence suggests that LH1 is nearly resonant with P; the localization of the excitation energy on P, however, may be slightly more favorable at lower temperatures due to the spectral inhomogeneity of the LH1 antenna (see below). Thus, the excitations may be spread more homogeneously over all pigments at higher temperatures. From the measured rate constant a distance of about 3 nm between the nearest neighbor and P was calculated, in reasonable agreement with the distance estimated on the basis of the dimensions of the RC. Similar results were obtained by Timpmann et al. (1991) from a picosecond fluorescence measurement at 77 K. These results on trapping/detrapping by the reaction center were further substantiated by measuring the amplitude of antenna bleaching or antenna fluorescence decay components in a time resolved experiment with selective reaction center excitation, and comparing it with the corresponding amplitudes with direct antenna excitation (Timpmann et al., 1993). It was concluded that with photochemically active reaction centers in the state PIQ, excitation energy is transferred back to the antenna with a yield of $25 \pm 5\%$ at room temperature. The corresponding figure for reaction centers in the state PIQ⁻ was $40 \pm 5\%$. With this measured yield, the antenna excited state lifetime of 60 ps, and the charge separation time of 3 ps, a simple kinetic model simulation showed that trapping (i.e. energy transfer from antenna to the reaction center) occurs with a time constant of 35–40 ps, and that detrapping occurs with a characteristic time constant of 7.5 ± 1.5 ps. Assuming a six-fold antenna coordination of the reaction center, these overall time constants correspond to pairwise trapping and detrapping time constants of approx. 35 and 45 ps, respectively (Timpmann et al., 1993). For a monocoordinate reaction center, as has been suggested on the basis of shape and symmetry of the reaction center (Pearlstein, 1992a), the pairwise rates would be a factor of six faster than this.

That energy transfer from the antenna to the reaction center is a slow rate limiting step in the exciton dynamics was recently also shown in experiments by Beekman et al. (1994) who studied the rate of excitation trapping in RC-LH1-only mutants of *Rb. sphaeroides* in which the Tyr M210 residue in the RC was mutated into Phe, Leu or His. The first two of these mutations induced a reduction of the rate of charge separation in the isolated reaction center by a factor of 3–5, probably by raising the

energy level of P⁺I⁻ relative to that of P*. However, the trapping time increased only by about 15% in membranes of these mutants, while on the other hand a phase in the decay of the LH1 excited state reflecting the electron transfer from I⁻ to Q increased in amplitude. Consequently, we suggest that the excitation transfer from a neighbouring LH1 to P and not the rate of charge separation dominates the trapping time. This would make the trapping in LH1-RC cores of photosynthetic purple bacteria 'diffusion limited', although the rate of excitation diffusion in LH1 itself is exceptionally high.

A comparison of the trapping time obtained from the measurements of Timpmann et al. (1993) with that predicted from a homogeneous random-walk model (Pearlstein, 1982) suggested that the LH1 antenna in the energy migration process behaves as if it were organized in clusters of BChl *a* molecules. The number of BChl molecules in each cluster was concluded to be at least two and could be as large as four, which would correspond to $\alpha\beta\text{BChl}_2$ to $(\alpha\beta\text{BChl}_2)_2$ as a minimum unit in this respect. Considering the difficulties associated with calculations of spectral overlap integrals and combining all available results on this matter (see above), it seems likely that $\alpha\beta\text{BChl}_2$ constitutes the minimum pigment-protein unit of the LH1 antenna.

The detrapping yield in *Rp. viridis* was also obtained, by measuring the time resolved antenna fluorescence with selective reaction center excitation and comparing the amplitude of fluorescence decay to the corresponding decay with direct antenna excitation (Timpmann et al., 1995). From the observed detrapping yield of $20 \pm 5\%$ at room temperature with photochemically active reaction centers (PI), it was concluded that trapping and detrapping dynamics in *Rp. viridis* is quite similar to that in the BChl *a*-containing purple bacteria.

Spectrally redshifted minor LH pigments have often been suggested to play a role in the trapping process, as specialized pigments concentrating the energy to the vicinity of the reaction center and making an optimized contact/entry between the reaction center and the antenna (Deinum et al., 1989; Bergström et al., 1988; Hunter et al., 1990). The need for such specialized contact pigments was examined by studying the trapping dynamics in a mutant of *Rb. sphaeroides* containing reaction centers and LH2 as the sole LH pigment, i.e. lacking the LH1 core antenna (Hess et al. 1993a). The fact that the overall trapping time at room temperature was identical

within experimental error to the trapping time in *Rb. sphaeroides* WT, and only approx. two times longer at 77 K, suggested that the energy transfer from the antenna to the special pair primarily is controlled by the spectral overlap between the participating pigments, and that specialized antenna-RC contact pigments only play a minor role in the trapping process.

It has already been mentioned that the oxidized primary donor P^+ is an efficient quencher of excitation energy from the antenna; in most purple bacterial species an antenna exciton lifetime approximately four times the lifetime with active reaction centers, i.e. 200–250 ps, is observed at both room temperature and 77 K (Sundström et al. 1986; Borisov et al. 1985; van Grondelle et al. 1987), but the mechanism of this efficient quenching is poorly understood. By measuring the P^+ quenching rate in a mutant of *Rb. sphaeroides* containing LH2 as the only antenna pigment, it was shown that this quenching is a factor of 1.5–2 less efficient for excitation energy delivered by LH2 as compared to LH1 (Hess et al. 1993a). It was suggested that the spectral overlap between antenna fluorescence and the broad P^+ absorption in the near-infrared region (~900–1300 nm) constitutes the basis for a relative efficient Förster energy transfer from the antenna to P^+ . The fact that the primary donor is preoxidized and cannot transfer electrons implies that the excitation energy is dissipated as heat in a radiationless process, or emitted as infrared fluorescence (>1300 nm) which will be difficult to detect with the detectors conventionally used.

2. Spectral Inhomogeneity of LH1

Early low temperature fluorescence measurements have indicated that below 100 K the fluorescence yield of (open or closed) *Rs. rubrum* starts to rise dramatically (Rijgersberg et al. 1980) and that the fluorescence polarization of LH1 and LH1-RC cores of all purple bacteria shows a marked dependence on the excitation wavelength (Bolt et al., 1981; Kramer et al., 1984b), suggesting that below 100 K the LH1 antenna behaves like a spectrally inhomogeneous system. Low temperature (77 K) picosecond absorption (van Grondelle et al., 1987), fluorescence (Freiberg et al., 1987; Freiberg et al., 1988a, 1988b; Timpmann et al., 1991) and absorption anisotropy (van Grondelle et al., 1987; Bergström et al., 1988a; Hunter et al., 1990) kinetics can also be given the

same interpretation. Early fluorescence and absorption decays indicated the presence of a 10–20 ps component on the high energy side of the absorption/emission spectrum that precedes trapping. Hence, LH1 is spectrally heterogeneous and consists of at least two, but possibly many spectral forms, as was discussed in section III.B. In all models fast (≤ 10 ps) energy transfer occurs from the major BChl *a* pool to the low-energy fraction.

At ultralow temperatures (4 K), the trapping efficiency for excitations by P drops to about 60% of its value at >100 K (Rijgersberg et al., 1980). Picosecond absorption measurements indicated an increase in the trapping time upon far-red excitation (Visscher et al., 1989). 4 K annihilation experiments showed that the major part of the fluorescence quenching occurred in the red wing of the emission spectrum (Deinum et al., 1989). Time-resolved fluorescence measurements at 4 K (Timpmann et al., 1991) on *Rs. rubrum* membranes, in which the primary donor was accumulated in the triplet state, revealed at least 10–20 ps components in the blue part of the emission spectrum, 100–200 ps components in the center and very slow components (1 ns) in the red-edge. All these results can well be explained by the ‘inhomogeneous broadening’ model described in III.B (Pullerits and Freiberg, 1991, 1992; Valkunas et al., 1992; van Mourik et al., 1993; Pullerits et al., 1994).

In contrast to the relatively slow transfer between P and its nearest neighbors (~30–40 ps at room temperature) and the slow equilibration phenomena observed at 77 K and 4 K, there are strong indications that the transfer among identical LH1 dimers (or tetramers) is much faster. From singlet-singlet annihilation measurements, the residence time of an excitation on a B880 molecule was estimated to be less than 1 ps (Bakker et al., 1983; Vos et al., 1986) and a recent detailed analysis of the annihilation experiment suggested a τ_{hop} of 0.65 ps (Valkunas et al., 1989). Time-resolved absorption anisotropy measurements of *Rs. rubrum* and *Rb. sphaeroides* showed that at room temperature during the first few picoseconds after excitation the polarization of the excited state is largely lost, independent of the excitation and probing wavelengths (Sundström et al., 1986; Bergström et al., 1988a; Hunter et al., 1990). It is very probable that this initial depolarization occurs as a result of ultrafast (sub-ps) energy transfer among spectrally similar BChl *a* dimers

(assuming that the dimer is the basic spectroscopic structure of LH1—see above). The ‘initial’ value of the anisotropy of 0.1 is in agreement with earlier polarized spectroscopy results and consistent with models proposed for LH1 (Breton et al., 1981; Kramer et al., 1984b; Hunter et al., 1989). Some further depolarization took place on a slower time-scale (10–30 ps), possibly reflecting the diffusion of the excitation through the LH1 domain. Also at 77 K the initial absorption anisotropy was about 0.1 in the main LH1 absorption band and its blue wing. Only upon excitation and probing in the low-energy wing ($\lambda > 900$ nm) highly polarized decays were observed ($r(0) = r(\infty) = 0.25$) (van Grondelle et al., 1987; Bergström et al., 1988a). This agrees with earlier fluorescence polarization measurements (Kramer et al., 1984b) and supports the idea that a minor fraction of the pigments in the low-energy wing of the LH1 absorption band acts as the final energy acceptor in LH1. Finally, the transient absorption measurements after picosecond excitation exhibit a strong bleaching at the red side of the LH1 absorption band and strong excited state absorption in the blue wing. Around the isobestic point fast additional absorption changes have been observed (van Grondelle et al., 1987; Bergström et al., 1988a, 1988b; Pullerits et al., 1994) which, due to the duration of the excitation pulse could not be time-resolved, but indicated an equilibration process within LH1 on a timescale of at most a few picoseconds.

Recently, Pullerits and Freiberg (1992) modeled energy transfer and trapping by a master equation approach, on the basis of inhomogeneously broadened LH1 and RC spectra. A hexameric arrangement of six ($\alpha\beta\text{BChl}_2$)₂ units around the RC analogous to the electron micrographs of *Rp. viridis* was taken as the structural basis of this model. The spectral properties of each unit were chosen randomly from the total inhomogeneously broadened pool and only three fitting parameters remained: the interunit hopping time, the hopping time to the RC and the homogeneous linewidth. At 77 K, a satisfactory fit was obtained with a single hopping time of 60 ps (implying a mean residence time of 12 ps) and a hopping time to the RC of 70 ps; extrapolating these results to room temperature yielded a perfect fit of the fluorescence data. At 4 K the fit was only qualitatively correct, in part due to the uncertainty about the homogeneous absorption and emission spectra at 4 K. The width of the inhomogeneous distribution

function (20 nm) was estimated to be about half of the bandwidth (40 nm).

The extrapolated hopping time of 60 ps between tetrameric clusters of BChl *a*, however, seemed too slow to be consistent with the annihilation and absorption anisotropy experiments. It was argued (van Mourik et al., 1993) that due to the use of periodic boundary conditions the simulation of Pullerits and Freiberg missed a phase in the relaxation due to energy transfer between different LH1-RC cores. Consequently, Pullerits and Freiberg had to attribute the observed 10–20 ps decay to an intra-LH1-RC core energy transfer process, which resulted in the slow hopping time. More recent accurate picosecond transient absorption and fluorescence measurements at 77 K (Pullerits et al., 1994), exciting LH1 in the blue wing and detecting the antenna transient absorption or fluorescence signals at various wavelengths over the absorption/fluorescence spectrum, showed that the decay of antenna excited states in the blue wing of the spectrum actually occurs with a 3–5 ps time constant and is coupled to an equally fast rise time of antenna bleaching/fluorescence in the red part of the spectrum. A master equation kinetic simulation of these experimental data, applying periodic boundary conditions to a unit containing several LH1-RC cores, resulted in a satisfactory fit of the 77 K picosecond absorption and fluorescence data using a hopping time of 2–3 ps (Pullerits et al., 1994). Although still larger than the hopping time extrapolated from annihilation experiments, the relative values are sufficiently close to make us confident about the correctness of the basic concepts. In this respect, a reevaluation of the annihilation experiment using a spectrally and spatially inhomogeneous antenna would be appropriate.

Very recent measurements using sub-100 fs pulses revealed that this picture is essentially correct, but that the fastest energy transfer processes occur on the few hundred femtosecond timescale (Chachivilis et al., 1994). Even faster processes (<100 fs) may also be present, representing relaxation between exciton states in a strongly coupled pigment (Pullerits et al., 1994b). In experiments with very short pulses (40 fs) an interesting longlived oscillatory decay of the antenna excited state population was observed (Chachivilis et al., 1994) and related to vibrational coherence in the BChl *a* pigment molecules. In the future it will be interesting to investigate the nature

of this coherence and its role in the energy transfer processes.

B. *Rhodospseudomonas viridis*

Until quite recently there was an almost complete lack of knowledge about the energy transfer dynamics in the LH1 antenna of *Rp. viridis*. The main reason for this was the absence of a suitable picosecond laser source in the wavelength range of BChl *b* absorption (960–1030 nm). At present, however, modelocked dye lasers and solid state lasers have become available that operate in the desired part of the spectrum and consequently, many new results on *Rp. viridis* may be expected in the near future. Using the picosecond photo-induced electric gradient technique, Trissl and coworkers (Deprez et al., 1986; Trissl et al., 1990) reported a trapping time of 40 ps in *Rp. viridis* whole cells with active reaction centers. Bittersmann et al. (1990) employed low-intensity excitation pulses and time-resolved fluorescence detection and reported a 80 ps fluorescence decay time. This difference in lifetimes may at least partially be ascribed to the fact that the electric measurements by Trissl et al. were performed with high intensity pulses due to which the excited state lifetime could have been shortened by singlet-singlet annihilation. Picosecond absorption measurements using low-intensity, tunable infrared (960–1020 nm) pulses provided more detailed results about the *Rp. viridis* excitation transfer dynamics (Zhang et al., 1992a). It was shown that the room temperature excited state lifetime is 60 ps in open centers, 90 ps in centers with reduced secondary acceptor (PIA_A^-) and 150 ps in centers with oxidized primary electron donor. Measurement of the time-resolved absorption anisotropy and isotropic absorption kinetics at several wavelengths at 77 K did not reveal any multi-exponential decay at the blue edge of the LH1 absorption spectrum (as was observed for BChl *a*-containing purple bacteria). The observation of a low, on a picosecond timescale constant polarization, ($r(0) = r(\infty) \leq 0.1$), is consistent with rapid (sub)picosecond energy transfer between differently oriented BChl *b* antenna molecules, and agrees with earlier steady-state measurements (Breton et al., 1985). Motivated by the observed single exponential antenna excited state decay and fast depolarization, the energy transfer and trapping in *Rp. viridis* was modeled by a homogeneous random-walk model (Pearlstein, 1982). Good agreement between

experiment and prediction was obtained provided the P^+IQ^- -PIQ bleaching spectrum measured in *Rp. viridis* membranes (Kleinherenbrink et al., 1992) was used to obtain the absorption spectrum of P in calculating the Förster spectral overlap integrals for energy transfer to/from P (Zhang et al., 1992a). It is known that the absorption spectrum of isolated reaction centers is blueshifted by about 20 nm at room temperature (Kleinherenbrink et al., 1992), which severely influences the overlap ratio for trapping and detrapping. However, the use of the bleaching spectrum is not completely free from problems since it may contain some contributions from a BChl *b* bandshift (see below). From this analysis (Zhang et al., 1992a) it was also concluded that energy transfer from antenna to the special pair (and escape from the reaction center) in *Rp. viridis* is fast, approx. 6 ps, based on the assumption that the antenna is organized as monomeric BChl *b* molecules and the reaction center has a six-fold coordination; with a mono-coordinate reaction center the trapping time would have to be approx. 1 ps in order to fit the experimental results. For the BChl *a*-containing purple bacteria it was mentioned above that the antenna most likely is organized in small clusters of $\alpha\beta$ -polypeptides holding 2–4 BChl molecules. If this also is the case for *Rp. viridis*, which is reasonable to believe, trapping and detrapping dynamics would in fact be very similar to that of the BChl *a*-containing purple bacteria, with relatively slow (25–30 ps) energy transfer from the antenna to the reaction center and very fast energy equilibration within the antenna.

A study of the efficiency of charge separation in *Rp. viridis* LH1-RC complexes as a function of temperature showed, (Kleinherenbrink et al., 1992) surprisingly, that the quantum yield of charge separation was independent of the excitation wavelength at 300 K and at 6 K, but the absolute efficiency, as measured by the amount of P^+ formed upon flash excitation, dropped to 55% upon cooling to 6 K. The fluorescence excitation spectrum showed no contribution from direct RC excitation in the wavelength range 780–860 nm. The effective rate of transfer from neighbouring pigments to the special pair was estimated to be $(1.3 \text{ ns})^{-1}$ at 6 K. Kleinherenbrink et al. (1992) suggested that this rate can only be compatible with the Förster theory for electronic energy transfer if the long-wavelength absorption bands are homogeneously broadened. However, low-temperature polarized fluorescence experiments on isolated LH1-RC complexes and

membranes (Monshouwer et al., unpublished) revealed highly polarized emission only upon excitation (with a narrow-banded laser) in the very red wing of the absorption spectrum, suggesting a similar behavior as the LH1 absorption bands of BChl *a*-containing purple bacteria (Kramer et al., 1984b; van Mourik et al., 1992a). Inhomogeneous broadening of the main absorption bands remained so far undetected and will further complicate the problem of excitation trapping at low temperatures. In membranes, the polarization effect is limited to the very red tail of the absorption band and therefore is probably difficult to detect with broad-band excitation (Deinum, 1991). Since time-resolved absorption (Zhang et al., 1992a) and fluorescence experiments at 23 K (Kleinherenbrink et al., 1993) only yielded a single decay time, the time for excitation energy transfer to these lowest states must be faster than a few picoseconds.

In general, we believe that the observed trapping kinetics and temperature dependence of the quantum yield for charge separation are not compatible with the proposed large energy difference between P^* and $LH1^*$ (Trissl et al., 1990; Zhang et al., 1992a; Kleinherenbrink et al., 1993). The calculation of this energy difference and of the relevant overlap integrals using the P^+ - P difference spectrum is possibly not correct. The difference spectrum measured in *Rp. viridis* membranes contains an unknown contribution of a BChl *b* bandshift, which may have caused an apparent blue shift to 1010 nm relative to the main absorption band (max at 1040 nm at 6 K). Also, the use of the spectrum of the isolated RC is not correct because that certainly is blue-shifted in position. The fact that trapping still has an efficiency of 55% at 6 K suggests that on the average P^* and $LH1^*$ are about equal in energy (apart from the entropic contribution). If both P and $LH1$ are inhomogeneously broadened, the number 55% may simply reflect the fraction of $LH1$ -RC cores in which P^* is the lowest energy state.

Excitation annihilation experiments (Deprez et al., 1986; Deinum et al., 1992a) have indicated significant competition between trapping by reaction centers and annihilation. The general theory for trapping, loss and annihilation (Den Hollander et al., 1983; van Grondelle, 1985) describes these results correctly if the finite duration of the laser pulse is accounted for (Deinum et al., 1991). At room temperature, the domains for annihilation are large (>15 RC- $LH1$ cores). At ultralow temperature, the annihilation becomes less efficient (which could be

due to inhomogeneity), but still sizable annihilation domains ($N_D > 100$) are estimated. This is consistent with the observation that the increase in fluorescence polarization occurs only in the very red edge of the absorption spectrum. Three effects may contribute to the relatively efficient energy transfer and annihilation at 4 K in *Rp. viridis*: (i) the $LH1$ -RC structure is highly organized and probably well connected, (ii) the width of the inhomogeneous distribution function is probably relatively small in the case of *Rp. viridis* (Monshouwer et al., unpublished) mitigating the effects due to lowering the temperature, and (iii), the Stokes shift of *Rp. viridis* is probably quite small, resulting in a high average transfer rate. Since in the excited state decay no 10–20 ps component is observed reflecting energy transfer within the inhomogeneous band (Zhang et al., 1992a; Kleinherenbrink et al., 1993) we have to conclude that this energy transfer process occurs at a rate of less than a few ps, even at 4 K.

V. Energy Transfer in LH2-Containing Purple Bacteria

A. Energy Transfer Pathways and Trapping in *Rhodobacter sphaeroides*

Rhodobacter (Rb.) sphaeroides is the best studied LH2 containing purple bacterial species. At room temperature and with open centers, picosecond absorption (Sundström et al., 1986) and fluorescence (Freiberg et al., 1988; Freiberg et al., 1989; Shimada et al., 1989) techniques monitoring the kinetics within the B850 or B875 absorption/emission bands, generally revealed a non-exponential decay with lifetime components of 20–40 and 70–100 ps. In fluorescence studies, a faster (< 10 ps) energy transfer component was dominant while a minor 40 ps phase corresponded to the decay observed in the single-color transient absorption measurements. The bi- (or multi-) exponentiality of the decay is a consequence of the complex antenna structure of this bacterium, and reflects the equilibration of energy between $LH1$ and $LH2$. Using a simple two-step equilibrium model involving $LH2$, $LH1$ and the RC it was shown (Sundström et al., 1986) that the measured trapping time of about 100 ps corresponds to an actual trapping time of 60 ps for the $LH1$ -RC core, i.e., the same value as observed for *Rs. rubrum* (Sundström et al., 1986) and $LH1$ -RC only mutants of *Rb. sphaeroides*

(Hunter et al., 1990). The very fast energy transfer step from B800 to B850 in LH2 is discussed in section VI.B.

In centers with oxidized primary electron donor (P^+), charge separation cannot occur and the excitation lifetime increases to 200–250 ps (Sundström et al., 1986; Freiberg et al., 1988; Freiberg et al., 1989; Shimada et al., 1989) similar to what was observed for *Rs. rubrum*. This shows again that the closed RC quenches antenna excitations rather efficiently. The LH1 \leftrightarrow LH2 equilibration appeared not to be affected by the RC redox state. Time-resolved absorption anisotropy experiments revealed a low ‘initial’ anisotropy ($r(0) \approx 0.1$) of the major LH2 (850 nm) absorption band. Such a behavior was also observed for the main LH1 absorption band of *Rs. rubrum* and is consistent with (sub-)picosecond energy transfer between neighbouring BChl molecules in LH1 and LH2 (Sundström et al., 1986; van Grondelle et al., 1987).

Measurements of energy transfer kinetics at low temperature (77 K) with improved spectral resolution permitted a much better resolution of the individual energy transfer steps (narrower spectral bands) and effectively unidirectional energy transfer. Recently, two-color pump-probe experiments were reported for *Rb. sphaeroides* at 77 K, in which the probing wavelength was varied over the 790–910 nm wavelength range (Zhang et al., 1992b). Excitation and detection in the B800 band showed that the approximate lifetime of the B800* excited state was between 1–2 ps at 77 K. The absorption changes in the B800 band were moderately polarized ($r(0) \approx 0.25$). Exciting the high-energy pigments (B800) and probing the arrival of the excitations on the low-energy pigments through the rise-time of the 910 nm ground state bleaching/stimulated emission revealed a major time-constant of about 10–12 ps, while the remaining part had a considerably slower rise of about 30–40 ps. Selective excitation of B850 in the wavelength range 830–860 nm and probing the arrival of excitations at 885 nm (in the middle of the LH1 band) or at 910 nm (at the edge of LH1 spectrum) showed that this biphasic risetime is the result of the spectral heterogeneity of B850, because excitation in the blue wing of the B850 spectrum resulted in a slower energy transfer to LH1. This wavelength dependent energy transfer can be represented by two spectral components with two different transfer times of 10 and 30–40 ps, respectively (Zhang et al., 1992b). However, it does not necessarily imply that there

exist two different forms of B850. The more likely explanation is that excitation in the blue wing of B850 results in more and possibly slower transfer steps than excitation of the main peak. Time-resolved fluorescence measurements have been interpreted in a similar way (Freiberg et al., 1988; Freiberg et al., 1989; Shimada et al., 1989) and Freiberg et al. (1989) proposed a model with two parallel pools of LH2, i.e. an inhomogeneity of both B800 and B850.

The 40 ps time-constant mentioned above, characterizing the B850 heterogeneity, was also observed in earlier single-wavelength pump-probe experiments (Sundström et al., 1986; van Grondelle et al., 1987) and on the basis of these experiments a sequential model was proposed, involving a single 30–40 ps step from LH2 to LH1. However, with the more detailed information from the two-color experiments (Zhang et al., 1992b) it is now clear that this relatively slow step involves only a minor part of the excitations and that the major part of the LH2 \rightarrow LH1 transfer is fast (< 5 ps). An accurate analysis of the absorption kinetics of *Rb. sphaeroides* (van Grondelle et al., 1987) and studies of the polarized spectroscopic (van Dorssen et al., 1988) and time-resolved absorption properties (Hunter et al., 1990) of an LH2-only mutant of *Rb. sphaeroides* suggested that at 77 K there is a pool of red pigments in LH2 (called B870) involved in the coupling of LH2 and LH1. It is highly likely that this ‘B870’ fraction originates from the inhomogeneous distribution of B850. Most time-resolved measurements available for *Rb. sphaeroides* thus show that energy equilibration over the entire antenna is fast ≤ 10 ps at both room temperature and 77 K. In combination with results from measurements of the trapping rate in the temperature interval 100–200 K, and results from measurements of detrapping yield and rate (Timpmann et al., 1993) in *Rs. rubrum* (see IV.A.1) this shows that energy transfer from the antenna to the reaction center is the rate limiting step in the overall energy migration and trapping process.

B. Energy Equilibration and Trapping in Other LH2-Containing Species

We will briefly summarize the results obtained with other LH2 containing purple bacteria. *Cm. minutisimum*, which has a pigment system very similar to that of *Rb. sphaeroides*, was studied with time-resolved fluorescence spectroscopy (Freiberg et al., 1988; Freiberg et al., 1989) and the results were very

similar to those obtained with *Rb. sphaeroides* on all essential points. Membranes of low-light *Rp. palustris*, in which the B800 band shows a pronounced exciton structure (possibly due to a tight packing of several B800 pigment molecules - see below) show ultrafast relaxation within the 800 nm exciton band, followed by excitation transfer via B850 to LH1 in at most a few ps (van Mourik et al. 1992c). The bacterium *Erythrobacter* sp. strain Och 114 having the unusual pigmentation B806–870, where B870 serves as LH1 and B806 as LH2, was investigated with time-resolved fluorescence spectroscopy (Shimada et al., 1990; Shimada et al. 1992). Despite the large energy difference between the two antenna species, energy was found to be transferred from B806 to B870 within the time resolution of the experiment (about 6 ps) at room temperature (Shimada et al., 1990), but significantly slower at 77 K (Shimada et al., 1992). A low-energy pigment component of LH1 (B888), contributing approximately 3 BChl/RC was also observed, with properties closely related to those reported for the low-energy components of *Rs. rubrum* and *Rb. sphaeroides*. The observed risetime of the B888 fluorescence of 9 ps agrees well with the observed rise-time of red-edge excitation in *Rb. sphaeroides* (Zhang et al., 1992b). A slower decay component in the B806 fluorescence, which was not observed as a corresponding risetime in the B888 fluorescence, suggested a heterogeneous decay pattern of B806, somewhat reminiscent of the situation for LH2 in *Rb. sphaeroides*. Low temperature experiments suggested that also in the B806 band energy transfer to low energy pigments precedes transfer to B870 (Shimada et al., 1992).

From a comparison of a five-component global analysis fit and a so-called global target analysis kinetic simulation to time-resolved fluorescence kinetic data of *Rb. capsulatus* membranes at room temperature, Holzwarth et al. (1993) arrived at conclusions that on several important points are in conflict with those described above for the very similar bacterium *Rb. sphaeroides*. Thus, it was concluded that, *i.* the overall antenna exciton dynamics is limited by the rate of charge separation (i.e. trap limited dynamics), and that the excited states of the LH1 core antenna and the special pair electron donor of the reaction center are equilibrated within less than 3 ps; and *ii.* LH2 → LH1 energy transfer at room temperature occurs with a time constant of 9 ps. Both of these conclusions are difficult to reconcile with most of the available data

for *Rb. sphaeroides* and similar bacteria. Thus, from direct measurements of trapping (Bergström et al., 1989; Visscher et al., 1989) and detrapping (in *Rs. rubrum* (Timpmann et al., 1993)) the energy transfer from the antenna to the special pair was shown to be slow, 35–40 ps, both at room temperature and lower temperature (100–200 K). Further, the suggestion of $\tau \leq 3$ ps equilibration time of the excitation energy over the LH1-special pair pigments is expected to lead to an approximately $1/N$ population probability of the special pair (N = number of LH1 antenna molecules per reaction center). Following selective excitation of P this would consequently lead to a much higher detrapping yield than the 25% experimentally found for *Rs. rubrum* at room temperature (Timpmann et al., 1993) (see also IV.A.1). This comparison relies on the reasonable assumption that *Rb. sphaeroides* and *Rs. rubrum* are similar in this respect. The LH2 → LH1 energy transfer time constant (9 ps) deduced from the analysis of the fluorescence data is considerably longer than what has been concluded for *Rb. sphaeroides* from transient absorption (van Grondelle et al., 1987; Zhang et al., 1992b) and time resolved fluorescence measurements at 77 K (Freiberg et al., 1988, 1989; Shimada et al., 1989), pointing to a LH2 → LH1 transfer time of ≤ 5 ps; at room temperature the transfer is most likely faster than this.

VI. Energy Transfer in Isolated Light-Harvesting Complexes and Mutants

A. LH1

If detergent-purified LH1 is analyzed on an LDS-polyacrylamide gel, a discrete set of complexes $(\alpha\beta)_n$ is observed with $n \geq 3$ (Westerhuis et al., 1987; Hunter et al., 1988). All complexes absorb around 870 nm and the absorption maxima shift slightly further to the red with increasing n (Westerhuis et al., 1987, 1992). Excitation annihilation (van Grondelle et al., 1983) and polarized fluorescence (Westerhuis et al., 1987, 1992) experiments have shown that the various BChl molecules in these LH1 complexes are well coupled. For the LH1-only mutant of *Rb. sphaeroides* M2192, annihilation experiments indicated large domains at room temperature ($N_D > 100$) (Vos et al., 1988).

The excited state decay of LH1 is slow, even at room temperature, and takes about 650 ps for the

detergent-isolated form (Sebban et al., 1985; Bergström et al., 1988a; Freiberg and Timpmann, 1992) and 450 ps for the LH1-only mutant M2192 (Hunter et al., 1990), which is consistent with what is expected for a spectrally 'homogeneous' pigment decoupled from any energy acceptors. At 77 K, excitation of LH1 of *Rb. sphaeroides* in the major absorption peak resulted in a biphasic decay with a fast ~20 ps phase dominant in the blue edge of the spectrum followed by a slow decay of the excited state with maximum amplitude in the red wing of the spectrum (900 ps in the detergent isolated LH1 complex, 400 ps in M2192 mutant of *Rb. sphaeroides*). Time-resolved absorption anisotropy of detergent isolated LH1 (Bergström et al., 1988a) and the LH1-only mutant M2192 (Hunter et al., 1990) showed that (sub)picosecond depolarization occurs, probably as a result of very fast ($\geq 10^{12} \text{ s}^{-1}$) energy transfer within a minimum unit of LH1. More recent and more accurate transient absorption measurements of *Rs. rubrum* chromatophores at 77 K with blue wing excitation at 870 nm and probing in the range 885–905 nm showed that the decay of bleaching in the blue part of the spectrum occurs with a lifetime of approx. 3–5 ps and is correlated with an equally fast risetime of bleaching/stimulated emission on the red side of the spectrum (Pullerits et al., 1994), see section IV.A.2. Time- and spectrally resolved fluorescence experiments of detergent-isolated LH1 of *Rs. rubrum* were performed at low temperatures down to 4 K (Freiberg and Timpmann, 1992). The observed kinetics depended strongly on the excitation wavelength; the shortest decay times of 10–20 ps were observed on the blue side of the emission spectrum, whereas above 940 nm the emission was essentially monoexponential with a decay time of 940 ps at 4 K. In all cases the kinetics were taken to reflect energy transfer in a spectrally heterogeneous system. Measurement of the polarized LH1 fluorescence spectrum as a function of narrow-banded excitation at 4 K showed a characteristic shift of the emission maximum which was interpreted to reflect energy transfer within an inhomogeneously broadened cluster of coupled BChl *a* molecules (van Mourik et al., 1992a).

B. LH2

Energy transfer properties of a variety of LH2 complexes have been studied extensively over the past few years, and they all demonstrate rather similar

characteristics. Both stationary and time-resolved absorption and fluorescence experiments have indicated that energy transfer among the B850 pigments is fast ($< 1 \text{ ps}$) and leads to ultrafast depolarization of the excited state. At 77 K spectral equilibration phenomena were observed to take place on a 10–20 ps time-scale (Bergström et al., 1988b), very similar to LH1.

The most conspicuous feature of LH2 is the energy transfer process from B800 to B850, which may be one of the best studied photosynthetic energy transfer processes. At room temperature, the emitting B800 excited state is fully equilibrated with the B850 excited state (van Grondelle et al., 1982). From early fluorescence yield measurements it was estimated that at 4 K this energy transfer process occurs within 2–3 ps (van Grondelle et al., 1982). Later experiments with picosecond time-resolution indicated a time-constant of 1–2 ps at 77 K and somewhat faster rate at room temperature (Bergström et al., 1986, 1988b). In the so-called B800–820 complex of *Rp. acidophila* strain 7050 the energy transfer from B800 to B820 was observed to take place within 0.5 ps at 77 K, consistent with the improved spectral overlap for B800 → B850 transfer (Bergström et al., 1988b). In a transient absorption experiment with 0.2 ps time-resolution using the B800–850 complex of *Rb. sphaeroides*, Shreve et al. (1991) concluded that the room temperature energy transfer time is $0.6 \pm 0.1 \text{ ps}$ upon direct B800 excitation. Spheroidene excitation yielded a transfer time of about 2–3 ps (Trautman et al., 1990), which was later interpreted as sphaeroidene → B800 excitation transfer (Shreve et al., 1991). Direct sphaeroidene → B850 excitation transfer would still result in sub-ps kinetics (Shreve et al., 1991). Visscher et al. (1993a, 1993b) extended these measurements to LH2 complexes of several other species and to low temperature (77 K), by using low-intensity one-color pump-probe spectroscopy with 0.5 ps pulses. These measurements unequivocally showed that the B800 → B850 energy transfer time at room temperature is $0.7 \pm 0.1 \text{ ps}$ in *Rb. sphaeroides*. At 77 K the transfer rate slows down by a factor of 3–4, and was observed to be 2.4 ps in a chromatophore preparation of *Rb. sphaeroides* (Visscher et al., 1993a, 1993b). The same LH2 complex isolated and solubilized with LDAO displayed a slightly faster B800 → B850 transfer, 1.7 ps at 77 K, probably as a result of more extensive aggregation in the isolated complex than in vivo. Visscher et al. (1993a, 1993b) also measured the B800 excited state lifetime in

membranes of *Rp. palustris* HL and LL and in the detergent isolated B800–820 complex of *Rp. acidophila* strain 7050. In both species of *Rp. palustris* the excited state lifetime and thus the B800 → B850 energy transfer time constant, was found to be slightly shorter than in LH2 of *Rb. sphaeroides*, i.e. 1.5 ± 0.1 ps. For B800–820 the energy transfer at 77 K was even faster, ~ 0.8 ps. The temperature dependence of the B800 → B850 transfer time and variation with bacterial species suggested that the B800 → B850 transfer is principally controlled by the spectral overlap between the B800 donor and B850 acceptor pigments, at least at room temperature and 77 K. This was verified by subpicosecond absorption measurements on LH2 mutants of *Rb. sphaeroides* (Hess et al., 1994) in which the TyrTyr motif of the α -polypeptide at positions 44 and 45 had been replaced successively by PheTyr and PheLeu, resulting in spectral blueshifts to 839 and 826 nm, respectively (Fowler et al., 1992). The latter configuration is the same as that found in B800–820 of *Rp. acidophila*, and the energy transfer time from B800 measured in this mutant agreed very well with that observed in the native complex. The single mutations (Phe44, Tyr45 or Tyr44,Phe45) having an absorption band at 839 nm, intermediate between the 850 and 826 nm bands, displayed an intermediate excited state lifetime between that of B800–850 and B800–820, i.e. 1.5 ps. Spectral hole burning experiments were consistent with a B800 → B850 transfer time of 2.3–2.5 ps between 1.2 and 30 K in membranes of *Rb. sphaeroides* (van der Laan et al., 1990; Reddy et al. 1991, 1992a) and of 1.8 ps in membranes of *Rp. acidophila* (Reddy et al., 1992b). Hole burning experiments on the spectrally blueshifted LH2 mutants mentioned above (B839 and B826) at 1.6 K (van der Laan et al., 1993), exhibited a smaller variation of energy transfer time than what was observed in time resolved measurements with 500 fs pulses (Visscher et al., 1993a,b) and a much smaller variation than could be expected on the basis of the spectral overlap between the B800 homogeneous fluorescence spectral bandwidth and the B850 absorption. Consequently, it was suggested that energy transfer occurs from B800 to a broad vibronic structure of B850. A similar mechanism for B800 → B850 energy transfer at very low temperatures was earlier suggested by Reddy et al. (1992a) to account for hole burning results on B800 → B850 energy transfer of *Rb. sphaeroides*.

In the original model of Kramer et al. (1984a),

energy transfer among (at least two) B800 molecules was assumed to take place on a timescale (~ 1 ps) that competes with the B800 → B850 transfer to explain the observed low polarization of the B800 emission upon selective Q_x -excitation. Subsequent room temperature and low-temperature absorption anisotropy measurements using single wavelength pump-probe spectroscopy resulted in different $r(0)$ values, somewhat dependent on the wavelength of excitation/probing, on the species and on temperature (Bergström et al., 1986, 1988b). However, a high (0.3–0.35) and time independent anisotropy was generally observed in the B800 band, suggesting only limited B800 ↔ B800 energy transfer, in apparent disagreement with the model of Kramer et al. (1984a). Anisotropy measurements with 0.5 ps pulses within the B800 absorption band of several species (*Rb. sphaeroides*, *Rp. palustris* HL and LL, and *Rp. acidophila* B800–820) at 77 K identified and discussed problems associated with obtaining dynamical information from the observed anisotropies (Visscher et al., 1993b). It was concluded that the initial B800 anisotropy in all studied species was high (≥ 0.35), but that in most cases the rate and extent of anisotropy decay could not be unambiguously ascertained due to interference from strong and depolarized B850 excited state absorption. Nevertheless, the results suggested at the most partial depolarization on the time scale of the B800 excited state lifetime, i.e. within 5–10 ps. This implies that at 77 K B800 ↔ B800 energy transfer within the inhomogeneously broadened B800 band is slower than B800 → B850 transfer, or that transfer occurs between B800 molecules with close to parallel transition dipole moments. The dynamics within the 800 nm band were examined further in very recent time resolved absorption measurements with better time resolution (< 100 fs). An accurate description of the contribution from excited state absorption to the measured anisotropy kinetics (Hess et al., 1993b), confirmed and substantiated the earlier results obtained with lower time resolution (Visscher et al., 1993a, 1993b). Thus, at room temperature a 0.9–1.5 ps decay of anisotropy was observed in both *Rb. sphaeroides* and *Rp. palustris*, which is considerably slower than the isotropic B800 excited state decay (0.6–0.8 ps). At 77 K the anisotropy decay was slowed down to the extent that no decay was clearly discernible within the available observation window of approx. 5 ps, set by the B800 excited state lifetime. Simultaneously, the magic-angle decay of the B800

excited state, measured in the blue wing of the 800 nm band, was observed to be strongly nonexponential (Hess et al., 1993b), with a 200–300 fs decay component in addition to the previously detected 0.6–0.8 ps or ~2.4 ps lifetime at room temperature and 77 K, respectively. This very fast relaxation was found to be almost independent of temperature and, interestingly, it was not correlated to a similar decay of anisotropy, showing that if this process reflects energy transfer between spectrally dissimilar B800 molecules ($B800^{\text{blue}} \rightarrow B800^{\text{red}}$) the transition dipoles of the participating molecules have to be close to parallel. Early hole burning experiments on LH2 of *Rb. sphaeroides* did not resolve any wavelength dependence of the holewidth across the 800 nm band or broad holes on the red side of the spectrum (following blue excitation) indicative of downhill $B800^{\text{blue}} \rightarrow B800^{\text{red}}$ energy transfer (van der Laan et al., 1990; Reddy et al., 1991, 1992a). However, studies of *Rp. acidophila* 7750 (B800–850) showed that blue excitation produced such broad holes in the red wing of the B800 band (Reddy et al., 1992b). An analysis of the efficiency of spectral hole burning vs. the burning wavelength and vs. laser power in LH2 of *Rb. sphaeroides* showed that a narrow 2.4 ps hole was only present in the red wing of the B800 band (van der Laan et al., 1993). Upon burning at shorter wavelengths the holewidth gradually increased, indicating a shorter excited state lifetime in the blue wing of the 800 nm band. The shortest lifetime observed in that experiment was about 600 fs. Thus, independent results from femtosecond time resolved, hole burning and steady-state fluorescence polarization spectroscopies show that there exist fast relaxation processes within the B800 band, in addition to the decay associated to $B800 \rightarrow B850$ energy transfer. Energy transfer from ‘blue’ to ‘red’ B800 pigments ($B800^{\text{blue}} \rightarrow B800^{\text{red}}$) is a very likely origin of this relaxation process, but there still remains some ambiguity as to the relative orientation of the transition dipoles participating in the transfer process.

Excited state relaxation times on the several hundred femtosecond time scale have frequently been observed in various dye molecules in solution and attributed to vibrational relaxation or cooling and solvation processes (Elsaesser and Kaiser, 1992). Such processes are also to be expected in the pigment molecules of a biological pigment-protein complex, although little quantitative information so far is available. However, time resolved measurements on various porphyrin molecules (Bilsel et al., 1993) as well as on bacteriochlorophyll *a* in solution (Becker

et al., 1990; Åkesson and Sundström, unpublished) showed the presence of approx. 0.5–1 ps relaxation processes, that most likely reflect vibrational relaxation and cooling of the excited molecules. The necessity to consider such relaxation processes, in order to account in full detail for the dynamics observed in a biologically active system of dipole coupled chromophores, exhibiting energy transfer on the picosecond to subpicosecond time scale was therefore discussed (Visscher et al., 1993b).

Summary

The close association of carotenoids and bacteriochlorophylls in anoxygenic photosynthetic bacteria facilitates energy transfer processes between these molecules. A better understanding of the association between these two groups of pigments has been derived from significant, recent advances in: (1) The biochemical methodology for the separation and purification of pigment-protein complexes from photosynthetic bacteria; (2) The chemical procedures for the extraction, identification, and reconstitution of carotenoids into these complexes; (3) The analytical techniques for the chromatographic separation and purification of the carotenoid pigments; (4) The steady-state and time-resolved absorption and fluorescence spectroscopic techniques for exploring the nature of the excited states of carotenoids; and (5) Our understanding of the theoretical framework in which the photochemical properties of carotenoids may be cast. The present chapter will discuss these advances and attempt to provide a connection between the unique electronic structure of carotenoids and the manner in which they function as antenna pigments in photosynthesis.

I. Introduction

The abundance of carotenoids in photosynthetic preparations bears witness to the essential roles these pigments play in photosynthesis. Carotenoids are capable of at least three types of photochemical reactions in the photosynthetic apparatus: (1) Quenching of chlorophyll triplet states; (2) Quenching of chlorophyll singlet states; and (3) Singlet energy transfer from carotenoid to chlorophyll. The first two of these processes provide mechanisms by which carotenoids protect photosynthetic systems from singlet oxygen (generated by chlorophyll triplet states) and the harmful effects of excess light energy. We shall focus on singlet energy transfer from carotenoids, paying particular attention to prokaryotic photosynthetic bacteria. Recent advances in this area have come from systematic studies of the energies and decay rates of carotenoid excited states and measurements of the efficiencies of carotenoid-to-chlorophyll singlet energy transfer *in vivo*. In this chapter we shall explore the relationships between carotenoid electronic structure and the efficiency of energy transfer.

II. The Electronic Structure of Carotenoid Excited States

The photochemistry of carotenoids can be traced to the unique electronic properties of their conjugated π -electron frameworks (Zechmeister, 1962; Kohler 1993). Most carotenoids contain C_{40} carbon skeletons, corresponding to eight isoprene units. The number of conjugated C=C bonds in naturally occurring carotenoids ranges from 3 (e. g. phytoene) to 13 (e. g. spirilloxanthin) with 9–11 conjugated double bonds being typical for many of the carotenoids involved in photosynthesis (neurosporene, spheroidene, β -carotene, etc.). In addition, carotenoids with up to 19 double bonds have been obtained synthetically (Karrer and Eugster, 1951). The energies and dynamics of polyene excited states (the lowest energy excited singlet (S_1) and triplet (T_1) states are of particular importance in understanding energy transfer) are sensitive to the length of conjugation. The connection between biological function and the carotenoid structure is a topic of considerable interest.

Our current understanding of the low energy electronic states of carotenoids, in large part, is based on experimental and theoretical studies of shorter model systems (Hudson et al., 1982 and 1984; Kohler, 1991). Experimental studies of simple polyenes have exploited their relatively high fluorescence yields and their ability to be incorporated into low temperature n-alkane mixed crystals (Granville et al., 1979; D'Amico et al., 1980; Snyder et al., 1985; Simpson et al., 1987; Kohler et al., 1988). These crystals provide single, well-defined polyene conformations and homogeneous distributions of solvent/solute interactions resulting in vibronically-resolved absorption, fluorescence, and fluorescence excitation spectra. Such spectra lead to precise assignments of electronic and vibrational states and accurate determinations of electronic energies. Since energy transfer from carotenoids originates from vibrationally relaxed, electronically excited states, the 'zero-point' levels of these states are of particular relevance in understanding carotenoid/chlorophyll interactions. The high resolution experiments recently have been extended to model polyenes in molecular beams (Leopold et al., 1984; Heimbrook et al., 1984; Buma et al., 1990, 1991, 1992; Bouwman et al., 1990; Petek et al., 1991, 1992, 1993), resulting in an unprecedented view of the electronic and vibrational states of cold, isolated molecules. Although similar experiments are not yet feasible for carotenoids, these high-resolution results are critical for interpreting the typically broad optical spectra obtained from carotenoid solutions.

It is important to emphasize the profound importance of fluorescence spectroscopy in detecting and understanding the nature of the lowest energy S_1 states of polyenes/carotenoids. The high fluorescence quantum yields of intermediate length polyenes (e.g., octatetraene has $\phi_f \sim 0.6$ in low temperature glasses and mixed crystals (Gavin et al., 1978) has been a major factor in establishing these molecules as prototypical, linearly conjugated molecules. In contrast, shorter polyenes (e.g., unsubstituted dienes and trienes) and longer polyenes (e.g., β -carotene, spheroidene, and many other carotenoids of biological relevance) have fluorescence yields of 10^{-4} or less (Petek et al., 1992; Bondarev et al., 1988 and 1989; Gillbro et al., 1989; Cosgrove et al., 1990). The extremely low fluorescence yields of these compounds have presented significant barriers to the detection of their lowest excited singlet states (S_1)

This turns out to be a critical issue, since the lowest energy, $S_0 \rightarrow S_1$ absorptions in polyenes are extremely weak and difficult to detect on the tails of the $S_0 \rightarrow S_2$ absorptions responsible for the intense colors of the carotenoid family.

The $S_1 \rightarrow S_0$ and $S_0 \rightarrow S_1$ transitions have been directly detected in polyene/n-alkane mixed crystals using fluorescence and fluorescence excitation techniques, and it is to these experiments that we owe much of our current understanding of the nature of the S_1 states in linearly conjugated systems. The most characteristic signature of these spectra is the large ($\sim 2000\text{--}7000\text{ cm}^{-1}$) shift in energy ('Stokes-shift') between spectral origins (0-0) of the strongly allowed, $S_0 \rightarrow S_2$ absorptions and the $S_1 \rightarrow S_0$ emissions. In addition, the S_1 states exhibit anomalously long fluorescence lifetimes (Hudson et al., 1972, 1973, 1982 and 1984). These features can be explained by the following ordering of singlet electronic energies: $S_0(1^1A_g) < S_1(2^1A_g) < S_2(1^1B_u)$. See Fig. 1. The fluorescence thus corresponds to a symmetry-forbidden, $2^1A_g \rightarrow 1^1A_g$ transition which lies below the strong, symmetry-allowed $1^1A_g \rightarrow 1^1B_u$ absorption. The Stokes-shifts thus provide accurate measures of the $1^1B_u \rightarrow 2^1A_g$ energy differences. The above energy scheme has been verified by high-level calculations on model systems (Schulten et al., 1972 and 1976; Ohmine et al., 1978; Tavan et al., 1979 and 1986; Orlandi et al., 1991). Theory shows that simple molecular orbital models (e.g., Huckel theory which incorrectly predicts a $1^1A_g < 1^1B_u < 2^1A_g$ ordering for the lowest electronic states) do not adequately treat the effects of electron-electron repulsion of the π electrons in the polyene chains. Though the u and g symmetry labels (and the concepts of strictly 'allowed' or 'forbidden' transitions) apply only to polyenes with centers of symmetry (e.g., β -carotene), all polyenes seem to exhibit the same electronic energy orderings and similar relative transition strengths. We shall retain the idealized symmetry labels in discussing the low lying energy levels of carotenoids.

Extending the optical studies of model systems to carotenoids has been hampered by their broad, almost featureless spectra and extremely low fluorescence yields. Early reports of fluorescence from β -carotene indicated an emission origin coinciding with the origin of the strongly allowed, $1^1A_g \rightarrow 1^1B_u$ absorption (Cherry et al., 1968; van Riel et al., 1983; Haley and Koningstein, 1983; Watanabe et al., 1986; Bondarev et al., 1988, 1989). It is important to note that van

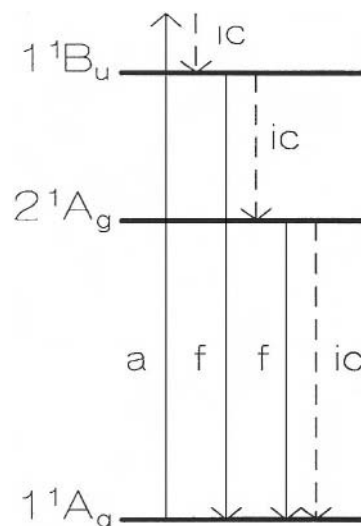

Fig. 1. Schematic representation of the ordering of excited state energies and the intramolecular photochemical processes (a, absorption; f, fluorescence; and ic, internal conversion) carotenoids and polyenes can undergo. The states are labeled by the idealized group theoretical representations in the point group C_{2h} .

Riel et al. (1983) and Bondarev et al. (1988) obtained fluorescence excitation spectra of the weak emission, thus correcting a fundamental shortcoming of the reports of β -carotene fluorescence by Cherry et al. (1968), Haley and Koningstein (1983) and Watanabe et al. (1986). The good agreement between the $1^1A_g \rightarrow 1^1B_u$ absorption and the fluorescence excitation spectra proved the existence of β -carotene fluorescence. Later work of Gillbro and Cogdell (1989) and Cosgrove et al. (1990) confirmed the presence of $1^1B_u \rightarrow 1^1A_g$ ($S_2 \rightarrow S_0$) emissions in β -carotene and related carotenols. The detailed studies of shorter polyenes allows us to identify the emission spectra of β -carotene and other long carotenoids as being due to $S_2 \rightarrow S_0$ fluorescence. $S_1 \rightarrow S_0$ ($2^1A_g \rightarrow 1^1A_g$) emission has not yet been detected in β -carotene, spheroidene, or other carotenoids with more than nine conjugated double bonds, leaving the location of their 2^1A_g states subject to indirect detection.

An early attempt to locate the low-lying 2^1A_g state in β -carotene was made by Thrash et al. (1977, 1979) using resonance Raman excitation profiles. This work suggested that the 2^1A_g state was $\sim 3500\text{ cm}^{-1}$ below the 1^1B_u state placing the S_1 (2^1A_g) states of β -carotene and other carotenoids well above the S_1 (Q_y) states of most chlorophylls. These energetics have been widely cited in discussions of the antenna function of carotenoids in photosynthesis (Siefer-

mann-Harms, 1985). However, a relatively small S_2 - S_1 energy difference for β -carotene was not consistent with trends noted in shorter polyenes (Snyder et al., 1985; Cosgrove et al., 1990). Furthermore, a later investigation of the Raman excitation profiles of β -carotene (Watanabe, et al., 1987) could not reproduce the Thrash et al. (1977 and 1979) results. This showed that Raman excitation profiles shared the same limitations as standard absorption measurements in detecting weak $1^1A_g \rightarrow 2^1A_g$ transitions on top of strong $1^1A_g \rightarrow 1^1B_u$ absorption tails. Location of the 2^1A_g state in β -carotene and other carotenoids thus has relied on the extrapolation of trends observed in the $2^1A_g \rightarrow 1^1A_g$ transition energies of shorter, more fluorescent polyenes.

Cosgrove et al. (1990) carried out a systematic study of the connection between the fluorescence properties of shorter polyenes (relatively strong emissions from S_1 (2^1A_g)) and longer carotenoids (weak emissions from S_2 (1^1B_u)). A series of carotenols with 7–11 conjugated double bonds was purified using HPLC techniques, and absorption, fluorescence, and fluorescence excitation spectra were obtained in 77 K glasses. The shorter, less conjugated members of this series exhibited the Stokes-shifted $S_1 \rightarrow S_0$ emissions of short model polyenes. Optical spectra of the carotenols are significantly broader due to well-understood complications brought about by twisting of the cyclohexenylidene end group (Christensen and Kohler 1973; Hemley and Kohler 1977). Nevertheless, as illustrated in the comparison of the fluorescence excitation and emission spectra of β -apo-12'-carotenol and hexadecaheptaene (Fig. 2), there is sufficient resolution in the carotenol spectra to allow the accurate identification of electronic origins. An important feature of Fig. 2 is the almost identical $2^1A_g \rightarrow 1^1A_g$ transition energies of the two heptaenes. This illustrates that in β -apo-12'-carotenol the loss in conjugation due to the nonplanarity between the ring and side-chain is offset by the stabilizing effects of the isoprenoid structure, making hexadecaheptaene an unexpectedly appropriate model for the more complicated carotenol. (By implication, we might predict that the electronic states of β -carotene will have energies quite similar to those of corresponding states of model polyenes with eleven co-planar double bonds.)

Cosgrove et al. (1990) found that the fluorescence of carotenols with more than eight conjugated double bonds was dominated by 'anti-Kasha' $S_2 \rightarrow S_0$ fluorescence as previously had been observed for β -

Fig. 2. Comparison of fluorescence and fluorescence excitation spectra of all-trans-2,4,6,8,10,12,14-hexadecaheptaene (dashed lines) and all-trans- β -apo-12'-carotenol (solid lines). The fluorescence spectrum of hexadecaheptaene in *n*-pentadecane at 77 K was obtained by exciting at 414 nm, and the fluorescence excitation spectrum monitored the emission intensity at 558 nm. The fluorescence spectrum of β -apo-12'-carotenol in 77 K EPA was obtained by exciting at 413 nm. The excitation spectrum was obtained by monitoring the fluorescence intensity at 650 nm. This figure from Cosgrove et al. (1990) was reproduced with permission.

carotene (van Riel et al., 1983; Watanabe et al., 1986; Bondarev et al., 1988; Gillbro et al., 1989). The cross-over from $S_1 \rightarrow S_0$ to $S_2 \rightarrow S_0$ emissions was attributed to a larger $S_2 \rightarrow S_1$ energy difference and the resultant decrease in $S_2 \rightarrow S_1$ radiationless decay (following the 'energy-gap law' of Englman and Jortner, 1970). This allows S_2 emission to compete with internal conversion. The lack of S_1 fluorescence prohibits the direct observation of the S_1 state in longer carotenoids. Nevertheless, trends noted in the model polyenes suggested 2^1A_g energies considerably lower than those originally suggested by the work of Thrash et al. (1977 and 1979).

DeCoster et al. (1992) extended the Cosgrove (1990) study to provide a systematic comparison of the energy levels of a series of α,ω -dimethylpolyenes (for which the vibronic resolution allows accurate measurement of electronic energies) with a series of iso-structural spheroidene analogs varying only in their extent of conjugation (7, 8, 9 and 10 double bonds). See Fig. 3. The energies of the S_2 and S_1 electronic origins are summarized in Fig. 4. The Cosgrove (1990) study points to the following conclusions: (1) The S_2 - S_1 energy difference increases with increasing conjugation, (2) The S_2 and S_1 energies

Fig. 3. The structures of several polyenes and carotenoids discussed in the present work

of the more highly substituted spheroidenes are lower than those of α,ω -dimethylpolyenes with the same conjugation, (3) Spheroidene (like β -carotene) is essentially an S_2 emitter, (4) Of particular interest for this review is the comparison of the extrapolated S_1 energies of spheroidene and β -carotene with the S_1 energies of bacteriochlorophylls and chlorophylls. These extrapolations place the S_1 (2^1A_g) energy of spheroidene at $14,000$ – $14,500\text{ cm}^{-1}$, above the S_1 levels of bacteriochlorophylls, allowing singlet energy transfer to occur via the spheroidene 1^1A_g state. However, the data presented in Fig. 4 strongly suggest

the possibility that the S_1 state of β -carotene (11 double bonds) lies below the S_1 state (Q_y) of its chlorophyll acceptor.

Recent estimates of the 2^1A_g energies of spheroidene, β -carotene and other long carotenoids appear to span a rather wide range. For example, Watanabe et al. (1993) suggest a 2^1A_g energy for spheroidene of $14,900\text{ cm}^{-1}$ (hexane)/ $14,600\text{ cm}^{-1}$ (CS_2). Mimuro et al. (1993) have reported the observation of the $2^1A_g \rightarrow 1^1A_g(0-0)$ transition for neurosporene at $\sim 16,000\text{ cm}^{-1}$, an energy considerably above the $15,300\text{ cm}^{-1}$ obtained by DeCoster et al. (1992) from fluorescence spectra (Fig. 4). The fluorescence assigned to $2^1A_g \rightarrow 1^1A_g$ emission by Watanabe et al. (1993) has almost all of its intensity in a single vibronic band (673 nm) analogous to a porphyrin derivative. This contrasts with the extended vibronic development of typical $2^1A_g \rightarrow 1^1A_g$ polyene emissions (e. g. Fig. 2). Analysis of the weak, long wavelength absorption spectrum of neurosporene (Mimuro et al., 1993) probably overestimates the 2^1A_g zero-point energy. Franck-Condon envelopes of polyene $2^1A_g \leftarrow 1^1A_g$ absorptions show a steep monotonic rise in vibronic intensities with increasing energies due to the $(\Delta E)^{-2}$ energy dependence of vibronic mixing between the 2^1A_g and 1^1B_u states (Petek et al., 1991). This is clearly evident in high resolution spectra of model polyenes (Simpson et al., 1987; Kohler et al., 1988). The $2^1A_g \leftarrow 1^1A_g(0-0)$ bands are thus extremely weak compared to higher energy vibronic bands, making them difficult to detect in low resolution experiments.

Similar uncertainties in estimates of the 2^1A_g energy of β -carotene are probably of more relevance, given the possibility that this state may not have enough energy to participate in energy transfer to chlorophyll a ($S_1(Q_y)$ energy of $\sim 15,000\text{ cm}^{-1}$ (Sauer (1975))). For example, Andersson et al. (1992a) have obtained $S_1 \rightarrow S_0$ fluorescence spectra from the shorter members of a series of β -carotene analogs. Based on estimates of (0-0) energies of shorter members of this series (unlike the spectra of spheroidenes and model polyenes, the fluorescence spectra of the carotene analogs are not sufficiently resolved to observe electronic origins), these authors estimate a β -carotene 2^1A_g energy of $\sim 14,500\text{ cm}^{-1}$. This is significantly higher than the value predicted from extrapolation of the data presented in Fig. 4 and might permit energy transfer from 2^1A_g . Andersson et al. (1992a) also suggest that the $S_2 \rightarrow S_1$ energy gap does not increase with increasing conjugation, a

Fig. 4. $S_0 \rightarrow S_1$ ($1^1A_g \rightarrow 2^1A_g$) and $S_0 \rightarrow S_2$ ($1^1A_g \rightarrow 1^1B_u$) transition energies for α, ω -dimethylpolyenes and spheroidenes as a function of conjugated length. Energies of the S_1 states are the electronic origins (0-0 bands) observed for $S_1 \rightarrow S_0$ fluorescence in room temperature methanol. Energies of the S_2 states are the electronic origins (0-0 bands) observed for $S_0 \rightarrow S_2$ absorption in room temperature methanol. Dimethyl polyene data are from Morey and Christensen (unpublished data) and Kohler et al., (1988). Chlorophyll a ($Q_x = 575$ nm, $Q_y = 660$ nm) and bacteriochlorophyll a ($Q_x = 573$ nm, $Q_y = 769$ nm) transition energies in diethyl ether at room temperature are taken from Sauer (1975). This figure from DeCoster et al. (1992) was reproduced with permission.

result inconsistent with trends noted both in model polyenes and the spheroidenes. Haley et al. (1992) recently suggested a β -carotene 2^1A_g energy of $\sim 14,200 \pm 400$ cm^{-1} , based on the *maximum intensity* of the reflectance spectrum in zeolite. However, as discussed above, a broad spectrum does not facilitate the identification of a relatively weak electronic origin which very likely lies on the long wavelength tail of the 700 nm peak. Another intriguing result is the recent observation of a weak absorption background in the inverse Raman (Raman loss) spectrum of canthaxanthin (Jones et al., 1992). This shows evidence for a low lying absorption at ~ 600 – 700 nm, though the identification of the (0-0) band of the $2^1A_g \leftarrow 1^1A_g$ transition again is subject to considerable uncertainty. Though the earlier (Thrash et al., 1977, 1979) estimates of the 2^1A_g energy of β -carotene clearly should be abandoned, higher resolution spectroscopic work will be needed to accurately locate the $2^1A_g \leftarrow 1^1A_g$ electronic origins in β -carotene and other long carotenoids.

III. The Dynamics of Carotenoid Excited States

A wide variety of methods have been employed for measuring the excited state dynamics of carotenoids. Indirect methods include ground state depletion

(Dallinger et al., 1981b; Wylie and Koningstein 1984), lifetime broadening of resonance-Raman spectral lines (Haley and Koningstein 1983), time resolved resonance-Raman spectroscopy (Noguchi et al., 1989; Hashimoto and Koyama 1990; Kuki et al., 1990) and emission yield determinations (Shreve et al., 1991a; Gillbro and Cogdell 1989; Cosgrove et al., 1990; Katoh et al., 1991; Mimuro et al., 1991; and Andersson et al., 1991). The direct methods are picosecond (Wasielewski and Kispert 1986; Gillbro and Cogdell 1989) and femtosecond (Shreve et al., 1991b and 1991c, Frank et al., 1993) time resolved transient absorption measurements.

A. Dynamics of S_1 States

The lifetimes of the 2^1A_g states of a range of carotenoids have now been investigated. Using picosecond transient absorption spectroscopy, S_1 lifetimes of 8.4 ± 0.6 ps for β -carotene, 5.2 ± 0.6 ps for canthaxanthin and 25.4 ± 0.2 ps β -8'-apocarotenal in toluene were found (Wasielewski and Kispert, 1986). Wasielewski et al. (1989) also measured the temperature dependence of the lowest excited singlet state lifetime of all-trans- β -carotene and fully deuterated all-trans- β -carotene in 3-methylpentane. In this work the authors reported an 8.1 ± 0.5 ps 2^1A_g lifetime for all-trans- β -carotene and a 10.5 ± 0.6 ps 2^1A_g lifetime for fully deuterated all-trans- β -carotene.

The weak dependence of the 2^1A_g lifetime on isotopic substitution suggests that conformational changes in the C-H bending and stretching modes are not primary factors in the decay of the 2^1A_g state of carotenoids to the ground state. It was postulated that changes in the frequencies of the C-C stretching modes along the carbon backbone of the carotenoid provide the appropriate accepting modes for nonradiative decay of the 2^1A_g state.

Shreve et al. (1991a,b) used femtosecond ground state depletion/recovery techniques to record an 11 ps lifetime of the 2^1A_g state of β -carotene in CS_2 . These authors extended their studies to carotenoids extracted from photosynthetic bacteria and found a 9.1 ps lifetime of the S_1 state of spheroidene in cyclohexane. Noguchi et al. (1989), Hashimoto and Koyama (1990) and Kuki et al. (1990) used picosecond time-resolved resonance Raman spectroscopy to examine the 2^1A_g states of β -carotene and spheroidene and concluded that the lifetime of the 2^1A_g states of these molecules must be at least 10 ps. Thus, several workers have converged on the range 10 ± 2 ps for the lifetimes of the 2^1A_g states of both β -carotene and spheroidene. (See also below.) In addition, Gillbro and Cogdell (1989) used picosecond ground state depletion/recovery experiments and measured the lifetime of the 2^1A_g state of spheroidenone, a carbonyl-containing derivative of spheroidene, to be 15 ps in CS_2 .

Monitoring time-resolved fluorescence from the 2^1A_g state is another manner in which one may probe the S_1 dynamics of shorter carotenoids. The time-resolved fluorescence decay profile of fucoxanthin ($n = 8$) in CS_2 displayed a major kinetic component of 41 ps, while that of β -8'-apocarotenal in the same solvent was 16 ps (Kato et al., 1991). Andersson et al. (1992) measured a 2.0 ns lifetime for emission from the 2^1A_g state of a β -carotene analog having 5 double bonds.

In an attempt to understand the controlling features of nonradiative decay of the 2^1A_g state of carotenoids, Frank et al. (1993) analyzed a series of four *all-trans*-carotenoids: 3,4,7,8-tetrahydrospheroidene, 3,4,5,6-tetrahydrospheroidene, 3,4-dihydrospheroidene, and spheroidene (Fig. 3). These molecules have π -electron conjugations that systematically increase from 7 to 10 carbon-carbon double bonds. Otherwise, they are structurally identical. The $S_1 \rightarrow S_n$ absorptions decayed with single-exponential kinetics revealing S_1 lifetimes of $\tau = 407 \pm 23$ ps for 3,4,7,8-tetrahydrospheroidene, 85 ± 5 ps for 3,4,5,6-

tetrahydrospheroidene, 25.4 ± 0.9 ps for 3,4-dihydrospheroidene, and 8.7 ± 0.1 ps for spheroidene in petroleum ether. The data were analyzed in terms of the energy gap law for radiationless transitions (Englman and Jortner, 1970).

$$k_{ic} = A \cdot \exp(-\gamma\Delta E/\hbar\omega_M) \quad (1)$$

where k_{ic} is the internal conversion rate constant, in this case very well approximated by $1/\tau$ because k_{ic} for polyenes is much larger than the S_1 radiative rate constant, $k_f \sim 10^6$ to 10^7 s $^{-1}$. A is a pre-exponential factor that depends on the S_1 - S_0 energy difference, ΔE ,

$$A = \frac{C^2 \sqrt{2\pi}}{\hbar \sqrt{\hbar\omega_M \Delta E}} \quad (2)$$

For the four spheroidenes A can be safely approximated as a constant. $\hbar\omega_M$ is the energy of the high frequency 'acceptor' modes (presumably C=C stretches of ~ 1600 cm $^{-1}$), and γ can be related to the relative displacement of the potential surfaces in the two electronic states. The $S_1 \rightarrow S_0$ transition energies deduced for 3,4,5,6-tetrahydrospheroidene, 3,4,7,8-tetrahydrospheroidene and 3,4-dihydrospheroidene compounds from fluorescence experiments (DeCoster et al., 1992) were 18,400 cm $^{-1}$, 16,700 cm $^{-1}$ and 15,300 cm $^{-1}$, respectively. The $S_1 \rightarrow S_0$ transition energy for spheroidene has not previously been assigned. A fit of the energy gap law expression to these data yielded a 2^1A_g (S_1) state energy value of 14,100 cm $^{-1}$ for spheroidene, in good agreement with the value determined by extrapolation from fluorescence studies ($\sim 14,000$ cm $^{-1}$).

In a similar fashion, Andersson and Gillbro (1992b) studied a systematic series of β -carotene analogs. In this study, analogs of β -carotene possessing 5, 7, 9, 11 (β -carotene), 15 and 19 conjugated double bonds were analyzed by femtosecond transient absorption experiments. The S_1 decay rates were found to increase with the number of carbon-carbon double bonds in qualitative agreement with the energy gap law. The variation in the 2^1A_g energies for this series of carotenoids was so extensive, however, that the full energy dependence including the explicit $1/\sqrt{\Delta E}$ functionality in the pre-exponential term (Eq. (2)) must be considered in treating the data.

B. Dynamics of S_2 States

The lifetimes of the 1^1B_u states of a range of carotenoids have been directly measured. Shreve et al. (1991a,b) used femtosecond transient absorption measurements and determined the room temperature lifetimes of the 1^1B_u states of β -carotene and spheroidene to be 200–250 fs and 340 fs, respectively. The lifetimes varied slightly depending upon the solvent. This group also found that the 1^1B_u state decayed into a second excited state which had a lifetime of 11 ps for β -carotene and 9.1 ps for spheroidene. This second state is in all probability the 2^1A_g state.

C. Connection Between Direct and Indirect Measurements of S_1 and S_2 Dynamics

The fluorescence yield of any state can be expressed as:

$$\Phi_f = \frac{\tau}{\tau_r} \quad (3)$$

where τ is the lifetime and τ_r is the natural radiative lifetime of the state (Strickler and Berg, 1962). The natural radiative lifetime of the S_2 (1^1B_u) state (but not the S_1 (2^1A_g) state) of a carotenoid can be estimated by integrating its absorption profile. This procedure yields a value of about 1 ns for the S_2 radiative lifetime of β -carotene (Gillbro and Cogdell 1989; Shreve et al., 1991a). Fluorescence quantum yields lead to lifetimes of \sim 200 fs for the 1^1B_u states of β -carotene and spheroidene. This number agrees very well with the direct kinetic measurements of Shreve et al. (1991a,b).

The yield of S_1 emission from the previously described β -carotene analog having 5 carbon-carbon double bonds was $7 \pm 3 \times 10^{-3}$ (Andersson et al., 1992). This value, combined with the 2.0 ns lifetime of this state, yields a natural radiative lifetime for the 2^1A_g state of 300 ns. If similar natural radiative lifetimes are assumed for the β -carotene analog with 7 carbon-carbon double bonds and for β -carotene (11 carbon-carbon double bonds), then fluorescence yield measurements indicate lifetimes of their 2^1A_g states of \sim 240 ps and 3–10 ps, respectively. These values are in good agreement with the lifetimes determined by direct time-resolved absorption measurements and ground state recovery experiments (Andersson and Gillbro, 1992).

IV. Implications for Energy Transfer

The efficiency, ϵ , of energy transfer between two molecules is defined by

$$\epsilon = \frac{k_{ET}}{k_{ET} + \sum_i k_i} \quad (4)$$

where k_{ET} is the rate constant for energy transfer and k_i represents any one of several alternative excited state decay pathways. Energy transfer from carotenoids to chlorophylls can easily be demonstrated by comparing the absorption and chlorophyll fluorescence excitation profiles from antenna pigment-protein complexes isolated from photosynthetic bacteria or algae. Normalization of the two spectral profiles at a specific wavelength (e. g. the maximum of the bacteriochlorophyll Q_x transition near 600 nm in the B800–850 complex from photosynthetic bacteria) allows the calculation of ϵ . Efficiencies measured in this manner range from greater than 90% for spheroidene in the B800–850-complex from *Rhodobacter (Rb.) sphaeroides* wild type strain 2.4.1 (Cogdell et al., 1981; Noguchi et al., 1990; van Grondelle et al., 1982) to \sim 25% for the carotenoids, spirilloxanthin, rhodopin, and lycopene in the B880 complex from *Rhodospseudomonas (Rp.) acidophila* (Angerhofer et al., 1986). In general, the longer chain carotenoids show lower efficiencies of energy transfer to chlorophylls (Frank and Cogdell, 1993).

These steady state experiments are particularly interesting when comparing a systematic series of complexes. For example, Frank et al. (1993) analyzed the B850 complex from the carotenoidless mutant *Rb. sphaeroides* R-26 after it had been reconstituted with the four spheroidene analogs discussed above (Fig. 3). This study attempted to provide a systematic approach to exploring the effect of excited state energies, spectral overlap and excited state lifetimes on the efficiency of carotenoid-to-bacteriochlorophyll singlet energy transfer. The efficiencies of energy transfer for the four reconstituted complexes could be rationalized from changes in spectral overlaps and an increase in the rate of $2^1A_g \rightarrow 1^1A_g$ internal conversion with increasing conjugation. The work suggested that the general trend of lower efficiencies of energy transfer from carotenoids to bacteriochlorophyll for longer chain carotenoids (e. g. spirilloxanthin) may be due to the 2^1A_g states of these

molecules lying below the S_1 state of bacteriochlorophyll. Augmenting these studies with transient dynamics data carried out directly on the isolated pigment-protein complexes would test this hypothesis.

Upon excitation of the B800–850-complex from *Rp. acidophila* strain 7750, Wasielewski et al. (1986b) observed a bleaching of the carotenoid absorption, which was restored with a time constant of 5.6 ± 0.9 ps. The rise-time of a bleaching of a bacteriochlorophyll band at 860 nm occurred in 6.1 ± 0.9 ps indicating the arrival of the carotenoid excitation at the bacteriochlorophyll site. Similar experiments were carried out by Gillbro et al. (1988) on the B800–850-complex from *Rps. acidophila* strain 7050. Energy transfer from the carotenoid to the bacteriochlorophyll took place in 3 ± 1 ps. Femtosecond time-resolved experiments were carried out (Trautman et al., 1990b) on the thylakoid membrane preparations from the diatom *Phaeodactylum tricorutum* and from *Nannochloropsis sp.* The time for the carotenoid-to-chlorophyll energy transfer in the latter species was found to be $< 240 \pm 40$ fs (*i. e.* instrument limited). Energy transfer in the diatom was bi-exponential with transfer times 500 ± 100 fs and 2.0 ± 0.5 ps and relative amplitudes of $1.7 \pm 0.7:1$.

Using femtosecond time-resolved techniques, Trautman et al. (1990a) and Shreve et al. (1991b) studied the B800–850 complex isolated from *Rb. sphaeroides* strain 2.4.1. The data were interpreted within the framework of a model whereby the carotenoids transfer energy to both the 800 nm and 850 nm-absorbing bacteriochlorophylls with the majority of the carotenoids present in the complex transferring their energy directly to the 850 nm bacteriochlorophylls in ~ 300 – 400 fs. The remainder of the carotenoids transfer their energy via the 800 nm bacteriochlorophylls to the 850 nm-absorbing molecules. The best fit of the dynamics data requires that energy transfer can originate from both the 1^1B_u and the 2^1A_g states of the carotenoid. The suggestion that energy transfer from carotenoids may originate from their 1^1B_u (S_2) states opens up the possibility of S_2 transfer in higher plant systems where S_1 might be too low to participate in energy transfer to chlorophyll *a*.

A fundamental goal of research in this area is to relate the efficiencies and kinetics of carotenoid/chlorophyll energy transfer to the electronic structures and excited state dynamics of the donors and acceptors. Energy transfer between unlike molecules

usually is explained using one of two established models. These are the dipole-dipole or coulomb (Förster) mechanism or the electron exchange (Dexter) mechanism. (Förster 1948, 1965; Dexter, 1953; see also Chapter 15 by Struve in this volume). Which of these applies to energy transfer between antenna carotenoids and chlorophylls will depend critically on the answers to the following questions: (1) How do specific molecular features (e.g. distance, geometry, structure, extent of conjugation, stereochemistry, functional groups, etc.) control energy transfer? (2) Which carotenoid excited electronic states (1^1B_u or 2^1A_g) participate in the transfer and how is the overall energy transfer efficiency partitioned between them? (3) Which chlorophyll electronic states (those associated with the Q_x or Q_y transitions or other states) are involved in the transfer?

In principle, which mechanism (coulomb or exchange) operates between carotenoids and chlorophylls can be determined by analyzing how various molecular features affect the efficiency of energy transfer. Singlet energy transfer measurements using steady state and direct dynamics techniques need to be carried out on several different types of complexes including: (1) Well-defined pigment-protein complexes where a range of different carotenoids can be incorporated into a single controlled binding site. As alluded to above, this has recently been provided by Frank et al. (1993), but more work in this area is needed; (2) A variety of antenna complexes whose structures are known and have one carotenoid molecule bound in a single site. In experiments of this sort, the distances between donor and acceptor molecules can be correlated with the measured rates of the energy transfer. 3-dimensional structures of antenna complexes that contain chlorophylls and carotenoids are forthcoming (Cogdell et al., 1985; Papiz et al., 1989; Guthrie et al., 1992). With data on these complexes, a thorough understanding of the factors that control energy transfer between carotenoids and chlorophylls will ultimately be possible.

Acknowledgments

The authors wish to thank Veeradej Chynwat and Susan Lund for their assistance in the preparation of this review. This work was supported in the laboratory of H. A. F. by grants from the National Institutes of Health (GM-30353) and the University of Connec-

ticut Research Foundation. R. L. C. acknowledges the donors of the Petroleum Research Fund, administered by the American Chemical Society, and a DuPont Fund grant to Bowdoin College for support of this research.

Summary

Recent years have nullified an old illusion that all that is needed for a complete picture of photosynthetic excitation transfer and trapping dynamics is detailed structural information about the system. This still seems to be only a prerequisite. The present chapter highlights the problems concerning the coupling of light-harvesting antennas to reaction centers. Structural, kinetic as well as functional aspects of the coupling are considered. As the antenna-reaction center coupling is largely governed by the specific protein medium, interactions of pigments with their protein surroundings and the elastic properties of these proteins are studied by employing high hydrostatic pressure technique. Excitation transfer from the antenna to the reaction center takes place in tens of picoseconds. The reaction center is a rather perfect trap. In conditions of photosynthesis, only about a quarter of the energy entering the reaction center is transferred back to the antenna. A conclusion is made that future progress in the field is expected by a more detailed study of the dynamical properties of pigment-protein complexes.

I. Introduction

In the previous encyclopedia about the photosynthetic bacteria, issued 15 years ago, the contemporary understanding of the antenna-reaction center coupling problem was reviewed by Zankel (1978). His conclusions were briefly as follows: Energy transfer from antenna pigments to the reaction center (RC) is channeled through the longest-wavelength antenna component. Transfer from the antenna to the RC takes place in tenths of nanoseconds. The same time is characteristic of the transfer between long-wavelength antenna components. Energy in an active RC becomes trapped in about 7 ps. Within this time a fraction of the energy entering the RC is transferred back to the antenna. A spectrally homogeneous model was considered sufficient to interpret most of the available experimental data, though Zankel realized that this was an oversimplification. The results of emerging picosecond time-resolved kinetic studies remained contradictory and confusing at that time.

The aim of this chapter is to review recent developments in the study of the coupling between the antenna and the RC in photosynthetic bacteria. In this respect, purple photosynthetic bacteria represent without doubt the most extensively studied and best characterized systems. We shall see, however, that even in these relatively simple objects ('hydrogen atoms of photosynthesis') our knowledge is far from being complete and further studies are necessary. The presentation given here is selective rather than comprehensive. The author has focused on what are, from his point of view, some of the most interesting and relevant items of the problem, trying to examine what is understood and what is not.

The contents of this chapter are closely related to (and sometimes overlapping) that of several others in the book, which are referenced where appropriate.

II. The Concept of a Photosynthetic Unit

The concept of a photosynthetic unit (PSU) forms the basis of the modern perceptions of the primary processes of photosynthesis. It originates from the

Abbreviations: BChl – bacteriochlorophyll; *Cm.* – *Chromatium*; PSU – photosynthetic unit; *Rb.* – *Rhodobacter*, RC – reaction center; *Rp.* – *Rhodospseudomonas*; *Rs.* – *Rhodospirillum*; *Tc.* – *Thiocapsa*

experiments by Emerson and Arnold (1932). They have determined that, on the average, one oxygen molecule per 2500 chlorophyll molecules is formed when *Chlorella* cells are illuminated with a single light flash of saturating intensity. Dividing this number by 8, the minimum number of light quanta per oxygen molecule evolved, one reaches a conclusion that about 300 chlorophyll molecules cooperate in producing oxygen. In order to explain this cooperation it was postulated that the absorbed light quantum can transfer between chlorophyll molecules until it becomes trapped at a specific site where the energy is used to drive the photochemical reaction. The trap was given a special name: reaction center.

The statistical ensemble consisting of the RC and all the light-absorbing pigment molecules contributing excitation energy to this RC, has been defined as a PSU. The organization of the photosynthesis apparatus as PSUs increases the effective optical cross section of the RC (for review, see Mauzerall and Greenbaum, 1989).

The photochemistry leading to the evolution of oxygen and its coupled dark reactions occur within milliseconds, after which the original state is restored. In case of a moderate solar energy fluence every chlorophyll molecule absorbs a photon on the average once per second. This means that in the antenna of an approximate size of a hundred chlorophyll molecules, virtually each photon absorbed can effectively be utilized by a single RC.

The major experimental proof of the PSU concept was given in the early 1950s by Duysens (1952). Energy transfer between different pigments was observed in fluorescence studies in which the energy absorbed by one type of pigments sensitized emission from a spectrally distinct pigment. A small decrease of the near infrared absorption band was observed in the bacteria under illumination, which was correctly attributed to excitation energy trapping by the mechanism of photochemical bleaching of a small fraction of bacteriochlorophyll (BChl) molecules.

According to the PSU concept, the primary steps of photosynthesis comprise: (i) absorption of a photon by antenna pigments; (ii) transfer of excitation energy through the antenna to the RC pigments; (iii) trapping of energy at the RC by light-driven oxidation reaction of a special RC complex; (iv) a sequence of electron transfer steps within the RC.

III. Structure and Organization of Real Photosynthetic Systems

A. Antennas

An insight into the molecular organization of the photosynthetic apparatus has been given by a number of interdisciplinary studies involving spectroscopy, crystallography, biochemical and genetic analyses. Although much is known about the structure of RCs (see Chapter 23 by Lancaster et al.), similar information about the antenna systems is still very incomplete.

Antenna systems, like RCs, represent biopolymers containing pigment molecules. BChl-containing antennas are located either within a cytoplasmic membrane, like in purple bacteria (see Chapter 16 by Zuber and Cogdell), or within extra-membrane vesicles (chlorosomes) attached to the membrane, like in green bacteria (see Chapter 20 by Blankenship et al.). While the membrane part of the antenna of green bacteria is similar to that in purple bacteria, the composition and organization of chlorosomes is completely different. The recently discovered heliobacteria are unique in the sense that their photosynthetic apparatus is fully contained in the cell membrane (see Chapter 31 by Ames).

Mauzerall and Greenbaum (1989) motivate the great variability of antenna structures with the limitations to the size of the PSU which is set by the finite radiative lifetime. Nature takes advantage of several macromolecular organizational principles to minimize the loss in efficiency of energy utilization. Reduction of the dimensionality of energy transfer, as it takes place in the chlorosomes, is one of the possibilities. The specific organization of membrane-bound pigment-protein complexes, ensuring the energy funneling towards RCs, as can be found in some purple bacteria where the RC is surrounded by core antenna complexes which in turn are surrounded by peripheral antenna complexes absorbing at higher energy, is another one. By these means the size (number of antenna pigments per RC) of the PSU can be increased to 1000 molecules and more.

Difficulties with the crystallization of membrane antenna proteins do not allow an application of powerful X-ray structural analyses in full as yet. Electron microscopy (Miller, 1982; Welte and Kreutz, 1982) of freeze-fractured thylakoid membranes of *Rhodospseudomonas* (*Rp.*) *viridis* indicates an ordered

pattern (with a lattice constant about 10–12 nm) of hexagonal particles. A large central RC structure (5–7 nm in diameter) protrudes from both sides of the membrane and is surrounded by six smaller antenna structures. In another purple bacterium, *Rp. marina*, cyclic structures with an approximate diameter of 10 nm for both membranes with RCs and RC-less core antenna complexes have been revealed (Meckenstock et al., 1993).

The photosynthetic membranes of bacteria are not actually crystalline, despite a good periodic arrangement of morphological complexes seen in averaged electron-microscopic pictures (Engelhardt et al., 1985). The real structural nonuniformities may be blurred by instrumental reasons. Specifically, the RC complex is an ellipsoid with an approximate cross-section of 4 times 7 nm rather than a symmetric structure (see Chapter 23 by Lancaster et al.).

Many of the various antenna pigment-protein complexes of bacteria can now be isolated in a spectrally and functionally intact form. It appears that the RC is always associated with core antenna complexes of an almost fixed stoichiometric ratio: 20–40 antenna BChl molecules per RC (Varga and Staehelin, 1985). The peripheral antenna forms the variable component of the photosynthetic apparatus depending on growth conditions. In an early stage of the membrane development the mean distance between the complexes is larger than in a mature organism. In such membranes the energy transfer between the peripheral antenna and the core is inhibited (Pradel et al., 1978).

It is possible to tackle the spatial relationship problem from the other side by trying to restore the excitation transfer function by incorporation of the isolated complexes into artificial liposome membranes. Such attempts have been proved successful in the case of antennas from *Chromatium* (*Cm.*) *minutissimum* (Moskalenko et al., 1992). However, the energy transfer conditions created were less optimal than those in the native state.

Fundamental for the formation of functionally active antenna pigment clusters are protein polypeptides that are responsible for the hierarchical organization of the entire antenna based on a specific polypeptide aggregation. In purple bacteria the antenna consists of pairs of chemically different hydrophobic polypeptides, α - and β -polypeptides (see Chapter 16 by Zuber and Cogdell). Each of these membrane-spanning polypeptides hosts 50–60

amino acid residues. Protein polypeptides not only provide the environment, but also determine the position and orientation of pigment molecules as well as the distance between them (1–2 nm in an $\alpha\beta$ -pair). Two to three BChl and one to two carotenoid molecules are non-covalently bound to an $\alpha\beta$ -heterodimer. The actual size of the in vivo $\alpha\beta$ -aggregates is still under debate. The reconstitution of the antenna from separately isolated α - and β -polypeptides and pigments has been demonstrated (see Chapter 21 by Loach and Parkes-Loach). It has been proposed that the basic building element is $\alpha\beta(\text{BChl})_2$ and two basic elements are sufficient to form a complex which has spectral characteristics similar to the native core antenna complex. It is likely a weakly coupled aggregate of two dimers where two BChls are strongly coupled (see Chapter 17 by Sundström and van Grondelle). The BChl dimer may be similar to the RC primary electron donor.

B. Structural Aspects of Antenna-Reaction Center Coupling

Little is known about the spatial relationships and interactions of RC polypeptides with light-harvesting complexes. Three different arrangements of peripheral antenna complexes and core complexes with respect to RCs in the photosynthetic membrane plane have been proposed: (i) peripheral antenna complexes surround and structural connect core complexes, which in their turn host the pool of RCs (Monger and Parson, 1977); (ii) an isolated RC, surrounded by core complexes, in a pool of peripheral antenna complexes (Deinum et. al., 1991b); (iii) an arrangement where both peripheral and core complexes have close spatial relationships with the RC (Drews, 1985).

The ultimate purpose of these arrangements is to form an effective heterogeneous excitation energy transfer system towards the RC. Some of the peripheral complexes, however, seem to be more remote and, correspondingly, less effective energy mediators (Moskalenko and Toropygina, 1988; Freiberg et al., 1989). Reversible chemical cross-linking studies (Drews, 1985) give strong evidence that close spatial contacts (about 1 nm) exist between both the α and β polypeptides of the core antenna complex and the H protein subunit of the RC. The H subunit does not bind pigments. Its protein backbone spans the membrane once (five times in the case of L

and M subunits) and forms a globular structure outside the membrane that makes extensive contact with the cytoplasmic side of the L and M subunits (see Chapter 23 by Lancaster et al.).

A close spatial contact of core antenna complexes with the RC is a prerequisite of an effective energy utilization. The dilution of the membrane by lipids results in the uncoupling of the antenna and RC with respect to energy transfer (Takemoto et al., 1985).

In membranes the core antenna BChl molecules bound to $\alpha\beta$ -polypeptides lie asymmetrically on the periplasmic side. The special pair of the RC is also localized on the periplasmic side. This specific location is the basis for two-dimensional energy transfer parallel to the membrane plane within and between antenna complexes and the RC. The pigments of the core antenna, like the primary donor pigments, have their molecular plane oriented perpendicular to the membrane plane. The long-wavelength Q_y transition dipoles of antenna and RC pigments are believed to lie approximately parallel to the membrane plane (see Chapter 16 by Zuber and Cogdell).

IV. Trapping of Energy by the Reaction Center

The migration of singlet excited states from the antenna to the RC has intrigued theorists since the pioneering work of Franck and Teller in 1938 (for discussion see Robinson, 1967). The first clear experimental demonstration of an effective trapping of antenna excitations by RCs was given by Vredenberg and Duysens (1963). They also observed an increase of the fluorescence yield from photosynthetic bacteria when the photochemical machinery became saturated by the incoming light energy.

As to the kinetics of the excitation transfer through the antenna and from the antenna to the RC, the early experimental evidence was scanty and inconsistent. Thus, Zankel and Clayton (1969) and Zankel (1978) concluded that the average trapping time constant is rather slow, about a nanosecond. This was supported by the data of Govindjee et. al. (1972) who found that the fluorescence lifetime of bacteria increases from 0.3–1 ns as the RC traps are closed. Borisov and Godik (1970), however, have proposed much shorter lifetimes, around 50 ps for the photoactive RCs and 0.5 ns for the inactive, closed ones. This conclusion was based on a single-frequency phase fluorimetric measurements. The possibility to resolve picosecond decays by this technique was obscure and the data

fell under criticism (see, e.g., Zankel, 1978). Another source of difficulties is the dependence of kinetics on the excitation intensity that is crucial when single picosecond pulses are used for excitation (for review, see van Grondelle, 1985; Valkunas et al., 1991).

These inconsistencies start to find clarification with the use of a new-generation of picosecond lasers and recording techniques (for review, see Freiberg, 1986). An important feature of such instruments is a high pulse repetition rate. In experiments employing single picosecond pulses, it is almost always the case that excitation intensities are considerably higher than in natural photosynthesis. Singlet-singlet type excitation annihilation processes may then prevail over photosynthetically relevant excitation quenching processes (Campillo and Shapiro, 1978). New spectrometers allow a low-fluence excitation more characteristic of natural photosynthesis, together with picosecond and even subpicosecond time resolution.

A. The Effect of the Reaction Center State

It was first shown by Sebban and Moya (1983) using the bacterium *Rhodobacter (Rb.) sphaeroides* and Freiberg et al. (1984) using *Rhodospirillum (Rs.) rubrum* that the variable fluorescence lifetime of the core antenna, associated with the redox state of the RC, changes from 50–60 ps in the case of active RCs to about 250 ps on closing the RCs. Later, a similar behavior was observed in a number of other bacteria.

Borisov et al. (1985) have summarized how the picosecond fluorescence from the antenna of *Rb. sphaeroides* and *Rs. rubrum* reacts to the closing of RCs. Almost a single fluorescence emission decay lifetime at different incident light levels was observed which simply increased as the RC traps were oxidized due to the increased light level. In contrast to these studies, Woodbury and Bittersmann (1990) found that the decay of fluorescence emission was nonexponential at all excitation intensities. The increase of the overall emission decay time was not only due to an increase in the initial fast excitation trapping time, but also to a substantial contribution from a second, longer-lived emission component which grew in as the traps were inactivated by high light level. Only recently, it was established (A. Freiberg and N. Woodbury, unpublished) that most of the described discrepancies can be explained by different excitation conditions used by different groups. In the case of a very small excitation volume

as used in the measurements of Woodbury and Bittersmann (1990), diffusion of excited PSUs out of the illuminated volume and unexcited PSUs into this volume should be taken into account in order to obtain the correct kinetics. All the relevant data, including these corrections, seem to verify that the fluorescence yield as well as the fluorescence lifetime of an antenna are directly governed by the rate of energy trapping on active RCs.

Vredenberg and Duysens (1963) assumed that closed RCs neither trap nor quench antenna excitations. This assumption was based on the observed bleaching of the long-wavelength absorption band of photooxidized RCs, resonant with the antenna fluorescence (Duysens, 1952). Energy transfer from the antenna to the RC presumably takes place via the Förster dipole-dipole mechanism (see Chapter 15 by Struve). Because the absorption of the RC is almost lost, they assumed that the Förster overlap integral will become close to zero and so will the trapping/quenching rate.

Later studies proved that the reality is more complex. There are a number of different inactive (closed) RC states, not just a single one. All of them are able to quench excitations in the antenna (Godik and Borisov, 1977; Heathcote and Clayton, 1977). The coupling mechanism in specific cases, however, needs further clarification. Depending on the redox potential of the medium, the excitation light intensity, the availability of electron donors, temperature, and other factors, the following RC states have been quantified (Godik and Borisov, 1977):

active state	C P I Q,
inactive states	C ⁺ P ⁺ I Q,
	C ⁺ P ⁺ I Q ⁻ ,
	C P I Q ⁻ ,
	C ⁺ P I Q ⁻ .

Letters denote the important molecular constituents of the RC: C is the cytochrome electron donor complex, P is the BChl dimer primary donor, I is the bacteriopheophytin intermediate electron acceptor, Q is the primary quinone electron acceptor. When P is photoexcited, it becomes oxidized and the electron transfer proceeds via I to Q, and from there to a secondary quinone acceptor until the electron

Table 1. Antenna fluorescence lifetimes in the picosecond range in *Rs. rubrum* and *Tc. roseopersicina* for different reaction center states at room temperature

RC state	<i>Rs. rubrum</i>	<i>Tc. roseopersicina</i>
	lifetime (ps)	
C P I Q	60 ± 10	75 ± 10
C ⁺ P ⁺ I Q	250 ± 20	210 ± 20
C ⁺ P ⁺ I Q ⁻	120 ± 10	
C P I Q ⁻	80 ± 10	90 ± 10
C ⁺ P I Q ⁻		280 ± 20

eventually returns to P. This electron transfer sequence results in trapping and stabilizing the energy of light excitations harvested by the antenna (for review, see Bixon et al., 1992).

Different RC states quench antenna excitations with different efficiencies as shown in Table 1, where the data relevant to the bacteria *Rs. rubrum* and *Thiocapsa (Tc.) roseopersicina* from various publications are gathered together (Freiberg et al., 1984; Godik et al., 1985; Borisov et al., 1985; Godik, 1989). When compared with the BChl lifetime in isolated core antenna complexes or in a RC-less mutant (about 650 ps at room temperature, according to Sebban et al. (1985) and Freiberg and Timpmann (1992)), it appears that when present RCs are always efficient antenna fluorescence quenchers.

Recently, it was found that in two bacteria, the BChl *g* containing *Heliobacterium chlorum* and the BChl *b* containing *Rp. viridis*, fluorescence is quenched more strongly when the primary donor is oxidized than when it is reduced (Deinum et al., 1991 a, 1992). Accordingly, the fluorescence lifetime decreases after the closing of RCs (Kleinherenbrink et al., 1993), instead of increasing, which was observed in the 'normal' BChl *a* containing bacteria. This was interpreted as due to the fact that antenna levels are lower in energy than those of a reduced primary donor. In these conditions the Förster overlap integral may well increase and the antenna fluorescence decrease upon photooxidation of the primary donor when compared to the reduced state of the donor. Although this is in principle compatible with the Förster mechanism of energy transfer, the quantitative aspects of this interpretation remain to be proved. The same concerns the quantitative aspects of the coupling mechanism in 'normal' cases. Some of the problems encountered by the Förster mechanism of quenching have been underlined by Sebban (1985). The primary electron donor in higher

plant Photosystem II, P680, also appears to be an equally effective quencher of chlorophyll fluorescence in the oxidized and in the reduced state (see, e.g. Freiberg et al., 1992, 1994).

B. 'Up-Hill' Energy Trapping

Because of the Stokes shift of the donor emission spectrum the Förster overlap integral has a larger value if the acceptor molecule absorption spectrum is red-shifted with respect to that of the donor. As a result, in the inhomogeneous ensemble excitations tend to accumulate on the molecules with lowest energies. When the pigments with redmost absorption spectra belong to the primary donor or to antenna pigments adjacent to it, the spectral uni-directionality results in a spatially directed energy transfer towards the RC. This is how the photosynthetic systems should be and generally are arranged, so far as the peripheral antenna is concerned. Otherwise, excitations may end up in a local minimum apart from the RC and get lost.

In many cases, the primary donor is not an energetic trap compared to all the core antenna pigments present. *Rp. viridis* is probably the most studied representative of this class of systems. In natural membranes the primary donor absorbs at 985 nm and the antenna pigments, at 1015 nm at room temperature (Kleinherenbrink et al., 1992). Note that *Rp. viridis* like *Rs. rubrum* possesses only the core antenna proteins, arranged concentrically in a single circle around the RC. In a structure optimized in such way excitations always stay adjacent to the RC until they are trapped. The trapping rate stays relatively high until the thermal energy, kT , and the gap between the 0-0 transition energies (not just between the absorption maxima) of the antenna and the RC pigments are comparable. In *Rp. viridis* the primary donor is at 150 cm^{-1} or about 217 K higher energy with respect to the antenna pigments. Thus, trapping via the long-wavelength antenna does not kinetically impede an efficient utilization of light energy at room temperature. The quantum yield of charge separation is even more conservative. This follows from the well-known relation between the yield of the primary photochemistry, Y , and the rate constants of trapping, k_t , and the competing loss processes, k_l : $Y = k_t / (k_t + k_l)$. The quantum yield stays high as long as $k_t > k_l$. This may explain the almost 50% quantum yield of charge separation in *Rp. viridis* at 6 K (Kleinherenbrink et al., 1992).

Picosecond time-resolved measurements on purple bacteria have shown that the energy equilibration between the proximal and the core antenna as well as over the core antenna is very fast and it is essentially complete within 10 ps (Freiberg et al., 1987, 1989; van Grondelle et al., 1987; Timpmann et al., 1991; Müller et al., 1993; Pullerits et al., 1994). The transfer rate between the antenna and the RC (the pairwise trapping rate) is probably slower, considering the several times longer lifetime of antenna fluorescence, a short charge separation time (3 ps) and the generally-accepted spatial organization of the antenna and the RC in the membrane. The latter aspect is very important, though it does not necessarily allow a complete picture of excitation transfer dynamics (Valkunas et al., 1992).

At room temperature the trapping rate constant cannot be measured directly, because of the interference with thermal equilibration processes within the antenna. Measurements at 77 K have given the following estimates for trapping time constants from the long-wavelength antenna: 35 ps in *Rb. sphaeroides* and 75 ps in *Rs. rubrum*. The trapping time is constant over the temperature range 177–77 K and it is believed to be not much different at room temperature (Visscher et al., 1989). Crude estimates for trapping times in *Rp. viridis* are about 10 ps (Zhang et al., 1992) and 1.3 ns (Kleinherenbrink et al., 1992), respectively at room temperature and at 6 K. Analyses of the room-temperature femtosecond pump-probe data in membranes of *Rb. capsulatus* lead Xiao et al. (1994) to the conclusion that the excitation energy transfer and trapping is limited by the overall rate of energy transfer between the antenna and the RC. The viewpoint that there exist some rate-limiting energy transfer steps in the antenna or from antenna to RC is shared by several others (van Grondelle et al., 1987; Freiberg et al., 1989). At the same time, Müller et al. (1993) are confident that their picosecond time-resolved fluorescence emission data of *Rb. capsulatus* could only be interpreted if the equilibration time for the excited states of antenna and RC is very short, <3 ps. These opposite views show that at this point our knowledge is, perhaps, still incomplete.

It has been proposed by Trissl (1993) that the possible reason for the development of long-wavelength antenna and spectrally broad heterogeneous absorption bands is an advantage which is evolutionarily obtained via the adaptation of photosynthetic organisms to the spectrally filtered

light caused by self-absorption. Trissl (1993) has also achieved a good agreement between the measured long-wavelength fluorescence lifetime and the theoretically predicted one, assuming a rate-limited trapping from thermally equilibrated antenna states. Small (<2 nm) and uniform pigment-pigment distances have been utilized which is inconsistent with the known PSU organization described above. The original Förster formula (see, e.g. Förster, 1965) contains a number of uncertain parameters when photosynthetic systems are considered which limits its direct use. These have been discussed by Pullerits and Freiberg (1992). Here it suffices to note that in the formula the refractive index appears in the fourth power, but even the applicability of this average macroscopic constant on the needed microscopic level is not obvious. We will return to this specific problem later. Usually, these 'details' are overlooked and the distances between pigments are adjusted in order to get the needed transfer rates. Naturally, such a 'determination' of the structure is arbitrary and should be taken with caution.

V. Detrapping of Excitation Energy from the Reaction Center

The process opposite to trapping–detrapping, is even less well characterized. Some early measurements of the antenna fluorescence yield upon excitation at the wavelengths corresponding to the absorption from RC pigments, appear to suggest that not very extensive back-transfer of excitation energy from the RC to the antenna occurs in purple bacteria at room temperature (Clayton and Siström, 1966; Olson and Clayton, 1966; Ebrey, 1971; Wang and Clayton, 1971). However, the relatively limited knowledge of the pigment origin and not so well defined experimental conditions at the time of these measurements make these results at the best qualitative in nature. Much more recent steady-state fluorescence yield measurements on *Rp. viridis* and *Rs. rubrum* (Kleinherenbrink et al., 1992) suggest that at least at 6 K RCs behave as absolute traps. The extent of detrapping is very low, only some few per cent. On the basis of time-resolved absorption measurements with antenna-RC complexes from *Cm. minutissimum* (Abdourakhmanov et al., 1989) the energy detrapping efficiency at room temperature was estimated to be 10–20%.

It is important to have more detailed and quantitative information on the detrapping process,

Fig. 1. The antenna-signal amplitude ratio measured at the peak of the decay curves of *Rs. rubrum* chromatophores with open and closed RC as a function of the excitation wavelength: absorption data (squares, right-hand scale); fluorescence data (crosses, left-hand scale).

because of at least two reasons. First, it tells us about the efficiency of the RC as an energy trap, and secondly, is of additional help in assessing the trapping rate, since the two processes—trapping and detrapping, are related to each other. The possibility of learning something about trapping via detrapping is particularly interesting because the detrapping can be tested at room temperature, and thus it yields the trapping rate at room temperature, which cannot be directly measured, as noted before.

Timpmann et al. (1993) have measured the energy back-transfer efficiency from the RC to the antenna in *Rs. rubrum* chromatophores at room temperature by using two types of picosecond time-resolved measurements, absorption and fluorescence methods. Due to the additional possibility to discriminate against unwanted signals, the time-resolved measurements are superior over the steady-state measurements. The RC pigments in *Rs. rubrum* can be almost selectively excited through the 800 nm absorption band of the accessory monomeric BChl.

Figure 1 offers compelling evidence that there is a substantial back-transfer of excitation energy from the RC to the antenna. The excitation of the chromatophores within the 800 nm absorption band of the RC results in picosecond absorption and fluorescence signals, demonstrating the presence of antenna excitations. Different amplitudes of the signals result from different dark-adapted RC states (PBIQ in absorption and PBIQ⁻ in fluorescence experiments). After taking into account the antenna absorption in the 800 nm region, the part of energy detrapped from the RC back to the antenna is determined to be $25 \pm 5\%$ for active RCs and $40 \pm 5\%$ when the primary quinone acceptor was pre-reduced. The yield obtained for active RCs is in remarkably good agreement with the room-temperature data, derived in other bacteria: 10–20% in *Cm. minutissimum* (Abdourakhmanov et al., 1989), $15 \pm 10\%$ in *Rb. capsulatus* (Xiao et al., 1994) and $20 \pm 5\%$ in *Rp. viridis* (Timpmann et al., unpublished).

From the back-transfer data for active RCs in the state PBIQ the following rate constants corresponding to the trapping/detrapping kinetic model of Fig. 2 have been found: $k_1 = (40 \pm 5 \text{ ps})^{-1}$ and $k_{-1} = (7.5 \pm 1.5 \text{ ps})^{-1}$. For RCs in the state PBIQ⁻, respectively $k_1 = (35 \pm 5 \text{ ps})^{-1}$ and $k_{-1} = (6.5 \pm 1.5 \text{ ps})^{-1}$. The pairwise detrapping rate, k_D , is related to the total detrapping rate, k_{-1} , from the RC to all the nearest q antenna molecules coordinating the RC by

$$k_D = k_{-1} / q \quad (1)$$

The pairwise trapping rate, k_T , could be derived, in good approximation at room temperature, from the following equation (N is the number of spectrally equivalent pigments or aggregates of pigments):

$$k_1 = k_T q / N \quad (2)$$

The obtained results, when combined with the

Fig. 2. A simplified kinetic model of energy transfer between the antenna and the RC. k_2 represents the charge separation rate in the RC and k_{-2} , the charge recombination rate. Slow loss rate constants have been omitted.

previous knowledge of the energy transfer rates in purple bacteria, suggest that the most crucial step of the overall energy transfer process in the photosynthetic pigment system of the purple bacteria is the energy transfer from the core antenna molecules to the RC ones. It is rather arbitrary whether the energy transfer in this situation is considered diffusion-limited or trapping-limited.

VI. Pigment-Protein Couplings According to High Hydrostatic Pressure Studies

The dynamic behavior and functioning of pigment-protein complexes is among other factors governed by the properties of protein due to important couplings between protein polypeptides and pigments with the protein surrounding (Pancoska et al., 1990). The protein matrix provides a large number of local conformations which lead to inhomogeneous broadening effects on spectra and support various dynamic processes, e.g. electronic excitation and electron transfer processes. Also, different low-frequency modes in proteins and their postulated glass-like structure (Iben et al., 1989) may have a profound effect on the dynamics of photosynthetic systems. Until now, relatively little attention has been paid to these problems, especially, as far as photosynthetic pigment-protein complexes are considered.

Therefore, and also because of the connection with the current actively disputed subject about the origin of the large spectral red shift of the near-infrared absorption bands of BChls in photosynthetic pigment-protein complexes when compared to those in organic solvents, we will consider the elastic properties of photosynthetic pigment-proteins in some detail here (Freiberg et al., 1993; Tars et al., 1994).

A. Solvent- Versus Pressure-Induced Spectral Shifts

It is well known that when a molecule is dissolved in a solvent, its spectrum shifts, usually towards lower energy. The shift is evidently induced by the interaction between the solute molecule and the surrounding medium. In the case of a nonpolar molecule in a nonpolar isotropic medium the major contribution to the shift is due to the dispersion interaction, i.e. an interaction via the fields of the

Fig. 3. Absorption spectra of light-harvesting pigment-protein complexes from membranes of the purple bacteria *Rs. rubrum*, measured at room temperature under pressures of 1 atm, 5.5 kbar and 9.1 kbar.

induced dipole moments. This contribution to the spectral solvent shift (expressed in cm^{-1}) is given by the following expression (see, e.g. Andersson et al., 1991):

$$\nu - \nu_0 = \frac{3(\alpha_g - \alpha_e)}{2hca^3} \frac{II'}{I + I'} \frac{n^2 - 1}{n^2 + 2} \quad (3)$$

Here ν and ν_0 are the transition frequencies of a molecule in the medium and in the gas phase; α_g and α_e are electronic polarizabilities of the molecule in the ground and in the excited electronic state, h is Planck's constant, c is the velocity of light; a is the Onsager cavity radius of the solute, I and I' are the ionization potentials of the solute and the medium molecules, and n is the refractive index of the medium at a given transition wavelength. Since molecules in the excited state are generally more polarizable than in the ground state ($\alpha_e > \alpha_g$ in Eq.(3)), a red solvent shift commonly occurs. A linear relationship between the absorption band maximum ν in solution and the Lorentz-Lorenz function $(n^2 - 1) / (n^2 + 2) = (4/3)\pi N\alpha_s$ characterizing the electronic polarizability of the medium (α_s is the electronic polarizability of the solvent molecules and N is their number in the molar volume) has been established for many solute-solvent systems. In particular, this relationship has proved to hold in the case of both chlorophylls (Renge, 1992) and carotenoids (Andersson et al., 1991) in nonpolar media.

Pressure leads to changes in the interaction between the molecule and the surrounding medium and,

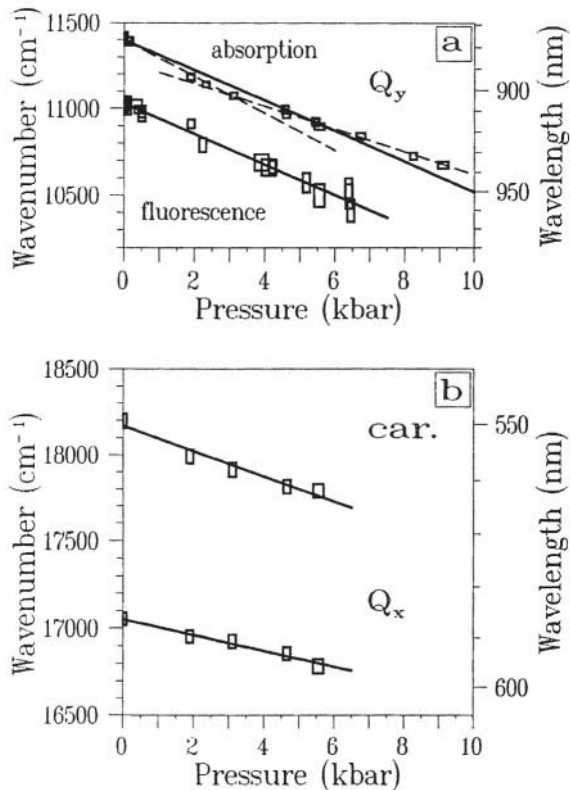

Fig. 4. Shifts of the spectral band peaks as a function of pressure at room temperature. The width and height of the rectangles denoting the experimental points characterize experimental inaccuracies. Straight lines serve as guides for the eye. (a) $S_1 \leftarrow S_0$ transition in BChl absorption and fluorescence emission spectra. (b) $S_2 \leftarrow S_0$ transitions in the BChl and carotenoid absorption spectra (the O-O band shift is shown for carotenoid only).

consequently, to the shift of spectral bands. However, it is not easy to see from Eq.(3) the functional dependence of this shift.

Figure 3 shows the room-temperature absorption spectra of light-harvesting pigment-protein complexes between 450 and 1050 nm at three different pressures: 1 atm, 5 kbar and 9.1 kbar (1 bar = $10^5 \text{ N/m}^2 = 0.99 \text{ atm}$). The most intensive band at 880 nm belongs to the Q_y transition in aggregated BChl molecules in the protein surrounding. A much weaker band around 590 nm corresponds to the Q_x transition in the same molecule. Three blue bands (at 485, 513 and 549 nm) represent vibronic transitions between the ground and the second electronic excited state in the spirilloxanthin molecule. One can see in Fig. 3 a substantial red shift of the Q_y absorption band and of spirilloxanthin bands with the increase of pressure.

The shift of the Q_y band is accompanied by a band broadening, the integral absorption remaining practically unchanged. The position of the Q_x band seems to be relatively less sensitive to pressure than the spirilloxanthin bands.

Although the pressure dependence of the spectral band shifts has both linear and quadratic terms, the latter contribution is relatively small (Fig. 4; Tars et al., 1994). The pressure coefficients, $\Delta\nu / \Delta P$, determined as slopes of a single straight line fitted to the data points in the plot of the band peak position versus the pressure were found to have the following values: $-86 \pm 5 \text{ cm}^{-1}/\text{kbar}$ for the BChl Q_y band, $-45 \pm 5 \text{ cm}^{-1}/\text{kbar}$ for the Q_x band and $-74 \pm 5 \text{ cm}^{-1}/\text{kbar}$ for all the spirilloxanthin vibronic bands.

From the pressure-induced shifts of the spirilloxanthin spectral bands the local refractive index in the surrounding of the spirilloxanthin molecule can be calculated following Eq.(3) and by using the solvatochromic data. At atmospheric pressure $n = 1.51$ and it increases to $n = 1.58$ at 5.5 kbar. It has been suggested that the surrounding of the spirilloxanthin molecule may to a great extent consist of the aromatic amino acid residues of the protein (Andersson et al., 1991).

Some years ago a simple expression was deduced (Laird and Skinner, 1989) for the pressure-induced shifts of spectral bands of impurity molecules dissolved in solid media:

$$\Delta\nu(P) = 2\kappa(\nu_m - \nu_0)\Delta P \quad (4)$$

Here $\kappa = -(1/V)(dV/dP)_T$ is the isothermal compressibility of the medium in the neighborhood of the guest molecule and $\nu_0 - \nu_m$ is the solvent (matrix) shift at normal pressure (see Eq.(3)) with respect to the inhomogeneous band maximum ν_m . In deriving Eq. (4), the elastic properties of the matrix were considered as isotropic and homogeneous. This is certainly not the case for proteins, as they are both heterogeneous and anisotropic. S. H. Lin (unpublished) has considered the case where the heat bath molecules are not isotropically distributed around the solute molecule. The result is similar to the Eq. (4), but without the numerical coefficient 2. Evidently, the linear pressure dependence given by these equations holds for sufficiently low pressures only. If either the compressibility or the solvent shift is known, the other can be determined from the pressure-induced spectral shift experiment.

B. Compressibility of the Protein Matrix

The gas phase transition frequencies for different carotenoids are known from solvatochromic data. For the 0-0 vibronic transition of the spirilloxanthin $\nu_0 = 21700 \pm 700 \text{ cm}^{-1}$ (P. O. Andersson, unpublished), which gives for the solvent shift $\nu_m - \nu_0 = -3550 \pm 700 \text{ cm}^{-1}$. With the given pressure coefficient and the equation derived by Lin (unpublished) we calculate $\kappa(\text{car}) = 20 \pm 4 \text{ Mbar}^{-1}$. The gas phase frequencies of native BChl aggregates are not available for understandable reasons and neither are the corresponding solvent shifts. Here, in a limiting case, which presumably gives a larger solvent shift and thus a diminished compressibility, we will use the frequencies determined from solvatochromic measurements of monomeric BChl molecules (Renge, 1992): $\nu_0 = 13341 \pm 24 \text{ cm}^{-1}$ for Q_y and $17660 \pm 79 \text{ cm}^{-1}$ for Q_x transitions. With these data we have $\kappa(\text{BChl } Q_y) = 44 \pm 4 \text{ Mbar}^{-1}$. From the pressure shift of Q_x band we obtain $\kappa(\text{BChl } Q_x) = 50 \pm 10 \text{ Mbar}^{-1}$.

As can be seen, within the limits of experimental accuracy rather close compressibility values have been obtained from different transitions in the same BChl molecule. On the contrary, different molecules, BChl and spirilloxanthin, give clearly different compressibility values.

From the present data and the relatively short range of dispersion forces it seems evident that the chromophores probe the local structure of the protein matrix surrounding them and that the protein elastic properties are locally specific. A somewhat higher flexibility of BChl location in the light-harvesting protein complexes may stem from the specific binding of pigment molecules to protein polypeptides and the package of $\alpha\beta$ heterodimers into larger oligomers, leaving easily compressible voids. Both α and β polypeptides carry one BChl molecule, but the binding site of the spirilloxanthin molecule is shared by the two polypeptides (see Chapter 16 Zuber and Cogdell). Also, pressure-induced changes in excitonic coupling between chromophores in dimers and larger aggregates, resulting in the additional red shift of the lower excitonic component, could contribute to an overestimated compressibility in this case.

The perturbation induced by the external factor in the described experiments is substantial. At the highest applied pressure it constitutes 20–40% of the ‘internal pressure’ which could be defined as the pressure one

would have to apply in order to achieve a band shift comparable to the solvent shift. In other terms, it corresponds to the decrease of the average distance between protein molecules by 3–9%.

The estimated local compressibilities at room temperature fall into the typical range of bulk compressibilities of various proteins, organic solvents, polymers and molecular crystals. These organics are approximately by an order of magnitude more compressible than observed in inorganic crystals. In crystals, a single set of elastic moduli characterizes all the elastic properties of the crystal. In protein macromolecules, various local elastic constants are needed in order to understand their properties and functioning. A quantitative correlation between the observed pressure effects and structural changes is still not available.

VII. Concluding Remarks

Retracing the Introduction to this chapter, one can conclude that the 15-years-ago understanding of the antenna-RC coupling problem was qualitatively correct. Although modern experimental techniques have allowed the specification of many important details and made the picture much richer, the basic concepts have remained essentially unchanged. However, the field is still highly descriptive and progress in quantifying the underlying mechanisms is too slow. Some of the pending important problems were pointed out in the main text.

Recent years have destroyed an old illusion that all we need for a complete picture of excitation transfer and trapping dynamics is detailed structural information about the system. This structural information still seems to be only a prerequisite for a deeper understanding of excitation transfer, which will require the application of many approaches.

One of the achievements of the reviewed period, unfortunately not paid due attention in this chapter, is the realization that different inhomogeneous effects constitute a primary characteristic of the protein medium. At the same time, both the kinetics and the dynamics of the antenna-RC coupling are largely governed by the specific protein medium. Future progress is expected through exploiting this knowledge.

Acknowledgments

It is my pleasant duty to thank all my collaborators, first of all V. I. Godik, T. Pullerits and K. Timpmann together with whom we have been searching the puzzles of photosynthesis and whose excellent contribution to the subject I have partly reviewed here. I am grateful to L. Juhansoo and E. Vaik for their help in preparation of the manuscript.

Summary

Green photosynthetic bacteria contain antenna complexes known as chlorosomes. These complexes are appressed to the cytoplasmic side of the inner cell membrane and function to absorb light and transfer the energy to the photochemical reaction center, where photochemical energy storage takes place. Chlorosomes differ from all other known photosynthetic antenna complexes in that the geometrical arrangement of pigments is determined primarily by pigment-pigment interactions instead of pigment-protein interactions. The functional role of the proteins found in chlorosomes is not well understood. The bacteriochlorophyll *c*, *d* or *e* pigments found in chlorosomes form large oligomers with characteristic spectral properties significantly perturbed from those exhibited by monomeric pigments. Because of their close spatial interaction, the pigments are thought to be strongly coupled electronically, and many of the optical properties result from exciton interactions.

In addition to chlorosomes, the green sulfur bacteria contain another unique antenna complex known as the bacteriochlorophyll *a* protein, or the Fenna-Matthews-Olson (FMO) protein. This complex was the first pigment-containing photosynthetic complex to have its high resolution structure determined. It has been intensely studied by spectroscopic and theoretical methods.

This review summarizes existing knowledge on the chemical composition and properties of chlorosomes, the evidence for the oligomeric nature of chlorosome pigment organization and proposed structures for the oligomers, the properties of and possible functions of chlorosome proteins, the kinetics and mechanisms of energy transfer in chlorosomes, and the structure and spectroscopic properties of the FMO protein.

I. Introduction

Green photosynthetic bacteria contain two unique antenna complexes. Chlorosomes are found in both the green sulfur bacteria and the green filamentous bacteria. In addition to chlorosomes, a bacteriochlorophyll *a*-containing protein known as the Fenna-Matthews-Olson (FMO) protein is found in the green sulfur bacteria. Together, they constitute the bulk of the antenna pigments in these organisms. Interest-

ingly, the two types of complexes represent the extremes of pigment organization, with the FMO protein being a classic pigment-protein, where the protein serves as a scaffold to which pigments are attached, while the chlorosome is organized on a completely different principle, with self-assembled pigment oligomers and relatively little direct pigment binding by the few proteins that are present.

Chlorosomes are membrane-associated antenna complexes found only in green photosynthetic bacteria. Cohen-Bazire et al. (1964) first reported chlorosomes and called them *Chlorobium* vesicles. A comprehensive account of the early work on chlorosomes is given by Pierson and Castenholz

Abbreviations: BChl – bacteriochlorophyll; *Cb.* – *Chlorobium*; CD – circular dichroism; *Cf.* – *Chloroflexus*; FMO protein – Fenna-Matthews-Olson BChl *a* protein; LD – linear dichroism; *Pc.* – *Prosthecochloris*; *Pd.* – *Pelodictyon*

(1978), which should be consulted for references to the older literature. Staehelin et al. (1978, 1980) proposed that the name of this complex should be changed to chlorosome (green body) in recognition of the fact that these structures are more widely distributed than is implied by the name *Chlorobium* vesicle, and this term has become universally adopted. Previous reviews of chlorosome antennas can be found in Olson (1980a), Blankenship et al. (1988b), Zuber and Brunisholz (1991), Holzwarth et al. (1992) and van Grondelle et al. (1994).

There are two families of green photosynthetic bacteria, the green sulfur bacteria (Chlorobiaceae) and the green filamentous bacteria (Chloroflexaceae) (Trüper and Pfennig, 1992; Pierson and Castenholz, 1992). The two groups are only distantly related to each other by the criterion of 16S rRNA comparison (Gibson et al., 1985; Woese, 1987) and have very different reaction centers and integral membrane antenna complexes, as well as entirely distinct metabolic and ecological characteristics (see Chapters 1, by Imhoff, 3 by Pierson and Castenholz, 4 by Van Gemerden and Mas, 30 by Feiler and Hauska, 32 by Feick et al. and 40 by Sirevåg for further discussion of these characteristics). Yet these widely separated bacterial lines contain chlorosomes, remarkably similar antenna complexes, the presence of which can be considered to be their primary common characteristic. The possible evolutionary significance of this unusual situation has been discussed by Pierson and Olson (1989) and Blankenship (1992), and is considered below in section IX of this chapter.

Chlorosomes contain bacteriochlorophyll (BChl) *c*, *d* or *e*, usually as a complex mixture of structurally similar yet distinct structures (see below and Chapter 8 by Senge and Smith). BChl *c* is the main chlorosome pigment in many green sulfur bacteria, and is also found in all known green filamentous bacteria. BChls *d* and *e*, which are structurally related to BChl *c*, are found only in various species of green sulfur bacteria. All these pigments were formerly known as *Chlorobium* chlorophylls, and collectively are now referred to as chlorosome chlorophylls (Smith, 1994). BChl *c* (*d* or *e*) is found inside the chlorosome and is thought to be associated with rod-elements ca. 5–10 nm in diameter that have been visualized by electron microscopy (see Chapter 13 by Oelze and Golecki).

It is now quite clear that the mechanism of pigment organization in chlorosomes must be substantially different than is found in more familiar pigment-

proteins. Chlorosomes contain surprisingly little protein, relative to the large amount of pigment present. Although there is considerable variation in the values reported in the older literature, much of this difference is almost certainly due to varying degrees of purity of the chlorosome preparations used (Pierson and Castenholz, 1978; Schmidt, 1980). Feick and Fuller (1984) reported a protein to BChl *c* ratio of approximately 2.2:1 (w/w) in *Chloroflexus* (*Cf.*) *aurantiacus*. A recent determination gave ratios of protein to BChl of about 0.5:1 (w/w) in *Chlorobium* (*Cb.*) *tepidum* (Chung et al., 1994). These values are in contrast to ratios much greater than one invariably found in other pigment-proteins. For example, the FMO protein from *Cb. tepidum* has seven BChl *a* molecules (911.5 Da each) associated with a monomer of protein of molecular mass 40,165 Da, (Dracheva et al., 1992) giving a protein to pigment ratio of 6.3:1.

The role of the small amount of protein in the chlorosome remains controversial. Some workers maintain that protein is necessary in some way to stabilize the chlorophyll structures in the chlorosome while others maintain that proteins serve only to give the chlorosome the correct shape. Possible structural and mechanistic consequences of this relatively small protein content are discussed in detail below in sections III, IV and V.

II. Chlorosome Composition

Purified chlorosome preparations can readily be obtained from cell homogenates either simply after cell breakage (Schmidt, 1980), or after further treatment with detergents (Feick and Fuller, 1984) or chaotropes (Gerola and Olson, 1986). Chlorosomes from both types of green bacteria contain lipids, proteins and carotenoids as well as chlorophylls.

A. Bacteriochlorophylls *c*, *d* and *e*

1. Structure and Distribution

All green bacteria contain either BChl *c*, *d* or *e*. The structures of these pigments are shown in Fig. 1 (also see Chapter 8 by Senge and Smith). The numbering used in Fig. 1 is the IUPAC system. Much of the older literature uses the Fischer system, in which position 3 is numbered 2, 3¹ is 2a, 8 is 4, 12 is 5, 13¹ is 9, 13² is 10 and 20 is δ . The chlorosome chlorophylls have

Fig. 1. Structures of the chlorosome chlorophylls, bacteriochlorophylls *c, d* and *e*.

several distinctive structural features in common. These include the OH group at the 3¹ position and the lack of the carboxymethyl substituent found in most chlorophylls at the 13² position. The stereochemistry at the 3¹ position can be either R or S, and is often found as a mixture of diastereomers. There is a trend toward S stereochemistry at the 3¹ position as the substituents at the 8 and 12 positions become more bulky (Bobe et al., 1990; Smith, 1994; Chapter 8 by Senge and Smith). In contrast to the Chloroflexaceae which contain almost exclusively BChl *c*, the major light-harvesting pigments in different types of Chlorobiaceae are BChl *c, d* or *e*. A given organism usually contains a mixture of different homologs of only one of the three pigments, although in some strains of *Cb. vibrioforme* and *Cb. limicola*, both BChl *c* and *d* are often found (see below).

Bacteriochlorophylls *c, d* and *e* can be distinguished by the absorption maxima of their Q_y band both in vivo and in vitro (Oelze, 1985; Scheer, 1991; Hawthornthwaite and Cogdell, 1991; Hoff and Ames, 1991). A characteristic feature of the bacteriochlorophyll in the chlorosomes is that its red absorption maximum is red shifted 70–80 nm with respect to that of the monomeric form observed in organic solvents. This spectral shift is largely due to

aggregation, and is discussed in detail below. Spectroscopic properties of chlorosome chlorophylls in a variety of solvents have been reported by Fetisova and Borisov (1973) and Brune et al. (1988b).

In cell suspensions of different strains of green sulfur bacteria the long wavelength Q_y absorption for the BChl *c* containing species lies between 745 nm and 760 nm. For the BChl *d* and BChl *e* containing species the corresponding values are 725–745 nm and 715–725 nm, respectively (Gloe et al., 1975; Hawthornthwaite and Cogdell, 1991; Hoff and Ames, 1991; Chapter 1 by Imhoff). At 5 K Otte et al. (1991) found that intact cells of *Prosthecochloris (Pc.) aestuarii*, *Cb. vibrioforme* and *Cb. phaeovibrioides* which contain BChl *c, d*, and *e* respectively, have absorption maxima at 758, 746 and 728 nm.

The biosynthetic pathways of BChls *c, d* and *e* have not been studied in the same detail as those of other chlorophyll-type pigments. Suggestions that there may be some unusual steps in these pathways are provided by the observations that anesthetic gases specifically inhibit biosynthesis of these pigments (Ormerod et al., 1990) and that there is a specific effect of vitamin B₁₂ on chlorosome formation (Fuhrmann et al., 1993). Smith and co-workers have investigated the unique methylation that results in

much of the pigment diversity found in green bacteria (Bobe et al., 1990). None of the proteins involved in pigment biosynthesis in green bacteria have been isolated nor the genes that code for them identified.

2. Variations of Bacteriochlorophylls in Chlorobiaceae

In some green sulfur bacteria, the degree of methylation of the chlorin ring is dependent on the growth condition of the culture. Broch-Due and Ormerod (1978) observed that when *Cb. vibrioforme* was grown under low light intensities for four to five months there was a change in the in vivo absorption maximum in the red from 742 nm to 756 nm. Based on spectra of methanol extracts of the cells they concluded that the cells had mutated from a BChl *d*-containing form to a BChl *c*-containing form (Fig 1). Later, Smith and coworkers (Smith and Bobe, 1987; Bobe et al., 1990) found that cultures of *Cb. vibrioforme* strain B1-20 and *Cb. vibrioforme* strain NCIB 8327 responded to reduced light conditions in the culture by methylating substituents at the 8- and 12- positions of the bacteriochlorophylls. Eventually, BChl *d* was converted to BChl *c* in the last strain mentioned.

Concomitant with the increased methylation of the bacteriochlorophylls in the 8-, 12-, and 20-positions a red shift of the in vivo antenna pigment system is observed. In nature this could possibly be of advantage for the bacteria in competing for available light. Huster and Smith (1990) suggested that the homologation process increases the hydrophobic interactions between the individual bacteriochlorophyll molecules, giving rise to larger aggregates in the chlorosome antenna and thereby increasing the chance for light capture. Nozawa et al. (1992b) reported that the aggregation properties of different homologues of purified BChl *d* are strongly dependent on the nature of the peripheral substituents. Recently, similar results were reported for pigments from *Cb. limicola* (Uehara et al., 1994).

Otte et al. (1991) spectrally resolved at least two different pools of bacteriochlorophyll within the chlorosomes of green sulfur bacteria. The results were interpreted in terms of a lateral gradient promoting directional energy transfer to the antenna components in the membrane. Causgrove et al. (1992) came to a similar conclusion for BChl *e*-containing chlorosomes through analysis of energy transfer rates in isolated chlorosomes. Other data related to this

question in both families of green bacteria are discussed in Section VII.

In all three types of bacteriochlorophyll isolated from green sulfur bacteria the major esterifying alcohol is the C-15 isoprenoid, farnesol. Thus, in batch cultures of *Cb. limicola* grown for 21 days, Caple et al. (1978) found that 91% of the esterifying alcohols of the BChl *c* molecules was *trans*, *trans*-farnesol with minor amounts of five additional alcohols, where *cis*-9-hexadecen-1-ol and *trans*-phytol each comprising 3% of the total. Otte et al. (1993) identified the esterifying alcohols in *Cb. vibrioforme* and *Cb. phaeovibrioides* by mass spectrometry. In addition to farnesol, various minor esterifying alcohols were found, including phytol, oleol, cetol, 4-undecyl-2-furanmethanol and decenol.

3. Variations of Bacteriochlorophylls in Chloroflexaceae

The BChl *c* composition of Chloroflexaceae consists only of the 8-Et, 12-Me homologue (Gloe and Risch, 1978; Brune et al., 1987b; Bobe et al., 1990). The main esterifying alcohol is stearyl with phytol and all-*trans* geranylgeraniol as minor components (Risch et al., 1979). Fages et al. (1990) and Larsen et al. (1994) reported the presence of two additional alcohols in *Cf. aurantiacus*; hexadecanol and octadec-9-enol. It has been observed that *Cf. aurantiacus* can take up exogenous long chain fatty alcohols and incorporate them into the BChl *c* as the esterifying alcohol, thus changing the homolog distribution. By addition of short chain (C10, C12) or long chain (C20) alcohols novel BChl *c* homologs could also be formed (Larsen et al., 1995). Chlorosomes from *Cf. aurantiacus* contain trace quantities of BChl *d*, as well as substantial amounts of both the R and S diastereomers at the 3¹ position of BChl *c*, with a ratio that is somewhat dependent on culture conditions (Brune et al., 1987b; Bobe et al., 1990; Fages et al., 1990; Larsen et al., 1994).

Why are the bacteriochlorophyll molecules within the chlorosomes of one species of green bacteria present in so many different homologous forms? Is this a functional adaptation or is it simply a result of 'slippage' in the biosynthesis of these pigments? Are the chemically distinct pigments uniformly distributed within the chlorosome or is there a spatial and energetic gradient with the shorter wavelength-absorbing pigments further from the membrane, thus 'funneling' excitations toward the membrane and

increasing the efficiency of trapping by the reaction center? If this is so, how is such a nonuniform distribution of pigments achieved during assembly of the chlorosome? Unfortunately, none of these questions can be answered definitively, and for many of them almost no information is available.

In conclusion, it is clear that chlorosomes are not homogeneous with respect to pigment composition, as indicated by the wide variety of bacteriochlorophylls present with different esterifying alcohols and peripheral substituents in the chlorin ring, as well as different stereochemistries at the 3' position, all of which are sensitive to culture conditions.

B. *Bacteriochlorophyll a*

In highly purified chlorosomes from *Cf. aurantiacus* Schmidt (1980) found a specific BChl *a*-complex with a characteristic absorption maximum at about 790–795 nm in amounts corresponding to about 5% of the BChl *c* content of the chlorosomes (Fig. 2). Similar results were subsequently reported by Sprague et al. (1981a), and Feick et al. (1982). There is now a considerable body of evidence that shows that the molar ratio of BChl *c* to BChl *a*, both in whole cells and in isolated chlorosomes depends strongly on growth conditions (Pierson and Castenholz, 1978; Sprague et al., 1981b; Feick and Fuller, 1984; Oelze, 1992; Lehmann et al., 1994a; Larsen et al., 1994; Foidl et al., 1994; see also Chapter 13 by Oelze and Golecki). The molar ratio of BChl *c* to Bchl *a* in isolated chlorosomes ranges from approximately 25:1 in cells of *Cf. aurantiacus* grown under low light intensity (Feick et al., 1982) to 2:1 in log-phase cells grown at high light intensity (Lehmann et al., 1994a). This special form of BChl *a*, known as B790 or B795 after the wavelength of the Q_y absorption band, was proposed to be associated with a M_r 5.8-kDa protein (Feick and Fuller, 1984). The evidence concerning this assignment is discussed in Section II E.

Chlorosomal BChl *a* has also been observed in the green sulfur bacteria, where most of the BChl *a* is found in the water-soluble FMO-protein (section VI). Fig. 3 shows absorption and fluorescence spectra of chlorosomes isolated from three species of green sulfur bacteria. In highly purified chlorosomes isolated from *Cb. limicola*, the level of BChl *c* is much higher than that of BChl *a*, with a molar ratio of approximately 100:1 (Gerola and Olson, 1986). This is contrast to the substantially higher amounts

Fig. 2. Absorption (solid line) and fluorescence emission spectra (dashed line) of isolated chlorosomes from *Cf. aurantiacus*. Fluorescence excitation was at 460 nm. Figure courtesy of Judy Zhu.

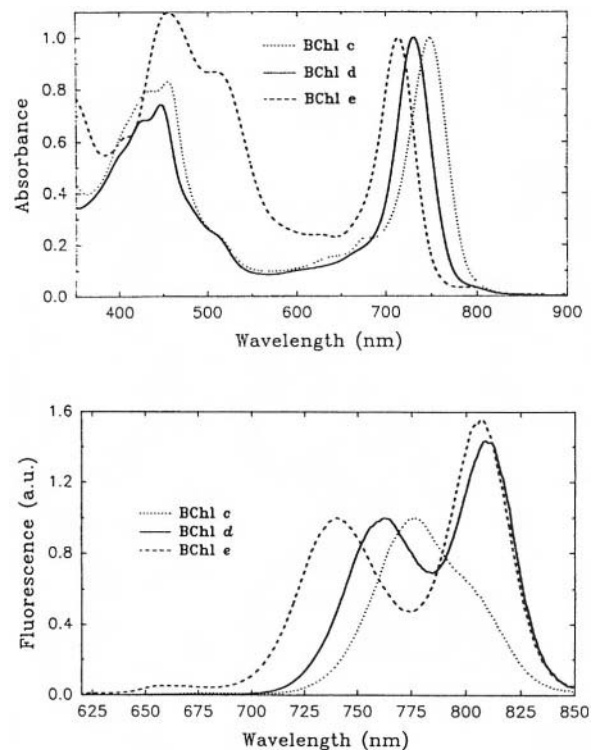

Fig. 3. Absorption (A) and fluorescence (B) of chlorosomes isolated from *Chlorobium limicola* (BChl *c*), *Chlorobium vibrioforme* (BChl *d*) and *Pelodictyon phaeoclathratiforme* (BChl *e*). Figure reproduced with permission from Causgrove et al. (1992).

of BChl *a* found in chlorosomes of *Cf. aurantiacus*, as indicated above. The presence of chlorosomal BChl *a* was detected in intact cells of three species of Chlorobiaceae by absorbance and fluorescence spectroscopy at 5K (Otte et al., 1991) and in isolated chlorosomes and membranes by time-resolved fluorescence spectroscopy at room temperature (Causgrove et al., 1992). The chlorosomal BChl *a* in these species not only had similar spectroscopic properties but also was present in approximately the same ratio to the total BChl. Similar results were reported recently by Van Noort et al. (1994).

B795 is generally believed to function as an intermediate in the energy transfer between the chlorosome and the membrane-embedded antennas and reaction centers. This conclusion is based primarily on spectroscopic data in *Cf. aurantiacus* (Betti et al., 1982; Van Dorssen and Ames, 1988; Mimuro et al., 1989; Holzwarth et al., 1990b; Müller et al., 1990, 1993; Miller et al., 1991) and various species of green sulfur bacteria (Otte et al., 1991; Causgrove et al., 1990b, 1992; Van Noort et al., 1994). While this position in the energy transfer sequence very strongly suggests that the BChl *a* is indeed physically located in the region of the chlorosome that is proximal to the membrane, this has not been demonstrated directly. More work is needed to clarify the environment of BChl *a* in chlorosomes, especially in light of reports that suggest multiple spectral forms of BChl *a* in chlorosomes (Mimuro et al., 1994b; Savikhin et al., 1994b).

C. Carotenoids

Isolated chlorosomes from both types of green bacteria contain substantial amounts of carotenoids (Schmidt, 1980). In the Chlorobiaceae the major carotenoid is the aromatic chlorobactene (Liaaen Jensen et al., 1964), which is also detected in the thermophilic *Cb. tepidum* (Wahlund et al., 1991). In the chlorosome fraction of *Cb. limicola* chlorobactene comprises 69%, neurosporene 21% and lycopene 8% of the total carotenoid content (Schmidt, 1980). In the brown-colored *Cb. phaeobacteroides* the carotenoids are solely isorenierate/beta-isorenierate absorbing at 505 nm in the intact cell (Overmann et al., 1992).

In chlorosomes isolated from *Cf. aurantiacus* β - and γ -carotene and a hydroxy derivative of the latter comprise 36%, 43%, and 12% respectively of the total (Schmidt, 1980). These are the principal

carotenoids in whole cells (Halfen et al., 1972). Schmidt (1980) reported that two-thirds of the hydroxy- β -carotene in the chlorosomes was glucosidated. The glucoside of hydroxy- β -carotene increased relative to the other carotenoids in the chlorosomes isolated from cells grown at either high light-intensities or at suboptimal temperatures and may therefore possibly have a role in protecting the photochemical systems from photodamage (Schmidt et al., 1980). Interestingly, some of the glucosides of the hydroxy- β -carotene has been found to be acylated with either C16:0 or C16:1 fatty acids. Some of these compounds are probably located in the envelope of the chlorosome, because they are lost from the chlorosome fraction after SDS treatment (K. Matsuura and S. Takaichi, personal communication).

Much of the carotenoid in *Cf. aurantiacus* is not associated with either the chlorosome or the cytoplasmic membrane. This carotenoid is localized in structures known as wax oleosomes (Beyer et al., 1983), and is recovered as a copious bright orange floating pellet upon cell breakage followed by ultracentrifugation. The amount of this fraction is greatly increased in cells grown at higher light intensity, imparting a distinct gold color to the cultures, hence the name *aurantiacus* (Pierson and Castenholz, 1974a,b). The function of this carotenoid is not known, although it probably does not transfer energy to bacteriochlorophyll due to the very short distance dependence of carotenoid to chlorophyll energy transfer (see Chapter 18 by Frank and Christensen). It is therefore probably ineffective at driving photosynthesis. The efficiency of carotenoid to BChl energy transfer in whole cells of any species of green bacteria apparently has not been measured quantitatively, although Van Dorssen et al. (1986b) found an apparently high efficiency of energy transfer from carotenoid to BChl *c* in isolated chlorosomes.

D. Lipids

The primary distinguishing characteristic of the lipid content of chlorosomes from both families of green bacteria is the presence of large amounts of glycolipids, which are rare or absent from most purple bacteria. The glycolipids are significantly enriched in the chlorosomes compared to the cytoplasmic membranes (see Chapter 10 by Imhoff and Bias-Imhoff).

In total lipid extracts of *Cf. aurantiacus* cells, wax esters comprised 45 mol %, polar lipids 36 mol %

and chlorophylls and carotenoids 11 and 8 mol %, respectively (Beyer et al., 1983). Wax esters are rarely found in bacteria, but in *Cf. aurantiacus* they are dominating both in oleosomes and spindle-shaped bodies found in a floating fraction after cell breakage and also in the chlorosomes and plasma membrane fractions (Beyer et al., 1983). The dominating wax ester in *Cf. aurantiacus* is the fully saturated C₃₆ (Knudsen et al., 1982). Because the wax-esters are very hydrophobic molecules, the authors speculated that they might be a component of the presumed hydrophobic interior of the chlorosomes, although this has not been examined in isolated chlorosomes. Interestingly, the mesophilic *Cb. limicola* does not possess any wax esters, in contrast to the thermophilic *Cb. tepidum* (Knudsen et al., 1982; Wahlund et al., 1991). This suggests a possible role for the wax esters in maintaining a structural integrity of membranes or hydrophobic domains during growth at elevated temperature.

The polar lipid fraction from chlorosomes contains phospholipids and glycolipids in addition to the bacteriochlorophylls (Schmidt, 1980). Monogalactosyldiglycerol (MGDG) is found in chlorosomes from both types of green bacteria and *Cf. aurantiacus* also contains a diglycosyldiglycerol with glucose and galactose as carbon moieties (Knudsen et al., 1982). It has been suggested that the MGDG has a structural role in the chlorosomes by forming a monolayer covering the cytoplasmic boundary of the chlorosome (Cruden and Stanier, 1970). However, Holo et al. (1985) were not able to correlate the content of bacteriochlorophyll and galactolipids in cells grown under different conditions where different amounts of bacteriochlorophyll are produced, even though it has been reported that an enlargement of the average chlorosome volume up to a factor of 1.9 can take place in cells of *Cf. aurantiacus* (Golecki and Oelze, 1987). The work of Holo et al. (1985) also indicated that the chlorosome proteins are masking the galactose moieties on the galactolipids by comparing the agglutination pattern with *Ricinus* lectins before and after tryptic digestion of the chlorosome proteins.

The preferred location of glycolipids in chlorosomes in both families of green bacteria suggests that there may be an important role for these lipids in chlorosome structure and function. Recently, Uehara et al. (1994) have demonstrated that aggregated BChl *c* with spectral properties very close to those of the pigments in vivo can be assembled in aqueous

suspensions if MGDG is included, lending strong support to this idea. Similar results were reported by Hirota et al. (1992) and Miller et al. (1993a,b) using protein-free fractions from cell extracts. See also Section IIIB. Thus, there is the suggestion that these lipids have a specific role in the pigment organization in chlorosomes. More work is needed on the localization and composition of lipids in chlorosomes and the properties of pigment aggregates as a function of lipids.

E. Proteins

The protein composition of chlorosomes is now reasonably well established for *Cf. aurantiacus* and is beginning to be so for the green sulfur bacteria. The possible functional role(s) of these proteins continues to be a controversial subject, as is discussed in Section VI.

Purified chlorosomes from *Cf. aurantiacus* contain three major proteins with molecular weights of 18, 11 and 3.7 kDa based on electrophoretic mobility on SDS-PAGE, and smaller amounts of a 5.8 kDa protein (Feick and Fuller, 1984). The 3.7 kDa M_r polypeptide was chemically sequenced by Wechsler et al. (1985b), who reported a molecular mass of 5.6 kDa and proposed a structural model for how this protein might bind BChl *c* to seven Gln and Asn residues. Later, the protein was determined to have an actual molecular weight of 5.7 kDa and to be processed at the carboxyl terminus from a longer preprotein (Theroux et al., 1990). The gene that encodes this protein is known as *csmA* (Theroux et al., 1990; Bryant, 1994). Assertions that this protein is a degradation product of much larger cellular proteins (Griebenow et al., 1990) cannot be correct, given the gene sequence.

Feick and Fuller (1984) proposed that the minor 5.8 kDa peptide observed in chlorosomes from *Cf. aurantiacus* is associated with the B795 BChl *a* found in all chlorosomes (see Section IIB). This assignment was made on the basis of protease digestion experiments that showed a correlation between the 790 nm absorption and the amount of this protein. In addition, the amount of this protein correlated with chlorosomal BChl *a* content in samples derived from cells grown under differing light intensity (Feick and Fuller, 1984). This putative 5.8 kDa pigment-protein has never been purified and biochemically characterized. Whether it is actually the binding site for chlorosomal BChl *a* has recently

been questioned by Lehmann et al. (1994a). These authors reported a partial amino acid sequence of a peptide in this molecular mass range. A lack of correlation between the amount of the 5.8 kDa peptide and BChl *a* content was observed by Foidl et al. (1994) in cultures of *Cf. aurantiacus* grown under a variety of culture conditions. No homolog to the 5.8 kDa protein has yet been identified in green sulfur bacteria, although the much lower content of BChl *a* in these chlorosomes might well make its identification difficult.

Much of the protein in chlorosomes from six strains of green sulfur bacteria is accounted for by a 6.2–6.3 kDa polypeptide (Wagner-Huber et al., 1988, 1990; Chung et al., 1994). This protein is almost certainly the homolog to the 5.7 kDa CsmA protein found in *Cf. aurantiacus*. The sequence identity among the 6.2 kDa polypeptides isolated from *Cb. tepidum*, *Cb. vibrioforme*, *Pelodictyon luteolum*, *Prosthecochloris aestuarii*, *Cb. limicola* and *Cb. phaeovibrioides* is more than 90% and the sequence identity of these polypeptides to the 5.7 kDa polypeptide of *Cf. aurantiacus* is 30% (Fig. 4) (Wagner-Huber et al., 1988; Zuber and Brunisholz, 1991; Chung et al., 1994).

The sequence similarity between the CsmA proteins from the two families of green bacteria, although modest, clearly suggests a functional

similarity and evolutionary relationship between these proteins in the chlorosomes of both green filamentous bacteria and green sulfur bacteria. The proteins are found in cellular structures that are very similar in terms of both overall morphology and function. In addition, all CsmA proteins from all green bacteria that have been examined so far are synthesized as precursor proteins that are post-translationally processed to cut 20–27 amino acids from the carboxyl terminus of the preprotein (Theroux et al., 1990; Chung et al., 1994). This type of processing is very unusual, so the similarity of this feature in the two groups of green bacteria is probably significant. Finally, the gene organization surrounding the *csmA* gene is similar in two green sulfur bacteria, *Cb. vibrioforme* and *Cb. tepidum*, as compared to *Cf. aurantiacus* (Theroux et al., 1990; Chung et al., 1994). All three organisms contain similar upstream and downstream open reading frames, although in the green sulfur bacteria an additional gene is found, known as *csmC*. This gene is not present in this location in *Cf. aurantiacus* and there is so far no evidence in this organism for any chlorosome protein with a similar sequence.

The sequences of all known CsmA proteins are compared in Fig. 4. None of the seven Asn and Gln residues proposed by Wechsler et al. (1985b) as possible BChl *c* binding sites in *Cf. aurantiacus* are

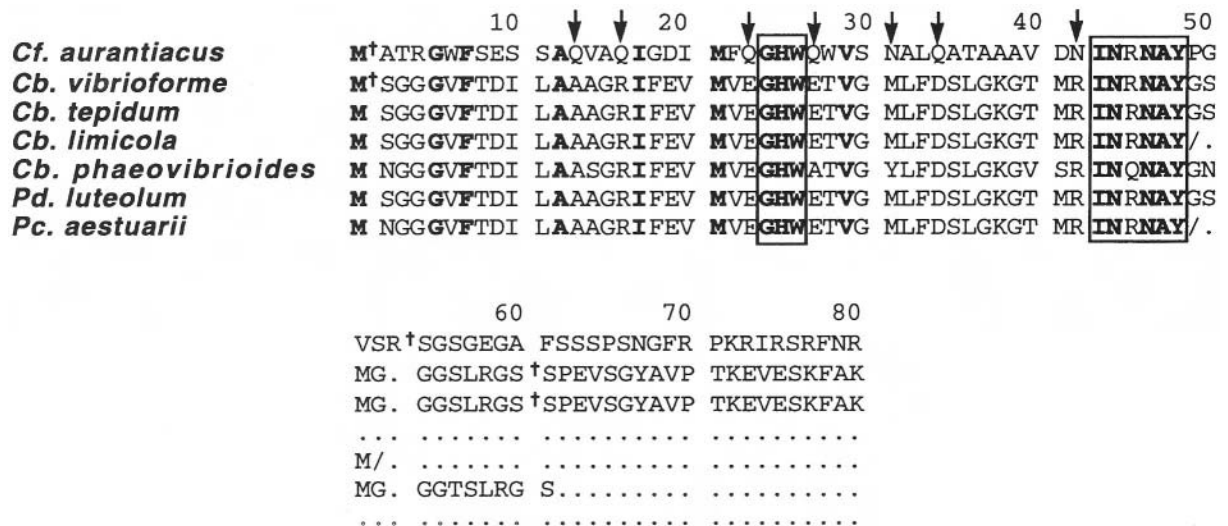

Fig. 4. Amino acid sequences of the CsmA proteins. Conserved residues are indicated by boldface and conserved stretches are boxed. Protein processing is indicated by †. Incomplete sequences are indicated by /. Residues proposed to be BChl *c* binding sites by Wechsler et al. (1985b) are indicated with arrows. The sequence for *Cf. aurantiacus* is from Wechsler et al. (1985b) and Theroux et al (1990), *Cb. vibrioforme* and *Cb. tepidum* from Chung et al. (1994), *Cb. limicola*, *Cb. phaeovibrioides*, *Pd. luteolum* and *Pc. aestuarii* from Wagner-Huber et al. (1988).

conserved in the CsmA proteins from green sulfur bacteria (arrows in Fig. 4), strongly suggesting that this assignment is incorrect. However, there are two conserved regions in the aligned sequences, which are boxed in Fig. 4. Lehmann et al. (1994a) have proposed that the His in the first of these regions could bind to the Mg of a BChl *c* in pigment oligomers.

A comparison of the hydropathy plot of the 6.3 kDa *Pelodictyon* protein with that of the 5.7 kDa *Cf. aurantiacus* protein supports this idea (Fig. 5). Both proteins have a hydrophilic region between residues 21 – 29 surrounded by hydrophobic segments on each side. The hydrophilic segments have a conserved amino acid sequence: Gly His Trp. In both proteins the hydrophobic region closest to the N terminus has a high potential for forming an alpha helix (Garnier et al., 1978), and in the case of the 5.7 kDa protein from *Cf. aurantiacus* the estimated length of this alpha-helix is about half of what is found for membrane-spanning proteins.

The sequences of the genes encoding the 11 and 18 kDa proteins have recently been determined (Niedermeier et al., 1994). The two genes, *csmM* and *csmN*, are cotranscribed as part of an operon (see Chapter 54 by Shiozawa). The sequences of the 11 and 18 kDa CsmM and CsmN proteins from *Cf. aurantiacus* are shown in Fig. 6 (Niedermeier et al., 1994). The two proteins exhibit a substantial degree of identity in the central region, and have similar hydropathy plots, suggesting that they are the descendants of an ancestral protein for which the gene underwent duplication and subsequent divergence.

A 7.5 kDa polypeptide is also a major protein component in chlorosomes from *Cb. limicola* and *Cb. tepidum* (Gerola and Olson, 1986; Gerola et al., 1988; Højrup et al., 1991; Chung et al., 1994). This protein has been sequenced (Højrup et al., 1991) and the gene that codes for it has been given the designation *csmB* (Bryant, 1994). Analysis of the amino acid sequence of the CsmB and CsmA proteins shows that there is less than 18% identity between the sequence of the 7.5 kDa CsmB protein of *Cb. limicola* and of either the 6.2 kDa CsmA polypeptide from the Chlorobiaceae or the 5.7 kDa CsmA protein from *Cf. aurantiacus*. However, Gerola et al. (1988) reported that the hydropathy plots and secondary structure profiles for the 7.5 kDa and 5.7 kDa proteins are similar. The 7.5 kDa polypeptide could not be found in detergent prepared chlorosomes from Chlorobiaceae lacking the baseplate (Wagner-Huber

Fig. 5. Hydropathy plots of the CsmA proteins from *Cf. aurantiacus* and *Pd. luteolum*. Sequences taken from Wechsler et al. (1985b), Theroux et al (1990) and Wagner-Huber et al. (1988).

et al., 1988) and it has been proposed that this protein is part of the baseplate binding the chlorosomes to the FMO protein (Højrup et al., 1991).

Some additional proteins with molecular weight between 9 and 38 kDa have been detected in chlorosomes from *Cb. limicola* (Gerola and Olson, 1986) whereas in *Cb. phaeobacterioides* and in *Cb. tepidum* only a 34.5 kDa protein was detected in addition to the low molecular weight polypeptide (Stolz et al., 1990). In contrast, chlorosomes isolated from *Cb. tepidum* by Chung et al. (1994) were found to contain a significantly larger number of proteins. These authors also noted that the sensitivity of different proteins to silver staining versus Coomassie blue staining was very different. This suggests that the protein composition of chlorosomes from green sulfur bacteria may be more complex than has previously been thought.

III. In vitro Aggregates of Chlorosome Chlorophylls

A large body of evidence has been accumulated that, taken as a whole, very strongly indicates that some sort of aggregated or oligomeric pigment complex is present in chlorosomes in vivo. An important component of this evidence is studies of the spectral properties of BChl *c* and related pigments in a variety of solvent systems in which pigment aggregates form spontaneously. These aggregates exhibit a substantial red shift of their absorbance spectra,

which arises from strong exciton-type interactions among the pigments. Depending on the details of the solvent system, the pigment concentration and the precise pigment involved, a range of aggregated species can be formed, ranging from dimers, through intermediate species to very large oligomers that readily precipitate from solution.

A. A. Krasnovsky was a pioneer in the study of chlorophyll aggregation in solid films and in colloidal suspension, and first proposed the concept of aggregated pigments as models for pigment organization in chlorosomes of green bacteria. Krasnovsky and coworkers (Krasnovsky and Pakshina, 1959; Krasnovsky et al., 1961, 1962, 1966; Bystrova et al., 1979; Krasnovsky and Bystrova, 1980) showed that purified BChl *c* from green sulfur bacteria exists in solid films in a 740-nm form very similar to the spectral form seen in native chlorosomes and whole cells. Formation of the aggregated pigment required the presence of Mg in the macrocycle (Krasnovsky et al., 1966), but did not require water or other polar groups (Bystrova et al., 1979), which are required to form long-wavelength absorbing aggregated forms of other photosynthetic pigments (Katz et al., 1991). They further showed by IR spectroscopy that the 740-nm form was an aggregate involving the 13¹-keto groups and also that the 3¹ OH group was involved in the aggregation. While the six-coordinated Mg structural model that they proposed (Bystrova et al., 1979) has since been superseded by other models discussed below, this seminal work was instrumental in shaping the thinking of all subsequent workers.

A. Aggregates in Nonpolar Solvents

Shortly after the proposals by Krasnovsky discussed above, Smith et al. (1983) demonstrated that the same type of spectra could be achieved with BChls *c*, *d* and *e* and Zn methyl bacteriopheophorbides *c* dissolved in n-hexane: methylene chloride (200:1). The addition of methanol converted the long-wavelength aggregate to monomers. Metal-free bacteriopheophorbides did not form aggregates under any conditions. An oligomeric aggregate was proposed with coordination of the 3¹-hydroxyl on one BChl *c* to the Mg of another BChl *c*, but this model did not propose any involvement of the 13¹ carbonyl group (see Section VA). Olson et al. (1985) reported absorption and CD spectra of BChl *c* in the same solvent system and carried out exciton calculations assuming the Krasnovsky structural model.

Brune et al. (1987b, 1988a) carried out similar experimental studies with BChl *c* from *Cf. aurantiacus*. (This pigment is a complex mixture of homologs, the major component of which is 8-ethyl-12-methyl BChl *c* stearyl ester in a racemic mixture of diastereoisomers with different configurations at the 3¹ chiral center). BChl *c* in hexane formed an oligomer with absorption and fluorescence emission spectra closely resembling those of *Cf. aurantiacus* chlorosomes. FTIR studies showed that the 13¹-keto group of BChl *c* is involved in forming the oligomer. Pyrochlorophyll *a*, which is structurally very similar to BChl *d*, but lacks the polar OH group at the 3¹ position, did not form long wavelength aggregates under the same conditions in which the chlorosome

chlorophylls readily form aggregates.

Olson and Pedersen (1988, 1990) showed that 4-isobutyl homologs of BChl *c*, which exist mainly in the 3¹-S configuration, form aggregates in CCl₄ whose absorption (747 nm maximum) and circular dichroism spectra resemble those of chlorosomes from green sulfur bacteria. These aggregates in water-saturated CCl₄ are oligomers consisting of 20–40 chlorophyll molecules (Uehara and Olson, 1992). FT-IR studies (Uehara et al., 1991) showed a keto-carbonyl stretching peak at 1641–3 cm⁻¹, tentatively assigned to a carbonyl group hydrogen bonded to a 3¹-hydroxyethyl group in the oligomer.

The fluorescence emission spectrum of the oligomer in CCl₄ peaks at ca. 760 nm (Olson and Pedersen, 1990), and two fluorescence decay times of, 19 and 67 ps have been measured (Causgrove et al., 1990a). These two decay times suggest that the oligomer/polymer is probably a mixture of more than one species, both of which absorb at ca. 747 nm.

Tamiaka et al. (1992, 1994) also showed that synthetic Zn chlorins in n-hexane-methylene chloride form aggregates with absorption maxima at 740 nm. Cheng et al. (1993) have demonstrated that Zn and Mg methyl bacteriopheophorbides *d* form aggregates with maxima at ca. 730 nm. These results show that the long hydrocarbon tail of the chlorophyll molecule is not required for oligomer formation.

Chiefari et al. (1995) recently reported an extensive study of aggregation of BChl *c* isolated from *Cf. aurantiacus*. They found that in dichloromethane the S diastereomer at the 3¹ position, but not the R, formed the 750 nm aggregate as monitored by UV-Vis, FTIR and NMR spectroscopy.

B. Aggregates in Aqueous Systems

BChl *c* will also form aggregates spontaneously in an aqueous medium in the presence of detergents or lipids (Hirota et al., 1992; Miller et al., 1993a,b; Uehara et al., 1994). In the two former studies, chlorosomes from *Cb. limicola* and *Cf. aurantiacus* were extracted with chloroform/methanol. The crude extracts, containing BChl *a* and *c* and lipids but no protein, were dissolved in methanol and then dispersed in buffer. The latter study used purified pigments and lipids, in particular MGDG. The extracts spontaneously formed aggregates with the spectral properties similar to those of BChl *c* in the chlorosome. Electron micrographs of aggregates from *Cb. limicola* showed a rather heterogeneous

distribution of stain-excluding bodies with sizes ranging from 40 to 400 nm. The aggregates from *Cf. aurantiacus* were somewhat more uniform in size with a range of diameters between 70 and 170 nm. (The dimensions of the aggregates are comparable to those of chlorosomes).

The aggregates show fluorescence, CD and LD spectra similar to those for intact chlorosomes. In addition, treatment of the aggregates with 1-hexanol causes a reversible shift from 740 nm to 670 nm just as in intact chlorosomes (see Section IV F).

IV. Spectroscopic Probes of Chlorosome Structure

A. Linear Dichroism and Fluorescence Polarization

A number of studies have all clearly demonstrated that the Q_y transition dipole moment of the BChl *c* in chlorosomes is oriented generally parallel to the long axis of the chlorosome. Early work on chlorosomes from *Cf. aurantiacus* using stretched polyvinyl alcohol films (Betti et al., 1982) or compressed gels (van Dorssen et al., 1986b) came to this general conclusion, but did not give as precise a value for the angle between the transition dipole and the chlorosome axis as did later measurements (Van Amerongen et al., 1988; Griebenow et al., 1991a; Van Amerongen et al., 1991). The early measurements almost certainly suffered from incomplete orientation of the chlorosomes and therefore provided only lower limits of the degree of BChl *c* organization in chlorosomes. Van Amerongen et al. (1988) measured the linear dichroism (LD) of chlorosomes from *Cf. aurantiacus* between 250 and 800 nm and found that the transition moments corresponding to the 741-nm and 461-nm BChl *c* absorption bands make angles of 20° and 30° respectively with the long axis of the chlorosome. Subsequently, Griebenow et al. (1991a) measured an average angle of 15 ± 10° for the 740-nm BChl *c* absorption band. The results of Van Amerongen et al. (1991) using fluorescence polarization gave very similar results.

Matsuura et al. (1993) analyzed chlorosomes from *Cf. aurantiacus* by both three-dimensional LD and circular dichroism (CD). Three-dimensional orientation of chlorosomes in polyacrylamide gels was carried out by uniaxial compression along the x-axis and uniaxial stretching along the z-axis without

changing the y-axis. It was assumed that the 10-nm axis of the chlorosomes oriented along the x-axis of the gel, and that the 30-nm and 100-nm axes of the chlorosomes oriented along the y- and z-axes respectively. The results confirmed the conclusions from earlier work that the Q_y transition moment is oriented along the long axis of the chlorosome, and that the BChl *a* component in the baseplate has its Q_y transition moment oriented nearly perpendicular to the long axis of the chlorosome.

Two slightly different spectral components of BChl *c* were indicated by the difference in the shapes of the main Q_y -bands in A_{\parallel} and A_{\perp} in the experiments of Matsuura et al. (1993). The absorption spectra were deconvoluted and two major components were found at 727 and 744 nm. The polarization values calculated for these two components were 0.59 and 0.76 respectively measured from the y-axis. These two components could also rationalize the various CD spectra observed in terms of two simple exciton-type spectra with the opposite order of positive and negative components (see Section IV B). BChl *c*744 was partially converted to BChl *c*727 by the addition of 0.5–0.6% 1-hexanol.

Considerably less work has been reported on the LD of chlorosomes from green sulfur bacteria. Fetisova et al. (1986) measured the LD of chlorosomes from *Cb. limicola* and found that the transition moment corresponding to the 730-nm band was parallel to the long axis of the chlorosome. The angle reported was $0 \pm 7^\circ$ for the ca. 740-nm band. Whether this value is significantly different from the $15 \pm 10^\circ$ values reported above for *Cf. aurantiacus* is not yet clear.

Kinetic studies of fluorescence polarization and transient photodichroism are discussed in section VI E.

B. Circular Dichroism (CD)

Whereas LD gives information about long-range order in the chlorosome, CD gives information about the local environment of the pigment molecules. The CD spectra reported for chlorosomes and oligomeric pigments arise primarily from excitonic interactions among the strongly coupled pigments. Surprisingly, the CD spectra that have been reported are extremely variable in intensity, number of components and even sign. These dramatically different CD spectra often arise from samples with essentially identical absorption spectra. There is as yet no quantitative

understanding of these effects.

Early CD spectra of chlorosomes were reported by Betti et al. (1982), Olson et al. (1985) and Van Dorssen et al. (1986b). Brune et al. (1990) investigated the CD spectra of chlorosomes from both *Cb. limicola* f. *thiosulfatophilum* and *Cf. aurantiacus* and found that both had similar spectra with positive peaks at 735 nm (*Cf.*) or 747 nm (*Cb.*) and negative peaks at 752 nm (*Cf.*) or 770 nm (*Cb.*).

Treatment of chlorosomes with 0.3% sodium dodecylsulfate removes absorbance attributable to BChl *a* but does not change the CD spectrum of the remaining BChl *c* (Brune et al., 1990). This suggests that in the presence of this concentration of detergent the BChl *c* sees the same local environment as in the native chlorosome.

Griebenow et al. (1991a) obtained both CD and LD spectra of *Cf. aurantiacus* chlorosomes. Intact chlorosomes were compared with so-called 'GEF-chlorosomes' (GEF=Gel-Electrophoretic-Filtration) that are essentially free of BChl *a* and proteins. The LD spectra were very similar, but the CD spectra of various preparations showed pronounced differences in the magnitude as well as the shape of the spectra and the number of maxima. The set of different CD spectra obtained could be simulated by linear combinations of two basic spectra. This suggests a variation in the relative amounts of two different species in the chlorosome samples.

Niedermeier et al. (1992) reported that proteolytically modified chlorosomes exhibit a 10–20-fold larger CD signal than do native chlorosomes, but the published CD spectra were sign-reversed in comparison with those of Blankenship et al. (1988a) and Brune et al. (1990). Lehmann et al. (1994b) reported an extremely large CD in chlorosomes from *Cf. aurantiacus* that had been treated with hexanol and proteinase K and the hexanol subsequently removed by dialysis. They correlated this large CD with the presence of large structures apparent in electron micrographs, that appeared to be aggregates of chlorosomes. The giant CD effect is well known in systems with large macromolecular assemblies whose dimensions are comparable to the wavelength of light (Keller and Bustamante, 1986). This may possibly be the explanation for at least part of the extreme variability in reported CD spectra of chlorosomes and pigment oligomers.

The factors that influence the extremely variable CD spectra of chlorosomes and aggregates are not well understood, and this represents an area where

considerable progress is needed, both in biochemically defining the conditions needed to obtain reproducible spectra and theoretically interpreting those spectra in the context of structural models of pigment organization.

C. Hole Burning Spectroscopy

Fetisova and coworkers (Fetisova and Muring, 1992, 1993, Fetisova et al., 1994) examined whole cells of *Cb. limicola*, *Cf. aurantiacus* and *Cb. phaeovibrioides* at 1.8 K using holeburning spectroscopy in fluorescence excitation and emission spectra and found persistent hole spectra that were consistent with a strongly exciton-coupled BChl *c* (*d* or *e*) chromophore system. The 0-0 band of the lowest exciton state was directly detected in each organism, with wavelengths of 774 nm, 752 nm and 739 nm, respectively for the three organisms. The linewidths of the 0-0 bands are relatively narrow, 90–100 cm^{-1} , indicating that the amount of inhomogeneous broadening in the absorption spectra is relatively small. This result seems to argue against suggestions from other groups that much of the spectral width of the Q_y absorption band arises from unresolved distinct spectral components in the chlorosome chlorophylls, although it is not yet clear if there is really a discrepancy that is quantitatively important, as the different techniques measure the pigment distribution rather differently. This point is discussed further in Section VII.

D. Resonance Raman and Infrared Spectroscopy

Vibrational spectroscopy, especially resonance Raman, has been extremely valuable in narrowing down the possibilities for the structural arrangements of pigments in chlorosomes. A reasonably consistent picture of the environment of various functional groups is now available, in particular, the Mg, the 13¹ keto group and the 3¹ hydroxyl group.

Lutz and van Brakel (1988) studied chlorosomes from both *Cb. limicola* and *Cf. aurantiacus* and found a single, sharp band at 1639–1640 cm^{-1} (*Cb.*) or 1641–1642 cm^{-1} (*Cf.*). They assigned this band to most of the C-13¹ carbonyls (BChl *c*) sharing identical interaction sites. A single, sharp band at 1607 cm^{-1} (*Cb.*) or 1609 cm^{-1} (*Cf.*) was assigned to methine bridge stretching which is sensitive to the coordination number of the Mg atom. From the position of the

band it was concluded that the Mg coordination number was five. This assignment was supported by the finding of a second band at 1552 cm^{-1} , also sensitive to coordination number. Lutz and van Brakel concluded that in chlorosomes of *Cb. limicola*, in particular, BChl *c* occurs as oligomers involving a single C-13¹ carbonyl ligand on each Mg atom. They did not assign a role to the 3¹ OH, as this group is not directly observable using resonance Raman.

Using FTIR, Blankenship et al. (1988a) and Brune et al. (1988a) found that a 1650 cm^{-1} band assigned to the 13¹ keto group in *Cf. aurantiacus* chlorosomes shifted to 1680 cm^{-1} upon exposure to pyridine vapors. This technique had been introduced earlier by Bystrova et al. (1979) in studies on oligomeric pigments isolated from green bacteria. Both groups proposed models for pigment organization, invoking six-coordinate Mg, with ligands from the 3¹ OH group and the 13¹ keto group. Brune et al. (1988a) also proposed structural models that maintained five coordinate Mg, but involved both the 3¹ OH group and the 13¹ keto group in intermolecular interactions. These models are discussed in more detail in Section V A.

Nozawa et al. (1990a) essentially confirmed the resonance Raman results of Lutz and van Brakel (1988), concluding that the Mg is five coordinate, but they interpreted their 1642 cm^{-1} (*Cf. aurantiacus*) band in terms of a 13¹ carbonyl either H-bonded to an OH group or coordinated to an Mg atom.

Hildebrandt et al. (1991) also used chlorosomes from *Cf. aurantiacus* and observed peaks at 1595, 1605, 1645 and 1715 cm^{-1} . The 1595 cm^{-1} peak was suggested as a possible indication of six coordination for a portion of the BChl *c* molecules, and the 1715 cm^{-1} peak was taken as evidence for a second conformational state of the 13¹-carbonyl group. The 1645 cm^{-1} peak was assigned to the 13¹-carbonyl group coordinated to a Mg atom in agreement with Lutz and van Brakel (1988). More recently, the same group, taking advantage of a wider range of model compounds reinterpreted the data of Hildebrandt et al. (1991) in terms of only five coordinate Mg (Hildebrandt et al., 1994). There now appears to be consensus that essentially all the chlorosome chlorophylls in chlorosomes are five coordinate.

Feiler et al. (1994) found that the 13¹ keto frequencies from three green sulfur bacteria were essentially identical to each other, and slightly different from the spectra in *Cf. aurantiacus*, suggesting a somewhat different arrangement of

pigments in the chlorosomes from the two classes of organisms. They also found that the C-7 formyl group of BChl *e*. in *Cb. phaeobacterioides* chlorosomes does not enter into any intermolecular interactions.

E. Nuclear Magnetic Resonance (NMR)

Nozawa and coworkers (1990b, 1991, 1992a, 1994) used the technique of Cross Polarization/Magic Angle Spinning (CP/MAS) ^{13}C NMR to investigate the ^{13}C -carbonyl group of BChl *c* in *Cf. aurantiacus* and BChl *c* ring current shifts in *Cb. tepidum*. They found evidence for an H-bond between the ^{13}C -carbonyl group and the 3^1 -hydroxyl group. On the basis of CP/MAS NMR experiments, Nozawa et al. (1991) proposed a stepped, parallel chain model in which the 3^1 -hydroxyl group ligates the Mg atom of one BChl *c* while simultaneously H-bonding to the ^{13}C -carbonyl group of another. More recent results from the same group (Nozawa et al., 1992a,b, 1993, 1994) have been interpreted in terms of a 'ring overlap' model, which is discussed in Section V B.

F. Effects of Polar Molecules

Bystrova et al. (1979) showed that the addition of polar molecules such as methanol or pyridine broke up the long wavelength absorbing in vitro aggregates of BChl *c* in nonpolar solvents. The action of these polar species is almost certainly to coordinate to the Mg in the center of the BChl *c* macrocycle, thus displacing the 3^1 OH (or ^{13}C keto) groups from adjacent molecules and converting the oligomer into monomeric pigments.

This same concept was applied to dried films of chlorosomes by Blankenship et al. (1988a) and Brune et al. (1988a), and the disaggregation followed by absorption spectroscopy and FTIR. Brune et al. (1987b) introduced the amphipathic molecule hexanol, which has similar effects on BChl *c* organization in chlorosomes in aqueous buffer solutions. They found that the effect could be partially reversed by dilution of the hexanol into buffer. More complete reversibility of the hexanol effect was demonstrated by Matsuura and Olson (1990).

Matsuura et al. (1993) showed that the characteristic linear dichroism of BChl *c* in chlorosomes (see Section IV A) was completely abolished upon the hexanol treatment. Remarkably, the dichroism returned to the control level upon removal of the

hexanol. This suggests that an oligomeric structure that was very similar to that in untreated chlorosomes self-assembled from the disrupted pigments when the hexanol was removed.

The environment of pigment in hexanol-treated chlorosomes is not yet well understood. The absorption spectrum appears to be very similar to that of monomeric pigment. However, it is clearly still contained within the chlorosome and is still able to transfer energy to the BChl *a* in the chlorosome baseplate, yet exhibits no long range ordering or evidence for exciton-type interactions characteristic of closely packed pigments (Matsuura and Olson, 1990; Matsuura et al., 1993). The pigment is converted upon hexanol treatment from the highly packed form present in the untreated chlorosome into a state that exhibits no spectral evidence for order or pigment-pigment interactions, yet is still contained within the envelope of the chlorosome and carries out efficient energy transfer to BChl *a* in the baseplate.

V. Structural Models for Pigment and Protein Organization in Chlorosomes

A wide range of structural models for BChl *c* organization in oligomers and chlorosomes have been proposed. The detailed structure of the oligomeric complexes formed by BChl *c* and related pigments is not yet known, and there may be several related but distinct structures that are found in both in vitro systems and in chlorosomes.

It is interesting to compare the BChl *c* oligomers with the 740 nm absorbing chlorophyll oligomer that forms in wet hydrocarbon solvents (Katz et al., 1991). The structure of the 740 nm Chl species is known in detail (Chow et al., 1975; Kratky and Dunitz, 1975, 1977). The spectral properties of this species are in many ways similar to those of the BChl *c* oligomers, in particular the very large absorption red shift. However, the structure of the Chl oligomer is by necessity different from that of the BChl *c* oligomer, because the former structure involves bridging by water between the C- ^{13}C carboxymethyl substituent and the Mg of an adjacent molecule. BChl *c* lacks the carboxymethyl substituent at the ^{13}C position, (as does pyrochlorophyll) so this arrangement is not possible. Furthermore, water is not required for formation of BChl *c* oligomers (see below). It is likely that the 3^1 OH group of BChl *c* has the same function of coordinating to the Mg as does the

bridging water in the 740 nm Chl species. However, in case of BChl *c* the group is internal to the molecule rather than part of the solvent, so the details of the geometry of the pigment organization must be different.

A. Models Invoking Local Interactions Among Functional Groups

Figure 7 compares some of the local structural models that have been proposed by various workers. The original Krasnovsky model (Fig. 7A) includes coordination of both the 3¹ OH and the 13¹ keto group, and proposes that the Mg is hexacoordinate. A slight modification of this was proposed by Blankenship et al. (1988a) in which the Mg was hexacoordinate but out of the plane of the macrocycle (Fig. 7C). We now know from resonance Raman that essentially all the BChl molecules have pentacoordinate Mg, so these models have largely been abandoned (see Section IV D).

The Smith et al. (1983) model (Fig. 7B) and the Lutz and van Brakel (1988) model (Fig. 7D) have pentacoordinate Mg, but in the former case the 13¹ keto group is left free, while in the latter the 3¹ OH is free. A variety of evidence, summarized in Sections III and IV, indicates that both these groups are directly involved in oligomer formation.

Two models that are consistent with the absorbance, FTIR, and resonance Raman data were proposed by Brune et al. (1988a) and are shown in Fig. 7E and F. In both models the Mg atom of BChl *c* is 5-coordinated as suggested by the resonance Raman data discussed in Section IV D. In the model shown in Fig. 7E the BChl *c* molecules are arranged in antiparallel chains, with the molecules in each chain linked by H-bonds between the 3¹-hydroxyl and the 13¹ keto groups. BChl *c* molecules in opposite chains are attached by hydroxyl ligation of the central Mg atoms. In the model shown in Fig. 7F the interacting BChl *c* molecules are arranged in parallel, stepped chains. Each BChl *c* molecule is linked to the next by 3¹-hydroxyl-to-Mg ligation and to the one after the next by 3¹-hydroxyl-to-13¹-keto H-bonding. Most of the recent large scale models of pigment organization discussed in the next section are similar to one or the other of these two models. Alden et al. (1992) favored the parallel chain model of Brune et al. (1988a) because of exciton calculations that indicate that it and not the antiparallel chain model could more easily explain the magnitude of the observed red

shift in oligomers. However, Nozawa et al. (1993) favored an extension of the antiparallel chain model that included more than a single row of pigments in the oligomer, also on the basis of exciton calculations. This has been termed the 'ring overlap model'. Recently, Chiefari et al. (1995) proposed an extension of the parallel chain model that also includes more than two chains of pigments.

Nozawa et al. (1991, 1992a, 1993, 1994) have proposed a number of variations on these models in which the pigments are arranged either face-to-face, back-to-back or piggyback, and have calculated the geometries of the pigments. Some of these models are also similar to a model proposed on the basis of NMR by Smith et al. (1986) for the solution structure of a BChl *d* dimer.

In organic solvent systems of somewhat higher polarity than those that favor the formation of long wavelength absorbing oligomers, a highly fluorescent intermediate-sized aggregate of BChl *d* with absorption maximum at 693 nm (710 nm for BChl *c*) is observed (Brune et al., 1987b, 1988a,b; Olson and Peterson, 1990; Olson and Cox, 1991; Uehara and Olson, 1992; Cheng et al., 1993). Olson and Cox (1991) proposed that this species is a tetramer, on the basis of log concentration vs. log concentration plots. In contrast, Causgrove et al. (1993) proposed a hexameric trimer of dimers model for this species. They argued that this species is probably not a building block of the large oligomers that mimic the *in vivo* environment in chlorosomes.

B. Models of Larger Scale Pigment Organization

Several attempts have been made to synthesize the local structure models discussed above with the larger scale information that comes primarily from electron microscopic investigations. While it is not yet clear which if any of these models is correct for either BChl *c* oligomers in solution or for BChl *c* in chlorosomes, they represent a new and important phase in this subject in which the molecular level interactions probed primarily by spectroscopy are correlated and reconciled with the larger scale structures visualized by microscopic techniques. Several of these models are reproduced in Fig. 8.

An interesting model for BChl *c* in chlorosomes has been developed by Katz and coworkers (Worcester et al., 1986, 1993; Katz et al., 1991). In their model system, aggregates of various chlorophylls are formed by addition of stoichiometric amounts of water to

Fig. 7. Structural models for the 740 nm BChl *c* oligomer. A. Bystrova et al., 1979; B. Smith et al., 1983; C. Blankenship et al., 1988a; D. Lutz and van Brakel, 1988; E,F. Brune et al., 1988a. Reproduced with permission from Alden et al. (1992).

rigorously dry solutions of a particular chlorophyll in nonpolar organic solvents such as D-toluene and D-octane. However, with BChl *c* no water is required for aggregate formation (see Section III A). The aggregates formed by BChl *c* from *Chlorobium* in

deuterated octane/toluene (1:1) are hollow cylinders 11–12 nm in diameter (determined by neutron scattering), and the absorption peak is at 750 nm. In the model of Worcester et al. (1986), the BChl *c* cylinders resemble the rod elements in chlorosomes

Fig. 8. Structural models for pigment organization into rodlike structures. Reproduced with permission from: Model A, Nozawa et al., 1993; Model B, Matsuura et al, 1993; Model C, Nozawa et al., 1994.

of green sulfur bacteria in shape and dimensions. However, the Q_y transition dipoles of the pigments in the Worcester et al. (1986) model are not parallel to the long axis of the tube. This appears to be inconsistent with the linear dichroism results in chlorosomes discussed in Section IV A, so this model is probably not a valid representation of the pigment structure in chlorosomes.

Several rod element models that are essentially a three dimensional extension into a tube of the antiparallel chain model first presented by Brune et al. (1988a) have been presented by Nozawa et al. (1992a,b, 1994) and Matsuura et al. (1993). The macrocycles are oriented in such a way that the tails are either all arranged towards the inside of the tube (Fig. 8A) (Nozawa et al., 1992a, 1993), or with alternate tails toward the inside and outside (Fig. 8C) (Nozawa et al., 1994). In most cases, the planes of the pigment macrocycles are essentially perpendicular to the surface of the tube, although in others, the pigments are covering the surface of the tube like scales on a snake (Fig. 8B) (Mimuro et al., 1992; Matsuura et al., 1993).

Perhaps the most ambitious and interesting of this new generation of larger scale structural models has been proposed by Holzwarth and Schaffner (1994). These authors used computer molecular modeling and energy minimization techniques to build up structures involving as many as 40 molecules of BChl-ide *d*. The basic local geometry is essentially the parallel chain model shown in Fig. 7e. In the Holzwarth and Schaffner model, the pigment

macrocycles are perpendicular to the surface of the tube, and the hydrocarbon tails are oriented toward the outside of the tube, leaving a large hole of about 50Å diameter down the center. It is not clear what might fill this hole in the chlorosome. The C-8 and C-12 aliphatic substituents are oriented towards the hole, so this region is predicted to be very hydrophobic.

C. Conclusions from *in vitro* Models and Spectral Studies on Chlorosomes

While it is not yet possible to give a definitive structure for the pigment oligomers present in the *in vitro* aggregates or in chlorosomes, certain conclusions can be safely drawn. 1). Chlorosomes contain pigment oligomers in which the basic geometry of the oligomer is determined by pigment-pigment interactions (The oligomers are possibly associated as a group with proteins, see Section V). 2). The Mg atoms in the BChl *c* molecules in chlorosomes are essentially all pentacoordinate. 3). The 13¹-carbonyl of each BChl *c* interacts strongly with a functional group on another BChl *c*. 4). The 3¹-hydroxyethyl group is involved in oligomer formation and is most likely to be directly coordinated to a Mg atom and hydrogen bonded to the 13¹-carbonyl group. 5). The BChl *c* molecules are close together and oriented in such a way that they exhibit strong excitonic interactions. 6). BChl *c* molecules show long range ordering with the Q_y transition moments aligned parallel to the long axis of the chlorosome.

D. Pigment-Protein Organization in Chlorosomes

While essentially all workers now agree that some sort of pigment oligomer is present in chlorosomes, there is still no consensus on the role(s) of proteins in chlorosome structure and function. The role of proteins in the organization of the bacteriochlorophyll molecules within the chlorosome has been a controversial subject for many years. Feick and Fuller (1984) presented a model for *Cf. aurantiacus* chlorosomes with the 5.7 kDa protein placed inside the rod elements forming a framework for the BChl *c* molecules and with the 11 and 18 kDa polypeptides located in the chlorosome envelope. Wechsler et al. (1985b) determined the primary structure of the 5.7 kDa CsmA protein and proposed that each protein binds seven BChl *c* molecules. They further suggested that each of the globular subunits in the rod elements observed in freeze-fracture EM are composed of 12 of these 5.7 kDa polypeptides. However, this view now seems unlikely, based on sequence comparisons of CsmA proteins from a number of organisms (see Section II E).

In contrast, Griebenow and Holzwarth (1989) and Holzwarth et al. (1990a,b) by means of detergent treatment and gel-electrophoresis obtained a protein-free preparation (so-called 'GEF chlorosomes') from *Cf. aurantiacus* cells in which the spectral properties of the BChl *c* molecules were similar to those of native protein-containing chlorosomes (Holzwarth et al., 1992). Furthermore, Wullink et al. (1991) localized antigenic sites of the 5.7 kDa protein to the envelope of the *Cf. aurantiacus* chlorosomes. These results were interpreted as indicating that the 5.7 kDa polypeptide is not embedded in the rod-structures participating in the organization of BChl *c* molecules as predicted in the models of Feick and Fuller (1984) and Wechsler et al. (1985b).

Niedermeier et al. (1992) investigated the effect of thermolysin treatment on the protein composition of *Cf. aurantiacus* chlorosomes. The 11 and 18 kDa proteins were degraded within 20 seconds after addition of the protease. Longer treatment also led to the digestion of the 5.7 kDa protein and simultaneously a change in the absorption intensity and rotational strength of the BChl *c* molecules. However, the authors were not able to correlate the decrease in the 740 nm absorption and the disappearance of the 5.7 kDa chlorosome protein and suggested that at least some of the BChl *c*

molecules within the native chlorosomes could be arranged as aggregates of BChl *c* molecules. Lehmann et al. (1994a) found that the ratio of pigment to protein in *Cf. aurantiacus* chlorosomes changed substantially when cells are grown under different light intensities and concluded on the basis of protease treatment experiments and CD spectra that the 5.7 kDa protein binds to pigment oligomers, possibly by way of the conserved His residue (Fig. 4).

Treatment of chlorosomes from *Cf. aurantiacus* with low concentrations of LDS resulted in a fraction with a full complement of proteins and antenna BChl *c* absorbing at 740 nm but at the same time the characteristic ellipsoid shape of the chlorosome was changed to a more spherical form (Miller et al., 1993b). At higher concentrations of the detergent a protein-free fraction possessing the same absorption spectrum was obtained. This fraction appeared in electron micrographs as stain excluding spheres with the same overall dimension as intact chlorosomes. Miller et al. (1993b) concluded that the protein-free spheres probably are micelles of BChl *c* molecules since the same structures could be produced when dispersing purified BChl *c* molecules into buffer.

Currently we are left with the question of the relationship between these protein-free structures or 'GEF chlorosomes' (Griebenow and Holzwarth, 1989) produced after detergent treatment and native chlorosomes. It may be that the BChl *c* molecules in the intact chlorosome are organized in oligomeric structures similar to those observed in artificial aggregates with no protein involvement at all. On the other hand, it is possible that removal of proteins either by detergent treatment or proteolysis disrupts the normal pigment organization and the BChl *c* molecules then spontaneously form aggregates which coincidentally have the same spectral properties as those of intact chlorosomes, and possibly a similar structure. We think, however, that the name 'chlorosome' should be restricted to subcellular preparations that have the characteristic ellipsoidal shape and which contain proteins, lipids, carotenoids, etc.

E. Structural Model for Overall Chlorosome Organization

Figure 9 shows a schematic model presenting our current picture of the organization of proteins and bacteriochlorophyll in the chlorosome antenna of *Cf. aurantiacus*. The model is based on data obtained

Fig. 9. Proposed model of the organization of proteins and pigments in chlorosomes of *Cf. aurantiacus*. For details see text.

from freeze-fracture electron microscopy, cross-linking experiments, surface-exposed localization of antigenic sites of the chlorosome proteins as well as the basic conclusions about the pigment organization and involvement of proteins from many lines of evidence, as discussed above.

The model depicts the BChl *c* molecules as being organized in rod-forming polymeric structures extending the full length of the chlorosome. No proteins are involved in the structural arrangement of the chlorophyll molecules: the polymeric structures are formed solely by pigment-pigment interactions as in artificial aggregates of BChl *c* molecules. However, in the model it is envisaged that the 5.7 kDa chlorosome protein penetrates deeper into the chlorosome core than do the 11 and 18 kDa proteins which are more exposed at the surface of the envelope of the chlorosome. In the 5.7 kDa protein the α helix region near the N terminus is long enough to penetrate the proposed monolayer of lipids forming the envelope of the chlorosome so that the conserved hydrophilic section with the His residue contacts the Mg-atom of a BChl *c* molecule in the rod element nearest the envelope. The 5.7 kDa 'aggregate-binding' CsmA protein might also be responsible for breaking up the aggregates into small domains of about 30 BChl *c* molecules, the unit of functionally connected BChl *c* molecules as determined by annihilation studies in *Cf. aurantiacus* using picosecond spectroscopy (Miller et al., 1991). The striation of the rod elements observed in the freeze-fracture EM may appear where the 5.7 kDa protein separates two pigment domains.

VI. Kinetics and Pathways of Energy Transfer in Chlorosomes

A. Overall Pathway of Energy Transfer

The overall energy transfer pathway of green bacteria is described by the scheme:

The latter steps of the energy transfer process are different in the green sulfur bacteria compared to the filamentous green bacteria, due to the substantial differences in the reaction centers and membrane-bound antenna complexes. Also, the filamentous green bacteria do not contain the FMO complex that is clearly an intermediate in the energy transfer pathway in all green sulfur bacteria.

The chlorosome antenna system is a classic example of the 'funnel' concept of photosynthetic antennas. Almost every successive pigment species in the scheme above has progressively red-shifted absorption and fluorescence spectra. The descending energy levels thus provide an energetic gradient of excitations into the reaction center. Absorption and fluorescence spectra and lifetimes, especially when coupled with careful biochemical resolution and separation procedures, can give insight into the pathway and mechanism of excitation transfer and trapping. Phycobilisomes found in cyanobacteria and red algae are another example of a peripheral antenna complex that has a substantial energy gradient, although there seems to be no structural relationship between the two classes of antennas, either in terms of pigments or proteins, and they are almost certainly independent evolutionary innovations.

Early fluorescence spectra that demonstrated energy transfer from BChl *c* to BChl *a* in green sulfur bacteria were measured by Krasnovsky et al. (1962, 1963) and the first quantitative measurements of this process were made by Sybesma and Olson (1963). Betti et al. (1982) and Van Dorssen et al. (1986b) reported fluorescence spectra of isolated chlorosomes from *Cf. aurantiacus* and Van Dorssen et al. (1986a) measured spectra from *Cb. limicola* chlorosomes. The role of B795 BChl *a* in the chlorosome baseplate in the energy transfer pathway was proposed on the basis of these and other studies.

B. Anomalies in the Fluorescence Yields and Lifetimes in Chlorosomes

A number of studies have pointed out a curious phenomenon in chlorosomes (in particular those from *Cf. aurantiacus*), that the intensity of BChl *c* and even in some cases the B795 BChl *a* fluorescence emission is remarkably insensitive to the integrity of the later steps in the energy transfer pathway. Normally, one expects that if the acceptor that receives excitations is removed, then the fluorescence intensity of the donor is greatly increased. This is because the major deactivation pathway for the excited state of the energy donor is energy transfer to the acceptor, so that when this pathway is lost, other pathways, such as fluorescence, must assume a larger role in the excited state decay. A dramatic example of this effect is given by Brune et al. (1990), in which the B795 baseplate was eliminated using SDS treatment, a method introduced by Griebenow and Holzwarth (1989). The fluorescence due to the B795 pigments is completely lost, but the intensity of the 750 nm fluorescence arising from the BChl *c* is virtually unaffected. Steady-state fluorescence measurements can be deceptive, in that low amplitude but long-lived components that are quantitatively not important in excited state decay pathways can dominate the steady state fluorescence spectra. However, time-resolved measurements also clearly show that the principal 10-15 ps lifetime of the BChl *c* excited states is virtually unaffected by the presence or absence of the B795 pigments (Holzwarth et al., 1990b; Miller et al., 1991).

There are at least two possible explanations for this unexpected result. First, the treatments that disrupt the energy transfer pathway may introduce new decay processes that were not present in the intact sample. These new quenching processes would then take the place of the energy transfer process that normally deactivate the excited state, with the result that the observed intensities and kinetics of BChl *c* emission are not greatly affected. While this effect can explain the observed results, it does so in an ad hoc way and requires the apparently fortuitous generation of just enough quenchers to almost precisely compensate for the loss of the energy transfer acceptors. However, it is not clear what happens to the B795 pigments upon SDS treatment, so that the existence of a chemically damaged pigment whose absorption is buried under the large BChl *c* absorption envelope yet was still able to quench excitations, is certainly

possible. It is also clear that chlorosomes are highly susceptible to excited state quenching, so this explanation seems plausible.

The other major way of explaining the near independence of the BChl *c* emission on the integrity of the energy transfer pathway is to propose that the observed BChl *c* emission arises from a pool of pigments that are not directly involved in the energy transfer to B795, and that the mainstream energy transfer is so rapid that the majority of BChl *c* antenna pigments contribute almost nothing to the steady-state emission spectrum. This explanation is also somewhat ad hoc, in that it proposes a functional heterogeneity in the BChl *c* and a putative ultrafast energy transfer process that is not yet well documented. However, some recent measurements do suggest that there is such an ultrafast component and that some excitations absorbed in BChl *c* are transferred to pigments absorbing in the 800 nm region on the femtosecond time scale (Savikhin et al., 1994b). Whether or not this can quantitatively account for the observations discussed above is not yet clear.

C. Kinetics of Energy Transfer within Chlorosomes

Borisov et al. (1977) and Fetisova and Borisov (1980a,b) made early time-resolved fluorescence measurements on subcellular complexes of *Cb. limicola*, and concluded that about 90% of the BChl *c* molecules transferred energy to BChl *a* in 20–50 ps. Brune et al. (1987a) made the first measurements of fluorescence lifetimes in isolated chlorosomes, and reported lifetimes of less than 30 ps for BChl *c* emission in *Cf. aurantiacus*.

A number of recent studies of the kinetics of energy trapping in green bacterial systems have been carried out by several groups using time-resolved fluorescence and absorption methods, with samples ranging from freshly isolated whole cells under physiological conditions to isolated complexes of various sorts at both room and low temperatures to purified oligomeric pigments. The data generally support a sequential energy transfer pathway from the BChl *c* (*d* or *e*) pigments in the body of the chlorosome to the baseplate to the membrane-bound antenna complexes and finally to the reaction centers. However, there are some inconsistencies in the available data that have not been resolved, so that a complete picture has not yet emerged. In particular,

the question of whether or not a graded series of different spectral forms of BChl *c* creates an energetic funneling within the chlorosome, is not at all clear. While there is substantial evidence that there are different spectral forms of BChl *c* within the chlorosome, some data argues that they are not important in the main energy transfer pathway. Also, recent studies suggest that there are ultrafast excited state decay and rise components in these systems that were not observed in the majority of reported studies due to insufficient time resolution.

Excitation annihilation in the chlorosome system is a consideration that must be addressed, in particular for the baseplate pigments, where energy tends to accumulate. This effect is a particular concern in this system because so many pigments are coupled together in a single chlorosome, and the use of high powered lasers will inevitably introduce multiple excitations into a single chlorosome. Depending on the details of the experimental arrangement, either singlet-singlet or singlet-triplet annihilation may dominate. While in many experiments annihilation effects may introduce undesirable complications in the observed fluorescence yields and excited state kinetics, this type of experiment can also yield useful information about pigment organization. Unfortunately, these effects have not yet been very thoroughly studied in the chlorosome system and much remains to be learned from this sort of experiment.

Vos et al. (1987), observed clear evidence for annihilation in chlorosomes from both *Cf. aurantiacus* and *Cb. limicola*, using flash-induced fluorescence yield measurements, and determined domain sizes for excitation diffusion at room temperature and 4K. In *Cb. limicola*, the domain size at room temperature was essentially the entire chlorosome, when dithionite was included, while it was much smaller if dithionite was not added or at low temperatures. For *Cf. aurantiacus*, the domain size was much smaller and could not be accurately determined at room temperature. Gillbro et al. (1988) and Miller et al. (1991) reported no intensity effects on BChl *c* excited state lifetimes in isolated chlorosomes from *Cb. limicola* and *Cf. aurantiacus*. In *Cf. aurantiacus*, the amplitude of the absorbance changes were affected, however, and a domain size of 30 BChl *c* was determined (Miller et al., 1991). Van Noort et al. (1994) observed evidence for annihilation effects in the baseplate region of chlorosomes from *Cb. vibrioforme*.

1. Energy Transfer Kinetics in *Chloroflexus aurantiacus*

In *Cf. aurantiacus* a major component of the BChl *c* excited state decay exhibits a lifetime of 10–15 ps, along with small amplitudes of longer components. This pattern has been observed by a number of groups using both time-resolved fluorescence and absorption techniques (Mimuro et al., 1989; Blankenship et al., 1990; Holzwarth et al., 1990b; Miller et al., 1991; Lin et al., 1991; Müller et al., 1993; Savikhin et al., 1994b). In addition to this component, Savikhin et al. (1994b) found substantial femtosecond timescale decay components in the BChl *c* decay.

Several, but not all, studies have found that the 10–15 ps BChl *c* decay is matched by a rise component in the baseplate BChl *a* 795. Mimuro et al. (1989) failed to observe such a correspondence in the decay of the BChl *c* emission and the rise of the BChl *a* emission at 805 nm, either by single photon timing or streak camera techniques. However, Müller et al. (1990) Holzwarth et al. (1990b) and Causgrove et al. (1990b) did observe corresponding rise and decay components, although the amplitudes of the decay and rise components were significantly different. Savikhin et al. (1994b) observed complex multi-exponential kinetics in the 800 nm region, including an ultrafast bleaching, interpreted as a femtosecond timescale excitation transfer from BChl *c* to B795 (or to a small pool of extremely red-shifted BChl *c* pigments). A slower rise was observed on the red edge of the B795 band, which was interpreted as energy transfer between two distinct pools of B795. Several earlier studies have also suggested that the B795 pigments have more than one spectral component. Mimuro et al. (1989, 1992, 1994a,b).

2. Energy Transfer Kinetics in Green Sulfur Bacteria

In the green sulfur bacteria the lifetimes of BChl *c*, *d* or *e* excited states are generally somewhat longer than in *Cf. aurantiacus*, as long as the redox-activated quenchers are reduced (see Section IX). Lifetimes of BChl *c*, *d* or *e* for all the green sulfur bacteria are in the 50–100 ps range (Fetisova et al., 1987, 1988; Gillbro et al., 1988; Blankenship et al., 1990; Causgrove et al., 1990b, 1992). Some of the early literature on energy transfer in these organisms may have mistakenly assigned the very short lifetimes

observed under aerobic conditions to energy transfer processes, while it now seems more likely that quenching processes are responsible for the short lifetimes observed under such conditions (see Section IX).

D. Minor Spectral Species as Energy Transfer Intermediates Within Chlorosomes

In phycobilisome antenna complexes, clear evidence for sequential energy transfers from more blue-shifted to more red-shifted pigments has been obtained (see Van Grondelle et al., (1994) for recent review). Whether such a 'funneling' takes place within chlorosomes is as yet unclear. While a number of steady-state studies using various types of spectroscopy have clearly indicated the presence of multiple pigment species in chlorosomes (Otte et al., 1991; Griebenow et al., 1991a; Matsuura et al., 1993; Mimuro et al., 1994a,b), it is much less clear whether or not these intermediates are important in mainstream energy transfer. Holzwarth et al. (1990b) observed a 5 ps fluorescence component in *Cf. aurantiacus* chlorosomes in which the BChl *a* of the baseplate had been removed, which was interpreted in terms of an intermediate BChl *c* species in the energy transfer in intact chlorosomes (Müller et al., 1993). However, transient absorption studies with femtosecond time resolution on intact chlorosomes do not reveal any evidence for spectral development of the sort that would be expected if this were indeed the case (Savikhin et al., 1994b), and it may be that this component is only present in samples that have had the baseplate removed. The important question of whether or not energetic funneling processes take place within chlorosomes remains unresolved.

E. Kinetics of Energy Transfer Measured with Polarized Light

A number of time-resolved measurements have been made in chlorosome systems using polarized light, and the results from different laboratories and using a range of organisms are generally consistent both with each other and with steady-state measurements. These kinetic studies generally support the ideas of pigment organization discussed in Sections IV and V. Fetisova et al. (1987, 1988) found that the polarization of fluorescence from BChl *c* in both *Cf. aurantiacus* and *Cb. limicola* was high ($p = 0.41-0.42$) and nearly

constant during the entire BChl *c* excited state lifetime. Similar results were reported by Freiberg et al. (1988) and Mimuro et al. (1994a). Gillbro et al. (1988) reported lower polarizations ($p = 0.2$) in *Cb. limicola*, as did a later report from the same group (Miller et al., 1991). Lin et al., (1991) using absorption difference techniques, observed an initial anisotropy $r(0)$ of 0.4 and also observed a 4–7 ps component of the anisotropy decay that was somewhat wavelength dependent, with a final $r(\infty)$ of 0.24 to 0.32. Savikhin et al., (1994b), using the highest time resolution absorption difference instrumentation employed in this system to date, found for *Cf. aurantiacus* $r(0)$ of 0.39–0.40 and $r(\infty) = 0.30-0.37$ throughout the BChl *c* absorption band. They observed a faster anisotropy decay (0.3–1.5 ps) than observed by Lin et al. (1991). In addition, Savikhin et al. (1994b) observed coherent oscillations in the BChl *c* region of the spectrum that damped within 1 ps, which were interpreted in terms of vibrational coherences in the pigment aggregates.

No evidence for $r(0) > 0.4$ has been obtained in any studies reported to date, despite the use of instrumentation with femtosecond time resolution. Such high values have been predicted in certain situations by Knox and Gülen (1993) (discussed in Chapter 15 by Struve) and are observed in FMO trimers (Section VIIIE) (Savikhin et al., 1994a; Savikhin and Struve, 1994). While the significance of these observations is not yet entirely clear, the differences may reflect the much stronger electron coupling of pigments in chlorosomes compared to FMO trimers.

In contrast to the observations discussed above that there is little depolarization of excited states within the lifetime of the BChl *c* (*d* or *e*) pigments, transfer to the baseplate BChl *a* leads to substantial depolarization. This is in agreement with numerous steady-state fluorescence and linear dichroism studies that concluded that these pigments have substantially different orientations (Section IVA). Fetisova and coworkers found in *Cb. limicola* (Fetisova et al., 1987, 1988; Freiberg et al., 1988) and *Cf. aurantiacus* (Fetisova et al., 1988) that this depolarization was complete ($r(\infty) = 0$) in 120 ps. Miller et al. (1991) observed an anisotropy decay in *Cf. aurantiacus* at 800 nm of 7.6 ps using transient absorption, but found a larger residual anisotropy $r(\infty) = 0.13$. Mimuro et al. (1994a) reported fluorescence anisotropy decay times of 70 ps in *Cf. aurantiacus* and $r(\infty) = -0.09$. Savikhin et al. (1994b) observed 8–9 ps anisotropy

decay in transient absorption in the 800 nm region in *Cf. aurantiacus*, with $r(\infty) = 0.04-0.12$, depending on wavelength of excitation and detection. Van Noort et al. (1994) observed 20 ps depolarization with $r(\infty) = 0$ in the 800 nm region of *Cb. vibrioforme*.

F. Kinetics of Energy Transfer Within Membranes and into the Reaction Center

The major component of decay of the BChl *a* 795 in *Cf. aurantiacus* is about 40 ps at room temperature, (Mimuro et al., 1989; Causgrove et al., 1990b; Müller et al., 1990, 1993) which is matched by the rise of the emission of the B808–866 complex in the membrane (Causgrove et al., 1990b; Müller et al., 1990, 1993). This process is substantially interrupted at low temperatures (Mimuro et al., 1992, 1994b).

The energy transfer time from B808 to B866 is extremely rapid and has not been resolved in intact systems, although Vasmel et al. (1986) estimated it to be 6 ps, on the basis of steady-state fluorescence spectroscopy. This transfer time has been measured as 5 ps in isolated B808–866 complexes (Griebenow et al., 1991b). This ultrafast energy transfer is similar to the results in the analogous B800–850 complexes found in purple bacteria (see Chapter 17 by Sundström and Van Grondelle). The chemical sequences of the B808–866 peptides have been determined by Wechsler et al. (1985a, 1987).

The energy transfer time from B866 to P870, the reaction center special pair has been measured both in samples with oxidized and reduced P870. Brune et al. (1987a) observed a time of 218 ps for this process at 77 K. In room temperature measurements, Nuijs et al. (1986) found a time of 200 ps, while Mimuro et al. (1989) reported 250 ps, and Müller et al. (1993) observed 200 ps. In all these experiments the reaction centers were almost certainly in the oxidized state, so this time represents trapping by P870⁺. Müller et al. (1990) reported 106 ps for this process, although the redox state of the trap was not known with certainty.

In samples where P870 is reduced, the trapping times of B866* by P870 are substantially faster. Causgrove et al. (1990b) observed 43 ps for this process, while Müller et al. (1993) reported it to be 70–90 ps. While this apparent discrepancy has not yet been resolved, the former time is more in agreement with what is found for the same process in purple bacteria with open traps (see Chapter 17 by Sundström and Van Grondelle).

VII. The Fenna-Matthews-Olson (FMO) Bacteriochlorophyll *a* Protein

A water-soluble BChl *a*-containing protein was isolated and characterized from two green sulfur bacteria by Olson and coworkers (Olson and Romano, 1962; Olson, 1966, 1971, 1978, 1980a,b, 1994; Thornber and Olson, 1968; JM Olson et al., 1969, 1973, 1976a,b; RA Olson et al., 1969a,b). The FMO protein was the first chlorophyll-containing protein to have its structure determined to atomic resolution. For this reason, much of our current understanding of the principles of pigment-proteins derives from studies of this system. This includes the fact that the pigments are held precisely in place in the protein by specific interactions with protein groups, that His is usually the fifth ligand to Mg, that the complex exhibits threefold rotational symmetry and that exciton coupling is important in determining the absorption and CD spectra of pigment-proteins. These features are now known to be generally true for most pigment-proteins. However, in other respects, the FMO protein is an atypical antenna complex, in that no other complex has been isolated that is similar in overall protein fold.

The FMO protein is found in all green sulfur bacteria that have been surveyed, but is clearly not present in the filamentous green bacteria. In the green sulfur bacteria, some FMO protein remains associated with the reaction center even after extensive purification (Feiler et al., 1992; Okkels et al., 1992; Oh-Oka et al., 1993; Kusumoto et al., 1994). The chlorosome, the FMO protein and the reaction center core itself apparently constitute the complete set of antenna complexes in green sulfur bacteria. Earlier work (Swarthoff and Ames, 1979; Swarthoff et al. 1981) had suggested that there might be an additional membrane-bound antenna complex, although this now appears not to be the case. It is, however, unclear why a fraction of the complexes remain tightly associated with the reaction centers, while the majority of them are readily dissociated. The tightly associated FMO complexes have the same apparent molecular mass and identical N-terminal amino acid sequence as does the easily dissociated pool of FMO protein. Also, DNA hybridization experiments in *Cb. tepidum* indicate that only one gene with sequence similar to the FMO protein is present, arguing against multiple forms of the protein with slightly different primary structure and therefore slightly different properties (Dracheva et al., 1992).

A. X-ray Structure

The structure of the FMO-protein from *Pc. aestuarii* 2K has been determined to a resolution of 1.9 Å by Matthews and coworkers (Fenna and Matthews, 1975; Matthews et al., 1979; Matthews and Fenna, 1980; Tronrud et al., 1986). The amino acid sequence was

determined by Daurat-Larroque et al. (1986), and the combined structure has recently been described by Tronrud and Matthews (1993). The crystallization of the FMO protein from *Cb. tepidum* has been reported, and an X-ray structure of the protein from this organism is in progress (J. Allen, personal communication).

Fig. 10. Subunit of the FMO-protein from *Pc. aestuarii*. A. BChl *a* pigments (phytol tails removed for clarity). B. BChl *a* pigments and α carbon backbone. Drawn from coordinates supplied by Tronrud and Matthews (1993). Figure courtesy of Y.F. Li and J.P. Allen.

The FMO-protein is a trimer, and each subunit consists of a protein fold variously described as a string bag, taco shell or a distorted hollow cylinder. The protein surrounds seven BChl *a* molecules (See Fig. 10). One end of the cylinder is open, but this opening is covered in the trimer. The wall of the cylinder that faces the outside of the trimer is composed almost entirely of 15 strands of β -sheet. The side of the cylinder in contact with adjacent subunits consists of short lengths of α -helix together with regions of irregular conformation.

The seven BChl *a* molecules occupy the space within an ellipsoid of axial dimensions, $45 \times 35 \times 15$ Å. The ligands to five of the BChls are His (110, 145, 290, and 298). BChl 2 is liganded to a water molecule, and BChl 5 is liganded to the backbone carbonyl of residue 242. The average center-to-center distance between porphine rings is 12 Å for nearest neighbors. The phytol chains lie close together. The tails of BChls 4, 5 and 6 are parallel and form a planar structure between porphine rings 5 and 6 and the β -sheet of the outer wall. The tails of BChls 2, 3 and 7 lie in extended conformation in the inner space between porphine rings. The tail of BChl 1 is bent into a U-shaped loop.

Each BChl molecule is anchored to the protein through extensive hydrogen bonding and liganding to the Mg atom in addition to hydrophobic interactions through the phytol tail. The position and orientation of each BChl molecule are controlled mainly by specific interaction with protein, rather than with other BChl molecules.

The subunits are tightly packed in the trimer, which is approximated by an oblate ellipsoid of revolution 57 Å \times 83 Å (Fenna et al., 1974). The closest distance between BChl molecules in adjacent subunits is 24 Å. In trigonal crystals, the trimers are close packed, and the closest distance between BChl molecules in adjacent trimers is about 30 Å. In vivo, the trimers appear to form a two-dimensional trigonal crystal plate between the chlorosome and the plasma membrane (Olson, 1980a).

B. Amino Acid Sequence

The polypeptide chain of the FMO-protein from *Pc. aestuarii* consists of 366 amino acids (Daurat-Larroque et al., 1986). In *Cb. tepidum* the sequence of the FMO-gene has been completed, and the deduced amino acid sequence shows 78% identity with the FMO-protein from *PC. aestuarii* (Dracheva

et al., 1992). The six residues that ligand BChl molecules in *Pc. aestuarii* are conserved in *Cb. tepidum*. The sequences of the FMO proteins from these two organisms are compared in Fig. 11.

C. Absorption, Fluorescence and Circular Dichroism Spectra

The FMO-proteins from *Pc. aestuarii* and *Cb. limicola* show quite similar absorption and CD spectra at 20–25 °C, but distinctly different spectra at temperatures of 77 K and below (Olson et al., 1976a). These low temperature differences show that the excitonic interactions between the BChl molecules in the two FMO-proteins are not exactly the same. Combining the absorption and CD data at 5K for the two FMO-proteins, Whitten et al. (1980) deduced that all the spectra were consistent with seven excitonic components at 793,801–2,806,810,814–6, 819–20, and 823–25 nm. Extinction coefficients ($\text{mM}^{-1} \cdot \text{cm}^{-1}$) at the absorption maxima at 20–25° C are listed as follows: 37 (267 nm), 49 (343 nm), 67 (370.5 nm), 28.4 (603 nm), 13.4 (745 nm) and 154 (809 nm) (Olson, 1978).

The fluorescence emission peak at 20–25 °C is at 818 nm (Sybesma and Olson, 1963; Olson, 1966). At 77 K it sharpens and shifts to 831 nm, and the fluorescence yield increases from 0.19 at 293 K to 0.29 at 77 K (Olson, 1971).

D. Theoretical Analysis, Transient and Hole-Burning Spectroscopies

Because of the wealth of structural and spectral data available, the FMO protein has been very intensely studied using theoretical methods. In a series of calculations of increasing levels of sophistication (Philipson and Sauer, 1972; Olson et al., 1976a; Pearlstein and Hemenger, 1978; Gudowska-Nowak et al., 1990; Pearlstein, 1988, 1991, 1992; Lu and Pearlstein, 1993), a reasonable theoretical fit to the absorption and CD spectral data for *PC. aestuarii* has finally been obtained. The seven pigments within a subunit of the trimer are strongly coupled by exciton interactions, with coupling strengths of from 100–375 cm^{-1} . Coupling between trimers is weaker, with coupling strengths of 20 cm^{-1} or less. Each of the seven pigments in a subunit has a slightly different site energy as a result of pigment-protein interactions. The 21 coupled pigments give rise to two sets of states, a set of 7 polarized parallel to the symmetry

subunits in the trimer, while the physical explanation for the faster processes is not yet clear.

VIII. Redox Modulation of Energy Transfer in Green Photosynthetic Bacteria

A growing body of evidence suggests that the energy transfer system in the green sulfur bacteria may be regulated *in vivo* by redox potential. The first indications for this effect were reported by Karapetyan et al. (1980), who observed an increase in the fluorescence of the FMO protein upon addition of dithionite. Van Dorssen et al., (1986a) and Vos et al., (1987) observed dramatic effects of dithionite on chlorosomes.

A. Effects on Efficiency of Energy Transfer

In 1990, a redox-activated regulation of energy transfer in the green sulfur bacteria was proposed (Wang et al., 1990; Blankenship et al., 1990). This effect appears to involve a direct chemical titration of redox-active groups in the chlorosome antennas, and was observed in whole cells, isolated membranes and purified chlorosomes. There is no evidence for nor reason to suspect phosphorylation in this system, as the effect is easily observed in purified systems with no phosphorylation substrates present. In the oxidized form, the redox-active groups efficiently quench excited states in the antenna system, reducing the overall energy transfer efficiency from nearly 100% to 10% or less. Redox titrations of fluorescence in isolated chlorosomes gave a midpoint potential of -146 mV vs NHE at pH 7, with a pH dependence of -59 mV per pH unit (Blankenship et al., 1990, 1993).

B. Effects on Excited State Lifetimes in Chlorosomes

The excited state lifetimes of BChl *c* (*d* or *e*) are dramatically affected by the redox potential. At low potential (which has generally been achieved by addition of dithionite) there is clear evidence for energy transfer from BChl *c* (*d* or *e*) to BChl *a* in the baseplate, and an excited state lifetime of 50–100 ps depending on the species (Blankenship et al., 1990, 1993; Causgrove et al., 1990b). Under oxidizing conditions these lifetimes are reduced to 10–15 ps and no characteristic rise is observed in the baseplate BChl *a*. The simplest explanation for the effects on

both the energy transfer efficiency and the excited state lifetime is that quenchers are formed in the chlorosomes at high redox potentials. These quenchers provide a rapid nonradiative decay pathway that effectively competes with energy transfer. Possible mechanisms of this effect are considered in Section VIII D.

C. Effects in the FMO Protein

A similar redox modulation of the excited state lifetime is present in the Fenna-Matthews-Olson (FMO) protein (Karapetyan et al., 1980; Blankenship et al., 1993; Zhou et al., 1994). In this case the excited state lifetime is dominated by a 60 ps decay component at high redox potential and a 2 ns component at low potential (Zhou et al., 1994). The latter time is typical for an isolated antenna complex (Van Grondelle et al., 1994), while the shorter time is thought to reflect quenching processes within the protein.

D. Possible Mechanisms and Functional Significance

The redox modulation effect appears to operate on at least two levels, within the chlorosome itself and in the FMO protein. Whether these two effects have similar molecular mechanisms is not yet clear. Do these redox effects on the antenna system reflect a real cellular control mechanism? It is too soon to reach a final decision on this question, but a plausible case can be made that such an effect would serve to protect the cell from transient exposure to oxidizing conditions, in particular to oxygen. The green sulfur bacteria contain a reaction center that has very low potential iron sulfur centers as early acceptors and reduces ferredoxin directly in a manner similar to Photosystem I (see Chapter 30 by Feiler and Hauska). The reduced ferredoxin is freely diffusible in the cell cytoplasm and it is utilized in addition to NAD(P)H as the reducing substrate for its carbon reduction cycle, which is a reverse TCA cycle rather than the Calvin cycle (for reviews see Buchanan, 1992 and Chapter 40 by Sirevåg). The reduced ferredoxins will readily react with oxygen to form superoxide (Orme-Johnson and Beinert, 1969; Asada, 1994), which leads to a variety of damaging photooxidative products, including hydroxyl radicals. The system is thus very vulnerable to autooxidation, probably more so than Photosystem I, which contains a complex

system of protective enzymes including superoxide dismutase and ascorbate peroxidase (Asada, 1994).

Green sulfur bacteria are obligate anaerobes and do not possess any respiratory activity. In nature they are found in a variety of environments, often just below the chemocline in stratified lakes (Trüper and Pfennig, 1992; Ormerod, 1992). Under these conditions they are likely to be exposed occasionally to moderate oxygen levels and a mechanism that provided even partial protection from oxidative damage would be of enormous adaptive advantage. Of course, there is an important difference between respiratory activity and protection from oxidative damage, and the two do not have to go together. *Cb. limicola* has been reported to contain superoxide dismutase activity (Asada et al., 1977), although it is not clear from the original paper that a pure culture was used rather than the co-culture with sulfate-reducing bacteria that was utilized extensively in the older literature.

By preventing charge separation under oxygenic conditions by quenching excitations in the antenna system, green bacterial cells avoid producing these toxic substances entirely. Thus, while these organisms apparently do not have an active mechanism for removing oxygen from their environment, they may have a system that permits them to survive transient exposures to oxygen without incurring cellular damage. No information is available as to whether green sulfur bacteria possess any of the other components of the system that protects oxygenic organisms from photooxidative stress.

The redox effects are largely missing in both whole cells and isolated chlorosomes of the green nonsulfur bacterium *Cf. aurantiacus*. (Vos et al., 1987; Wang et al., 1990), although some preparations of isolated chlorosomes do exhibit some redox-induced fluorescence increase (J. Zhu and R. E. Blankenship, unpublished observations). *Cf. aurantiacus* has an entirely different physiology and ecology with respect to oxygen. Most strains respire and usually lives in close proximity to cyanobacteria, and therefore is often under aerobic, even hyperoxic conditions (Pierson and Castenholz, 1992). However, *Cf. aurantiacus* is not vulnerable to oxidative damage in the same way that the green sulfur bacteria are. It has a reaction center that is similar to that found in the purple bacteria, and therefore does not directly reduce ferredoxin (see Chapter 32 by Feick). Its carbon reduction cycle, while not fully understood, clearly does not involve free ferredoxin as does the

reverse TCA cycle (see Chapter 40 by Sirevåg). Therefore, a redox modulation effect such as has been found in green sulfur bacteria would provide no selective advantage for *Cf. aurantiacus*, and actually would prevent them from carrying out photosynthesis under most natural conditions.

The chemical mechanism for the redox effects on energy transfer in green bacteria is not yet understood and the mechanism active in chlorosomes may be entirely different from that in FMO proteins. Aggregated pigments formed from pigment extracts exhibit dithionite effects on fluorescence similar to those observed in chlorosomes (Matsuura et al., 1992). Similar results have been observed with HPLC purified pigments, where the magnitude of the redox effect correlates with the time that has elapsed since the purification (P. I. Van Noort and R. E. Blankenship, unpublished observations). This suggests that a trace impurity can cause such a result, although it does not prove that this is the mechanism for the effect in vivo. In FMO proteins, it has been suggested that modified amino acids may be involved in the redox effect, although no direct evidence has been found for such an effect (Zhou et al., 1994).

IX. Evolutionary Considerations

The very similar morphology, pigment content and functional role of the chlorosomes in the two families of green bacteria strongly suggests an evolutionary relationship between them, despite the fact that there is considerable evolutionary distance between the two families by almost any other criterion (see above). This disjunction between the chlorosome properties and other characteristics has prompted suggestions that the information coding for chlorosome components may have been transferred between otherwise unrelated organisms (Olson and Pierson, 1987; Pierson and Olson, 1989; Blankenship, 1992).

The recent availability of sequences coding for some chlorosomal proteins gives new information with which to make this comparison. As discussed above, the 30% sequence identity (as well as processing and gene organization) between the 5.7 kDa CsmA protein from *Cf. aurantiacus* and the 6.3 kDa CsmA protein from the green sulfur bacteria is highly suggestive of an evolutionary connection between these two proteins. However, this is the only case in which such a relationship has been found so far. To some extent, this may reflect the fact that the

information needed to make such comparisons is only just now beginning to become available. The picture will undoubtedly become much clearer when more sequences of chlorosome proteins have been determined, as well as information concerning proteins involved in biosynthesis of other chlorosome components such as BChl *c*, *d* and *e*, as well as glycolipids.

Finally, gene organization patterns may be revealing. If, for example, the genes needed for synthesis of critical chlorosome components are clustered and in a similar overall order in the two families, it is highly likely that at least that part of the genome derive from a common ancestor. This sort of gene clustering is found in purple bacteria, where almost all the information needed to synthesize the photosynthetic apparatus is contained in a conserved order in a 43 kB cluster of genes (see Chapters 50 and 58 by Alberti et al. and Bauer, respectively). Some information of this sort may be forthcoming in the green bacteria, as genome mapping in several species is in progress (R. Sirevåg, personal communication).

Summary

The preparation and characterization of a dissociated intermediate of LHI has been achieved for each of five different photosynthetic bacteria and several of their mutants. On the basis of nearly identical spectroscopic and biochemical properties, together with the demonstration that in each case native LHI can be formed by association, it is concluded that the isolated complex represents a fundamental structural subunit of the core light-harvesting complex and probably occurs universally in bacterial LHI complexes. The composition of the subunit is assigned to $\alpha_1\beta_1\cdot 2\text{BChl}$ on the basis of biochemical and spectroscopic characterization. Upon association to form LHI, this subunit complex initially dimerizes and then further associates.

The subunit complexes prepared from these bacteria can be fully dissociated to their fundamental components and the subunit complex and LHI reformed by subsequent reassociation. Beginning with separately isolated α - and β - polypeptides and BChl *a*, reconstitution to form the native subunit complex was demonstrated for each of three BChl *a*-containing bacteria (*Rhodospirillum rubrum*, *Rhodobacter sphaeroides*, and *Rhodobacter capsulatus*). A similar reconstitution of the subunit complex of a BChl *b*-containing organism (*Rhodopseudomonas viridis*) has also been accomplished. In addition, LHI has been reconstituted as well for the three BChl *a*-containing systems. Using properties of the subunit- and LHI-type complexes as assays, hybrid reconstitution experiments were conducted, the results of which indicate the importance of a conserved core region of amino acids for subunit and LHI formation, as well as the likelihood of ion-pairing as stabilizing interactions in the N-terminal region of the polypeptides. Chemical and enzymatic modification of the polypeptides have provided further support for these tentative conclusions and minimal structural features required for formation of the subunit complex and LHI were also better defined by these modifications.

The BChl binding site has been probed by use of structural analogs of BChl in the reconstitution experiments with polypeptides of *Rhodospirillum rubrum* and *Rhodobacter sphaeroides*. Structural requirements including the Mg, carbonyl group at C3¹ and the carbomethoxy group at C13² were indicated. Comparative association constants for many reconstituted systems were measured and used to initially evaluate the contribution of various structural elements to the highly specific formation of the subunit and LHI complexes. Based on these experimental results and analyses of the stabilizing interactions, certain structural features of the subunit complex are proposed that involve cross-hydrogen bonding and a pseudo-plane of symmetry.

Reconstitution of wild-type LHI has been successfully achieved with the α - and β -polypeptides from *Rhodospirillum rubrum*, BChl *a* and spirilloxanthin as well as with the α - and β -polypeptides from *Rhodobacter sphaeroides*, BChl *a* and spheroidene. Appropriate structure and function was demonstrated by measuring absorption, CD and fluorescence excitation spectra and by examining protection of BChl from degradation by the combination of light and air.

Beginning with the isolated or reconstituted subunit complex and isolated reaction centers (RC) of *Rhodospirillum rubrum*, the photoreceptor complex was formed by association of these complexes. This LHI-RC complex exhibited native absorbance and CD spectra as well as a quantum yield of 1.0 for energy utilization from BChl of LHI to cause charge separation in the RC.

Abbreviations: BChl – bacteriochlorophyll; BChl *a* is implied unless BChl *b* is indicated; Car – carotenoid; CD – circular dichroism; Chl – chlorophyll; *Cm.* – *Chromatium*; cmc – critical micelle concentration; Da – daltons; K_{Assoc} , K_{A} – association constant for binding; Kcal – kilocalories; LHI – core light-harvesting complex, also called B875, B890, etc. depending on the far-red absorption maximum; LHII – peripheral light-harvesting complex, also called B800–850, for example; OG – n-octyl β -D-glucopyranoside; PRC – photoreceptor complex which contains LHI and RC; *Rb.* – *Rhodobacter*; RC – reaction center; *Re.* – *Rhodocyclus*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*

I. Introduction

In his thesis research, Duysens (1952) determined that the energy absorbed by the bacteriochlorophyll (BChl) pigments was efficiently transferred from shorter wavelength species to BChl species absorbing at longer wavelengths, downhill in energy flow. This energy was shown to be ultimately transferred to the reaction center (RC) where photochemistry was initiated (Clayton, 1962). The longest wavelength light-harvesting component was found to occur in a fixed stoichiometry to the RC whereas the shorter wavelength components varied in their stoichiometry to the RC in response to environmental conditions (Aagaard and Sistrom, 1972). Monger and Parson (1977) proposed that the long wavelength components, called the core light-harvesting complexes (LHI) were the most intimately associated with and interconnected the RC. They further suggested that the shorter wavelength complexes (peripheral LH, also called LHII) were more distant from the RC and surrounded the LHI-RC system. This arrangement would best facilitate efficient energy flow. The modern era of photophysics has seen the confirmation of the sequential path of energy migration (Hunter et al. 1989) and the era of membrane biochemistry has confirmed the existence of the expected peripheral and core BChl-protein complexes (Thornber et al., 1983; Drews, 1985; Cogdell, 1986).

Because LHI complexes can now be isolated and are well-characterized (Feick and Drews, 1978; Sauer and Austin, 1978; Cogdell and Thornber, 1979; Broglie et al., 1980; Cogdell et al., 1982; Picorel et al., 1983; Drews, 1985; Sundström and van Grondelle, 1991; Zuber and Brunisholz, 1991; Brunisholz and Zuber, 1992), there is great interest in determining their structure and how their structure relates to function. The goal of the research described in this review is to determine the interactions that stabilize this BChl-protein complex and to understand how the structure enables its function. The question of whether all LHI of photosynthetic bacteria have fundamentally the same structure is timely to consider. Each wild-type, BChl *a*-containing LHI has a long-wavelength absorption maximum which is red-shifted to about the same extent (the range is between 99 and 119 nm relative to BChl in acetone except for thermophiles such as *Chromatium (Cm.) tepidum* (Jensen et al., 1964; Zuber and Brunisholz, 1991; Hawthornthwaite and Cogdell, 1991)). Even though the magnitude of the shifts are similar, one can not

assume that all these wavelength shifts have the same structural origin (Gottstein and Scheer, 1983; Scherz and Parson, 1986; Brunisholz and Zuber, 1988; Pearlstein, 1988; Braun and Scherz, 1991; Thompson et al., 1991; Thompson and Fajer, 1992). Moreover, the circular dichroism (CD) spectra of LHI complexes show considerable variation among the photosynthetic bacteria (Bolt et al., 1981 a,b; Kramer et al., 1984; Cogdell and Scheer, 1985), indicating some differences in structure do exist. Whatever these differences may be, however, they seem to have no effect on function since all LHI complexes for which there are appropriate measurements seem to show very high efficiency of excited singlet state transfer to the RC (Loach and Sekura, 1968; Sebban, 1985).

Important information relating to the question of a common structure has been obtained from biochemical analyses of isolated LHI. LHI typically consist of associated complexes of two small polypeptides, α and β , which occur in a 1:1 ratio, and in the ratio of 2 BChl per $\alpha\beta$ -pair (Broglie et al., 1980; Cogdell et al., 1982; Picorel et al., 1983; Theiler et al., 1985; Drews, 1985; Picorel and Gingras, 1988). The uniform existence of these small polypeptides, their fixed stoichiometry to BChl, and the fact that many such units, approximately twelve in number, must associate to form the LHI which associates with one RC, suggests that the same fundamental structure may exist in all LHI.

The determination of amino acid sequences for the α - and β -polypeptides of LHI from many photosynthetic bacteria (Zuber and Brunisholz, 1991; Brunisholz and Zuber, 1992) and the advent of molecular genetics methodology (Bérard et al., 1986; Scolnik and Marrs, 1987; Bélanger and Gingras, 1988; Kiley and Kaplan, 1988; Coleman and Youvan, 1990; Wiessner et al., 1990; Wellington et al., 1992) have made possible the first real insights into structure-function relationships. Recently, structural subunits formed by dissociation of the LHI have been isolated from several different bacteria (Miller et al., 1987; Chang et al., 1990b; Heller and Loach, 1990; Meckenstock et al., 1992). Comparison of these subunits has shown that they all exhibit extremely similar absorption and CD properties as well as biochemical behavior. Thus, it appears that there may be a fundamental building block that is the same in all LHI of photosynthetic bacteria. In addition, both the subunit complex (also referred to as B820) and LHI can be reversibly dissociated and reconstituted from individual components (Parkes-Loach

et al., 1988; Loach et al., 1994).

The ability to reconstitute the complex from its individual components is a uniquely powerful tool for evaluating structural relationships in LHI (Parkes-Loach et al., 1990; Loach et al., 1994). Use of this methodology allows assessment of structural requirements of the BChl and carotenoid (Car), as well as the protein. In combination with spectroscopic measurements, it should be possible to obtain detailed structure-function information for LHI complexes as well as for their interaction with RC, peripheral LH complexes and each other. This review will summarize results obtained using the methodology for subunit preparation and reconstitution. Considering these results along with other knowledge of LHI, some comments about possible structural elements for the subunit complex and LHI will be offered.

II. The Structural Subunit of LHI

Structural subunits of the LHI of several bacteria have been isolated by using detergent methodology (Loach et al., 1985; Miller et al., 1987; Heller and Loach, 1990; Chang et al., 1990b; Meckenstock et al., 1992; Visschers et al., 1992). These subunit complexes are smaller in size and have blue-shifted Q_y absorption maxima relative to LHI, but are still substantially red-shifted relative to free BChl in detergent (Fig. 1). Upon further addition of detergent, the subunit complexes can be dissociated into their individual polypeptides and free BChl. By decreasing the detergent concentration, the subunit and the LHI complexes can be quantitatively reassociated (Parkes-Loach et al., 1988; Heller and Loach, 1990; Chang et al., 1990b).

A. Preparation

1. General Procedures

The first bacteria from which structural subunits of LHI were isolated were wild-type *Rhodospirillum (Rs.) rubrum* and its G-9 carotenoidless mutant (Loach et al., 1985; Miller et al., 1987). Membrane fractions from these bacteria required a wash step in Triton X-100 and EDTA before they were susceptible to forming the subunit complex. On the other hand, membrane preparations from *Rhodobacter (Rb.) sphaeroides* (wild-type and a LHII(-) mutant) did

Fig. 1. Absorption spectra of the dissociated subunit complex of *Rs. rubrum* in 4.5% OG ($\lambda_{\max} = 777$ nm), the subunit complex formed by lowering the OG concentration to 0.72% ($\lambda_{\max} = 820$ nm), and reassociated LHI formed by further decrease in OG concentration to 0.36% ($\lambda_{\max} = 872$ nm). The subunit complex and LHI spectra were corrected for sample dilution. Figure reproduced from Parkes-Loach et al. (1988) with permission.

not require extensive treatment, but simply Car removal by extraction with a hydrocarbon solvent. In general, as Cogdell and Thornber once concluded about isolation of RC and LH complexes from different photosynthetic organisms, each system is unique and procedures are not necessarily interchangeable (Cogdell and Thornber, 1979; Thornber, 1986). This has been our experience for the preparation of the subunit complex of LHI from different bacterial species, and might also be extended to include various mutants of a single species. Even so, some general observations seem to apply. In the bacteria we have examined, it has been necessary to remove Car, or work with a carotenoidless mutant to successfully prepare high yields of the subunit complex. After the membranes are appropriately prepared, they are susceptible to formation of the subunit complexes upon addition of increasing amounts of *n*-octyl β -D-glucopyranoside (OG). For BChl *a*-containing organisms, the subunit complex of LHI is separated from RC and LHII (if present) by gel filtration chromatography on a Sephadex G100 column.

An interesting question to address is what role Car plays in LHI structure. Use of carotenoidless mutants, or Car removal prior to exposure to detergent, was required for quantitative formation of a stable subunit complex in the four bacteria we have studied (*Rs. rubrum*, Miller et al., 1987; *Rb. sphaeroides*, Chang et al., 1990b; *Rb. capsulatus*, Heller and Loach,

1990; *Rhodospseudomonas (Rp.) viridis*, Parkes-Loach et al., 1994). Prior Car removal was also necessary for the preparation reported by Meckenstock et al. (1992) of the subunit isolated from *Rp. marina*. In a recent report of a subunit preparation from *Rs. rubrum*, the Car was not removed prior to subunit formation, but none was found in the isolated subunit complex (Visschers et al., 1992). On the other hand, two preliminary reports indicate the presence of Car in subunit-containing fractions *Cm. purpuratum* (Kerfeld et al., 1994) and *Rhodocyclus (Rc.) gelatinosus* (now called *Rubrivivax gelatinosus*) (Jirsakova and Reiss-Husson, 1993), although the amount of Car was greatly reduced in the latter. Further characterization of such systems will be of interest.

All experimental results are consistent with the following equilibria where the lower case 'd' refers to detergent that solvates the component.

Thus, addition of Car shifts equilibrium (2) toward LHI at all detergent concentrations and decreases the concentration of B820_d . Depending on the value of the equilibrium constants for reactions (1) and (2), B820_d may or may not be observed as the detergent concentration is varied (Ghosh et al., 1988a; Heller and Loach, 1990). The early work of Ogawa and Vernon (1969) suggested to us that removal of Car might be a useful step in our goal to reversibly dissociate LHI.

Some caution should be noted with regard to carotenoid extraction. The most effective solvent (petroleum ether or benzene) and the behavior of the membrane fractions are different for preparations from different bacteria. Variables such as the age of the lyophilized chromatophores or photoreceptor complex (PRC)-enriched membrane fractions, the temperature, and the ratio of membrane material to organic solvent are important. Each of these parameters must be evaluated for each membrane system to which extraction is applied. Excellent reproducibility was found when the exact same set of extraction parameters were applied to membrane preparations from one bacterium.

Another key factor for preparation of the subunit complex has been the choice of detergent. Some of the earliest biochemical experiments designed to

isolate membrane complexes were conducted with membranes from photosynthetic organisms (Gingras, 1978; Thornber et al., 1978 and references therein). One reason for this is that these membranes have built-in monitors of structural integrity (the pigments of LH complexes and the redox centers of RC). Development of early methodology focused on isolation of intact LH and RC complexes. From these studies it was found that various detergents, organic solvents and chaotropic agents seemed to fall into the following categories: too gentle for separation of complexes (cholate, most chaotropic agents), somewhat effective and gentle (detergents such as deoxycholate and Deriphat), quite effective and not too disruptive (Triton X-100 and OG), effective but moderately disruptive (lauryl dimethylamine-N oxide, lithium dodecyl sulfate, cetyl dimethylammonium bromide, low concentrations of butanol) and too harsh (sodium dodecyl sulfate, high concentrations of organic solvents). For subunit preparation of LHI, OG is exceptionally effective. The reason for this is unclear, although size, hydrophilic/hydrophobic balance and ability of the polar moiety to participate in multiple hydrogen bonding are likely to be important. In our experience, few detergents can be successfully used to reversibly dissociate LHI. We found the following order of effectiveness: $\text{OG} > \text{n-octyl } \beta\text{-D-thioglucoopyranoside} > \text{n-nonyl } \beta\text{-D-glucoopyranoside} > \text{octanoyl, nonanoyl and decanoyl N-methylgluconamide, lauryl maltoside}$ (Miller et al., 1987). In work from other laboratories, subunit complexes were observed in systems using LDAO and sodium cholate (Ghosh et al., 1988a,b) and subunit complexes were isolated using *n*-octyl-*rac*-2,3-dipropylsulfoxide (Visschers et al., 1992), sucrose mono-N-decanoate in Tris buffer containing EDTA and 60% ammonium sulfate (Jirsakova and Reiss-Husson, 1993) and *n*-dodecyl maltoside and OG (Kerfeld et al., 1994).

2. *Rhodospirillum rubrum*

The first organism with which we worked to isolate LH and RC complexes was *Rs. rubrum*. It was chosen because it has only one LH complex, the LHI, and its photosynthetic unit size (number of BChl/RC) was one of the smallest known. From our earlier experiments in which PRC were isolated (Loach et al., 1970a) we found that LHI and RC withstood a number of procedures which were used to remove other components from the membrane (Hall et al.,

1973). Our strategy was to first remove everything from the membrane that was not required to maintain native LH and RC physical properties and function. Among the treatments that were effective in removing other polypeptides (assayed by SDS-PAGE) was a wash step with high Triton X-100 concentration (3%) and EDTA. This treatment seemed to effectively solubilize many of the components of the bc₁ complex, F₀ and F₁ components of ATP synthase and perhaps metabolite transport components.

The enriched-PRC preparations were used for development of procedures to quantitatively and reversibly separate LHI from RC. Many procedures were tried that gave poor yields (less than 50%) and/or were largely irreversible. The motivation for requiring quantitative separation and reversibility was twofold, both relating to eventual extrapolation back to the *in vivo* system. First, by obtaining quantitative yields, it would be possible to account for all LH and RC complexes in the membrane. It is prudent to note that nearly all commonly used RC preparations give low yields of between 20% to 50% (Feher and Okamura, 1978; Gingras, 1978; Vadeboncoeur et al., 1979) so that the question can be raised as to whether there might be other important components or structural differences in the intact membrane that were missed because of the low yield. Secondly, as Racker (1985) pointed out in his pioneering work with bioenergetic membranes, the only way to understand how the *in vivo* complexes really work is to reconstitute them from their individual components. We felt that a less than a quantitative accounting of all components would compromise eventual conclusions.

Upon addition of OG to the PRC-enriched membranes of the carotenoidless G-9 mutant, the long wavelength absorption band of BChl *a* in LHI underwent a systematic transition to an 820-nm-absorbing species (Loach et al. 1985, Miller et al. 1987). After extraction of Car from the PRC-enriched membranes prepared from wild-type cells, the same transition could be demonstrated. The 820-nm-absorbing material of both systems could be quantitatively reassociated to reform the 873-nm-absorbing complex by lowering the OG concentration. Thus, quantitatively-reversible conversion was achieved.

In membranes in which LHI was converted to the 820-nm form, light energy absorbed at this wavelength was poorly transferred to the RC. Therefore, it was likely that physical separation of

LHI subunits from the RC had occurred. The two complexes were separated by gel-filtration chromatography under conditions where the 820 nm form was stable. This purification step could be refined to achieve > 95% yield of both the subunit of LHI (based on reassociation of B820 to form LHI) and the RC (Miller et al., 1987). Only the α - and β -polypeptides of LHI were present in the B820 material and a stoichiometry of $\alpha_1\beta_1 \cdot 2\text{BChl}$ was determined. Preparations of the subunit complex in detergent solution were stable for several days if kept anaerobic and dark, but they degraded rapidly in light and air. The preparation can be lyophilized and stored at -15°C for months to years without degradation. The long-wavelength maximum for the subunit preparation at 20°C is 820 ± 1 nm which shifts to 825 nm on cooling to 77 K (Visschers et al., 1991).

The subunit complex of wild-type *Rs. rubrum* has also been prepared using *n*-octyl-*rac*-2,3-dipropyl-sulfoxide (Visschers et al., 1992). In this case, the membranes were not treated with Triton X-100/EDTA nor was the Car first removed, but Car was not observed spectrally in the subunit. The yield of the subunit complex was not as high as for that described above using OG, but the spectral properties were similar to those of the OG preparation.

3. *Rhodobacter sphaeroides*

After developing the procedures that were successful for preparation of the LHI subunit from *Rs. rubrum*, we extended the methodology to another bacterium, *Rb. sphaeroides* (Chang et al., 1990b). This organism contains the peripheral LH complex, B800-850, as well as LHI. The Triton X-100-EDTA wash step used with membranes from *Rs. rubrum* could not be used with *Rb. sphaeroides* membranes because it resulted in solubilization of large quantities of BChl-containing material. It was found that washing wild-type membrane vesicles with 0.01 M Tris buffer (pH 7.3) containing 0.05 M EDTA was effective in yielding a membrane preparation in which Car could then be extracted and that formed a subunit complex upon OG addition. For a LHII⁻ mutant, PUC705-BA, this Tris-EDTA wash was unnecessary.

The above membrane preparations could then be extracted with petroleum ether (wild-type cells) or benzene (PUC705-BA cells) to remove Car without removing BChl. The LHI of these extracted systems could then be titrated with OG to produce a subunit complex and RC (and also LHII with wild-type

cells). Separation of products was achieved in a manner similar to the procedure used for the subunit preparation with *Rs. rubrum* material.

The overall yield of the subunit complex from wild-type cells could be optimized to obtain over 80% of both LHI and RC while somewhat lower yields (about 50%) were obtained from PUC705-BA (LHII⁻). HPLC analyses, together with determination of the N-terminal amino acid sequences of HPLC-purified polypeptide components, demonstrated that only the LHI α - and β -polypeptides were present in a stoichiometry of 1:1. The stabilities of the subunit preparations were similar to those of *Rs. rubrum*. The long-wavelength maximum for the subunit preparation at 20 °C, as well as at 77 K, was 825 ± 1 nm (Chang et al., 1990b; Visschers et al., 1991).

The subunit complex of *Rb. sphaeroides* was also prepared from an LHII⁻ mutant, M2192, by dialyzing isolated LHI against the detergent *n*-octyl-*rac*-2,3-dipropylsulfoxide, but the subunit was not separated from remaining LHI and solubilized BChl (Visschers et al., 1992). Absorption and CD spectra of this subunit were similar to those formed with OG. Fluorescence polarization and transient triplet-singlet spectra indicated a similar BChl *a* dimer interaction for both detergent preparations.

4. *Rhodobacter capsulatus*

As was the case with membrane preparations from *Rb. sphaeroides*, the use of Triton X-100 and EDTA severely modified the membranes of *Rb. capsulatus*, resulting in irreversible degradation of LHI upon OG addition (Heller and Loach, 1990). In the case of the membrane preparation from *Rb. capsulatus*, no wash step was necessary prior to Car removal. Benzene was used to remove Car from membrane fractions of both wild-type cells of *Rb. capsulatus* and a LHII⁻ mutant, MW442. The preparations could then be titrated with OG and the subunits isolated using the same procedure as with the *Rs. rubrum* and *Rb. sphaeroides* material.

Curiously, the membrane fraction of a LHII⁻ carotenoidless mutant of *Rb. capsulatus*, SB203E, did not behave like the comparable carotenoidless mutant, G-9, of *Rs. rubrum*. Addition of OG to this sample caused formation of monomer BChl only (absorbing at 777 nm), although subsequent dilution did result in a small amount of subunit formation. Successful reversal from the 777-nm material to LHI was demonstrated (Heller and Loach, 1990).

The overall yields of subunit complex were typically about 45% with material isolated from the mutant MW442 (LHII⁻) and much lower (about 20%) with that from wild-type cells (Heller and Loach, 1990). The isolated subunit complex of *Rb. capsulatus* was not as stable as those from *Rs. rubrum* and *Rb. sphaeroides*, which probably resulted in increased loss of BChl during isolation by gel-filtration chromatography. Only the LHI α - and β -polypeptides were present in the subunit complex and were found to be in a stoichiometry of 1:1 as determined by HPLC analyses, identification of the N-terminal amino acid sequences of HPLC-purified polypeptide components and UV absorption of the protein. The long-wavelength maximum for the subunit preparation at 20 °C was consistently 815 ± 1 nm. This shorter wavelength probably reflects the smaller association constant than those of subunit complexes from *Rs. rubrum* and *Rb. sphaeroides* because, for solutions of the subunit complex of *Rb. capsulatus*, more free BChl absorbing at 777 nm was present. If the absorption contribution due to free BChl was subtracted, the long-wavelength absorption maximum of the subunit complex was near 819 nm. The latter value was also observed in reconstitution experiments where formation of the subunit complex was optimized by using high protein concentration and low BChl concentration.

5. *Rhodospseudomonas viridis*

Rp. viridis was selected as an interesting organism to study and compare to *Rs. rubrum*, not because of the similarities (a single LHI antenna and 50% homology in the α - and β -polypeptides) but because of the differences. These differences include: (1) the chromophore, which is BChl *b* in *Rp. viridis* rather than BChl *a* as in *Rs. rubrum*, (2) the additional LHI polypeptide, γ , in *Rp. viridis*, and (3) lamellar stacking of membranes in *Rp. viridis* rather than the vesicular membrane structure of *Rs. rubrum*.

Because of the instability of BChl *b*, it has not been possible to obtain high reversibility for reassociation of LHI from the subunit complex. However, the conversion of LHI to a structural subunit has been achieved in high yield as well as the partial reversal (25%) to reform LHI (Parkes-Loach et al., 1994). As with the first three bacteria, Car removal was necessary before OG was effective in causing an absorption change reflecting formation of the subunit. As in the case of membrane material

from *Rb. sphaeroides* and *Rb. capsulatus*, no treatment prior to benzene extraction of Car was required. OG titrations of the Car-depleted membranes resulted in a similar set of absorption changes as was observed in the other bacteria, except that the sample had to be kept anaerobic, with reductant present and at low temperature (0 °C). Because of the difficulty in maintaining these conditions during the steps required for isolation of the subunit (such as column chromatography), such preparation has not yet been attempted.

The most effective method for converting LHI into the subunit complex was by addition of OG to Car-extracted membrane preparations at room temperature (22 °C). This treatment resulted in the dissociation of LHI into free BChl *b*, absorbing at 809 nm, and the polypeptides. Upon chilling to 0 °C, high yields of the subunit complex (greater than 80% using expected extinction coefficients based on those from BChl-*a*-containing subunit complexes (Chang et al., 1990a)) were obtained (Parkes-Loach et al., 1994). The long-wavelength maximum for this BChl-6-containing subunit complex was found to be at 895 ± 5 nm, representing an identical shift in energy relative to free BChl *b* and LHI of *Rp. viridis* as was determined for subunit complexes of BChl-*a*-containing bacteria relative to free BChl *a* and their LHI.

6. *Rhodopseudomonas marina*

Rp. marina has a LHI, but no peripheral LH and its intracytoplasmic membrane structure is lamellar like *Rp. viridis* instead of vesicular like *Rs. rubrum*, *Rb. sphaeroides* and *Rb. capsulatus* (Zuber and Brunisholz, 1991). LHI from *Rp. marina* was found to be very stable upon isolation (Meckenstock et al., 1992). In comparison to *Rs. rubrum* LHI, the α -polypeptide of *Rp. marina* is 75% homologous and the β -polypeptide is 53% homologous (Brunisholz et al., 1989). In an initial step to form the subunit complex of *Rp. marina*, Meckenstock et al. (1992) prepared membranes containing LHI, RC, and cytochromes in 0.5% LDAO which were then dialyzed against 50 mM potassium phosphate buffer, pH 8.0 and subsequently lyophilized. The dried material was extracted several times with benzene to remove Car and then resuspended in 1% OG to convert LHI to the subunit form. The subunit complex was purified in the same manner as for the other subunit preparations summarized above. The biochemical

composition of this subunit preparation was identical to that reported for *Rs. rubrum*; the α - and β -polypeptides were present in a stoichiometry of 1:1 with two BChl *a* per $\alpha\beta$ pair. Absorption, CD, and fluorescence emission spectra were also very similar to those of the subunit complex of *Rs. rubrum*. The % yield of subunit was not reported.

7. *Rhodocyclus gelatinosus*

Jirsakova and Reiss-Husson (1993) have described the formation of a subunit complex from a LHI isolated from *Rc. gelatinosus*. The subunit was formed in 0.2% sucrose mono-N-decanoate in 0.1 M Tris-HCl, 1 mM EDTA, pH 8.0 and 65% ammonium sulfate and separated from remaining LHI by chromatography on Sepharose 6B-CL gel. Absorption and CD properties were similar to those of subunit preparations from other bacteria but without addition of carotenoid, the subunit could not be reassociated to reform LHI. A unique feature of this subunit complex is that it was formed from LHI that still contained Car. Most of the Car was lost as the subunit was formed but a variable amount of about 20% still remained with the subunit-containing fraction. Upon addition of the native carotenoid (hydroxyspheroidene) of this bacterium to the subunit complex, a native-like LHI complex could be formed upon dialysis (Jirsakova and Reiss-Husson, 1994). Addition of different carotenoids that were structurally similar to the hydroxyspheroidene gave little or no LHI formation, indicating that the native carotenoid seems to be very important in the LHI structure in *Rc. gelatinosus*.

8. *Chromatium purpuratum*

Kerfeld et al. (1994) have described the preparation of LHI from *Cm. purpuratum*, a purple sulfur bacterium, in which 1.5% n-dodecyl maltoside and 1.5% OG were used to solubilize the membrane. Upon purification, a membrane fraction separated into an RC-LHI complex and a fraction with a typical subunit complex absorption spectrum. Car was present in the LHI before treatment and was still present in the subunit-containing fraction. The subunit preparation could not be induced to reform the native LHI complex by dilution of the detergent concentration. These are very interesting results because *Chromatium* are purple sulfur organisms whereas all other bacteria from which subunit complexes have

so far been prepared are purple nonsulfur bacteria.

B. Characterization of Subunit Structure

1. Composition

Each subunit preparation that has been well-characterized (*Rs. rubrum*, *Rb. sphaeroides*, *Rb. capsulatus*, *Rp. marina*, *Rc. gelatinosus*) contains only the LHI α - and β -polypeptides, which occur in a 1:1 stoichiometry. The ratio of 2 BChl per $\alpha\beta$ -pair has been well-established for the preparations from *Rs. rubrum* and *Rp. marina*. Lipids and other factors have not been reported in these preparations, although such analyses have not been exhaustive.

2. Subunit Size

The first indication of the molecular weight of the subunit complex was from gel-filtration chromatography of the subunit complex prepared from *Rs. rubrum* (Miller et al., 1987). In these experiments, blue dextran, which eluted at the void volume, separated from and preceded the RC which in turn preceded and separated from the subunit complex. The subunit could also be separated from free BChl and the uncomplexed α - or β -polypeptides which followed it. From the average of many experiments, the peak of the subunit fraction of *Rs. rubrum* eluted at 37,500 Daltons (with values varying within $\pm 3,500$ Da) when compared to hydrophilic proteins used as molecular weight markers. Integral membrane proteins bind large amounts of detergent relative to water soluble proteins (Guidotti, 1978). If it is assumed that the subunit complex binds an amount of detergent equal to its molecular weight, which is a reasonable estimate based on its relative hydrophobic surface and based on detergent binding for known integral membrane proteins (for example, rhodopsin is reported to bind 1.1 mg Triton X-100/ mg protein; Guidotti, 1978), then the subunit complex molecular weight could be either $\alpha_2\beta_1\cdot 2\text{BChl}$ (M. Wt. = 14,000 Da) or $\alpha_2\beta_2\cdot 4\text{BChl}$ (M. Wt. = 28,000 Da), although the data suggest the former.

Several other studies of the subunit complex have resulted in suggestions that it has an $\alpha_2\beta_2\cdot 4\text{BChl}$ structure. In an ultracentrifugation study of LHI from *Rs. rubrum*, Ghosh et al. (1988a) observed several different molecular weight species in the octyl-pentaoxyethylene detergent system used for these measurements. These species were presumed

to be different aggregate states of the subunit for which they concluded that the $\alpha_2\beta_2\cdot 4\text{BChl}$ (24–27 kDa) species best described the subunit complex (Ghosh et al. 1988b). A similar conclusion was reached by Meckenstock et al. (1992) for the subunit complex of *Rp. marina* based on gel filtration experiments. The molecular weight they determined was 32,000 Da not corrected for detergent binding, which is similar to the value of 37,500 Da obtained with *Rs. rubrum* subunit complexes.

Sturgis and Robert (1994) have investigated the equilibrium between the subunit and its dissociated products absorbing at 777 nm. On the basis of low temperature resonance Raman spectra and the lack of effect of added BChl on the equilibrium, it was concluded that BChl was still bound to the α - and/or β -polypeptide in the dissociated state that absorbs at 777 nm, and that the subunit complex was an $\alpha_2\beta_2\cdot 4\text{BChl}$ structure. However, the lack of effect on the equilibrium by added BChl is counter to the experience of our laboratory in conducting reconstitution experiments and in measuring association

Fig. 2. Molecular weight of the subunit complex determined by gel filtration chromatography on Sephadex G-100. V_e = elution volume at peak of sample; V_o = elution volume at peak of blue dextran. Elution buffer was 0.05 M potassium phosphate, pH 7.5 which contained 5 mM MgSO_4 and 0.75% OG. The three protein standards (asterisks) were horse heart cytochrome *c* (mol. wt. = 12 kDa), bovine serum albumin (mol. wt. = 66 kDa), and γ -globulin (mol. wt. = 156 kDa). B820 rub indicates the value for the subunit complex of *Rs. rubrum* (data from Miller et al., 1987; Parkes-Loach et al., 1988) and B820 sph/cap indicates the values for the subunit complexes of *Rb. sphaeroides* (data from Chang et al., 1990b) and *Rb. capsulatus*, data from Heller (1992).

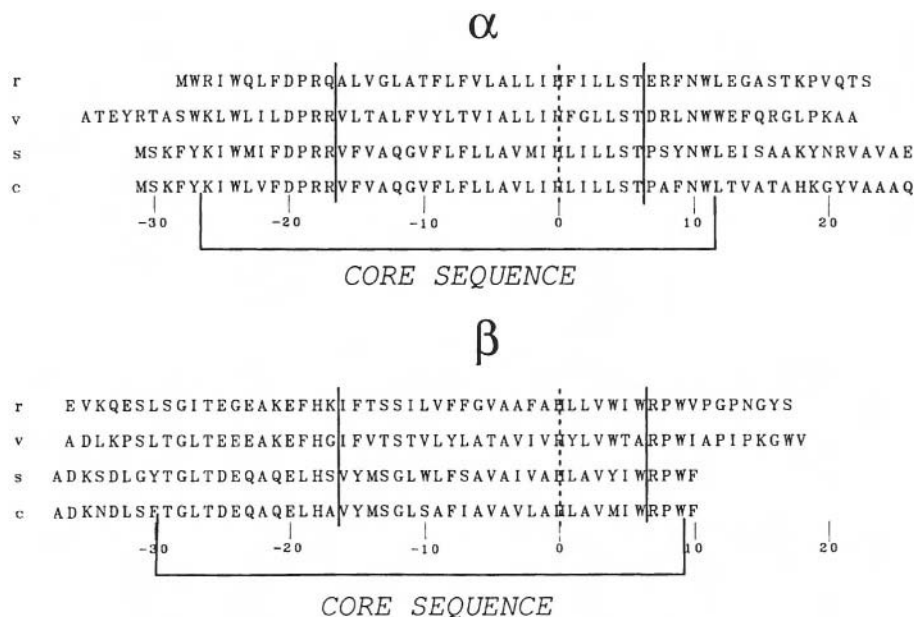

Fig. 3. Amino acid sequences of the α - and β -polypeptides of four bacteria. *r*, *Rs. rubrum* (Brunisholz et al. 1981, Gogel et al. 1983, Brunisholz et al. 1984, Bérard et al. 1986); *v*, *Rp. viridis* (Brunisholz et al. 1985, Wiessner et al. 1990); *s*, *Rb. sphaeroides* (Theiler et al. 1985, Kiley et al. 1987); *c*, *Rb. capsulatus* (Tadros et al. 1984, 1985; Youvan et al. 1984). For ease of comparison, the histidine residue nearest the C-terminus was used for alignment and defined as the zero position. The core sequence defines the area of highly-conserved residues.

constants (see Section IV.C). The explanation of the differences in these observations remain to be determined.

In experiments conducted using our preparations of subunit complexes from *Rb. sphaeroides* and *Rb. capsulatus* (Chang et al., 1990b; Heller and Loach, 1990; Heller, 1992; Chang and Heller, unpublished results), we have observed that the subunit complexes consistently eluted later than the comparable complex from *Rs. rubrum*. A comparison of these molecular weight determinations is shown in Fig. 2, where the value for the subunit complex from *Rs. rubrum* is shown to be 37,500 Da and that for *Rb. sphaeroides* and *Rb. capsulatus* is 24,500 Da. The variation in values obtained with different preparations from the latter two organisms was only about $\pm 1,500$ Da. The difference in the apparent molecular weight values for the *Rb. sphaeroides* and the *Rb. capsulatus* subunit complexes compared to the *Rs. rubrum* subunit complex may be a reflection of the difference in amount of detergent bound. From a comparison of the amino acid sequences of the α - and β -polypeptides (Fig. 3) it is apparent that the membrane-spanning segments of both polypeptides from *Rs. rubrum* are less polar than those of *Rb. sphaeroides* and *Rb. capsulatus*. Because this is the region that is expected

to bind detergent (Deisenhofer and Michel, 1991), a somewhat higher percentage of detergent binding to the subunit complex of *Rs. rubrum* would be expected. It might also be noted that in OG titrations of LHI, higher detergent concentrations were required to stabilize the subunit complex of *Rs. rubrum* compared with those necessary to stabilize the other two (typically, 0.70% vs. 0.64%).

In their experiments with *Rc. gelatinosus*, Jirsakova and Reiss-Husson (1993) also reported an apparent molecular weight in the 18–25 kDa range as determined by gel filtration chromatography. If the assumption is made that the subunit complexes isolated from *Rb. sphaeroides*, *Rb. capsulatus* and *Rc. gelatinosus* bind an amount of detergent equal to their weight, then the corrected value of about 12,500 Da would agree well with the molecular weight expected for an $\alpha_1\beta_1\cdot 2\text{BChl}$ structure. Due to the uncertainty of detergent binding and the extent to which the subunit complexes deviate from the assumed spherical shape, the conclusion that the composition of the subunit complex is an $\alpha_1\beta_1\cdot 2\text{BChl}$ is only tentatively made. A further discussion of the size of the subunit complex based on spectroscopic evidence is found in the next section.

Fig. 4. Absorption (top) and CD (bottom) spectra of subunit complexes prepared from wild type *Rs. rubrum* (---), *Rb. sphaeroides* PUC705BA(—) and *Rb. capsulatus* B800-850 mutant, MW442 (....). All spectra were normalized to correspond to an absorbance of 1.0 cm^{-1} at the Q_y absorption maxima. Reproduced from Chang et al. (1990b) with permission.

3. Spectroscopy

A variety of spectroscopic measurements contribute to our knowledge of the size and structure of the subunit complex. Based on CD measurements, at least 2 BChl interact strongly, thus implying a minimal $\alpha_1\beta_1\cdot 2\text{BChl}$ unit (Fig. 4; Chang et al., 1990a; Visschers et al., 1991). From fluorescence polarization (Visschers et al., 1991), triplet-singlet spectroscopy and singlet-triplet annihilation (van Mourik et al., 1991; van Mourik et al., 1993) and the relationship between the emission maximum and the excitation wavelength as a function of temperature (Visschers et al., 1993a), the subunit spectral properties clearly

arise from strongly-coupled BChl dimers (exciton pairs) which cannot transfer energy to other such pairs. This makes the $\alpha_2\beta_2\cdot 4\text{BChl}$ structure very unlikely because two dimeric pairs would exist within energy transfer distance. Because the fluorescence is highly polarized, any such pair of dimers must either not transfer excited state energy between them or both dimers must exist in an essentially parallel configuration. Furthermore, since singlet-triplet quenching is not observed, further restrictions are placed on the possible distance between such pairs. The only subunit structure consistent with these restrictions is that containing one set of polypeptides and one pair of BChl (i.e., an $\alpha_1\beta_1\cdot 2\text{BChl}$).

From resonance Raman spectroscopy, the Mg^{2+} in BChl is 5-coordinate and is unchanged in the subunit complex of *Rs. rubrum* relative to LHI (Chang et al., 1990a). Presumably the 5th ligand is provided by a histidine in each case (Robert and Lutz, 1985). There are significant differences in the resonance Raman and FTIR spectra of LHI of *Rs. rubrum* compared to its subunit complex (Chang et al., 1990a; Visschers et al., 1993b; Sturgis and Robert, 1994). In each case, these changes in resonance Raman spectra were completely reversible upon reforming LHI.

C. Association of Subunits to Form LHI

1. Procedures

The subunit complexes of *Rs. rubrum*, *Rb. sphaeroides* and *Rb. capsulatus* are formed only in OG concentrations near the critical micelle concentration (cmc) and lowering that OG concentration results in association to form a LHI-type complex.

In our work, reassociation has most often been accomplished by chilling the subunit to 0 °C (at this temperature the cmc of OG has increased to above the actual OG concentration), or by dilution of the OG concentration in the sample. As was noted earlier (Eq. (2)), the equilibrium is also displaced toward LHI by addition of Car. Increasing the concentration of the subunit also displaces the equilibrium towards LHI and more detergent is required to prevent LHI formation. The value of n in Eq. (3) is at least 2 and probably 3 or larger, which explains the high sensitivity to the subunit concentration.

2. Properties of the Reassociated LHI

The NIR absorption spectra of reassociated LHI of *Rs. rubrum*, *Rb. sphaeroides* and *Rb. capsulatus* match very closely the absorption spectra of the corresponding in vivo Car-free LHI complexes. The long-wavelength absorption bands of these LHI complexes are very similar to each other in λ_{\max} (typically between 868 and 875 nm), extinction coefficients, and half-widths. The major function of excited singlet state energy transfer is also restored as demonstrated by the highly efficient energy transfer from BChl of reconstituted LHI of *Rs. rubrum* to the RC of *Rs. rubrum* (see section XII).

Of special interest are the CD spectra of the reassociated LHI. Although the CD spectra of the subunit complexes of *Rs. rubrum*, *Rb. sphaeroides* and *Rb. capsulatus* with BChl *a* are extremely similar (Fig. 4), the CD spectra of the in vivo LHI complexes from different species are quite different (Bolt et al., 1981a,b; Kramer et al., 1984; Cogdell and Scheer, 1985). Thus, even though the absorption spectra and energy transfer function are nearly identical, structural subtleties exist that greatly affect the CD spectra. It is therefore quite significant that each LHI, prepared from reassociation of its respective subunit complex, displayed its own particular native CD spectrum (Parkes-Loach et al., 1988; Chang et al., 1990a,b; Heller and Loach, 1990). Since these CD spectra are unique to each LHI, they are useful as criteria for probing the quality of reassociated and reconstituted systems and indicate that the structure of the reassociated complexes are identical to the native forms. Other spectroscopic data that indicate reassociated LHI has a native structure are those of resonance Raman spectra in which changes that occurred upon forming the subunit complex from LHI of *Rs. rubrum*, were reversed upon subsequent reassociation to LHI (Chang et al., 1990a).

The relationship between the subunit and LHI provides insight into the structure of LHI. When, after appropriate treatment of the membrane, LHI is converted into the subunit complex by the addition of OG, a set of isosbestic points can be observed through about half of the titration and then a second set seems to exist through the rest of the titration (Miller et al., 1987; Heller and Loach, 1990; Chang et al., 1990b; Parkes-Loach et al. 1994). This observation suggests that only two species are in equilibrium initially and at the end of the titration,

but an intermediate may be present between the subunit complex and LHI. Experimental results that bear directly on the relationship between the subunit and LHI were obtained by a stopped-flow dilution experiment in which the kinetics of subunit association to form LHI were found to be bimolecular in the subunit concentration with no other apparent intermediates (van Mourik et al., 1992). It should be noted, however, that the maximum wavelength reached in these experiments was approximately 860 nm. In our experience, the shift in the wavelength maximum to about 860 nm is fast (within a few seconds), but the final 12 to 15 nm shift is much slower (requiring hours to days). Thus, although the first product may result from a dimerization of the subunit, further association and/or rearrangement is probably involved in forming LHI. Fluorescence polarization measurements of *Rs. rubrum* LHI (Deinum et al. 1989) and *Rs. rubrum* LHI reassociated from its subunit complex (Visschers et al., 1991) were in good agreement, giving low polarization values, and indicating that in LHI, excitation energy is shared by a number of BChl molecules with non-parallel configuration. These results further suggest that after initial dimerization, a larger cluster of subunits forms.

If the long-wavelength band shift to approximately 860 nm is primarily associated with dimerization of the subunit, then the next question to address is whether there is a change in structure of the BChl binding sites upon dimerization and LHI formation. In this regard, it is of interest that both the subunit complex and LHI of *Rs. rubrum* exhibit inhomogeneous spectral broadening (Visschers et al., 1993a; van Mourik et al., 1993). This would be expected for a simple association with little perturbation in the fundamental subunit structure, but of course, it does not constitute proof.

As with most structural elements that become well-defined, it is possible to look back at earlier experimental data and possibly explain observations that were not understood at the time. This is certainly true with the structural subunit of LHI, since many shorter wavelength forms have been observed as a result of detergent or other treatment of photosynthetic bacterial membranes (Vernon and Garcia, 1967; Thornber, 1971; Cuendet and Zuber, 1977; Thornber et al., 1978, for example). These shorter wavelength species have, in general, been irreversibly formed. Among such early observations, a spectral inter-

mediate absorbing near 820 nm was observed upon oxidative degradation of chromatophores. In these experiments, the membrane fraction of *Rs. rubrum* was oxidized with K_2IrCl_6 to selectively degrade BChl (Loach et al., 1963). As degradation progressed, the long wavelength absorption band shifted from 881 to shorter wavelengths, forming a band near 820 nm as an intermediate. In these experiments, if degradation of BChl was random, and if interacting subunits give rise to the LHI spectra, it might be expected that partial degradation of BChl might allow direct observation of some surviving subunit complexes.

The oxidation of BChl in LHI was further studied in isolated complexes by Picorel et al. (1984). In these studies, it was possible to reversibly oxidize part of the BChl in the LHI preparation and demonstrate the existence of the cation radical by EPR. The EPR signal was narrowed to 3.5 G (relative to 13.0 G for monomeric BChl cation radical in organic solvent (McElroy et al., 1969)). The narrowed signal could be explained by the sharing of the unpaired electron by a group of approximately 12 BChl molecules (Picorel et al., 1984). These results suggest six $\alpha\beta$:2BChl subunit complexes are in close association in LHI. The suggestion of a close association of six $\alpha\beta$:2BChl subunits (three $\alpha_2\beta_2$:4BChl) is also consistent with the preliminary results of crystallographic studies of LHII (Papiz et al. 1989), B800–820 (Guthrie et al. 1992) and LHI (Nunn et al., 1992). The following equilibria would be consistent with stopped-flow dilution data (van Mourik et al., 1992) and observations suggesting a $(\alpha_2\beta_2$:4BChl)₃ structure:

D. Conclusions

LHI is constructed from a fundamental unit, $\alpha_1\beta_1$:2BChl, which can be isolated as a stable detergent complex from many photosynthetic bacteria. The two BChl molecules of the subunit form a strongly-interacting exciton pair which are proposed to be arranged as shown in Fig. 5 and are about 11 Å apart (center-center) (Visschers et al., 1991). The structural suggestions in Fig. 5 will be further discussed in

section X. The removal of detergent to form LHI, results in an initial dimerization (van Mourik et al., 1992). Further subunit association most likely occurs before the properties of LHI are fully attained. Thus, the red-shift from 820 nm to 873 nm would be ascribed to additional protein interaction due to close packing of additional α -helices of both α - and β -polypeptides and the existence of other subunit BChl pairs at distances between 8 to 15 Å (BChl exciton dimer center to BChl exciton dimer center). When present, Car binds to further stabilize the association of the subunits to form LHI, interacting between associated $\alpha_1\beta_1$:2BChl units. For further extrapolation to the structure of native LHI, it is desirable to have more information on the associated intermediate state(s) as well as fully formed LHI,

III. Reconstitution of Subunit Complexes and LHI from Separately-Isolated Components

A. Reversible Dissociation of Subunit Complexes

One of the original goals in dissociating the LHI was to develop methodology to dissociate the complex fully to its fundamental components and then reassociate them to reform LHI in high yield (> 90%). It was therefore with considerable satisfaction that we found the subunit complex of *Rs. rubrum* could be further dissociated to its fundamental components by increasing the OG concentration and then the subunit subsequently reformed by reducing the effective OG concentration (Parkes-Loach et al., 1988). Such reversible dissociation was also demonstrated for the subunit complexes of *Rb. sphaeroides* (Chang et al., 1990b), *Rb. capsulatus* (Heller and Loach, 1990) and *Rp. viridis* (Parkes-Loach et al., 1994), the last of which is a BChl-*b*-containing organism.

B. Reconstitution of the Subunit Complex and LHI from Separately-Isolated Polypeptides and BChl a

Since the subunit complex could be dissociated into its component polypeptides and BChl, it was clear that it should be possible to reconstitute the subunit and LHI complexes with separately-isolated polypeptides and BChl, unless some additional undetected component present in dissociated

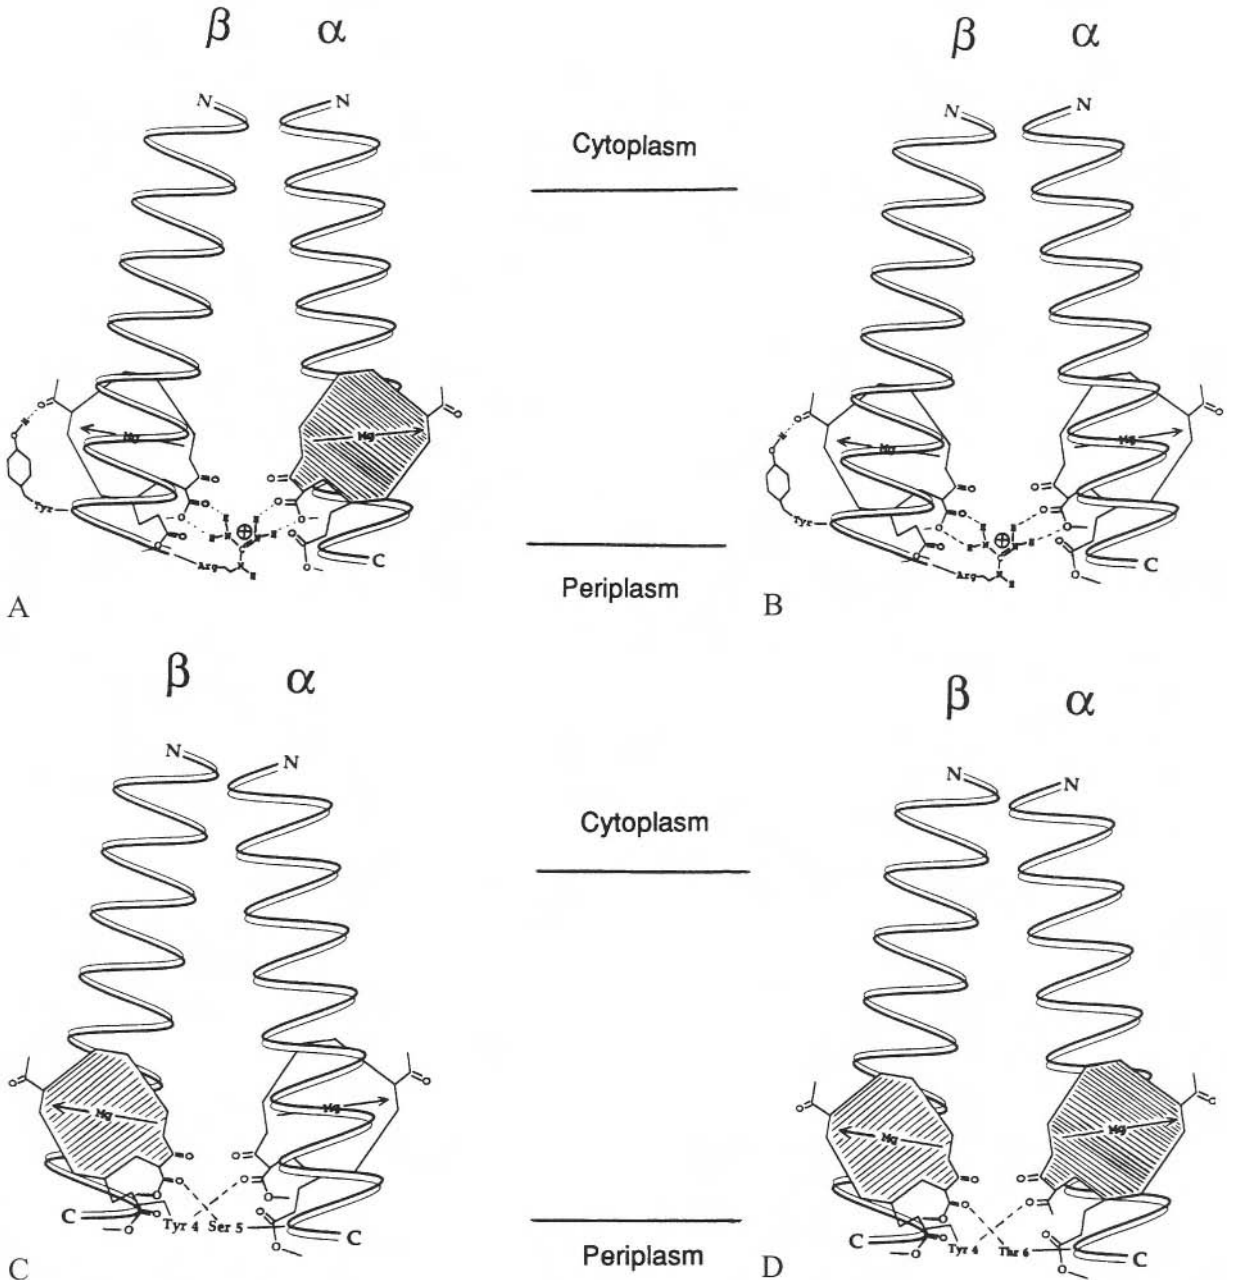

Fig. 5. Four variations of a model of the structural subunit of LHI. The sinusoidal lines represent the membrane-spanning α -helical portion of the α - and β -polypeptides without sidechains. The two BChl are represented by their outlines with Mg at their centers. The Q_y transition of each BChl molecule is depicted by the arrows running from pyrrole ring III to pyrrole ring I. The centers of the two BChl molecules are 11 Å apart. Each of the two BChl molecules are drawn with their Q_y axes rotated (one clockwise 8.5° and one counterclockwise 8.5°) along an axis passing through their Mg atoms, parallel to the membrane plane and perpendicular to the direction of the Q_y transition. Although not shown, one of the BChl molecules is also to be rotated 17° along an axis perpendicular to the membrane plane and passing through its Mg atom. Two further small displacements of one of the BChl by about 1 Å results in a final angle of 24° between the two Q_y axes. These exciton BChl dimer representations are modeled after that presented in Visschers et al. (1991). The α -helical membrane-spanning regions are drawn with an angle of 17° between them. In (A) and (C), one of the polypeptides is intended to be closer to the viewer than is its bound BChl so that the BChl is on the back surface of one polypeptide and on the front surface of the other. In (B) the BChl are intended to be on the back surface of both polypeptides, while in (D) they are intended to be on the front surface. In each of the four dimers, different edges of the α - and β -polypeptides α -helices are adjacent. In (A) and (B), the two amino acid side chain structures shown represent Tyr 4 and Arg 7 of the β -polypeptide of *Rb. sphaeroides*.

membrane material was required. The polypeptides used for reconstitution were extracted from the membranes with organic solvents, separated from lipid and other components by gel filtration chromatography, dialyzed against water, lyophilized and often further purified by reverse-phase HPLC. The pure polypeptides were resuspended in OG-containing buffer, BChl *a* was added and the OG concentration was adjusted to optimally stabilize the subunit complex. After the subunit complex was formed, LHI-type complexes were then formed by using the same procedures as was previously described for reassociating the subunit complex. Reconstitution of subunit and LHI-type complexes with BChl *a* has been demonstrated using the α - and β -polypeptides of LHI of *Rs. rubrum* (Parkes-Loach et al., 1988; Loach et al., 1994), *Rb. sphaeroides* (Loach et al., 1994), *Rb. capsulatus* (Loach et al., 1994), and *Rp. viridis* (Parkes-Loach et al., 1994).

From studies of these reconstituted systems, two important conclusions can be made: (1) only mature protein coded for by the *puf A* and *puf B* genes is required for *in vitro* LHI assembly and (2) the amino acid sequence of each polypeptide contains sufficient structural information to direct specific complex formation with BChl. These conclusions should not be interpreted to mean that no other protein factors are involved in the *in vivo* assembly of LHI in the membrane, but it does establish that such factors may not be required, and if an additional factor is involved, it likely plays no role in the eventual structure of LHI.

C. Formation of a Subunit-type Complex with the β -Polypeptide alone and BChl *a*

Because the subunit and LHI complexes could be reconstituted from individual components, it was possible to evaluate the role of each component and begin to probe structure-function relationships. For the α -polypeptides isolated from *Rs. rubrum*, *Rb. sphaeroides*, *Rb. capsulatus*, and *Rp. viridis*, no direct spectroscopic evidence for BChl binding was obtained when the α -polypeptide alone was reconstituted with BChl (Parkes-Loach et al., 1988; Loach et al., 1994; Parkes-Loach et al., 1994); that is, under conditions where the subunit complex readily forms when both polypeptides are present, no red-shift in the Q_y band (or any absorption change of BChl) was observed in the presence of the α -

polypeptides alone. In addition, no change in the very weak molar ellipticity of monomeric BChl (Sauer, 1978; Parkes-Loach et al., 1988) in detergent solutions was noted in the presence of the α -polypeptides, even at high concentrations of the peptide (unpublished results). On the other hand, BChl-BChl oligomerization was significantly retarded in the presence of α -polypeptides under LHI-forming conditions, indicating that the α -polypeptide has an effect on BChl-BChl aggregation. As the detergent concentration is lowered to LHI-forming conditions, the BChl apparently binds to His of the α -polypeptide with a higher affinity than that exhibited for BChl oligomer formation.

In the case of the β -polypeptide alone of *Rs. rubrum*, *Rb. sphaeroides* and *Rb. capsulatus*, a very specific complex is formed at typical subunit-forming conditions. This complex has absorption, CD, and fluorescence polarization properties identical to those of the subunit complexes formed when the respective α -polypeptides are also present (Parkes-Loach et al., 1988; Visschers et al., 1991; Loach et al., 1994). However, the ratio of BChl: β -polypeptide is 1:1 in such complexes prepared from the β -polypeptide of *Rs. rubrum* (Loach et al., 1989) or from *Rb. sphaeroides* (unpublished data) rather than 2:1 as is observed in each normal heterodimer subunit complexes. Because the β -polypeptides all have two conserved His (whereas all α -polypeptides have only one), and since a His is thought to provide the ligand coordinated to each BChl (Roberts and Lutz, 1985), one might suggest that, in the subunit complex, only the β -polypeptides are involved in coordinating BChl, one molecule on each of its two His. In this case, the structure of the β -only complex would be ascribed to a β_2 :2BChl complex where one β -polypeptide plays a role usually fulfilled by the α -polypeptide and the other one binds a pair of BChl. However, the spectral properties of the exciton pair for such a BChl dimer would be expected to be significantly different from those observed. In addition, recent reconstitution experiments with a truncated β -polypeptide from *Rs. rubrum* containing only one histidine, His 0 (see Fig. 3 for amino acid numbering), demonstrated that the subunit complex can still be formed (see section VII.C). Therefore, each β -polypeptide in the β -only subunit-type complex most probably has a BChl coordinated to the imidazole side chain of its His at position 0. When the α -polypeptide is present, the native subunit complex, $\alpha\beta$:2BChl, would have one

BChl coordinated to His 0 of the α -polypeptide and the other BChl coordinated to His 0 of the β -polypeptide.

IV. Probing the BChl Binding Site by Reconstitution with BChl Analogs

A. Common Binding Requirements

Using reconstitution of the subunit complex and LHI as assays for specific BChl binding, several BChl *a* analogs have been evaluated primarily with α - and β -polypeptides from *Rs. rubrum* and from *Rb. sphaeroides*, but also to some extent with the α - and β -polypeptides of *Rb. capsulatus* and *Rp. viridis* (Parkes-Loach et al., 1990; unpublished results). Most of the analogs tested gave similar results with each set of polypeptides and these will be discussed first. For reference, Fig. 6 shows the structure of BChl *a*. Neither a subunit complex or a LHI-type complex was formed with either the *Rs. rubrum* or *Rb. sphaeroides* polypeptides when analogs lacked Mg^{2+} , the carbomethoxy group at C13² or the bacteriochlorin oxidation state of the macrocycle. In addition, when the carbonyl group at C3¹ was absent, no LHI-type complex was formed. In this latter case, a subunit-type complex could be formed with polypeptides from *Rs. rubrum* but not with those from *Rb. sphaeroides*. This difference will be discussed in section IV.B.

Changes in structure that were compatible with forming both subunit-type and LHI-type complexes with polypeptides from either bacteria included a change in the side chain at C8 to a double bond (BChl *b*) and variation of the esterifying alcohol of the BChl at C17³. In the latter case, even with an ethyl group as the esterifying alcohol, both the subunit complex and LHI were formed.

From these analog studies, it can be concluded that the Mg^{2+} , C13² carbomethoxy group and C3¹ carbonyl group are important structural features for BChl binding with α - and β -polypeptides from both *Rs. rubrum* and *Rb. sphaeroides*. The Mg atom is clearly involved in coordinating a group from the protein (most likely a histidine imidazole group (Robert and Lutz, 1985)). It is likely that the oxygen atoms of the C3¹ carbonyl and the C13² carbomethoxy groups are involved in hydrogen bonds with donor groups from the protein. We have so far not been able to test the carbonyl group at C13¹ specifically because of the lack of appropriate analogs.

Fig. 6. Structure of BChl *a*. R is geranylgeranyl for BChl *a* isolated from *Rs. rubrum* and phytol for BChl *a* isolated from *Rb. sphaeroides*.

B. Differences in Binding Requirements between *Rs. rubrum* and *Rb. sphaeroides*

Two of the BChl analogs behaved differently in reconstitution depending on the polypeptides used. One of these, C13² OH-BChl *a*, under the assay conditions chosen, forms both a subunit-type complex and a LHI-type complex with the polypeptides from *Rb. sphaeroides*, but the complexes were not as stable as when native BChl *a* was used (Davis et al., unpublished). However, with polypeptides from *Rs. rubrum*, only a small red-shift in the wavelength maximum (from 778 nm to 781 nm) was observed under subunit-forming conditions and no LHI-type complex formed (Parkes-Loach et al., 1990). It must be concluded that different binding constraints exist at the C13² carbomethoxy site with the two sets of polypeptides. Thus, under the conditions selected for the comparison, the addition of the hydroxyl group at C13² destabilizes complex formation with polypeptides from *Rb. sphaeroides* and prevents formation of a subunit or LHI complex with polypeptides from *Rs. rubrum*.

The second analog that behaves differently with the two sets of polypeptides is 3-vinyl BChl *a*. In this case, no evidence for interaction was found for the polypeptides of *Rb. sphaeroides*, but a subunit-type

complex formed with *Rs. rubrum* polypeptides (Davis et al., unpublished). This subunit-type complex with *Rs. rubrum* polypeptides could not be converted to a LHI-type complex. From these data, it may be concluded that the carbonyl group at C3¹ is required for formation of LHI for both bacteria but not for formation of the subunit with *Rs. rubrum* polypeptides. These results showing differences between binding will be especially useful in identifying binding elements between the polypeptides and BChl and will be discussed further in section VIII.

C. Measurement of Association Constants for Formation of the Subunit Complex

Because the subunit complex can be reversibly formed from LHI and reversibly dissociated to its individual components, association constants for each of these equilibria can presumably be measured. Although these constants are highly dependent on the detergent concentration, relative values can be determined at fixed detergent concentration. The availability of such information is helpful in understanding the contributions made by some of the interactions that stabilize the subunit complex and that play a role in LHI formation.

Some association constants for forming the subunit complex are listed in Table 1. The molecularity of the reaction measured is assumed to be:

or

From the values of these constants, the high affinity of binding is apparent. Less than μM concentrations

of the polypeptides and BChl are sufficient to quantitatively form many of the subunit complexes, even in the presence of 0.75 % OG. Thus, the high affinity of binding in forming the subunit complex and LHI allow the subtleties of binding interactions to be probed.

It is interesting that the relative stability of these subunit complexes formed with only the β -polypeptides of *Rs. rubrum*, *Rb. sphaeroides* or *Rb. capsulatus* vary more than 200-fold. In fact, even comparing the K_{Assoc} values of the β -polypeptides of *Rb. sphaeroides* and *Rb. capsulatus* which have 80% identity in their amino acid sequences, there is a 200-fold difference (Table 1). Moreover, the wavelength maximum of the Q_y absorption band of the subunit seems to reflect the strength of binding with the greater red shift correlating with stronger binding (*Rb. sphaeroides*, 825 nm > *Rs. rubrum*, 819 nm > *Rb. capsulatus*, 816 nm). The role of the α -polypeptide of *Rs. rubrum* in stabilizing the subunit complex of *Rs. rubrum* is also apparent, increasing the K_{Assoc} 6- to 10-fold. Contributions to the binding energy by various structural elements will be discussed in more detail in section VIII.

D. Competitive Inhibitors to BChl Binding

In testing BChl *a* analogs, the criteria for complex formation were a red shift in the long-wavelength absorption band and characteristic CD properties at specific concentrations of protein, BChl and OG. These properties are very sensitive to the way in which the two molecules of BChl in the dimeric pair interact with each other. Many of the analogs tested may have a high affinity for the polypeptides, but fail to show a red shift in the Q_y absorption band, presumably either because of changes in interaction

Table 1. Association constants for formation of the subunit complex¹

Bacteria	Polypeptide(μM)	$K_A (\text{M}^3) \times 10^{-16}$	% Variation
<i>Rs. rubrum</i>	β (3)	3.09	13
	β (6)	2.13	20
	α (3) + β (3)	19.9	12
<i>Rb. sphaeroides</i>	β (3)	22.1	22
	β (6)	73.0	12
	α (3) + β (3)	12.5	14
<i>Rb. capsulatus</i> ²	β (6)	0.28	

¹ Unpublished results. Equilibria were measured in 0.05 M potassium phosphate buffer, pH 7.5, containing 0.75% OG, 22 °C. The molecularity assumed for the reaction is: $\alpha + \beta + 2\text{BChl} \rightleftharpoons \alpha\beta_2\text{BChl}$.

² These data are less reliable because of the weak complex formed. The value given represents the largest value of those obtained.

in the dimer due to a different geometry or due to differing properties of the molecular orbitals in the ground and excited states of the analog molecule compared to BChl *a*. One of the analogs we expected to have some affinity for the binding site was 3-acetyl-Chl *a*, even though its chlorin oxidation state has a slightly different geometry than the bacteriochlorin oxidation state of BChl; the two molecules are otherwise structurally the same. However, experimentally, no red-shifted species were observed. If a complex were forming but exhibited no red-shift in the Q_y band, such binding could be determined by evaluating the extent to which the analog might compete with BChl *a* for its binding site(s). A variety of analogs were examined in this way and their relative effectiveness determined. Examples of analogs tested for competitive inhibition were vinyl BChl *a*, chlorophyll *a* (Chl *a*), chlorophyll *b* (Chl *b*), hemin dimethyl ester, manganese protoporphyrin IX dimethyl ester, and manganese hematoporphyrin IX dimethyl ester. Each of these molecules is able to coordinate an imidazole group of His and each contains several oxygen atoms in locations similar to those that occur in BChl *a*. All were effective in preventing formation of the normal subunit complex with BChl *a* at concentrations of analog comparable to that of BChl *a*. For comparison to the association constants of Table 1, we determined the competitive binding constant of Chl *a* with the *Rb. sphaeroides* β -polypeptide (3 μ M), to be 1.47×10^{17} . Thus, by the use of competitive binding methodology, a wide variety of analogs can be used to probe the nature of BChl binding.

E. Reconstitution Studies Using DMSO

A different approach to reconstitution and competitive binding was used by Berger et al. (1992). They started with LHI isolated from *Rs. rubrum* and dissociated the complex in 0.02 M Tris buffer, pH 8.0 containing 0.3% LDAO and 20 to 30% DMSO. Reconstitution was carried out by adding concentrated BChl *a* or analog in DMSO, at about 5 times the original BChl concentration. After one hour at 4 °C, the sample was diluted 10-fold with 1 M NaCl, 0.02 M Tris buffer, pH 8.0. The reconstituted LHI-type complexes were separated from excess BChl, or analog, by gel filtration HPLC using Tris buffer (0.02 M, pH 8.0) containing 1 M NaCl and 1 to 5% cholate as eluent.

In these experiments the subunit complex was not

observed as an intermediate either upon dissociation or reassociation. It is unclear whether the α - and β -polypeptides dissociated during the treatment, but with excess BChl *a* addition under reassociation conditions, good yields of the 873-nm-absorbing complex were obtained. Berger et al. (1992) found that BChl a_p , BChl a_{gg} , and BChl *b* formed red-shifted LH-type complexes while pyro BChl a_{gg} , 13²-OH-BChl a_{gg} , Chl *a* and Chl *b* did not. These results were similar to those reported by Parkes-Loach et al (1990) for reconstitution assays with these analogs in OG. In addition, Berger et al. (1992) found no evidence for binding of 3 (α -hydroxy ethyl) BChl a_{gg} . Because the amount of analog and remaining BChl a_{gg} were determined analytically after each reconstitution, the relative effectiveness of the analogs in displacing BChl a_{gg} , and therefore presumably binding to the protein, could be compared. They found the order of effectiveness to be pyroBChl a_{gg} > BChl a_p > 13²OH BChl a_{gg} > BChl *b* > Chl *a*, Chl *b* >> 3 (α -Hydroxy ethyl) BChl a_{gg} .

V. Reconstitution of Car to Form Wild-Type LHI with BChl *a* and Polypeptides of *Rb. sphaeroides* and *Rs. rubrum*

Car is found in all wild-type bacteria; only mutants grown under laboratory conditions can exist without carotenoids (Ke, 1971; Cogdell and Frank, 1987). One or two Car molecules are bound per $\alpha\beta$ polypeptide pair in LHI, depending on the bacterial species (Cogdell, 1985a; Cogdell, 1986). Since the presence of Car displaces the subunit complex/LHI equilibrium towards LHI, all reconstitution experiments where it was desirable to form the subunit complex were conducted without Car. When the goal was to reconstitute the wild-type LHI, Car was added to the BChl and the α - and β -polypeptides under conditions where the subunit complex was in equilibrium with free BChl *a* and α - and β -polypeptides (Davis et al., 1995). The amount of subunit complex decreased and LHI was formed under these initial mixing conditions which are normally unfavorable for LHI formation. Upon decreasing the detergent concentration as is usually done to form LHI, the reconstituted LHI-type complex had an additionally red-shifted, long-wavelength BChl absorption maximum (usually to between 879 and 883 nm compared to 871 to 875 nm without Car). As further evidence for the near native

Fig. 7. CD spectra of *Rb. sphaeroides* PUC705BA (B800–850⁻) chromatophores (top) and reconstituted LHI without carotenoid (middle) and with carotenoid (bottom). Data from Davis et al. (1995). Note that the material measured for the top spectrum still contains RC while the other two systems do not.

structure of Car-containing, reconstituted LHI complexes, a red shift in the CD spectra in the Q_y region of BChl occurred (Fig. 7). Both of these properties were consistent with those displayed by in vivo wild-type LHI. In addition, the reconstituted Car had a characteristic red shift in its absorption spectrum and displayed CD properties in the 400 to 550 nm region similar to those of the in vivo state (Fig. 7). This is an especially sensitive probe of the

binding environment since Car in organic solvent is not optically active (Cogdell et al., 1976).

Successful Car reconstitution has been achieved with BChl *a* and the α - and β -polypeptides of two photosynthetic bacteria, *Rs. rubrum* and *Rb. sphaeroides* (Davis et al., 1995). In addition to the absorption and CD spectra, measurement of Car function was also conducted. The functional role of Car seems to be two-fold (Cogdell and Frank, 1987): to act as an accessory pigment and to protect BChl from degradation. As an accessory pigment, it absorbs light in a wavelength region where BChl has little absorption, and then transfers this excitation energy to BChl of LHI. The efficiency of transfer of such Car excited singlet state energy to BChl can be estimated by measuring fluorescence excitation spectra (Goedheer, 1959). We chose two bacteria that differ greatly in their efficiency: for *Rs. rubrum* LHI the efficiency of transfer is 30–32% (Goedheer, 1959; Noguchi et al., 1990; Cogdell et al., 1992) while for *Rb. sphaeroides* LHI it is near 70% (Kramer et al., 1984; Cogdell et al., 1992). Spirilloxanthin is the native Car of *Rs. rubrum* S1 (van Neil et al., 1956; Schmidt, 1978). When this Car was reconstituted with the α - and β -polypeptides of *Rs. rubrum* and BChl *a*, a 30% efficiency for transfer of excited singlet state energy was determined from fluorescence excitation spectra (Davis et al., 1995). This compares very favorably to that of the intact membranes, indicating excellent reconstitution of function as well as structure. Interestingly, if spheroidene (the major native Car of *Rb. sphaeroides* 2.4.1 (Schneour, 1962; Schmidt, 1978) was used as the reconstituted Car with the α - and β -polypeptides of *Rs. rubrum*, absorption and CD properties of both BChl and Car were similar to those of wild-type LHI of *Rb. sphaeroides* and the relative efficiency of transfer of excited singlet state energy was increased to 75% (Davis et al., 1995), essentially the same as the value found in LHI of *Rb. sphaeroides*.

Spheroidene affects the BChl absorption and CD spectra the same way in both the *Rs. rubrum* and *Rb. sphaeroides* systems. Also, spheroidene's absorption maxima are red-shifted the same amount in both systems, the CD spectra have the same properties, and spheroidene's efficiency of energy transfer is identical in both systems, even though spirilloxanthin in the native *Rs. rubrum* system has a much lower yield of energy transfer. Therefore, the way in which spheroidene is bound in *Rs. rubrum* and in *Rb. sphaeroides* must be very similar. In this instance,

the efficiency of energy transfer reflects the fundamental properties of the specific Car molecules (the energy level of the $2^1\text{Ag}(S_1)$ states relative to that of the BChl Q_y absorption band and the lifetime of the Car excited state (Frank et al., 1993)) and does not seem to be perturbed significantly by the protein. This is in contrast to the results reported by Noguchi et al. (1990) for *Chromatium* light-harvesting complexes where the protein did perturb the properties of the Car.

The second *in vivo* role of the Car is to quench the excited triplet state of BChl when it is produced (Cogdell, 1985b; Cogdell and Frank, 1987). This quenching occurs by transfer of excited triplet state energy from BChl *a* to the Car, which in turn, rapidly dissipates the energy and returns to the ground state. If the excited state occurs on BChl in the absence of Car, it can interact with oxygen and the BChl is subsequently degraded. A simple assay for evaluating this protective role by Car can be used in which the photodegradation of BChl is measured. Because triplet energy transfer is highly sensitive to distance and orientation between the donor and acceptor molecules, this assay is an effective probe for *in vivo*-like structure. If membrane vesicles (chromatophores) are illuminated with high-intensity radiation in air, BChl is degraded over time (Fig. 8; Davis et al., 1995). The data for chromatophores of wild-type cells shows the protective role of Car as compared to chromatophores of G9 cells, a carotenoidless mutant. Also shown in Fig. 8 is the relative stability of BChl in reconstituted LHI with and without Car. It can be seen that LHI reconstituted with Car resulted in marked stabilization of BChl toward photodegradation. This effective photoprotection indicates that the Car-BChl distance and orientation are very similar in reconstituted and *in vivo* complexes. Thus, beginning with the isolated α - and β -polypeptides, BChl *a* and Car, wild-type LHI has been reconstituted and displays *in vivo*-like structure and function.

VI. Reconstitution of LHI-type Complexes Using Mixed Polypeptides

The LHI polypeptides have been isolated from many photosynthetic bacteria and their amino acid sequences have been determined (Zuber and Brunisholz, 1991; Brunisholz and Zuber, 1992). Certain structural elements are highly conserved,

Fig. 8. Time dependence of LHI BChl degradation as measured at the λ_{max} of the Q_y band for wild type *Rs. rubrum* chromatophores (□), *Rs. rubrum* G-9 chromatophores which lack carotenoid (∗), and reconstituted *Rs. rubrum* LHI with (○) and without (△) carotenoid.

such as His 0 in the α -polypeptides, the two His residues in the β -polypeptides and the stretch of apolar amino acids in each polypeptide that have been assigned the role of spanning the membrane as an α -helix (Zuber, 1986). By comparison of these sequences, a core region can be identified in which there is substantial sequence homology as well as highly conservative changes (see core regions marked in Fig. 3). Because of these conserved core regions, it might be expected that the α -polypeptide of one bacterium could be paired with the β -polypeptide of another bacterium to reconstitute hybrid subunit and LHI complexes. Furthermore, such mixed polypeptide experiments might be useful in highlighting important structural elements necessary for complex formation.

Since reconstitution of subunit complexes from pure components has been demonstrated for three different bacteria (*Rs. rubrum*, *Rb. sphaeroides*, and *Rb. capsulatus*), these polypeptides were used for hybrid reconstitution experiments. The polypeptides of *Rp. viridis* were also employed since they have also been well-characterized in homologous reconstitution experiments with BChl *a* and BChl *b* (Parkes-Loach et al., 1994). Several conclusions may be drawn from the hybrid reconstitutions with these four sets of polypeptides (Loach et al., 1994). (1) Because half the hybrid combinations of α - and β -polypeptides with BChl *a* successfully formed subunit and LHI-type complexes, the experimental results support the supposition that a core region of the

amino acid sequence may be sufficient for formation of functional complexes. The expectation that regions of the α - and β -polypeptides that show little or no homology are not required for subunit and LHI formation was confirmed. The amino acid sequences outside of the core region may be important for the assembly of LHI in vivo where membrane insertion and assembly with the RC are important. (2) A region sensitive to charge exists between amino acids at positions -17 to -26 of both the α - and β -polypeptides (see Fig. 3 for amino acid sequences and numbering). In the hybrid reconstitution experiments there were two general cases where reconstitutions of a LHI were unsuccessful. In one of these, the β -polypeptide of *Rs. rubrum* did not form LHI with any α -polypeptide other than its own. A possible explanation of this result is that the existence of an additional cationic residue in the core region of the *Rs. rubrum* β -polypeptide at position -17 could result in charge repulsion of the *Rs. rubrum* β -polypeptide with all α -polypeptides other than its own. In the other general case, the α -polypeptide of *Rp. viridis* failed to support LHI formation with any β -polypeptide other than that of *Rp. viridis*. The reasons for this are not obvious.

VII. Probing Structural Requirements for Formation of the Subunit Complex and LHI by Reconstitution with Modified Polypeptides

On the basis of the reconstitution results from the experiments with heterologous combinations of polypeptides, and from other reported experiments in which the importance of certain amino acids were evaluated by site-directed-mutagenesis (Bylina et al., 1988; Dörge et al., 1990; Stiehle et al., 1990; Babst et al., 1991; Fowler et al., 1992), it appeared useful to selectively modify polypeptides by chemical and enzymatic treatment. In the results to be summarized in this section, the amino and carboxyl groups of α - and β -polypeptides were modified chemically. Also, the α -polypeptide was shortened in the N-terminal region by chemical means and both the α - and β -polypeptides were shortened from the N- and C-terminal ends by enzymatic modification.

A. Chemical Modification of Charged Groups

A traditional biochemical approach in evaluating the

importance of charged amino acid residues is to chemically modify them and determine the effect on biological activity. By selecting specific polypeptides whose amino acid sequences contained a single lysine (e.g., the α -polypeptide of *Rs. rubrum*), the group could be modified, for example, by acetylation, and the effect on reconstitution of the subunit complex and LHI evaluated. Conditions for quantitative modification of the ϵ -amino group of the lysine residue were developed for this simple system and then applied to polypeptides containing multiple lysine residues (Heller, 1992). Using this approach, the lysine side chains of the α - and β -polypeptides of *Rs. rubrum* and *Rb. capsulatus* were modified by acetylation and the carboxyl groups of the same polypeptides were modified by esterification (converting the carboxyl groups to carboxymethyl groups); both of these procedures removed charged groups. Conditions were selected to achieve as complete a modification as possible of all susceptible groups. Each modified polypeptide was isolated by HPLC and tested in reconstitution assays. The results can be summarized in the following way. In cases where the modified residues were located outside the core region, derivatization of these charged residues had no effect on reconstitution. Examples include the single lysine in the α -polypeptide of *Rs. rubrum* and the single lysine on the β -polypeptide of *Rb. capsulatus*. These results are consistent with those reported by Gogel et al. (1986) in which the single lysine of the α -polypeptide was chemically modified with dansyl chloride and found to have no effect on LHI properties. However, in cases where conserved lysine residues were modified within the core region (the α -polypeptide of *Rb. capsulatus* and the β -polypeptide of *Rs. rubrum*), the ability of these polypeptides to support formation of LHI with their homologous partner was eliminated or significantly impaired.

For reconstitution systems containing only the β -polypeptide and BChl *a*, the subunit complex formed well in the case of the acetylated β -polypeptide of *Rb. capsulatus* but it was destabilized in the case of the acetylated β -polypeptide of *Rs. rubrum*. These results are parallel to those obtained for LHI formation in that only in the case where the modification was of lysine residues outside the core sequence was there no effect on formation of the subunit complex.

In the case of the carboxyl groups, esterification of each polypeptide was conducted but it was not easy to determine whether the esterification reaction had

gone to completion. In addition, there are more potential carboxyl groups to derivatize, making isolation of modified polypeptides more difficult. Some general trends in the results were observed and followed expectations according to whether the modified groups were in the core region of amino acid sequence (Heller, 1992)

The conclusions from these experiments clearly indicate the likely involvement of cationic amino acid side chains of the core region in stabilization of both the subunit complex and LHI. The results of esterification are less definite, but are consistent with a presumed role of several Glu and/or Asp in the core region providing anions to ion-pair with the conserved cationic groups.

B. Chemical Modification by Limited-Acid Hydrolysis

All of the α -polypeptides from LHI of bacteria where the amino acid sequences are known (Zuber and Brunisholz, 1991) contain the sequence... Asp-Pro... in their hydrophilic N-terminal region (Fig. 3). The peptide bond connecting these two amino acids is known to be much more labile to acid than other peptide bonds (Landon, 1977). This bond can be specifically cleaved by limited acid hydrolysis, and the truncated α -polypeptide (e.g., of *Rs. rubrum*, Pro-Arg-Gln-Ala....) isolated by HPLC (Meadows et al., 1995). It should be noted that three highly conserved amino acids are removed in such a split (Arg or Lys at position -26; Trp at position -24; and Asp at position -20). When this truncated α -polypeptide of *Rs. rubrum* was tested for its ability to support formation of the subunit complex and LHI with the normal β -polypeptide of *Rs. rubrum*, each complex formed but the stability of the LHI-type complex was markedly reduced.

C. Truncation of Polypeptides by Hydrolysis with Proteolytic Enzymes

Among the family of specific proteases are endoproteinase Lys-C and endoproteinase Glu-C which specifically hydrolyze the bond on the carbonyl side of Lys and Glu, respectively. In the experiments summarized below, we found these enzymes to maintain their activity and specificity in 2.0% OG (Meadows et al., 1995). By selecting hydrolysis

conditions (amount of enzyme, length of hydrolysis time, etc.), it appeared to be possible to isolate by HPLC all products for each polypeptide treated. Some of the polypeptides prepared in this way are illustrated below (see Fig. 3 to compare to the native polypeptide sequences). The sequence shown is the polypeptide remaining after protease treatment and isolation. The dots indicate that the amino acid sequence toward the amino- or carboxy-terminus is the same as that of the native polypeptide.

C-terminal truncated *Rs. rubrum* α -polypeptides

The two truncated C-terminal α -polypeptides were completely active in reconstitution experiments with native *Rs. rubrum* β -polypeptide. Thus, the C-terminus of the α -polypeptide can be shortened by 10 amino acids without affecting either subunit or LHI formation when tested with the native β -polypeptide. This result is consistent with expectations, since the amino acids removed are not highly conserved. Two of the N-terminal truncated β -polypeptides of *Rs. rubrum*, Glu-Phe-His-Lys.... and Phe-His-Lys-Ile...., when reconstituted with the native α -polypeptide of *Rs. rubrum*, were found to form normal subunit complexes but only partially formed LHI-type complexes, which were unstable. Of considerable interest is the fact that the N-terminal

truncated Ile-Phe-Thr-Ser... from the *Rs. rubrum* β -polypeptide alone or with the normal *Rs. rubrum* α -polypeptide still formed the subunit complex, although the ΔG for formation was reduced by about 2 kcal mol⁻¹ (Meadows et al., 1995). Even though a highly-conserved N-terminal region including the His at position -18 was removed, the subunit complex could still be formed. Clearly, although His -18 may be involved in stabilizing the subunit complex, it is not an absolute requirement. In contrast, no LHI-type complex could be demonstrated with this truncated β -polypeptide together with the native *Rs. rubrum* α -polypeptide. Presumably, too many stabilizing interactions had been lost, including those involving His -18.

The most stable subunit complex that we have examined is that prepared with the β -polypeptide only of *Rb. sphaeroides*. We were therefore especially interested in whether the N-terminal truncated β -polypeptide, Leu-His-Ser-Val... from *Rb. sphaeroides*, would still form a stable β -only subunit complex. This was indeed found to be the case, indicating the importance of groups within and immediately flanking the nonpolar, membrane-spanning α -helical region in forming the β -only subunit complex. The LHI-type complex with the native *Rs. rubrum* α -polypeptide (used in this experiment because of its strong interaction with all β -polypeptides) and the N-terminal truncated β -polypeptide of *Rb. sphaeroides*, Leu-His-Ser-Val... was quantitatively formed but absorbed at 847 nm and was quite unstable.

VIII. Analysis of Stabilizing Interactions in Subunit Complexes

In order to fully understand structure-function relationships in the subunit complex and LHI, it is important to evaluate the contributions made by specific binding elements. Using the experimental data from the research reviewed here, it is possible to tentatively identify and estimate the importance of some specific interactions. The ability to isolate and reconstitute subunit complexes is of immense help in this regard.

Stabilization of the subunit complex will be addressed first. The stabilization energy of the subunit complex in 0.75% OG is very large, 24 kcal mol⁻¹, calculated from $K_{\text{Assoc}} = 19.9 \times 10^{16}$ for formation of the subunit complex using the α - and β -polypeptides of *Rs. rubrum* and BChl *a* (Table 1). Possible

interactions contributing to the stabilization of the subunit complex might include the following: (1) coordination of the ligand to the Mg atom of BChl, (2) hydrogen bonding between the protein and BChl, (3) hydrogen bonding between amino acid side chains of the polypeptides, (4) ion-pair interaction between the polypeptides, and (5) knob-hole (packing) interaction between polypeptide α -helices (Dunker and Jones, 1978).

The first of these interactions clearly contributes to BChl binding since, on the basis of resonance Raman data, it has been concluded that the imidazole group of His is coordinated to BChl (Robert and Lutz, 1985) and reconstitution with BPh does not form either subunit complexes or LHI (Parkes-Loach et al., 1990). From model studies (Cotton, 1976), the strength of Mg coordination to imidazole can be estimated to be between 4 and 6 kcal mol⁻¹ in nonpolar solvents such as carbon tetrachloride. Since there are two BChl per subunit complex, each coordinated to an imidazole group of His, this interaction is responsible for approximately half the binding energy in the subunit complex.

The experimental data from reconstitutions using BChl *a* analogs indicated that at least two hydrogen bonds between the protein and BChl were important with polypeptides from *Rb. sphaeroides* (involving the C3¹ carbonyl and the C13² carbomethoxy groups of the BChl), while at least one seemed important with the polypeptides from *Rs. rubrum* (involving the C13² carbomethoxy group). Each such bond may contribute between 2 and 4 kcal mol⁻¹ to complex formation in the nonpolar environment of these integral membrane proteins (Tinoco et al., 1985). Since there are two BChl molecules in the subunit complex of *Rs. rubrum*, two hydrogen bonds (one in each molecule) to a carbomethoxy group at C13² might be expected. From the comparison of reconstitution results with β -polypeptides from different bacteria, the special stability displayed by the subunit-type complex prepared with the β -polypeptide only of *Rb. sphaeroides* can only be attributed to hydrogen bond interaction in the region of BChl binding. This is because a much less stable subunit complex was formed with the highly homologous β -polypeptide only of *Rb. capsulatus* whose amino acid sequence only differs significantly from that of *Rb. sphaeroides* by the loss of two hydrogen bonding side chains (Loach et al., 1994 and section X). In addition to hydrogen bonding involving Arg 7, cross hydrogen bonding from groups

such as Tyr (Trp) 4 and/or Trp 6 of the β -polypeptide to BChl coordinated to the α -polypeptide and/or from Ser 5 and/or Thr 6 of the α -polypeptide to BChl coordinated to the β -polypeptide would further stabilize the dimeric structure.

From hybrid reconstitution experiments and reconstitution with truncated or chemically modified polypeptides, at least one ion-pair (with hydrogen bonding) appears to contribute to stabilization (Loach et al., 1994; Meadows et al., 1995). This contribution is approximately 3 kcal mol⁻¹ when calculated from the weakening of association observed in the absence of this pair of ions. Finally, comparison of the subunit complex of *Rs. rubrum* formed with the BChl analog containing an ethyl ester at position C17³ instead of geranylgeranyl indicated that the native esterifying alcohol contributed about 1.5 to 2.0 kcal mol⁻¹ to stabilize complex formation (unpublished results).

If the energies of stabilization for the four known interactions discussed above are added together for the *Rs. rubrum* system (2 × 5 kcal mol⁻¹ for coordinated ligands + 4 × 2 kcal mol⁻¹ for hydrogen bonding to BChl + 3 kcal mol⁻¹ for an ion pair + 2 kcal mol⁻¹ for the esterifying alcohol contributions = 23 kcal mol⁻¹), the elements primarily responsible for stabilization of the subunit complex in 0.75% OG are largely defined. These estimates indicate that there is little hydrogen bond interaction between polar amino acid side chains of the two polypeptides except for the above mentioned ion-paired groups, nor is there extensive stabilization by knob-hole packing between the polypeptides in the subunit complex in 0.75% OG. Thus, there seem to be four kinds of interactions that stabilize the subunit complex; in descending order of the magnitude of their contribution to the stabilization energy, they are ligand coordination to Mg, cross hydrogen bonding to BChl, ion pair formation, and packing assisted by the esterifying alcohol.

IX. Analysis of Stabilizing Interactions in LHI

Estimating the relative contributions of structural elements in the stabilization of LHI is more difficult due to the uncertain molecularity of the association reaction. As a first step, the assumption might be made that all interactions that stabilize the subunit complex are also important in formation of LHI. In the absence of the small amphipathic detergent molecules that are important in stabilizing the subunit

complex, some of the subunit interactions could be stronger, perhaps by a few kcal mol⁻¹.

Equilibria between the subunit complex and LHI could be estimated from data obtained at 0.73% OG for reconstitution of LHI at high protein and BChl *a* concentration (Loach et al., 1989). If, in consideration of the results of the stopped flow dilution experiments of van Mourik et al. (1992), the initial association reaction is assumed to be a dimerization of the subunit complex

then,

$$K_{\text{Assoc}} = [\alpha_2\beta_2 \cdot 4\text{BChl}] / [\alpha_1\beta_1 \cdot 2\text{BChl}]^2$$

Using the data from reconstituting LHI at high protein and BChl *a* concentration (Loach et al., 1989), $K_{\text{Assoc}} = 1.7 \times 10^5$ corresponding to a $\Delta G^\circ = -7.1$ kcal mol⁻¹. If further association then occurs to form a species with spectral properties equivalent to LHI, which we feel is likely to be the case, one might consider

for which,

$$K_{\text{Assoc}} = (\text{LHI}) / ((\alpha_2\beta_2 \cdot 4\text{BChl})_3)^3$$

A conservative estimate of this latter K_{Assoc} would be $\approx 10^{10}$, corresponding to an additional $\Delta G^\circ \approx -14$ kcal mol⁻¹.

In reconstitutions where Car is present, the wild-type LHI complex is formed at 0.73% OG at approximately ten-fold lower concentrations of subunit complex than in the absence of Car (Davis et al., 1995). Thus, for the reconstitutions with polypeptides from *Rs. rubrum* with BChl and Car

for which

$$K_{\text{Assoc}} \approx 1 / [6 \times 10^{-7}]^3$$

corresponding to a $\Delta G^\circ \approx -25$ kcal mol⁻¹. Further association presumably occurs to form a wild-type LHI complex. Clearly, even in the presence of 0.73

% OG, when Car is present, the subunit complexes strongly associate to form wild-type LHI.

If the reconstitution is conducted in the presence of phospholipids (phospholipid:BChl = 20:1), the LHI forms quantitatively even at the lowest concentrations of protein, BChl and Car that we can measure (approximately 1×10^{-7} M). One could conservatively estimate that the ΔG° for this initial step in association of the subunit complex in the presence of lipid is ≈ -10 kcal mol⁻¹ in the absence of Car (Eq. (5)), and ≈ -30 kcal mol⁻¹ in its presence (Eq. 7).

From the results obtained with the hybrid reconstitution experiments and with the truncated polypeptide experiments in the absence of Car, the following insights may be offered. Because most of the N-terminal truncated α - or β -polypeptides of *Rs. rubrum* supported formation of LHI-type complexes, but gave much lower yields, and because the complexes were less stable, specific interaction between these N-terminal regions most likely makes a major contribution to the stability of LHI. There are three pairs of strictly-conserved amino acids that may form specific ion pairs and/or hydrogen bonds (see further discussion in the next section). If one of these is involved in stabilizing the subunit complex, then the other two may be involved in stabilizing the initial associated product and each contribute about 3 kcal mol⁻¹. These interactions would account for a significant fraction of the ΔG° estimated for the association indicated by Eq. (5). It is interesting to note that unlike truncation of the N-terminus, truncation of the C-terminal region of the α -polypeptide of *Rs. rubrum* by ten amino acids did not appear to have a significant effect on stability of the reconstituted LHI (Meadows et al., 1995).

In addition to the possible ion pair interaction in the hydrophilic N-terminal region, hydrogen bonding between polypeptides (possibly including the BChl) in the otherwise nonpolar, membrane-spanning regions may be important. The special stability displayed by the subunit-type complex prepared with the β -polypeptide only of *Rb. sphaeroides* was attributed to this kind of interaction (section VIII)

Also, knob-hole packing of the α -helices is probably quite important to the stabilization to LHI. Such packing does not seem to be a very significant factor in the detergent-stabilized subunit complex, probably because the mixed micelles formed, composed of protein and detergent, satisfy the major hydrophobic driving force to minimize the exposure

of hydrophobic surface to water. Decreasing the detergent concentration to below that necessary to support the mixed protein-detergent micelle structure would result in a strong hydrophobic force for subunit association. When the detergent concentration is decreased in the presence of phospholipid, the subunit complex presumably incorporates into the lipid bilayer of the proteoliposome with the lipid replacing detergent on the protein's hydrophobic surface. However, more restrictions to motion occur in the hydrocarbon tails of the phospholipid in comparison to detergent binding, especially in the region near the lipid head group. Thus, phospholipid may not effectively compete with polypeptide-polypeptide interaction in the bilayer of the proteoliposome and, as a result, extensive association of the subunit complexes occurs.

Of special interest is the stabilization due to the presence of Car. Although Car causes only a small perturbation in the structure of the BChl in LHI, as indicated by a small red-shift in the absorption and CD spectra in the Q_y-band region, its presence results in a significant increase in stability of the complex. Such stability presumably stems from specific packing between the rigid conjugated double bond chain of the Car molecule with its periodically protruding methyl groups and the $\alpha_1\beta_1$ -2BChl units.

X. Implications for the Structure of the Subunit Complexes

The models for the subunit complex suggested in Fig. 5 are based on a consideration of the results of biochemical and spectroscopic characterization of the subunit complexes from different bacteria, and from reconstitutions with systematically modified components. Essential features are the following:

- (1) The composition of the subunit complex is $\alpha_1\beta_1 \cdot 2\text{BChl}$.
- (2) One BChl is coordinated to the imidazole group of the His 0 of the α -polypeptide and one is coordinated to His 0 of the β -polypeptide.
- (3) The two polypeptides are closely packed with the two BChl 11 Å apart (center to center), the planes of their macrocyclic rings are parallel to the axes of the α -helical polypeptides and there is an angle of about 24° between their Q_y axes (axis

through rings I and III). The Q_y axes are approximately perpendicular to the α -helical axes.

(4) Two or more hydrogen bonds/BChl are proposed to further fix the molecules in space and provide their specific orientations. The tail-to-tail orientation of the Q_y axes was chosen for all models because this maximizes the possibilities for cross-hydrogen bonding between BChl bound to one polypeptide and amino acid side chains of an adjacent polypeptide in the subunit complex $\alpha_1\beta_1$ -2BChl. Also significant in our thinking is that this orientation would provide a reason why the subunit is such a stable entity rather than a mixture of oligomers as one might expect in head-to-tail orientations. In addition, these subunit complexes are constructed with an element of symmetry. The location of possible hydrogen bond donors in the amino acid sequence are indicated in Fig. 9.

A key feature of models (A) and (B) in fig. 5 is that Arg 7 of the β -polypeptide is suggested to provide a bridge between the two BChl molecules by hydrogen bonding, for example, to the carbomethoxy oxygens at C13² of both BChl. The charge on the cationic guanidino group of Arg may also contribute to the red-shift of the long-wavelength band of BChl (Davis et al., 1981; Eccles and Honig, 1983; Fowler et al., 1993). It has been found in experiments with site-directed-mutations of Arg 7 (in *Rb. capsulatus*) that normal-appearing LHI was formed (Babst et al., 1991). Although this result may be viewed as evidence that this highly conserved amino acid does not play a key role in formation of LHI, as noted below, if this group is merely one of many stabilizing features in LHI, its absence may not be sufficient to prevent LHI formation. In this regard, it will be important to quantitatively evaluate its role in formation of the subunit complex.

Two different groups may also contribute to cross-hydrogen bonding; one hydrogen bond donor on the α -polypeptide and one on the β -polypeptide, both at position 6 (for the sake of clarity, these are not shown in Figs. 5A and 5B). One of these could be contributed by Thr 6 of the α -polypeptide interacting with an oxygen of BChl which is coordinated to His 0 of the β -polypeptide. The second could be Trp 6 of the β -polypeptide (except

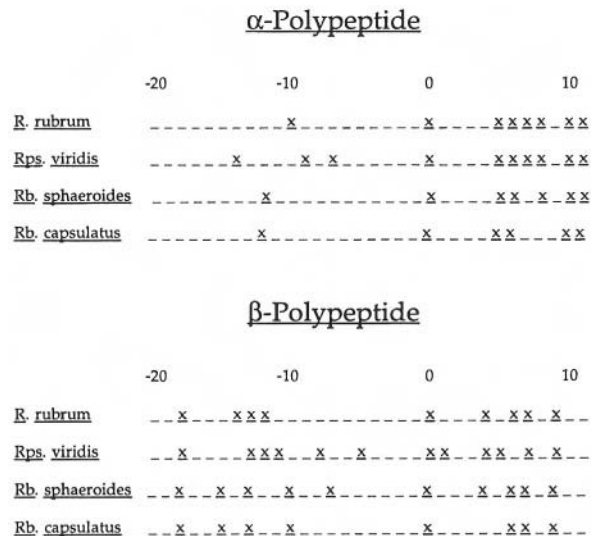

Fig. 9. Potential hydrogen bond participating side chains in the region -18 to +11.

for *Rp. viridis*; recall that the weakest subunit complex is formed with *Rp. viridis* β -polypeptide) contributing a hydrogen to bond with an oxygen atom of the BChl coordinated to His 0 of the α -polypeptide. A further possible hydrogen bond could involve Tyr (or Trp) 4 of the β -polypeptide and the carbonyl at position C3¹ of the BChl molecule coordinated to His 0 of the same β -polypeptide (see Figs. 5A and 5B).

Alternative models featuring multiple cross-hydrogen bonding are shown in Figs. 5C and 5D. These two models are not meant to exclude a role for Arg 7 as a bridging ligand, but the focus here is on Tyr (Trp) 4. The involvement of Tyr (or Trp) 4 in such hydrogen bonding could explain why the β -polypeptide of *Rb. sphaeroides* forms a highly stable subunit complex while that of *Rb. capsulatus* (whose Met at this position is incapable of donating a hydrogen to hydrogen bond formation) does not (Chang et al., 1990b; Heller and Loach, 1990; Loach et al., 1994); there are only two significant differences in the amino acid sequences in the apolar core region of these two bacteria (the other is at position -7). Furthermore, the fact that the β -only subunit complex formed with the β -polypeptide of *Rb. sphaeroides* is about ten-fold more stable than that formed with the β -polypeptide of *Rs. rubrum* could reflect the greater hydrogen

bond strength of Tyr 4 compared to Trp 4, respectively. Also in the models of Figs. 5C and 5D, the conserved Ser 5 and Thr 6 of the α -polypeptides, respectively, are proposed to be involved in a hydrogen bond to the carbomethoxy group at position C13² or the keto group at group at position C13¹ of the BChl. Other possible hydrogen bond donor groups of the protein further toward the C-terminus that are highly conserved include Trp 9 of the β -polypeptide and Asn 10 and Trp 11 of the α -polypeptide. Interestingly, a change of this latter residue to Phe in *Rb. sphaeroides* was reported to result in a normal expression of LHI, but caused a blue-shift of the $Q_y \lambda_{max}$ to 853 nm (Olsen et al., 1994).

Because BChl is very likely bound within the membrane but near the aqueous interface (Loach et al., 1985), hydrogen bonding between water molecules and the oxygen atoms of BChl are also important to consider. From this perspective, it should be noted that BChl is protected from deleterious interactions with oxygen, hydrogen ions and hydroxide ions in both the subunit complex and LHI form relative to BChl in OG (unpublished results). Such marked stability to extremes of pH and oxygen presumably means that the C-terminal portion of the polypeptides cover the otherwise exposed edge of the BChl that would be at the aqueous interface and, as a consequence, protect it from interacting with water. Even so, a sequestered water molecule may be an important structural element required to stabilizing the binding site and could also act as a bridge between the two BChl.

(5) The two esterifying alcohol groups are suggested to immediately turn after the ester linkage resulting in the isoprenoid chain running towards the N-terminus next to the apolar α -helical regions of the polypeptides, one in front and one behind the approximate plane of the BChl dimer.

(6) Three sets of ion pairs may occur between groups in the N-terminal region of the α - and β -polypeptides. Arg-18, Asp-20 and Lys(Arg)-26 of the α -polypeptide may be paired with Glu-20, His-18 and Glu(Asp)-25, respectively, of the β -polypeptide. Polypeptide conformations in this region are probably not extensively α -helical because of the Pro in the α -polypeptides and several

Gly in the β -polypeptides in their N-terminal amino acid regions. Reconstitution experiments utilizing α - or β -polypeptides with truncated N-terminal regions indicate that only the postulated ion pair involving Asp-20 of the α -polypeptide and His-18 of the β -polypeptides may be important for stabilizing the subunit complex. On the other hand, evidence from these experiments indicates that all three interactions are of importance in stabilizing LHI.

It is also necessary to account for the subunit-type complex formed with only the β -polypeptide. In fact, the ability to explain the formation of a highly similar environment for an exciton pair of BChl with only the β -polypeptide is a key point of the models presented in Fig. 5. The structure of this complex is suggested to be basically the same as that for the native subunit complex in which either Arg 7 is used to bridge between the two BChl molecules ((A) and (B)), or Tyr 4 is cross-hydrogen bonding as in (C) and (D). Then, in a manner similar to the native subunit complex, Trp 6 (except for *Rp. viridis*) of a second β -polypeptide could provide hydrogens for hydrogen bonds to BChl coordinated to His 0 of the other polypeptide; the lack of Trp 6 in *Rp. viridis* is consistent with this suggestion since the latter fails to form a stable subunit complex without an α -polypeptide.

Further stabilization of the β -only subunit complexes of *Rs. rubrum*, *Rb. sphaeroides*, and *Rb. capsulatus* could come from an ion pair formed between His 18 of one polypeptide and Glu 20 of the other. Both are highly conserved amino acids, which may stabilize the subunit-type complex in the same way as was suggested for His 18 of the β -polypeptide and Asp 20 of the α -polypeptide in the native subunit complex.

Very recently, the structure of LHII from *Rp. acidophila* has been determined in crystals prepared from LHII isolated in OG (McDermott et al., 1995). Many of the structural features of LHII undoubtedly have relevance to the structure of LHI and its subunit complex reviewed here. Because this crystallographic information became available very late in the final proof stage of this review, an in-depth analysis cannot be attempted. It is interesting to point out, however, that the BChl molecules apparently responsible for the 850 nm absorption band of LHII are coordinated to His 0 of the α - and β -polypeptides as predicted, and two different fundamental repeating $\alpha_1\beta_1 \cdot 2\text{BChl}$

units can be considered. In one of these repeating units, the distance and orientation of the two BChl are strikingly similar to those suggested in Fig. 5 for the subunit complex of LHI. In addition, in both LHII and LHI, Tyr and Trp side chains in the C-terminal region of the α -polypeptides are involved in hydrogen bonds to the C3¹ keto group of BChl. While no hydrogen bonds to the protein were found between the oxygen-containing groups at positions C13¹, C13², or C17³ of the BChl of LHII, such bonding may be unique to LHI and responsible for the stability of the subunit complex of this species. (Also see Chapter 16 by Zuber and Cogdell.)

XI. Minimal Structural Requirements to Form LHI

In examining structural features involved in the formation of the subunit complex, a variety of binding elements could be probed because the detergent concentration was sufficiently high to satisfy all hydrophobic surfaces without recourse to unspecific self-aggregation. However, under conditions for LHI formation, the detergent concentration is purposely maintained below that necessary to stabilize the subunit-detergent, mixed micelle. Thus, the driving force for LHI formation is fundamentally the hydrophobic force which is very large and would result in non-specific aggregation if specific association did not occur first. Recognizing that self-aggregation will occur under LHI-forming conditions, the question we wish to address is what interactions are responsible for forming the very specific, associated state, LHI.

It is reasonable to speculate that, for LHI formation, all BChl molecules may be required to be coordinated to a His at position 0 because of the large stabilization energy involved in this interaction and the restrictive geometry of the coordination sites. On the other hand, the much smaller energy of a hydrogen bond, the six oxygen atoms available on the periphery of BChl and the possibly more flexible environment in the region of these oxygens probably means that some differences exist in the groups participating in hydrogen bonding in different bacteria. It seems unlikely that all of the oxygen atoms on BChl would be involved in hydrogen bonding or that so many bonds would be necessary for stabilizing the subunit complex. On the other hand, evidence summarized in this review indicates

that in LHI at least three of the four oxygen-containing groups are likely to be involved in hydrogen bonding interactions with the protein. Thus, caution should be exercised in evaluating the results of site-directed-mutation experiments; a native-like LHI complex could form in a mutant even with the removal of a normal hydrogen bond participant. In this regard, measuring K_{Assoc} for appropriate reactions may be essential for proper evaluation.

A special role in forming LHI from the subunit complex is suggested for the carbonyl group at the C3¹ position, a group unique to BChl. From resonance Raman measurements (Robert and Lutz, 1985; Chang et al., 1990a; Visschers et al., 1993c) and BChl analog studies (Parkes-Loach et al., 1990; unpublished results) this keto group is required and is strongly interacting with the protein in LHI but not (or much less so) in the subunit complex. This group contains the only potential hydrogen bonding oxygen atom on this side of the molecule; the other five oxygen atoms are clustered together on the other side of the molecule. In the suggestions for the structure of the subunit complex shown in Fig. 5, the carbonyl group at C3¹ is ideally suited to direct association of the subunit complex to form LHI. Of particular interest in this regard are potential hydrogen-bond-donating amino acids such as Trp 9 of the β -polypeptide and Trp 11 of the α -polypeptide. Consistent with this suggestion, a site-directed mutant reported by Olsen et al. (1994), in which this latter residue was changed to Phe, resulted in a 23 nm blue-shift of the $Q_y \lambda_{\text{max}}$ indicating a significant effect on LHI structure. It may also be purposeful to use an amino acid side chain as far away from the center of BChl binding as Trp 9 of the β -polypeptide and Trp 11 of the α -polypeptide in order to use the flexibility in the C-terminal portion of the polypeptide to allow it to fold back over the BChl edge, thus fulfilling an important role in protecting BChl from the aqueous environment.

Because the β -polypeptides alone of *Rs. rubrum*, *Rb. sphaeroides* and *Rb. capsulatus* can form the subunit complex but not LHI, and if the structure of LHI is basically due to the subunit in an associated state, it might be expected that a modified β -polypeptide or a native β -polypeptide of some other species might be able by itself to form LHI. The properties of the β -polypeptide of *Rp. viridis* fulfill this expectation as does the truncated β -polypeptide of *Rb. sphaeroides* (LHSVYM...).

In characterizing the subunit complex and the

reconstitution behavior of the α - and β -polypeptides of *Rp. viridis*, it was found that with only the β -polypeptide and BChl *a* (not BChl *b*), a LHI-type complex was readily formed (Parkes-Loach et al., 1994). Therefore, the *Rp. viridis* β -polypeptide contains all the structural requirements necessary to form a LHI-like complex with BChl *a*. On the other hand, the subunit complex was not appreciably formed with only the β -polypeptide of *Rp. viridis*, although it was stabilized by the presence of any α -polypeptide (Loach et al., 1994). Interestingly, the truncated β -polypeptide of *Rp. viridis*, FHGIF....., still showed behavior nearly identical to that of the native β -polypeptide even though most of the N-terminal region was removed (Meadows et al., 1995). This result again suggests that there are strong interactions in the membrane spanning segment of the polypeptide that primarily direct the nature of association when the detergent concentration is decreased so that the hydrophobic force driving association causes a LHI-type complex to form.

The other β -polypeptide that we found to form a stable LHI-type complex was the N-terminal truncated β -polypeptide of *Rb. sphaeroides*, Leu-His-Ser-Val... . As indicated before, this truncated polypeptide does form a stable subunit-type complex as well. This example is especially interesting because the extra hydrogen bonding capability in the apolar region (relative to the β -polypeptide of *Rb. capsulatus*) seems to be responsible for formation of a very stable subunit complex. Perhaps these hydrogen bonding groups are also helpful in LHI formation when the hydrophilic N-terminus is removed.

To our surprise, two modified α -polypeptides have been observed to form LHI-type complexes by themselves with BChl *a*, the N- and C-terminal-truncated α -polypeptides of *Rs. rubrum*. Whereas the native α -polypeptide of *Rs. rubrum* will not form either a subunit-type complex or LHI-type complex without the β -polypeptide, the N-terminal truncated α -polypeptide, Pro-Arg-Gln-Ala... and the C-terminal truncated α -polypeptideLeu-Ser-Thr-Glu still did not form subunit complexes, but both formed stable LHI-type complexes (Meadows et al., 1995). These results can be explained by, and lend support to the structural suggestions shown in Fig. 5. For example, in Figs. 5(A) and 5(B) Arg 7 is used as a bridging group providing hydrogen bonds to both BChl molecules of the exciton dimer. An Arg is located at position +8 in the α -polypeptide of *Rs. rubrum* compared to the strictly conserved position +7 in all

β -polypeptides. On the other hand, consistent with the suggestions indicated in Figs. 5C and 5D, Ser 5 and Thr 6 of the truncated α -polypeptides could perhaps play the role of Trp 4 and Trp 6 of the *R. rubrum* β -polypeptide.

Consideration of the results showing formation of a LHI-type complex with a single polypeptide, along with information discussed in earlier parts of this review, lead to the following suggestions for minimal structural requirements for formation of LHI:

- (1) a single membrane spanning α -helical polypeptide that can associate with itself (reasonable knob-hole fit and without charge repulsion).
- (2) a histidine residue approximately one-third of the way into the apolar region that serves to fix one dimension of BChl binding, holding this amphipathic molecule in its most stable location relative to the aqueous interface.
- (3) three or more cross-hydrogen bonding elements that serve to link two BChl molecules in a dimeric structure.

If the above are valid conclusions, then the question arises as to why living organisms seem to have opted to build the subunit structure and LHI with heterodimer polypeptides instead of homodimer polypeptides. Use of the latter would have been simpler. Perhaps the answer to this question is to be found in the need for specificity and control, both of which are hallmarks of living systems. The diversification in using two different polypeptides, especially such small ones, considerably enhances the uniqueness of the subunit complex. Highly specific recognition is presumably required for proper binding of LHI to RC as well as LHI to LHI and in some species, LHI to peripheral LH complexes (LHII). There is also the possibility of a built-in control feature for energy distribution and utilization in the form of sites for phosphorylation (Allen, 1992a,b). Another possible need for specific recognition is to provide binding for Car molecules, an important component of wild-type cells. This latter consideration can actually be tested in reconstitution experiments using appropriately-modified polypeptides capable of forming LHI-type complexes either as homodimers or heterodimers.

From the point of view of designing macromolecules (proteins) to perform specific functions, it

is instructive that polypeptides as small as those of the LHI contain so much information. Whereas a polypeptide containing as few as 30 amino acids seems to be sufficient to specifically bind BChl and form a unique associated system, requirements for other forms of recognition and binding (e.g., to the RC) may require the additional polypeptide structure.

XII. Interaction of LHI with RC

The preparation of the subunit complex and the ability to reconstitute this complex and the LHI from their fundamental components offers an exceptional opportunity to examine the interaction of LHI with RC. By addition of RC of *Rs. rubrum* and phospholipid to the subunit complex of *Rs. rubrum* at 0.80% OG at room temperature, proteoliposomes containing photoreceptor complexes (PRC) were then formed by chilling the sample to 4° C (Bustamante and Loach, 1994). These proteoliposomes were stabilized at room temperature by first decreasing the OG concentration at low temperature and then warming the sample. The absorption and CD properties of this reassociated system appeared to reproduce those of membrane vesicles prepared from whole cells. In addition, energy absorbed by BChl of the LHI was transferred to the RC with ideal efficiency; that is with a quantum yield = 1.0.

In these reassociation experiments, at the concentration employed, there was no evidence for interaction between the subunit complex and the RC in 0.70% OG at room temperature (Bustamante and Loach, 1994). These are the conditions, as described earlier, for the dissociation of LHI from the RC in the subunit preparation procedure. Energy transfer from BChl of the subunit complex to the RC was very low, indicating that large distances separate the two complexes. The interaction energy between these complexes is in a delicate balance in the presence of 0.70% OG as indicated by the fact that the equilibrium can be shifted toward formation of PRC by increasing the concentration of either the RC or the subunit complex of LHI. In addition, binding of the LHI to the RC did not result in major changes in the absorption and CD spectra of either complex.

Evidence that there is specific binding *in vivo* between LHI and RC comes from several sources. According to liposome fusion experiments, the peripheral LH complex, but not the LHI, can be easily separated from the RC (Westerhuis et al.,

1989). Secondly, by the judicious choice of detergents and separation methods, the PRC complex can be isolated intact from several organisms (Loach et al., 1970a,b; Hall et al., 1973; Loach et al., 1980; Jay et al., 1984; Dawkins et al., 1988; Hara et al., 1990; Agalidis et al., 1991; Vasil'ev, 1991). Finally, in the subunit-RC reassociation experiments, the efficiency of transfer of excitation energy from BChl of the LHI to the RC was only 20% (quantum yield of 0.2) when a hybrid reassociation was attempted with the subunit complex of *Rb. sphaeroides* and RC from *Rs. rubrum* (Bustamante and Loach, 1994). In further studies it should be possible to establish interactions responsible for specificity in binding by using selectively-modified, reconstituted LHI.

In considering the types of interaction that may occur between LHI and RC to stabilize the PRC, the following are possible: (1) ion pairing, (2) hydrogen bonding especially in the nonpolar region, (3) knob-hole packing of nonpolar regions, and (4) other specific binding of amino acid side chains or polypeptide structural motifs that would most likely occur external to the membrane-spanning α -helical segments. It seems pertinent to consider that amino acid residues of the RC with their side chain groups exposed to the membrane (where they would interact with lipid, LHI and possibly other protein complexes, but do not contact the cofactors or adjacent polypeptides of the RC) are very poorly conserved (16% homology among known reaction center sequences). On the other hand, 42% of residues are conserved for those amino acid residues contacting the cofactors or adjacent RC polypeptides (Yeates et al., 1987)). This result indicates a lower level of specific interaction likely exists in knob-hole packing with LHI in the α -helical, membrane-spanning regions.

In some of our reassociation experiments, the RC was subjected to proteinase K treatment before addition to the subunit complex. This treatment resulted in total hydrolysis of the H-polypeptide (perhaps leaving the membrane-spanning segment intact) and removal of much of the hydrophilic portions of the L and M polypeptides. Even so, no effect on subsequent association with LHI was observed. These results, together with the fact that there are few hydrophilic regions of LHI, indicates that any ion pair stabilization must occur near the membrane interface, not further out in the aqueous environment. Also, there would not seem to be enough protein left to form a highly specific LHI receptor

site. These considerations suggest that initial studies should focus on the membrane interface region where there is a higher probability of specific structural elements important for LHI-RC interaction. Preparation of certain site-directed mutations of the RC, together with reconstitution of selectively modified LHI, should allow identification of the LHI-RC binding region(s).

Acknowledgments

We gratefully acknowledge Peggy L. Bustamante, Christine M. Davis, Barbara A. Heller, Kouji Iida, Kelley A. Meadows, Mamoru Nango and Paul A. Recchia for their contributions to this manuscript in the forms of research data and insightful discussions. This work was supported by grant GM 11741 to PAL from the US Public Health Service.
