Preface to the Second Edition

I am pleased to present the second edition of the *Textbook of Clinical Pediatrics*. The first edition of this textbook (published in 2001) proved to be both a scientific and a clinical success. Scholarly reviews recommended the book as a primary textbook for residents and medical students and an excellent resource for practicing pediatricians as well as other pediatric health care providers.

The primary goal of the editor of any clinically oriented textbook is to make sure that the text is comprehensive, with updated knowledge, and draws together best practices in practical clinical management. This can be achieved only by utilizing the expertise of those colleagues who have special knowledge and talent in the discipline of pediatrics as a whole and in its various sub-specialties. It is with great pleasure that I welcome along with Harb Harfi and Hisham Nazer, the new co-editors—Dr. Bruder Stapleton (University of Washington School of Medicine), Dr. William Oh (Brown University School of Medicine) and Dr. Richard Whitley (University of Alabama School of Medicine) who have brought in their deep knowledge and practical expertise to harness the best available knowledge in pediatrics. All of us together are also delighted to welcome our very eminent panel of outstanding leaders who performed the role of editing various topical sections on pediatric sub-specialties strengthening them with their specialized knowledge, authority, and experience. The second edition includes an expanded team of 17 new section editors who contribute to a wider coverage and scope of this new edition. We are pleased to welcome our 389 expert contributors from leading medical schools and medical centers around the world who contributed chapters.

This second edition constitutes a major revision, update, and reorganization of the textbook based on systematic reviews of advances in pediatric science and clinical application while retaining the reader- and practitioner-friendly features of the first edition. It is designed to cover contemporary pediatrics totally in logical sequence and with maximum authority. All pediatric sub-specialties are covered and discussed. The textbook's size and number of illustrations have been increased significantly. The scope of this text is wider than most other textbooks of pediatrics—this is deliberate and reflects the growth of knowledge in the field as well as the changing trends in medical practice and education. The contents have therefore been redeveloped to serve as a substantial and comprehensive pediatric text, balanced scientifically and clinically to be a problem- and evidence-based global reference for clinicians.

To this end, many fields have been extensively rewritten, including—genetic disorders, neonatology, infectious diseases, blood diseases, endocrine disorders, cardiology, pediatric oncology, developmental, learning and behavioral disorders, allergic disorders, primary immunodeficiency disorders, respiratory disorders, neurology, kidney and urinary tract disorders, disturbances in acid-base and electrolyte disorders, critical care, rheumatology, pediatric orthopedics, and disorders of the skin. Three new sections have been added on pediatric surgery (intended to help practitioners to benefit from the knowledge and clinical management experience of medically important pediatric surgery problems through the eyes of expert pediatric surgeons), on adolescent medicine (an important new area of knowledge related to the practice of pediatrics), and on drug dosing in pediatrics (providing important reference information to busy practitioners on dosage and value).

A total of 155 new chapters have been added including—principles of genetic testing, treatment of genetic disorders, surfactant replacement therapy, ECMO, neonatal neurology, common procedures in neonatology, ethics and decision making in neonatology, autism spectrum disorders, children in disaster, nutritional modulation of intestinal gene expression, animal and human bites, infection associated with medical devices, Chlamydial infections, Listeria monocytoenes, Mycoplasma infection, Actinomycosis, influenza, 2009 H1N1, rotaviruses and noro-and caliciviruses, innate immune defect, immune dysregulation, cutaneous disorders of neonate, pediatric surgical dermatology, skin barrier management and topical treatment in pediatric dermatology, pain amplification syndromes, autoinflammatory diseases, post-infectious arthritis and related conditions, probiotics in gastrointestinal disorders, capsule endoscopy in childhood, intestinal transplantation in children, mitochondrial hepatopathies and Reye's syndrome, pulmonary complications of the immunocompromised patients, cardiovascular genetics, sudden cardiac

death and pre-participation sports screening, secondary cardiac morbidities, noninvasive cardiovascular imaging, interventional cardiology, cardiomyopathies and heart transplantation, acute respiratory failure, mechanical ventilation, and infections in PICU.

In addition there are chapters on the management of snake bites and spider bites, clinical disorders associated with altered potassium metabolism, care of the child refusing blood products, thrombosis, sleep and its disorders in childhood, stroke in children, headache and head pain, pediatric neurorehabilitation and many others.

The textbook places special emphasis on the clinical aspects of various practical pediatric problems. Actual prototype case histories, intended to reinforce the basic principles in clinical management, are presented in sections where it contributes to an enhanced understanding of the subject, such as genetic disorders, inborn errors of metabolism and immunology.

Sections also have been enriched with chapters on clinical scenarios that form the basis for discussion of the relevant clinical problem and are commonly encountered by practitioners and residents, such as anemia, child with recurrent infections, failure to thrive, cough, chest pain, abdominal pain, diarrhea, vomiting, abdominal masses, limping child, heart murmur, metabolic acidosis, metabolic alkalosis, proteinuria, hematuria, and enlarged lymph nodes. These chapters provide an overview of the background for these clinical problems as well as an approach for managing the problem.

Wherever possible, the textbook has based its contents on the best available evidence. The level of evidence preferred is the systematic review of randomized control trials. It is the editors' earnest hope that these efforts provide for a significant enhancement of the management and care for sick children around the world.

On a personal note, I would also like to add for those interested, a short history of the development of this work. It was several years ago in Benghazi (Libya), my home town, where I thought to edit a textbook that would cover new ground clinically and yet be of global relevance. Dr. Hassan Majeed was the first person who accepted the idea and gave his guidance and support. Dr. Ahmad Teebi contributed to the first edition as section editor for genetic disorders. Both were inspiring teachers with unique clinical competence (Majeed syndrome, Teebi syndrome). It is sad that both these giants of clinical pediatrics passed away in 2010. Majeed and Teebi will not be forgotten and will be missed by all who were inspired by them to work with children.

The editors and I also thank the staff at Springer who did a great job to ensure the best major reference work possible. Particularly, Sandra Fabiani, Anil Chandy, and Sunali Mull from Springer's major reference work division as well as Marion Kraemer and Sverre Klempe from the Clinical Medicine editorial division.

For this new edition, I also appreciate and acknowledge the support of the Faculty of Medicine, Umm Al-Qura University.

The editors and I like to dedicate this textbook to our contributors and section editors. It is their book and it is their work that has given our textbook its strength and authority.

September 2011

Abdelaziz Y. Elzouki
Makkah, Saudi Arabia

Preface to the First Edition

It is with great pleasure, that we launch the first edition of the *Textbook of Clinical Pediatrics*. The textbook went through several stages of ideas, development, design, writing, revision, editing and extensive critical review by authorities in their field before it was submitted for publication. All the above stages demanded a great amount of effort. The aim was to produce a textbook that has both a global appeal and interest and would help practicing pediatricians, pediatric residents and family practitioners to manage sick children in a practical way, but on a sound scientific basis. The textbook is also intended to help pediatricians in training who are preparing for board or membership examinations and to function as a desk reference with updated information for practicing physicians and pediatricians. Our aim was also to develop a textbook that covers in some detail prevalent childhood diseases. In doing so, we are privileged to acknowledge the contribution of over 100 distinguished pediatricians and scientists from 34 well-known medical schools, major hospitals and health centers from five continents. Therefore, this textbook is enriched with international experience in childhood health care.

Almost all pediatric subspecialties are well covered in this textbook, including blood diseases, neoplastic disorders, infectious diseases, respiratory disorders, allergic disorders, immunodeficiency disorders, inborn metabolic disorders, rheumatic disorders, cardiovascular disorders, diseases of the kidney and urinary tract, nutritional disorders, neonatology, endocrinology, oral and craniofacial disorders, gastrointestinal and liver disorders, neurological disorders, skin diseases, orthopedic, otolaryngology, ophthalmological disorders, pediatric poisoning, critical care, burns, acid base and electrolytes disturbance. The textbook puts special emphasis on the clinical aspects of various practical pediatric problems. Prototype actual case histories, to enforce the basic principles in clinical management, are presented in sections where we think it will make the subject more understandable, such as in inborn errors of metabolism and immunology. Some sections also have been enriched with a chapter on a clinical scenario that forms the basis for discussion of relevant clinical problems. For example, in the hematology section, there is a chapter on approach to a child with anemia; in the kidney and urinary tract disorders section there is a chapter on clinical approach to a child with urinary tract obstruction; in the section on malignant and neoplastic disorders, there is a chapter on clinical approach to a child with abdominal mass, and lymph node enlargement; in the immunology section, there is a chapter on approach to a child with recurrent infection; and in the genetic section, there is a chapter on approach to the child with dyamorphic features.

We would like to dedicate this textbook to all those who contributed to it either directly, such as our contributors, section leaders and supportive staff, or indirectly by being supportive and patient during the preparation, writing and editing of this text, including our families and colleagues. Special appreciation is due to the staff of Lippincott Williams & Wilkins who took a keen interest and labored to ensure the best book possible. We particularly thank Ellen DiFrancesco and James D. Ryan, Vice President of Lippincott Williams & Wilkins.

We wish to give a special mention and acknowledgment to King Khalid Foundation, Saudi Arabia for their generous contribution and support.

Genetic Disorders

Bruce R. Korf

1 Genetics in Pediatric Medicine

Bruce R. Korf

Introduction

Genetics has long been recognized as playing an integral role in pediatric medicine, given that many genetic disorders are congenital or have their onset in childhood. Medical genetics came of age as a discipline in the 1950s, with the discovery of the chromosomal basis of disorders such as Down syndrome and the advent of treatment for inborn errors of metabolism and newborn screening in the 1960s. Over the ensuing years, great progress has been made in both diagnosis and management of genetic disorders, congenital anomalies, and chromosomal abnormalities. Nevertheless, through most of the past 50 years, two notions have been associated with medical genetics. First, it was perceived that medical genetics focused on rare, if not obscure, conditions – conditions that were important to the individuals and families that are touched by them, but having an impact on only a small slice of medicine. The second notion was that, with the exception of some inborn errors of metabolism, most genetic disorders were untreatable, and that geneticists were far better at diagnosing and counseling than at managing their patients' problems. In recent years, both of these notions are being dispelled. Although it has long been recognized that genetic factors predispose to both rare and common disorders, it is only recently that the tools of genomics have made it possible to identify these genes and thereby develop predictive tests and understand pathophysiology. Moreover, insights into basic mechanisms of disease are revealing approaches to treatment that were previously out of reach. The scope of genetics in pediatric practice therefore has expanded to include both rare and common disorders, and to encompass the full spectrum of care, from prevention through diagnosis and treatment. This chapter will provide an overview of medical genetics in pediatric medicine, exploring this spectrum of activity and laying the groundwork for the more detailed chapters that follow.

The Scope of Genetics in Pediatrics

It has been estimated that 71% of children admitted to the hospital are there due to complications of a genetic disorder or a congenital anomaly. These include a wide range of conditions, including chromosomal abnormalities, mutations in single genes, inborn errors of metabolism, and congenital anomaly syndromes. More common multifactorial conditions such as asthma are not counted in this tally; if all disorders with a genetic contribution were included, then virtually all children with non-traumatic illnesses in the hospital would be there by virtue of a genetic predisposition. In this section the major classes of genetic contributions to ill health will be considered.

Chromosomal Disorders

Chromosomal abnormalities were among the first genetic disorders to be amenable to laboratory testing. In 1959, shortly after techniques that permit the study of mitotic chromosomes were introduced, trisomy 21 was found to be the basis for Down syndrome. In the years that followed, several other disorders associated with abnormalities of chromosome number were described – trisomies 13 and 18, and sex chromosome aneuploidies such as Turner syndrome and Klinefelter syndrome. Initial approaches permitted only gross changes of chromosome number, or extreme gains or losses of material or rearrangements to be identified. Another wave of discovery ensued when in the late 1960s chromosome banding techniques were developed, along with approaches to high-resolution analysis. This yielded a much larger number of disorders associated with more subtle chromosomal rearrangements. A third technological advance that revealed the basis for additional genetic disorders was the advent of fluorescence in situ hybridization (FISH). This began the era of molecular cytogenetics, in which purified fragments of DNA were labeled with fluorescent dyes and hybridized to homologous sequences on the chromosomes, marking the chromosomal loci corresponding to the DNA fragments. This permitted the detection of regions of gain or loss of material that were too small to visualize with the microscope. Several disorders were attributed to changes in gene dosage, and by the mid-1990s, FISH had become a standard and critical tool in clinical cytogenetics. Currently, a fourth wave of

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_1,

discovery is underway that is dramatically changing the diagnostic approach. This employs molecular cytogenetic analysis, including array comparative genomic hybridization or SNP arrays, collectively referred to as "cytogenomic arrays." In array comparative genomic hybridization, DNA from a patient and reference "normal" DNA are labeled with different fluorescent dyes and allowed to compete for hybridization to thousands of DNA fragments attached to a glass "chip." Gains or losses of material in the patient sample can be visualized by unequal hybridization to a specific fragment. This approach offers much higher resolution than is possible with FISH, which relies on hybridization to fixed whole chromosomes. It also permits a rapid scan of the entire genome for gain or loss of material, with no need to specify in advance a region of interest. Cytogenomic arrays are revealing rearrangements that could not have been detected with cytological means, often in children with relatively nondescript phenotypes characterized mainly by developmental impairment or autism spectrum disorders.

The phenotype associated with chromosome abnormalities occurs due to genetic imbalance, that is, gain or loss of genetic information. Most trisomies and all monosomies involving non-sex chromosomes are lethal in early development; only trisomies 13, 18, 21, X, and Y are compatible with live birth, and trisomies 13 and 18 usually are lethal early in life. Each chromosome contains hundreds to thousands of genes, many of which are highly regulated, so that having a missing or an extra copy has profound effects on development. Gains or losses of smaller regions of a chromosome are more likely to result in live birth, but still have significant phenotypic effects. It is becoming clear that some small rearrangements are not associated with recognizable phenotypic consequences, and probably are common benign variants (polymorphisms). Others may be phenotypically important, causing problems such as developmental delay or autism.

To the pediatrician, the typical "signature" of a chromosomal abnormality was a defined constellation of congenital abnormalities constituting a syndrome, such as Down syndrome. Usually these are recognized at birth or in early childhood, although sex chromosome abnormalities such as Turner syndrome or Klinefelter syndrome might not be suspected until later on. In most cases, the child would be the only affected member of the family, except in the rare case of translocation, in which balanced carriers could have children with unbalanced karyotypes.

The microdeletion and microduplication syndromes also have well-defined phenotypes, although their number is sufficiently large that the pediatrician may not be familiar with all of the disorders. Although usually sporadic, there are instances where the condition is transmitted as a dominant, since an affected parent may be able to reproduce and can pass the chromosome with the deletion or duplication on to a child. The very subtle gains or losses now being found with array comparative genomic hybridization may produce complex malformation syndromes, or more selective effects on a single developmental system. Both sporadic and inherited versions may occur.

Inborn Errors of Metabolism

The term "inborn errors of metabolism" was coined by the British physician Archibald Garrod, working in the first decade of the twentieth century. He recognized a set of inherited conditions in which there was an apparent block in some essential metabolic pathway. The paradigm was further developed later in the century with the discovery that phenylketonuria, at the time a common cause of several developmental impairment, was due to accumulation of toxic metabolites of phenylalanine due to the lack of activity of the enzyme phenylalanine hydroxylase.

Inborn errors of metabolism represent breakdowns of biochemical pathways due to genetic mutations that interfere with the function or production of a specific enzyme or coenzyme. The phenotypes are the result of some combination of accumulation of substrate and/or deficiency of product. In some cases, such as phenylketonuria, the substrate is soluble and circulates throughout the body, causing toxicity. In other cases, the substrate may be an intracellular component, leading to engorgement of cells and consequent tissue or organ damage. The latter is the case for lysosomal storage disorders.

Inborn errors of metabolism have been among the first of genetic disorders to be amenable to treatment. Disorders such as phenylketonuria are treated by restriction of dietary intake of the offending substance, phenylalanine in this case. In some cases, residual enzyme activity can be stimulated using coenzymes or other pharmaceuticals, or biochemical approaches can be used to remove toxic substrates. Lysosomal storage disorders are now increasingly treatable by infusing purified enzyme, modified chemically so that it is taken up into cells to replace missing enzyme. Eventually, approaches of gene replacement may be possible to effect true "cures" of some inborn errors.

Most inborn errors of metabolism are inherited as recessives, in that both alleles that encode an enzyme must be altered by mutation to produce the phenotype. This results from the catalytic properties of enzymes; heterozygotes with half the normal amount of enzyme

activity still produce sufficient activity to avoid a phenotype. Because of this, most couples at risk do not know that they are carriers until an affected child is born. In some cases, where a disorder is common in a specific population, individuals may be screened before childbearing to identify carriers. This is the case, for example with Tay–Sachs disease, a lysosomal storage disorder that is more common in individuals of Ashkenazi Jewish or French Canadian background. Advances in genetic testing now make it possible to offer screening for a large number of recessive disorders, both rare and common, regardless of ancestry. This approach raises questions of clinical utility, however, that remain unanswered.

Inborn errors of metabolism tend to be progressive disorders. In most cases, this is due to gradual accumulation of toxic substrates. Those associated with soluble factors usually do not present until after birth, since the toxic material crosses the placenta and is cleared by the mother in utero. These disorders present in infancy or childhood, but by the time symptoms are recognized irreversible damage may be done. This has led to newborn screening programs to enable presymptomatic detection and prompt institution of treatment. Newborn screening is practiced throughout the developed world; the scope of testing is rapidly expanding due to new technologies, most notably tandem mass spectrometry used for detection of a large array of metabolites. The pediatrician is usually the first responder to an abnormal newborn screen, and needs to be familiar with the immediate care and availability of specialists in biochemical genetics.

Single Gene Disorders

This term is used to describe disorders associated with mutation of specific individual genes. Inborn errors of metabolism are a special case of single gene disorders, as discussed earlier. In fact, no condition is truly due solely to mutation in a single gene. All genes function in a complex physiological environment in which there are multiple interactions between genes and gene products. To some extent, this complexity may explain differences in phenotype between two individuals with the same disorder. Nevertheless, although no disorder is totally determined by the effects of a single gene, there are many examples where mutations in specific genes lead to dramatic phenotypes.

The first single gene disorder to be characterized at the molecular level was sickle cell anemia, a recessive trait due to mutation of a single nucleotide in the beta globin gene. It is found primarily in individuals with ancestry traced to sub-Saharan Africa, where being a carrier conveyed relative resistance to malaria. The single base change alters the chemical properties of beta globin so as to alter the structure of the red cell, which interferes with its traverse through small vessels, leading to pleiotropic effects on many systems of the body.

Several thousand single gene disorders have been defined, cataloged in Mendelian Inheritance in Man, initially a book and now an online database (www.ncbi.nlm.nih.gov/omim/). These include both exceedingly rare and surprisingly common disorders with all possible modes of inheritance: recessive and dominant, autosomal, sex-linked, and maternal (mitochondrial). Some, such as cystic fibrosis or Marfan syndrome, are likely to be familiar to pediatricians. Others are so-called private syndromes that have only been seen once, in a specific individual family. Many have onset in childhood, whereas others, such as Huntington disease, usually have onset in adulthood.

The major advance in the field of single gene disorders in recent years has been the advent of molecular diagnostic testing. There has been an exponential increase in the number of disorders that have been associated with mutation in specific genes in recent years, and once the gene is identified, molecular genetic testing becomes possible for diagnostic purposes. Testing is offered for many of these in both commercial and academic laboratories, and databases are available to guide the clinician to laboratories where testing is offered (e.g., www.genetests.org). Tests for very rare disorders may be available on a clinical basis in a limited number of laboratories, or on a research basis in some. The increasing availability of genetic testing makes it easier to provide a definitive diagnosis and offer anticipatory guidance and counseling regarding risk of recurrence.

As the genes associated with specific conditions are identified, the pathophysiology of these disorders can be brought to light. This is revealing fundamental mechanisms of the control of critical cellular processes, and is opening avenues of possible treatment. Treatments may include the use of pharmacological agents that modulate these pathways, or, eventually, perhaps the substitution of cells or genes to overcome the defect. Although many of these disorders are well established by the time of birth, there is a possibility that progressive symptoms may be prevented and even established symptoms ameliorated.

Multifactorial Disorders

It has long been recognized that some disorders tend to cluster in families, yet do not segregate according to

Mendel's laws as single gene conditions. This includes rare congenital anomalies, such as spina bifida, and more common conditions such as asthma. Aside from familial clustering, these conditions tend to be concordant in identical twins more often than in sibs, yet even identical twins are not always concordant with respect to disease. This has led to the model of multifactorial inheritance, in which liability to a disease phenotype is due to a combination of genetic and nongenetic factors; the latter includes environmental factors and others, such as chance.

Until recently, the genetic approach to multifactorial disorders was limited to empirical recurrence risk counseling, using population data to estimate risk. Since the introduction of genomic approaches, however, it has become possible to identify the genes that predispose to both rare and common disease. Much of this work has been based on genetic association, that is, finding genetic variants that are seen more often in those with a condition than in unaffected controls. Variants are now known throughout the genome, and advances in genotyping technology have made it possible to do whole-genome scanning for association in large case-control cohort studies. This has led to a flood of discovery of genes associated with disease, though in most cases the contribution of any specific genetic factor is small.

The clinical impact of identification of genes associated with multifactorial disorders is just beginning to be felt. Predictive testing to identify individuals at risk may be possible if specific genetic variants are strongly associated with disease. These associations, however, are not the equivalent of diagnostic tests, and relative risks may be very modest. An additional benefit of identification of genetic factors in multifactorial disease may be the discovery of cellular mechanisms of disease, leading to new approaches to prevention or treatment.

Cancer Genetics

Several lines of evidence have implicated genetic changes as contributing to cancer. This includes the occasional instance of familial segregation of cancer, the occurrence of chromosomal abnormalities in cancer cells, the fact that mutagens are also usually carcinogens, and the observation that DNA repair disorders are associated with increased risk of cancer. In recent years, it has become clear that genetic changes are at the heart of the process of cellular transformation to malignancy and malignant progression. Two major types of genes, referred to as oncogenes and tumor suppressor genes, have been identified that underlie these processes.

Oncogenes behave in a dominant manner; mutation leads to activation of the genes, which in turn cause the cell to escape from normal controls that limit cell division. Tumor suppressor genes behave in a recessive manner in the cell, so that mutation of both alleles is found in tumor cells. Most oncogene mutations are acquired somatically. Mutation of the two alleles of a tumor suppressor gene may be somatic events, but in some cases the first mutant allele is inherited. This leads to cancer predisposition syndromes, in that individuals who inherit a mutant allele are at vastly increased risk of cancer if the other allele is mutated in a somatic cell. These syndromes are typically inherited as dominants, since it is the first of the two mutations that constitutes the inherited trait. Although most of these disorders, such as breast and ovarian cancer syndrome, are of adult onset, some, such as familial adenomatous polyposis or familial medullary thyroid carcinoma can have onset in childhood.

Recognition of genetic contributions to malignancy is changing clinical practice at many levels. Familial cancer predisposition syndromes may be amenable to genetic testing to identify individuals at risk, so that surveillance or management strategies can be instituted. Understanding the genetic pathophysiology of cancer is leading to new insights into possible avenues of treatment, and the development of a new set of pharmacological agents that target the aberrant cellular pathways.

The Genetic Approach

The pediatrician will usually be the first to recognize the possibility of a genetic disorder in a child, or will be the first to hear of an inborn error of metabolism identified by newborn screening. Early diagnosis can be important for many reasons. In some cases, treatment can be started before irreversible damage is done; this is the basis for newborn screening, as has been noted. Prompt diagnosis can also provide a basis for recurrence risk counseling; some couples only learn that they are at risk of having a child with a genetic disorder after their *second* affected child is born. Finally, establishing a diagnosis can help a family understand the basis for their child's problem, providing a basis for predicting future problems and avoiding an odyssey of fruitless medical testing.

Family History

The family history is the most powerful and least expensive of genetic tests. Patterns of inheritance will be covered

in a later chapter, but the pediatrician should be familiar with the basic Mendelian modes of recessive and dominant inheritance, as well as the difference between autosomal and sex-linked inheritance. Recent discoveries have expanded the concept of inheritance to encompass maternal transmission of traits encoded in the mitochondrial DNA and complex patterns of inheritance due to the phenomenon of genomic imprinting.

Ideally, a three-generation family history would be obtained at the time when a child is first seen, and updated at subsequent visits. Standard pedigree symbols used in assembling the family history are shown in *Fig. 1.1*. It is important to ask about miscarriages and early childhood deaths, as some individuals will not remember to include this important information when asked about the family. Complex family relationships, including adoption, should also be noted.

Obtaining and documenting a family history is time-consuming, and may be difficult in the course of a routine pediatric visit. The family can be encouraged to assemble the basic information outside the visit, using family get-togethers as an opportunity to gather information about relatives. There are tools available to assist in this process, such as the US Surgeon General's "My Family Health Portrait" (https://familyhistory.hhs.gov/fhh-web/home.action).

Clues to Genetic Disorders

Given the diversity of genetic disorders, there is no single "red flag" that will invariably identify all children at risk. As noted, newborn screening will identify some children early in life. The specific targets of the screening program vary regionally; the pediatrician should

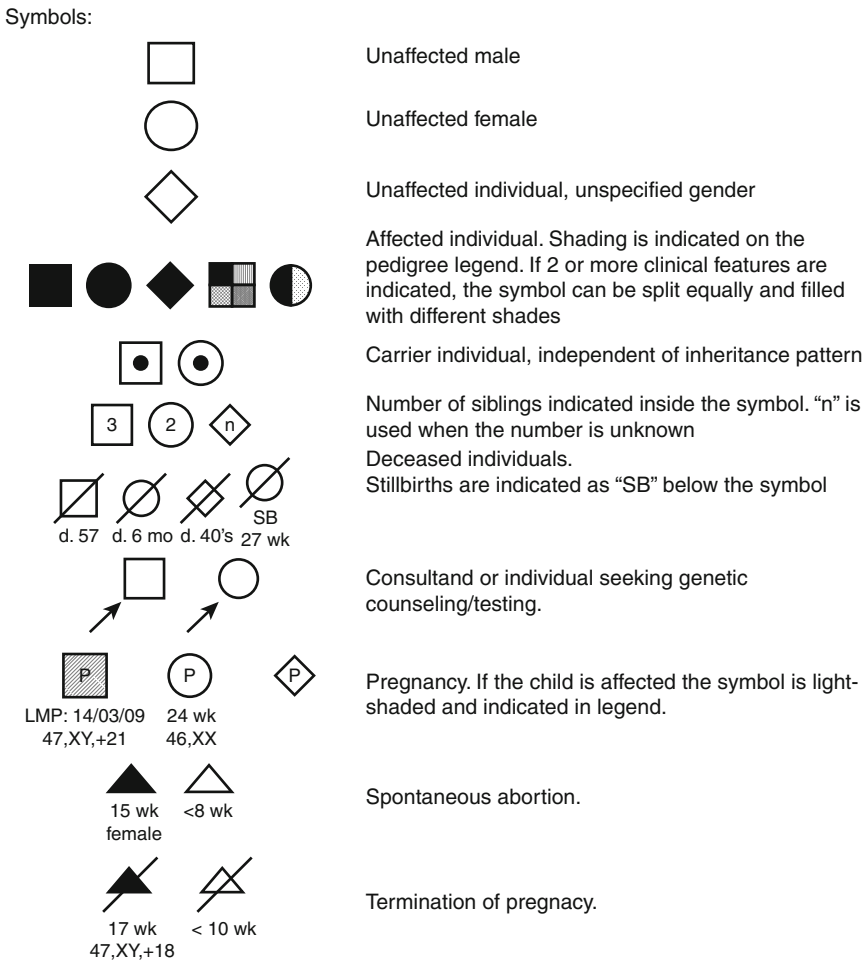

Figure 1.1
(Continued)

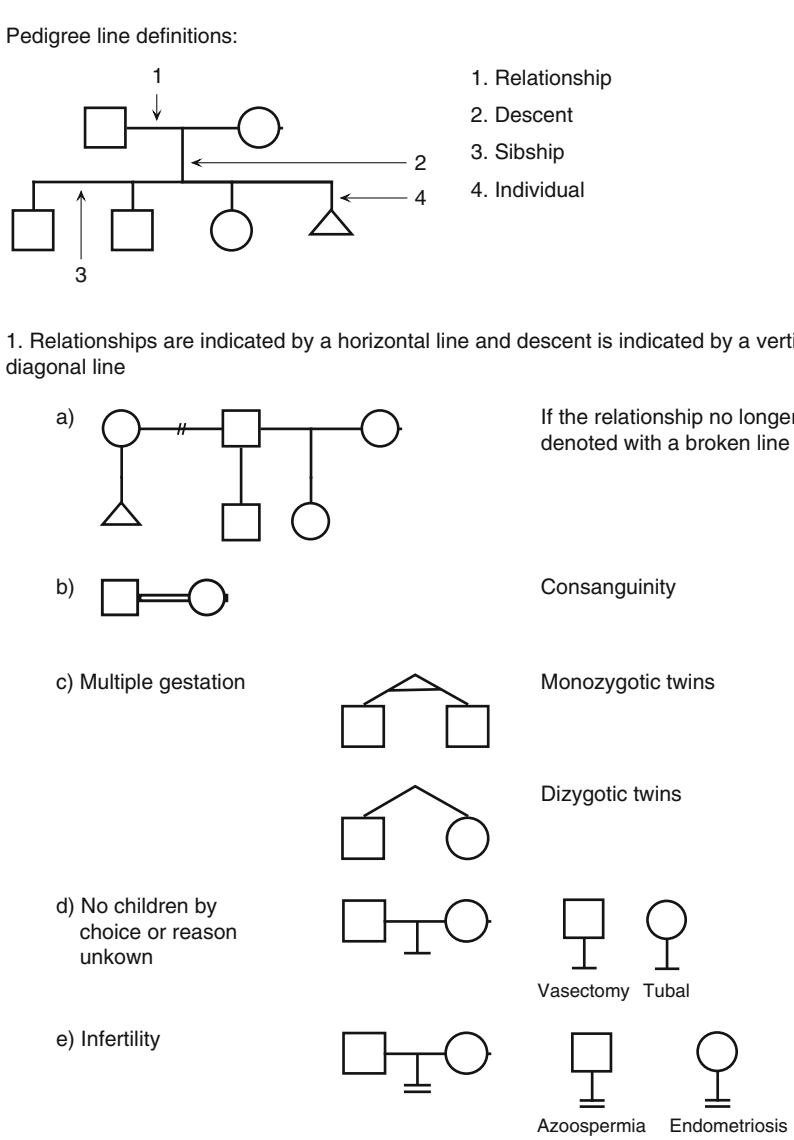

Figure 1.1
Standardized symbols used in the construction of a pedigree (Courtesy of Dr. Gabriela Repetto)

become familiar with the disorders subject to newborn screening in the local community. In the absence of newborn screening, there are some clues that may be helpful.

The value of family history has already been noted. It is important to recognize, however, that many children with genetic disorders are the first to be affected in their families. This is common with recessive disorders, in which both parents are carriers, but neither parent, and probably no close relative, is affected. Chromosomal disorders are usually sporadic, but a family history of others with congenital anomalies or developmental delay, or recurrent spontaneous abortion, may be a clue to a familial chromosome rearrangement. Dominant disorders can be passed from generation to generation, but the phenotype may be variable, and some affected parents are unaware of their diagnosis prior to the birth of an affected child. Also, some dominant disorders arise spontaneously due to new mutation in a child. In some cases, one of the parents may have additional mutated sperm or egg cells (germline mosaicism), and therefore may be at risk to have additional affected children.

Many congenital anomalies are associated with a genetic etiology, either single gene, chromosomal, or multifactorial. A specific constellation of anomalies may suggest a defined syndrome, but many of these are rare and difficult to recognize. The presence of two or more congenital anomalies in a child may suggest a genetic etiology and should prompt referral to a geneticist for further investigation. There are common variants, referred to as "minor anomalies," such as a single transverse palmar crease, that convey less significance. This topic is discussed in the chapter on congenital anomalies.

Specific single gene disorders are highly varied, so it is difficult to state a rule that will insure their recognition. The pediatrician should be alert to clues such as failure to thrive, especially in a child with intrauterine growth retardation, unusual body habitus, macro- or microcephaly, disproportionate limb to body size, developmental delay or regression, autism spectrum disorder, and distinctive skin pigmentation as clues. Specific syndromes may only become clear with the passage of time, and may require a trained eye to be recognized. Increasingly, genetic testing is available to confirm a suspected diagnosis, and array comparative genomic hybridization may reveal an otherwise unsuspected gain or loss of genetic material.

Genetic Testing

The possibility of chromosomal analysis, FISH, array comparative genomic hybridization, and molecular genetic testing has already been mentioned; these are covered in greater detail in later chapters. The pediatrician will likely work together with genetic professionals in ordering and interpreting these tests, but should be familiar with basic principles that govern genetic testing.

Genetic tests can be assessed in terms of analytic validity, clinical validity, clinical utility, and the ethical implications of testing. Analytical validity relates to the degree to which the test result correctly identifies the presence or absence of a particular mutation. For the most part, genetic tests tend to have a high degree of analytic validity, barring the possibility of human error such as sample mix-up. It should be remembered, though, that genetic tests are unlikely to be repeated once done, unlike most other medical tests. Therefore, if an error is made, it may be difficult to detect.

Clinical validity refers to the degree to which the test diagnoses or excludes a particular disorder. Many genetic variants are nonpathogenic; although some are common and are easily dismissed as being clinically significant, some benign variants are rare and may be unique to a particular family. Sometimes, a mutation will have obvious effects on the function of the gene. For example, a mutation that causes premature termination of translation of a gene product has a high likelihood of being clinically significant. Other times, it may be more difficult to know whether a variant is significant. The laboratory should report both the nature of the mutation and the evidence that supports pathogenicity.

The phenomena of non-penetrance and genetic heterogeneity may further complicate interpretation of clinical validity. Some mutations are pathogenic, but the phenotype is not invariably seen, or may only be seen after a long period of time. Such disorders are said to be non-penetrant or to exhibit age-dependent penetrance. Finding a mutation therefore does not guarantee that a disease phenotype will occur, or say when it will occur. Genetic heterogeneity means that multiple different mutations in one or several genes can lead to the same phenotype. A negative genetic test may not exclude a specific diagnosis if some of these mutations are not included in the test.

Clinical utility refers to the degree to which the test informs clinical management. Some tests can diagnose disorders that are already evident clinically. Unless the test reveals prognosis or severity, it may add little to the care of the individual, though it could still be useful as a basis for genetic counseling. Also, some tests may reveal risk of disease for which there is no intervention. Whether it is worth ordering an expensive test that may also cause anxiety if there is no intervention to alter the outcome is a matter of debate and, to some extent, personal choice.

Finally, the ethical implications of testing need to be considered. Individuals with a positive genetic test may be subject to anxiety, stigmatization, and discrimination. In some regions, federal or regional laws may offer some degree of protection from some of these risks. There are also questions about whether genetic tests should be done in children. The consensus in the medical genetics community is that testing is justified in children if the child will immediately benefit from the results of testing. This is the case, for example, in diagnostic tests for a child with symptoms of a genetic disorder. On the other hand, tests that predict predisposition to adult-onset disease where there is no intervention that can be offered to the child are best left to adulthood, when the child is old enough to understand the implications of testing and provide informed consent.

Management of Genetic Disorders

Diagnosis of a genetic disorder should be a prelude to management strategies to help the child and family deal

with the disorder. Management usually begins with explanation of the diagnosis, the underlying genetic mechanisms, natural history of the disorder, and available interventions. This will often be done by a genetic professional working in partnership with the pediatrician. Even if there is no treatment, the family may benefit from a discussion of the likely course of the disorder and interventions that may ameliorate the effects. Genetic counseling can explain the risks of recurrence to the parents or other family members, and the availability of interventions such as prenatal or preimplantation diagnostic testing. Many parents will feel guilt at the birth of a child with a genetic disorder and wonder if they in some way "caused" the condition. Genetic counseling can help parents understand what is known about etiology and may help assuage feelings of guilt.

As noted earlier in the chapter, genetic disorders are increasingly becoming amenable to treatment. Outcomes range from essential elimination of the phenotype to improvement in quality of life and comfort for the patient and family. Most currently available treatments focus on dietary manipulation, coenzyme supplementation, enzyme replacement, or substrate reduction for inborn errors of metabolism. Surgical correction of congenital anomalies such as congenital heart defects can be lifesaving. Other disorders may benefit from therapeutic interventions to reduce the burden of disease. Examples include use of antibiotics and pancreatic enzymes in cystic fibrosis or use of steroids in Duchenne muscular dystrophy. Individuals with cancer predisposition syndromes can be offered surveillance such as colonoscopy in familial adenomatous polyposis, or risk-reduction strategies, including surgery.

The success of therapy in recent decades has significantly improved life expectancy in many individuals with genetic disorders. This is dramatically exemplified by Down syndrome and cystic fibrosis, where survival into adulthood is now more the rule than the exception. This is creating challenges of transition from pediatric to adult care, given that physicians who care for adults may have little experience in management of these disorders previously thought of as "pediatric."

Insights into pathogenesis of disease are increasingly offering the hope of new targeted approaches to treatment. These may include drugs that affect the specific cellular pathway involved in disease, as well as the prospect of gene replacement or cellular therapies involving stem cell approaches. The ability to treat genetic disorders is a rapidly moving area of research; it is important, therefore, that physicians who manage children with genetic disorders have access to current information on available treatments and clinical trials for new treatments.

Medical Genetic Professionals

Although the pediatrician will likely be the first to recognize the possibility of a genetic disorder in a child, diagnosis and management may benefit from referral to a genetic specialist. Medical genetics is a recognized specialty for physicians in many parts of the world, with defined courses of training and specialty certification. In addition, genetic counselors are health professionals with specific training in genetic counseling. Physician geneticists are skilled at establishing a diagnosis and providing a plan for management. Genetic counselors are trained to review family history for risk of genetic disorder, provide counseling regarding options to manage risk, including prenatal diagnosis, and working with a physician to provide long-term management.

Pediatrics in the Genomic Era

Since the introduction of tools of molecular genetics in the mid-1970s, there has been a gradual advance in the ability to diagnose and manage genetic disorders. The pace of discovery and translation to clinical application accelerated considerably, however, beginning in the mid-1990s with the initiation of the human genome project. The completion of the sequencing of the human genome has ushered a new era in the study of rare and common disorders, and offers to significantly change the landscape of medical practice.

The Structure and Function of the Human Genome

It is now estimated that there are approximately 20,000 genes comprising the human genome, significantly fewer than had been estimated prior to the Human Genome Project. It has become apparent, however, that there is a surprising degree of complexity in the genome that goes far beyond the diversity of coding sequences represented by these 20,000 genes. Indeed, the entire set of protein-encoding gene comprises only a very small proportion of the coding capacity of the genome (*Fig. 1.2*).

Aside from protein-encoding genes, there is a wealth of both expressed and non-expressed sequences. There are blocks of highly repeated DNA sequences located at the centromeres and near the ends (telomeres) of each of the chromosomes; these do not encode proteins but probably play a role in maintaining the structural integrity of the chromosome. Many of the sequences that are transcribed encode RNAs that are not translated into protein. These

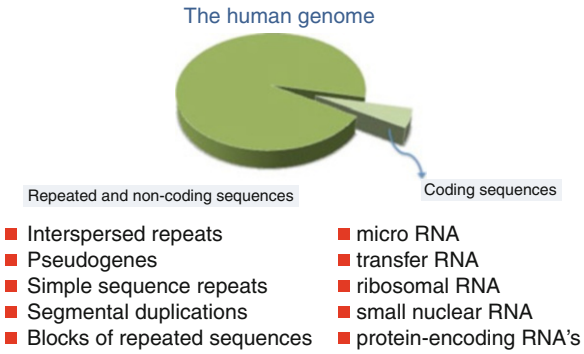

Figure 1.2
Composition of the human genome. Only a small portion encodes protein or RNA that is transcribed but not translated into protein

include transfer and ribosomal RNAs, small nuclear RNAs involved in RNA splicing, and micro RNAs that play a role in gene regulation. There are also a very large number of sequences that are repeated thousands of times in the genome. These include sequences called transposable genetic elements, which can move from place to place in the genome using enzymes that copy RNA into DNA (reverse transcriptase) and that promote recombination of extrachromosomal DNA sequences with chromosomal DNA. These elements comprise a remarkable proportion of the genome and have been major drivers of genome rearrangement and, hence, of evolution.

The full range of types of DNA sequences, their function, and regulation are just beginning to come to light. Recent studies suggest that a very large proportion of sequences may be transcribed, even though only a small proportion encodes protein. Moreover, the boundaries that comprise a protein-encoded gene are not always clear; examples have been found of separate adjacent genes that are transcribed as a single RNA.

Genomic Testing

Traditional approaches to molecular genetic testing have focused on analysis of individual genes, one at a time. This requires prior knowledge of the appropriate target for testing, and may be limited if the gene is very large or the diversity of mutations is great. In a sense, whole genome testing has a longer history, if one considers cytogenetic analysis as a whole genome "scan." The resolution of such a study, however, is very low, so only the grossest of changes can be detected. As discussed above, cytogenomic arrays afford a much higher resolution screen for changes in gene copy number without a need to select a specific region for analysis.

Other genomic approaches are permitting wide scale analysis both of DNA sequence variation and patterns of gene expression. These "high-throughput" approaches are based on an increasing variety of technological advances. Hundreds of thousands of single nucleotide polymorphisms can now be genotyped for a few hundred dollars. Sequencing of the entire coding region of the genome can be done for a few thousand, and whole genome sequencing, now costing a few tens of thousands of dollars, is expected to cost under $1,000 within the next few years. Already, genome analysis has become the approach of choice to identify the gene underlying a rare genetic disorder. It is likely to become a mainstream approach to genetic testing within the next decade.

Genomic Medicine

The ability to study the human genome at extremely high resolution will vastly alter the approach to medical care in all areas of specialty. This will include advances in genetic testing as well as new insights into pathogenesis that will guide treatment. It is likely that medical decisions will increasingly be informed by genetic and genomic tests, although the clinician may not always be aware that this is happening in the background. The volume of genomic information is likely to be so large that it will only be useful if coupled with electronic health records and computational approaches to guide medical decision-making.

Genomic testing may also permit disease stratification and selection of an appropriate mode of therapy. It is likely that common diseases such as hypertension are really symptom complexes that reflect a variety of underlying pathophysiological mechanisms. If genetic factors that underlie these different mechanisms can be identified, it may become possible to select a pharmacological therapy based on the specific genetic profile of a given individual. This approach is sometimes referred to as "personalized medicine." The hope is that it will lead to more effective treatments and fewer side effects.

Genetic testing can also be used to customize drug dosage to the physiology of an individual. Many aspects of the way drugs are absorbed, metabolized, and excreted, as well as how they interact with cellular targets, are under genetic control. In some cases, common genetic variants explain why drug doses that are nontoxic in some individuals lead to side effects in others, or conversely why doses that are effective in some are insufficient in others. Such pharmacogenetic tests will likely be another component of

the personalized medicine paradigm, and are already being used to a limited extent to titrate drug dosage to the needs of a specific individual.

Genetic diagnosis has already been revolutionized in the genomic era, but is likely to undergo further evolution in the years to come. If whole genome sequencing is done on a wide scale, it may be the case that all possible genetic tests will already have been done on a child before he or she presents with symptoms of disease. Genetic testing may become more a matter of querying the DNA sequence database than ordering any particular test. The challenge is likely to be sorting out clinically significant from nonsignificant variants. Moreover, the definition of "clinically significant" will need to be carefully considered. Some of the genetic changes found will be associated with a phenotype, but not necessarily one that would be classified as "disease." Even variants that predispose to disease may have a double role – increasing risk of one condition while decreasing risk of another, perhaps.

Conclusion

Genetics has played an important role in pediatrics for at least the last half century, and most pediatricians are aware of the need to understand the basic principles of genetics. The notion that medical genetics deals exclusively with rare, untreatable disorders is rapidly being dispelled. Genetic and genomic approaches can greatly improve diagnostic efficacy for rare disorders, and increasing knowledge of disease mechanisms will allow interventions to improve health and quality of life for many. Most importantly, the scope of genetic medicine is undergoing a vast expansion, to the point where it will touch all areas of medicine, and people at all ages. In the coming generation, genetics and genomics will increasingly be incorporated into the basic fabric of all medical practice.

2 Approach to Single-Gene Disorders

Taosheng Huang · Steven Keiles

Single-gene disorders have a straightforward inheritance pattern, and the genetic causes can be traced to changes in specific individual genes. A particular disorder could be rare; however, as a group, single-gene disorders are responsible for a significant percentage of pediatric diseases. Autosomes refer to the numbered chromosomes (chromosome 1–22), as opposed to the sex chromosomes, X and Y. Every individual carries two copies of each autosome and, therefore, also has two copies of every gene carried on those chromosomes, one inherited from each parent. Based on the location of the relevant genes, single-gene traits can be divided into autosomal inheritance and sex-linked. Autosomal inheritance, depending on whether one or two mutant alleles are required to cause a phenotype, can be divided into autosomal dominant or autosomal recessive. Based on Mendel's laws, the two alleles segregate and pass to different offspring, as shown in ❯ *Fig. 2.1*; A and A' will pass to different individuals, as will a and a'.

Terminology

- *Allele*: Specific version of a gene.
- *Mutation*: Nucleotide change in a gene. This may result in a recognizable phenotype, including a genetic disorder.
- *Phenotype*: Observable physical manifestations of a genotype.
- *Genotype*: Genetic constitution of an individual.
- *Homozygote*: Genotype consisting of identical alleles of a particular gene.
- *Heterozygote*: Genotype consisting of different alleles for the same gene.
- *Compound heterozygote*: Genotype consisting of two different mutations at each allele.
- *Penetrance*: Proportion of individuals carrying a mutation who exhibit a specific phenotype.
- *Expressivity*: Variations of a phenotype in individuals carrying a particular genotype.
- *Pleiotropy*: A single-gene mutation that can affect several traits.
- *Age-dependent penetrance*: A phenomenon in which a phenotype is increasingly expressed with age. For example, in Huntington disease, a majority of individuals with the mutation will not express a clinical phenotype until late age (❯ *Fig. 2.2a*).
- *Anticipation*: A phenomenon in which clinical symptoms become apparent at an earlier age and are more severe as a gene is passed from generation to generation. For example, in myotonic dystrophy, as the mutated gene is passed on, the severity of muscle weakness can become more severe and the age of onset earlier (❯ *Fig. 2.2b*).
- *Genetic heterogeneity*: The occurrence of similar phenotypes resulting either from distinct mutations in the same gene (allelic heterogeneity) or mutations in different genes (locus heterogeneity).
- *Germline mosaicism* or *gonadal mosaicism*: A situation in which precursor cells of the ova and the spermatozoa are a mixture of wild type and mutant cells (❯ *Fig. 2.3*).
- *Sex-influenced phenotype*: Preferential expression of a trait in a particular sex. For example, alopecia is more common in males, and in contrast, breast cancer is more common in females. Although the disease genes are found on the autosomes, in these situations, the phenotypes are influenced by the sex.

Autosomal Dominant Inheritance

Autosomal dominant inheritance is the most common form of inheritance. Here, mutation on one allele is sufficient to cause an individual to express the phenotype. A review of the family history will typically demonstrate affected individuals in every generation. The risks for all members who carry a genetic mutation would be 50% for each offspring to be affected (see ❯ *Fig. 2.4a* and ❯ *b*). In some families, however, a dominant trait may appear to skip an individual or a generation. This could be the result of someone who has not exhibited symptoms yet (incomplete penetrance) or who has not been diagnosed because of being mildly affected (variable expression). Some of the

Mendel's law of segregation. The father (*left*) is heterozygous for A and A'; the mother (*right*) for a and a'. Offspring can receive either of the father's alleles and either of the mother's alleles, giving four possible combinations, shown at the bottom

more common dominantly inherited conditions include Marfan syndrome (*Fig. 2.5*), Huntington disease, tuberous sclerosis complex, and neurofibromatosis (*Table 2.1*).

Case Presentation

Mr. Williams is a 22-year-old man who was previously healthy. He presents to a primary care physician with a 2-day history of chest pain. A physical examination shows that Mr. Williams' weight is 150 lbs and his height 6′8″. He has long fingers, severe scoliosis, and near-sightedness. The rest of his physical exam is unremarkable. Mr. Williams is referred to a cardiologist to rule out coronary arterial disease. The cardiologist tests him on the treadmill. After the treadmill exercise, Mr. Williams' echocardiogram shows dilated aorta and aortic aneurysm. He is admitted to hospital for emergency surgery. It is found that he has a nearly dissected aorta, with leaking of the blood into the chest. He recovers well after emergency surgery. He is referred to a genetics clinic to rule out Marfan syndrome. His clinical features meet the diagnostic criteria of Marfan syndrome, and molecular tests confirm the diagnosis. He has three children, two girls and one boy. All look healthy and their physical examinations are unremarkable. Diagnostic molecular test results reveal that the two girls carry the same mutation in the fibrillin gene. Therefore, a diagnosis of familial Marfan syndrome is established.

The severity and clinical presentation of Marfan syndrome can vary greatly. Another factor that can increase the difficulty in making a diagnosis is that up to 50% of cases are the result of spontaneous mutations in the affected child and, therefore, will not be associated with a positive family history. It is also possible for a parent to be so mildly affected that a diagnosis is not made previous to having a more severely affected child. Advances in molecular diagnosis and the ability to sequence the *FBN1* gene, which encodes the protein fibrillin and is the site of mutations in individuals with Marfan syndrome, have allowed more families to obtain an accurate diagnosis. It is also important to confirm the presence of a mutation in affected children to allow for identification of additional at-risk individuals in the family. Once a mutation has been identified in an affected child, it becomes easy to cost-effectively screen other family members.

The Features of Autosomal Dominant Inheritance

- One mutated allele at a locus is sufficient to cause a phenotype
- Inherited from parent to child
- Fifty percent risk to each offspring of an affected individual
- Those who do not inherit the gene cannot transmit it
- Males and females equally likely to be affected

Autosomal Recessive Inheritance

Autosomal recessive inheritance means that both copies of a particular gene must carry a mutation in order for the phenotype to be expressed. If only one copy is inherited, that person is referred to as a carrier, and, in general, will not express the phenotype (see *Fig. 2.6*). Some common autosomal recessive conditions are illustrated in *Table 2.1*. Most commonly, a child is affected with a recessive condition if both parents are carriers and each transmits a mutated gene to the child. The likelihood of this occurring when both parents are carriers would be 25% (see *Fig. 2.6*, aa). Some of the more common diseases inherited in this fashion include cystic fibrosis and sickle-cell anemia, which are also routinely included in most state newborn screening programs in the United States.

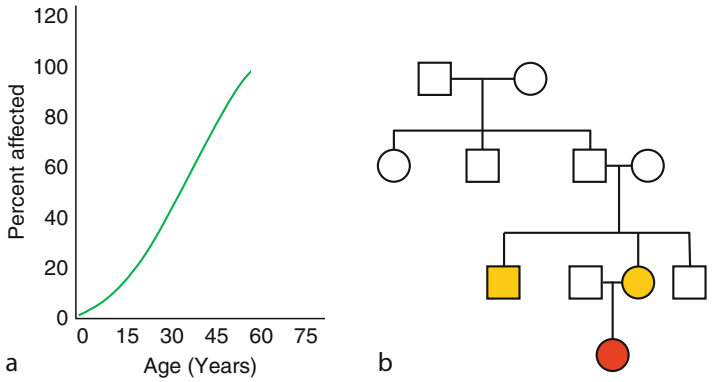

Figure 2.2
Age-dependent penetrance (a), a phenotype is increasingly expressed with age; and anticipation (b), clinical symptoms become apparent at an earlier age and are more severe as a gene is passed from generation to generation

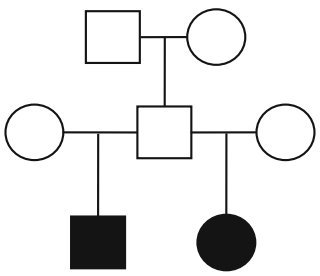

Figure 2.3
Germline mosaicism. The spermatozoa are a mixture of wild type and mutant cells

The Features of Autosomal Recessive Inheritance

- Both alleles must be mutated to produce a phenotype (homozygous), one from each parent (who are heterozygous carriers)
- "Horizontal inheritance" – siblings affected, generally not parents or children
- Males and females equally likely to be affected

Case Presentation

A 6-month-old male infant presents in the clinic with a chronic cough. Review of the history reveals that he was treated for an upper respiratory infection on two other occasions at 2 and 4 months, respectively. At birth he was 75th percentile in both height and weight but he has trended downward since then and is currently in the 50th percentile of height and only 10th percentile in weight. The remainder of the physical exam is unremarkable and he appears to be meeting all milestones of development. He is treated for another respiratory infection, and it is recommended that he return to clinic in 2 months to assess his growth. He returned to the clinic in 3 weeks, however, with the same chronic cough and inability to clear mucus from the lungs. A review of the chart indicates that he had a negative newborn screening test for cystic fibrosis. Given the symptoms, a fecal elastase and sweat test are ordered. The fecal elastase is normal and the sweat test comes back in the borderline range. A *CFTR* DNA mutation panel is ordered and also comes back negative. Based on these findings, cystic fibrosis is no longer considered by his physician. The parents seek another opinion since there is still a persistent chronic cough. At this visit a deep throat culture is obtained and the patient is confirmed to be growing *Pseudomonas aeruginosa* and is treated with tobramycin. In addition, a comprehensive CFTR sequence analysis is ordered which reveals two known cystic-fibrosis-disease-causing mutations. The parents are then tested and each is found to carry one of these mutations, thereby confirming the diagnosis of cystic fibrosis.

Sex-Linked Traits

Sex-linked traits are associated with mutations in genes that are located on the sex chromosomes. Males have a Y-chromosome and only one X-chromosome, whereas females have two X-chromosomes without a Y; therefore,

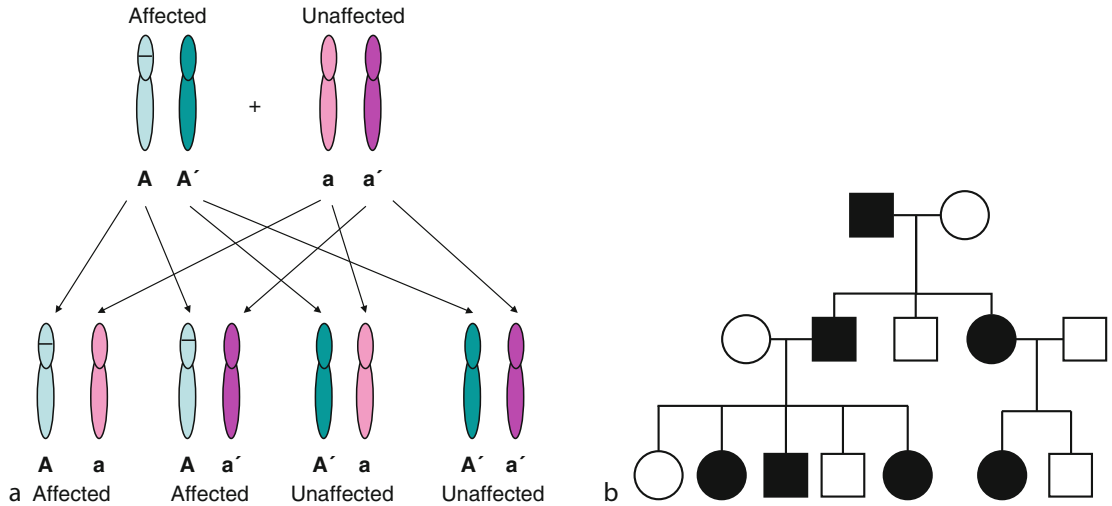

Figure 2.4
(a) Autosomal dominant trait. The risks for all members who carry a genetic mutation would be 50% for each offspring to be affected. (b) Autosomal dominant pedigree. Affected individuals in every generation

Figure 2.5
Boy with Marfan syndrome at age 12 with tall stature and joint hypermobility

the inheritance pattern for this group of traits is quite different from those that are due to mutation in genes on the autosomes. If the mutant gene is located on the X-chromosome and the father is affected, he will transmit this mutant allele to all of his daughters but none of his sons. In contrast, if the mutated gene is located on the Y-chromosome it will be passed to all of his sons. In females, the mutated gene will be transmitted to both sons and daughters 50% of the time (*Fig. 2.7*). Some common X-linked conditions are illustrated in *Table 2.1*.

X-Inactivation

Since males have only one X-chromosome and the Y-chromosome is much smaller and has far fewer genes than the X-chromosome, it seems that males and females are genetically imbalanced. This dosage difference is compensated for by X-inactivation. X-inactivation, also known as Lyonization, is a process in which one of the two copies of the X-chromosome in females is inactivated early in development. As shown in *Fig. 2.8*, for an individual cell, which of the two copies of the X-chromosome is inactivated is random. Once an X-chromosome is inactivated, however, it will remain inactive. If an individual cell has more than two X-chromosomes, still only one will be active. X-inactivation is controlled by the X-inactivation center (XIC), which is necessary and sufficient to cause X-chromosome inactivation. The inactivated X-chromosome is packed into a high density of heterochromatin and can be seen in the nucleus as a "Barr body." A small number of genes on the inactivated X-chromosome are expressed. The ends of the X and Y contain homologous genes that escape inactivation on

Table 2.1
Common conditions of Mendelian Inheritance

Inheritance pattern	Disease	Gene	Clinical features
AD	Marfan's syndrome	FBN1	Displacement of lens
		TGFBR2	Bone overgrowth
			Joint laxity
			Scoliosis
			Dilation of aorta
	Huntington's disease	HD	Progressive motor, cognitive, and psychiatric disturbance
			Chorea voluntary movement
			Cognitive decline
			Change in personality and/or depression
	Neurofibromatosis	NF1	Multiple café au lait spots
			Axillary and inguinal freckling
			Cutanis neurofibroma
			Iris lisch nodules
	Achondroplasia	FGF-R3	Short stature
			Disproportionately short arms and legs
			Large head
			Frontal bossing
			Middle-face hypoplasia
			Delayed motor skills
			Normal intellect and lifespan
	Familiar hypocholestrolemia	LDLR	Elevated cholesterol levels in blood
			Premature cardiovascular disease
AR	Cystic fibrosis	CFTR	Chronic lung infection
			Pancreatic insufficiency
			Meconium illium
			Infertility in males
	Sickle-cell disease	HBB	Anemia
			Acute and chronic pain resulting from ischemia secondary to vaso-occlusive events
			Bacterial infection
			Splenic sequestration
	Phenylketonuria	PAH	Mental retardation in untreated patients resulting from accumulation of phenylalanine
X-L D	Rett syndrome	PECP2	Repetitive hand movements in females
			Deceleration of head growth
			Seizure disorder
			No verbal skills
			Constipation
			Growth failure

Table 2.1 (Continued)

Inheritance pattern	Disease	Gene	Clinical features
	Incontinentia Pigmenti	HPEX	Skin lesions variable in different stages
			Blistering at birth
			Linear hypopigmentation
			Alopecia
			Hypodontia
X-L R	Duchenne muscular dystrophy	DMD	Progressive muscular degeneration
			Psuedo-hypertrophia
	Hemophilia A	F8	Bleeding secondary to factor-A deficiency
	Fragile-X Syndrome	FMR1	Mental retardation
			Macrocephaly
			Prominent ears

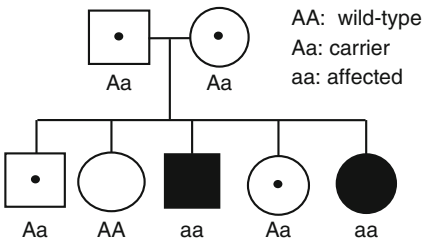

Figure 2.6
Autosomal recessive inheritance. "Horizontal inheritance" – siblings affected, generally not parents or children; males and females equally likely to be affected

the X. These regions are referred to as pseudo-autosomal. Both sexes will have two copies of every gene from the pseudo-autosomal region.

X-linked conditions can be classified into X-linked dominant or X-linked recessive. A classic example of an X-linked recessive disorder is Duchenne muscular dystrophy (DMD) (*Table 2.1*). DMD is characterized by progressive muscle degeneration and weakness. Symptoms typically manifest in a male at an early age. Muscle weakness progresses from proximal to distal. Psuedo-hypertrophy of the calves is often seen early in the course. As the disease progresses, muscle loss occurs and myocytes are eventually replaced by fat and fibrotic tissue. Before reaching the teenage years, the majority of patients have difficulty walking. Most become wheelchair bound by early adolescence. Skeletal deformities can occur secondary to muscle weakness. Some patients with DMD also develop cardiomyopathy; some will have intellectual impairment. DMD is caused by a mutation of the dystrophin gene on the X-chromosome. Dystrophin is a component of the protein-complex in skeletal muscle (*Fig. 2.9*). Loss of dystrophin results in an increased calcium release in the sarcolemma, and then cell death.

DMD and Becker muscular dystrophy, or BMD, are allelic disorders. DMD is mainly caused by a deletion or frameshift or stop mutation in the dystrophin gene. In contrast, the milder phenotype of BMD is due to mutations that maintain the dystrophin reading frame. Females who are heterozygous carriers of a mutation in the dystrophin gene are usually asymptomatic, though some may experience mild weakness.

X-Linked Recessive Traits

- The clinical phenotypes are always expressed in males, but are usually not expressed or only mildly expressed in females. Therefore, mutated genes may be transmitted through a series of unaffected females (*Fig. 2.8*).
- All daughters of affected males are unaffected. Female carriers will transmit the mutant gene to 50% of her sons who will be affected, and to 50% of her daughters, who will be carriers.
- New mutations could occur, especially if the mutations are genetically lethal (i.e., not compatible with reproduction). Those mutations will be replaced by novel mutations.

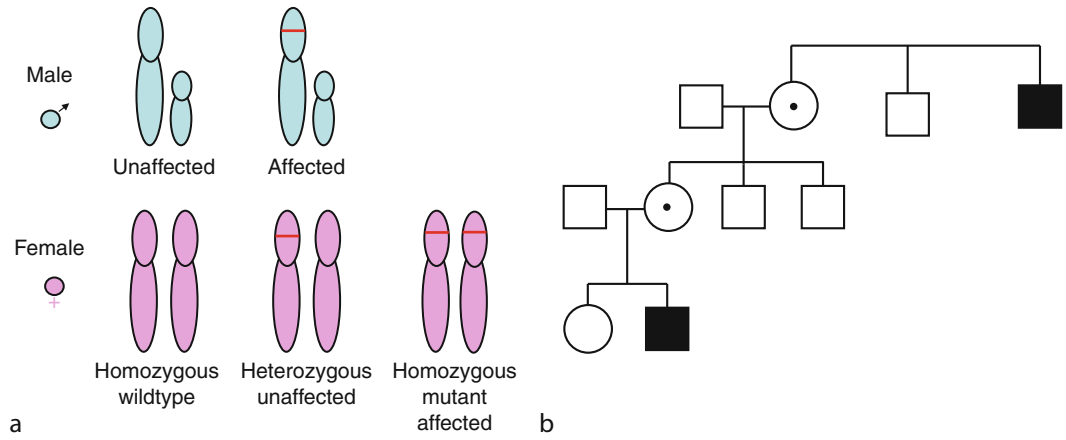

Figure 2.7

(a) X-linked recessive traits. The clinical phenotypes are always expressed in males, but are usually not expressed or only mildly expressed in females unless homozygous and compound heterozygous mutations occur. (b) Pedigree demonstrating X-linked recessive traits skipping generations through unaffected, carrier women

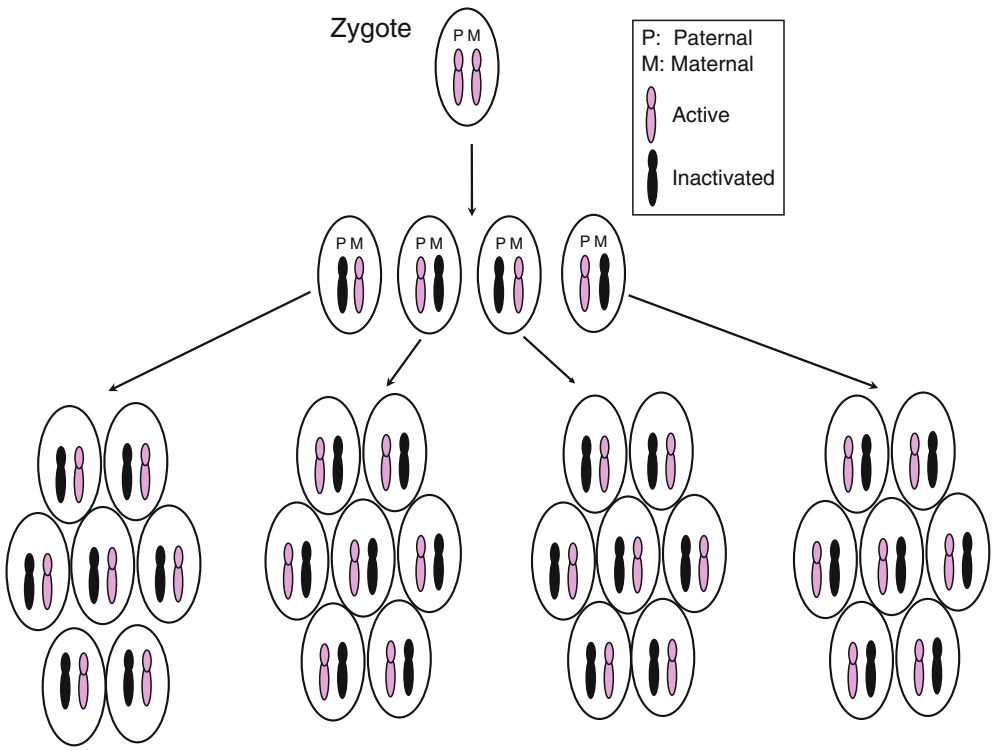

Figure 2.8

X-chromosome inactivation. In females, one of the two copies of the X-chromosome is inactivated randomly. Once an X-chromosome is inactivated, however, it will remain inactive. X-inactivation is controlled by the X-inactivation center (XIC), which is necessary and sufficient to cause X-chromosome inactivation

Figure 2.9
Dystrophin staining of skeletal muscle from a DMD patient. (Courtesy of Hart G.W. Lidov M.D., Ph.D. Department of Pathology, Children's Hospital Boston, Boston, MA) (a) H&E stained frozen section of skeletal muscle from a 6-year-old boy with Duchenne dystrophy. Fibers are slightly more rounded than usual for age, the diameter of fibers is more variable than normal, there is increased connective tissue between fibers (endomysial fibrosis) and scattered basophilic fibers (regenerating fibers) are present. Degenerating or necrotic fibers and inflammatory cells are sometimes seen in this condition, but are not prominent in this image. (b) A muscle biopsy from a child, without neuromuscular disease, immunostained for dystrophin. The brown reaction product, indicating the location of dystrophin, is found as a layer along the plasma membrane of all muscle fibers, a subsarcolemmal location. (c) Immunoperoxidase staining for dystrophin, in the same patient as above. Dystrophin is completely absent in most fibers, although a small cluster of dystrophin positive fibers are seen in the lower right, so-called revertant fibers

X-Linked Dominant Traits

For X-linked dominant conditions, the phenotypes in females are generally milder than in males. Therefore, daughters and sons of affected females are at 50% risk of being affected. All daughters but no sons of affected males will be affected. An example of an X-linked dominant condition is Rett syndrome (*Fig. 2.10*, *Table 2.1*). In a female, classical Rett syndrome is a progressive neurodevelopmental disorder. Clinical features include normal psychomotor development during the first 6–18 months of life followed by a period of developmental stagnation, then rapid regression in language and motor skills. During the progressive period, the typical clinical signs are repetitive stereotypic hand movements. Other clinical features include screaming, inconsolable crying, and autistic tendencies. Head growth may begin decelerating as early as 3 months of age. Brain size may be smaller than normal, but microcephaly is not an invariant feature of Rett syndrome. Seizures occur in 90% of affected females. Generalized tonic-clonic seizures and partial complex seizures are common. Failure to thrive is also often seen in affected females. It is possible that this may be associated with oropharyngeal and gastroesophageal incoordination, which cause poor feeding. In classical Rett syndrome, the female can survive into adulthood. Most males with Rett syndrome do not survive pregnancy, but some affected males present with severe neonatal encephalopathy, which usually results in death before age two.

Figure 2.10
Five-year-old girl with Rett syndrome. She had normal developmental milestones until 18 months of age and then lost most speech capability at 2½ years

Case Presentation

A 3-year-old girl born of non-consanguineous parents presented to the clinic with aggressive behavior since 1 year of age. She had normal developmental milestones until 18 months of age. However, she seemed to plateau in development and then lost most speech capability at 2½ years. There was no history of seizures or hyperventilation. On examination she had hypotonia, unusual hand movements, and autistic behavior. There was no ataxia. Her systemic examination was normal. She was diagnosed as being autistic. At age 5 years, she was reevaluated at a genetics clinic in an effort to determine an underlying cause for her delay. A review of her history confirmed that there had been no developmental progression beyond the 2-year level despite several years of intensive intervention. The history and exam revealed moderate dementia, partial apraxia, and microcephaly. She also had constant wringing movements of hands, patting, clapping, was easily annoyed, and could utter only two to three meaningless words. Based on the clinical findings and history, a diagnosis of Rett syndrome was made and a DNA blood test was sent for confirmation. Results indicated a known mutation in the *MECP2* gene, thereby confirming the diagnosis of Rett syndrome.

Rett syndrome is caused by mutations of methyl CpG binding protein 2 (*MECP2*). This protein plays an important role in the function of neuronal cells. The protein binds to methylated DNA, interacting with other proteins to form a complex that leads to inhibition of gene expression. Methylation occurs in CpG islands, which are frequently found near the promoter region of a gene. Once MECP2 binds to DNA, the DNA will condense and become inactive. Recent studies show that MECP2 forms a complex with histone deactylase (hDac), which catalyzes the removal of an acetyl group on the histone, therefore blocking the transcription of the gene. Rett syndrome is often misdiagnosed as autism, cerebral palsy, or nonspecific developmental delay, and can be a frequent cause of delayed development in girls. Diagnosis is mainly clinical, after excluding neurodegenerative disorders and other causes of delayed development. Confirmatory DNA testing is available in several specialty labs. The treatment is mainly speech therapy and counseling.

Y-Linked Disorders

Disorders associated with Y-linked inheritance are relatively few. In this case, the disease-causing gene is on the Y-chromosome. Only males are affected and every son of an affected male is affected. Most Y-linked disorders involved male-sex determination, particularly due to mutation in genes controlling sperm quality and quantity. They are most commonly diagnosed in men who seek evaluation for infertility.

Maternal Inheritance

The mitochondrion is the site in the cell where the majority of the ATP is produced. Each mitochondrion contains multiple copies of a circular double-stranded DNA molecule that encodes 13 protein subunits of the respiratory chain. The vast majority of mitochondria are maternally inherited. Mitochondrial genome mutations can lead to failure of energy metabolism and follow a pattern of maternal inheritance. It should be noted, however, that most mitochondrial proteins are encoded by genes in the nucleus, and mutations display typical Mendelian inheritance (usually autosomal recessive). As shown in *Fig. 2.11*, a mutation at the A3243G position of the mitochondrial genome causes maternal inheritance of

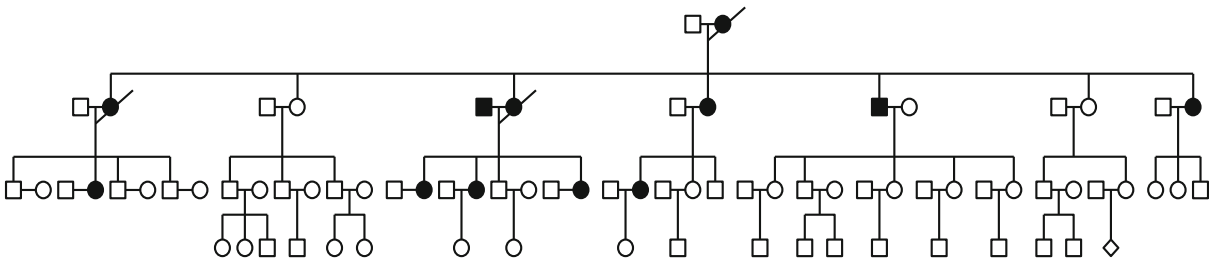

Figure 2.11
Maternal inheritance in mitochondrial diseases. The mutation in the mitochondrial genome is passed to offspring exclusively through women

diabetes. All affected individuals inherit the mutant mitochondrial genome from their mothers. No affected males pass the mutated genome to their offspring. Since each cell contains hundreds to thousands of mitochondria, each mitochondrion also contains multiple copies of the mitochondrial genomes. Therefore, the mutant and wild type mitochondrial genome can coexist, which is known as heteroplasmy. The degree of heteroplasmy can affect the clinical expression of the mutation.

Genomic Imprinting

For a majority of autosomal genes, the paternal and maternal alleles are both expressed. However, a small portion of genes are expressed in a parent-of-origin-specific manner. For example, gene *H19* on Chromosome 11 is only expressed from the maternal allele. In contrast, *IGF2* on the same chromosome is only expressed from the paternal allele. This phenomenon is referred to as genomic imprinting.

Prader–Willi syndrome is a typical example of a disorder of genomic imprinting. Prader–Willi syndrome is characterized by hypotonia, short stature, polyphagia, obesity, and small hands and feet. Hypogonadism and mental retardation also occur. The disorder results from lack of expression of a gene on chromosome 15 that is normally expressed from the paternal copy. A variety of types of mutation can lead to Prader–Willi syndrome. The most common is deletion of the region on 15q11.2. An alternative mechanism is uniparental disomy, in which both copies of 15 are derived from the mother. This can occur as shown in *Fig. 2.12*. Deletion of the maternal copy, or paternal uniparental disomy results in a different disorder – Angelman syndrome, characterized by seizures, developmental delay, and poorly coordinated body movements.

In summary, Mendelian disorders comprise an important component of pediatric genetic disorders. The most critical diagnostic tool is the family history. Being able to accurately analyze the pattern of inheritance can help making a diagnosis and identifying any at-risk family members. To analyze a pedigree, it is very important to know if transmission is vertical and to examine for male–male transmission (X-linked disorders will not have male-to-male transmission).

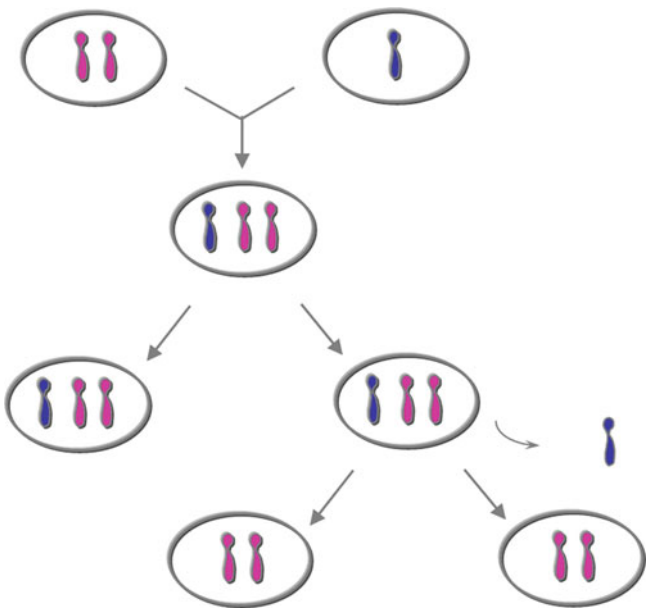

Figure 2.12

Genomic imprinting of Prader–Willi syndrome. A normal sperm is fertilized with an egg with two copies of chromosome 15, and this will result in trisomy 15. Since trisomy 15 is lethal, the cell will often find a way to remove one copy of chromosome 15. If the paternal chromosome 15 is eliminated, the remaining two copies of chromosome 15 will be both from the mother and result in maternal uniparental disomy. Since some genes are only expressed in paternal alleles and when two copies of gene are the maternal alleles, some of the genes normally expressed from the paternal allele are missing. In this case, this would result in Prader–Willi syndrome

In addition, it is also very helpful to examine the pedigree to determine if all the daughters of an affected father are affected. This could be an evidence of sex-linked-dominant mode of transmission. Does the trait skip a generation, indicative of non-penetrance? If the pedigree is large enough, determination of the segregation ratio is important (expect half of the offspring of affected individuals to be affected for a dominant trait).

3 Congenital Malformation Syndromes

Gabriela M. Repetto

The birth of a child with single or multiple congenital anomalies is a source of stress for the family and the healthcare team, even in the presence of a known family history of the condition or of prenatal diagnosis. Identifying the correct etiology is relevant to plan for appropriate interventions, to search for possible associated abnormalities, to establish a prognosis, and to predict recurrence risk. This chapter summarizes the clinical evaluation of the child with congenital anomalies in the context of a syndrome, defined as a *recognizable pattern of abnormalities that share a common underlying etiology.* Approaches to common clinical problems with a brief depiction of some relatively frequent syndromes are included. Several thousand syndromes have been recognized and their individual description is beyond the scope of this section. References to specialized textbooks or databases have been incorporated for further reading.

Definitions/Classifications

Dysmorphology is the term used to describe the study of congenital anomalies. It is estimated that 2–3% of newborns have *major congenital abnormalities*, that is, those that are present at birth and require surgical or medical treatment because of functional or cosmetic consequences. Most newborns with major congenital anomalies have isolated ones, but it has been estimated that about a third to a half of those with congenital abnormalities, or 0.7–1% of all newborns, have multiple anomalies.

Recognizable patterns of anomalies are usually categorized as syndromes, sequences, and associations. As mentioned above, a *syndrome* is a recognizable pattern of anomalies with a common underlying etiology. For example, individuals with Down syndrome have identifiable facial features, developmental delay and mental retardation, central hypotonia, risk of congenital heart disease, hearing and visual impairment, among others; these manifestations are due to the presence of additional material from chromosome 21. Marfan syndrome is characterized by tall stature with long extremities, pectus carinatum or excavatum, lens dislocation, aortic root dilatation, and other features (*Fig. 3.1*) that are the result of mutations in the *FBN1* gene encoding for fibrillin, an extracellular matrix protein. A *sequence* is defined as a group of anomalies resulting as a cascade from a single initial defect in morphogenesis. Robin sequence, for example, refers to the association of microretrognathia (small and receding chin), glossoptosis and respiratory distress with or without cleft palate. It is presumed that microretrognathia in early development is the initial defect, causing a displacement of the tongue backwards and upward to a position that interferes with palatal closure. Potter sequence is characterized by flat facial features, abnormal positioning of the extremities, and pulmonary hypoplasia – findings that are secondary to oligohydramnios – and this is due to renal agenesis. An *association* refers to a group of congenital anomalies that occur together with higher frequency than expected by chance, but without a known common etiology. For instance, VACTERL (or VATER) association includes vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal and limb defects. Though there is no agreement on how many of these anomalies are sufficient to establish the diagnosis of VACTERL (authors suggest anomalies in at least three different anatomic regions), it is relevant to be aware of this association, as the presence of one of the defects should prompt the clinician to carefully search for the others. MURCS association includes Mullerian duct (upper vagina and uterus) hypoplasia, renal and cervical vertebra defects, also of so far unknown etiology.

With the increasing knowledge on the pathogenesis and availability of molecular tests, some conditions previously categorized as associations are now classified as syndromes. One example is CHARGE syndrome (coloboma, heart disease, choanal atresia, renal anomalies, growth and mental retardation, genital hypoplasia, and ear anomalies): microdeletions and mutations in the *CHD7* gene have recently been identified as the cause of the multiple and apparently unrelated anomalies. *CHD7* is a member of the chromodomain helicase DNA-binding (*CHD*) genes that encode for a class of proteins that are thought to have pivotal roles in regulating chromatin structure and gene expression in early embryonic development.

Clinical series and large epidemiologic studies have shown that syndromes may be recognized in the neonatal

Arachnodactyly in a girl with Marfan syndrome

Figure 3.2
Third to fifth digit amputations due to amniotic bands

period in about 25% of newborns evaluated for congenital anomalies. A substantial portion of syndromes are recognized later in life, especially since several cardinal manifestations, such as developmental or growth delays can present in an age-dependant manner. This has practical implications for the clinician and the family, since arriving to a correct diagnosis may require long-term follow up and re-evaluation.

Several thousand syndromes have been delineated and many are described and catalogued in textbooks, such as Smith's Recognizable Patterns of Malformations and Syndromes of the Head and Neck, or computer or web-based clinical databases, such as the Baraitser-Winter Dysmorphology database (formerly London Dysmorphology database) and Pictures of Standardized Syndromes and Undiagnosed Malformations (POSSUM).

Etiology

On a pathogenic basis, congenital anomalies are classified as *malformations* (abnormal organ or tissue formation, as seen in congenital heart defects or spina bifida), *dysplasias* (abnormal organization of cells, such as skeletal dysplasias and lysosomal storage diseases), *deformations* (effect of extrinsic forces acting on an otherwise normal fetus or embryo, for example, intrauterine constraints leading to club foot), and *disruptions* (destruction of normal tissue, for example, by amniotic bands (*Fig. 3.2*), infections or hypoxia). Though there may be overlap within these categories, the classification has practical implications in terms of prognosis and recurrence risks. Patients with deformations tend to have relatively good therapeutic prognosis and low recurrence risks unless the underlying cause persists (such as uterine myomata or bicornuate uterus). Dysplasias are usually of genetic origin with recurrence risks that depend on the pattern of inheritance, and there is, in general, a paucity of curative therapies.

The term "congenital" (present at birth) does not in itself imply a specific etiology and is not synonymous with genetic cause. It has been estimated that chromosome abnormalities or rearrangements account for 5–10% of cases of major congenital anomalies, single gene defects for 10–15%, environmental (non genetic) causes such as infections or teratogens in 10%, polygenic/multifactorial (i.e., the result of an interaction between genetic and nongenetic factors) in 30–40%, and unknown cause in 30–50%.

Epidemiology

Birth defects surveillance systems have been implemented in different countries or regions to monitor the occurrence of congenital anomalies and conduct research geared towards understanding the causes, decreasing their consequences, and elaborating preventive strategies. The International Clearinghouse for Birth Defects Surveillance and Research (ICBDSR) (http://www.icbdsr.org) collects information from over 40 programs around the world, a strategy that has been useful in understanding the causes that underlie several defects.

Based on data provided by these monitoring systems, it has been estimated, as described above, that about 2–3% of newborns have major congenital abnormalities.

In addition, other relevant anomalies, such as growth failure, developmental delays, mental retardation, hearing or vision loss, may be evident later, so that, by age 5 years, approximately 7% of children may have major anomalies that warrant the search for an underlying etiology.

Major congenital anomalies were estimated to account for half a million deaths worldwide in 1997 and constitute a substantial cause of neonatal and infant mortality in both developed and developing countries. As infant mortality rates have decreased worldwide in the past 50 years, the relative contribution of congenital anomalies to infant mortality has increased. Major congenital anomalies are also one of the most frequent causes of pediatric hospitalization, accounting for a third to one half of admissions to tertiary care hospitals.

Common types of major anomalies include, among many others, congenital heart disease, cleft lip and/or palate, and neural tube defects (including anencephaly and spina bifida) that have average incidences of 8/1,000, 1.6/1,000, and 1.1/1,000 live births, respectively. There is evidence of geographic or ethnic differences in frequencies of several birth defects. For example, the incidence of neural tube defects was highest, almost 19/1,000, in the Netherlands and 5/1,000 in France in the early 1990s, before folic acid supplementation was widely implemented in these countries. Regional differences have also been observed in the incidence of cleft lip.

Clinical Manifestations and Diagnosis: The Clinical Evaluation of the Child with Congenital Anomalies

Finding the correct diagnosis for a patient with single or multiple congenital anomalies has several implications: existing knowledge of the natural history of the condition will allow planning for additional evaluations and necessary care, available information on the particular syndrome will serve as a prognostic guideline, and knowledge of the cause of the syndrome will be necessary to estimate risk of recurrence and to consider and implement available preventative measures. Nevertheless, it is estimated that a definitive diagnosis is reached in only approximately 20–50% of children with multiple anomalies.

A genetic evaluation of an infant or child with congenital anomalies should be considered in the presence of two or more major anomalies (including mental retardation and short stature), one major and multiple minor anomalies, or a major anomaly and/or multiple minor ones and a family history of congenital anomalies, recurrent miscarriages (>2), neonatal death, parental consanguinity and infants with congenital anomalies and a history of potential teratogen exposure (◉ *Table 3.1*).

Table 3.1

One or more major and/or multiple minor anomalies and family history of congenital anomalies, parental consanguinity, recurrent miscarriages or teratogen exposure
Known genetic syndrome
Neonatal death

As in every area of medicine, achieving a correct syndrome diagnosis starts with a detailed clinical history and physical examination. The clinical evaluation of a child with congenital anomalies requires thoroughness. Relevant elements of the clinical history include the pregnancy history (pregnancy planning, parental age, occupation and health status, exposure to drugs, medications, alcohol, evidence of maternal infectious diseases and chronic illness, fetal movements, oligo- or polyhydramnios, ultrasound or other antenatal screening results), delivery (gestational age, presentation and mode of delivery, birth weight, length and head circumference and their relationship to gestational age), as well as neonatal adaptation and behavior, including evidence of asphyxia, neurological and biochemical abnormalities, such as hypoglycemia or hypocalcemia. If the child is older, information on growth and development as well as the interval medical history may also provide important diagnostic clues.

The family history is also relevant to diagnosis, since there may be other relatives with similar or related findings, including more subtle ones, or it may reveal other individuals at risk of developing the disease or of transmitting it to their offspring. Information is gathered as a minimum of three-generation pedigree and should include affected individuals, miscarriages, and consanguinity. A useful way of summarizing the family history is the drawing of a pedigree using standardized symbols (◉ *Fig. 3.1*).

The physical examination of the affected child, and other family members if necessary, constitutes another crucial diagnostic element. Growth and proportions should be documented and compared to age-appropriate percentiles. The basic parts of the general and segmental physical exam are performed, but special attention should be given to findings that may constitute major or minor

Figure 3.3
Examples of minor anomalies. (a) Inner epicanthal folds and depressed nasal bridge, (b) preauricular pit, (c) multiple café au lait spots, (d) interdigital webbing, (e) blue sclerae

anomalies, as well as the distinction of the latter from normal variants. *Minor anomalies* are those that constitute morphologic abnormalities that are of no serious medical or cosmetic consequence, and are present in 4% or less of the population. They tend to be more frequent in areas of complex formation, such as the face, ears, and hands. Examples include epicanthal folds, preauricular tags or pits, hypo-or hyperpigmented maculae, etc. (*Fig. 3.3*). The identification of these minor anomalies is relevant since they may provide diagnostic clues in the evaluation of a child with major anomalies. Additionally, it has been shown that the presence of three or more minor anomalies may be associated with the presence of major ones in 20–90% of infants. Therefore, it has been recommended to search for major anomalies in newborns with multiple minor anomalies. It can be challenging for the clinician to distinguish these minor anomalies from *normal variants*, defined as structural variations without

Figure 3.4
Examples of normal variants. (a) (Incomplete) transverse palmar crease, (b) fifth finger clinodactyly

medical consequences that are common in a population, occurring with a frequency of 4% or greater, such as transverse palmar creases, fifth finger clinodactyly, etc. (*Fig. 3.4*). The clinician should be aware of ethnic differences in frequencies of these minor findings; for example, epicanthal folds are common in Asian individuals and would thus be considered a normal variant in these populations, but they are infrequent in Caucasian individuals and therefore, would be catalogued as a minor anomaly in them.

It is useful to obtain objective measurements and to compare them with available standards. These standards have been constructed predominantly with data from Caucasian individuals; therefore, comparisons may also need to be interpreted with caution when used for patients of other ethnic origins. Photographs obtained with informed consent are useful to document the condition and age-related changes as well as to facilitate consultation with pertinent specialists. Several sites have implemented telemedicine services to facilitate evaluation of patients in remote locations, and this type of service is likely to continue growing in the future, allowing for access to specialist consultation.

Useful laboratory tests to further assess the phenotypic features include imaging studies to search for malformations not evident on surface exam, hearing and vision evaluations, formal developmental assessments, and biochemical tests, for example mucopolysaccharides when a lysosomal storage disease affecting these metabolites is suspected, or cholesterol levels in the case of Smith-Lemli-Opitz syndrome – a severe defect in cholesterol biosynthesis that causes microcephaly, a distinctive facies, congenital heart disease, genital abnormalities, Y-shaped syndactyly between the second and third toes, high prenatal and neonatal mortality, and mental retardation in the survivors.

Once all this clinical information has been gathered, the next step is to consider possible differential diagnoses. The clinician needs to keep in mind that no single sign is pathognomonic of a syndrome, minor anomalies are seen in otherwise healthy children, and there can be crucial diagnostic signs and symptoms that may appear later in life.

For the experienced clinician, a diagnosis may be achieved through what is known as the "gestalt" or pattern recognition approach. Since most syndromes are individually infrequent, it is unlikely that all of them would have been seen or recognized by a physician. As mentioned above, there are useful textbooks and computer databases that may aid in the identification of a diagnosis. It must be emphasized that the accuracy of such diagnosis relies fundamentally in the adequate recognition, description and prioritization of signs and symptoms by the clinician. As expressed by Hunter, these databases should be considered "systems for experts" rather than "expert systems."

If possible, once a diagnostic hypothesis has been proposed, laboratory confirmatory tests should be performed. Specific genetic tests are not available for all recognizable syndromes. In some cases, the underlying genetic etiology is unknown; in others, cost or accessibility issues may make testing not feasible. These limitations should not preclude the implementation of adequate care measures and education of the patient and his or her family.

The most commonly used genetic test is the karyotype, and it should be considered in the presence of a known recognizable chromosome abnormality syndrome, or in children with multiple major congenital anomalies or minor anomalies, mental retardation, or short stature.

If a specific microdeletion or microduplication is suspected based on the clinical findings, fluorescence in situ hybridization (FISH) testing with specific probes is a necessary additional form of testing. Higher resolution testing for genomic imbalances, such as array comparative genomic hybridization (array-CGH), has been shown to increase the rate of detectable chromosome abnormalities from 5–10% to an average of 17–20%. If a specific monogenic disorder is recognized, molecular testing to identify the causative mutation will be useful for confirmation and, if indicated, to offer testing to other relatives at risk. The detection rate of molecular testing for most monogenic disorders is less than 100% and it is necessary to begin testing with the affected individual if available. Once a mutation has been found, testing can be offered to affected or at-risk relatives. Web-based databases of laboratories that perform genetic clinical and research tests and descriptions of their uses are listed in *Table 3.2*, along with other useful sources of genetics information.

Some inborn errors of metabolism can be a cause of congenital anomalies, and biochemical tests may also be useful as diagnostic tools. Smith-Lemli-Opitz syndrome, described above, is an example. Defects in mitochondrial energy production may cause central nervous system malformations and patients may have abnormalities in lactate and pyruvate levels and in urine organic acids that aid in orienting to a specific diagnosis.

It is estimated that in about 50% or more of the evaluated patients no diagnosis will be made, even after a complete evaluation. The family should be reassured that the lack of a specific diagnosis will not impede access to therapies and that an incorrect diagnosis may be more harmful than no diagnosis. It is relevant, in these cases, to reevaluate the child with certain periodicity, since new and/or more specific signs or symptoms may appear in the patient with age, and new diagnosis or diagnostic tests may have been described or developed. A summary of the approach is presented in *Fig. 3.5*.

Management of the Child with a Congenital Malformation Syndrome

Because syndromes can be so different in manifestations and consequences, it is not possible to describe specific recommendations in this chapter. Nevertheless, there are some common relevant points: Medical care, psychological support and education of the family are all integral parts of the care of infants and children with congenital malformation syndromes. Information given to the family regarding prognosis and available therapies should be realistic. Referral to support groups is usually beneficial and appreciated by the parents. Some useful resources for parents are listed in *Table 3.3*.

Anticipatory care guidelines for several common genetic syndromes have been published by the Committee on Genetics of the American Academy of Pediatrics. They include recommendations for the care of children and adults with achondroplasia, Down, fragile X, Marfan, neurofibromatosis type 1, Turner, and Williams syndromes. These are useful sources for the clinician involved in the care of these patients, and place emphasis on the early detection and management of the manifestations of these conditions. Some of these guidelines also include

diagnosis-specific growth charts and expected development. Other useful sources of clinical information can be found in the sites listed in *Table 3.2*.

Recurrence risks are estimated based on the specific diagnosis and its cause. In the case of monogenic disorders, estimates can be made based on Mendelian proportions if the type of inheritance of the syndrome is known. For autosomal recessive conditions, the risk of having an affected child is 25% for each pregnancy if both parents are carriers. In the case of autosomal dominant disorders, the risk to an affected parent to have an affected child is 50%. In some cases, new mutations give rise to autosomal dominant disorders, implying low recurrence risks, but this information needs to be taken with caution, because of the phenomena of incomplete penetrance (a parent has the mutation but shows no phenotypic consequence, but still has a 50% chance of inheriting it to his/her offspring) and gonadal mosaicism, that is, the presence of other gametes with the mutation, leading to the possibility of recurrence. For X-linked recessive disorders, carrier mothers have a 50% chance of having an affected son and a 50% chance of having a carrier daughter for each pregnancy if the father is unaffected. In the case of fathers affected with X-linked disorders, every daughter will be an obligate carrier and sons will be unaffected, since they will inherit a Y chromosome from their father. In X-linked dominant disorders, both males and females are affected, though phenotypes may be more severe (or even lethal) in males. All daughters and no sons of an affected father are affected; the risk to sons and daughters of an affected woman is 50%.

Most of the isolated anomalies described at the beginning of the chapter have a complex or multifactorial cause, with contributing genetic and nongenetic factors. Their risk of recurrence is usually estimated based on empirical data. Recurrence risks for a selection of common isolated congenital anomalies are summarized in *Table 3.4*.

Empiric figures are also used for recurrence risk estimation of common aneuplodies or other chromosome abnormalities, which take into account the type of abnormality, the mode of ascertainment (e.g., through the birth of a child with anomalies, or through recurrent miscarriages), parental karyotype, and parental age.

The prognosis will depend on the underlying diagnosis, the manifestations in the particular child, and the

availability and access to care. Particular issues arise in the presence of a diagnosis associated with poor survival in the neonatal or early infancy periods. Examples include trisomy 13, trisomy 18, or lethal skeletal dysplasias. In these cases, diagnostic confirmation allows to plan for appropriate and proportionate care and support of the child and family.

Approaches to Some Common Clinical Problems and Anomalies

A significant proportion of pediatric patients are referred to genetics evaluation due to a categorical problem or a specific major anomaly. As expressed above, the identification of the underlying cause may aid in the care, prognosis, and recurrence risk estimation. A brief description of key elements in the genetic evaluation of children with suspected syndromic causes of short stature, congenital heart disease, or cleft lip/palate is given below.

Syndromes Associated with Short Stature

Short stature, whether of prenatal or postnatal onset, is a relatively common medical problem, and a frequent reason for genetics evaluation. There are a wide number of causes, including normal variation as well as nutritional, gastrointestinal, renal, endocrine, and social causes that interfere with growth, among others. Nevertheless, short stature is also frequent in syndromes; therefore, genetic causes may need to be evaluated in a substantial portion of infants and children manifesting growth problems. As described above, the clinical evaluation is crucial, and should include a thorough pregnancy history in search for prenatal onset of growth deficiency, maternal illness, exposure to teratogens, etc., medical history in search for other illnesses and evaluation of growth velocity. Family history is important to assess the growth pattern, final height, age at puberty, and presence of hereditary diseases. The physical examination, in addition to the growth parameters, should include a search for major or minor anomalies that might provide clues to the underlying diagnosis. A helpful tool is the measurement of body segments to evaluate body proportions, in addition to height or length. These measurements include arm span (measured from the tip of one middle finger of one hand to the other with the arms fully extended in the horizontal plane) that normally is similar to total height or length. Measurements of lower and upper segments and of limb segments are also useful to assess body proportions. Standards have been published for these more specific dimensions, but should be used with caution since they have been obtained from North American individuals.

The presence of disproportion suggests a skeletal dysplasia. These are abnormalities in growth and development of bone and cartilage and usually affect bones or parts of bones differently, resulting in disproportion. If a skeletal dysplasia is suspected, the laboratory evaluation requires a radiologic skeletal survey, including anteroposterior (AP) and lateral (L) views of the skull, full spine and knees, and AP views of the thorax, pelvis, upper and lower extremities, hands, and feet. On occasion, and due to the age-dependant process of bone ossification, some abnormalities will not be evident in X-rays of infants and small children and therefore clinical and radiologic reevaluation will be required. One of the most common types of skeletal dysplasia is achondroplasia, due to mutations in the *FGRF3* gene that encodes for fibroblast growth factor receptor 3. Patients have short stature with short spine and limbs, macrocephaly, and normal intellectual abilities (*Fig. 3.6*).

Many other conditions show short stature without (or with more subtle) disproportion. Some examples are Williams syndrome, with features that include supravalvular aortic stenosis, hypercalcemia, developmental delays, and recognizable facial features; Russell-Silver syndrome, with relative macrocephaly, limb asymmetry, café-au-lait macules and clinodactyly of the fifth fingers; or Seckel syndrome, with severe pre- and post-natal growth failure, microcephaly that can be more pronounced than the short stature, prominent nose, micrognathia, and varying degree of mental retardation (*Fig. 3.7*).

Karyotype should be included in the evaluation of children with short stature. Several studies have shown that about 20% of girls with pathologic short stature have Turner syndrome. This is characterized by congenital heart disease in 30–40%, puffy hands, and feet at birth due to lymphedema (*Fig. 3.8*) webbed neck, widely spaced nipples, and ovarian dysgenesis, among other features. Molecular diagnosis is available for a constantly increasing number of conditions associated with syndromic and non-syndromic short stature.

Syndromes Associated with Congenital Heart Disease

Congenital heart disease (CHD) is one of the most common major congenital anomalies; with an estimated incidence of 8/1,000 live births. Genetic causes are being

Figure 3.6
A boy with achondroplasia, with a height of 115 cm at age 10 years

Figure 3.7
A girl with Seckel syndrome, with a length of 65 cm at age 2 years

increasingly identified not only for syndromic CHD, but also for nonsyndromic or isolated defects, thereby improving the understanding of the etiology of these anomalies. Several chromosomal syndromes include CHDs: 40–50% of newborns with Down syndrome have CHD and it is recommended that a cardiac evaluation, including an echocardiogram, be performed at the time of diagnosis. Frequent defects include common atrioventricular canal, ventricular septal defects (VSD), and atrial septal defects (ASD). CHD is also frequent in girls with Turner syndrome, with anomalies such as coarctation of the aorta, bicuspid aortic valve, valvular aortic stenosis, and risk of aortic dissection in adulthood. Some chromosome microdeletion syndromes also lead to an increased risk of CHD. About 60–75% of patients with chromosome 22q11 or velocardiofacial syndrome have defects in the cardiac outflow tract, such as tetralogy of Fallot, interrupted aortic arch and VSD, along with developmental delays, cleft palate or velopharyngeal insufficiency, among other features (*Fig. 3.9*). Patients with Williams syndrome, due to a microdeletion at chromosome region 7q11, frequently have supravalvular aortic stenosis, peripheral pulmonary

Figure 3.9
A boy with velocardiofacial syndrome (22q11 deletion). (a) facial features, including bulbous or round nasal tip and minor ear anomalies, (b) bifid uvula

artery stenosis or pulmonic valve stenosis associated with short stature, hypercalcemia, and hypertension.

CHD is also a relevant feature of several monogenic syndromes. The majority of patients with Noonan syndrome have CHD; characteristic types include dysplastic pulmonary valve leading to stenosis, and/or hypertrophic cardiomyopathy. Other syndromes, such as Costello and cardio-facial-cutaneous, share similar features (CHD, short stature, developmental delays, and characteristic facial features) and are due to mutations in *PTPN11*, *SOS*, and *KRAS* genes that are part of a common signaling pathway.

CHD can also be a part of syndromes due to teratogenic exposure. Examples include maternal phenylketonuria and maternal diabetes, fetal alcohol syndrome, and retinoic acid embryopathy. In addition, some teratogens can mimic the effect of genetic abnormalities, a phenomenon known as phenocopy. For example, DiGeorge sequence (abnormalities in the embryonic development of the third and fourth branchial arches and pouches leading to cardiac outflow tract defects, thymic and parathyroid aplasia or hypoplasia, resulting in immune deficiency and hypocalcemia respectively) can be caused by prenatal exposure to retinoids or by chromosome 22q11 microdeletion (*Fig. 3.9*).

Cardiovascular disease can also present later in several syndromes, so early awareness of the diagnosis can help in planning for appropriate screening and prevention. As mentioned above, girls with Turner syndrome can develop aortic dissection in adulthood and it is recommended for them to have regular cardiological evaluation in adulthood even if the person did not have CHD. Individuals with Marfan syndrome can have dilatation and dissection of the aorta, a life-threatening complication that can be partly reduced in rate with the use of beta-blockers or angiotensin II-receptor blockers.

Syndromes Associated with Cleft Lip or Cleft Palate

Orofacial clefts are relatively frequent major anomalies, and are second in frequency to congenital heart defects. As has been described for cardiac defects, most cases of orofacial clefts are isolated, that is, without other anomalies (but still may have a genetic etiology) and a proportion of individuals have syndromic clefts. From a pathogenic point of view, cleft lip with or without cleft palate (CL±P) is considered distinct from cleft palate (CP), they occur separately in families, and the former is more frequent than the latter (1–2/1,000 and 1/500 live births, respectively). CL±P is more commonly associated with other anomalies than CP alone.

Several common syndromes are associated with orofacial clefts: CL±P is frequent in trisomy 13 and 18, and CP, whether in overt or submucous forms, is seen in 70–80% of patients with chromosome 22q11 deletion or velocardiofacial syndrome. Monogenic syndromes that may manifest clefts include Stickler (CP with myopia, hearing loss, and arthropathy) (*Fig. 3.10*), Larsen syndrome (CP with flat facial profile and multiple joint dislocations), and van der Woude syndrome (one of the few conditions in which affected family members can have either CL±P or CP, associated with lip pits).

Teratogens can also be a cause of clefting. CL±P is seen in patients with fetal alcohol syndrome (with growth

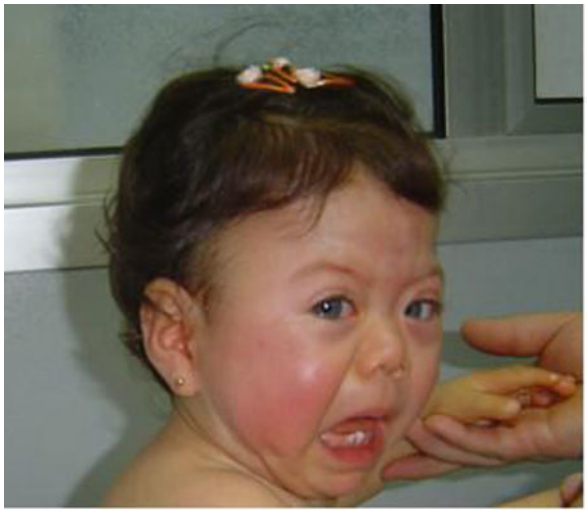

Figure 3.10

deficiency, variable mental retardation, microcephaly, short palpebral fissures, and flat philtrum), fetal hydantoin syndrome (short stature, mental retardation, hypoplasia of distal phalanges and small nails), and fetal valproate syndrome (with congenital heart disease and spina bifida).

Prevention

As neonatal and infant mortality from infections and complications of prematurity have decreased worldwide, there has been a relative increase in morbidity and mortality from congenital anomalies, both in an isolated manner and in the context of syndromes. Most cases of congenital malformation syndromes will arise in families without a previous history, making the identification of couples at risk difficult. Most common chromosome abnormalities are sporadic, as is the case of the majority of instances of Down and Turner syndromes. With respect to monogenic disorders, de novo or new mutations occur for a large proportion of autosomal dominant (as in achondroplasia and neurofibromatosis type 1, among others) or X chromosome-linked conditions (e.g., Rett syndrome and Goltz syndrome), and most individuals with autosomal recessive conditions have healthy heterozygous carrier parents (as in Smith-Lemli-Opitz syndrome or Seckel syndromes).

Nevertheless, a proportion of these seemingly unexpected conditions have known, identifiable risk factors, such as advanced maternal age for chromosome aneuploidies, advanced paternal age for de novo dominant mutations, parental consanguinity for autosomal recessive syndromes, teratogen exposures, such as fetal alcohol syndrome and chronic uncontrolled maternal illnesses, such as diabetes mellitus or phenylketonuria. Hence, the Latin American Collaborative Study of Congenital Malformations (ECLAMC, for Estudio Colaborativo Latinomericano de Malformaciones Congénitas) has proposed a "Decalogue for Prevention of Congenital Anomalies" focused on the avoidance of known risk factors such as unintended pregnancy, advanced maternal age, deficient prenatal controls, rubella, self-medication, alcohol, smoking, malnutrition, occupational risks, and poor health care.

In addition to these preconceptional preventative measures, options are available for antenatal screening or diagnosis of several syndromes. First and second trimester screening for common aneuploidies such as trisomies 21 and 18 is usually performed by a combination of maternal age, ultrasound markers (most commonly nuchal translucency), and/or biochemical markers. Screening has incidentally been found to be useful to identify fetuses at risk for other conditions such as Smith-Lemli-Opitz syndrome as well as adverse perinatal outcomes. Fetal ultrasound is also useful to identify structural anomalies that may suggest the existence of a syndrome. These screening procedures are useful to select pregnancies that warrant further studies, such as invasive karyotype or molecular testing (by chorionic villous sampling, amniocentesis or chordocentesis) or additional studies such as fetal magnetic resonance imaging.

Education is also a crucial part of prevention. This can be accomplished through genetic counseling, defined as "the process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease" (National Society of Genetic Counselors, www.nsgc.org). This process includes, in the case of congenital malformation syndromes, providing information to the patient and/or family about the specific diagnosis, mode of inheritance, occurrence or recurrence risks, and the available therapeutic and preventative alternatives.

Case Histories

Case 1

You are called to evaluate a term adequate-for-gestational-age (AGA) newborn with feeding difficulties and respiratory distress. On physical examination you note that the

newborn shows mild tachypnea with mild intercostal retractions but normal pulse oxymetry in the supine position. You find that she has microretrognatia and a cleft of the soft palate, without other evident anomalies. You position her on her side and the respiratory rate and pattern normalize. The pregnancy history is unremarkable. The mother has high myopia and a history of chronic joint pain, and has been given the diagnosis of arthritis of unknown etiology; the rest of the family history is noncontributory. Given the association of microretrognathia, cleft palate, and respiratory difficulties, you consider that she has Robin sequence. This malformation could be "non-syndromic," of unknown cause, or perhaps due to fetal crowding or decreased intrauterine mobility. You also learn that about 40–50% of cases can be caused by syndromes, the most common ones being 22q11 microdeletion (or velo-cardio-facial) syndrome (◉ *Fig. 3.9*) and Stickler syndrome (◉ *Fig. 3.10*), a connective tissue disorder due to mutations in *COL2A1*, *COL1A1*, *COL9A1*, or *COL11A1*, genes encoding for collagen chains. Karyotype and FISH 22 studies are normal in your patient, and you request an ophthalmologic evaluation that shows that the newborn has high myopia, like her mother. Stickler syndrome is characterized by arthropathy, flat vertebrae, myopia with risk of retinal detachment, Robin sequence, and deafness. You review the maternal X-rays, and they are consistent with this diagnosis. You conclude that the newborn and her mother have Stickler syndrome, and in addition to managing her airway and feeding problems, you make a plan to continue to follow the baby's and mother's vision and hearing, as well as future musculo-skeletal manifestations. The family is counseled that Stickler syndrome is inherited as an autosomal dominant condition and that the probabilities of recurrence are 50% for each subsequent pregnancy. Molecular analysis of the *COL2A1* gene identifies the causative mutation, information that may be used for prenatal diagnosis or other at-risk relatives.

Case 2

A term AGA, 5-day old newborn boy has hypotonia and feeding difficulties, with loss of 12% of his birth weight. On physical examination, he is noted to have a narrow forehead, small hands and feet, small male genitalia, and cryptorchidism. He has moderate hypotonia, poor Moro and suck reflexes, and normal deep tendon reflexes. He is also noted to have hypopigmentation of his skin, hair, and irides compared with his family. He is diagnosed with central hypotonia. Brain imaging studies are normal. Given his findings, the diagnosis of Prader-Willi syndrome (PWS) is considered. Confirmatory genetic studies show a normal karyotype, absent paternal contribution on chromosome 15 methylation analysis, and a microdeletion in the proximal part of chromosome 15 (15q11q13), consistent with the suspected diagnosis. PWS is a genetic disorder due to the absence of the paternal genes in chromosome region 15q11q13. In this case, it was due to a small deletion in the region. PWS is characterized by neonatal central hypotonia with transient feeding difficulties and failure to thrive in the first year or two of life. Children subsequently develop hyperphagia and obesity, short stature, hypogonadism, developmental delays, and mild to moderate mental retardation. Given the transient nature of the infantile feeding difficulties, nasogastric tube feedings were started on the patient, and referral was made to an Early Intervention Program, as well as follow up by an endocrinologist. PWS due to 15q11q13 microdeletion is usually a sporadic condition, and the parents were informed that the risk of recurrence in future pregnancies is probably low (≈1% or less).

4 Cytogenetic Testing and Chromosomal Disorders

Joris Robert Vermeesch · Karen Buysse

Cytogenetic Testing

It took until 1956 before the correct number of human chromosomes of 46/cell was determined by Tjio and Levan. The discovery of the correct number of human chromosomes lead to the subsequent discovery that trisomy 21 is the cause of Down syndrome. Soon thereafter, a series of associations of different birth defects with specific chromosomal imbalances became apparent. First, the chromosomes 13 trisomy (Patau syndrome), trisomy 18 (Edwards syndrome), and monosomy and trisomy X syndromes were identified. Subsequently, smaller segmental chromosomal imbalances such as 5p- and 4p- were proven to cause birth defects. These associations launched cytogenetic genetic testing as a routine diagnostic tool and resulted in systematic screening for children with birth defects. These screenings, in turn, resulted in the identification of thousands of chromosomal imbalances associated with specific syndromic features.

Initially, chromosome studies were performed using simple staining techniques that only allowed the detection of entire groups of chromosomes. The degree of precision was increased in the 1970s with the introduction of chromosome banding techniques. These techniques enabled the detection of individual chromosomes and segments (bands) within chromosomes. Although chromosomal karyotyping allows a genome-wide detection of large chromosomal abnormalities and translocations, it has a number of inherent limitations: (1) it takes 4–10 days to culture the cells, visualize the chromosomes and perform the analysis; (2) the resolution is limited to 5–10 Mb depending on (a) the location in the genome, (b) the quality of the chromosome preparation, and (c) the skill and experience of the cytogeneticist; (3) it requires skilled technicians to perform a Giemsa-banded karyotype analysis, which increases employment costs and can lead to organizational difficulties in small laboratories.

With the introduction of fluorescence in situ hybridization (FISH), the detection of submicroscopic chromosomal imbalances (imbalances not visible by conventional karyotyping because they are too small) became possible. In FISH, labeled DNA probes are hybridized to nuclei or metaphase chromosomes to detect the presence, number, and location of small (submicroscopic) regions of chromosomes. FISH is routinely applied to confirm the clinical suspicion of known microdeletion syndromes. Some common examples are the detection of the velocardiofacial (VCFS, 22q11 deletion, OMIM 192430), William's (7q11.23 deletion, OMIM 194050) and Prader-Willi (15q11.2–13 deletion, OMIM 176270) syndromes. FISH also detects deletions in the gene-rich subtelomeres, which are involved in mental retardation and a number of syndromes, such as the Wolf–Hirschhorn (deletion 4p, OMIM 194190) and chromosome 1p36 deletion (OMIM 607872) syndromes.

Unfortunately, FISH can only detect individual DNA targets rather than the entire genome. To overcome this problem, multicolor FISH–based karyotyping (SKY, MFISH, and COBRA FISH) was developed, which enables simultaneous detection of all chromosomes. Another technology allowing the genome-wide detection of copy number aberrations was introduced in 1992 and termed comparative genomic hybridization (CGH). In CGH, test and reference genomic DNAs are differentially labeled with fluorochromes and then co-hybridized onto normal metaphase chromosomes. Following hybridization, the chromosomes are scanned to measure the fluorescence intensities along the length of the normal chromosomes to detect intensity ratio differences that subsequently pinpoint to genomic imbalances. Overall, the resolution at which copy number changes can be detected using these techniques are only slightly higher as compared to conventional karyotyping (>3 Mb) and experiments are labor intensive and time consuming.

By replacing metaphase chromosomes with mapped DNA sequences or oligonucleotides arrayed onto glass slides as individual hybridization targets, the resolution could be tremendously increased. Following hybridization of differentially labeled test and reference genomic DNAs to the target sequences on the microarray, the slide is scanned to measure the fluorescence intensities at each

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_4,

target on the array. The normalized fluorescent ratio for the test and reference DNAs is then plotted against the position of the sequence along the chromosomes. Gains or losses across the genome are identified by values increased or decreased from a 1:1 ratio ($\log_2$ value of 0), and now the detection resolution only depends on the size and the number of targets on an array and the position of these targets (their distribution) on the genome. A schematic overview of the technique is provided in *Fig. 4.1*. This methodology was first described in 1997 and is termed "matrix CGH" or "array CGH". Array CGH has initially been employed to analyze copy number changes in tumors with the aim to identify genes involved in the pathogenesis of cancers. More recently however, this methodology has been optimized and applied to detect unbalanced constitutional human rearrangements. With improved protocols, it rapidly became clear that not only larger insert BAC clones were appropriate targets for array CGH, but also smaller-sized cDNA fragments, PCR products, and oligonucleotides. In addition to comparative hybridization using two differentially labeled DNA samples, single sample hybridization can also be compared versus different reference arrays. This approach is the basis of the so-called SNP arrays.

Genome-wide array CGH has been called molecular karyotyping in analogy with conventional karyotyping. Because many cytogeneticists object to this term, most recently, the term "cytogenomic array" has been put forward to refer to high-resolution array-based whole genome testing for genomic copy number (recommendation of the consortium of International Standards on Cytogenomic Arrays (ISCA), https://isca.genetics.emory.

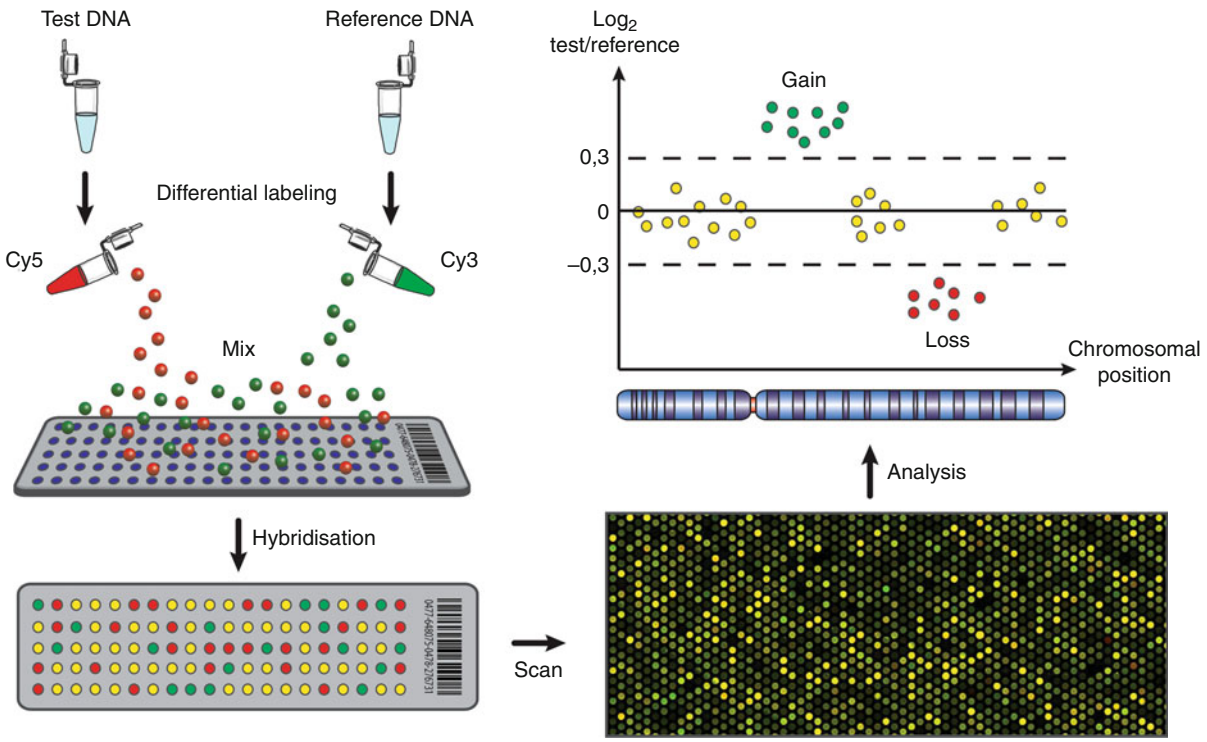

Figure 4.1

Principle of array CGH. Equal amounts of test and reference DNA are differentially labeled with fluorochromes (e.g., Cy5 and Cy3), mixed and when necessary supplemented with Cot-1 DNA to block repetitive sequences. This mixture is denatured and hybridized on a microarray slide on which DNA probes (e.g., BACs or oligonucleotides) are immobilized. Slides are scanned and fluorescent intensities quantified from the image. Signal intensity ratios are plotted corresponding to the genomic position of the DNA probe and represent the relative DNA copy number of the test DNA in comparison with the reference DNA

edu/iscaBrowser/learnabout.jsp). The implementation of genome-wide arrays as a tool to screen children with developmental anomalies has increased the diagnostic yield significantly. A series of early studies showed diagnostic yields between 9% and 25%. A meta-analysis of patients with congenital and mental anomalies on 13,926 subjects reported an overall diagnostic rate of 10% for causal anomalies and a retrospective analysis of 36,325 patients revealed abnormalities in about 19% of the patients. While conventional G-banding has a diagnostic yield of about 3% in similar patient populations, it can be concluded that molecular karyotyping is outperforming conventional karyotyping for the detection of causative chromosomal imbalances in patients with birth defects. Therefore, the technology is currently complementing traditional cytogenetic testing and is recommended as a first-tier diagnostic test for children with developmental disorders.

Types and Incidences of Chromosomal Abnormalities

Microscopically Visible Chromosomal Imbalances

All chromosomal imbalances that can be detected by conventional karyotyping are microscopically visible. These aberrations are either numerical (abnormal chromosome number) or structural (altered structure).

Numerical Chromosome Aberrations

Normal humans are diploid, meaning they have 22 pairs of autosomes and one pair of sex chromosomes. The presence of three sets (triploidy) or four sets (tetraploidy) can occasionally occur; however, these are not viable.

Numerical aberrations result from the loss (monosomy) or gain (trisomy) of an individual chromosome. Autosomal monosomies are inviable, while the absence of one X chromosome may result in a liveborn girl with Turner syndrome (45,X). A few autosomal trisomies are compatible with life. Fetuses with trisomy 13 (Patau syndrome) and trisomy 18 (Edwards syndrome) can survive to term but usually die shortly after birth due to severe congenital anomalies. Individuals with trisomy 21 (Down syndrome) can stay alive longer, with an average life span reaching up to 55 years. In addition, sex chromosomal trisomies and tetrasomies are often encountered; the best known is Klinefelter syndrome (47,XXY).

Structural Chromosome Aberrations

Structural chromosomal aberrations result from double-strand breaks and inappropriate DNA repair leading to translocations, deletions, duplications, inversions, isochromosomes, and ring chromosomes (*Fig. 4.2*). They may involve single or multiple chromosomes. One can distinguish rearrangements without and with loss or gain of chromosomal segments. The former are most often not associated with an abnormal phenotype, while the latter most often cause developmental disorders. Carriers of apparently balanced rearrangements, however, are at risk for having children with chromosomal imbalances.

In translocations, chromosomal segments between two or more chromosomes are exchanged. Robertsonian translocations are translocations between two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22). There is no loss of euchromatin and the carriers are normal. In reciprocal translocations, segments between two chromosomes are exchanged. The translocation is termed balanced if no chromosomal material has been lost or gained. Inversions represent a special type of apparently balanced rearrangement. In an inversion, the rearrangements occur intrachromosomally and a chromosomal segment is inverted. If the inversion occurs within one chromosomal arm it is called "paracentric" (not including the centromere); if it occurs in two chromosomal arms it is termed "pericentric" (spanning the centromere). Carriers of balanced translocations and inversions are usually normal, but developmental anomalies are detected in 6% of de novo translocation carriers. The presence of a developmental disorder can be due to (1) the breakage of a gene resulting in a dominant disorder or in a recessive disorder if the second allele is also mutated, (2) a position effect on a gene flanking the breakpoint, or (3) the gain of function via the creation of a fusion gene. Recently, it was shown that 40% of the apparently balanced translocation carriers with developmental disorders have submicroscopic imbalances at the breakpoints or elsewhere in the genome that may be disease causing.

If genetic material is gained or lost, the abnormality is called unbalanced. If there is loss of a chromosomal segment it is called a deletion, or if there is a gain, a duplication. The presence of both a large deletion and duplication suggests the presence of an unbalanced translocation. Those usually result from the transmission of the unbalanced products during the meiosis of a balanced translocation-carrying parent. Occasionally unbalanced

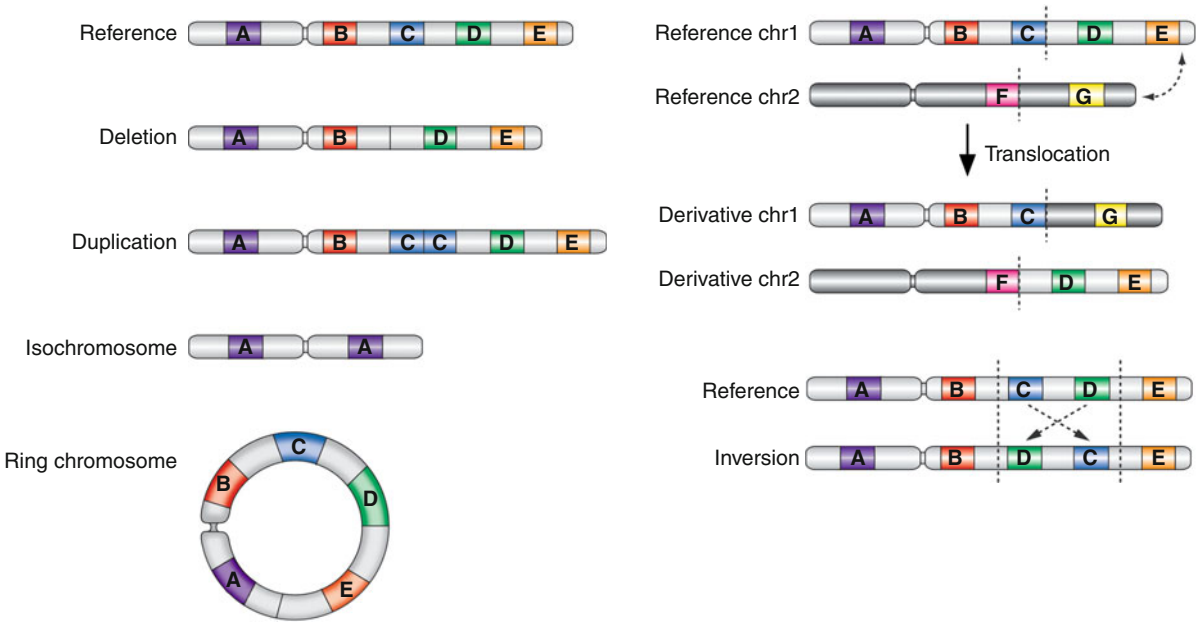

Figure 4.2

Schematic overview of structural chromosomal rearrangements. A deletion results in the loss of chromosomal material (segment C), while there is a gain of material (two copies of part C) in a duplication. Duplication of one arm and deletion of the other arm gives rise to an isochromosome, while fusion of the short and long arms of a chromosome leads to a ring chromosome. In a translocation, part of one chromosome is transferred to another chromosome. In this example, there is an exchange between segments D and E of chromosome 1 and segment G of chromosome 2. An inversion results in a reversed orientation of genetic material (inversion of segments C and D)

translocations arise de novo. The deletion or duplication of one or more dosage-sensitive genes usually results in developmental disorders.

Incidence of Chromosomal Abnormalities

Studies performed in the late 1960s and early 1970s (i.e., before the widespread use of prenatal diagnosis and pregnancy intervention) provide estimates for the frequencies of chromosomal abnormalities at birth. A combined survey of 68,159 livebirths and of 34,910 liveborns found that 0.65–0.84% of newborns or 1 in 119–154 livebirths had a major chromosomal abnormality (*Table 4.1*). Trisomy 21 (Down syndrome) was shown to be the most frequent chromosomal anomaly, with an incidence of 1.2–1.7/1,000 liveborns. Sex chromosome aneuploidies were the next most common, with approximately one XYY and one XXY in every 900–1,000 male and one XXX in every 900–1,000 female livebirths. Structural balanced rearrangements had a frequency of approximately 2/1,000 livebirths.

Structural rearrangements can occur de novo or be the consequence of the unbalanced transmission of a parent carrying a chromosomal rearrangement. However, all arose de novo at one point. It is estimated that de novo balanced reciprocal translocations arise at birth with a frequency of 1.6×10^{-4} and unbalanced rearrangements with a frequency of 2.9×10^{-4}.

Submicroscopic Imbalances

The first methodology to enable the visualization of imbalances below the resolution of regular light microscopes was FISH. Recurrent syndromes were proven to be caused by recurrent submicroscopic imbalances. Once the imbalance was characterized, metaphase spreads or interphase nuclei of patients with similar phenotypes could be screened with locus specific probes for the loss or gain of a specific locus. This methodology requires careful clinical examinations in order to instigate appropriate genetic testing.

Table 4.1
Incidence of chromosomal abnormalities in newborns

Type of abnormality	Rate per 1,000 Benn and Hsu (2004)	Rate per 1,000 Nielsen and Wohlert (1991)
Autosomal trisomies		
+13	0.04	0.09
+18	0.13	0.29
+21	1.2	1.69
Sex chromosomes males		
47,XYY	1.03	1.18
47,XXY	1.03	1.57
Other	0.73	0.17
Sex chromosomes females		
45,X	0.24	0.53
47,XXX	1.09	1.06
Other	0.36	0.06
Structural balanced		
Robertsonian	0.9	1.23
Reciprocal and insertional	1.21	1.74
Structural unbalanced		
Deletions & duplications	0.4	0.34
Marker chromosomes	0.2	0.66
Total	6.24	8.42

With the advent of cytogenomic arrays, a true revolution in the analysis of genomes in general and especially the analysis of the genomes of patients with mental retardation and developmental anomalies is taking place for two reasons: (1) It has now become possible to screen the genome at very high resolution for copy number changes and (2) no *a priori* clinical identification is required to enable correct cytogenetic testing. In the last 5 years, more pathogenic copy number changes have been linked to developmental disorders than in the 50 years before.

Recurrent Submicroscopic Rearrangements

Recurrent imbalances often result from nonallelic homologous recombination (NAHR) between low-copy repeats (LCRs) flanking the commonly deleted or duplicated region (see Recurrent Submicroscopic Imbalances). Many of such recurrent imbalances, also known as *genomic disorders*, were identified before the array era and were often known as clinically well-delineated syndromes and are typically screened for by FISH. The first recurrent imbalance identified was the imbalance at 17p12 associated with Charcot-Marie-Tooth disease type 1A (CMT1A, OMIM 118220). A list of well-known recurrent submicroscopic imbalance syndromes is shown in *Table 4.2*. With the advent of molecular karyotyping, a series of novel recurrent imbalances causal for or associated with MR/MCA (mental retardation/multiple congenital anomalies) have been identified and these are listed in *Table 4.3*.

Nonrecurrent Submicroscopic Rearrangements

For several genomic regions, overlapping rearrangements have been identified that show variable breakpoints in each patient. Despite the different sizes, these nonrecurrent imbalances share a shortest region of overlap (SRO) for which a copy number change may lead to similar phenotypes in different patients. Two pertinent examples are the *MECP2* gene duplications at Xq28 and the 12q14 microdeletion syndrome.

Table 4.2

Microdeletion/duplication syndromes associated with developmental disorders identified before the advent of array CGH

Syndrome	Chromosome location	Deletion incidence	Parental origin	Deletion size (Mb)	Gene (incidence)
Sotos	5q35	ND	Paternal (90%)	2.2	*NSD1* (10%)
Williams	7q11.23	1/20,000–1/50,000	Equal	1.6	CGS
8p deletion	8p23.1	ND	Maternal	5	CGS
Prader–Willi	15q11.2–13	1/20,000	Paternal	3.5	CGS
Angelman	15q11.2–13	1/20,000	Maternal	3.5	*UBE3A* (10–15%)
Smith–Magenis	17p11.2	1/25,000	Equal	4	*RAI1* (ND)
Neurofibromatosis 1	17q11.2	1/40,000–1/80,000	Maternal	1.5	*NF1* (90–95%)

Table 4.3

Newly recognized interstitial microdeletion/duplication syndromes identified by array CGH and associated with developmental disorders

Name	Size (Mb)	OMIM	Clinical features	Reference
1q21 microdeletion (TAR syndrome)	0.5	27400	Hypomegakaryocytic thrombocytopenia and bilateral radial aplasia	(Klopocki et al. 2007)
1q21 microdeletion & microduplication	1.35	612474 and 612475	Asymptomatic to severe developmental delay and multiple congenital anomalies, susceptibility locus for neuropsychiatric disorders	(Brunetti-Pierri et al. 2008; Mefford et al. 2008)
3q29 microdeletion	1.6	609425	MR, mild FD including high nasal bridge and short philtrum	(Ballif et al. 2008; Willatt et al. 2005)
3q29 microduplication	1.6	611936	Mild/moderate MR, MC, obesity	(Ballif et al. 2008; Lisi et al. 2008)
7q11.23 microduplication	1.5	609757	MR, speech and language delay, autism spectrum disorders	(Somerville et al. 2005)
15q13.3 microdeletion	1.5	612001	MR, epilepsy, FD, digital dysmorphisms	(Sharp et al. 2008)
15q24 microdeletion	1.7		MR, growth retardation, MC, digital abnormalities, genital abnormalities	(Sharp et al. 2007)
16p13.11 microdeletion	1.7		MR, MC, seizures	(Hannes et al. 2009; Ullmann et al. 2007)
17p11.2 microduplication	3.7	610883	MR, infantile hypotonia, autistic features	(Potocki et al. 2007)
17q21.31 microdeletion	0.5	610443	MR, hypotonia, typical face	(Koolen et al. 2006; Sharp et al. 2006; Shaw-Smith et al. 2006)
22q11.2 distal microdeletion	1.4–2.1	611867	MR, growth delay, mild skeletal abnormalities, FD.	(Ben-Shachar et al. 2008)

FD facial dysmorphism, *MC* microcephaly, *MR* mental retardation

Mechanisms Causing Genomic Disorders

Mutations causing chromosomal rearrangements can occur during both meiosis and mitosis. Classically, meiosis has been considered the main period during which chromosomal rearrangements occur. Chromosomes are very active during meiosis, because the homologues pair, synapse, and crossover. During this process, multiple DNA nicks are generated and it is likely that some of the rearrangements originate as a result of these processes. The recent discovery of large-scale chromosomal rearrangements in the cleavage stage embryo makes it likely that many chromosomal rearrangements originate at this time. How the chromosomal breaks originate remains unclear.

Aneuploidies

The majority of aneuploidies arise via meiotic nondisjunction events, though mitotic nondisjunction events are also a frequent cause of constitutional aneuploidies. Nondisjunction is defined as the failure of homologous chromosomes to segregate symmetrically at cell division. If the pair of homologues comprising a bivalent at meiosis I fail to separate, one daughter cell will have two of the chromosomes while the other will have none (*Fig. 4.3a*). Nondisjunction may also occur in meiosis II when the chromatids fail to separate (*Fig. 4.3b*). In both meiotic errors, the conception ends up trisomic or monosomic. The majority of the nondisjunction events appear to occur at meiosis I. An alternative mechanism for nondisjunction is premature separation of the chromatids. First, homologues fail to pair during meiosis I. These univalents are prone to predivide, that is, separation of the two chromatids, and subsequently these chromatids segregate independently (*Fig. 4.3c*). Since the frequency of meiotic errors increases with advanced maternal age, not surprisingly the overwhelming majority of aneuploidies are of maternal origin.

Recurrent Submicroscopic Imbalances

Recurrent rearrangements are often flanked by low-copy repeats (LCRs). LCRs or segmental duplications (SDs) are segments of DNA that map to two or more genomic locations, are >1 kb in size and share a sequence identity of at least 90%. Segmental duplications account for about 5% of the human genome. Due to their high degree of sequence homology, these segmental duplications provide substrates for nonallelic homologous recombination (NAHR) in which crossing over occurs between two similar sequences at nonallelic positions that erroneously align in mitosis or meiosis (*Fig. 4.4*). Depending on their location and orientation, they give rise to various types of rearrangements. Misalignment and subsequent recombination between two LCRs that are in direct orientation on the same chromosome cause deletions and duplications, while inversions are driven by LCRs that are in

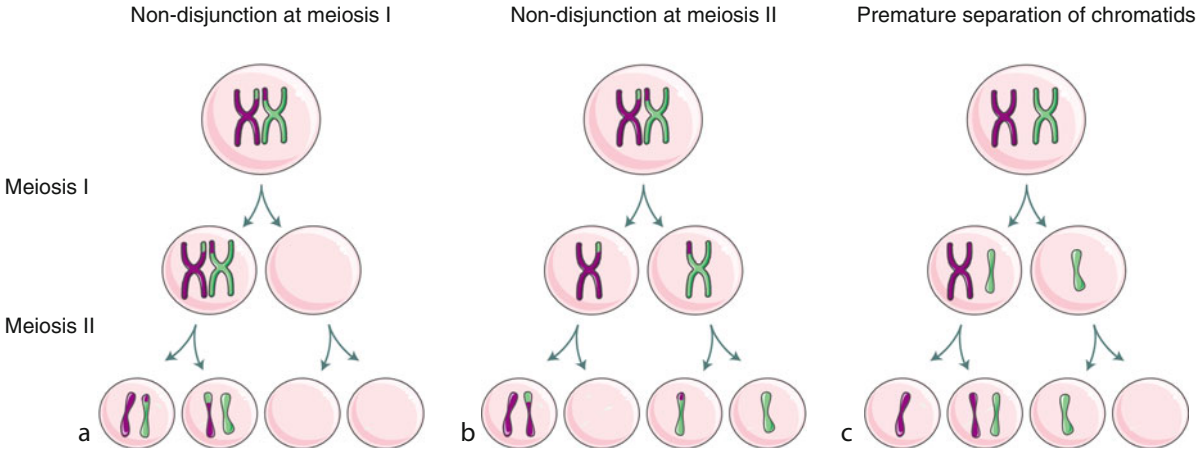

Figure 4.3

Different possibilities for nondisjunction during meiosis leading to trisomic or monosomic conceptions. (a) Nondisjunction at meiosis I; (b) nondisjunction at meiosis II; (c) premature separation of the chromatids of one of the homologous chromosomes at meiosis I and subsequent random migration of the chromatid to either pole at meiosis II

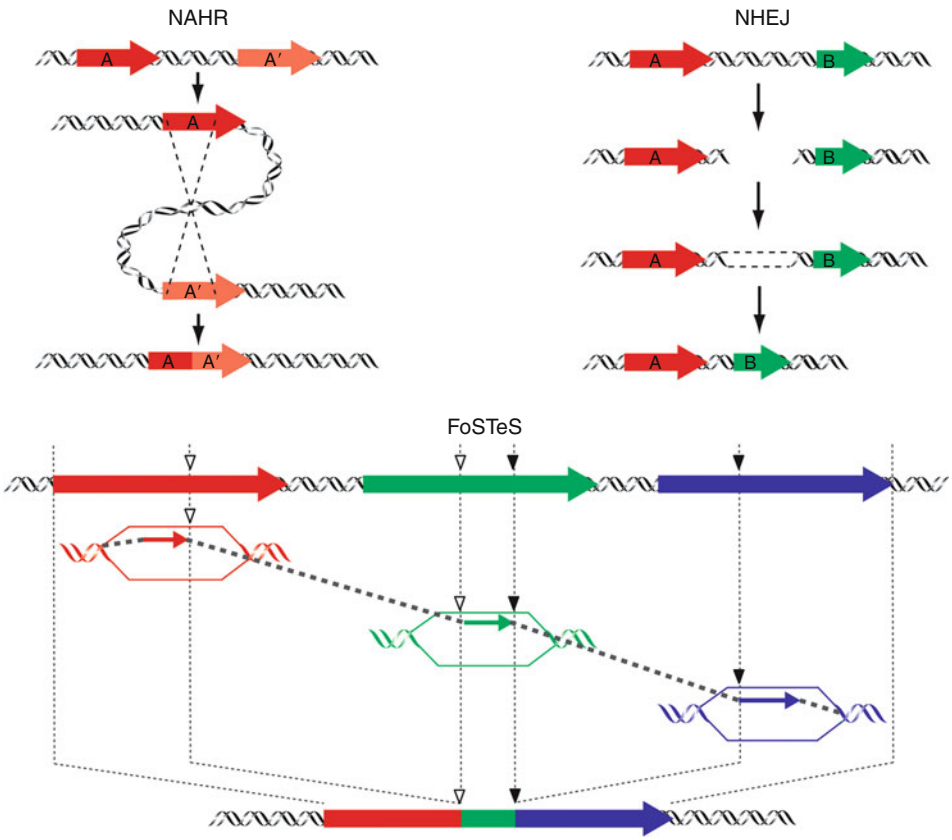

Figure 4.4

Schematic representation of nonallelic homologous recombination (NAHR), nonhomologous end-joining (NHEJ), and Fork Stalling and Template Switching (FoSTeS) mechanisms that lead to chromosomal rearrangements. The examples shown here lead to genomic deletion. *Upper left panel*: an intrachromatid NAHR event. The arrows A and A′ depict two highly homologous low-copy repeats (LCRs) that are in direct orientation. The LCRs align at nonallelic positions and subsequent recombination results in deletion of part of the two LCRs and the segment in between them. *Upper right panel*: a NHEJ event. Double-strand breaks (DSB) occur between two sequences that share no homology, represented as differently sized arrows (A and B). The NHEJ system modifies and rejoins the two ends, resulting in the deletion of the segment between the two DSBs. *Lower panel*: a FoSTeS × 2 event. The arrows depict three substrate sequences that do not share extensive homology. However, the small open and filled triangles depict a site of microhomology between the respective sequences. The leading strand of the first fork invades the second fork via the site of microhomology and primes its own further synthesis using the second fork as template. This event happens again between the second and third fork, leading to the deletion of the two fragments flanked by each pair of microhomology sites. This results in the juxtaposition of genomic sequences from multiple distinct regions yielding a complex deletion (Adapted from Gu W, Zhang F, Lupski JR (2008) Mechanisms for human genomic rearrangements. Pathogenetics 1:4)

opposite orientation on the same chromosome. NAHR between LCRs on different (nonhomologous) chromosomes leads to translocations. Recombination may occur between LCRs on the same chromatid (intrachromatid), on sister chromatids (intrachromosomal or interchromatid) or on homologous chromosomes (interchromosomal). The efficiency of NAHR is influenced by the distance, size, and degree of homology between two LCRs. Larger genomic rearrangements tend to correlate with larger LCRs and most genomic disorders result from NAHR between LCRs that are 10–400 kb in length and have >96% sequence identity.

NAHR can also be mediated by highly homologous repetitive sequences such as *Alu*'s (a class of SINEs, short interspersed nuclear elements) and LINEs (long interspersed nuclear elements) or LTRs (long terminal repeats), thus accounting for some of the nonrecurrent rearrangements.

The incidence of those recurrent genomic disorders varies and their estimated incidence for well-established recurrent disorders is indicated in *Table 4.2*.

Nonrecurrent Submicroscopic Imbalances

Nonhomologous End-Joining (NHEJ)

NHEJ is one of the two major repair mechanisms (the other being homologous recombination) for double-strand breaks (DSB) in mammals. After detection of the DSB and molecular bridging of the broken DNA ends, modifications are made to the ends to make them compatible for the final ligation step (*Fig. 4.4*). This process implies two important characteristics of NHEJ: it does not require sequence homology at the breakpoints and it leaves an "information scar" at the rejoining site due to the addition or deletion of several nucleotides. Interestingly, breakpoints of nonrecurrent rearrangements that are apparently caused by NHEJ are often located within LCRs or repetitive elements such as LTR, LINE, *Alu,* and MER2 DNA elements. This indicates that NHEJ may be stimulated and regulated by specific genomic features.

Fork Stalling and Template Switching (FoSTeS)

By breakpoint sequence analysis of nonrecurrent *PLP1* duplications associated with Pelizaeus-Merzbacher disease, Lee et al. discovered an unexpected complexity that is inconsistent with a simple recombination model. Within the duplicated sequence, they found interspersed stretches of DNA that were triplicated or of normal copy number and additional sequence complexity at the junctions. They proposed a model of replication Fork Stalling and Template Switching to explain these complex duplication and deletion rearrangements. During DNA replication, the replication fork stalls or pauses at a DNA lesion and the leading or the lagging strand disengages and switches to another replication fork where it anneals on the invaded site by virtue of microhomology and restarts DNA synthesis (*Fig. 4.4*). The replication forks are in physical proximity, but may be separated by sizeable linear distances, even megabases away. This procedure of disengaging, invading/annealing and synthesis/extension could occur multiple times in series (that is FoSTeS × 2, FoSTeS × 3 and so on), causing the observed complex rearrangements. Depending on whether the invaded fork is located downstream or upstream, this will result in a deletion or a duplication event, respectively.

Interestingly, the genomic positions at which FoSTeS occurs show a very complex genomic architecture including multiple LCRs, cruciforms, and palindromes that may stimulate and facilitate the FoSTeS mechanism. As opposed to NAHR and NHEJ, a single-strand DNA lesion is the initiating damage rather than a double-strand break.

Microhomology-Mediated Break-Induced Replication (MMBIR)

As an alternative to FoSTeS, the MMBIR model has been proposed in which the rearrangement is initiated by a single-end double-strand DNA break resulting from a collapsed replication fork. This model is based on the break-induced replication model observed in yeast. The single-strand 3′ tails from the broken replication fork will anneal with microhomology on any single-stranded DNA nearby, where it forms a new replication fork. The replication in this new fork is of low processivity and the extended end will dissociate and invade different templates. Multiple template switches generate complex rearrangements until there is reestablishment of processive replication (*Fig. 4.5*). Again, complex genomic architecture may play a role in this process by generating secondary DNA structures such as cruciforms and hairpin loops that expose single-stranded sequence.

Molecular Mechanisms Leading to Phenotypes

There are several ways in which chromosomal rearrangements can lead to a clinical phenotype. The most obvious mechanism is altering the copy number of dosage-sensitive genes that are encompassed within the rearrangement (*Fig. 4.6a*). When the breakpoint is located within a gene, it will be disrupted, leading to loss-of-function. The disruption can occur either through deletion (*Fig. 4.6b*), duplication, or translocation, as well as inversion (*Fig. 4.6c*). Alternatively, new transcripts can be created at the breakpoint through gene fusion (*Fig. 4.6d*) or exon shuffling. This leads to gain-of-function mutations, a mechanism that is

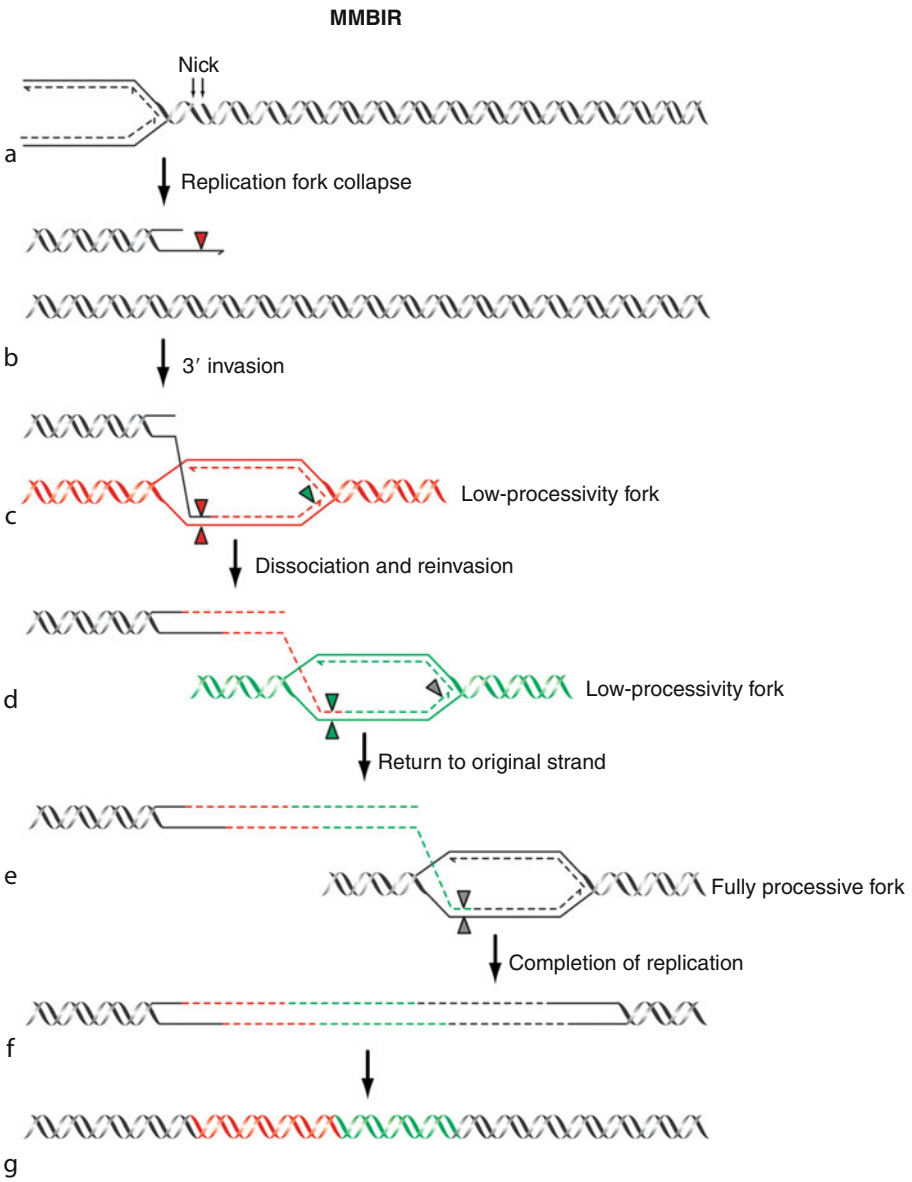

Figure 4.5

Schematic representation of microhomology-mediated break-induced replication (MMBIR). Successive switches to different genomic positions forming microhomology junctions (filled triangles) are shown. When a replication fork encounters a nick in a template strand (a), one arm of the fork breaks off, producing a collapsed fork (b). The single-stranded 3′ end will invade a site of microhomology (filled triangle) and form a new low-processivity fork (c). The extended end will dissociate repeatedly and reform the fork on different templates, using sites of microhomology (d). When the switch returns to the original sister chromatid (e) it will form a processive replication fork that completes replication (f). The final product contains sequences from different regions (g). Whether the return to the sister chromatid occurs in front of or behind the position of the original collapse determines if there is a deletion or duplication (Adapted from Hastings PJ, Ira G, Lupski JR (2009) A microhomology-mediated break-induced replication model for the origin of human copy number variation. PLoS Genet 5:e1000327)

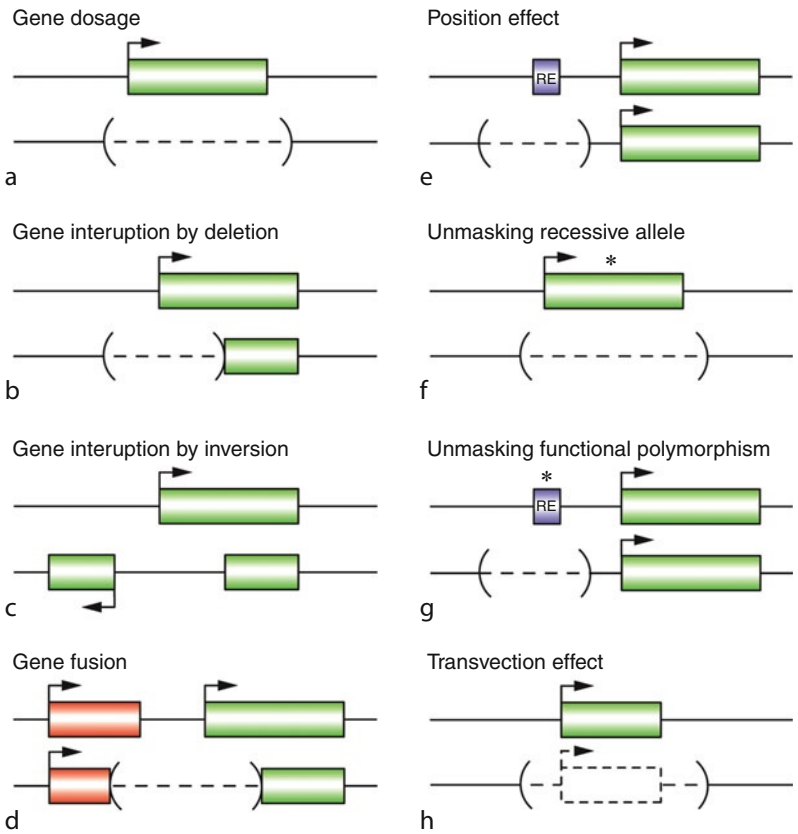

Figure 4.6

Molecular mechanisms by which chromosomal rearrangements can influence phenotypes. The rearrangement can encompass a dosage-sensitive gene that causes disease (a); disrupt a dosage sensitive gene through deletion (b); duplication, translocation or inversion (c); create a fusion gene (d); exert a position effect by affecting a regulatory element (e); unmask a recessive allele (f) or functional polymorphism (g) on the homologous chromosome; and interrupt effects of transvection (h) where the deletion of a gene affects communication between alleles. Genes are depicted as rectangles, regulatory elements as RE and an asterisk (*) indicates a point mutation (Adapted from Lupski JR, Stankiewicz P (2005) Genomic disorders: molecular mechanisms for rearrangements and conveyed phenotypes. PLoS Genet 1:e49 and Feuk L, Carson AR, Scherer SW (2006) Structural variation in the human genome. Nat Rev Genet 7:85–97)

prominent amongst cancers associated with specific chromosomal translocations. The rearrangement can also influence the regulation of a nearby gene by position effects (*Fig. 4.6e*). Deletion, duplication, or translocation of important regulatory elements may alter gene expression at distances as far as ~1 Mb from the target gene. Dosage-insensitive genes can also cause disease if a deletion of the gene unmasks a recessive mutation or a hypomorphic allele on the homologous chromosome (*Fig. 4.6f*) or when the deletion unmasks a functional polymorphism in a regulatory element of the remaining allele (*Fig. 4.6g*). Another way in which deletions can convey a phenotype is by interrupting transvection, where communication and interaction between two alleles on homologous chromosomes is disturbed (*Fig. 4.6h*).

Indications for Cytogenetic Testing

Indications in Children

Intellectual disability and developmental disorders affect up to 3% of the population and remains to this day an enormous etiological challenge. The finding of the cause is of great importance not only to the individual, his or her parents, and family but also to the treating physician. For

the individual, it adds to the identification of appropriate medical and related therapies, indicates medical interventions/referrals, presymptomatic screening for associated complications, educational planning, and elimination of further unnecessary evaluations. For the family, it forms a step toward the acceptance of the disability and the basis to understanding the cause, the reason and the recurrence risks. Carrier testing and reproductive options become a reality. It also allows social support and contact with other similarly affected families. The ongoing etiological evaluation in a bid to attain a diagnosis does thus have a significant role to play in the all-round care of the intellectually disabled individual and the family.

The etiology of intellectual disability is extensive and ranges from acquired/environmental (sequelae of prematurity, pre- and postinfections, trauma, and neurotoxicity – alcohol, metals), to chromosomal (aneuploidy, genomic imbalances – microdeletions and duplications), and to monogenic disorders. The rate of etiological diagnosis is influenced by the level of the intellectual disability – the more severe, the higher the diagnostic success. A systematic literature review of the usefulness of classical karyotyping, subtelomere screening, and molecular genetics investigations in institutionalized individuals with mental retardation indicated 0% etiological detection in borderline to mildly retarded individuals as opposed to 6.5% (range 0.8–13.0%) in those moderately to severely/profoundly retarded. Also, the differences in setting, the patient selection criteria, study protocols, technological advances, definition of a positive diagnosis, method of classification, and expertise of the clinician have been factors resulting in the varying rate of diagnosis.

In a systematic etiological study of 471 institutionalized individuals with mild to profound intellectual disability, 92.6% of which were males, Van Buggenhout et al. reported 49.5% without known cause. Chromosomal anomalies accounted for 21.2% (87 or 18.5% of the 471 individuals had Down syndrome), monogenic disorders 13%, and acquired causes 14.6%.

This was, however, before the era of array comparative genomic hybridization (array CGH). The initial studies using this new technology on selected cohorts of individuals with an intellectual disability and dysmorphism made use of around 3,500 BAC clones, resulting in an average resolution of 1 Mb. The rate of genomic imbalance detection was between 9% and 25%. The few studies at higher, 100 kb resolution, have also detected about 10% of pathogenic submicroscopic aberrations. The chromosome imbalances occur throughout the genome. Once the validity of the technique to detect chromosomal constitutional imbalances was demonstrated it was rapidly introduced into the genetic diagnostic laboratories as a routine technique in the genetic diagnostic workup of patients with learning disabilities and/or multiple congenital anomalies.

In addition to the identification of pathogenic imbalances in patients with intellectual disabilities, several studies have proven associations of copy number variants (CNVs) with several other conditions or specific patient groups: Lu et al. reported an incidence of 17.1% imbalances in neonates with various birth defects. Thienpont et al. report a frequency of 17% causal imbalances in patients with heart diseases. Finally, CNVs are now believed to be an important cause of neuropsychiatric conditions such as autism spectrum disorders and psychiatric diseases such as schizophrenia. Hence, also for these indications it is or will be warranted to perform cytogenetic testing.

Indications in Parents

Balanced translocations are relatively common in the population. The translocation heterozygote (carrier) may have a risk to have a child with developmental disorders because of a segmental aneusomy. Typically, the imbalance in the child is due to a segment of one of the participating chromosomes being duplicated, and a segment of the other chromosome being deleted. This confers a partial trisomy and a concomitant partial monosomy. In families where more than one child is born with developmental disorders and/or families with recurrent miscarriages, a chromosomal investigation is warranted.

In addition, when an imbalance is identified in a child, it is common practise to determine whether or not the imbalance is derived de novo or was inherited. When terminal imbalances are identified, the presence of a balanced translocation in one of the parents should be investigated. In addition, for submicroscopic interstitial imbalances, the presence of a balanced insertional translocation in one of the parents can be present.

Interpretation Issues

Chromosomal Polymorphisms

Chromosomal polymorphisms or heteromorphisms are structural chromosome variants that are widespread in human populations and have no effect on the phenotype. These variants are most often found at the centromeric regions of chromosomes 1, 9, and 16, the distal part of the long arm of the Y chromosome and the short arms of the

acrocentric chromosomes. In addition to these recurrent imbalances, many more cytogenetically visible but apparently benign imbalances have been described. An excellent overview on this topic is provided in the article by Barber , *Directly Transmitted Unbalanced Chromosome Abnormalities and Euchromatic Variants*, and the collected data is online available at the "Chromosome Anomaly Collection" at http://www.ngrl.org.uk/Wessex/collection.

Submicroscopic Chromosomal Polymorphisms (The Blurred Boundary Between Benign and Pathogenic CNVs)

Besides the identification of disease-associated CNVs, molecular karyotyping has also uncovered large numbers of copy number variants between normal individuals. Thus far, single-nucleotide polymorphisms have been considered the main source of genetic variation; hence the discovery of an unexpected large number (12% of the genome) of apparently benign copy number variants, regions of 1–1,000 kb that are present in different copy numbers in different individuals, was rightly called the discovery of the year 2007, according to *Science* magazine.

A number of array CGH studies had demonstrated the presence of polymorphic copy number variants. In a first large systematic study, Redon et al. mapped all CNVs using both array CGH and single nucleotide polymorphism (SNP) genotyping arrays on the 270 individuals of the HapMap collection from ancestry in Europe, Africa, and Asia. In the human genome, 1,447 submicroscopic copy variable regions were uncovered. This involves about 12% of the genome and includes hundreds of genes in deletions, duplications, insertions and complex multisite variants. These nonpathogenic variations are scattered throughout the human genome and contain also 12% of the genes, including a large number of genes known to be involved in genetic disorders and registered in OMIM. Recent fine mapping studies have revealed that those CNVs can result in intragenic variation resulting in different splice variants, the use of different exons and even new gene products. The most comprehensive population-based CNV map so far consists of 11,700 CNVs and is estimated to include about 80–90% of common CNVs greater than 1 kb in length. Although the authors indicate that those common CNVs are highly unlikely to account for much of the missing heritability for complex traits, they suggest that CNVs might contribute appreciably to rare variants involved in common and rare diseases.

The consequence of the detection of large numbers of benign CNVs is that, at present, the clinical significance of a novel CNV remains often unclear. The traditional rules of thumb used when analyzing genomes by conventional karyotyping are not applicable anymore. The identification of a large de novo cytogenetically visible imbalance was usually sufficient to confidently associate it with the disease phenotype. However, it is obvious that smaller imbalances carrying few or no genes may not at all be associated with a disease phenotype. Equally, it is becoming clear that de novo copy number variation arises frequently. Van Ommen estimated that copy number changes arise every one in eight births. Hence, not all de novo copy number changes would be pathogenic.

To determine which, if any, CNVs might be associated with the disease phenotype, the collection of large numbers of patient genotypes and phenotypes is required. Several efforts are currently ongoing to collect both large numbers of phenotypes and genotypes. These efforts will eventually allow pinpointing highly penetrant CNVs, revealing which imbalances are causal and which imbalances are spurious. The best-known open source examples are the DatabasE of Chromosomal Imbalances and Phenotype in Humans using Ensembl Resources with acronym DECIPHER which is organized at the Sanger institute (https://decipher.sanger.ac.uk/) and the European Cytogenetics Association Register of Unbalanced Chromosome Aberrations, ECARUCA, a register with a basis in Nijmegen, The Netherlands (http://www.ecaruca.net).

In addition, several large-scale collaborative efforts are underway to map population-embedded, apparently benign CNVs. These data are collected in the database of genomic variants (DGV, http://projects.tcag.ca/variation/). To fine map those imbalances, increasingly higher resolution arrays are being used. Those efforts aim to identify CNVs with likely minor or no developmental consequences.

While the mapping of apparently benign and pathogenic CNVs is an important endeavor, it is not sufficient to predict whether an imbalance will cause an abnormal phenotype. Apparently benign CNVs can cause autosomal recessive, autosomal dominant, and X-linked disorders, and imprinted regions may only cause disease dependent on the parental origin. In addition, variable expressivity and penetrance may obscure the pathogenic relevance of CNVs. It is not only becoming clear that interindividual phenotypic variation is caused by benign copy number variations, but more and more it is realized that even well-known disease-causing copy number variations may occasionally be tolerated and be part of the normal human phenotypic spectrum. For example, the 22q11 deletion as well as the duplication can cause both heart anomalies and midline defects such as cleft palate. However, both the

familial inherited 22q11 deletion and duplication have now recurrently been reported. The parent carrying the 22q11 duplication is phenotypically normal. Similarly, subtelomeric imbalances are known to be a major cause of birth defects and mental retardation. In contrast to the view that these imbalances are always causal and result in phenotypic anomalies, several reports indicate that several subtelomeric imbalances, up to 10 Mb in size, may not result in obvious phenotypic anomalies.

More recently identified recurrent imbalances with variable penetrance are the 16p13.1 region and the 1q21 region. During the screening of patients with mental handicap and developmental anomalies, reciprocal deletions, and duplications of the 16p13.1 region were recurrently observed. This 1.65 Mb rearrangement involves 15 genes. At first, it was unclear whether these imbalances were causing the developmental problems in patients because of two reasons: First, the imbalance, be it deletion or duplication, was often observed to be inherited from an apparently normal parent. Second, the phenotypes associated with either the deletion or duplication are quite variable. An association study showed that the deletion is a risk factor for mental handicap while the duplication is more likely to be a benign variant. Interestingly, Law et al. reported the prenatal diagnosis of a de novo 16p13.11 microdeletion by array CGH. Because of the unclear clinical significance, the pregnancy was not terminated and an apparently healthy baby was born. Chromosome 1q21 harbors two flanking regions, where, recently, recurrent reciprocal rearrangements were detected in patients with MR/MCA. The deletions and duplications are mediated by nonallelic homologous recombination of flanking low-copy repeats. All 30 investigated patients with thrombocytopenia absent radius (TAR) syndrome carry a 200 kb deletion on chromosome 1q21.1. Analysis of the parents revealed that this deletion occurred de novo in 25% of affected individuals. Intriguingly, inheritance of the deletion along the maternal line as well as the paternal line was observed in the other patients. The absence of this deletion in a cohort of control individuals argues for a specific role played by the microdeletion in the pathogenesis of TAR syndrome. It is hypothesized that TAR syndrome is associated with a deletion on chromosome 1q21.1 but that the phenotype develops only in the presence of an additional as-yet-unknown modifier (mTAR). Recently, the first prenatal diagnosis of TAR by array CGH was reported.

Mefford and colleagues identified 20 individuals with a recurrent 1.35 Mb deletion distal from the TAR region from a screen of about 5,000 patients ascertained with mental retardation and/or associated congenital anomalies (MR/MCA). The microdeletions arose de novo in six patients, were inherited from a mildly affected parent in three patients, and were inherited from an apparently unaffected parent in five patients. The absence of the deletion in about 5,000 control individuals represents a significant association with disease. In addition, the reciprocal duplication was also enriched in children with mental retardation or autism spectrum disorder although very few cases have been observed to conclude statistical significance.

It seems likely that those recurrent rearrangements with variable penetrance and expressivity are only the tip of an iceberg of a large number of structural variants with diverse and complex phenotypes that will elude both traditional syndromic classifications as well as evade traditional Mendelian inheritance patterns. The elucidation of their association with disease will require genotyping and phenotyping large numbers of patients and controls. These imbalances pose challenges to the clinician upon interpreting array CGH data. It seems likely that, in the future, the interpretation will be aided by computerized expert systems to aid the interpretation of a genomic profile.

Technical Issues in Array CGH

Quality Parameters

In a clinical setting, it is of utmost importance to detect all chromosomal abnormalities (i.e., to avoid false negatives) without calling false positives. In other words, both the sensitivity, which is the ability to detect a true positive result, and the specificity, which is the correct assessment of true negatives, should be as high as possible. This is dependent on the resolution of the platform, but also on the quality of the hybridization experiment. Therefore, strict quality parameters such as a maximum allowable standard deviation, appropriate thresholds, and algorithms for CNV calling and a minimum number of flagged reporters (i.e., those that are excluded from analysis due to technical artifacts) need to be maintained.

Chromosomal Rearrangements Missed by Array CGH

Array CGH is often touted to be able to replace conventional karyotyping in a diagnostic analysis of pediatric disorders. However, it should be realized that some chromosomal anomalies would be missed.

Inherent to the technique, balanced chromosomal rearrangements (inversions and balanced translocations) are not detected. When balanced rearrangements are detected prenatally on karyotypes, parents are usually tested and if a "normal" parent carries the same rearrangement, the translocation is considered benign. If the rearrangement is de novo, counseling is very difficult and the risk for developmental defects is estimated to be 6%. Array CGH analysis of patients with developmental anomalies and de novo translocations has revealed that about 45% of these are actually imbalanced. Considering that de novo translocations occur in about 1/1,000 births with 6% pathogenic and half of these detectable by array CGH, this would leave 0.003% pathogenic translocations undetected if no karyotype is performed.

Also neither triploidies, 69,XXX and 69,XXY, nor tetraploidies are readily detected. The use of DNA from a patient with Klinefelter (47,XXY) as a control does result in aberrant X and Y chromosome ratios, enabling the detection of XXX triploidies and all tetraploidies.

It should also be borne in mind that array CGH results represent the additive and not the allele-specific copy number. In this way, the true inheritance pattern can be masked and what looks like a de novo event may actually be the inheritance of a copy number variant in one of the parents. Carelle-Calmels and colleagues have recently reported a striking example. FISH analysis of the parents of a girl carrying a deletion at 22q11.2 revealed an unexpected rearrangement of both 22q11.2 regions in the phenotypically normal father. He carried a 22q11.2 deletion on one copy of chromosome 22 and the reciprocal duplication on the other copy of chromosome 22. Quantitative expression analysis of the genes located in the critical DiGeorge/VCFS region showed genomic compensation, consistent with the normal phenotype of the father. As the total copy number in the father equals the reference copy number, this would not have been detected by array CGH and the rearrangement would have been classified as de novo. The finding of the mirror rearrangement in the father has tremendous clinical consequences for genetic counseling, as there is a 100% risk of an unbalanced outcome.

Technical Standards for Cytogenetic Laboratories

A broad range of platforms including BAC, oligonucleotide, and SNP arrays has become commercially available, greatly facilitating the introduction of molecular karyotyping in the diagnostic setting. For the clinical implementation of array CGH in cytogenetic laboratories, the following technical standards should be achieved. The chosen methodology has to be validated with known aberrations, the performance of the arrays evaluated by internal and external quality controls, standard protocols have to be established, and the effective resolution of the platform has to be determined, as this differs from the theoretical resolution of the array as provided by the manufacturer. When reporting array CGH results, referral should be made to the platform, effective resolution, procedures, and quality parameters used. The detected aberrations should be defined according to the ISCN 2009 nomenclature with reference to the appropriate genome build in order to guide standardization across different cytogenetic laboratories.

Mosaicism

Chromosomal mosaicism can be defined as the coexistence, within one conceptus, of two or more distinct cell lines that are genetically identical except for the chromosomal difference between them, these cell lines having been established by the time that embryonic development is complete (the point at which the embryo becomes a fetus). Thus, the different cell lines are fixed in the individual and are a part of his or her chromosome constitution.

The phenotype associated with any particular type of mosaicism can be expected to be highly variable, reflecting the differences in the proportions of normal and abnormal cells. Mosaicism has been detected for all different chromosome abnormalities described in the section Types and Incidences of Chromosomal Abnormalities. Mosaicism is especially common for (small) marker chromosomes. Clinically, mosaicism can be suspected when a patient shows nonsymmetrical features, pigmentation lines, or specific syndromic features known to be associated with certain forms of mosaicism.

In order to detect mosaicism, sufficiently many cells must be analyzed. In most cytogenetic laboratories, 15–20 karyotypes are analyzed. This will allow the detection of a chromosomal abnormality with a certainty of 95% when present in 22–28% of the cells. With arrays it is equally possible to detect low-grade mosaicism. With the BAC arrays mosaicism as low as 7% could be detected. The degree of mosaicism that can be detected depends on the standard deviation of the array as well as on the size of the imbalance. In general, mosaicism down to 30% should readily be detected.

Current State of the Art and Future of Cytogenetic Testing

Current State of the Art

Any cytogenetic laboratory should be skilled in all conventional and molecular cytogenetic techniques. These include G-banded karyotyping, fluorescent in situ hybridizations, and array CGH. G-banded karyotyping has been available for more than 40 years and has the advantage that there is a widely accepted and uniform technique with an international system of cytogenetic nomenclature (ISCN). By contrast, cytogenomic arrays are much newer. Because of this novelty, there is still discussion about the best platforms to use, there is not yet a comprehensive knowledge base about the clinical consequences of all CNVs, the language to describe CNVs is still evolving. Currently, some recommendations are provided by the International Standard Cytogenomic Array (ISCA) Consortium:

- Cytogenomic array testing standards should not be specific to a particular array platform. Arrays based on BAC, oligonucleotide, or SNP probes can achieve the recommended coverage and level of resolution.
- In order to perform the same intended purpose as a karyotype, cytogenomic arrays must have uniform coverage to detect all areas of imbalance greater than or equal to 400 kb throughout the genome.
- Cytogenomic array testing can be prioritized over G-banded karyotyping. Cytogenomic arrays will detect many more submicroscopic genomic CNVs than the number of balanced rearrangements it would miss.
- G-banded karyotyping should always be available to patients with a family history of a rearrangement or a history of multiple miscarriages. In addition, G-banded karyotyping should still be offered in settings where both tests will be covered by insurance.

Decision Tree(s) for Array CGH Interpretation

Cytogenomic arrays have moved from bench to bedside for the genetic screening of patients with mental retardation and/or congenital anomalies. The advent of commercially available microarrays has facilitated the implementation of this technique in clinical diagnostic laboratories. As described earlier, the incomplete understanding of structural polymorphism and the appreciation that many disorders show a high degree of clinical variation and incomplete penetrance is blurring clear-cut genotype–phenotype correlations. As a consequence, the causality of many smaller CNVs often remains to be elucidated and the clinical interpretation of the detected CNVs has become a major challenge for diagnostic laboratories. To aid in the assessment of the clinical significance of a CNV, several decision trees that can be used as a guideline have been proposed. These decision trees all include three major steps as outlined in *Fig. 4.7*. The first step is to identify known causal CNVs, which include: (1) CNVs that overlap with well-established as well as recently recognized microdeletion and microduplication syndromes, (2) CNVs that overlap with pathogenic CNVs detected by other (microarray) studies in patients with similar phenotypes, and (3) CNVs that encompass known OMIM genes that have been associated with the phenotype observed in the affected patient. In this way, the pitfall of unintentionally disregarding a causal CNV as a benign variant is avoided because the fact is that some CNVs have been described as benign variants but reside in regions that are known to be associated with disease or are at recessive loci that are only pathogenic in the homozygous state. The second step is to remove normal benign variants (also known as common CNVs) that have been detected in healthy individuals and are thus less likely to account for the patient's phenotype. The third step is to determine the inheritance for the remaining CNVs. Aberrations that occur de novo in the patient are more likely to be pathogenic, especially when they are relatively large and/or contain several genes. For inherited CNVs and CNVs of unknown inheritance, the clinical interpretation is more complicated and these CNVs are currently classified as of unknown clinical significance. However, as international efforts are underway to map both pathogenic and benign CNVs (see Submicroscopic Chromosomal Polymorphisms (The Blurred Boundary Between Benign and Pathogenic CNVs)), it can be expected that a significant proportion of these CNVs will turn out to be causal, thus increasing the diagnostic yield in patients with mental retardation and/or congenital anomalies.

Future

Conventional and molecular cytogenetic testing will remain important since it provides information about the location of the abnormality. With the advent of arrays, the connection between the visible localization of the abnormality is somewhat lost. This trend is likely to

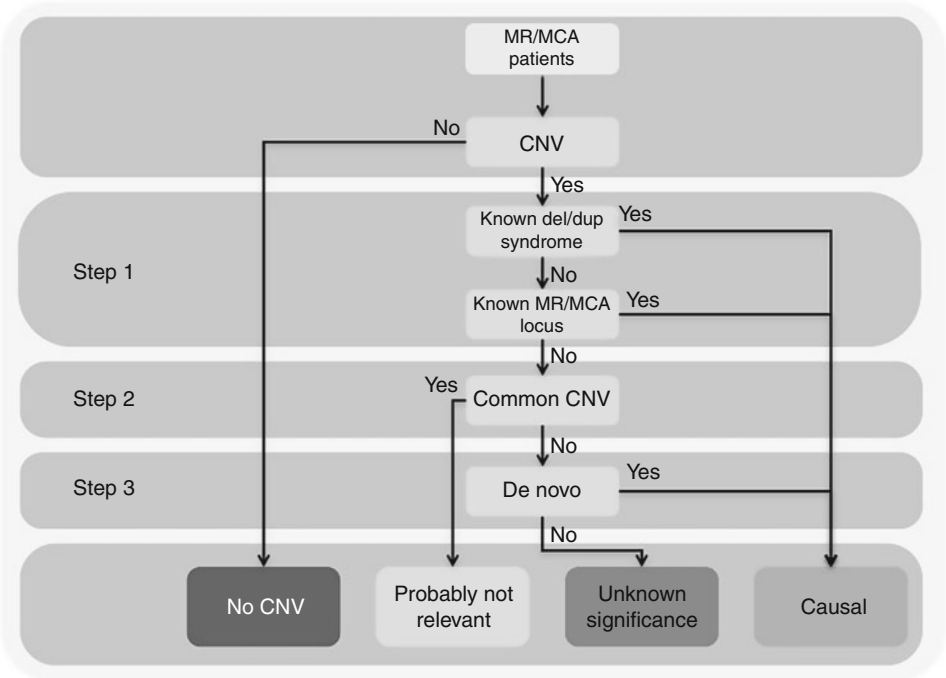

Figure 4.7
Decision tree for the assessment of clinical relevance for a particular CNV. Step 1: Identify known causal CNVs. Step 2: Discard common CNVs. Step 3: Determine the inheritance. Details are described in the text (Adapted from Buysse K, Delle Chiaie B, Van Coster R et al. (2009a) Challenges for CNV interpretation in clinical molecular karyotyping: lessons learned from a 1001 sample experience. Eur J Med Genet 52:398–403)

continue with the advent of full genome sequencing techniques. The latest technical revolution in human genetics is next-generation sequencing (NGS). Its strength lies in the ability to process millions of sequence reads in parallel rather than 96 at a time. Several platforms using different techniques are commercially available (Roche's 454 sequencing, Illumina's Solexa Genome Analyzer technology, and the SOLiD platform from Applied Biosystems), but they all rely on cyclic-array sequencing, which involves the sequencing of thousands to millions of immobilized DNA features by iterative cycles of enzymatic manipulation and imaging-based data acquisition. Depending on the platform, NGS generates hundreds of megabases to gigabases of nucleotide-sequence output in a single instrument run.

It is expected that costs will drop and that genome sequencing of individuals will be commonplace in the foreseeable future. If it will become feasible to assemble complete genomes as well as accurately determine copy numbers, full genome sequencing may ultimately replace cytogenetic as well as molecular genetic testing.

Concluding Remarks

In this chapter, the aim was to touch upon the important aspects of cytogenetic testing and provide a basic text on the topic for pediatricians new to the field. Considering that several books and numerous articles have been written about this topic, it is realized that the resume presented here is incomplete and biased. For those interested, a number of excellent books on the topics touched upon here are referred to. To help pediatricians in the interpretation of cytogenetic results and counseling of those results with patients, the books "Chromosome abnormalities and genetic counselling" as well as "The principles of clinical cytogenetics" are recommended. Phenotypic information about chromosomal imbalances has been collected by Schinzel in "Catalogue of unbalanced chromosome aberrations in man". Clinicians closely interacting with obstetricians and involved in prenatal diagnosis can consult "Genetic disorders and the fetus". Those interested to know more about the mechanisms underpinning genomic disorders

are referred to "Genomic disorders: the genomic basis of disease".

Over the last 50 years, cytogenetics has become a cornerstone of genetic testing of children with birth defects and developmental anomalies. Conventional karyotyping is rapidly replaced or at least complemented by array screening. In the future possibly full genome sequencing will enable both mutation and copy number detection in all individuals with developmental disorders. Certainly, knowledge about the organization and location of chromosomal aberrations is important for counseling and family planning, and therefore cytogenetics is here to stay, perhaps under a new name – "cytogenomics?"

5 Principles of Genetic Testing

Margaret A. Chen

An Introduction to Clinical Molecular Genetics

There is a general misperception that heritable genetic disorders are rarely encountered in clinical pediatrics. At least 2% of live born infants have a genetic disease, and genetic disorders are responsible for more than 30% of pediatric hospital admissions. Moreover, congenital anomalies, many of which are caused in part by genetic factors, are the leading cause of infant mortality. It is therefore of utmost importance for the general pediatrician to recognize when a patient may have a genetic condition and to be able to order the appropriate test(s).

The Human Genome Project was completed in 2003, and with its completion it was determined that the human genome contains 20,000–25,000 genes. By 2008, more than 2,000 single-gene disorders were catalogued in Online Mendelian Inheritance in Man (OMIM). The identification of the genes responsible for these disorders has been the result of a technological revolution in molecular genetics.

Today, genetic testing is becoming increasingly important in medical practice. Such testing can be used to confirm a clinically based diagnosis and may be especially helpful when disorders show clinical and/or radiographic overlap. Moreover, genetic testing is performed for purposes other than diagnosis. For example, genetic testing can identify individuals harboring a deleterious mutation or mutations prior to onset of symptoms, as well as asymptomatic carriers of autosomal recessive traits. Genetic testing is playing an increasingly important role in diagnosis, medical management, and family planning. Because the results of genetic testing may have implications for individuals besides the individual being tested, genetic counseling is always recommended and most clinical molecular diagnostic laboratories require informed consent prior to testing.

Indications for Molecular Testing

The vast majority of genetic testing performed in the pediatric population is diagnostic in nature. There are a number of situations where molecular genetic testing is warranted. Clinical indications include multiple congenital anomalies, dysmorphic features, developmental delay (in either speech or motor milestones), intellectual impairment of unknown etiology, growth abnormalities, ambiguous genitalia, failure to develop secondary sexual characteristics, congenital heart defects, solid tumors or hematological malignancies, and a positive newborn screen. Genetic testing may also be performed in asymptomatic children if there is a family history for a single-gene disorder of childhood onset that has been confirmed by laboratory diagnostics and such testing contributes to medical management and/or relieves parental anxiety.

Through careful examination of a family pedigree, it may be possible to ascertain mode of inheritance, and this may provide a clue to diagnosis. Although most physicians are familiar with basic Mendelian inheritance, there are several pitfalls in pedigree analysis. Variable expressivity can affect the ability of the physician to diagnose a genetic disorder. For example, there may be variation among family members in visible features, disease severity, age of onset, and/or rate of disease progression. Disease penetrance is another factor that can affect the pediatrician's ability to diagnose a genetic disorder. Penetrance refers to the expression of the mutant phenotype and is expressed as the percentage of individuals who have the mutant allele and are actually affected. Most genetic disorders show incomplete penetrance, meaning that not all individuals who have the disease genotype manifest symptoms. Nonpenetrance refers to the situation in which the mutant allele is inherited but is not expressed. Other factors that might complicate pedigree analysis and impede accurate diagnosis include the occurrence of new mutations, mosaicism, and phenocopies. New mutation can lead to a child being affected without family history. Mosaicism due to post-zygotic mutation can cause a parent to display few or no signs of a disorder. A phenocopy mimics the clinical picture that is usually produced by a specific genotype and may be caused by an environmental factor. Finally, there are multifactorial disorders that result from a combination of both genetic and environmental factors; they often recur in families but do not show the characteristic

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_5,

transmission typically seen with single-gene disorders. Multifactorial traits can be common, and include neural tube defects, non-syndromic cleft lip with or without cleft palate, congenital heart defects, and diabetes. A non-Mendelian inheritance pattern may also be seen with genetic disorders that arise from mutations in the mitochondrial genome. Disorders that result from mutations in mitochondrial DNA are only passed through maternal cell lineage; as a result, while both males and females can be affected, only females can pass the gene mutation to their offspring. Finally, mutations in imprinted gene regions may also show non-Mendelian inheritance; this topic will be discussed in further detail later in this chapter.

Genetic testing is performed for more than diagnosis of affected individuals. For example, carrier testing is possible. Heterozygous carriers of autosomal recessive and X-linked recessive disorders can be identified via direct DNA analysis. (While carrier testing is also performed to detect individuals with balanced chromosomal rearrangements, such testing needs to be performed using traditional cytogenetic techniques rather than molecular diagnostics.) Prenatal diagnosis is also feasible if a familial mutation (or mutations) has been identified. Traditionally, fetal samples are obtained via chorionic villus sampling at 10–12 weeks gestation or amniocentesis at 15–20 weeks gestation. Because both methods are invasive and pose some risk to the fetus, attempts are currently being made to study free fetal DNA found in the maternal circulation. This type of analysis is only being performed in a research setting, but early reports suggest it is possible to identify trisomies and paternally inherited mutations using this method.

Presymptomatic testing can likewise be performed, including predictive testing and predispositional testing. Predictive testing and predispositional testing are different, because a positive test result is interpreted differently for each. Predictive testing is performed for late-onset conditions such as Huntington disease, and a positive result implies that the individual will eventually develop the disorder with certainty. In contrast, a positive result for predispositional testing implies that the person is at increased risk for disease development, but such testing cannot firmly establish future disease. Predispositional testing may include *ApoE* genotyping for Alzheimer's disease (where presence of the ε4 allele confers increased disease risk), and *CAPN10* and *TCF7L2* genotyping for increased risk to develop type 2 diabetes. Because such risk factors are neither necessary nor sufficient for disease development and may not lead to effective risk reduction strategies, many experts advise against genetic testing for susceptibility alleles.

There are situations in which presymptomatic testing is justified. Presymptomatic testing is often performed for familial cancers, where test results play a critical role in medical management. Sequencing of *BRCA1* and/or *BRCA2* genes can provide information regarding risk to develop breast and/or ovarian cancer; results influence decisions regarding surveillance, Tamoxifen treatment, or prophylactic mastectomy and oophorectomy. Similarly, mutation testing of the *APC* gene can provide information regarding risk to develop colon cancer. Mutations resulting in a truncated APC protein are associated with familial adenomatous polyposis, a highly penetrant disorder where mutation carriers have a near 100% risk of developing colon cancer if left untreated. Identification of a mutation allows other at-risk family members to be tested. Unlike many other cases of presymptomatic testing in children, testing for a familial *APC* mutation has clear medical benefit. Children who are at 50% risk for familial adenomatous polyposis (i.e., children of a mutation carrier) normally must undergo annual sigmoidoscopy surveillance beginning at 10 years of age. A negative genetic test result would allow the child to avoid the sedation and discomfort associated with this medical procedure.

With a few noted exceptions, such as the one described above, genetic testing of minors in the absence of clinical presentation remains controversial. Numerous articles and position statements have been written on this subject. In 1995, the board of directors of both the American College of Medical Genetics and the American Society of Human Genetics issued a joint report regarding the ethical, legal, and psychosocial implications of genetic testing in children and adolescents. The primary justification for genetic testing in minors is that the testing should provide timely medical benefit. In addition, testing may also be justified when there is substantial psychosocial benefit to the competent adolescent (e.g., to help with decision-making regarding reproduction, education, and career). Genetic testing for adult-onset disorders or to determine carrier status should generally be deferred until the individual is old enough to make this decision voluntarily. Of course, it has been argued that prohibiting genetic testing in minors deprives the individual and the family of potentially important health information that might be used to make important lifestyle decisions, including limiting environmental exposures and risk behaviors. ❯ *Table 5.1* summarizes the benefits and risks of genetic testing in children.

Table 5.1
Benefits and risks of genetic testing in children

Category	Benefits	Risks
Medical issues	Clarify diagnosis	Ineffective or potentially harmful preventive or therapeutic interventions
	Improve prognosis through early therapeutic or preventive intervention	
	Increase surveillance	
	Avoid costly and/or risky unnecessary surveillance	
	Limit environmental exposures	
	Reduce risk behaviors	
Psychosocial issues	Reduce uncertainty and anxiety	Loss of autonomy
	Gradual adjustment by child to diagnosis	Increased anxiety and/or guilt
	Financial planning	Altered self-image/Diminished self-esteem
	Informed decision-making regarding education, employment, insurance, and personal relationships	Parents' changed perception of child
		Altered expectations regarding education, career, marriage, and life activities
	Alert other family members regarding their own risk	Stigmatization
		Employment and/or insurance discrimination
		Incidental determination of other family members' genetic status

Ordering a Diagnostic Genetic Test

Almost all clinical molecular diagnostic laboratories examine genomic DNA derived from lymphocytes. Blood samples are simple to collect and such testing may obviate the need for tissue-specific biochemical testing requiring invasive biopsy. Another advantage to DNA testing is that heterozygous carriers of autosomal recessive disorders can be definitively diagnosed, whereas carrier testing using an enzymatic assay might provide an ambiguous result (e.g., the result may overlap with those from either normal individuals or affected homozygotes).

DNA may be extracted from tissues and fluids besides peripheral blood. A number of diagnostic laboratories will accept mucosal cells from buccal swabs and saliva collections. Furthermore, genomic DNA may be extracted from cultured fibroblasts, especially when mosaicism is suspected. Prenatal testing of fetal cells from amniotic fluid and chorionic villi is routinely performed. In laboratories performing cancer diagnostics, DNA extracted from a solid tumor may be compared to DNA derived from lymphocytes; such examination may reveal either a loss of heterozygosity or a novel oncogene in the tumor sample. A number of laboratories in the United States perform mitochondrial DNA testing in addition to genomic DNA testing. Finally, a few clinical laboratories examine cDNA derived from messenger RNA (mRNA); such testing is performed to confirm a suspected splicing error.

Molecular genetic testing is categorized as non-waived, high-complexity testing. Although the Food and Drug Administration (FDA) does not currently regulate genetic testing in the United States, this may occur in the future. Presently, all diagnostic laboratories that report patient results must comply with the Clinical Laboratory Improvement Amendments (CLIA) that were legislated by Congress in 1988. As part of CLIA'88, regulations have been established by the Department of Health and Human Services (HHS) to ensure the quality and reliability of diagnostic testing performed on human specimens for disease diagnosis, prevention, or treatment. In addition, the Centers for Disease Control and Prevention (CDC) and the Centers for Medicare and Medicaid Services (CMS) have been working with other federal agencies and professional organizations since 1997 to promote the quality of genetic testing and appropriate use of genetic tests in health care. In order to maintain CLIA certification, clinical labs must undergo inspections, usually every 2 years. CLIA-certified laboratories follow good laboratory practice and provide information to ordering

physicians regarding the selection of appropriate tests, intended use of the test, indications for testing, testing methodology and limitations, plus cost.

In 1997, the Department of Energy Task Force on Genetic Testing proposed three criteria for the evaluation of genetic tests, including analytic validity, clinical validity, and clinical utility. Analytic validity refers to how well the test predicts the presence or absence of a particular gene or genetic change. Analytic validity includes both analytic sensitivity and analytic specificity. Molecular genetic testing may consider analytic sensitivity to be the proportion of samples that have a positive test result or known mutation and that are correctly classified as positive. In contrast, analytic specificity in molecular testing is the ability of a test method to differentiate target sequences, alleles, or mutations from other sequences (e.g., homologous genes). A general definition of clinical validity is the accuracy with which a test identifies or predicts a patient's clinical status. Clinical validity takes into account clinical sensitivity and specificity, as well as positive and negative predictive values. Clinical sensitivity is the clinical detection rate, while clinical specificity is the proportion of individuals who do not have the clinical phenotype and test negative. The positive predictive value of a test is indicated by the proportion of individuals with a positive test result who have, or will develop, disease; in contrast, the negative predictive value of a test is equal to the proportion of individuals with a negative test result who do not have, and will not develop, disease. Finally, the clinical utility of a test takes into account the risks and benefits resulting from test use. Clinical utility refers to whether the test can provide information about diagnosis, treatment, medical management, or disease prevention.

In March 2010, the National Institutes of Health announced that it is creating a public database that can be used to search for information about the availability, validity, and utility of genetic tests. Until the NIH Genetic Testing Registry (GTR) is operational, the GeneTests Web site (www.genetests.org) can be used to obtain information about molecular genetic tests currently offered by CLIA-certified laboratories.

Types of Changes Associated with Heritable Disorders

Disease-associated genetic changes can occur anywhere in the genome, from the level of a chromosome down to the level of a single nucleotide. Although most changes may involve aberrations in gene dosage or gene sequence, epigenetic modifications can also lead to a disease phenotype. Cytogenetic testing, including the application of microarrays, is covered in Chap. 4 "Cytogenetic Testing and Chromosomal Disorders". In this section, the focus is on molecular diagnosis at the level of individual genes.

In the early days of molecular testing before the availability of direct mutation analysis, linkage studies were performed to follow a gene mutation through a family. In linkage studies, a genetic marker in close proximity to the gene of interest is tracked through the family to follow inheritance of the disorder. Because linkage analysis requires samples from multiple family members and not just the proband, such studies can be difficult to perform. Furthermore, linkage testing is not always informative for a particular family. Another limitation of linkage analysis is that the results always involve some uncertainty, because recombination may occur between the marker locus and the disease locus. Nevertheless, a number of clinical molecular laboratories continue to offer linkage analysis, especially when the disease gene is large and mutations are difficult to identify.

Most molecular testing performed today involves direct mutation analysis. With the completion of the Human Genome Project in 2003, molecular analysis is now possible for a very large number of single-gene disorders. The technique used for mutation detection is specific for the gene being tested and the type of mutation most likely to be found. For example, congenital myotonic dystrophy is the result of a large CTG trinucleotide expansion in the *DMPK* gene; this type of large expansion can only be confirmed with Southern Blot. Multiplex ligation-dependent probe amplification (MLPA) was first described in 2002 as a novel method to detect copy number variants, including small-scale exon deletions and duplications. Because this method is simple, cost-effective, and high-throughput, MLPA is used to detect deletions associated with many different disorders, including Duchenne or Becker muscular dystrophies (both caused by deletions within the *DMD* gene encoding dystrophin) and Type I spinal muscular atrophy (SMA) (Werdnig–Hoffmann disease, usually caused by homozygous deletion of exon 7 in the *SMN1* gene). Quantitative PCR is yet another method used to detect gene deletions or duplications at the level of a single exon within a gene of interest.

Gene sequencing is currently the gold standard used for mutation detection when variations at the single nucleotide level are the main cause of disease pathogenesis. Dideoxy terminator-based sequencing (i.e., Sanger sequencing) has been in use for at least 30 years and continues to be used by most clinical laboratories because it is amenable to automation. Identifiable DNA alterations

include frameshift mutations (due to small insertions and deletions) and base pair substitutions (point mutations). Although nucleotide changes may occur anywhere in the genome, clinical diagnostic laboratories often limit analysis to exons (i.e., protein coding regions) plus approximately 20 base pairs of flanking noncoding intronic DNA.

A few different types of sequence variants are easy to classify as pathogenic. Examples include nonsense mutations that lead to the production of a termination codon and alterations at invariant GT-AG sequences at splice donor and splice acceptor sites. In most other cases, interpretation of sequence variants is complex. Many genes are large and highly polymorphic (meaning more than one form of DNA sequence may exist at a particular site). Some variations are specific for particular ethnic groups and are not associated with a disease phenotype. Base pair substitutions may be synonymous or non-synonymous in nature. Synonymous changes (i.e., silent mutations) are those that lead to no foreseeable protein alteration. Such variants can be associated with disease, however, as they may lie in an important regulatory element and affect gene expression. In contrast, non-synonymous substitutions (i.e., missense mutations) are those that lead to a change in the encoded protein. Such changes may be deleterious or non-deleterious. To confidently classify a missense mutation as pathogenic, several factors must be taken into account, including the following: (1) Has the variant been previously reported in the literature or in a public database? (2) Does the variant co-segregate with the disease? (3) Are other mutations found in *cis* (i.e., on the same chromosome)? (4) Does the mutation fall in a conserved protein domain? (5) Is there evolutionary conservation of the encoded amino acid in other animal species? (6) Does the amino acid change affect the function of the protein?

Limitations of DNA Sequencing

As with other genetic testing techniques, DNA sequencing has limitations. First, and most important, sequencing of DNA requires an initial suspected clinical diagnosis. Even when a specific diagnosis is entertained, the genetic factor(s) responsible for the disorder may not be known or completely understood. Many genetic disorders are heterogeneous, meaning that a mutation in one of several genes may lead to the disease phenotype. Genetic heterogeneity can lead to a false-negative test result if the wrong gene is examined.

A false-negative test result can also occur because DNA sequencing cannot detect all possible variants. Although small microdeletions and microduplications several nucleotides in length can be detected, sequencing will not detect larger-sized copy number changes. Also, sequencing will not detect positional rearrangements of genetic material, including gene inversions, translocations, and inversions of larger chromosomal segments. Furthermore, because most clinical laboratories only sequence coding regions that give rise to protein, changes in nucleotide sequence within a promoter region or deep within an intron may go undetected.

In contrast to false-negative results, false-positive results can occur when variants of unknown significance are incorrectly classified as being associated with disease. As previously mentioned, variants of unknown significance can be difficult to classify as benign or pathogenic; often, parental studies are necessary to interpret an affected child's result.

Another limitation to direct DNA sequencing is this test technique will not detect epigenetic modifications. Such modifications are described in greater detail below.

Epigenetics

Epigenetic changes play an important role in pathogenesis of some disorders. Epigenetic factors affect the expression of genes without altering the genotype. Improper epigenetic programming can lead to consequences similar to the effects of a genetic mutation. Aberrant epigenetic programming can lead to inactivation of a gene that is normally expressed, or activation of a gene that is normally silenced.

Epigenetics is a normal cellular phenomenon that involves heritable transmission of information from one generation of cells to the next; this information is transferred through DNA and chromatin modifications, rather than specific alterations in the DNA sequence. Methylation of cytosines at CpG dinucleotides in promoter regions constitutes one form of epigenetic modification; the addition of phosphate, acetyl, and ubiquitin groups to histone proteins constitute other forms of epigenetic modification. Two important cellular processes, X inactivation and genomic imprinting, are examples of normal epigenetic mechanisms that can be associated with disease.

Although females normally have two X chromosomes and males have one, the quantity of X-linked gene product is usually the same in males and females due to the dosage compensation that occurs due to X inactivation (Lyonization). As a consequence, X chromosome aneuploidy usually has a milder clinical presentation than aneuploidy involving an autosome (chromosomes 1–22),

and therefore monosomy for the X chromosome (Turner syndrome) and trisomy X are relatively common. There are other important clinical implications of X inactivation. A woman who carries an X-linked recessive mutation on one of her two X chromosomes may express the mutant phenotype if most of her cells happen to have inactivated the X chromosome carrying the normal gene. Female expression of X-linked recessive disorders such as Fragile X syndrome and hemophilia has been reported.

Genomic imprinting is a developmental mechanism that occurs during gametogenesis and early development in a subset of genes. Imprinting mediates differential expression of a gene depending on whether it is inherited from the mother or the father (otherwise known as a "parent-of-origin" effect). To achieve allele-specific expression, special control elements known as imprinting control regions (ICRs) are regulated at imprinted loci via epigenetic modifications such as methylation of CpG dinucleotides and histone modifiers normally associated with transcriptional repression.

Several genetic disorders result from consequences of genomic imprinting (❯ *Table 5.2*). Diseases associated with small deletions may occur due to lack of expression of essential imprinted gene(s) on the intact homologue; likewise, diseases associated with uniparental disomy (where two copies of a chromosome are inherited from one parent and no copies are inherited from the other parent) may also result from failure to express essential imprinted genes. Prader–Willi syndrome and Angelman syndrome are two pediatric genetic disorders that are associated with imprinting. Prader–Willi syndrome, characterized by infantile hypotonia, developmental delay, childhood obesity, and hypogonadism, can result from either a deletion of the paternally inherited chromosomal segment 15q11-13 or from maternal uniparental disomy for chromosome 15. In both cases, the affected child fails to express crucial gene products because multiple maternally inherited genes in this chromosome region are imprinted and therefore are not expressed. Angelman syndrome, a clinically distinct condition characterized by severe intellectual impairment, seizures, ataxia, and apraxia, results from differential expression of other genes at 15q11-q13; however, Angelman syndrome is associated with a deletion of the maternal copy of chromosome 15q11-13 or paternal uniparental disomy. DNA sequencing studies have shown that approximately 10% of patients with Angelman syndrome have mutations in the maternally expressed copy of the *UBE3A* gene.

Silver–Russell syndrome (SRS) and Beckwith–Wiedemann syndrome (BWS) are two other genetic disorders that are associated with genomic imprinting. SRS is characterized by prenatal and postnatal growth retardation, relative macrocephaly, and a triangular-shaped face. In contrast, individuals with BWS display an overgrowth phenotype, abdominal wall defects, and a predisposition to develop certain malignancies, including Wilms' tumor. The first evidence that Silver–Russell syndrome is a disorder related to genetic imprinting came from Kotzot et al. in 1995. This group was the first to report maternal uniparental disomy of chromosome 7 in affected patients. Other researchers later reported a link between Silver–Russell syndrome and epigenetic changes in a specific region on the short arm of chromosome 11 at 11p15. Interestingly, Beckwith–Wiedemann syndrome is also associated with methylation defects in this same region. This specific area of chromosome 11p15 can be divided into two distinct imprinted domains, where the imprinting centers ICR1 and ICR2 play a critical role in regulating allele-specific expression of at least five different genes, including *H19*, *Insulin-Like Growth Factor II* (*IGF II*), *CDKN1C*, *KCNQ1*, and *KCNQ1OT1* (*LIT1*). Imprinting center 1 (ICR1) controls the expression of two genes, *H19* and *Insulin-Like Growth Factor II* (*IGF II*), in an opposite manner. ICR1 normally ensures that IGF II, a fetal growth factor, is expressed only from the paternal allele, and ensures H19, a noncoding RNA, is expressed only from the maternal allele. Loss of ICR1 methylation (so-called ICR1 "hypomethylation") has been found in approximately 30% of patients with Silver–Russell syndrome. Conversely, "hypermethylation" of ICR1 can be found in 2–7% of patients with Beckwith–Wiedemann syndrome. In these BWS patients, methylation of ICR1 on both parental chromosomes leads to biallelic silencing of *H19* and biallelic activation of *IGF II*. Nevertheless, most patients with Beckwith–Wiedemann syndrome have epigenetic changes in the ICR2-controlled imprinting domain as opposed to the ICR1-controlled imprinting domain. ICR2 is normally methylated only on the maternal allele. This imprinting control region regulates the allele-specific expression of the cyclin-dependent kinase inhibitor *CDKN1C*, the potassium voltage-gated channel *KCNQ1*, and the noncoding RNA *KCNQ1OT1* (*LIT1*). Approximately 50% of patients with Beckwith–Wiedemann syndrome show hypomethylation of ICR2.

Cancer Genetics in the Pediatric Population

There are a number of malignancies predominantly found in children. As previously mentioned, Wilms' tumor, a nephrogenic malignancy, may be found in association

Table 5.2
Genetic disorders associated with imprinting defects

Genetic disorder	OMIM#	Estimated incidence	Chromosome	Gene(s)	Imprinted (inactivated) parental allele	Protein	Clinical features
Prader–Willi syndrome	176270	1 in 10,000	15q11-13	*SNRPN* plus others (including *MKRN3* and *NDN*)	Maternal	Small nuclear ribonuclear protein polypeptide N	Infantile hypotonia, developmental delay, childhood obesity, hypogonadism
Angelman syndrome	105830	1 in 20,000	15q11-13	*UBE3A*	Paternal	Ubiquitin-protein ligase E3A	Severe mental retardation, apraxia, ataxia, seizures
Beckwith–Wiedemann syndrome	130650	1 in 14,000	11p15.5	*H19*	Paternal	(Untranslated mRNA)	Overgrowth, hemihypertrophy, macroglossia, omphalocele, neonatal hypoglycemia, predisposition to tumorigenesis (especially Wilms tumor)
				IGFII	Maternal	Insulin-like growth factor II	
				CDKNIC	Paternal	Cyclin-dependent kinase inhibitor 1 C	
				KCNQ1	Paternal	Voltage-gated potassium channel	
				KCNQ1OT1(LIT1)	Maternal	(Untranslated mRNA)	
Silver–Russell syndrome	180860	Wide variation in reports	11p15.5	*H19*	Paternal	(Untranslated mRNA)	Intrauterine and postnatal growth retardation, relative macrocephaly, triangular-shaped facies
			7p11.2-p13	*GRB10* (Candidate locus)	Maternal	Growth factor receptor-bound protein-10	

with Beckwith–Wiedemann syndrome. However, this tumor can also be found in isolation, or in association with another inherited syndrome called WAGR (an acronym for Wilms' Tumor/Aniridia/Genitorurinary anomalies/mental Retardation). WAGR is a contiguous gene syndrome associated with a deletion of several genes on chromosome 11p13.

Retinoblastoma is a solid tumor of the eye that is usually not associated with a syndrome. There is a form of retinoblastoma that is familial and presents bilaterally; it is the result of an inherited mutation in the tumor suppressor gene *RB1*. Children who have inherited an *RB1* mutation on chromosome 13 tend to present at a very early age and are six times more likely to develop other types of cancer later in life.

Specific gain-of-function mutations in the *RET* proto-oncogene on chromosome 10q11.2 are associated with multiple endocrine neoplasia, types 2A and 2B (MEN 2A and MEN 2B). Individuals with MEN Type 2 are at risk to develop medullary thyroid carcinoma, pheochromocytoma, and benign parathyroid tumors. It is recommended that prophylactic thyroidectomy be performed before the age of 6 years in children with MEN2A and before the age of 3 years in children with MEN2B.

In contrast to the solid tumors just described, there are several types of hematological malignancies predominantly found in infants and young children. One form of leukemia with a poor prognosis is acute lymphocytic leukemia (ALL) resulting from a defined translocation of chromosomes 4 and 11. Normally, chromosome 4

encodes AFF1, an ATP/GTP binding transcription factor, and chromosome 11 encodes MLL, a histone methyltransferase that acts as a global regulator of gene transcription. The t(4;11)(q21;q23) translocation leads to the production of an MLL-AFF1 fusion product whose role in leukemogenesis is not completely understood.

Pharmacogenetics in Pediatrics

Pharmacogenetics is the study of heritable variation to help determine drug metabolism and response to therapeutic agents. The goal is to minimize adverse drug events and maximize efficacy. Pharmacogenetics is currently being used in the areas of psychiatry, anesthesiology, hematology, and oncology to prevent adverse events and design optimal treatment regimens.

Genetic testing of the *TPMT* gene in children with acute lymphocytic leukemia (ALL) has been shown to be cost-effective. Chemotherapy for ALL typically includes treatment with several different thiopurines, including 6-mercaptopurine (6-MP) and 6-thioguanine (6-TG). Decreased levels of TPMT are associated with particular polymorphisms; these weak alleles lead to decreased thiopurine clearance and fatal toxicity in a small percentage of treated children. In contrast, individuals with high TPMT activity are fast metabolizers who show decreased therapeutic effect; these individuals may need a higher drug dose for sufficient response.

Population-Based Genetic Screening

Genetic screening consists of genetic testing at the population level. Carrier screening is available for people who have no personal or family history of a condition, but who may have a greater than average chance of carrying a particular gene mutation due to ancestry. A negative carrier screening test significantly lowers, but does not completely eliminate, the risk of being a disease carrier. This is because carrier screening detects specific mutant alleles, and less common mutations may go undetected. The goal of carrier screening is to help identify couples who are at risk for having an affected child to allow them to make informed reproductive decisions. For a screening program to be successful, the disorder should be clinically severe, there should be a relatively high frequency of carriers in a population, a reliable genetic test must exist, and there must be access to genetic counseling.

Population-based carrier screening for Tay–Sachs disease has been performed in individuals of Ashkenazi Jewish heritage since 1969. The scope of carrier screening in the United States broadened in 2001 when the American College of Obstetricians and Gynecologists and the American College of Medical Genetics recommended that cystic fibrosis (CF) carrier screening be offered to all couples planning a pregnancy or seeking prenatal care following review by an NIH Consensus Development Panel. The frequency of cystic fibrosis varies by ethnicity, and includes an estimated disease incidence of 1 in 3,300 Caucasians. Therefore, approximately 1 in 28 individuals of Northern European descent carries a mutation in the *CFTR* gene. The American College of Medical Genetics and the American College of Obstetricians and Gynecologists currently recommend population CF carrier screening for 23 specific *CFTR* mutant alleles.

In November 2008, the American College of Medical Genetics published an SMA carrier screening practice guideline recommending that SMA carrier testing be offered to all expectant couples regardless of race or ethnicity. Spinal muscular atrophy (SMA) is the most common inherited cause of early childhood mortality, and the second most common fatal autosomal recessive disorder after cystic fibrosis. The estimated incidence of SMA is 1 in 10,000 live births, and the estimated carrier frequency ranges from 1 in 40 to 1 in 60 individuals, depending on heritage.

Newborn screening is another example of population-based genetic testing. Newborn screening is a widely accepted public health program that integrates sample collection, laboratory testing, follow-up, diagnosis, treatment of identified disease, and tracking of long-term outcomes. Although the majority of conditions examined are numerous inborn errors of metabolism, other conditions include hemoglobinopathies, endocrine disorders, and cystic fibrosis. The main goal of newborn screening is to detect disorders that are threatening to long-term health before patients become symptomatic, since early treatment may significantly reduce mortality and morbidity.

Newborn screening began in the 1960s when Robert Guthrie developed a system for collecting small blood samples on filter paper (known as a Guthrie card). Guthrie developed an initial screening test for phenylketonuria (PKU) using a bacterial inhibition assay. This assay was later used to detect a number of additional amino acidopathies. By the end of the twentieth century, newborn screening programs had rapidly expanded. Because newborn screening programs have traditionally been state-mandated programs, there has been inconsistency regarding the number and types of diseases that are screened from state to state. In order for a disorder to be considered for newborn screening, the testing must be

relatively cost-effective, and some early intervention must exist that will reduce morbidity and mortality. In addition, the screening test must be sensitive, specific, and ideally have a high positive predictive value. Screening programs choose quantitative cutoffs that minimize both false-positive and false-negative test results. In 2005, the American College of Medical Genetics Newborn Screening Expert Group recommended a universal panel of metabolic disorders that should be included in every newborn screening program in the United States.

All patients who have an initial positive newborn screen require more definitive confirmatory testing. The American College of Medical Genetics publishes ACTion (ACT) sheets on its Web site that provide management guidelines for infants who screen positive; in many cases, the guidelines include DNA studies. In addition, there are several genetic disorders covered by newborn screening programs where molecular testing is part of the screening process. Many states screen neonates for cystic fibrosis using a combination of first-tier immunoreactive trypsinogen testing and second-tier DNA mutation analysis. Pilot programs in Wisconsin and Massachusetts have been initiated to screen for severe combined immunodeficiency syndromes (SCIDs). These programs use quantitative PCR to examine T-cell receptor excision circles (TRECs) produced during normal T-cell development. Abnormally low levels of TRECs may be indicative of an immunodeficiency syndrome and therefore require appropriate follow-up. Because the Wisconsin pilot program was able to successfully identify a newborn with SCID shortly after program implementation, it is expected that other state newborn screening programs will develop similar testing in the near future.

Looking Ahead: The Future of Molecular Genetic Testing

This chapter provides a brief overview of molecular genetic testing, including its current uses and limitations. Development of novel testing methodologies has greatly advanced this subspecialty of clinical laboratory-based genetics, and it is now possible to test for a very large number of single-gene disorders. Many patients who have previously tested negative for a genetic condition may benefit from retesting, since methods have changed substantially over the past decade. In instances where genetic testing remains uninformative, DNA can be isolated and stored (i.e., "banked") for future analysis.

It is expected that the field of molecular genetics will continue to rapidly evolve, and the technological limitations present today will be overcome tomorrow. Indeed, it is now possible to sequence the entire human genome of a single individual. This has become possible with the development of non-Sanger-based sequencing (so-called next-generation sequencing) that is based on a sequencing-by-synthesis technology first reported in 2005. This approach is extremely powerful and is capable of greatly outperforming automated Sanger sequencing at a fraction of the cost.

Technological advances are expected to improve the state of human health, but they also raise complex ethical and legal issues. To help address some of these concerns, the National Human Genome Research Institute (NHGRI) and the Department of Energy (DOE) set up the ELSI research program to study the ethical, legal, and social implications (ELSI) of genetic research. Information gathered from ELSI has been used to examine questions regarding genetic privacy and genetic discrimination. In 2008, the Genetic Information Nondiscrimination Act (GINA) was signed into law by President Bush. GINA protects Americans against health insurance and employment discrimination based on an individual's genetic information. The passage of GINA was a milestone that now paves the way for people to take advantage of personalized medicine with reduced fear of discrimination.

6 Principles of Therapeutics

Maria Descartes · Edward J. Lose

The medical treatment of genetic disease is now at the stage that the field of infectious disease was at after Koch's postulates were formulated. The causes of disease and malformations due to changes in the genetic sequence or outside of the genetic code (epigenetic modification) have been rapidly catalogued over the last few decades. Treatment of genetic disease has been so far mainly palliative in nature and generally addresses the pleiotropic manifestations. The complications of many genetic disorders are increasingly amenable to some form of medical or surgical treatment. Accomplishing a more disease-specific treatment of genetic disorders has remained an elusive goal, yet the growing number of therapeutic responses shows that progress has been made in controlling and reducing associated symptoms. The foundation of future-directed therapy for genetic disorders is based on the understanding of genetic disease at the molecular level.

Systemic Therapy

Many genetic syndromes exhibit organ or multisystem malformations. The surgical and medical treatment of these complications is long established, and results in prolonged survival with improved quality of life. These treatments include congenital heart disease repair, orthopedic surgery for skeletal malformations, neurosurgery for hydrocephalus, and many more. Although successful, these interventions are not unique to genetic disease and do not specifically address the underlying pathology (*Fig. 6.1*).

Organ Transplantation

Organ transplantation involves replacing the malfunctioning organ along with the relevant somatic stem cells and differentiated cells. Liver transplantation is used for a number of metabolic disorders, including urea cycle disorders, organic acidurias, homozygous familial hypercholesterolemia, and severe forms of glycogen storage disease. The liver disease associated with cystic fibrosis and α-1-antitrypsin deficiency may also be treated with liver transplantation. Somatic stem cells are capable of self-renewal and differentiation into different cell types, making them excellent candidates for cellular therapy. Liver repopulation by transplanted hepatocytes is a promising approach.

Hematopoietic Cell Transplantation

Transplantation of hematopoietic (multipotent) stem cells from bone marrow (HCT) has been used for the past 2 decades in immunodeficiency, lysosomal, and peroxisomal disorders. The rationale of this treatment is based on providing the missing enzyme through donor cells within and outside the blood compartment. The great majority of transplants have been performed in patients with Hurler syndrome (MPSI), Hunter syndrome (MPSII), Sanfilippo syndrome (MPSIII), Maroteaux–Lamy syndrome (MPSVI), X-linked adrenoleukodystrophy, metachromatic leukodystrophy, globoic-ceroid leukodystrophy (including Krabbe disease), and others (Pelizaeus–Merzbacher, Zellweger syndrome, and vanishing white matter disease).

Allogenic hematopoietic cell transplantation (HCT) is the only treatment with curative potential for sickle cell disease and beta-thalassemia. Successful treatment relies on a permanently viable engraftment as opposed to a transient engraftment. Availability of matched donor, graft failure, and transplantation-related mortality remain limiting factors.

Unrelated cord blood (UCB) transplantation is the utilization of umbilical cord blood as a stem cell source. The use of cord blood has several advantages over bone marrow as a source of stem cells. The recipients are more tolerant of histoincompatible blood than other donor cells. Placental cord blood is widely available and transplantation from unrelated donors appears to be as effective as from a matched donor, at least for Hurler syndrome and neonatal Krabbe disease. Still investigational is the use of mesenchymal stem cells (MSCs) infusions. Mesenchymal stem cells are pluripotent cells that have the potential of differentiating into various cells of meshencymal origin: osteoblast, chondrocytes, adipocytes, and astrocytes.

In mice, inducible pluripotent stem cells (iPS cells) have been created from skin fibroblasts and effectively transformed into hepatocytes. In the model utilized, the

Various levels of treatment for genetic diseases (Pharmacol Rev 2007 59:225–250

subject mice were homozygous for fumarylacetoacetate hydrolase deficiency (hereditary tyrosinemia). The FAH -/- cells died and the iPS cells effectively replaced the entire liver. Human iPS cells have been generated and considerations for trials include the following conditions: α-1-antitrypsin deficiency, familial hypercholesterolemia, glycogen storage disease type 1 (von Gierke disease), hereditary tyrosinemia, and Crigler–Najjar syndrome.

Therapy at the Extracellular Level

Metabolic Pathway Modification

Inborn errors of metabolism are the archetype of genetic disorders. Newborn screening programs are the most widespread genetic tests performed. These programs are effective in modifying or preventing complications because early therapy is often easily implemented. Treatment is targeted at restricting dietary intake of the substrates early in the metabolic pathway, increasing excretion of toxic metabolites, replacing deficient substances, and altering the primary metabolic rate. To achieve metabolic balance and stabilization of symptoms, these strategies are used individually or in combination.

Dietary therapy is a long-established and effective method of managing genetic disorders (*Table 6.1*). Dietary modification has been used successfully in aminoacidopathies, urea cycle disorders, and diseases of carbohydrate metabolism. Dietary restriction is usually a lifetime commitment and can be imposing to the family and the patient. Total protein restriction is necessary and sometimes severe for disorders of amino acid catabolism and the urea cycle. This must be balanced by supplying essential substrates and cofactors to allow for growth and development. Sugar restriction for disorders of carbohydrate metabolism can be as simple as limiting lactose consumption in galactosemia or as difficult as limiting total glucose consumption in pyruvate dehydrogenase deficiency. Patients with fatty acid oxidation defects usually require acute management only and are otherwise allowed a relatively unrestricted diet.

Table 6.1
Disorders that respond to dietary therapy

Disorder	Restriction	Supplementation
Aminoacidopathies		
Phenylketonuria	Phenylalanine	Tetrahydrobiopterin for responsive patients
	Total protein	
Tyrosinemia Tyrosenemia I? or tyrosemia I and II? Tyrosemia I is usually responsive with NTBC (nitisinone) also known as: 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3 cyclohexanedione	Phenylalanine	
	Tyrosine	
Homocystinuria	Methionine	Pyridoxine for responsive types, betaine, folate, hydroxycobalamin
	Total protein	
Carbohydrate metabolism defects		
Pyruvate carboxylase deficiency	High carbohydrate and high protein diet to avoid activation of gluconeogenesis	Citrate supplementation, biotin, aspartic acid, triheptanoin
		Thiamine, carnitine, lipoic acid
Pyruvate dehydrogenase deficiency	Glucose/Carbohydrates	Fat intake
	Branched chain amino acids	Thiamine, lipoic acid
		Cornstarch
		Protein
Hereditary fructose intolerance	Fructose, sucrose	
	Sorbitol	
Galactosemia	Galactose, lactose	
Fatty acid oxidation defects		
Short chain acyldehydrogenase deficiency	None	Carnitine
Medium chain acyldehydrogenase deficiency	None	Carnitine
Long chain acyldehydrogenase deficiency	None	MCT oil and low fat diet
Trifunctional protein deficiency	Long chain fats	MCT oil, carnitine, DHA
Organic acidemias		
Branched chain organic acidurias		
Maple syrup urine disease	Isoleucine, leucine, valine	
Isovaleric acidemia	Leucine	Levocarnitine and glycine
Propionic acidemia	Isoleucine, valine, methionine, threonine	Levocarnitine and biotin
Methylmalonic acidemia	Isoleucine, valine, methionine, threonine	Folate, betaine, and levocarnitine Cyanocobalamin for cobalamin responsive patients
Glutaric Acidemia Type 1	Lysine, hydroxylysine, tryptophan	Levocarnitine, riboflavin
	Tryptophan	
Urea cycle defects		
In general	Total protein	
N-Acetylglutamate synthetase deficiency		Carbamylglutamate

Table 6.1 (Continued)

Disorder	Restriction	Supplementation
Carbamoylphosphate synthetase deficiency		
Ornithine transcarbamylase deficiency		Arginine, citrulline
		Sodium benzoate
		Sodium phenylacetate
Citrullinemia		Arginine
Arginosuccinic aciduria		Arginine
Arginase deficiency		

Limited understanding of the metabolic pathway and interactions involved in disease progression still poses a barrier to effective treatment. Despite a reduction in the occurrence of cataracts and mental retardation with the institution of lactose restriction in galactosemia patients, 81% of females with this disorder experience premature ovarian failure and 56% of males and females have delayed vocabulary and articulation milestones. Additionally, intercurrent illness and stress may provoke a crisis in otherwise stable patients. Rapid response with dietary modifications and intravenous therapy can avert deterioration in many cases.

In a number of metabolic disorders, the efficiency of the defective enzyme or an alternative pathway can be enhanced by the administration of large amounts of the vitamin cofactor. The administration of cofactor may overcome reduced affinity of the mutant enzyme for the cofactor or stabilize the enzyme. Nonresponsive patients generally have a mutation that result no residual enzyme activity.

Phenylketonuria (PKU) is the first genetic disorder for which a screening process was introduced in the 1960s. PKU is traditionally treated with a phenylalanine-restricted diet. Tetrahydrobiopterin is a cofactor that binds to the affected enzyme, phenylalanine hydroxylase. A tetrahydrobiopterin analog, Sapropterin, is the first non-dietary treatment for patients with phenylketonuria (PKU). Sapropterin dihydrochloride (Kuvan®) is a synthetic formulation of the active 6R-isomer of tetrahydrobiopterin, a naturally occurring cofactor of phenylalanine hydroxylase. The mechanism of action appears to be related to its effect in augmenting and stabilizing abnormal phenylalanine hydroxylase molecules, thus increasing the clearance of phenylalanine from the body. It is approved to treat hyperphenylalaninemia in patients ages 4 or more years with tetrahydrobiopterin-responsive phenylketonuria.

For disorders characterized by accumulation of toxic metabolites, excretion of the offending substance is the preferred therapeutic method. Additionally, the offending substance can be reduced by activation of alternative pathways, inhibition of normal feedback inhibition, and pharmacologic agents used to promote elimination.

Nitrogen scavengers such as sodium benzoate, phenylbutyrate, or phenylacetate are utilized in patients with urea cycle disorders. They promote nitrogen elimination and avoid toxic accumulation of the ammonium ion. Adjunct clearance mechanisms are used in disorders characterized by failure of normal metabolic clearance to excrete excess amounts of substrate. Chelation therapy with penicillamine and trienetine are used to increase copper excretion in Wilson disease. Serial phlebotomy is the treatment of choice in hemochromatosis to remove the excess iron.

Hereditary tyrosinemia type I is due to a deficiency of fumarylacetoacetase, which leads to the accumulation of fumarylacetoacetate and maleylacetoacetate. Both chemicals are then metabolized via an alternative pathway to succinylacetone – the metabolite responsible for many of the neurological symptoms of this disorder. In addition to dietary restriction of tyrosine and phenylalanine, 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) is used to divert the tyrosine catabolism pathway upstream of homogentisic acid toward a normally dormant urinary excretion pathway. This reduces the levels of fumarylacetoacetate, maleylacetoacetate, and succinylacetone, thus reducing or averting the hepatic complications of the syndrome such as cirrhosis and hepatocellular carcinoma. Allopurinol has been used similarly in disorders leading to hyperuricemia like Lesch–Nyhan syndrome, and hematin is used in acute intermittent porphyria to decrease the activity of δ-aminolevulinic acid synthetase, thereby reducing porphyrin production.

Replacement of a deficient substrate can also be an effective treatment. Smith–Lemli–Opitz syndrome is a disorder of cholesterol biosynthesis. Cholesterol supplementation has provided some benefit to patients with this

disorder. Large doses of carnitine are effective in carnitine transport defects.

Protein Replacement Therapies

Protein replacement therapy refers to production, purification, and administration of the missing protein to the patient. This therapy is used in several hereditary disorders, including cystic fibrosis, hereditary angioedema, coagulation disorders, α-1-antitrypsin deficiency, immunoglobulin deficiencies, endocrine disorders, and lysosomal storage diseases (Table 6.2).

Enzyme replacement therapy is effective in the nonneurological symptoms of mucopolysaccharidosis types I, II, IV, and VI, Pompe, and Niemann–Pick B (not approved), but has not yet proven to be beneficial in storage diseases that primarily affect the central nervous system, since the replacement enzymes do not efficiently cross the blood–brain barrier.

Metabolic inhibition

Another approach to the therapy of lysosomal storage disorders due to defects in enzymes involved in glycosphingolipid degradation (including Gaucher disease types 1, 2, and 3, Fabry disease, Tay–Sachs disease, Sandhoff disease, and G_{M1} gangliosidosis) is substrate reduction therapy (SRT). SRT is a biochemical approach that makes use of substrates that inhibit and therefore reduce the rate of macromolecule synthesis. Miglustat (*N*-butyl-deoxynojirimycin/NB-DNJ) inhibits the initial committed step in glycosphingolipid synthesis, therefore reducing the substrate of the missing enzyme. For example, children with Tay–Sachs disease accumulate high levels of G_{M2} ganglioside in brain cells, which causes cell death. Decreasing the synthesis of G_{M2} would presumably decrease cell death and moderate the course of the disease. Miglustat has been approved in Europe and the United States for the treatment of the mild form of Gaucher type 1 and in Europe for the treatment of Neiman–Pick type C. Miglustat is in clinical trials in adults and children with juvenile G_{M2}, Tay–Sachs, and Sandhoff disease, and in young children under the age of 2 with Tay–Sachs and Sandhoff disease. Some affected individuals or parents of those affected do explore with their physicians the option of using this treatment on an "off-label" basis.

Treatment of the Molecular Mechanism

Marfan syndrome affects 1 in 5,000 individuals and is a systemic connective tissue disorder caused by mutations in the gene for fibrillin-1. It was originally thought that the clinical manifestations of Marfan syndrome were solely

Table 6.2
Protein replacement therapy

Disease	Protein	Trade name
Cystic fibrosis	Digestive enzymes	Multiple
Hereditary angioedema	C1 inhibitor	Cinryze
Coagulation disorders		
For example, Hemophilia A	Factor VIII	
α-1-Antitrypsin deficiency	α-1-Antitrypsin	Prolastin
Immunoglobulin deficiencies	Intravenous immunoglobulin	IVIG
Gaucher disease	Glucosidase	Imiglucerase (Cerezyme), velalglucerase (VPIV)
Fabry disease	α-Galactosidase	Agalsidase-beta (Fabrazyme, Replagal)
Type 1 Hurler, Scheie, Hurler-Scheie	α-L-Iduronidase	Aldurazyme
Type 2 Hunter	Iduronate-2-sulfatase	Idurulfase (Elaprase)
Type 4 Morquio		
A	Galactosamine-6-sulfatase	
B	α-Galactosidase	
Type 6 Maroteaux–Lamy	*N*-Acetylhexosamine-4-sulfatase	Galsulfase (Naglazyme)
Pompe	Acid α-glucosidase	Alglucosidase alfa (Myozyme, Lumizyme)

the result of the production of abnormal fibrillin-1, resulting in changes in the structural integrity of the affected organs. Recent molecular and animal studies have shown that it is a developmental abnormality due to altered transforming growth factor-beta signaling. In the mouse model of Marfan syndrome, the use of an antagonist (Losartan) of the transforming growth factor beta-angiotensin II signaling pathway has been shown to prevent and reverse manifestations of the disease, including aortic root dilation. Losartan is currently undergoing clinical trials.

Therapy at the Intracellular Level

Protein Enhancement Therapy: Chaperones

Inherited mutations can disrupt native protein folding, thereby producing proteins with an abnormal three-dimensional conformation. These misfolded proteins, which may otherwise be sufficiently active, are consequently retained and degraded in the endoplasmic reticulum-associated degradation pathways. The most widely known of these is the ΔF508 mutation in the cystic fibrosis transmembrane conductance regulator.

Among the newest therapeutic modalities is the utilization of low-molecular-weight compounds known as chaperones to stabilize the functional form or three-dimensional shape of a mutated protein in the endoplasmic reticulum. The binding of the chaperone molecule allows the protein to fold into its correct three-dimensional conformation and be properly trafficked through the endoplasmic reticulum. The protein then resumes its proper path to the correct site in the cell. Pharmacological chaperone therapy is in early stage clinical trials for lysosomal storage diseases: Fabry disease utilizing 1-deoxygalactonojirimycin which is a potent inhibitor of α-galactosidase. The inhibitor is given in low quantities which paradoxically enhances the intracellular activity of the residual enzyme.

Transcriptional Therapy

Increasing knowledge of gene expression will allow another potential tool for therapy, transcriptional therapy. Transcriptional therapy is aimed at modulating, modifying, or reactivating genes. These types of modifications of the genome include: reducing the expression of a dominant mutant gene product by RNA interference (RNAi), increasing the expression of a gene that can compensate for the effect of the mutation at another locus, and increasing the amount of messenger RNA (mRNA) of silent or poorly expressed genes.

Hereditary angioedema (AD inheritance) is a potentially fatal disorder due to a mutation in complement 1 (C1) esterase inhibitor. Affected individuals have unpredictable episodes of submucosal and subcutaneous edema. If the upper respiratory tract is involved, this disease can be fatal. Danazol, an attenuated androgen, is used in the long-term prophylactic treatment of this condition, by increasing the abundance of C1 inhibitor mRNA. Current treatment for sickle cell disease includes hydroxyurea, which results in an increased production of fetal hemoglobin. A promising strategy in the treatment of hemoglobinopathies such as sickle cell disease and β-thalassemia is the use of drugs that induce DNA hypomethylation. These drugs increase the abundance of fetal hemoglobin (HbF, $\alpha 2\gamma 2$). HbF is normally underexpressed in adults (<1% of total hemoglobin) as a result of normal globin switching in infancy. The underexpression of the HbF is in part due to methylation of the promoter of the γ-globin gene. This methylation can be inhibited by cytidine analogs, such as decitabine (5-aza-2′deoxycytidine).

Conditions that are the result of pathologically silenced (hypermethylated) genes could theoretically be treated with drugs that cause DNA demethylation, thereby reactivating normal transcription. Fragile X syndrome is the result of pathological silencing of the FMR1 gene (Xq27.3) due to an abnormal trinucleotide repeat (CGG) expansion near the FMR1 promoter. The nucleotide analog 5-azadeoxycytidine (5-azadC) is an irreversible inhibitor of DNA methyltransferases, which predominantly methylate CpG dinucleotides in the human genome. In vitro treatment of fragile X cells with 5-azadC lead to reactivation of FMR1 transcription. Drugs that target other forms of gene inactivation are also being investigated (e.g., histone acetylation). Other candidates are conditions that result from deletion or uniparental disomy of an imprinted gene.

Pathological changes can result from the production of a gene product that is toxic to the cell, as in Huntington disease. Additionally, an abnormal collagen chain produces a structurally weakened collagen triple helix in osteogenesis imperfecta. Diminishing the amount of the mutant protein without altering the production of the normal allele may ameliorate the phenotype. This goal might be reached by creating double-stranded RNA molecules that are degraded prior to translation. RNA interference (RNAi) technology utilizes RNAi directed against the mutant mRNA, which inactivates the specific mRNA transcribed

by the mutant allele while not binding and inactivating the mRNA transcribed by the normal allele.

Translational Therapy: Stop-Codon Read-Through Drugs

One-third of inherited diseases are the result of mutations that create premature termination codons. These include cystic fibrosis, muscular dystrophy, hemophilia, familial hypercholesterolemia, lysosomal storage disorders, and several types of cancer. Aminoglycosides (gentamicin) can suppress premature translational termination induced by nonsense mutations and prompt ribosomes to generate full-length proteins. In preclinical and pilot clinical studies, this therapeutic approach shows promise in reducing or eliminating the phenotype by promoting protein synthesis. The challenge ahead is to maximize efficacy and minimize side effects.

Pathway Modification

Several genetic syndromes are the result of mutations in known pathways that control transcription. Sirolimus (rapamycin) is an immunosuppressant medication with activity in the mTOR pathway (see *Fig. 6.2*). This results in blocking of cytokine-initiated signaling. The mTOR pathway is affected in several syndromes such as tuberous sclerosis complex (TSC) and the Ras pathway syndromes – neurofibromatosis, Noonan syndrome, cardiofaciocutaneous syndrome, Costello syndrome, and LEOPARD syndrome. These syndromes are marked by the constituitive activation of ras-signaling the mTOR

pathway. Rapamycin and other mTOR inhibitors are currently in clinical trials to gauge effectiveness in preventing the formation and growth of neurofibromas in NF1 and various manifestations of TSC.

Cell Replacement Therapy

The isolation and utilization of pluripotent and totipotent embryonic stem cells has previously been restricted to the creation of recombinant animal models of human disease. Recently, these stem cells have been stimulated to follow known differentiation pathways which yield specific cell types. These manufactured cells might then correct human disease resulting from the lack of secreted products, or urged to differentiate in situ to replace the diseased cells. There are currently multiple entries in ClinicalTrials.gov regarding stem cell research. Some examples of diseases are listed in *Table 6.3*.

Gene Therapy

In principle, this approach seems straightforward. It is possible now to create mutant animal phenotypes and to correct them utilizing recombinant technology. The application to humans is problematic. One cannot reverse the embryologic development of a human fetus; therefore, altering a structural defect is not currently possible. The diseases considered for gene therapy are thus restricted to those associated with continuously replicating cells such as hematopoietic cells and epithelial cells, or enzyme defects in accessible cells. The mechanism of molecular modification utilizes both random insertion of a correct genetic sequence into the genome and homologous recombination to correct the specific mutation. For each specific combination of vector, transgene and target tissue one or two of the following problems predominate: gene silencing, insertional mutagenesis, phenotoxycity, immunotoxicity, horizontal transmission of the donated DNA, vertical transmission (Mingozazi F, High KA. Therapeutic in vivo gene transfer for genetic disease using AAV: progress and challenges).

The vectors utilized to deliver the DNA therapy must be taken up by mammalian cells and ultimately the DNA must travel to the nucleus and become incorporated either by insertion or homologous recombination. Eukaryotic viruses such as adeno-associated viruses (AAV) have been most commonly utilized. The mammalian cells are efficient in the uptake of AAV, and the therapeutic DNA sequence is effectively delivered to the nucleus where recombination or insertion takes place.

If the desired effect is to suppress gene expression, then small inhibitory RNA strands (siRNA) can be used. The siRNA binds selectively to mRNA strands and the resulting double-stranded RNA is degraded by the cell prior to translation. The delivery systems for siRNA are numerous and summarized in a table. The siRNA incorporation is transient and does not yield a long-term solution.

Children with cystic fibrosis have temporarily incorporated exogenous DNA in their lungs utilizing an adenovirus vector, but the underlying stem cells were not transfected and the effect was transient. Another setback occurred with the death of a patient with OTC deficiency. It is believed that an immune response to the vector was the cause of death. The same results have occurred with a child who was being treated for severe combined immunodeficiency disorder (SCID). These issues have been addressed and therapies have been formulated for many disease states.

Newer trials are being undertaken with the hope of correcting mutations in target organs. There are currently many trials utilizing gene therapy. A few examples are listed in *Table 6.4*.

Neonatology

Martin Keszler

7 The Field of Neonatology

William Oh

During the eighteenth century, the care of sick infants was extremely primitive resulting in an extremely high infant mortality rate: 290/1,000 live birth or a whopping 29%. In the next century, persistently high infant mortality rate raised concerns of depopulation and potential lack of military enrollees which prompted the European governments' initiatives to improve maternal and child health. The late nineteenth century witnessed the beginning of some attempts to improve neonatal care with the advent of primitive but effective warming devices. This simple intervention resulted in improvement of infant mortality rate. In the United States the reduction of infant mortality was dramatic dropping from 100/1,000 to approximately 35/ 1,000 live birth from 1915 through 1940s (*Fig. 7.1*). This reduction was in part a result of the decline in neonatal mortality rate from 44 to 25/1,000 live births.

In the nineteenth century, attempts to provide better care of the high risk infants were done by midwives and obstetricians. Ironically, pediatricians were not involved. A French obstetrician Stephane Tarnier was credited for developing the incubator, which markedly reduced the mortality rate of infants under 2,000 g from 66% to 38%. Pierre Budin another French obstetrician was generally considered as one of the pioneers in improving neonatal care by extending the works of Tarnier and introducing the principles and methods of neonatal care. Martin Couney, a physician who championed the cause of premature care immigrated to the United States and brought the idea of improving premature care by the use of incubators. He was a clinician as well as a showman. He took the advantage of novelty of the care of premature infants with incubator and brought it to the public by showing them in various venues including fairs in cities such as Buffalo, New York, and Chicago. One vignette regarding the Chicago exhibition is that Dr. Couney presented the premature babies in the incubators to the public charging fees and made quite a bit of profit. Unfortunately, many of the infants developed diarrhea ending in death to some that prompted the closure of the show.

At about the same time, the first premature nursery was established at Sarah Morris Hospital of Michael Reese Hospital in Chicago in 1934. The nursery was directed by Dr. Julius Hess with the assistance of a very dedicated nurse, Evelyn Lundeen. This probably marked the beginning of modern Neonatology because in addition to being an excellent and dedicated clinician for this nursery, Dr. Hess started to engage in research for new knowledge to improve the care of the premature infants. The two pioneers also published textbook devoted to the principles and methods of premature care, many of which are still valid today. Other publications that enhanced the knowledge in the care of newborn soon followed and a new science was born. This era also marked the gradual introduction of pediatricians into the care of the newborns both in the delivery room and in the nursery.

At the end of World War II, several advances were responsible for the marked improvement of neonatal care. In addition to continued use of the incubator as a warming device for premature and other high risk infants, the discovery of blood type, introduction of blood transfusion, use of oxygen, fluid therapy, and antibiotics markedly improved the outcomes of the high risk infants. Advances in knowledge through clinical investigation such as establishing the diagnosis of congenital rubella syndrome, and identification of the cause of Rh erythroblastosis continued to improve the progress of the field. Some notable technological advances included the use of tiny needles (butterfly needles) designed by Dr. Robert Usher that allowed for intravenous fluid infusion as well as provision of sodium bicarbonate that improved outcomes of infants with respiratory distress syndrome. The technique of exchange transfusion was extremely valuable for the treatment of severe Rh erythroblastosis.

Some of the interventions were made without solid evidence of efficacy or freedom from potential harms. An example of this phenomenon was clearly illustrated with the oxygen treatment story. Liberal use of oxygen became commonplace in the 1950s not only to treat respiratory distress, but also more benign conditions, such as periodic breathing. While oxygen was responsible for saving many infants by reducing death or morbidity form hypoxia, ignorance of its potential adverse effects led to the tragic epidemic of retrolental fibroplasia (now known as retinopathy of prematurity) that blinded thousands.

During the past 5 to 6 decades, the emergence of the vibrant and productive subspecialty of Neonatology within Pediatrics has been witnessed; the evolution of the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_7,

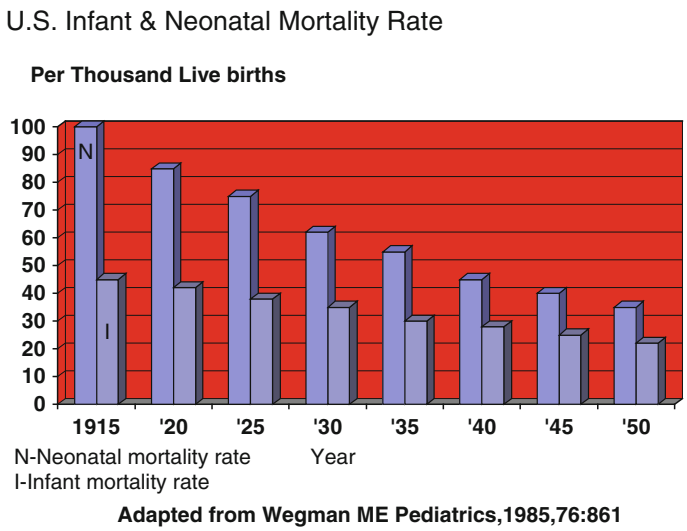

Figure 7.1
US infant and neonatal mortality rate per thousand live births

specialty was very nicely documented by Alistair Philip. It is not entirely clear when and how the term Neonatology came about, although it is most likely that the term was introduced by Alexander Shaffer who used the term in his textbook in 1960. The emergence of this subspecialty along with tremendous advances in medical care for the high risk infants have resulted in marked improvement in neonatal mortality rate in industrialized countries. Lee et al have shown that from 1950 to 1975, the US neonatal mortality rates have fallen significantly from 20 to 11.5/1,000 live births. This fall was not associated with any change in important demographic variables such as birth weight and gestational age that might affect neonatal mortality rates, clearly suggesting that the improvement is a result of improved medical care provided by the clinicians in this specialty. In 2005, the US neonatal mortality rate has fallen further to a low of 4.54/1,000 live births. This remarkable change in statistics was associated with the lowering of gestational age range for viability. In the 1950s and 1960s, only the very preterm infants (32 plus weeks of gestation) had a realistic chances of survival. In fact, in those days, in many countries, the neonatal survival statistics only list those who are 28 weeks in gestation or above. Today, the threshold of viability in the developed countries is close to 24–25 weeks. Unfortunately, the improvement in survival rate in the most immature infants has not been associated with improved outcomes of these infants at 2 years corrected age and in resource-limited circumstance, provision of intensive care to these infants may not be appropriate. The lowering of the threshold of viability also sparks intense debate among neonatologists, ethicists, and many concerned parties as to how far is too far in saving these tiny babies. The debate is also a result of very high morbidity rates among survivors of the extremely low birth weight and preterm infants. Most parties in this debate consider 22–23 weeks gestation as futile while the center of intense disagreement is for infants in the 24–25 weeks gestation because of increasing chances of survivors but the rate of poor neurodevelopmental abnormality remains high. Substantial differences exist even between industrialized countries with the Dutch drawing the line for intensive care at 25 weeks and the Japanese attempting to save infants as immature as 22 weeks. These difficult issues are further addressed in the chapter on Chap. 37, "Ethics and Decision Making in Neonatology" elsewhere in this section.

The improvement in neonatal mortality rates during the past half century is a result of many advances derived from plethora of accomplishments in basic science, translational and clinical research, and the implementation of these research findings into clinical practice by the neonatologists as the core clinician leaders working with obstetricians, medical and surgical subspecialists, along with a cadre of multidisciplinary personnel who are involved in

neonatal care. These advances include, among others, the use of antenatal steroids for acceleration of fetal maturation, surfactant for the treatment of hyaline membrane diseases, antibiotics for neonatal sepsis, inhaled nitric oxide for persistent pulmonary hypertension, and hypothermia for infants with hypoxic ischemic encephalopathy just to name a few. A more detailed list of these advances is presented in *Table 7.1*. These therapies are also described in detailed in various chapters of this section.

Historically, in the 1950s and 1960s the venue for the care of sick neonates was primarily located in a number of premature nurseries around the country which were associated with obstetrical wards and were designed primarily for the care of premature babies. The high risk term infants were generally cared for in the pediatric wards. The responsibility for the care of these infants was generally assumed by pediatricians who were interested and dedicated to this particular group of high risk infants. These clinicians were ably supported by dedicated and experience nurses. As more sophisticated and useful medical advances such as mechanical ventilation, were introduced to the field, there was a transition of the venue from premature nurseries to neonatal intensive care units (NICUs). The high risk term infants were integrated into the neonatal intensive care units. The clinicians who were responsible for the delivery of care in these units gradually organized themselves into a distinct group of physicians and over time, the specialty of Neonatology became a reality.

At around the mid-1960s an important event occurred that was in part responsible for improved neonatal outcomes: the implementation of perinatal regionalization. The concept emerged from the clear demonstration in a Canadian study that neonatal mortality rate was markedly lower when the high risk infants were cared for in institutions with neonatal intensive care units. At about the same time, there was strong interest in regionalizing medical programs which include cardiac care and others; the neonatal regionalization program was benefitted by the endorsement of the American Medical Association which strengthened its implementation. The strategy was further enhanced by the publication by March of Dimes and supported by key medical organizations including American Academy of Pediatrics (AAP) and American College of Obstetricians and Gynecology (ACOG) of a document entitled "Toward Improving the Outcomes of Pregnancy." The Program called for the designation of various levels of obstetric and neonatal facilities in a region in accordance with their capabilities to care for infants with graded levels of risk. The Program established the core infrastructure nationwide of having the Tertiary Care Center in a region serving as the leader in providing care to the high risk

Table 7.1
Introduction of perinatal therapies that improved neonatal care and outcome during the past six decades

Decades	Therapy
1950s	First-generation antibiotics
	Blood transfusion; exchange transfusion
	Incubators: Armstrong, Hess bed
1960s	Assisted ventilation: Intermittent positive pressure ventilation
	Incubator: Air shields isolette
	Negative pressure ventilator
	Usher's butterfly needles; umbilical vessel catheterization
	Newborn screening (PKU and Hypothyroidism)
1970s	Assisted ventilation: Continuous positive airway pressure
	Antenatal steroids
	Tocolysis for preterm labor
	Phototherapy for hyperbilirubinemia
	Central line placement/parenteral nutrition
	Rhogam for prevention of Rh disease
	Cyclooxygenase inhibitors for patent ductus arteriosus
	Noninvasive diagnostic technology (echocardiography, cranial ultrasound, other advanced imaging techniques)
1980s	Assisted ventilation: High-frequency ventilation; extracorporeal membrane oxygenation
	Cardiac surgery for congenital heart disease
	Extracorporeal oxygenation for cardiac surgery and cardiorespiratory failure
1990s	Surfactant therapy for hyaline membrane disease
	Inhaled nitric oxide for pulmonary hypertension
	Indomethacin prophylaxis for intraventricular hemorrhage
	Intraparatum antibiotic prophylaxis for neonatal group B Streptococcus sepsis
	Fetal surgery
	Laser therapy for severe retinopathy of prematurity
	Assessment of neurodevelopmental outcomes of high risk infants
2000s	Hypothermia for term infants with hypoxic ischemic encephalopathy
	Gentle ventilation to prevent bronchopulmonary dysplasia
	Probiotics for prevention of necrotizing enterocolitis

mothers and infants. Each tertiary care center is associated with several Level I and II facilities with appropriate transfer and retrotransfer guidelines for the high risk mothers and infants. The AAP and ACOG published specific guidelines that defined the various levels of perinatal care facilities that serve as the blue print for local implementation.

To support the medical staffing of these facilities, the American Board of Pediatrics have approved a 3-year Fellowship Program for Neonatal Perinatal Medicine to train a cadre of neonatologists to deliver high-quality clinical care. The 2007 statistics showed that there are approximately 5,000 + board certified or eligible neonatologists in North America who served this function. Because of unabated high preterm birth in the United States, it appears that there will be continuing need for this workforce to staff the neonatal intensive care units. Many of the trainees came from various parts of the world. Most of them returned to their home countries and set up neonatal programs to deliver intensive care for the high risk newborns. The establishment of these programs in part account for the improvement of the neonatal mortality rates worldwide, particularly in the developing countries.

The Future

Clinicians and scientists in the field of Neonatology have come a long way in achieving improved outcomes of the high risk newborns worldwide. There are many challenges ahead that may positively or negatively impact continuing efforts to achieve the goal of improving the outcomes of pregnancy. The list below in by no means all inclusive but deserves consideration.

- Preterm birth – Over the past decades, there have been significant monetary investment and efforts by many scientists to uncover the cause of preterm birth with the goal of reducing its incidence. Unfortunately, to date, the etiology of preterm labor is still incompletely understood and during the past several years, the incidence of preterm birth has inched up, in part due to an increase in the birth of late preterm infants. This group of infants has higher neonatal morbidity rate than term infants and has required NICU admission. The reduction of late preterm birth from planned cesarean section by quality improvement approach would be an appropriate and likely an effective approach.
- Congenital anomalies, which occur in approximately 3% of live birth, represent an important risk factors for admission to the NICU. Both syndromic and nonsyndromic congenital anomalies account for a significant portion of admissions to the NICU, taxing medical and surgical resources in their care. To date, very little is known in regard to the causes of various significant anomalies. Research in this area should be of high priority.
- Treatment-related Injury – This is another area that deserves high priority in basic science and clinical investigation. Our attempts to increase survival involve therapies that often produce iatrogenic consequences. Prime examples are bronchopulmonary dysplasia from treatment of neonatal respiratory failure in very low birth weight infants, retinopathy of prematurity in extremely low birth weight infants due to oxygen toxicity, and short bowel syndrome in very low birth weight infants with surgical necrotizing enterocolitis. Strategies that will prevent the occurrence of these posttreatment complications are urgently needed, because these conditions produce long-lasting disability, often with poor neurodevelopmental outcomes. Adoption of lower oxygen saturation targets may be one effective intervention, because virtually all complications of prematurity are meditated to some degree by oxygen radical injury.
- Technology evaluation – Delivery of care to high risk infants often requires sophisticated technology. The intervention may produce harms if its safety is not fully evaluated. The use of the technology should be evidence based and fully evaluated for safety and potential adverse effects. Drugs used in newborns should undergo similar rigorous evaluation for safety and efficacy.
- The impact of noxious environmental stimuli on the neurodevelopmental outcome of critically ill newborns is being increasingly recognized. Attention to these environmental factors and on pain control along with developmentally supportive care hold promise for improving functional outcomes in extremely preterm survivors of neonatal intensive care.
- Behavioral research – As the survival of high risk infants (particularly the extremely low birth weight infants) increases there is a need to evaluate the neurodevelopmental and behavioral outcomes of the survivors. The goal is to identify potential deficits and formulate appropriate neuroprotective and other behavioral interventions to improve outcomes.
- Family Center Care – Involvement of families in the care of high risk infants has been shown to benefit both patients and their families. Future model of care in neonatal intensive care unit needs to incorporate the family center concept in its construction and design to allow for operational implementation of this important concept.

While the history of neonatology is a story of triumph over life-threatening conditions and enormous improvements in survival of extremely premature infants it has been punctuated by a multitude of serious missteps and errors that led to unnecessary morbidity and mortality in thousands of infants. Sadly, the well-publicized retrolental fibroplasia epidemic is but one example of the consequences of uncritical acceptance of new therapies. Other examples include such apparently benign interventions as routine use of Sulfa drug prophylaxis in all preterm infants, which led to a sixfold increase in kernicterus and a doubling of mortality affecting thousands of infants and empiric treatment with large doses of Chloramphenicol, which led to the Gray baby syndrome and numerous unnecessary deaths in the 1950s. Hexachlorophene baths for prevention of staphylococcal infection led to neurotoxicity and permanent brain damage in thousands of infants in the 1960s. More recent examples from the 1990s and beyond indicate that modern neonatology is not immune from serious errors in judgment. Hyperventilation/hyperoxia was widely used to treat persistent pulmonary hypertension without ever being subjected to prospective clinical trials and resulted in increased rates of chronic lung disease, periventricular leukomalacia, and sensorineural hearing loss in large number of term infants. Liberal use of dexamethasone for treatment/prevention of bronchopulmonary dysplasia was a universally accepted therapy for more than a decade before a significant increase in cerebral palsy was recognized.

The urgent nature of our work makes it tempting to embrace new promising therapies without waiting for adequate evidence of safety and efficacy. The examples cited above should serve as a cautionary note for neonatologists around the world to remember the first dictum of medicine: "Primum non nocere" (first, do no harm).

8 Intrauterine Development/Pregnancy

Hector Mendez-Figueroa · Edward Chien

General Introduction

Knowledge of obstetrical complications and its impact on the condition of the newborn is of valuable interest to the Pediatrician. Complications can occur in normal pregnancies that can be associated with neonatal depression. High-risk pregnancies are associated with increased risk of preterm birth and intrauterine growth restriction. These complications are associated with both increased infant morbidity and mortality. The condition of the newborn maybe impacted by both antepartum and intrapartum events. Understanding terminology and common obstetrical complications will allow for more directed management and improved communication between Obstetricians and Pediatricians.

The complete assessment of the neonate should include knowledge of the antenatal course. Maternal-fetal interactions can impact overall fetal well-being. For example, maternal nutrition and exposure to tobacco affects fetal birth weight. Socioeconomic, education, and employment status affect pregnancy outcomes indirectly. Chronic medical conditions such as hypertension, diabetes, and autoimmune diseases are associated with adverse perinatal outcomes, including a direct impact on birth weight (*Table 8.1*). Even methods of conception can have implications for the newborn (e.g., assisted reproductive techniques and imprinting errors). All these factors highlight the importance and the need for Pediatricians to understand and appreciate maternal status and its implications. This chapter focuses on common obstetric conditions and practices that will assist a Pediatrician in evaluation of the newborn.

Antepartum Fetal Assessment

The health of the fetus is assessed multiple times throughout pregnancy using a variety of different tools. These assessments often begin prior to conception and continue through pregnancy up to delivery. A variety of tests are used to define risk or identify fetal anomalies. Tests performed in the third trimester are often used to assess fetal well-being. The overall basic principles, indications, and implications for each test will be reviewed.

Prenatal Diagnosis

One of the greatest advances in modern perinatal medicine is the evolution of prenatal diagnosis. The major factors contributing to these advances include the wide use and development of ultrasound technology and understanding of genetic basis of human diseases. These advances have allowed for earlier diagnosis and earlier intervention. Earlier diagnosis has allowed parents more time for preparation and adjustment to the special needs of their future children. Prenatal identification of congenital malformations allows the neonatal team to prepare for interventions immediately at delivery.

Noninvasive Prenatal Diagnosis

Ultrasound

In the past three decades, ultrasound has become the one of the most common obstetrical procedures performed prenatally. In developed countries, the use of ultrasound is almost universal. The increase in power outputs has provided better resolution and sensitivity, allowing identification of smaller lesions at earlier gestational ages. The introduction of three-dimensional (3-D) and four-dimensional (4-D) ultrasound in the past decade is likely to further advance prenatal diagnostic accuracy. Ultrasound has not been shown to produce any adverse outcomes to the fetus, although the increase in power output limits can have biological effects. Because of these potential effects, the American College of Obstetrics and Gynecology (ACOG) continues to recommend its use only for specific medical indications.

Gestational-age determination/confirmation is one of the most valuable pieces of information obtained as well as one of the most common indications for first trimester ultrasounds. This diagnostic tool provides the most accurate method for confirming or establishing

Malabsorption disorders	Cyanotic heart disease
Chronic respiratory disease	Chronic kidney disease

Various medical conditions can affect birth weight directly and should be taken into consideration when treating low birth weight neonates

gestational age. Studies have demonstrated that biologic variability from LMP varies from 4 to 7 days, depending on if the examination is performed early or late during the first trimester. Examinations performed during the second trimester vary from 10 to 14 days, while those during the third trimester can be as great as 21 days. The use of ultrasound to confirm or determine gestational age has narrowed the gestational length distribution so that only 3% of pregnancies progress past 42 weeks compared to 10% prior to the wide use of ultrasound. Ultrasound confirmation is widely used to assist in delivery timing.

Ultrasound is also widely used to detect fetal malformations (birth defects). First trimester ultrasound is becoming more widely used to assess risk for aneuploidy and identify congenital malformations. Ultrasound examinations performed during the second trimester are performed routinely to evaluate fetal anatomy. In the United States, these exams are performed by individuals with diverse training and background (radiologists, obstetricians, and maternal-fetal medicine subspecialists). Examinations are often categorized as screening or targeted examinations. The ACOG and the American Institute of Ultrasound in Medicine (AIUM) provide a standard list of items to be evaluated in each type of examination (*Table 8.2*). The screening exam (aka, fetal survey, level 1, anatomic survey) is the most widely ordered evaluation and is commonly performed by obstetricians and radiologists. Targeted exams (aka Level 2 and higher, detailed, genetic sonogram) are performed for an identified risk factor such as advanced maternal age,

Table 8.2
Standard list of items to be evaluated during obstetrical ultrasound after first trimester

Level I ultrasound Anatomic survey[a]	Level II ultrasound Detailed exam
Anatomy in addition to level I anatomy	
Maternal adnexa and cervix	
Fetal number	
Fetal presentation	
Amniotic fluid volume

suspected congenital malformation, exposure to teratogens, or family history of a congenital malformation. These exams are commonly performed by individuals with advanced training in prenatal diagnosis (Maternal-Fetal Medicine or Radiologists with advanced training in ultrasound). Ultrasound is routinely used late in pregnancy to clarify a specific characteristic such as fetal presentation, placental location, and fetal size.

Another important aspect evaluated by ultrasound is fetal growth. Patterns of growth are impacted by various factors including race, age, fetal gender, maternal health status, cigarette smoking, and presence of congenital anomalies. The original nomograms for fetal size and weight were established in individuals residing around Denver, Colorado. It has been shown that altitude above sea level can impact fetal size. Various groups and investigators have developed nomograms from other populations that are specific for multiple gestations, fetal gender, maternal ethnicity, and geographical location. Definitions for growth abnormality are often regionally dependent. Two common terms that are often used interchangeably are small for gestational age (SGA) and intrauterine growth restriction (IUGR) but can imply different clinical meaning. SGA is most commonly used when referring to a fetus with an estimated fetal weight (EFW) less than the 10% but growing parallel to growth curve lines; this is often referred to as constitutionally small. IUGR, on the other hand, is a term used to infer a pathologic cause as the source for small size or decelerating growth.

Serum Screening

Much interest and resources have been invested in detecting abnormal fetuses by evaluating analytes of fetal and placental origin in maternal serum. Maternal serum alpha-fetoprotein (MSAFP), one of the original analytes found to have clinical utility, identified individuals at higher risk for neural tube defects. The association of low MSAFP values in women carrying a fetus with Down syndrome (trisomy 21) began the search to develop additional methods for screening low- and high-risk pregnancies. The majority of methodologies have been geared toward the identification of Down syndrome (*Table 8.3*), mainly focusing on combinations between first and/or second trimester analytes with and without ultrasound. These methods assess risk but are not diagnostic.

Screening has also expanded into single gene disorders by identifying carrier status for many conditions based on family history or other risk factors. These disorders include recessive metabolic disorders common to specific populations or disorders that have higher frequencies in the general population (i.e., cystic fibrosis, spinal muscular atrophy, etc.). The advances in human genetics has allowed for prenatal diagnosis in situations where single nucleotide abnormalities are known. ACOG and the American Society of Human Genetics (ASHG) continue to modify and expand recommendations for screening of inheritable disorders. These screening techniques identify a fetus at risk for specific disorders but are generally not diagnostic. Currently, positive screens will often require an invasive test for confirmation. Newer, less-invasive techniques are in development that will allow for both screening and diagnosis. These methods are based on detection of fetal DNA/RNA in maternal serum.

Table 8.3
Different strategies for detecting fetuses with chromosome abnormalities

Different strategies for detecting fetuses with chromosome abnormalities	
Measurement of nuchal translucency alone	Measurement occurs between 10 3/7 weeks and 13 6/7 weeks
First trimester serum screen	Measurement of serum PAPP-A and free βhCG
First trimester combined	Nuchal translucency measurement with first trimester serum screen
Triple screen	Measurement of second trimester alpha-fetoprotein, total hCG, and unconjugated estriol
Quad screen	Measurement of second trimester alpha-fetoprotein, total hCG, unconjugated estriol, and inhibin A
Full integrated screen	First trimester PAPP-A levels and nuchal translucency measured, as well as Quad screening during second trimester

Various strategies with different sensitivity and specificity have been developed over the years. *PAPP-A* pregnancy-associated plasma protein A, *fβhCG* free beta subunit human chorionic gonadotropin, *hCG* human chorionic gonadotropin

Cell-Free Fetal DNA

In 1997, the isolation of fetal DNA in maternal serum paved the way for new methods in prenatal diagnosis. Since this discovery, methods for isolating fetal DNA and RNA have improved. Disease processes that can be identified by DNA analysis have grown with sequencing of the human genome. Private corporations have now started to

offer diagnostic kits capable of diagnosing fetal sex and RhD genotype. As our knowledge increases and technology advances, these newer methods will expand and replace current procedures.

Invasive Prenatal Diagnosis

Screening techniques are widely used to identify subsets of the population at greater risk for specific conditions. Invasive diagnostic techniques are still required to identify affected individuals. This section describes the various techniques available to confirm a suspected diagnosis. Each of these techniques can be associated with increased pregnancy loss and, therefore, decisions to proceed must be weighed against the benefit from the information obtained.

Chorionic Villous Sampling

Chorionic villous sampling (CVS) entails obtaining a small amount of developing placental tissue during early gestation. First described in the early 1950s, it can be done at an earlier gestational age than other techniques. CVS is usually done between 10 and 12 weeks and can be done transcervically or transabdominally. The sample obtained contains both maternal and fetal cells that must be separated, making maternal contamination a concern. The risk of this procedure is pregnancy loss. A recent meta-analysis reported an average increase in pregnancy-loss rates of 0.7% within the first 14 days. CVS is not generally performed prior to 10 weeks gestation due to reports describing an increase in oromandibular-limb hypogenesis in procedures performed at earlier gestational ages. This procedure is referred to as a placental biopsy when performed in the second or third trimester and is associated with higher complication rates.

Amniocentesis

The removal of amniotic fluid through needle aspiration done under ultrasound guidance for years was considered the "gold standard" for prenatal diagnosis. This procedure is more commonly done in the second trimester after 15 weeks of gestation. There is a lower risk for maternal cell contamination. Cells recovered from the amniotic fluid are of fetal origin. Pregnancy-loss rates are generally lower than those reported for CVS. Recent studies have suggested loss rates as low as 0.2% within 14 days of the procedure. Amniotic fluid can be found to leak transiently in 1–2% of cases. Early amniocentesis is performed in some center prior to 15 weeks, but earlier procedures are associated with higher failure and loss rates. Amniocentesis can be used to assess fetal lung maturity during the third trimester in at risk pregnancies.

Percutaneous Umbilical Blood Sampling

Generally considered a more invasive procedure with increased morbidity, PUBS allows direct access to the fetal circulation. Under ultrasound guidance, a needle is introduced into the umbilical cord to obtain fetal blood. This allows for both diagnostic testing and therapeutic interventions. The main concern with PUBS is the higher risk of fetal loss when compared to other invasive procedures. The reported procedure related loss at institutions with expertise is approximately 2.3%. Indications and use of this procedure have decreased in recent years. The most common indication is hemolytic disease. In recent years, the incidence of this disease has dropped with the use of anti-D immunoglobulin. As techniques for isolating cell-free fetal DNA advance, the use of PUBS will become even more uncommon. PUBS has also been used as a method to administer medications directly to the fetus in a variety of disorders.

Prenatal Diagnosis of Congenital Malformations

The detection of congenital anomalies has increased in the past three decades. The development of microprocessors has revolutionized ultrasound technology and prenatal diagnosis. Preparation for the delivery of a newborn with a congenital abnormality is an obvious advantage provided by prenatal diagnosis. It is now possible to detect both lethal and nonlethal malformations during the prenatal period. The breadth of congenital malformations that can be detected prenatally has become too extensive to be covered in this format. More details can be obtained for specific disorders in other sources. ❯ *Table 8.4* provides a list of disorders that are commonly detected using antenatal ultrasound.

Central Nervous System

Central nervous system (CNS) malformations are one of the most common anomalies found antenatally with an incidence of approximately 1–2 cases per 1,000 births. The examination of the fetal brain and spine consists of identification of the falx cerebri, thalami, lateral cerebral ventricles, cistern magna, cerebellum, cavum septum pellucidum, and the bony structures enclosing the CNS. The structures evaluated during routine second trimester examination allow for detection of many major structural abnormalities. Neural tube defects such as anencephaly are routinely identified from visualization of the calvarium

Table 8.4
Commonly detected fetal disorders detected during antenatal ultrasound

Commonly detected fetal disorders
Multiple gestations

Umbilical cord cysts
Amniotic band syndrome

Ultrasound evaluation of the fetus have allowed for more disorders to be diagnosed prenatally

above the level of the orbits typical of anencephaly as early as the latter half of the first trimester (Fig. 8.1). Spina bifida is commonly associated with an abnormally shaped cerebellum (banana sign), calvarium (lemon sign), and enlarged ventricles (hydrocephalus/ventriculomegaly) (Fig. 8.2). High-resolution ultrasound examinations have led to a decline in the use of amniocentesis for detection of open neural tube defects. Although ultrasound provides high specificity and sensitivity, the detection of amniotic fluid acetyl cholinesterase remains the gold standard. Evaluation of the falx and ventricular atrium allows for identification of hydrocephaly, porencephalic cysts, holoprosencephaly, and other cystic abnormalities of the brain. Other imaging modalities such as fetal MRI can often assist in diagnosis but require special expertise.

Our current understanding of structural abnormalities and their implications is far from complete. Part of the limitation is secondary to imaging limitations and in part from understanding the progressive development of the fetal brain. Our ability to differentiate outcomes based on ultrasound findings is still limited. The advance in three-dimensional imaging may improve our ability to diagnose abnormalities.

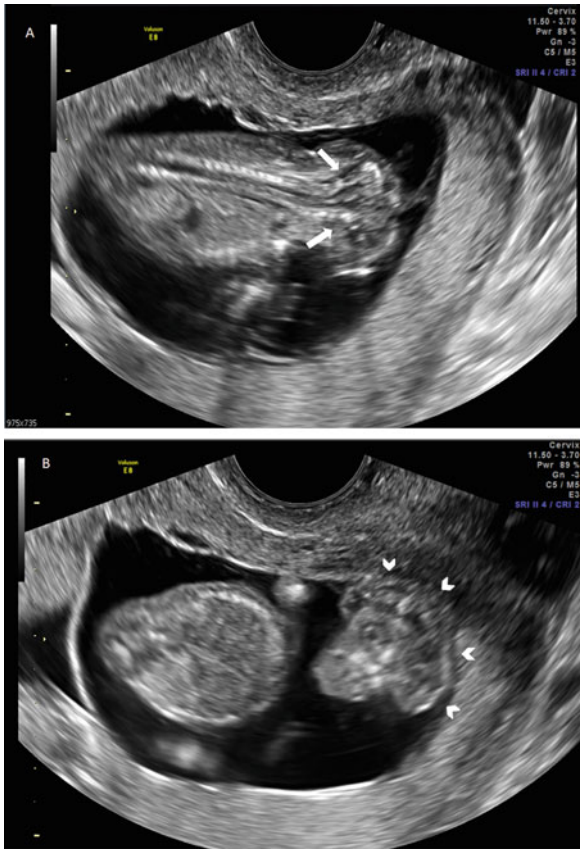

Figure 8.1
Transvaginal ultrasound done at 12 weeks gestation, revealing a fetus with anencephaly. (a) Coronal view of the fetal spine reveals an abrupt interruption in the caudal area (white *arrows*). (b) Coronal view of the fetal skull reveals exposed neuronal tissue with no calvarium (white *arrows*)

Cardiovascular System

Congenital heart disease is the most common group of severe congenital anomalies. The overall incidence is approximately 8–9 per 1,000 live births. Certain maternal conditions/exposures increase the incidence of these anomalies, e.g., poorly controlled pregestational diabetes, lithium therapy for bipolar disorder, and valproic acid for seizure disorders. More recently, commonly used medications have been associated with anomalies in the fetal heart; although, this relationship still needs to be confirmed. The standard examination of the fetal heart consists of evaluation of relative heart to thorax size, orientation of the heart, chamber size and number, and sometimes evaluation of outflow orientation. These views allow for detection of congenital heart defects such as hypoplastic left or right heart, significant stenotic valvular lesions, tetralogy of Fallot, and endocardial cushion defects that often distort the standard views. Conotruncal anomalies, septal defects, and lesions that are not associated with flow disturbance through the heart are less commonly detected because the standard views are often not distorted. The majority of septal defects are not associated with significant hemodynamic instability at birth and may not be appreciated during the fetal period (Fig. 8.3). Prenatal diagnosis provides the opportunity to deliver within a facility that is able to manage neonatal circulatory changes after birth.

Respiratory System

The normal fetal pulmonary system is characterized by homogeneous echogenicity. Abnormalities in development are identified based on relative proportion of thoracic and cardiac silhouettes, nonhomogeneous echo density, or the absence of amniotic fluid. Congenital thoracic lesions are being detected with increased frequency in recent years. Improvement in ultrasound technology

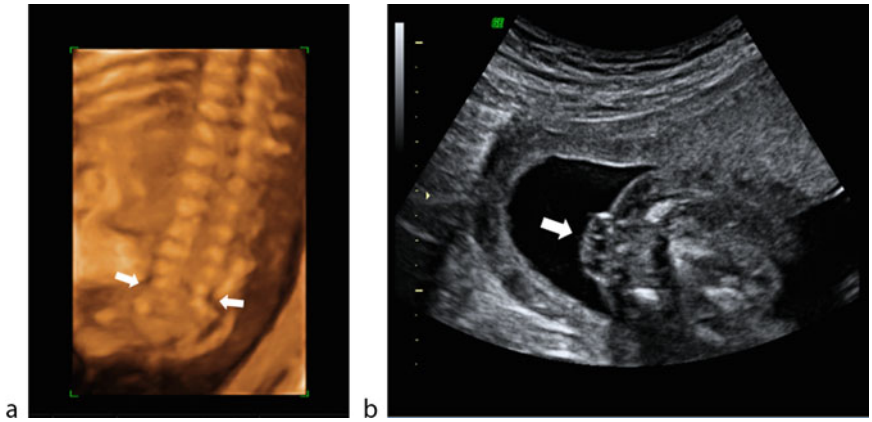

Figure 8.2
Ultrasound images of myelomeningocele diagnosed at 22 weeks. (a) 3-D skeletal reconstruction of fetal spine. Note the abnormal formation of the third sacral vertebra at the level of the defect (white *arrows*). (b) Transverse view of the fetal spine demonstrating the myelomeningocele sac (white *arrow*)

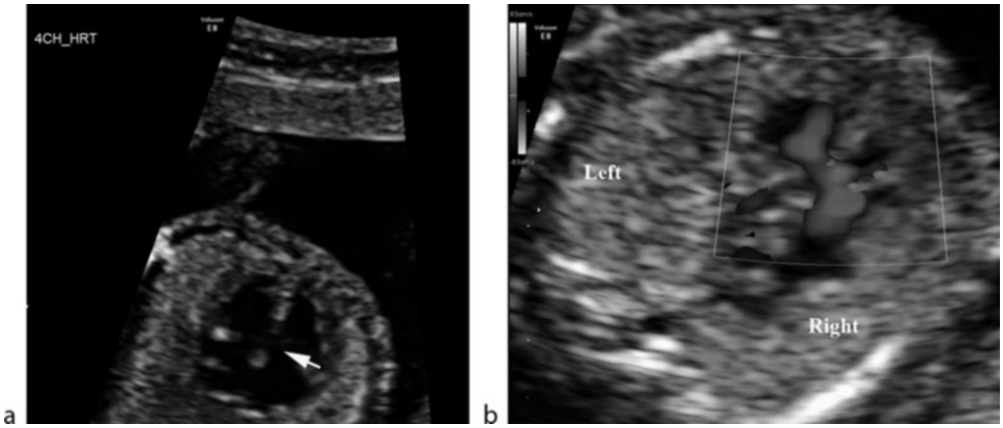

Figure 8.3

(a) Four-chamber cardiac view reveals the central defect and a single atrioventricular (AV) valve (white arrow). (b) Color Doppler confirming the presence of a defect in the interventricular septum. Right to left shunting is seen through the defect

and recognition are probably contributing factors. The two most common masses, bronchopulmonary sequestration (BPS) and congenital cystic adenomatoid malformation (CCAM), present as hyperechogenic lesions in or near the thoracic cavity (*Fig. 8.4*). They are often difficult to differentiate from each other. Both of these space occupying lesions can be associated with severe pulmonary hypoplasia by preventing normal growth and development of normal fetal pulmonary tissue.

Congenital diaphragmatic hernia (CDH) is another malformation that is frequently detected antenatally and can impact intrapartum management. It is defined as a defect in the embryologic development of the diaphragm, allowing herniation of abdominal organs into the thoracic cavity. Its overall incidence is approximately 1/2,500 to 1/5,000 live births. They are typically recognized due to a cystic chest lesion (stomach/intestine herniation) but can also present as a solid homogenous lesion (liver herniation). The compression effect of the abdominal organs in the thoracic cavity cause both pulmonary hypoplasia and pulmonary hypertension, leading to an overall mortality rate as high as 50%. Additional findings

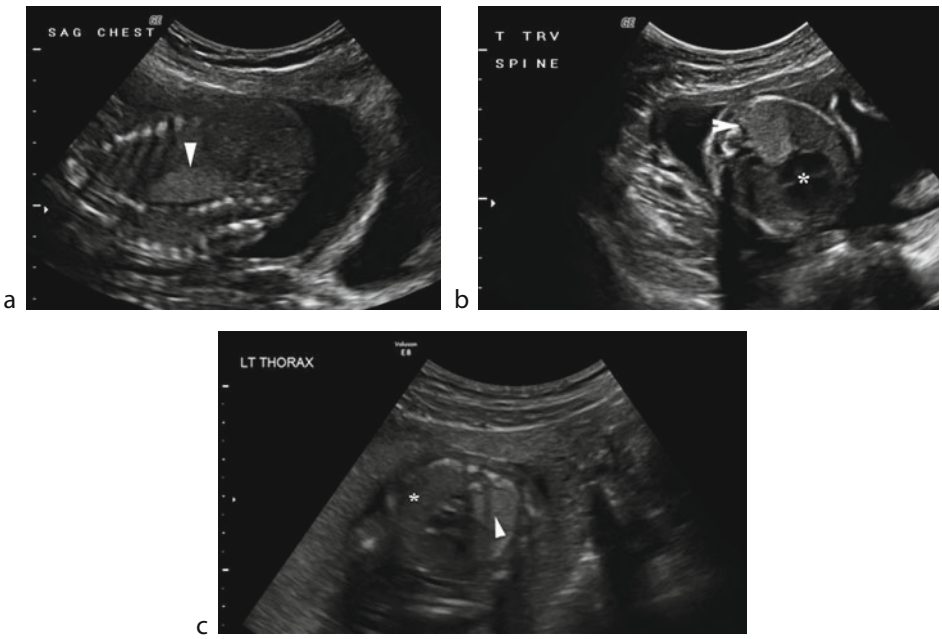

Figure 8.4
Congenital cystic adenomatous malformation (CCAM). (a) Parasagittal view through the fetal chest revealing the presence of hyperechogenic lung tissue suggestive of a CCAM (white *arrow*). (b) Transverse view of the chest at the level of the fetal heart (white asterisk). Note the presence of a hyperechoic tissue posterior to the heart (white *arrow*). (C). Another view of the CCAM revealing the difference in echogenicity characteristics between CCAM (white *arrow*) and normal lung tissue (white asterisk)

on ultrasound include deviation of the heart in the thoracic cavity. Prenatal detection may lead to improved outcomes by allowing for delivery in specialized neonatal centers.

Other structural abnormalities and complications can impact pulmonary development. Compression of the lungs by pleural effusions or absence of amniotic fluid during the midtrimester from renal anomalies can prevent normal lung development, leading to pulmonary hypoplasia. Skeletal dysplasias associated with restricted development of the thoracic cage can have similar effects. Unfortunately, current ultrasound technology prevents definitive determination of lung maturation or adequacy of pulmonary tissue.

Abdominal Malformations

The majority of antenatally detected abdominal lesions do not impact management in the delivery room but often require evaluation and/or intervention postnatally. Renal tract anomalies are detected in approximately 5/1,000 births. Obstructive renal lesions preventing normal egress of urine into the amniotic space, absence of kidneys or bilateral multicystic dysplastic kidneys can lead to pulmonary hypoplasia and impact delivery-room management. Intestinal atresias as a group are inconsistently identified antenatally. Proximal lesions can present with polyhydramnios or cystic abdominal lesions due to distention of the hollow viscous as in duodenal atresia (double bubble sign). Distal lesions are less frequently recognized. They more frequently present as echodense areas within the abdominal cavity rather than cystic lesions due to the lack of fluid from intestinal reabsorption.

Defects in the abdominal wall are the most common lesions of the abdominal cavity impacting delivery-room care. Gastroschisis is characterized by a right-sided periumbilical defect in the anterior abdominal wall (*Fig. 8.5*). Isolated gastroschisis is rarely associated with chromosomal abnormalities. Omphalocele, also a defect of the anterior abdominal wall, differs from gastroschisis in that the defect is covered by a peritoneal sac and is associated with abnormal development of anterior abdominal muscles, fascia, and skin. The incidence of

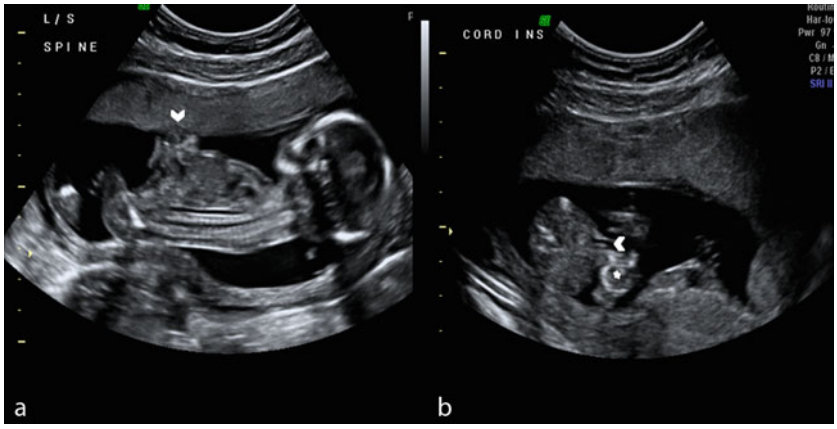

Figure 8.5
Fetal gastroschisis detected at 13 weeks gestations. (a) Sagittal view of fetal spine, note the interruption on the abdominal wall with protrusion of abdominal organs into amniotic sac (white *arrow*). (b) Cord insertion noted (white *arrow*) with intestines protruding from the right of cord insertion (white star)

this defect ranges between 1.5 and 3 per 10,000 births. Contrary to gastroschisis, omphaloceles are associated with a high rate of aneuploidy. Upon delivery of the affected neonate with an abdominal wall defect, the intestines and involved organs are draped in sterile wrapping to avoid loss of fluid and heat.

Tests of Fetal Well-being

A number of tests have been developed to assess the status of the fetus while in utero. These tests are based on recognition of normally developing fetal physiological processes or responses. The clinical context is important when interpreting these tests. *Table 8.5* shows the different antenatal fetal testing modalities available.

Fetal Movement Assessment

Maternal assessment of fetal movements has historically been used as a screening tool for detecting fetal compromise. Although it is widely used, the ideal protocol and interpretation remains controversial. Structured fetal movement monitoring is performed while the mother is sedentary so that she can focus on fetal movements. The goal is to perceive ten distinct movements in a 1–2 h period. Given the inexpensive nature of this method, most obstetricians recommend daily fetal movement assessment during the third trimester. The presence of fetal movement is considered a reassuring sign of fetal health.

Nonstress Testing

Nonstress testing (NST) is one of the most commonly used tests in obstetrics (*Fig. 8.6*). The basic principle governing this method of testing is the presence of fetal heart rate accelerations associated with fetal movement. The fetal baseline heart rate is assessed along with variability. Fetal heart rate variability indicates an intact autonomic regulatory system. Loss of this mechanism in the heart can result from depression of the central nervous system. Decreased variability is most commonly seen during normal fetal sleep cycles but can also result from pathological states that are associated with fetal acidosis occurring during anaerobic metabolism.

An NST is cataloged as reactive or nonreactive. The standard definition is an increase in fetal heart rate of 15 beats/min (bpm) from the baseline, lasting 15 s, occurring two or more times during a 20 or 30 min period in conjunction with fetal movement. The degree of heart rate acceleration is gestational age dependent with 15 bpm commonly seen at gestational ages of 32 weeks and above. At gestational ages less than 32 weeks, reactivity has been defined using an increase of only 10 bpm from baseline. The NST is considered reactive if there are two or more fetal heart rate accelerations within a 20–30 min period. An NST is considered nonreactive if it lacks a sufficient number of fetal heart rate accelerations. Testing is commonly extended for up to 40 min since fetal sleep cycles typically last less than 40 min. The NST is associated with a high false positive rate and is generally not recommended to be used in isolation for the assessment of fetal well-being when nonreactive.

Table 8.5

Tests used to assess fetal status

Name	Normal	Equivocal	Abnormal	Frequency
Fetal movement	>10 Movements in 1 h	1–9 Movements in 1 h	No movements	Daily
Nonstress test (NST)	Reactive	–	Nonreactive	2×/week
Contraction stress test (CST)	Negative	Equivocal	Positive	1–2×/week
Biophysical profile (BPP)	8–10/10	6/10	0–4/10	1–2×/week
Umbilical artery Doppler (systolic/diastolic ratio)	Gestational age dependent	–	Absent or reverse end-diastolic flow	1–2×/week
Middle cerebral artery peak velocity (MCA)	<1.5 MOM for gestational age	–	>1.5 MOM for gestational age	1×/week

Fetal status can be evaluated with multiple testing modalities

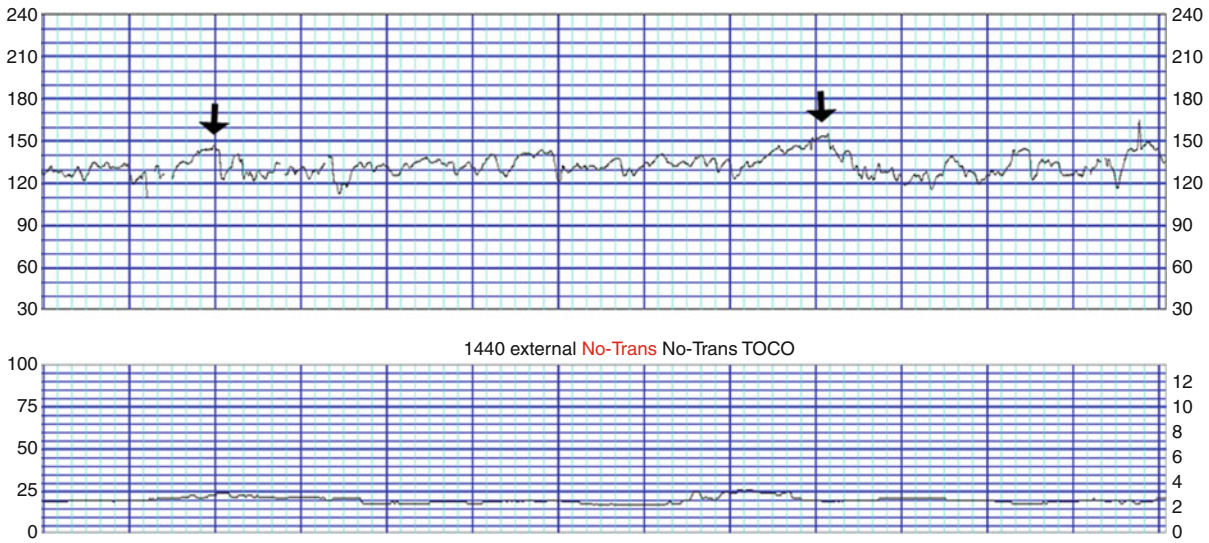

Figure 8.6

Nonstress fetal testing revealing two fetal heart rate accelerations in a 20-min period (Black *arrows*). Note the absence of contractions on the tocometer

Amniotic Fluid Index

In certain circumstances, ultrasound measurement of the amniotic fluid index (AFI) provides reliable information on fetal status. During the second half of the pregnancy, fetal urine is the major source of amniotic fluid. Similar to adults, the fetal circulatory system can redirect flow to maintain perfusion to vital organs. A decrease in placental perfusion can cause the fetus to redirect flow and decrease renal perfusion, leading to a decrease in urine/amniotic fluid production. The most widely used method of amniotic fluid assessment is the amniotic fluid index. This is performed by dividing the uterus into four quadrants and measuring the largest vertical amniotic fluid pocket in each quadrant. The sum of these four measurements is the AFI. During the third trimester, the AFI generally is between 8 and 25 cm. Oligohydramnios is generally defined as an AFI less than 5 cm and polyhydramnios

greater than 25 cm. Both abnormal measurements are associated with increased incidence of adverse perinatal outcomes. Oligohydramnios is associated with an increase in cesarean section rate for fetal distress and an increased risk of low Apgar score. Polyhydramnios has been associated with an increase in perinatal mortality rates, fetal anomalies, and an increased cesarean section rate. Oligohydramnios with intact membranes are often a reflection of a chronic condition impacting fetal well-being.

Biophysical Profile

Biophysical profile (BPP) is a more comprehensive test used to evaluate fetal status. The test is based on the principle that fetal well-being is associated with adequate oxygen delivery. With inadequate oxygen delivery, the fetus attempts to decrease oxygen consumption to preserve oxygen delivery to vital systems such as the CNS. These conservation efforts manifest itself in decreased fetal activity that can be evaluated by ultrasound.

The BPP consists of five components, an NST, and four parameters evaluated by ultrasound: fetal movement, fetal breathing, fetal tone, and amniotic fluid volume. The presence of each component is scored with a value of 2 if present or zero if not identified to be adequate. Scores range from 10 to 0. An inverse relationship has been observed between BPP scores and perinatal mortality. Scores have also been related to cord pH values obtained at cordocentesis, rates of admission to NICU, and low 5-min Apgar scores. Reassuring BPP scores are 8 and 10, while lower scores are followed by additional evaluation or delivery. The BPP is often used when a nonreactive NST is obtained.

Contraction Stress Test

The basis for this test is to assess placental functional reserve. The test is based on the principle that during contractions maternal blood flow to the placenta is interrupted, decreasing oxygen delivery to the fetus (*Fig. 8.7*). This transient reduction will be tolerated in a fetus with adequate reserves. In a fetus with inadequate placental reserve, the contractions will increase anaerobic metabolism producing fetal acidosis. The acidosis causes flattening of the fetal heart rate baseline. Hypoxia can also contribute to decreased myocardial function that is associated with late decelerations. A negative contraction stress test (CST) (normal/reassuring test) is defined as the absence of late decelerations; whereas a positive CST is one that has late decelerations in 50% or more of the contractions. Since its

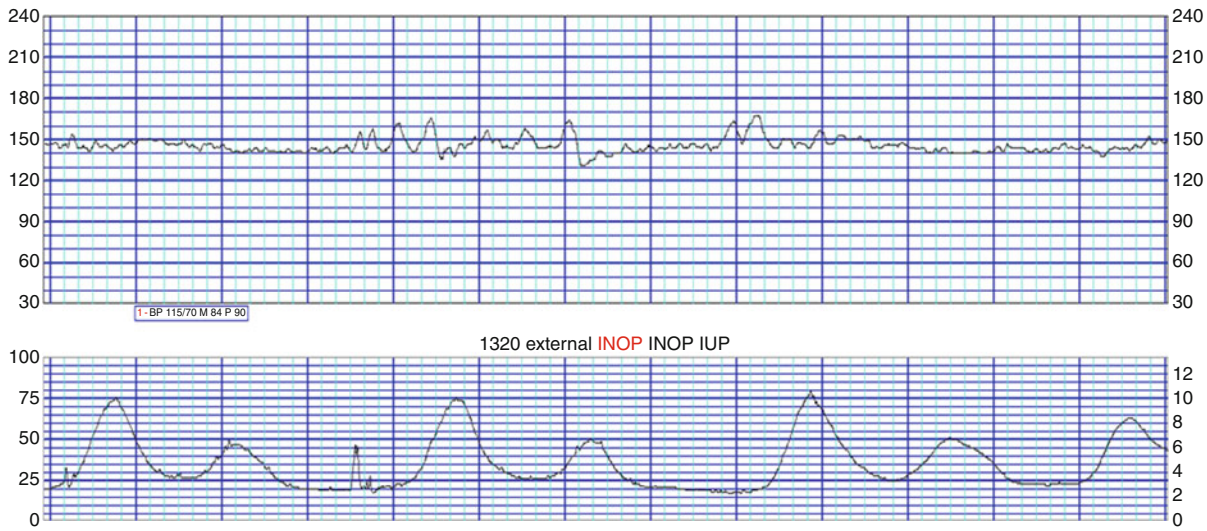

Figure 8.7

Contraction stress test done on a mother with pregestational diabetes at 34 weeks. Note the presence of more than three contractions (lower panel) in a 10-min period and the absence of late decelerations seen on the fetal heart rate (upper panel)

introduction into clinical practice, the use of CST in high-risk pregnancies has led to a reduction of stillbirth and unnecessary fetal interventions. It is most commonly used in pregnancies complicated by chronic maternal medical conditions.

Umbilical Artery Doppler Evaluation

During the past two decades, research assessing fetal status has focused on patterns of blood flow in the fetal circulation. The vessels with blood flow patterns having the greatest clinical utility are the middle cerebral artery and the umbilical artery. Peak velocities in the middle cerebral artery have been used to monitor for fetal anemia due to hemolytic disease but has found utility with other complications. The umbilical artery Doppler is most commonly used to evaluate pregnancies suspected of IUGR. The umbilical circulation is associated with declining resistance as pregnancy progresses. In pregnancies complicated by IUGR, the presence of increased vascular resistance suggests decreasing placental reserve (*Fig. 8.8*). This increase in resistance is reflected by an increase in the systolic to diastolic (S/D) ratio measured in the umbilical artery. The loss of continuous forward flow in the third trimester is associated with increased perinatal mortality in IUGR pregnancies and is often an indication for delivery to avoid stillbirth. Research into other arterial and venous fetal vessels have shown significant promise for assessing fetal status and may have additional clinical utility in the future.

Intrapartum Fetal Monitoring

Monitoring of the fetal heart rate by auscultation or with electronic monitors during labor has become universal in most developed countries. Although auscultation is still considered acceptable, most labor and delivery units have switched to electronic monitoring for a variety of reasons, including lower staffing requirements and improved documentation. Although the major goal of this obstetrical intervention is to detect fetal hypoxia and prevent subsequent injury, its implementation into clinical practice has not lead to a decrease in the rates of cerebral palsy. Other methods have been tested and have not been found to improve outcome (fetal pulse oximetry). New methods are undergoing clinical trials with initial studies suggesting some promise (STAN-ST-segment analysis).

Electronic Fetal Monitoring

Electronic fetal monitoring (EFM) is generally performed using an external Doppler device mounted on the anterior abdomen (*Fig. 8.9*). A Doppler signal is used to calculate the fetal heart rate. Internal fetal monitoring, using a fetal electrode attached to the fetal skin, is used in a similar fashion but measures the fetal heart rate by detecting fetal cardiac electrical activity. Technological advances have resulted in nearly identical patterns when comparing external and internal monitoring. Monitoring has been associated with high interobserver and intraobserver variability. In an effort to standardize interpretation, the National Institute of Child Health and Human Development in association with other medical professionals and experts developed a classification system aimed at standardizing fetal heart tracing analysis by all health care workers. Many of the obstetrical decisions, including route and timing of delivery, are based on individual interpretations of the fetal heart rate.

Fetal Pulse Oximeter

Fetal pulse oximeter (FOX) has been studied in an attempt to identify fetuses with diminished oxygen delivery to tissues. The technology consisted of a specialized sensor placed against the fetal face inserted through a dilated cervix after membrane rupture. The device measured fetal oxygen saturation through changes in light absorbance and emission of oxyhemoglobin. A large randomized controlled trial supported by the NICHD revealed fetal pulse oximetry monitoring did not lead to a reduction in the rate of cesarean sections nor did it result in improved newborn outcomes. A recent Cochrane review examining published trials of intrapartum pulse oximetry concluded that its use was not associated with a decrease in the overall cesarean section rate for non-reassuring fetal status.

ST-Segment Analysis

Recently, a new testing modality was introduced to evaluate fetal function and perfusion. ST-segment analysis is based on changes in repolarization of cardiac muscle associated with acid-base status and metabolism. The principle behind this technology was first observed in animal models; anaerobic myocardial metabolism was shown to be associated with changes in fetal ST waveforms. Small trials have reported mixed results with the introduction of this new device. Information from several large

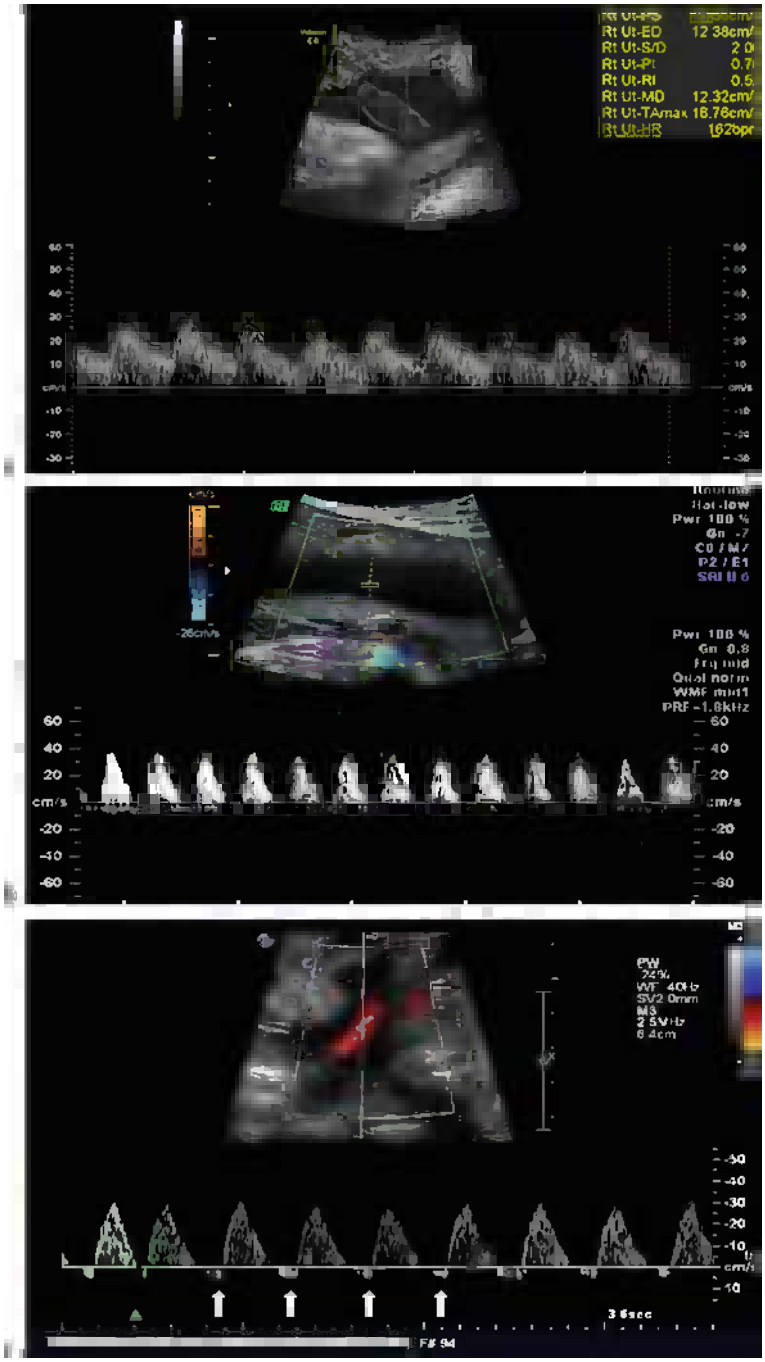

Figure 8.8

Umbilical Doppler velocimetry. Three different waveform patterns in umbilical artery Dopplers. (a) Normal umbilical artery blood flow as seen with a forward flow in diastole and a normal S/D ratio. (b) Absent end-diastolic flow. Note the forward flow during systole and the absence of flow during diastole. (c) Reverse end-diastolic flow. Flow is seen during systole, but there is retrograde flow during diastole (white *arrows*)

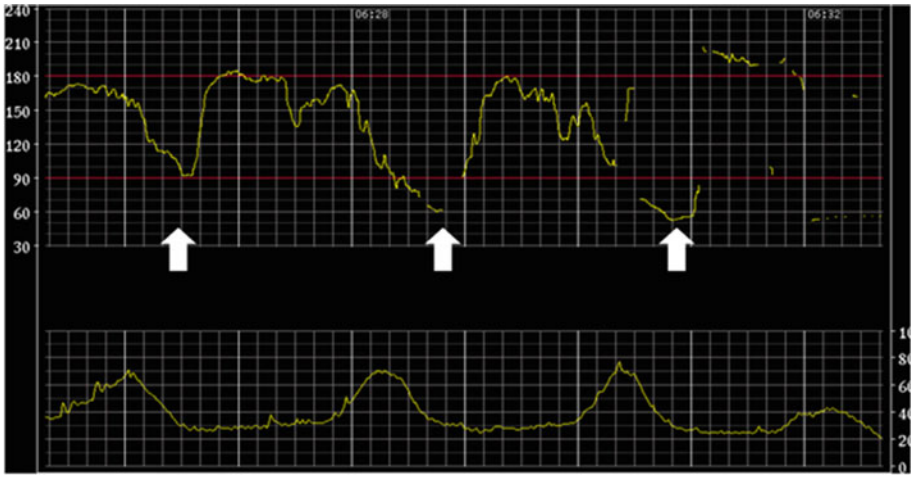

Figure 8.9
Illustration showing a case of late deceleration in the fetal heart rate. Notice the nadir of the heart rate occurs after resolution of the uterine contraction (white *arrows*). The fetal heart rate is also noted to have tachycardia after recovery suggestive of acidosis. The patient was taken to the operating room for an emergent cesarean section

randomized controlled trials currently underway will hopefully provide data that could allow its generalized clinical use.

Common Obstetrical Complications

Complications developing during or prior to pregnancy can have a negative impact on the fetus and neonate. The main factor outside of congenital malformations impacting neonatal outcome is prematurity. Preterm birth can result in chronic health problems and increased economic burden. Preterm birth is commonly divided into three major groups: spontaneous preterm birth, PPROM, and indicated preterm birth (*Fig. 8.10*). Conditions specific to pregnancy such as preeclampsia and gestational diabetes can impact neonatal condition. In addition, chronic health conditions such as essential hypertension and pregestational diabetes mellitus also can adversely impact neonatal health. Basic knowledge of these complications can allow for a more directed and tailored approach by the neonatal team.

Preterm Labor

No other subject in obstetrics has received more attention than preterm birth. The incidence of preterm birth has risen in the past two decades with current estimates of 12.7% in the United States, a 20% rise since 1990. Late preterm delivery, defined as the delivery between 34 and

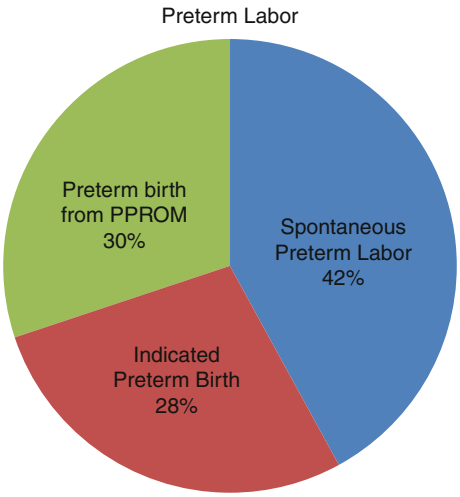

Figure 8.10
Pie chart distribution of preterm birth causes. Note that the most common cause of preterm birth is spontaneous

37 weeks, has seen the greatest increase. The rate of preterm birth is unequal across socioeconomic, ethnic, and racial groups. Non-Hispanic whites have seen the greatest increase in number of cases, although blacks still have the highest incidence overall.

Various factors have been linked to the increased rate of preterm birth. One factor believed to contribute significantly in the past decade is multiple gestations largely secondary to the increased use of assisted reproductive

Table 8.6

Periodontal disease

Various risk factors have been associated with developing preterm labor

Table 8.7
Singleton preterm-birth risk factors

Risk factor	Relative risk SPB <37 weeks	95% CI
Short cervical length < 25 mm	3.5	(2.7–4.6)
Fetal fibronectin positive	3.3	(2.5–4.2)
Previous spontaneous preterm birth	2.7	(2.1–3.5)
Low body mass index	2.5	(1.8–3.5)
Uterine contractions	1.8	(1.4–2.3)
Vaginal bleeding	1.5	(1.1–2.1)
Black race	1.5	(1.2–1.9)
Pelvic infection	1.3	(1.0–1.6)
Bacterial vaginosis	1.3	(0.98–1.6)

A short cervix (<25 mm) and a positive FFN have shown to have the highest relative risk for preterm birth

technology. In singleton pregnancies, a variety of risk factors are associated with an increase rate of preterm birth (*Table 8.6*). Both cervical length and fetal fibronectin (FFN) have been used as screening tests. A short cervix less than 25 mm and a positive FFN have shown to have the highest relative risk for preterm birth (*Table 8.7*). Prematurity is a major cause for increased perinatal morbidity. The complications of prematurity can affect all organ systems; it is the primary contributor to three of the most significant neonatal complications: respiratory distress syndrome (RDS), necrotizing enterocolitis (NEC), and intraventricular hemorrhage (IVH). The frequency of these complications is directly related to gestational age (*Table 8.8*). The incidence of major neurological morbidity, such as cerebral palsy (CP), is also inversely proportional to gestational age.

Because of the detrimental effects on fetal health caused by prematurity, much interest has been placed on prevention and management strategies. Antenatal steroids have been one of the most successful therapies introduced into modern obstetrics to decrease both morbidity and mortality. The American Congress of Obstetrics and Gynecology (ACOG) has endorsed the use of corticosteroids between 24 and 34 weeks with impending preterm birth to improve fetal lung maturity. Antibiotic prophylaxis for group B streptococcus is also a common strategy implemented when the carrier status has not yet been assessed. Tocolytic agents are widely prescribed with limited evidence of long-term benefit. The current indications for tocolytic use rests on delaying delivery to allow for administration of antenatal steroids or to transfer to a tertiary care center. Recently, magnesium sulfate has shown promise as a neuroprotective agent to prevent cerebral palsy. These limited therapies have been shown to have the greatest effect on improving neonatal outcomes. To date, therapies designed to treat preterm labor have been disappointing.

Prevention trials have shown some promise in reducing preterm birth. The treatments found to have the greatest effect in the past decade has involved the use of progesterone or its analogs. Two large randomized placebo-controlled trials have shown a benefit from weekly administration of intramuscular 17 alpha-hydroxyprogesterone caproate or daily administration of intravaginal progesterone in women at high risk for preterm birth. Other therapies, including bed rest, antioxidant vitamins, and fish oil, have not been shown to reduce preterm birth. Interventions such as smoking cessation can reduce a woman's overall risk for preterm birth. Surgical techniques such as cerclage placement have also been explored in an attempt to reduce preterm birth. Historically, cervical cerclages have been employed to decrease fetal loss and preterm labor in women with cervical insufficiency. Studies suggest some limited benefit in specific situations. The rate of preterm birth has paradoxically increased despite the use of different approaches, indicating the need for more research.

Preterm Premature Rupture of Membranes

Fetal membranes are composed of two layers: chorion and amnion, which become fused by the 14th week of gestation. They serve as a physical barrier, preventing bacteria

Table 8.8
Frequency of complications by gestational age at birth

	Gestational Age				
Complication	<24 weeks	24–28 weeks	28–32 weeks	33–36 weeks	>37 weeks

Abnormal neurological exam at age 2 (%)	75–85	43–60	21–35	5–9	–

Common medical complications found in preterm infants. The overall frequency is expressed in percentages

from entering the amniotic cavity at the same time serving as a "container" for amniotic fluid. *Preterm* premature rupture of membranes (PPROM) is a significant contributor to prematurity. A growing body of evidence has linked intraamniotic infections with local weakening and subsequent membrane rupture. Polyhydramnios, because of increased pressure on the membranes, can also lead to PPROM. Other risk factors have been identified that predispose women to PPROM (*Table 8.9*). They including: low socioeconomic status, multiple gestations, cigarette smoking, history of prior PROM and cervical conization. Labor is more likely to ensue after membrane rupture. Ninety-five percent of women that develop PROM will deliver within 22 h of rupture. If rupture of membranes occurs at less than 37 weeks, 75% of these cases will deliver within 1 week.

Table 8.9
Risk factors for premature rupture of membranes

Risk Factors
Intrauterine infection
Polyhydramnios
Low socioeconomic status
Multiple gestations
Cigarette smoking
h/o prior premature rupture of membranes
Cervical conization

Various risk factors have been associated with developing premature rupture of membranes

The diagnosis of fetal membrane rupture is based on history, examination, and confirmatory tests. Each of these tests has a high sensitivity and specificity but do not have 100% positive predictive value. To improve test performance, multiple tests are often combined to improve specificity and predictive value. Pooling, the visualization of fluid in the posterior vaginal fornix, can be amniotic fluid or urine. The nitrazine test is an assessment of pH. Amniotic fluid is neutral, typically above 6.0, and turns nitrazine to a deep blue color but can also turn blue from small amounts of blood. Ferning, allowing a sample of fluid to dry on a microscope slide, is the visualization of salt crystallization pattern that has similarity to the appearance of fern leaves. A variety of additional tests have also been introduced that detect specific proteins found at high levels in the amniotic fluid but absent or at low levels elsewhere (e.g., Amniosure).

Management of PPROM has focused on balancing the risk for infection and prematurity. The loss of the protective barrier function increases the risk for chorioamnionitis with reported incidence as high as 24%. The loss of amniotic fluid can also lead to pulmonary hypoplasia (when occurring in the second trimester), umbilical cord compression and contraction deformities secondary to prolonged compression. These risks are balanced against the known risks of prematurity.

Once rupture of membranes has been confirmed, the management often depends on gestational age. If PROM occurs at term or after 34 weeks, labor induction is generally recommended. For rupture of membranes occurring prior to 34 weeks, conservative management is considered. When rupture occurs between 32 and 34 weeks gestation, assessment of fetal lung maturity is advocated and delivery induced if mature; since prolonging latency would increase the potential risk of intrauterine infection with diminishing benefit to the fetus. For rupture less than 32 weeks, prolonging pregnancy with the administration of corticosteroids in the absence of intrauterine infection is recommended. Antibiotic prophylaxis in the setting of PPROM has been shown to improve outcome by

increasing the latency period from rupture to labor onset. A variety of antibiotic combinations have been evaluated that generally involve providing broad spectrum coverage of known perinatal pathogens. The most common combination involves ampicillin and erythromycin. Prophylaxis is commonly administered for a specified duration, typically 7 days. Patients are typically monitored as an inpatient with frequent assessments for infection. PPROM prior to 24 weeks is managed on a case by case basis due to the high morbidity and mortality.

Placental Complications

Abnormalities of placental location, function, and development are common contributing factors leading to a depressed neonate at birth. The two most common disorders associated with obstetric hemorrhage are discussed in this section.

Placental Abruption

Placental abruption is defined as the separation of a normally implanted placenta prior to birth. The overall incidence has been reported at 6.5 per 1,000 births. A variety of factors have been associated with higher rates (*Table 8.10*). Abruptions have been shown to present with varying severity from minor separation with limited symptoms (majority of cases) to complete separation associated with both maternal and neonatal morbidity/mortality. Abruption involving more than 50% of the placenta has been associated with fetal demise. The classical signs of abruption include third trimester vaginal bleeding with painful uterine contractions. Bleeding associated with placental abruption is typically maternal in origin, although fetomaternal hemorrhage can occur from disruption of the maternal-fetal interface. The separation can impact uteroplacental perfusion and fetal hypovolemia if fetomaternal hemorrhage occurs producing a depressed neonate. The majority of the observed infant morbidity is secondary to preterm delivery.

The diagnosis of abruption is clinical. A retroplacental collection of blood is seen in only 20% of cases. This high, false, negative rate for ultrasound has made this of limited value in diagnosis. Fetomaternal hemorrhage can be detected using the Kleihauer-Betke (KB) test. Fetal blood can be identified using the Apt test. Since the majority of bleeding is maternal in origin, this test is often negative. Vaginal bleeding is the presenting symptom in the majority of cases. Preterm contractions and uterine tenderness are also reported. Fetal compromise may be the only clinical finding in the absence of visible bleeding.

The management of abruption will depend on multiple factors, including gestational age, degree of bleeding, and overall fetal status. If abruption is suspected prior to 34 weeks but not severe enough to require immediate delivery, administration of corticosteroids is considered. The decision for delivery is individualized and dependent on the maternal and fetal status. Rapid progression of an abruption can lead to a precipitous delivery or an

emergent cesarean section. Neonatal anemia is a consideration at delivery in a depressed newborn. Abruptions can present as a chronic disorder that may be associated with intrauterine growth restriction and oligohydramnios.

Placenta Previa

The implantation of the placenta over the cervix is referred to as placenta previa (*Fig. 8.11*). The placenta can cover the cervix either completely or partially, commonly classified descriptively (complete, marginal/partial, low lying). Studies suggest that implantation of the placental edge within 2 cm of the internal cervical os is associated with significant hemorrhage, frequently leading to operative delivery in labor. This has led to the use of 2 cm as defining normal versus a low-lying implantation. Hemorrhage is the principal complication of a previa. The bleeding is mainly of maternal origin similar to an abruption. The incidence of placenta previa has been reported to be approximately 0.55% of all deliveries and is associated with a variety of risk factors (*Table 8.11*).

The presenting symptom in most cases of placenta previa is painless vaginal bleeding. The diagnosis of placenta previa is based on a clinical suspicion that is confirmed by ultrasound examination. It is important to note that placentas are found close to or on the cervix commonly during ultrasound examinations performed during the second trimester. Reevaluation in the third trimester is generally recommended for confirmation. The management of placenta previa depends on both the maternal and fetal status similar to abruptions. The goal is to try to reach a gestational age close to term. Because labor can increase the risk of bleeding, conservative management past 38 weeks is not typically advocated. The decision to manage these patients in an outpatient setting versus in-house observation is individualized. If delivery is anticipated at less than 34 weeks, corticosteroids for fetal lung maturity are often administered. Cesarean section is the recommended mode of delivery. In the presence of acute hemorrhage, neonatal depression can occur due to diminished uteroplacental perfusion. Fetal hypovolemia or anemia secondary to hemorrhage can occur and can lead to a depressed neonate, but this is far less common.

Table 8.11
Risk factors for placenta previa

Risk factors
Prior cesarean deliveries
Prior suction curettage
Uterine surgery
Age
Multiparity
Cocaine use
h/o Prior placenta previa

Various risk factors have been associated with developing placenta previa

Placenta Accreta

Placenta accreta is the abnormal invasion of the placenta through the decidua into the myometrium. In recent years, an upward trend in overall incidence has been observed due to the increased rate of cesarean section. With each cesarean section, the risk of developing a placenta accreta and placenta previa increases. Studies have found that the risk of previa with an associated accreta can range from 11% to 24% in women with history of one prior cesarean delivery. Placenta accreta can be associated with abnormal fetal growth due to abnormal placentation but is more of a problem for the mother with a high risk of severe hemorrhage, more so the deeper the abnormal invasion of the placental tissue into the myometrium (increta) or even beyond the uterus (percreta).

Vasa Previa

The presence of fetal vessels traversing within the fetal membranes in the vicinity of the cervix is defined as a vasa previa. These vessels can occur from insertion of the umbilical cord away from the placenta (velamontous insertion) or from vessels traversing between accessory (succinturate) lobes of the placenta. The exposure and lack of protection of these vessels makes them vulnerable to injury with the associated risk of severe fetal hemorrhage. Disruption of the vessels can lead to fetal exsanguination in a few minutes. The associated mortality with a ruptured vasa previa is close to 60%. The incidence is approximately 1 in 2,500 deliveries. The use of high-resolution and color Doppler ultrasound has increased the antenatal detection rate allowing for planned delivery. The timing of delivery is an area of much controversy, with some authors suggesting delivery at 35–36 weeks without assessment of fetal lung maturity.

Intrauterine Growth Restriction

One of the main methods of assessing fetal health is by the evaluation of fetal growth. Prior to the development of fetal ultrasound, growth was assessed by measurement of uterine size/fundal height. Since the development of ultrasound in the early 1980s, a combination of fetal measurements have served as the basis for determining fetal weight and growth. Today a variety of terms are used interchangeably to describe a fetus that is at risk for adverse outcome due to size or growth rate, including SGA (small for gestational age), FGR (fetal growth restriction), and IUGR (intrauterine growth restriction). Fetal growth is known to be influenced by gender, race, nutrition, and geographic location. It is recognized that fetal size at less than the 10% is associated with increased adverse outcome, but the majority of fetuses are normal. Differentiating a constitutional small fetus (SGA) from a pathologically small fetus (IUGR) is difficult by size alone. In addition, IUGR can be defined as a fetus that has not reached its growth potential, given that some pathological conditions in the mother will affect fetal growth without causing the weight to be below the 10% percentile. Differentiation is important because it can impact management decisions. A variety of different fetal growth curves have been developed that can be specific for a given population. Determining the cause of IUGR can be a daunting task. IUGR is often divided into fetal causes, maternal causes, and placental factors. IUGR occurs more commonly in the presence of fetal anomalies, aneuploidy, and congenital infections (*Table 8.12*).

Antenatal testing is generally prescribed after the diagnosis of IUGR has been made. Protocols for monitoring vary between institutions but generally involve a combination of monitoring of fetal movement, NST, amniotic fluid volume, ultrasound biometry, and vascular Doppler measurements. Doppler interrogation of the umbilical artery has been shown to aid in the evaluation of IUGR fetuses. Doppler studies that fail to show forward flow (absent or reverse flow) during diastole in the umbilical artery are at significant risk for stillbirth and is also associated with increased morbidity and mortality in the newborn period. Decision for delivery is dependent on antenatal testing results, progressive fetal growth, and gestational age.

Table 8.12
Common causes of intrauterine growth restriction

Common causes of IUGR		
Maternal	**Fetal**	**Placental**
Maternal hypertension (chronic hypertension, preeclampsia)	Chromosome abnormalities	Confined placental mosaic
Renal disease	Anomalies (congenital diaphragmatic hernia, congenital heart disease)	Placenta previa/accreta
Autoimmune disorders	Multiple gestation	Placental abruption
Cyanotic heart diseases	Fetal infection (cytomegalovirus, toxoplasmosis, malaria, rubella)	Placental infarction
Hemoglobinopathies		Circumvallate placenta
Severe lung disease		Large hemangiomas
Malnutrition		Velamentous cord insertion
Drugs (alcohol, cocaine, medications)		

Intrauterine growth restriction can have a maternal, placental, or fetal cause

Multiple Gestations

The incidence of multiple gestations has been on the rise in the past decade mainly due to assisted reproductive technology. Although multiple gestations account for less than 3% of all live births, they disproportionately contribute to perinatal morbidity and mortality. When compared to singletons, multiple gestations have an increased risk of low birth weight (relative risk [RR] of 8.6) and neonatal death (RR of 7.06). Preterm birth occurs in over 50% of twin gestations and even greater with higher-order multiples. The incidence of congenital abnormalities is also increased in multiples, occurring more than twice as often than singleton gestations.

Zygosity and placentation are important factors that can be used to assess risk. In twin gestations, birth outcomes and complications are related to type of placentation. Monozygotic twins have significantly greater morbidity and mortality than dizygotic twins. In monozygotic twinning, the timing of division determines the type of placentation (*Fig. 8.12*). Other pregnancy complications are also increased in individuals having multiple gestations, including a 2.62 RR for preeclampsia

Figure 8.12
Triplet gestation. Intrauterine pregnancies seen at 9 weeks. Note the presence of three separate gestational sacs. The membranes separating each sac appears thick, consistent with a triamniotic-trichorionic placentation

and a 1.8 RR for gestational diabetes that can impact newborn health. IUGR is also more common with multiple gestations.

Management of multiple gestations involves monitoring for these complications often with more frequent antepartum visits, testing, and ultrasounds. Twin-to-twin transfusion syndrome (TTTS) is a complication unique to monozygotic twins. This syndrome is characterized by unequal shunting of blood amongst twins through placental vascular communications. Interventions such as laser ablation of communicating vessels and reduction of amniotic fluid have been shown to improve outcomes. Monochorionic monoamniotic (mono-mono) pregnancies are at greater risk of morbidity and mortality than monochorionic diamniotic twins. Mono-mono twins are at high risk of cord entanglement in up to 71% of cases with a reported mortality rates of 50%. The timing of delivery in these cases should balance the risk of prematurity versus the risk of fetal death.

Maternal Medical Complications

Maternal medical complications frequently impact newborn outcomes. Some of these complications are specific to pregnancy such as gestational diabetes and preeclampsia, while other disorders are unrelated. As technology improves, individuals with chronic diseases often choose to bear children. It has become more important for physicians to understand potential implications of chronic diseases on pregnancy. Medical therapies can increase the risk for malformations and impact fetal development. Maternal medical diseases such as autoimmune diseases can cause neonatal effects such as neonatal lupus or neonatal Graves disease which are generally self-limited until clearance of the offending antibody. Optimal treatment of maternal medical diseases such as Type 1 diabetes mellitus or phenylketonuria (PKU) can decrease the risk of malformations. In this section, we will discuss two of the more common medical complications impacting newborn health.

Diabetes in Pregnancy

Diabetes mellitus is a common maternal condition, complicating 1–14% of all pregnancies. It is often classified based on time of diagnosis: during pregnancy (Gestational Diabetes) and prior to pregnancy (Type 1 and 2). Gestational diabetes and pregestational diabetes are generally associated with different risks to mother and fetus. Diabetes mellitus diagnosed during pregnancy may be preexisting but not diagnosed prior to pregnancy, which can occur in individuals for a variety of reasons. Management is based on the implicit risk in pregnancy.

Gestational Diabetes

Gestational diabetes (GDM) is the most common form of diabetes occurring during pregnancy. This disorder is

typically characterized by insulin resistance similar to type-2 diabetes mellitus. The main risks to gestational diabetes on pregnancy outcome are related to fetal and neonatal complications, although it is associated with higher incidence of cesarean section. A number of large multicentered studies evaluating the implications of mild gestational diabetes support routine screening in order to initiate therapy. These studies demonstrated that pregnancies complicated by mild gestational diabetes were at increased risk for fetal macrosomia and cesarean section. Pregnancy outcomes were associated with degree of hyperglycemia. In addition to increased birth weight, poorly controlled GDM has been associated with increased rates of respiratory insufficiency, neonatal hypoglycemia, polycythemia, hyperbilirubinemia, myocardial hypertrophy, and electrolyte abnormalities.

The associated neonatal morbidities can be directly associated with degree of maternal hyperglycemia, resulting in fetal hyperglycemia. Fetal hyperglycemia is associated with increased fetal pancreatic production of insulin that is believed to contribute to excessive fetal growth and neonatal hypoglycemia. In addition, the increased circulating glucose requires an increase in metabolic demand, resulting in increased oxygen consumption. This increased metabolic demand can lead to fetal acidosis and even fetal demise. Fetal acidosis can inhibit surfactant production that increases the need for respiratory support after birth. Increased oxygen consumption is likely to be the cause of increased red cell production, resulting in polycythemia and hyperbilirubinemia. In well-controlled GDM, the incidence of neonatal complications approaches that of the general population supporting the benefit of monitoring and medical interventions.

Pregestational Diabetes

In addition to the complications of GDM, pregnancies complicated by either Type-1 or -2 diabetes mellitus are at increased risk for additional complications. These complications are also related to the degree of hyperglycemia occurring during the first trimester. The main fetal risk is due to the increased risk of congenital malformations. Although malformations can occur in any organ system, the two most frequently affected by hyperglycemia in the first trimester are the cardiovascular system and the central nervous system. Congenital heart defects and neural tube defects are more frequently seen in fetuses of mothers with hyperglycemia during the first trimester. Glycosylated hemoglobin level obtained during the first trimester is used commonly to assess the degree of hyperglycemia affecting the fetus during the period of organogenesis. Patients identified at increased risk are often screened with targeted ultrasound examinations to evaluate for these complications as well as serum analytes like alpha-fetoprotein.

Fetal malformations are not the only factors contributing to the increased morbidity and mortality in pregnancies of women with pregestational diabetes. These pregnancies are at increased risk for indicated preterm birth from a variety of causes. Preeclampsia (PE) occurs more frequently and more often at earlier gestational ages. The duration of preexisting diabetes mellitus and the degree of end-organ disease can be associated with the risk for poor pregnancy outcome and frequency of early delivery. This is reflected in the commonly used White's Classification for diabetes in pregnancy (*Table 8.13*). Although large for gestational age, infants are commonly associated with diabetes in pregnancy, growth-restricted fetuses occur more commonly with White's class D and higher.

Preeclampsia

Hypertension frequently complicates pregnancy leading to premature birth. Preeclampsia similar to GDM is a pregnancy specific disorder that resolves after delivery

Table 8.13
White's classification for diabetes during pregnancy

Class	Definition
A	Diagnosed during pregnancy
A1	Diet-controlled
A2	Diabetes controlled with medication
B	Duration of disease <10 years or age of onset ≥20 years
C	Duration of disease between 10 and 19 years or age of onset between age 10 and 19
D	Duration of disease ≥20 years or age of onset prior to 10 years age
F	Nephropathy (>500 mg/day proteinuria)
H	Atherosclerotic heart disease
R	Proliferative retinopathy or vitreous hemorrhage
T	After renal transplant

Classification used to stratify diabetes during pregnancy

of the fetus. In contrast to GDM, therapeutic interventions to control blood pressure have shown limited benefit on neonatal outcomes. Women with preexisting hypertension are also choosing to become pregnant more frequently. The increase can be attributed to the delay in reproduction in many developed countries. Although most hypertensive women have successful pregnancy outcomes, these pregnancies are associated with increased maternal and neonatal morbidity and mortality. Preeclampsia superimposed onto chronic hypertension can occur at higher rates as well as higher incidence of growth restriction and stillbirth. Antihypertensive therapy can also affect pregnancy outcome. Angiotensin converting enzyme inhibitors, a commonly used class of antihypertensive therapy, are associated with significant adverse pregnancy outcomes and are proscribed during pregnancy.

Preeclampsia is a disease occurring during the second half of pregnancy. Although the cause for this disorder remains unknown, research over the past two decades has demonstrated that factors associated with angiogenesis and placental growth are involved. Similar to preterm birth, a variety of conditions can predispose to this complication including preexisting hypertension, nulliparity, renal disease, diabetes mellitus, and autoimmune diseases. The characteristic maternal findings associated with PE include hypertension and proteinuria but is not limited to the cardiovascular and renal systems. Although edema is no longer used as one of the defining characteristics, third spacing of fluid also contributes to significant morbidities. PE can affect any organ system in the body. Central nervous system vasoconstriction can lead to cerebral edema that may manifest as seizure activity (eclampsia) or in cortical blindness (amaurosis fugax). Hepatic vasoconstriction can lead to subcapsular bleeding and elevated transaminases. Microvascular angiopathy is a finding associated with PE that can be associated with increased platelet consumption and red blood cell fragility. PE manifesting as a combination of hemolysis, thrombocytopenia, and elevated hepatic transaminases is referred to as HELLP syndrome. Increased capillary leak can lead to pulmonary edema. Third spacing of fluid can lead to decreased intravascular volume that affects both renal and uterine perfusion. These serious complications often necessitate preterm delivery in order to prevent further deterioration of the maternal condition.

The neonate can also be affected directly by PE. Because PE is associated with abnormal placentation and increased vascular resistance, fetal growth restriction may be discovered at the onset of clinical symptoms. Decreased perfusion can result in fetal acidosis and a depressed neonate. Thrombocytopenia is commonly observed in the neonate born to mothers with severe forms of preeclampsia, probably due to increased platelet activation and consumption in the neonate similar to the mother. Neutropenia is also commonly seen in the infant. Delivery is generally prescribed when PE develops at term. Delivery is generally delayed when mild forms of PE develop prior to term. Delivery is expedited when individuals develop severe forms of PE, although in some cases delivery is delayed to allow for the administration of corticosteroids.

Summary

Effective communication between the obstetrician and pediatrician can positively affect the transition of the neonate after birth. Prenatal care has evolved over the past five decades from mainly monitoring maternal health to include assessing fetal health. The field of prenatal diagnosis has grown exponentially, allowing for the health care team to anticipate neonatal needs at birth and during the neonatal period. Obstetric care has also evolved with greater understanding of the effects of various therapeutic interventions on fetal health. Selection of medical therapy is often based on balancing the potential adverse effects on the fetus with the therapeutic benefit on the mother. This chapter summarizes the many different assessments and interventions used during pregnancy to monitor and improve pregnancy outcome. Although the timing of delivery may not always be to the benefit of the neonate, the obstetrician's decisions are an attempt to balance the needs of the mother and the fetus.

9 Transition to Extrauterine Life

Anton H. van Kaam

Introduction

The transition from intrauterine to extrauterine life is a complex process involving virtually every organ system in the body. The most dramatic changes are seen in the lung and the cardiovascular system, resulting in the transition from placental to pulmonary gas exchange. Failure to adequately make this transition can be life-threatening and these infants often require supportive care. In order to select the optimal intervention, it is essential to understand the normal physiology of respiratory and cardiovascular transition. It is important to realize that most data on neonatal transition are obtained from animal studies, because of the limitations in studying human fetuses and newborn infants at this critical time.

Respiratory Transition

The Fetal Lung

During intrauterine development the fetal lungs are filled with fluid, receive little blood flow, and take no part in gas exchange. Experimental studies in fetal sheep have shown that lung fluid is produced by the pulmonary epithelium as the net result of active chloride secretion via Cl^- channels and relatively low reabsorption activity of Na^+ channels. There is some efflux of liquid from the lung via the trachea, but this process is restricted by the fetal upper airway (mainly the glottis), thereby promoting the retention of fluid and causing a continuous distending pressure within the fetal lungs, which is critical to normal lung growth and development. Besides lung fluid, fetal breathing movements, which start as early as 10 weeks' gestation, also play an important role in maintaining fetal lung distension. During fetal breathing movements rhythmic contractions of the diaphragm seem to oppose the pulmonary recoil pressure, thereby preventing lung deflation. Although never directly measured in humans, animal studies indicate that the fetal lung volume is probably at or above functional residual capacity (FRC), i.e., the volume that remains inside the lung after a normal expiration. Fetal lung distension and the associated lung tissue stretch is an essential stimulus for normal lung growth and structural development. Studies in fetal lambs have shown that a reduction (lung liquid drainage, absent fetal breathing) or an increase (tracheal occlusion) in lung expansion causes, respectively, a decrease or an increase in lung growth.

As the fetal lung slowly matures to an organ capable of extrauterine gas exchange, it undergoes enormous structural and biochemical changes. Structurally, the lung passes through four developmental stages: the pseudoglandular (5–17 weeks), the canalicular (16–26 weeks), the saccular (24–38 weeks), and finally the alveolar stage (36 weeks 2 years). The most important hallmark of the biochemical maturation is the formation of pulmonary surfactant. Lamellar bodies – containing pulmonary surfactant – in the type II pneumocytes appear between 20 and 24 weeks' gestation, but actual secretion is delayed until 30 weeks' gestation. Besides playing a role in host defense, the most important function of pulmonary surfactant is stabilization of the alveoli after birth when air has entered the lung and the alveolar surface tension has greatly increased by the creation of an air–liquid interface.

As the fetal lung grows and matures, intrauterine gas exchange is governed by the placenta. It is important to realize that, compared to extrauterine life, the fetus lives in a relatively hypoxemic environment with arterial oxygen saturation of approximately 60%.

Clearance of Lung Fluid at Birth

In order to make the transition from placental to pulmonary gas exchange successful, fluid need to be cleared rapidly from the newborn lung. Although the precise mechanisms are still unclear, animal and a few human studies have provided some of the answers.

With the onset of labor, there is a dramatic change in the transepithelial ion and fluid movement in the fetal lung. The pulmonary epithelial cells stop secreting and start reabsorbing lung liquid by activating the so far dormant epithelial sodium channels. This shift from fluid

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_9,

excretion to absorption seems to be mediated by epinephrine, which is secreted in large amounts by the fetus at the onset of labor. Maternal thyroid hormone and glucocorticoids also play an important role by augmenting the absorptive response to epinephrine.

During labor, intrauterine pressures can increase up to 75 cmH_2O and these pressures are transmitted to the fetus causing changes in fetal posture and chest wall configuration. As a result, the intra-abdominal and intrathoracic pressures increase leading to an efflux of lung fluid. As the infant passes through the distal part of the birth channel, the pressure on the thorax may increase to as much as 200 cmH_2O, causing further egress of lung fluid (vaginal squeeze).

Despite these prenatal mechanisms promoting lung liquid clearance, the lungs and airways are still filled with fluid prior to the first breath after birth. Studies in rabbit pups using phase contrast imaging have shown that the entry of air into the airways is an essential part for completing the process of liquid clearance. As air enters the airways, fluid is pushed distally and moves into the interstitial compartment where it is gradually cleared via the pulmonary circulation and lymphatics.

Aeration of the Lungs After Birth

The basic goal of lung aeration after birth is to replace lung liquid by air and to build up a normal FRC of about 30 ml/kg of body weight. Although many theories such as thoracic recoil, frog breathing, and pulmonary capillary erection have been postulated to explain the start of lung aeration in spontaneously breathing newborn infants, it is now believed that the most important mechanism for air entry is the generation of a negative transpulmonary pressure via an inspiratory effort of the infant. Studies in newborn infants have shown that this inspiratory effort during the first breath consists of a diaphragmatic contraction and results in mean subatmospheric intrathoracic pressure of 52 cmH_2O (range 28–105 cmH_2O) producing a mean tidal volume of 38 ml (range 6–69 ml). Immediately after the first inspiration, expiration is postponed by closure of the upper airways (glottis), which prevents the inspired air to escape. This process, also called expiratory breaking, generates a high positive intrathoracic pressure (mean 71 cmH_2O, range 18–115 cmH_2O) during expiration, which facilitates the distribution of air within the lung and promotes lung liquid clearance. Following this first breath, almost half of the inspired tidal volume is maintained in the lung. It usually takes several hours to achieve a normal FRC.

The moment air enters the lung, it creates an air–liquid interface at the alveolar level, which greatly increases the surface tension and thereby the elastic recoil force of the lung. This increased recoil force tends to collapse the lungs as it encounters little resistance from the relatively compliant newborn chest wall. Pulmonary surfactant which lines the alveolar surface helps to counteract this tendency by reducing the surface tension. Normally surfactant is already present in the lung during the transition at birth, as it is secreted in the lung liquid from 30 weeks' gestation. Alveolar stretch during tidal breathing after birth results in the secretion of large quantities of surfactant from the type II pneumoctyes in the alveolar space. The newborn infant also maintains end-expiratory lung volume by extending the process of expiratory breaking beyond the first breath after birth. Studies in term newborn infants have shown that 90% of the breaths in the first minutes after birth contain some form of expiratory breaking, such as crying and grunting.

As mentioned previously, the placental gas exchange provides a hypoxemic fetal environment compared to the postnatal conditions. Studies in healthy vigorous term newborn infants have shown that oxygen saturation measured by pulse oximetry gradually increases from a median saturation of 65–70% at 1 min to 85–92% at 5 min and do not reach 95% until 7–10 min of life. However, many normal healthy term newborns do not reach saturation of 90% until after 10 min of life. Data on carbon dioxide (PCO_2) changes after birth in term newborn infants are limited, but seem to indicate that PCO_2 remains stable at approximately 50 mmHg during the first 5 min of life, after which there is a steady decline toward 40 mmHg at 30 min after birth.

Respiratory Transition in Preterm Infants

There are several reasons why preterm infants have an increased risk for failing to achieve normal respiratory transition at birth. First, studies in fetal sheep have indicated that the epinephrine-induced reabsorption of fetal lung liquid during labor is compromised during preterm delivery. Studies in preterm infants with respiratory distress syndrome also showed a reduced sodium transport capacity in the nasal epithelial cells. This less efficient prenatal clearance of lung liquid may hinder aeration of the preterm lung at birth. The fact that many preterm newborn infants are born by cesarean delivery contributes to these problems (see below).

Second, the preterm infants' muscle strength is often insufficient to create the high inspiratory pressures

needed to aerate the lungs during the first breaths. The highly compliant chest wall deforms during diaphragmatic contraction, thereby limiting the inspired tidal volume. Due to the deficit of pulmonary surfactant and the high chest wall compliance, preterm infants are unable to effectively counteract the high recoil forces of the lung, which reduces the lung gas volumes at the end of expiration (FRC). This is probably the reason why preterm infants frequently continue to use expiratory breaking during spontaneous breathing (manifested as grunting).

Finally, the preterm lung is structurally immature with the lungs of most infants still being in the saccular stage. This will reduce lung surface area and thus compromise gas exchange.

Today, most preterm infants receive antenatal steroids, which stimulate both the structural and biochemical (surfactant) maturation of the lung and the prenatal clearance of lung liquid in response to epinephrine. This way many preterm infants are now able to successfully aerate their lungs at birth and create a stable FRC with only nasal continuous positive airway pressure.

Due to the above mentioned differences in respiratory transition between preterm and term infants, most preterm infants will take a longer time to reach a preductal oxygen saturation of 90% (preterm 6.5 min vs term 4.7 min). In contrast to term infants who often do not need supplemental oxygen during their transition, greater proportion of the preterm infants less than 30 weeks' gestation need supplemental oxygen at some point during their transition.

Most preterm infants will need some supportive care during their respiratory transition after birth. Studies in preterm rabbit pups have shown that supporting the first breath with positive pressure at the airway opening using prolonged inspiration time (sustained inflation) and a positive end-expiratory pressure (PEEP) facilitates lung aeration. Applying this strategy in preterm infants significantly reduces the need for intubation in the delivery room and within 72 h of age. It is, however, important to realize that this support needs to be accurately tailored to the needs of each individual infant because inappropriate ventilator support (high tidal volumes, insufficient PEEP) during the first minutes after birth can cause irreversible lung injury which increases the risk for bronchopulmonary dysplasia (BPD).

Several randomized controlled trials have shown that restoring the surfactant function in preterm infants by administration exogenous surfactant soon after birth (prophylactic use) improves lung function and reduces mortality.

Respiratory Transition After Cesarean Section

Several studies have documented the high incidence of respiratory distress and neonatal intensive care admission in infants born by Cesarean section (CS) before the onset of spontaneous labor (elective CS). There are strong indications that this increased risk for pulmonary morbidity is caused by an abnormal respiratory transition.

As mentioned previously, lung liquid clearance starts before birth in response to the epinephrine surge at the onset of labor. Studies in fetal rabbits have shown that absence of labor and thus epinephrine results in excessive retention of lung fluids. Studies in infants with transient tachypnea of the newborn are consistent with this finding showing an immaturity of the transepithelial sodium transport.

Lung liquid clearance is facilitated by the intrauterine contractions prior to delivery and the vaginal squeeze as the infants passes through the birth canal. During elective CS, intrauterine contractions are absent and a study in newborn infants showed that the delivery pressures are halved compared with vaginal delivery. In addition, significantly fewer infants born by CS retained air at the end of their first breath. This probably explains the slower increase in postnatal oxygen saturation in newborn infants delivered by CS.

Cardiovascular Transition

The Fetal Circulation

The fetal circulation differs considerably from the extrauterine circulation because the placenta and not the lung provides intrauterine gas exchange. Placental oxygenated blood needs to be directed to the left side of the heart as efficiently as possible and poorly oxygenated blood returning to the right side of the heart needs to be directed to the placenta without passing through the liquid-filled lungs. This is accomplished by the presence of central shunts via the foramen ovale and the ductus arteriosus. After passing through the umbilical vein and the ductus venosus, oxygenated blood returning from the placenta enters the right atrium via the medial aspect of the inferior vena cava. The latter facilitates oxygenated blood to cross the foramen ovale into the left atrium. The left ventricle delivers the majority of its output to the heart, brain, and upper body for optimal oxygen use. Poorly saturated blood returning from the upper body via the superior vena cava and the lower body via the lateral aspect of the

inferior vena cava predominantly crosses the tricuspid valve. Most of the right ventricular output passes through the patent ductus arteriosus into the distal aorta and reaches the placenta via the umbilical arteries. Studies in fetal lambs have shown that only 8–10% of the right ventricular output passes through the lung. In human fetuses, this percentage increases from 13% at 20 weeks to approximately 20–25% in the third trimester. The main reason for the right ventricular output to bypass the lungs via the ductus arteriosus is the relatively high pulmonary vascular resistance compared with the low systemic vascular resistance. It has been suggested that the high pulmonary vascular resistance is caused by compression of small pulmonary arteries by the liquid filling the alveolar space, but hypoxic pulmonary vasoconstriction mediated through several vasoactive substances is the most important mechanism. The placenta is the biggest contributor to the low systemic vascular resistance.

Transitional Changes at Birth

For a successful transition from placental to pulmonary gas exchange at the time of birth, lung liquid clearance and aeration needs to be accompanied by a rapid increase in pulmonary perfusion. This means that the intrauterine central right-to-left shunts must close or reverse, a process triggered by a fall in pulmonary vascular resistance and an increase in systemic vascular resistance.

The fall in pulmonary vascular resistance, resulting in an eight- to tenfold increase in pulmonary blood flow at birth, is caused by physical changes at lung expansion and the concomitant increase in oxygenation. Studies in fetal lambs have shown that lung expansion decreases PVR by unkinking of small pulmonary arteries and by exerting a direct dilating effect on these same vessels via the increased alveolar surface tension at the air–liquid interface. In addition, pulmonary vascular resistance is decreased by the stretch-induced release of prostaglandins (PGI_2, PGD_2).

Oxygenation causes pulmonary vasodilatation via the synthesis of nitric oxide (NO), although the exact stimuli for NO production are not yet fully defined.

The systemic vascular resistance increases as soon as the umbilical cord is clamped and the low-resistance placental circulation is cut off. This will further decrease the ratio between the pulmonary and systemic vascular resistance and increase pulmonary perfusion.

Studies in newborn infants have also shown a rapid decrease in the ratio between pulmonary and systemic arterial pressure during the first 12–24 h after birth. This was accompanied by a decrease in ductal right-to-left shunt and an increase in left-to-right shunt. In most term infants, the ductus arteriosus will close within 48 h after birth. As soon as pulmonary blood flow increases, the left atrial filling pressure becomes higher than the right atrial filling pressure, causing the foramen ovale to close functionally; anatomical closure occurs days to weeks later.

Cardiovascular transition also results in a significant increase in cardiac output. Although the precise mechanisms responsible for this increased output are not fully understood, several explanations have been suggested. First, studies in fetal lambs have shown a thyroid hormone mediated increase beta-adrenoreceptor responsiveness during the last weeks of pregnancy, which potentiates the ability of the heart to increase its output in response to the catecholamine surge that occurs at birth. Second, the decrease in right ventricular afterload after birth probably reduces the constraining effect of the right ventricle on the left ventricle, allowing the latter to contract more efficiently in response to the large increase in preload at birth. Finally, cardiac output is probably stimulated by the increased cardiorespiratory and thermoregulatory work after birth.

Animal studies and human data clearly demonstrate that the process of labor is also important for cardiovascular transition. Labor results in key changes in the hormonal milieu of the fetus and impacts on the key mechanisms responsible for postnatal fall in pulmonary vascular resistance. Slower fall in pulmonary vascular resistance and increased incidence of persistent pulmonary hypertension have been documented in infants born by elective Cesarean delivery without labor, compared to infants born vaginally.

It is clear from the above that cardiovascular transition is a complex process consisting of several physical and biochemical changes. Failure of just one of these changes can jeopardize normal cardiovascular transition and lead to severe disease states such as persistent pulmonary hypertension of the newborn (see Chap. 15, "Respiratory System").

10 Delivery Room Management of the Newly Born Infant

Maximo Vento

Definition/Concept

According to WHO estimates, between 0.5% and 3% of approximately 120 million infants born every year suffer birth asphyxia requiring resuscitation, and some 900,000 of these newborns die each year, and a similar number will develop motor and/or neurocognitive dysfunctions. The incidence of birth asphyxia is higher in developing countries because of a higher prevalence of risk factors, namely, women are in poor health when they become pregnant; the incidence of pregnancy and delivery complications in these women is high; care during labor and delivery is often inadequate or nonexistent. Delivery room stabilization of the newborn is the most frequent intervention in the neonatal period; however, many newborns do not receive adequate care in the delivery room (DR) because birth attendants have not been adequately trained, necessary equipment is lacking, international guidelines are not put into practice and certain traditional practices are not only ineffective but may be also harmful.

In this chapter, the pathophysiology of asphyxia and resuscitation procedures will be described based on ILCOR 2010 guidelines and evidence-based information published in recent years.

Pathophysiology of Asphyxia

Cardiocirculatory Changes During Fetal to Neonatal Transition

Life in utero occurs in a low oxygen atmosphere. The fetus is persistently hypoxemic compared to the adult, and whereas human maternal arterial and venous pO_2 is ~12 kPa (90 mmHg) and 5.3 kPa (40 mmHg), respectively, the highest arterial or venous pO_2 in the late gestation fetus rarely exceeds 4 kPa (30 mmHg) .The pCO_2 of the fetus is slightly higher than adult levels with an umbilical venous pCO_2 from 35 to 45 mmHg (4.6–6 kPa).

During labor, the fetus experiences brief periods of ischemia and hypoxemia because with each uterine contraction, flow to the placenta (and the fetus if there is cord compression) decreases transiently, impairing placental gas exchange. However, the fetus is able to recover between each contraction and blood gases performed in the umbilical cord immediately after birth are within a "normal" range. Overstimulation of the uterus with oxytocin may lead to excessively frequent contractions with limited recovery time and thereby compromise fetal well-being.

To achieve successful transition to extrauterine life, the infant must accomplish dramatic cardiorespiratory changes. In the first minutes after cord clamping, with the initiation of breathing, lungs must be expanded and fluid inside the alveoli and airways must be rapidly absorbed. Pulmonary blood flow must increase dramatically, and intracardiac and extracardiac shunts initially reverse direction and subsequently close. The first breaths of a normal-term neonate exert negative pressures that may reach pressures as high as -80 cmH_2O. Expansion of the lungs and the increase in alveolar oxygen tension both mediate the fall in pulmonary vascular resistance and increase in pulmonary blood flow after birth. Premature infants and infants born by cesarean section, without the effect of labor, do not clear the lung fluid and expand their alveoli as easily as term babies born by vaginal delivery.

Pathophysiologic Changes During Asphyxia

Dawes et al. performed experiments with rhesus monkeys asphyxiated by sealing their heads in a bag containing saline immediately after delivered by cesarean section (*Fig. 10.1*). Respiratory rate increased for a few breaths and then stopped (primary apnea). However, after 1 or 2 min, gasping was re-initiated with vigor and higher frequency and was accompanied by thrashing movements of the extremities. In this period, spontaneous ventilation could be still induced by appropriate sensory stimuli. Simultaneously, HR dropped from 200 to 100 bpm. Respiratory efforts gradually decreased and completely ceased at around 8 min. Cardiac activity continued until

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_10,

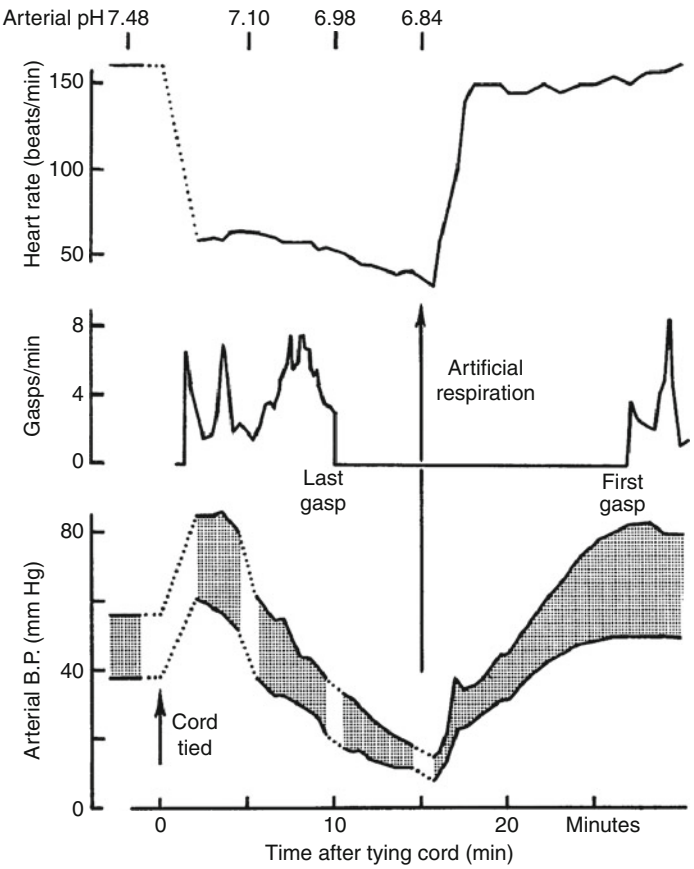

Figure 10.1

Time course of vital signs and acid base balance in an animal model of acute total asphyxia. The time course of partial and/or intermittent asphyxia may differ. Note the rapid response in HR following initiation of positive pressure ventilation (*Source*: Dawes GS, Jacobson HN, Mott JC et al (1963) The treatment of asphyxiated, mature foetal lambs and rhesus monkeys with intravenous glucose and sodium bicarbonate. J Physiol 169:167–184)

approximately 10 min. The period between the last gasp and cardiac arrest is known as secondary or terminal apnea. The time gap between secondary apnea and initiation of resuscitation correlates directly with the success of resuscitation.

Metabolic Changes in Asphyxia

Asphyxia is characterized by periods of hypoxia and ischemia. During hypoxia, limited oxygen availability decreases oxidative phosphorylation, resulting in a failure to resynthesize energy-rich phosphates, especially ATP, leading to alterations in cellular ion flux leading to cell cytotoxic edema. If an excess oxygen is given during reoxygenation, a burst of oxygen free radicals will be formed, further increasing cellular damage and inducing cell apoptosis, thus amplifying the initial damage caused by hypoxia/ischemia. Thus, limiting the oxygen amount given during resuscitation of the asphyxiated neonate is essential to prevent further increase in damage upon resuscitation.

Initial Actions

Anticipating the Need for Resuscitation

Personnel

Caregivers responsible for attending births in the DR should have an adequate training in basic neonatal resuscitation skills, which include evaluation of clinical status of the

newborn (HR, respiratory efforts, color, and tone), bag and mask ventilation, and cardiac compressions. One person should be always available for the care of each infant. In addition, a skilled caregiver trained in advanced neonatal resuscitation (intubation, ventilation, IV cannulation, use of drugs and fluids) should be available for second call for low-risk deliveries and present for all deliveries at high risk, where he or she should take the leadership of the procedure.

Equipment

Ideally, basic DR installations should be based on the DRICU concept (Delivery Room Intensive Care Unit) which means that technology used in the intensive care unit should be available in the delivery room to adequately provide care immediately after birth. Equipment should be applicable to any gestational age (23–44 weeks of gestation), and it should be regularly checked to ensure it is complete and operational (detailed description in *Table 10.1*).

Communication with the Obstetric Team and Identification of Newborn at Risk

Caregivers in charge of the neonate should request information from the obstetric eam regarding maternal medical condition, medication, and fetal status (*Table 10.2*).

Environment

Temperature

Neonates, and especially preterm infants, have a tendency toward hypothermia because of their diminished capability of generating heat (inability to shiver) and an increased ability to lose it (increased surface area to body-weight ratio, thin stratum corneum and extremely thin insulator of subcutaneous tissue). Therefore, if measures are not promptly initiated to counteract this negative heat balance, body temperature will fall, independently of the environment temperature, during the first 12 h of life. For the full-term newborn, both standard thermal care (removing wet blankets, promptly drying, and wrapping the infant in a warm blanket) and placing the dried infant under a radiant heater in a draft-free room at minimum 25°C are effective in maintaining normal body temperature. For preterm infants <28 weeks gestation, randomized controlled trials have shown that covering infants up to the neck in a transparent heat-resistant

Table 10.1
Equipment and drugs in the delivery room

Equipment
– Resuscitator with overhead warmer and light, and firm, padded, and heated mattress
– Two sources of medical oxygen
– Two sources of medical air
– Two blenders (air/oxygen)
– Clock with timer in seconds
– Warmed towels or other covering
– Polyethylene bag, or wrap, big enough for a baby less than 1,500 g birth weight.
– Stethoscope, neonatal size
– Suction catheters (6 F, 8 F, 10 F, 12 F)
– Oxygen/Air admixture supply (flow rate up to 10 L) with flow meter and tubing
– Face masks (various sizes)
– Oropharyngeal airways (sizes 0 and 00)
– Positive pressure ventilation (Two in case of twin deliveries):
• T-piece device
• Self-inflating bag with an oxygen reservoir and a manometer if available
• Flow-inflating bag with a pressure safety valve and manometer
– Laryngoscopes with straight blade (00, 0, 1), spare bulbs, and batteries
– Endotracheal tubes (sizes 2.5, 3, 3.5, and 4 mm ID)
– Endotracheal stylet or introducer
– Magill forceps, neonatal size
– Supplies for fixing endotracheal tubes and IVs (e.g., scissors, tape)
– End-tidal carbon dioxide detector (to confirm intubation)
• Chemical detector (e.g., Pedicap®)
• End-tidal CO_2 monitor
– Meconium suction device (to apply suction directly to endotracheal tube)
– Feeding tubes for gastric decompression
– Umbilical vein catheterization set and umbilical catheters (5 F) with suitable skin prep solution
– Syringes with needles (assorted sizes)
– Intravenous cannulae (assorted sizes)
– Pulse oximeter with sensors adequate for different gestational ages

Table 10.1 (Continued)

Drugs
– Adrenaline: 1:10 000 concentration (0.1 mg/mL)
– Volume expanders: Normal saline, O Rh –ve blood needs to be readily available for a profoundly anemic baby
– Sodium bicarbonate: 0.5 mmol/mL solution (4.2% concentration, or diluted 8.4%)
– Naloxone hydrochloride: 400 μg/mL solution
– Sterile water for injection

plastic (polyethylene/polyurethane wrapping) without previous drying results in a higher body temperature at admission (*Fig. 10.2*). Only the head is dried and covered with a cap. All resuscitation interventions can be performed with the plastic cover in place. Currently, there is no direct evidence that this procedure improves mortality or long-term outcome. Monitoring of body temperature should be considered, especially when resuscitation is prolonged, to avoid the small risk for inducing hyperthermia. When resuscitation is not required, the mother's body can keep the infant warm by using her as a heat source, placing the infant skin-to-skin on the mother's chest or abdomen and putting a blanket or warm wrap on top.

Avoidance of Hyperthermia

Of note is that babies born to febrile mothers (>38°C) have an increased risk of death, perinatal respiratory depression, neonatal seizures, and cerebral palsy. Therefore, normothermia (36.5–37.2°C) should be the target body temperature for newly born infants and iatrogenic hyperthermia must be avoided.

Evaluation of the Newly Born Infant

The assessment of the newborn's postnatal adaptation in the DR is usually done using the Apgar score, which evaluates five clinical signs: heart rate, respiratory effort, color, tone, and response to stimuli at 1 and 5 min (*Table 10.3*). To avoid interobserver variability, caregivers should be trained in assessing the different parameters of the Apgar score in a uniform manner, and objective means of evaluation should be pursued (e.g., pulse oximetry). Thus, an apneic infant should score "0", even if the infant is ventilated and inadequate respiratory efforts should score "1", also if the infant is ventilated. The premature infant that is hypotonic scores "1" for muscle tone, even though this may be physiologic for the gestational age.

Table 10.2
Identification of the newborn at risk

Maternal risk factors
• Prolonged rupture of membranes (>24 h)
• Bleeding in second or third trimester
• Severe pregnancy-induced hypertension
• Chronic hypertension
• Substance abuse
• Drug therapy (e.g., lithium, magnesium, adrenergic blocking agents, narcotics)
• Diabetes mellitus
• Chronic illness (e.g., anemia, cyanotic congenital heart disease)
• Maternal infection
• Chorioamnionitis
• Heavy sedation
• Previous fetal or neonatal death
• No prenatal care
Fetal risk factors
• Twins or triplets
• Preterm gestation (especially <35 weeks)
• Post-term gestation (>41 weeks)
• Large for dates
• Fetal growth restriction
• Rhesus, or other types of isoimmunisation, especially those causing hydrops fetalis
• Polyhydramnios and oligohydramnios
• Reduced fetal movement before onset of labor
• Congenital abnormalities which may affect breathing
• Intrauterine infection
Intrapartum risk factors
• Non-reassuring fetal heart rate patterns on CTG
• Abnormal presentation
• Prolapsed cord
• Prolonged labor (or prolonged second stage of labor)
• Precipitate labor
• Antepartum hemorrhage
• Thick meconium in the amniotic fluid
• Narcotic administration to mother within 4 h of delivery
• Forceps delivery
• Cesarean section under general anesthesia

Heart rate (HR) is the most relevant clinical sign indicating adequate postnatal adaptation and/or response to resuscitation. In addition, HR in the first minutes of life has prognostic value regarding mortality in the early

Newly born infant wrapped in poly-ethylene bag

Figure 10.2
Preterm newborn infant wrapped in polyethylene bag

Table 10.3
The Apgar score for evaluation of adaptation of the newborn infant after birth (32)

Sign	0	1	2
Heart rate	Absent	<100 bpm	>100 bpm
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Flaccid	Some flexion extremities	Active motion
Reflex irritability	No respond	Grimace	Vigorous cry
Color	Pale	Cyanotic	Completely pink

neonatal period. HR may be assessed by palpation of umbilical cord pulsations or direct auscultation of the *precordium*; however, randomized studies have shown that both of these methods could delay or underestimate the heart rate, compared to electrocardiography. Therefore, it is advised to use pulse oximetry for monitoring HR, especially in case of an extended resuscitation. Healthy newborn achieve a HR around 130 bpm (110–160 bpm) within the first minute of life; importantly, it should be consistently above 100 bpm within a minute after birth. Hence, if HR is persistently below 100 bpm, resuscitation should be initiated.

Assessment of the color also shows high interobserver variability, especially in preterm infants. This can be avoided with the use of pulse oximetry. It is important to understand that healthy-term newborns do not reach *preductal* oxygen saturations greater than 85–90% until 5 min and preterm infants not until 10–15 min after birth.

After initial breathing efforts, the newborn should then establish a regular pattern of respiration sufficient to maintain the HR >100 bpm. If a newborn exhibits an irregular respiratory pattern but is able to maintain an adequate HR, he/she should be closely observed but not given respiratory aid. However, if irregular breathing movements are unable to sustain HR >100 bpm, positive pressure ventilation (PPV) should be immediately applied. Importantly, in the presence of suprasternal, intercostal, and subcostal retractions, distending airway pressure should be immediately applied to help establish functional residual capacity. Finally, the absence of respiratory movements with persistent apnea generally associated with hypotonia non-responsive to stimuli, and bradycardia (HR <100 bpm) requires immediate PPV.

Newborns moving their extremities soon after birth do not require any assistance. However, if these responses are absent or weak, stimulation by rubbing the back with a dry soft towel should suffice. Other methods such as slapping, foot flicking, shaking, spanking, or holding the baby upside down are potentially dangerous and should not be used. If the infant does not respond promptly, PPV should be started.

An infant with good tone (moving the limbs and with a flexed posture) is unlikely to be severely compromised, whereas a floppy infant (not moving and extended posture) is likely to need active resuscitation. However, as indicated above, special attention should be paid especially to very premature infants for whom a hypotonic state is physiologic.

Airway and Breathing

Positioning

The newborn that needs PPV should be positioned on his/her back with the head in a neutral or slightly extended position (sniffing position) (*Fig. 10.3*).

Airway Suctioning

Routine oropharyngeal suction is not recommended; a normal newborn clears its airways effectively. However, if secretions are obstructing the airway, it should be suctioned with a special catheter with an adequate size (French gauge 10–12) and pressure not surpassing 133 cmH_2O (13 kPa). Suction should be brief (10 s) and performed carefully (not further than 5 cm from the lips) because it may cause laryngeal spasm, bradycardia, and/or delay the onset of spontaneous respiration.

Meconium-Stained Liquor

If meconium is passed into the amniotic fluid, it may be inhaled before or during delivery and lead to inflammation of the lung and airway obstruction. Complications of meconium aspiration are more likely in infants small for their gestational age, those born after term, and especially those with significant perinatal compromise.

In the presence of meconium-stained amniotic fluid, 2–9% of the neonates will develop meconium aspiration syndrome (MAS). Intrapartum oronasopharyngeal suctioning of meconium before delivery of the shoulders is no longer recommended. However, if meconium is thick, the baby is hypotonic and respiration is shallow or absent; the mouth, pharynx, and trachea should be suctioned under direct vision with the laryngoscope. If the infant is vigorous, endotracheal suction is not recommended because it may cause harm and does not improve the outcome.

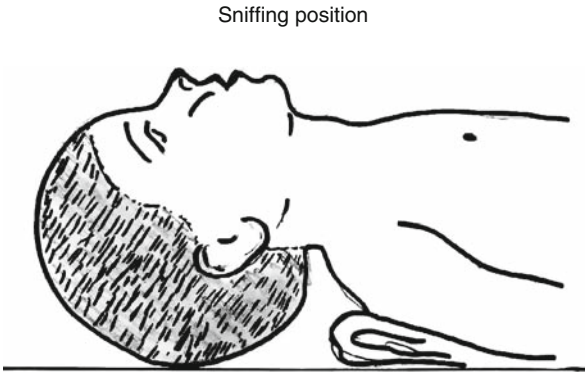

Figure 10.3
Infant in the "sniffing" position. Because of the prominent occiput of infants, positioning is facilitated by a rolled blanket placed under the shoulders (not under the neck!)

Ventilation Strategies: Initial Breaths

The establishment of adequate gas exchange by performing effective PPV at a rate of 30–60/min is without any doubt the single most effective maneuver to overcome bradycardia and hypoxemia. If HR does not improve and no thoracic expansion is observed, positioning of the face mask should be corrected to avoid leakage, which causes ventilation to be ineffective. Ensuring that the head position is correct (sniffing position described above) is essential to maintaining airway patency. In term infants, initial inflations, either spontaneous or assisted, create a functional residual capacity (FRC). The optimum pressure, inflation time, and flow required to establish an effective FRC have not been determined. However, peak inflating pressures of 30–40 cmH_2O have been shown to be effective to ventilate unresponsive term infants. Importantly, sustained inflation pressure of 30 cmH_2O for 5 s for the first breath seems to be more effective in achieving FRC than lower pressures for shorter periods of time. Once the newborn has achieved an adequate FRC, lower pressures in the range of 15–25 cmH_2O and a pace of 30–60/min seem to be adequate. However, the ILCOR 2010 guidelines state that optimal ventilation rates and pressures should be individualized according to each infant's response. The goal is to achieve a visible, but not excessive, chest rise and audible breath sounds. Excessively large tidal volume can lead to lung injury in less than a minute; therefore, careful attention to the pressure being applied is essential.

Assisted Positive Pressure Ventilation Devices

Three different devices have been successfully employed to ventilate newborn infants: self-inflating bag, flow-inflating

(anesthesia) bag, and T-piece mechanical device designed to regulate pressure.

Self inflating bags (Fig. 10.4a) are devices consisting of an elastic bag that re-expands due to its intrinsic recoil and does not depend on a gas source for inflation (although a gas source may be attached for administering gas admixture). It is simple and portable, allowing its use outside the hospital. It has a pressure limited pop-off valve that usually triggers at 40 cmH_2O, although these valves activate at a wide range of pressures, and therefore it is difficult to adjust to desired target values. Self-inflating bags do not administer PEEP effectively, even with a PEEP valve, are not capable of providing CPAP for infants with adequate respiratory effort but needing help to establish FRC, and do not permit adjustment of inspiratory times, therefore unable to deliver sustained inflation. Inspiratory fraction of oxygen cannot be precisely adjusted, and only with an additional reservoir administration of close to 100% oxygen may be achieved. The preferred size in neonatology is of 240 mL because it covers tidal volume needs of newborn infants (5–8 mL/kg).

Flow-inflating (anesthesia) bag (Fig. 10.4b) must be connected to a compressed gas source, which provides the gas admixture to inflate the bag when in use. If the face mask is not perfectly adjusted (leaks) or the flow is too low, the bag will collapse and ventilation will be rendered impossible. Special attention should be paid to the inspiratory pressure since these devices can reach very high pressures

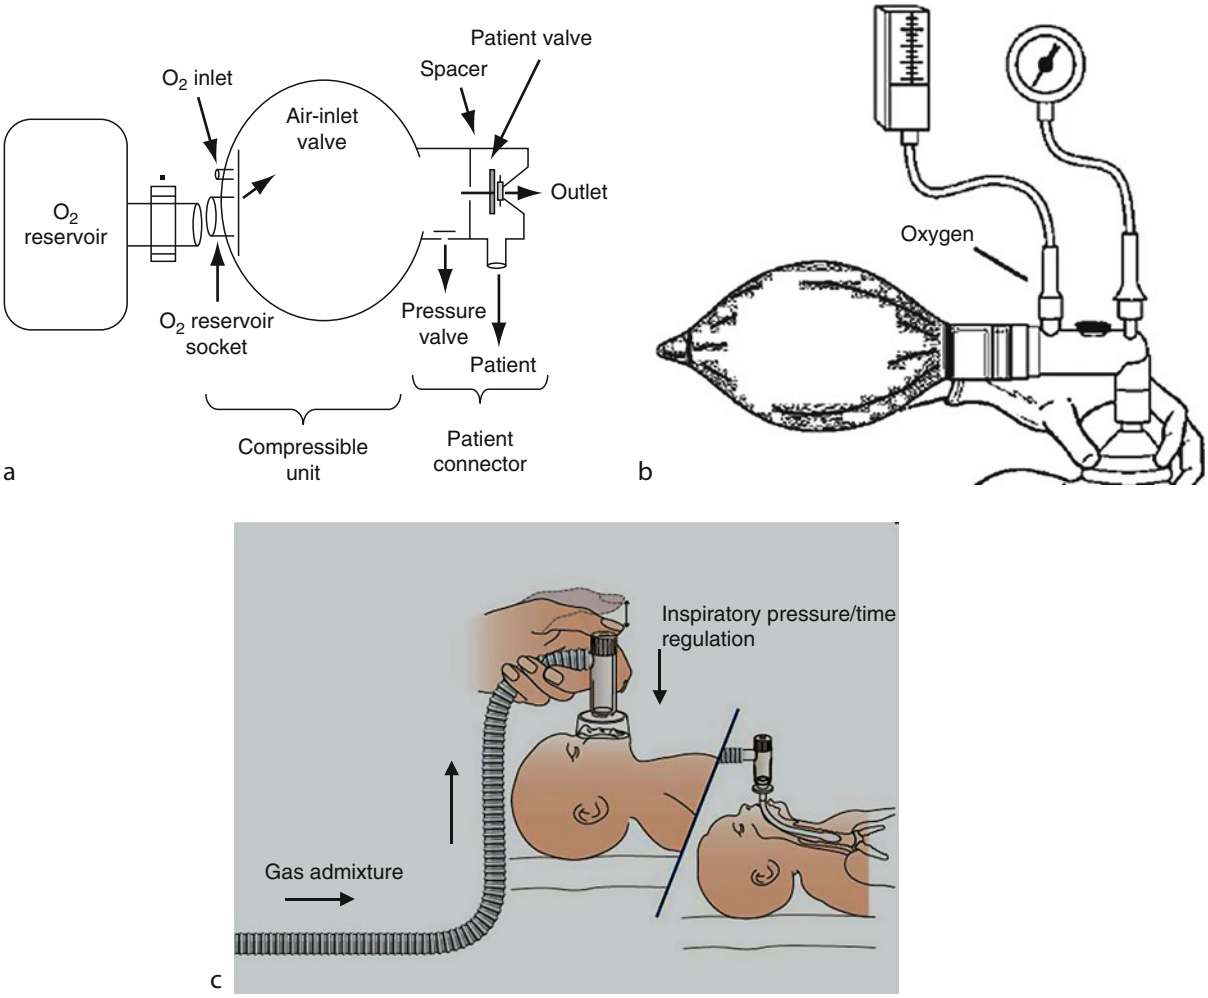

Figure 10.4

Devices for administering positive pressure in the delivery room (a) Self-inflating bag with reservoir and pop-off valve (b) Flow-inflating bag with oxygen supply and pressure manometer (c) T-piece resuscitator with gas admixture supply, inspiratory pressure/time regulation

which could cause pulmonary leaks. To avoid this, incorporating a pressure gauge and blow-off valve in the circuit is mandatory. Expiratory pressure (CPAP or PEEP) can be provided by controlling the pressure in the bag by adjusting the flow of gas into the bag and the rate of gas escape from the bag at the outlet valve. Flow-inflating bags can be used to deliver sustained inflations. However, these bags require substantially more skill and training than self-inflating bags and are generally limited to hospital settings.

The T-piece device (*Fig. 10.4c*) consists of an inlet arm to the patient through which the gas flows into a facemask or endotracheal tube (ETT). Positive inspiratory pressure (PIP) is achieved by interrupting the escape of gas through an outlet hole using a thumb or finger, so that the pressure rises and is displayed by a manometer. PIP is controlled by adjusting the release valve. The inflation time is voluntarily regulated by the caregiver by varying the duration of occlusion of the outlet hole; therefore, sustained inflation is easily administered. CPAP or PEEP is delivered automatically and the pressure varied by adjusting the outlet valve. This controls the rate of escape of gas when the outlet is not occluded (i.e. in expiration) and generates a set level of PEEP or CPAP. The level of PEEP or CPAP can also be adjusted by altering the gas flow in the system. T-piece resuscitator has been shown to deliver PIP and tidal volume that was closer to target values and more consistent than self-inflating bags. However, the preferred system may be that with which the caregivers are most acquainted and self-confident.

Interfaces for Administration of Respiratory Support

Noninvasive ventilation is generally performed with face mask (FM), although nasal prongs may also be used, and invasive intubation is performed using an endotracheal tube (ETT). Indications, advantages, and disadvantages of each interface will depend on the severity, gestational age, and/or experience of the caregiver. As a rule, FM is the first choice for moderately depressed neonates, while endotracheal intubation (ETI) is preferred for more severe conditions or as second choice when FM fails to adequately recover the newborn's HR.

FM is more gentle to the airway, easier to use and maintain expertise because it is frequently used in the DR. It is important that the FM is of the appropriate diameter according to the infant's birth weight and preferably with cushioned rims to avoid leakage. Available masks have diameters ranging from 35 to 72 mm that will provide adequate seal in newborns from 24 to 40 weeks gestation (*Fig. 10.5*). Adequate application of the mask is essential, and adequate training significantly reduces air leakage (*Fig. 10.6*). Controlled studies comparing FM versus intubation have shown that although inflation pressures were similar, inflation volumes, especially expiratory volumes, were difficult to assess with mask ventilation because of frequent leakage even with higher inflation pressures. FM ventilation seems to induce breathing by Head's paradoxical reflex, and therefore successful resuscitation is dependent to a substantial degree on the baby's spontaneous respiration. In severely asphyxiated babies, a brief trial with FM should be performed, but if after 30 s there is no improvement in HR (persistently <100/m) or the infant does not make effective respiratory effort or is profoundly bradycardic (<60 bpm), intubation should be considered, if a skilled person is available. Intubation is potentially the most injurious invasive procedure performed during neonatal resuscitation. Every effort should be made to stabilize an infant before attempting intubation to mitigate occurrence of bradycardia/hypoxia. Surfactant administration should be delayed until the baby has recovered. It's important to be gentle to avoid damaging the anatomical structures (oral route is easier for the non-experienced resuscitator), use an appropriate laryngoscope blade size – 0 or 00 (7.5 cm) for preterm babies, 1 (10 cm) for term infants, and ETT size, and depth of insertion (*Table 10.4*). Location of the ETT should always be clinically verified. The tip of the laryngoscope should be advanced over the tongue to the vallecula or on top of the epiglottis and elevated gently to reveal the vocal cords (*Fig. 10.7a*). Cricoid pressure may be helpful

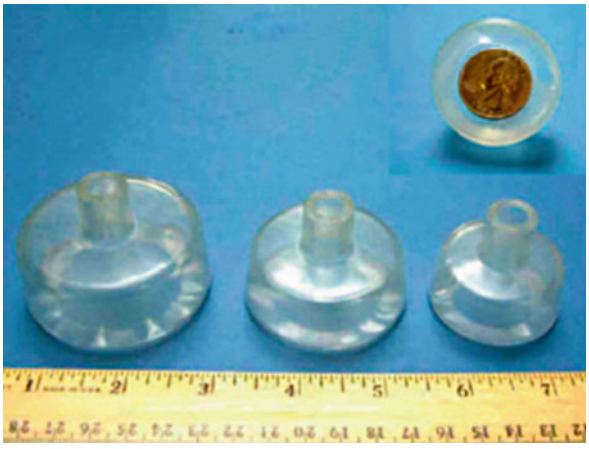

Figure 10.5
Different size masks for use in term and preterm infants. Choice of correct size is critical to achieve good seal

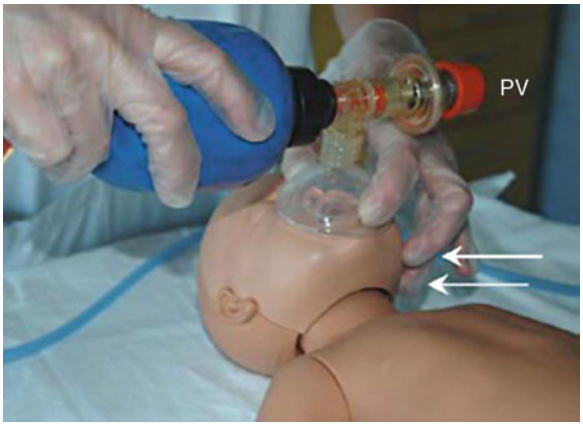

Figure 10.6
Correct technique for holding a face mask. Note the position of the fingers under the chin and the way they are able to position the infant's head while firmly holding the mask against the face. The mask should not press on the eyes, which could trigger a vagal reflex bradycardia

Table 10.4
Endotracheal tube sizes and depth of insertion from the lips

Weight (g)	Gestation (weeks)	Tube size (mm)	Depth of insertion from lip (cm)
< 1,000	< 28	2.5	6.5–7
1,000–2,000	28–34	3.0	7–8
2,000–3,000	34–38	3.0/3.5	8–9
> 3,000	> 38	3.5/4.0	> 9

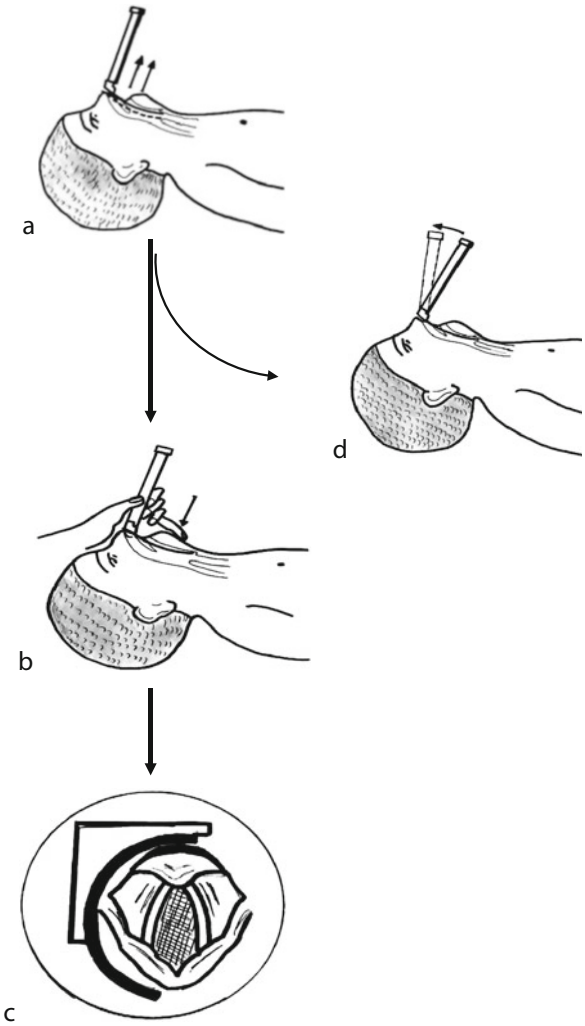

Figure 10.7
Technique of endotracheal intubation. Please see the text for explanation

(*Fig. 10.7b*). ETT should be inserted through the vocal cords to a depth indicated by marks on the tube, which should be annotated, and safely secured to avoid extubation or bronchial intubation (*Fig. 10.7c*). Common problems experienced during neonatal intubation:

- If the laryngoscope is advanced too far, the larynx will not be seen (*Fig. 10.7d*).
- If the blade does not support the tongue, it will obscure the view of the larynx.
- If the laryngoscope is not held slightly toward the left side, the larynx will not been seen.
- If the neck is flexed or overextended the larynx may not be seen.

The use of a stylet inside the ETT should be done with care to prevent damaging the trachea.

Most of the caregivers are successful in intubating in 30 s, and saturation and HR will not differ from those intubated in <20 s. Once the tube is secured, the position of the tip should be verified as soon as possible to avoid hypoxia/hypercapnia. Air entering both lungs and absence of sounds in the stomach can be detected by auscultation; however, in preterm infants, in special situations such as diaphragmatic hernia, or pneumothorax, this may be difficult. End-tidal carbon dioxide ($ETCO_2$) detectors or colorimetric CO_2 detectors may be used to rapidly verify if the ETT tip is in a correct position. Remarkably, colorimetric CO_2 detectors have been shown to be effective in confirming ET intubation or detecting a misplaced ETT within six inflations even in babies of less than 400 g. When CO_2 is detected, the color changes from purple to

yellow. If there is no color change, the likely causes are: the ETT is not in the trachea, the PIP is inadequate, or no CO_2 is being excreted because of absent lung perfusion due to cardiac arrest. If a colorimetric detector indicates the presence of CO_2, the operator can be certain that the airway is patent and fresh gas is being delivered into the lungs. Interestingly, the CO_2-detector has been shown to indicate the return of circulating rhythm during chest compressions, an observation recently confirmed in an animal model of neonatal resuscitation.

Special Circumstances: The Very Preterm Neonate

Postnatal adaptation of preterm infants <29 weeks requires almost always some respiratory support to establish functional residual capacity (FRC). Frequently, the infant has adequate respiratory effort, but is retracting. In that situation, provision of CPAP via a T-piece resuscitator, anesthesia bag, or ventilator is indicated to help the infant establish FRC, a task made more difficult for the preterm infant because of relative surfactant deficiency and very compliant chest wall. If atelectasis is allowed to develop, the marginal surfactant pool will be further reduced by surfactant inactivation, leading to respiratory failure. The benefits of sustained inflation to rapidly recruit lung volume and achieve homogeneous lung inflation remain unproven, but the maneuver is physiologically attractive. The dilemma between early intubation and surfactant administration or noninvasive CPAP is still under debate; however, the trend is toward noninvasive support in the DR. Observational studies have suggested that using early CPAP in very preterm infants may reduce intubation rate, need for oxygen, and incidence of BPD without increasing morbidity. The COIN trial, which compared early CPAP in spontaneously breathing infants born at 25–28 weeks with intubation showed no difference in mortality between both groups. Interestingly, at 28 days, the CPAP group had a significantly lower incidence of death or oxygen requirement, although by 36 weeks' gestation the differences disappeared. However, the CPAP group had significantly fewer days on ventilation. There were no significant differences in any complications of prematurity, except for an increased rate of pneumothorax in the CPAP group. Thus, preterm infants 25–29 weeks breathing spontaneously at birth should be initially supported with CPAP, titrating pressures and FIO_2 to meet HR and saturation targets. In case of respiratory failure, intubation and positive pressure with PEEP should be administered.

Laryngeal Mask

Laryngeal masks (LMA) are rarely used in newborn resuscitation. They only come in full-term size, although they have been successfully employed even in preterm newborns but not below 1,500 g. With increasing use of noninvasive ventilation in the DR and in the NICU, intubation skills might be increasingly difficult to maintain. Therefore, LMA insertion should be considered a valid alternative for problematic intubations and included in every resuscitation training program.

Oxygen Use in Resuscitation

Term Infants

The ILCOR 2005 statement concluded that there was insufficient evidence to specify the FIO_2 for initiation of resuscitation in the DR. Recently, a new meta-analysis was published including ten studies under which six randomized controlled trials in European countries fulfilled strict methodological criteria. A subgroup analysis of these European studies showed a reduction in mortality with RA resuscitation from 3.9% to 1.1% with a number needed to harm by use of 100% of 36. These recent data question the decision of the ILCOR 2005 guidelines and open the door to start resuscitation of full-term infants with room air and to adjust FIO_2 according to the infant's response, keeping in mind the normal course of SPO_2 in the first 10 min of life. Hence, in the ILCOR 2010 guidelines, air has been recommended as the preferred gas admixture to initiate ventilation of the depressed term or near term neonate. Nevertheless, a subgroup of newborn infants will benefit from the additional supply of oxygen (e.g., persistent pulmonary hypertension). At present, no scientific guidelines are available for the use of oxygen in newborns not responding to the initial steps of newborn resuscitation. Therefore, it seems reasonable to start supplying additional oxygen whenever a newborn is not responding despite adequate ventilation with room air. The focus for assessing response should be HR, keeping in mind that even normal newborn infants do not become pink (reach O_2 saturation >85%) until after 5 min. Importantly, it must be always emphasized that lung inflation/ventilation should be the priority. Once adequate ventilation is established, if HR remains low, there is no evidence to support or refute a change in the oxygen concentration that was used initially. Monitoring of SpO_2 by pulse oximetry makes it possible to adjust FIO_2 to achieve physiologic levels of oxygen saturation.

Preterm Infants

More limited information is available for resuscitation of preterm infants, in whom normal lung function cannot be assumed. Recently a series of studies reported that very preterm infants especially <27 weeks gestation will need additional oxygen in most cases, typically in the range of 30–40%. Therefore, for preterm infants, a higher initial FIO_2 may be appropriate, although evidence is currently not sufficient to recommend an optimal initial oxygen fraction.

Recommendations for therapeutic use of oxygen during and after resuscitation: (1) Positive pressure ventilation should be initiated with 21% oxygen in term infants. (2) Supplemental oxygen should be used if the baby remains deeply cyanotic or the heart rate is <100 bpm at 90 s of age. (3) Blended gases should be available in the DR and during transport to the NICU. (4) To avoid hyperoxemia, pulse oximetry should be available in DR were babies <32 weeks are delivered. It seems reasonable to avoid saturations >95% when supplemental oxygen is used, especially in preterm infants and those who suffered perinatal depression and thus are uniquely susceptible to oxygen free radical injury.

Circulation

In the newborn, cardiac output correlates with HR and rates <100 bpm will not support optimal tissue oxygenation. If HR is absent or intense bradycardia (<60 bpm) non-responsive to adequate ventilation is present ≥30 s, chest compressions (CC) should be initiated at a rate of approximately 100/min. The main goal of CC is to achieve/sustain sufficient diastolic blood pressure to assure coronary perfusion and restore effective myocardial function. The two-thumb method, which is generally considered more effective than the two-finger method, is performed by placing both thumbs on the lower third of the sternum, gripping the chest with the hands and supporting the back with the fingers, depressing the sternum about 1/3 of the anterior–posterior diameter of the chest or about 5 cm in term infants (*Fig. 10.8*). The official recommendation (although not evidence-based) is that CC should be coordinated with ventilation at a ratio of 3:1 and a rate of 120 "events" per minute to achieve approximately 90 compressions and 30 breaths per minute. However, there is good experimental evidence that adequate diastolic pressure is only achieved after several compressions and each interruption causes the diastolic pressure to fall back to 0, putting in question the appropriateness of frequent interruption of CC. Compressions are only effective if the lungs have first been successfully aerated, making the quality of the breaths and compressions more important than the rate. Cardiac compressions *do not* substitute for lack of adequate ventilation in the newborn infant; therefore, CC should not be allowed to interfere with the establishment of an airway and adequate ventilation.

Figure 10.8
The preferred two-thumb technique for cardiac compressions

Medication and Fluids

Epinephrine

Medications and fluids are rarely needed for resuscitation of newborn infants if the ABCs of resuscitation are carried out effectively. Bradycardia is usually caused by hypoxia and inadequate ventilation, and apnea is due to insufficient oxygenation of the brainstem. Both can be readily reversed in most newborns with adequate ventilation of the lungs and brief cardiac compressions, if indicated. However, if the infant remains bradycardic (<60 bpm) despite adequate ventilation and chest compressions for 1–2 min, drugs may be needed to improve cardiac contractility. Epinephrine is a sympathetic monoamine produced by the adrenal gland. It exerts its effects through the α_1-adrenoreceptors, causing peripheral vasoconstriction, and the β_1-adrenoreceptors, increasing HR, output, and cerebral blood flow. Importantly, cardiac effects are obtained by epinephrine's direct action on the myocardial fibers, and therefore it is essential to administer it as close to the heart as possible.

Umbilical vein is the most accessible and recommended site for administering drugs and fluids. Umbilical artery is not recommended because of serious side effects of vasoactive or hypertonic solutions administered into an artery. Access to peripheral veins in a shocky newborn is extremely difficult, and only very expert caregivers can access this route rapidly enough. Intraosseous lines are not commonly used in neonates because of the fragility of small bones and the small intraosseous space, particularly in the preterm infant. The intratracheal route should exclusively be used for epinephrine when umbilical venous access is not immediately available.

Epinephrine is recommended via the intravenous route (preferably via the umbilical venous catheter), and the dosage should be 0.01–0.03 mg/kg. The dosage can be repeated every 1–3 min. Intratracheal route may be used at higher dose (100 mcg/kg). Canadian guidelines recommend the use of the intratracheal route first flushed with 5 mL of saline while preparing for insertion of the umbilical catheter. Subsequent doses, if necessary, should be administered by the umbilical vein.

A flow diagram of newborn resuscitation is represented in *Fig. 10.9*.

Volume Expanding Fluids

Intravascular fluids should be considered when there is suspected blood loss and/or the infant appears to be in shock (pale, poor perfusion, weak pulse) and has not responded adequately to other resuscitative measures. The clinical assessment of shock is difficult in a hypovolemic neonate, and shock may not be evident at first in the asphyxial process. Early, there may be peripheral vasoconstriction, which helps maintaining an adequate perfusion of the vital organs (myocardium and brain). If resuscitation is effective, clinical signs of shock may become more evident and the clinician will be able to asses indication for fluid expanders with greater acuity. Most infants with mild to moderate depression are not hypovolemic, and their peripheral perfusion will improve spontaneously without the need for volume expansion.

In the absence of suitable blood for neonatal transfusion (preferably O-negative blood cross-matched against the mother's blood), isotonic crystalloid (normal saline) should be used. The initial dose is 10 mL/kg given by quick IV push. This dose may be repeated after observation of the response. In preterm infants, rapid push of intravascular fluids should be avoided because of increased risk of intraventricular hemorrhage. When needed, volume expansion should be given more slowly over 10 min, unless frank hemorrhage is present.

Sodium Bicarbonate

Routine use of Sodium bicarbonate is no longer recommended during newborn resuscitation. Mounting evidence indicates that it may not only lack benefit but may potentially make the situation worse by lowering intracellular pH, especially when adequate ventilation cannot be assured.

General Supportive Management

Glucose

Glucose administration is essential for adequate brain and cardiac metabolism, and it should not be delayed. Anaerobic metabolism is inefficient and increases glucose depletion. Low blood glucose at admission to the NICU after resuscitation was associated with poorer neurological outcome. A glucose rate of 8 mg/kg/min will assure brain metabolic needs and myocardial glycogen restoration. Administration of intravenous glucose should be started in the DR only after adequate oxygenation has been achieved because anaerobic metabolism of carbohydrates leads to the formation of additional lactic acid, worsening the acidosis.

Fluids

The urine output of any baby who has gone through an asphyctic episode should be closely monitored since a certain degree of renal insufficiency is always present in moderate to severe asphyxia. Thus, the possibility of fluid overload and electrolyte disturbance is present.

Feeding

Human studies have reported intestinal injury occurring in 6–29% of severely asphyxiated neonates, and newborn animal models of intestinal hypoxia-reoxygenation and ischemia-reperfusion have clearly demonstrated characteristic histopathologic lesions similar to those seen in necrotizing enterocolitis. Therefore feeding should be cautiously initiated, preferably with human milk, only after a period of clinical observation. There are no definitive clinical studies to inform the decision about how soon after an asphyxial insult it is safe to initiate feedings.

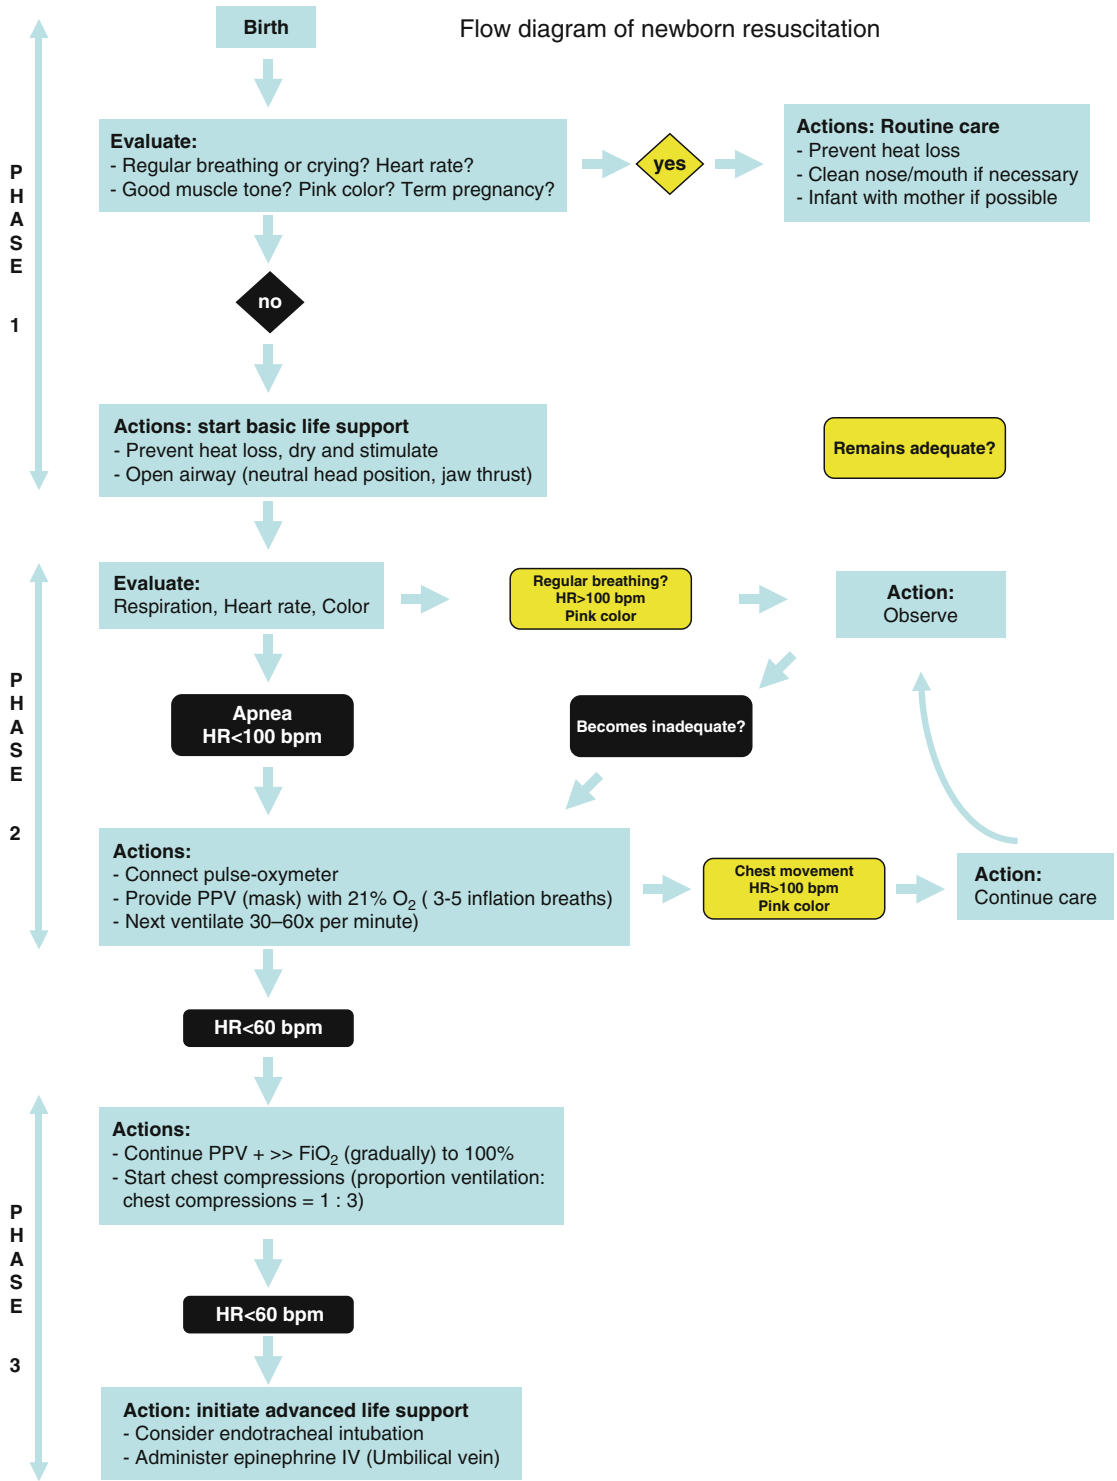

Figure 10.9
Flow diagram of newborn resuscitation

Ethical Issues

Initiating Resuscitation

Mortality and morbidity in the neonatal period is different according to the region and availability of resources. Caregivers should be aware of it before initiating or withholding resuscitation of a newborn with a specific gestational age or clinical condition. Increasingly, parents especially in highly developed countries want to take part in the decision of starting and continuing life support in severely compromised newborns. Religious beliefs and cultural traditions are also factors that should be taken into account.

Initial resuscitation does not mandate continued support. Therefore, not starting resuscitation and discontinuation of life-sustaining treatment during or after resuscitation are ethically equivalent and clinicians should not be hesitant to withdraw support when it becomes clear that functional survival is highly unlikely. If there is doubt whether to initiate or withhold resuscitation, it is best to start and later withdraw treatment when the situation has been clarified and discussed with the family and other experts. As a general rule, the following guidelines should be interpreted according to local vital statistics and societal principles or belief:

- When gestation, birth weight, or congenital anomalies are associated with almost certain early death and an unacceptably high morbidity is likely among the rare survivors, resuscitation is not indicated. Examples from the published literature from developed countries include:
  - Extreme prematurity (gestation of <23 weeks or birth weight <400 g).
  - Anomalies such as anencephaly and confirmed trisomy 13 or 18.
  - In conditions associated with a high rate of survival and acceptable morbidity, resuscitation is nearly always indicated.
  - In conditions associated with uncertain prognosis when there is borderline survival and a relatively high rate of morbidity and where the burden to the child is high, the parents' views on starting resuscitation should be supported.

Discontinuing Resuscitation

It is reasonable to consider discontinuing resuscitation if an infant that has not responded with any measurable HR after 10 min of *effective* resuscitation. In a systematic review, it was shown that 94% of newborns without any sign of life during the first 10 min after birth died or had severe neurological handicaps, and only 2% had moderate or minor handicaps. Data for infants of very low birth weight also suggest that survival is negligible if there is no heart beat after 10 min of appropriate cardiopulmonary resuscitation. Before resuscitation is stopped a second opinion should be sought if immediately available and wherever possible by agreement with parent(s). Local discussions are recommended to formulate guidelines consistent with local resources and outcome data.

11 General Care of the Newborn

Marcia Wenner VanVleet

Care of the Newborn

Whoever says "all newborns look alike" has not been in a nursery for more than a few minutes. Each newborn has their unique physical features and personalities from day 1. A few things are common to newborns of all types, shapes, and sizes but there are a lot of natural variations and findings of interest. This chapter will attempt to serve as a guide in the general medical care of these young patients.

Newborn History

Care of the newborn starts in the form of a complete history and physical. However, the newborn's history is really one of the mother's and the pregnancy. Even in the developed world, obtaining this accurate history can be complicated by the inconsistent transmission of data from the chart of one patient (the mother) in the outpatient setting to that of another (the newborn) in the inpatient setting. But due diligence is necessary to fully assess the newborn and to provide effective preventative care.

Maternal History

Although covered elsewhere in this textbook, it is important to emphasize that there are many preexisting maternal conditions that may affect the fetus as well as the health and subsequent management of the newborn. Some notable maternal conditions that the pediatrician should be aware of are breast disease (including any interventions that might interrupt lactogenesis), congenital heart disease, diabetes mellitus, developmental hip dysplasia (DDH – increases risk of DDH in newborn), fatty liver disease (associated with long-chain acyl-CoA dehydrogenase deficiency (LCAD) in newborns), genetic/heritable disorders, hypertension, infections (such as malaria and tuberculosis), mental health, polycystic ovary syndrome, autoimmune diseases (i.e., systemic lupus erythematosus where the newborn should be screened with and EKG for heart block), substance use (including tobacco and caffeine), social concerns, and thyroid disease (both hyper- and hypothyroidism).

A detailed history of the pregnancy is necessary for caring for the newborn. Key elements include: (1) medications, tobacco, alcohol, and illicit drug use during pregnancy, (2) medical conditions during the pregnancy including diabetes mellitus, pregnancy-induced hypertension or preeclampsia, (3) duration of the rupture of fetal membranes, (4) analgesics or anesthetics administered during labor, (5) infections or illnesses (keeping in mind geographically specific risks such as malaria), (6) mental health, especially anxiety and depression, and (7) compliance with care. The history of previous pregnancies, including miscarriages, previous child with congenital heart disease or neonatal illness, such as group B strep (GBS) sepsis or severe jaundice, also provides important clues. The pediatric care provider needs to obtain the results of maternal screening obtained during the pregnancy as recommended by organizations such as the American College of Obstetrics and Gynecology (ACOG). Key elements that should be obtained and clearly documented in the newborn's, record for every pregnancy include the items listed in *Table 11.1*.

The results from any prenatal ultrasonography should be obtained as these help in confirming gestational age, assessing the risk for conditions such as Trisomy 21, spinal dysraphisms, and with some notable exceptions, congenital heart disease. One ultrasound finding worth discussing in detail is that of fetal renal hydronephrosis. Many cases of fetal hydronephrosis will spontaneously resolve during the pregnancy. There is some small uncertainty in the exact measurement that should raise pediatric concern but 15 mm is concerning for blockage and most would agree that those with a diameter >8 mm warrant follow-up. Certainly, any cases with associated oligohydramnios should be evaluated. Additionally, males with bilateral involvement warrant postnatal renal ultrasonography in the birth hospital stay to rule out vesicoureteral reflux or posterior urethral valves. However, due to the relative dehydration of newborns, even negative postnatal screening should be repeated at 3–4 weeks. Antibiotic prophylaxis is indicated for those with evidence of bilateral involvement in utero, abnormal renal

architecture, collecting system dilatation, documented reflux, or hydronephrosis on postnatal ultrasound. Due to the high concentration of the drug and general susceptibility patterns, prophylaxis with Amoxicillin suspension (20–25 mg/kg, PO, once a day) is effective and well tolerated. Surgical consultation with a pediatric urologist should also be obtained to help coordinate ongoing assessment. Antibiotic prophylaxis should continue until repeat imagining is obtained at 3–4 weeks, including a VCUG when indicated.

Maternal medications and the consumption of other substances need to be reviewed by the pediatric provider as some may cause problems in the newborn. Antihypertensive medications may cause hypoglycemia in the newborn. Serotonin uptake inhibitors, tobacco, caffeine, and opiate containing narcotics either prescribed or otherwise, may cause toxicity or withdrawal symptoms in the newborn (which is discussed in detail in Chap. 34, "Miscellaneous Disorders").

Gestational Age

The physical examination of the newborn starts with the assessment of gestational age and in utero growth. In industrialized countries, most pregnancies currently have accurate dating through confirmation of gestational age with prenatal ultrasound. As a general rule, determinations from the first trimester are accurate to within ±1 week, those in the second trimester within 2 weeks, and third trimester within 3 weeks. However, second and third trimester dating by ultrasound may substantially underestimate true gestational age in the presence of abnormal fetal growth. Additionally, prenatal gestational age estimates can be confirmed with the use of the New Ballard score (see Web site listed in the Resources). With the trained examiner, this scale has been shown to have good reliability and validity. With the best estimate of gestational age, the clinician can then plot the birth weight, the head circumference, and the length on a standardized graph to evaluate fetal growth.

Growth Assessment

In September 2010, the Center for Disease Control and Prevention (CDC) published a recommendation that from birth to 24-month age groups, all clinicians should use the 2006 World Health Organization (WHO) graphs. The WHO charts were designed as a reference (goal) growth curves within breastfeeding populations from a sampling of countries (Brazil, Ghana, India, Oman, and the USA). The clinician, when interpreting the growth of infants who are formula fed should be aware that breastfed babies do gain more weight in the first 2–3 months, and then stabilize or slow down thereafter. These graphs are available on the organization's Web site with links in the reference section. Although the WHO is an international reference, clinicians may choose to use normative graphs developed within their own country, as there may be ethnic and demographic differences – though these were surprisingly small in the diverse population included in the WHO study. Preterm and late preterm infants (those with completed gestational age of 34^{+0}–36^{+6} weeks) are best plotted on the Fenton graph, until 50 weeks of corrected age. There are also condition-specific growth charts for infants with diagnoses such as Trisomy 21 and Turner's syndrome.

Newborns are categorized as either appropriate for gestational age (AGA), small for gestational age (SGA), or large for gestational age (LGA) based on their percentiles. Classically defined, SGA is below the 10th and LGA as above the 90th percentiles. However, more recent cutoffs are using either the 5th/95th or 3rd/97th percentiles as these approach the two standard deviations used to define abnormal versus normal distributions, or those constitutionally small or large. Some have also suggested that customizable birth weight centiles would help to distinguish between those whose weight is constitutional from those at risk from pathologic SGA or LGA. Traditionally, SGA infants were also divided based on whether the growth restriction has been symmetric or asymmetric with sparing of the head circumference. In an attempt to better understand the significance of being SGA, researches looked at the mortality and morbidity rates in

a large US population-based sample for those SGA at preterm versus term birth. They found higher rates of mortality and morbidity for all preterm births and a greater adjusted relative risk in relation to SGA at term than preterm. However, they also found that the adjusted excess mortality risk from SGA declined until term with a plateau after 37 weeks. Both SGA and LGA status has inherent risks that need to be addressed and are fully discussed in a subsequent chapter (see Chap. 13, "The High-Risk Infant").

Newborn Physical Examination

For all newborns, the examination should start with a general observation of the state (sleeping, awake and quiet, awake and stirring, or crying), color (pink, acrocyanosis, perioral cyanosis, or central cyanosis), and pattern or work of breathing (e.g., grunting, flaring, retractions). From there, generally the best approach to examining the newborn is to keep them warm and let them lead the sequence of the exam. This means that if they are quiet, one starts with auscultation of the heart and lungs and palpation of the femoral pulses (crying makes these small pulses a moving target). But if they are crying or unsettled, then it is best to start with other parts and work on consoling them. But wherever one starts, it is best to continue the examination in your set sequence so not to miss critical parts when you are interrupted with crying or regular newborn care. Included in *Table 11.2* is a description of an approach to complete examination of the newborn. The next section of this chapter will highlight normal findings or variants found in newborns.

Skin

Through the course of sequentially unwrapping part of the newborn, the examiner will eventually get to visualize the entire skin surface of the newborn for rashes and other lesions. Common skin findings unique to the newborn are discussed below:

Erythema toxicum: This very common rash occurs in almost 50% of newborns. These transient flesh-colored to whitish papules on erythematous macules that appear over the first few days (with about two thirds occurring between 24 and 48 h of life) spread with individual lesions that come and go, and then resolve spontaneously. These can appear in any distribution and commonly coalesce on the face, abdomen, and back. These papules have no known cause but are very common and contain

Key elements of newborn exam

General	*Abdomen*
• Wash hands prior to examining infant • Keep infant warm when examining (under warmer, blankets) • Support head/neck when moving infant • Assess maturity appropriately (term, preterm) • Assess intrauterine growth appropriately (AGA, SGA, LGA)	• Palpate for liver, spleen, kidneys, masses • Examine umbilicus visually; palpate for umbilical hernia
Order of exam	*GU*
• Auscultate heart and lungs while infant calm	• Boy: Examine penis for hypospadias; Palpate testes (undescended, hernia, hydrocele) • Girl: Examine hymen visually, labia
General appearance	*Anus*
• Note general appearance, distress, color, tone, spontaneous motor activity	• Visual check for patency • Visual assessment of placement of anus, measure if concerns
Skin	*Back*
• Examine skin; note birthmarks, jaundice, rashes if present	• Look for scoliosis, sacral dimple, or sinus tract
HEENT	*Extremities*
• Palpate fontanel (anterior, posterior), sutures, measure if concerns • Examine for cephalohematoma, caput • Check red-reflex • Examine pinnae: position, preauricular pits or tags • Check for septal dislocation or choanal atresia • Check for cleft palate (visually back to uvula and palpation)	• Palpate for femoral pulses • Examine hands/feet (creases, symmetrical size) • Examine gluteal and thigh folds for symmetry • Barlow/Ortolani tests
Chest	*Neuro*
• Palpate clavicles smoothness and symmetry • Auscultate heart • Auscultate lungs, work of breathing	• Root, suck, palmar grasp, cry • Examine for symmetric Moro

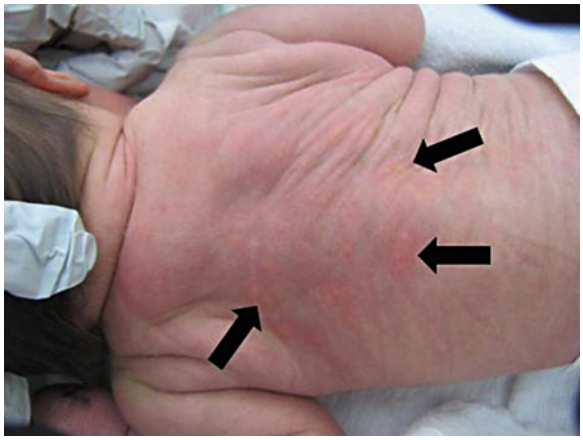

Figure 11.1

Figure 11.2
Classic scattered milia on a 2-day-old newborn (Photograph by Marcia W. Van Vleet, MD, MPH)

eosinophils, which suggest the involvement of a histamine pathway and as such might be a response to the general stress of delivery. The only rare potential complication of erythema toxicum is secondary infection (Fig. 11.1).

Harlequin change: This distinctive and well-demarcated color change is only seen in newborns and is a transient hemi color change with erythema on one half of the body and pallor on the other. It presents in the first few 2–5 days of life in approximately 10% of healthy newborns (although some have linked it to low birth weight, hypoxia, intracranial injury, prematurity, or use of prostaglandins). It may persist for 30 s to 20 min and has no long-term sequelae.

Milia: These are present at birth as white papules without erythema commonly occur on the face of up to 50% of newborns. They are inclusion cysts of sebaceous material with similar etiology to the Epstein pearls on the palate, Bohn nodules on the gingival ridge, and other inclusion cysts on any other midline structure including the foreskin of the penis. Milia can be seen on newborns born in any season but might have a slightly increased prevalence in the warmer months (summer in the northern hemisphere). Parent should be advised that these are not pimples and should not be squeezed but left alone. Of note, there are smaller sebaceous inclusion cysts that occur more frequently usually on the nose that are commonly although perhaps mistakenly called "milia" as well. Both "milia" lesions are self-limited and are reabsorbed by the body by 3 months of age (Fig. 11.2).

Neonatal acne: This is a relatively common transient form of the common teenage affliction that occurs in about 20% of infants and usually appears about 3 weeks after birth, although it rarely can be present at birth. It usually appears on the face, mainly on the cheeks, forehead, and chin as erythematous papules and pustules, or as white closed comedones. It is thought to be caused by transplacental passage of the mother's hormones and the newborn's own androgens. Male babies are more prone than females and spontaneous resolution is the rule. There is another form of acne that occurs after 3 months of age which is usually called infantile acne and seems to have a different etiology and is likely multifactorial, similar to the adolescent form.

Sucking blister: Occurring as the result of the fetus sucking in utero, these are apparent at birth. As such, their oval to circular shape and distribution on the dorsum of the hands, wrists, and forearms is characteristic. They may be fluctuant bullae that can be fairly large (up to 1.5 cm) which then quickly evolve to reveal a superficial erosion. There is a notable lack of other blisters, vesicles, or marked erythema that would otherwise suggest other etiologies. The residual hyperpigmentation or scaring heals on its own relatively quickly (Fig. 11.3).

Transient neonatal pustular melanosis (TNPM): These are small superficial white pustules on a non-erythematous base that easily unroof to reveal superficial, well-circumscribed scales and subsequent melanotic macules. Frequently, the pustules will be unroofed in utero or in bathing so only scales and freckling is observed on the initial exam. These can be frequently observed on the face, neck, abdomen, and lower back/sacrum. They also occur more frequently in those with darker skin coloring including Asian and African infants, with an overall incidence of

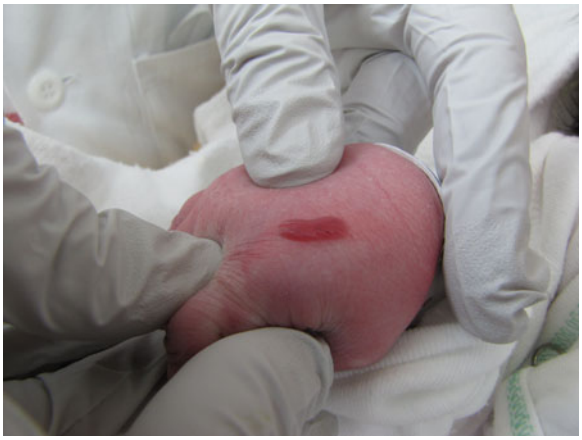

Figure 11.3
Characteristic appearance, shape, and distribution of a sucking blister seen on a newborn's initial examination (Photograph by Cindy Klipfel, MD)

0.2–4.4%. To confirm the diagnosis, it is best to observe lesions in all three forms (pustule, scale, freckle), but if gram stain were to be obtained, it would demonstrate neutrophils. Differential diagnosis of TNPM includes staphylococcal infection (usually erythematous and yellowish pustules), and herpes simplex virus (multiple forms classically with an erythematous base and clear vesicles that may cluster). It is very important in newborns to keep HSV in the differential diagnosis for any unknown rash as there are serious consequences if not treated immediately (discussed in detail in Chap. 27, "Neonatal infections").

Jaundice: This yellowish appearance to the skin and sclerae is very common in newborns and represents hyperbilirubinema, primarily due to physiologic increase in hematocrit of the newborn with shorter lifespan of neonatal erythrocytes and the slower/delayed conjugation in the newborn's liver. Most newborns, up to 60% of full term and 80% of preterm, will develop some degree of visible jaundice with most peaking in the first 3–4 days. For those born prematurely and those with extensive bruising or cephalohematomas, the maximal intensity may occur closer to 5–7 days of life. Although many newborns develop jaundice, its appearance in the first 24 h of life is pathological in nearly all cases. Jaundice generally moves from a cephalad to caudal progression and has historically been correlated to serum bilirubin levels with the loose rule of "Head= 5 mg/dL, chest =10 mg/dL, umbilicus=15 mg/dL" adapted from Kramer. Multiple studies have subsequently demonstrated; (1) a lack of agreement between examiners (at every level of training) and serum bilirubin levels, and (2) a very good negative predictive value for visual inspection (meaning no visual jaundice is predictive of not developing significant hyperbilirubinemia). Keren et al. recently found a negative predictive value of 98.6% for the complete absence of jaundice and the subsequent development of significant hyperbilirubinemia, defined as within 1 mg/dL of requiring phototherapy by the American Academy of Pediatrics (AAP) recommendations.

Birth marks: These should be described in quality and distribution in the newborn's documentation. Most are beyond the scope of this chapter/text but a few with unique characteristics in the newborn will be discussed.

Capillary hemangiomas: Although these are easy to diagnose later in infancy when they develop thickening, they can either not be apparent or have a subtle appearance that is difficult to diagnose in the newborn. When they are present in the newborn they can appear as a nondescript, slightly erythematous blanching macule or a spider like telangiectasia with irregular boarder and can frequently have a surrounding "halo" or blanching. Clinical course is sufficient for the diagnosis and management of most of these lesions. However, those over key organs such as the liver, spleen or spine, and when three or more appear on a patient warrant ultrasound investigation, as they may have deeper vascular connections. Capillary hemangiomas will progress over the first 6–12 months of life, and then will regress with 50% resolving by 5, and 90% by 9 years of age. Most need no intervention; however some will depending on location, such as if they interfere with binocular vision, obstruct airway or breathing, or lie over the liver, spleen or spine. Although a rare occurrence those lesions over the liver or spleen with vascular connections can become significant reservoirs potentially causing fluid shifts, and clinical instability. The development of large lesions can also rarely cause a Kasabach–Merritt syndrome with rapid platelet consumption and DIC (*Fig. 11.4*).

Nevus flammeus (aka Nevus Simplex, salmon patch): These erythematous macules with irregular boarders occur on the forehead, eyelids, glabella, nose ("Angel Kisses"), and most commonly on the nape of the neck ("Stork Bite"). They cross the midline and blanche, but otherwise can be difficult at times to differentiate in the newborn from more serious lesions such port wine stains which are usually unilateral. Those lesions that occur unilateral in the distribution of trigeminal nerve first branch (cranial nerve V1) covering the lateral canthus of the eye should be evaluated by ophthalmology and MRI imaging at 6 months of age to evaluate for the potential

Figure 11.4
Although most are not apparent on the newborn, this capillary hemangioma found at birth on a newborn's leg is characteristic for its blanching central purplish macule or telangiectasia with surrounding hypopigmentation or halo. Upon questioning, the mother also had a capillary hemangioma that spontaneously resolved by 5 years of age (Photograph by Cindy Klipfel, MD)

Figure 11.5
Nevus flammeus or simplex in the classic "Angel Kiss" distribution in the midline of the forehead. Although slightly less visible on this photograph, the patient also had one just under the nose on the upper lip (Photograph by Cindy Klipfel, MD)

for Sturge Weber syndrome. Clinical course of nevus flammeus or simplex is equally distributed in three groups: those that essentially remain the same, those that lighten, and those that totally disappear (*Fig. 11.5*).

Figure 11.6
Newborn with characteristic distribution of a dermal melanocytosis over the lower back and sacrum, as well as one on the left shoulder (Photograph by Marcia W. Van Vleet, MD, MPH)

Dermal melanosis: These melanotic lesions commonly with irregular borders and pigmentation that can vary from brown, blue-gray, to blue-black. Previously called "Mongolian spots" these can occur in any location they are commonly found on the back, sacrum, arms and legs. They can be found on any newborn but occur more commonly in those with more melanin or darker skin (up to 80% of African and Asian newborns). They can even appear even slightly more bluish in parts and might be confused with a blue nevus. Many will fade in adulthood but some may not totally disappear. There is otherwise no specific management or treatment necessary for these benign lesions except to monitor for changes (*Fig. 11.6*).

Head and Neck

Careful inspection of the head and neck of the newborn includes observation for shape and palpation of normal structures such as the sutures, anterior and posterior fontanels, as well as any abnormal bony prominences. Molding and overriding sutures are common, but should be documented to help interpret changes in head circumference. Molding, which generally resolves in 3–5 days is the result of compression of the head in utero either from being engaged in the pelvis or from passage through the birth canal. Overriding sutures are also due to similar causes and should resolve in 2–3 weeks with the expansion of normal growth of the brain. Palpation of the

sutures can also reveal craniotabes or a sensation of a "ping-pong" which is usually a normal variant in the newborn especially those born at lower gestational ages. These usually resolve with the natural ossification of bones, but if delayed should raise suspicion for alterations in ossification.

Fontanels and suture lines: These should be palpated and their size assessed (see *Fig. 11.7*). Sagittal sutures can be open with a normal gap of up to ½ cm. Midway along the sagittal suture a third fontanel exists in 6.3% of newborns, with a higher percentage found in those with Trisomy 21 or congenital rubella. The normal metopic suture also can be open, however when extremely large or deep can be suggestive of delayed ossification, including hypothyroidism. The anterior fontanel should be palpated for firmness, bulging, or depression with the newborn's head elevated to 30°. The fontanels can be measured by finding the mean of the distances of the axis, as shown in *Fig. 11.7*. This measurement may increase slightly in the newborn period as the molding and overriding sutures resolve. In the USA, the average size of the anterior fontanel at birth is 2.1 cm (range 0.6–3.6 cm). This statistic varies in ethnic groups with African Americans reported as slightly larger with average 3.6 cm (range 1.4–4.7 cm) and a reported mean in a sample from India of 3.37 cm (range 2.2–4.5 cm). Posterior fontanel averages 0.5 cm in size but also has ethnic differences (Black/African American reported average also slightly larger at 0.7 cm). These differences may either be related to constitutional differences or may be an effect of nutritional status. The fontanels then close over the course of the next 1½–2 years with the posterior closing first (average of 2 months) and the anterior closing at an average of 13.8 months (reported as 9–24 months), with the study from India finding that 50% had closed sometime between the 12 and 15 month exams (91.3% closed at 2 years).

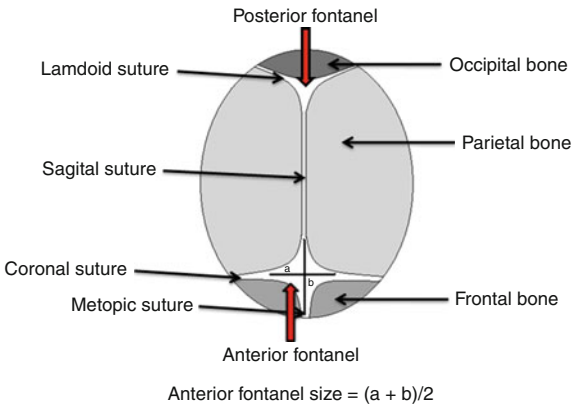

Figure 11.7
Schematic of newborn skull facing examiner (as seen from above). Note the demonstration of how to measure fontanel size as the average of the anterior–posterior and transverse diameters (Drawn by Marcia W. Van Vleet, MD, MPH [Adapted from Kiesler])

Ears: Complete examination of the newborn's ears includes visual inspection of the position, size, and external structures. With an otoscope internally visualize for the presence of a gray-white tympanic membrane. It will not be possible (due to small anatomy and likely obstruction by vernix) to distinguish the internal landmarks, but visualization is just to confirm the existence of the canal.

Eyes: The placement, position, spacing of the eyes, and size of the opening of the eyelids should be inspected visually. Normal palpebral fissure length in the newborn is over 5 mm. Rarely, the intercanthal distance may appear wide on the newborn due to a dacryocystocele. Although it might not be apparent on the first few days of life, the dacryocystocele classically presents with a bluish nodule palpable between the nose and inner canthus. Commonly, inspection of the eyes during the first few days is obscured by eyelid edema. Ideally, the eyes would be observed simultaneously for pupil symmetry and the red reflex. However, this is usually not possible in the newborn. The red reflex should be observed for any defects as well as white appearance suggestive of congenital glaucoma or retinal masses. In darker skinned newborns, the red reflex might be difficult to appreciate but should be visible in a dark room and may appear silvery in color. Visualization of the retinal vessels may be helpful in determining the presence of a red reflex. The eyes should be inspected for signs of infection (erythema, swelling, conjunctival injection, and purulent discharge). Please refer to the section below on the management of eye discharge.

Nose: The nose should be inspected for general symmetry or dislocation of the septum. Patency could be confirmed with movement of a thin tissue or cotton ball wisp under each nare while the contralateral nare is obstructed and newborn is sucking.

Mouth: It is important to visualize the newborn's mouth including the gums, the frenulum (both lingual and labial), the soft and hard palates and all the way back to the uvula. Having the newborn suck on the examiner's finger helps in assessing the pattern of tongue movements (milking front to back) and for how far the newborn is able to extend the tongue. Minimally, this would be past the gums, but ideally past the lips for optimal breastfeeding. Additionally, the hard and soft palate should be palpated to detect any submucosal clefts which

Figure 11.8
Newborn with two natal teeth found on the discharge exam. Note also the jaundice visible in the nasolabial folds when crying (Photograph by Cindy Klipfel, MD)

would not be detected on direct visualization alone. Absence of the uvula or a bifid uvula would also suggest a palate cleft. Common findings in the mouth include Epstein pearls (midline on hard palate), Bohn nodules (on gingivae), epulis, ranula, and neonatal teeth (*Fig. 11.8*).

Neck: The neck of the newborn should be inspected and palpated for tracheal deviation, and any masses (it is common to feel hyoid bone on newborns). Depending on their exact location, midline masses may represent thyromegaly or thyroglossal duct cysts, and those just anterior to the sternocleidomastoid muscle being brachial cleft (I, II, III) cysts or nodules.

Thorax

Examination of the thorax starts with auscultation of the heart and lungs. This can be done underneath the shirt so as to limit disruption of the calm newborn. Murmurs are very common in the first 24 h of life (up to 80%) and are discussed later in the chapter. Palpation of the point of maximal impulse is also important to help in the diagnosis of dextrocardia and hyperdynamic states (common during transitioning). Inspect the breathing pattern, shape (barrel, pectus, etc.), and symmetry of the chest. Palpate clavicles from sternal notch to acromion for continuity, smoothness, tenderness, and especially symmetry between to two sides. In the newborn period, the most sensitive presenting sign of a clavicular fracture is asymmetry and not the classic step off or crepitus (please refer to the Chap. 12, "Birth-Related Injury" for more details). Both males and females can have gynecomastia and possibly even milk discharge (a.k.a. "witches milk") from exposure to maternal estrogen in utero. Stimulation from palpation should be limited; however, other masses and mastitis can rarely occur.

Abdomen

Again examination starts with auscultation, this time for the presence of bowel sounds. Next, palpate for the size and texture of the liver, spleen, kidneys, and for the existence of any other masses. Visually inspect the umbilical cord for number of vessels, any erythema, swelling, or discharge. Variants to the umbilical cord include Wharton's jelly/umbilical hematoma (which can be fatal in utero but is of little significance in an otherwise stable newborn). Examination of the umbilical cord also includes palpation for abdominal contents and the base for any defects or bulging through the fascia consistent with an omphalocele or umbilical hernia.

Extremities

Examination of the lower extremities includes simultaneous palpation of the femoral pulses. The absence or asymmetry of the pulses would require immediate evaluation for coarctation of the aorta. However, in the newborn period, the pulses may exist even with a coarctation during the period of cardiovascular transition while the ductus arteriosus is open. Assess for symmetry of the major folds, knee height, leg length, and size of feet. Serial examinations of the newborn's hips are essential. Specifically, the Barlow (dislocation/subluxation) and Ortolani (reduction) tests should be performed to assess for hip stability. Commonly in the newborn, clicks or ligamentous laxity is felt without subluxation of the joint. Any actual movement of the hip greater than 5 mm or joint subluxation should be referred to orthopedics for placement in a Pavlik harness. Imaging in the newborn period is not necessary, but ultrasounds at 4–6 weeks of life may help to further assess those at increased risk (such as breech females and breech males with a family history) or the inconclusive exam. Orthopedics will follow serial hip ultrasounds to assess the progress of treatment. After about 6 months of age, MRI becomes the image of choice. Subluxation of other joints should also be referred to orthopedics for treatment and may be associated with certain syndromes. Grasp of all four

Figure 11.9
Newborn with postaxial polydactyly, on a thin pedicle with a nail (Photograph by Cindy Klipfel, MD)

extremities is important to assess both for neurological changes but also for general strength. Digits should be counted on both hands and feet. Although linked with many syndromes, syndactyly of the feet and polydactyly of the fingers, commonly occur in normal families. Thin-stalked supernumerary digits could be tied off by the pediatrician. When performed correctly (sufficiently tight and flush with the adjacent skin), the digit will drop off in several days, leaving no remnant. Creases of the hands and feet are important to assess as these may reflect in utero movements or conditions such as Trisomy 21 (non-pathognomonic single transverse palmar creases and prominent vertical crease on the foot) and fetal alcohol syndrome (hockey stick palmar crease) (*Fig. 11.9*).

Genitourinary (GU) System

External inspection of the female and male genitourinary system is important. For the female, this would include the clitoral hood, labia majora/minora, and the hymen. Frequently a newborn female will have milky white vaginal discharge, hymenal/vaginal tags, and possibly even serosanguinous vaginal discharge, all believed to be due to exposure to the mother's hormones (estrogen effects). Examination of male genitalia includes palpation of the testes. At least one of the testicles should be palpable in the scrotal sac. The absence of both should be investigated as soon as possible with ultrasonography. The penis should be examined for length (normal greater than 2 cm stretched on the full-term newborn), for chordee (curvature when erect), for penoscrotal web (a common form of chordee), for the course of the raphae, and for the location of the meatus. The raphae may be tortuous but should end near the 6 o'clock position. Raphae that do not should raise the examiner's diligence in looking for other GU findings as these rarely can be associated with hypospadias and torsion of the glans. The meatus should be midline central on the glans and no more than 5 mm in length. Longer length is suggestive of megameatus. Minor variations in the position of the meatus is normal; however, any that approach the edge of the glans or with other GU findings should be referred for urologic evaluation before circumcision. Frank hypospadias or epispadias are definite contraindications for circumcision. Ambiguous genitalia appear as a spectrum best summarized by Prader staging. However, the newborn physician should be aware that ambiguity of the genitalia has large social ramifications for the families.

Anus

Visual inspection of the anus and its position is important. Roughly, the anus should be about halfway between the scrotum or vaginal opening and the coccyx. The normal position of the anus has been described as the anal position index (API), or the ratio of the distance from anus to fourchette/scrotum to the total distance from the coccyx to fourchette/scrotum. In male newborns, this is a mean of 0.54 (95% CI 0.53–0.55) and in females it might be slightly anterior to this at about 0.45 (95% CI 0.44–0.46). Ratios less than the 95% CI warrant further investigation. Internal exam of the anus/rectum is not routinely necessary. Current recommendations that newborn screening temperatures be taken in the axilla (during the birth hospital stay) means that the physician needs to do careful inspection of the anus as the nurses may not detect cases of imperforate anus they would have with rectal temperatures (*Fig. 11.10*).

Back/spine

It is imperative to visually inspect a newborn's spine from head to sacrum for dimples, curvature (scoliosis), or masses. Simple dimples (<5 mm and superficial with visible base) in the intergluteal fold are very common. In the case of normal lower extremity tone and neurological exam, these do not warrant imaging. However, dimples that occur outside of the gluteal crease (more than 2.5 cm from the anus), or have any associated skin changes including tufts of hair, should be evaluated with an ultrasound in the first few weeks of life to rule out a tethered

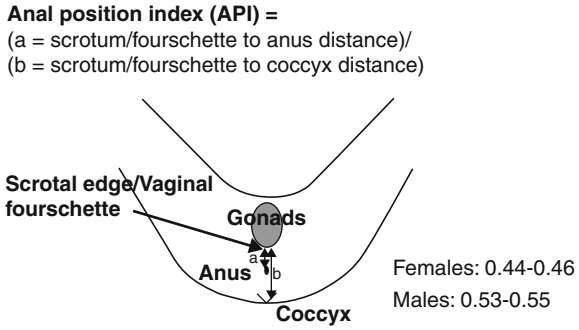

Figure 11.10
Schematic of how to measure the anal position index (API) (Drawn by Marcia W. Van Vleet, MD, MPH [Adapted from Davari])

cord. Any open spinal defects or neurological changes warrant immediate evaluation.

Neurobehavioral

The examination of the newborn needs to include a careful assessment of the general state, tone, posture, and reflexes. All newborns should have certain innate reflexes independent of gestational age. These reflexes include suck, moro, root, grasp of hands and feet, stepping, gallant, fencing, and deep tendon reflexes. At rest, the late preterm infant will have some flexion of their extremities, while full-term infants are more relaxed and extended when calm. Tone should be examined when the newborn is at rest, upright, and prone over the examiner's palm. The newborn when prone should not be either "stiff as a board, nor as floppy as a scarf." Preterm and even those late preterm infants will have subtle differences in their tone and magnitude of reaction to stimuli. But again, hypotonia and the absence of reactions to stimuli are abnormal at any gestational age. Newborns should show good state variability, by being able to go from sleep, to awake with cry, and back to calm during the exam. Poor state variability and "shutting down" are signs that the newborn is stressed. These stressed infants, as well as any found not to have intact reflexes, require immediate full evaluation including laboratory assessment looking for the existence of sepsis/meningitis and imaging of the central nervous system.

Newborn Screening

Primary screening in the newborn is very important to detect disease before irreversible damage or mortality. Some of these recommended screens are disease- or condition-specific (e.g., glucose screening for those SGA, LGA, or infants of diabetic mothers), and others are universal (e.g., hearing screening and metabolic newborn screening panels).

Glucose: It is recommended that newborns with risk factors for hypoglycemia such as those SGA, LGA, infants of diabetic mothers (IDM), IUGR, premature, evidence of perinatal stress or failure to adapt, and any with symptoms of hypoglycemia undergo routine glucose screening. Symptoms associated with hypoglycemia in the newborn include change in mental status (irritability, lethargy, stupor), poor feeding especially after feeding well, jitteriness or tremors, hypothermia, cyanotic spells or apnea, hypotonia, seizures, or coma. Screening can be done quickly and easily at the bedside with an appropriate whole blood point of care testing device. Not all such devices correlate well at lower glucose levels (some even at or below 55 mg/dL). Levels determined to require intervention should be confirmed by serum glucose analysis before but without delaying the first intervention. Variation in nursery protocols for the frequency of testing and the interpretation of results exist, as the evidence is not universally clear on the definition of hypoglycemia in the newborn. As summarized by Cornblath, the classic diagnosis of hypoglycemia in a newborn needs to meet Whipple's triad of (1) presence of characteristic clinical manifestations, (2) coincident with low plasma glucose level, and (3) resolution of the clinical symptoms once normoglycemia is established. However, it is probably that otherwise well, asymptomatic full-term newborns may tolerate glucose levels much lower than adults, questionably lower than preterm newborns, and perhaps below those previously suggested without adverse outcomes. What can be universally accepted is that newborns: (1) with hypoglycemia may present with a wide variety of nondescript symptoms or may be totally asymptomatic, (2) that any newborn with symptoms consistent with hypoglycemia should be treated more aggressively than those without, (3) that really low levels (less than $<$20–25 mg/dL (1.1–1.4 mmol/L)) require immediate correction with IV dextrose (please refer to Chap. for the IV management of hypoglycemia), (4) that prolonged hypoglycemia is probably worse than isolated events, and lastly (5) once hypoglycemia requiring intervention (cutoff is debatable but Cornblath suggests $<$36 mg/dL (2.0 mmol/L)) is documented, it is important to intervene, test to make sure that your intervention has worked ($>$45 mg/dL or 2.5 mmol/L), and then repeat testing prior to subsequent feedings (every 2–3 h) to make sure the newborn does not become hypoglycemic

again. Most newborns when feeding well will stabilize their glucose levels by 18–24 h of age, so primary screening in asymptomatic newborns after this time period is not necessary. Newborns that develop or continue with hypoglycemia warrant investigation for causes including sepsis and metabolic conditions including hyperinsulinemia.

Hearing: Universal hearing screening is recommended during the birth hospital stay as permanent hearing loss has been reported in up to 2.2 per 1,000 live births. Additional screenings to detect delayed onset hearing loss or deficits are based on risk factors (such as hyperbilirubinemia, exposure to ototoxic medications, cranial facial anomalies and associated syndromes, in utero infections like CMV, and family history) (see *Table 11.3*). Generally hearing screening in the newborn nursery in absence of the aforementioned risk factors can occur with otoacoustic emission testing (OAE). Those with risk factors, or failure of the OAE should undergo screening with the auditory brain stem response (ABR) testing. Early universal hearing screening has been demonstrated to be effective in detecting disease, in providing amplification when necessary at an earlier age, and in preventing long-term speech and developmental delays (including better performance on measures of social development, gross motor skills, quality of life, and overall scores). The Joint Committee on Infant Hearing in the USA has set forth the following goals for hearing screening programs: (1) that all infants

Table 11.3
Risk factors or markers associated with hearing deficits

In utero/familial factors	Neonatal/perinatal factors	Postnatal factors
In utero infections: • CMV (5–61%) • Rubella (50–76%) • Syphilis • HSV • Toxoplasmosis	Birth weight: • <1,500 g (2–10%) • <800 g (20%)	Prolonged NICU stay >5 days Seizures or apnea spells
Maternal exposure to aminoglycosides	Low APGAR scores: • 1 min: 0–5 • 5 min: 0–6	Respiratory markers: • Mechanical ventilation • ECMO • Persistent pulmonary hypertension
Family history of hearing loss during childhood	Syndromes: • Alport • Branchio-Oto-Renal • Cornelia de Lange • Jervell/Lange-Nielsen • Pierre Robin • Treacher–Collins • Trisomy 21 • Usher • Waardenburg (white forelock)	Hyperbilirubinemia • Requiring exchange • >22 mg/dL in BW >2,000 g • >17 mg/dL in BW <2,000 g
	Cranial facial abnormalities • Cleft lip/palate	Bacterial infections: • Meningitis (up to 30%) • Sepsis
	Neurodegenerative disorders • Charcot–Marie–Tooth • Friedreich ataxia • Hunter syndrome • Neurofibromatosis type I	Exposure to ototoxic medications: • Gentamicin (>2 days) • Tobramycin • Furosemide (Lasix) • Chemotherapy
		Birth-related or postnatal injury • Facial nerve • Head

should be screened by 1 month of age, (2) infants who do not pass should undergo additional hearing testing by 3 months of age, and (3) that infants diagnosed with hearing loss or deafness should start early intervention as soon as possible but no later than 6 months of age.

Hyperbilirubinemia: The most recent recommendations from the AAP in 2004 include the development of systematic screening processes that include universal risk assessments, parental education, early bilirubin level determinations that can be initiated by nursing staff based on clinical appearance, encourage and support of breastfeeding, and close follow-up for reassessment in the 48–72 h after hospital discharge based on the preceding determinations. Many, including the Canadian Pediatric Society and other opinion statements from experts, have recommended that each newborn have a determination of their bilirubin level prior to discharge from the birth hospital. Multiple studies have investigated universal screening with either a serum or transcutaneous bilirubin level in conjunction with hour-specific levels or nomograms and have found them to be effective in preventing excessive levels of hyperbilirubinemia. However, it is difficult to document the effectiveness of these universal screening methods in reducing the rate of kernicterus, because of its low incidence. Transcutaneous levels (TcB) should be confirmed with a serum level (TSB). Maisels et al. suggest obtaining a TSB level when the TcB is 70% of the TSB level for phototherapy, is greater than the Bhutani nomogram's 75th percentile (discussed below), >95% on a TcB specific nomogram, or when the TcB is >13 mg/dL after discharge.

In order to interpret the serum result obtained, we need to know if the newborn has any risk factors for hyperbilirubinemia. The effectiveness of all screening programs depends on close clinical follow-up and awareness that up to 10% of newborns do not follow the course predicted by these nomograms (primarily the late preterm infants and those with hemolysis of any cause). One of the most important of these factors is gestational age (preterm at largest risk, but those less than 38 weeks are also at increased risk), because the preterm infant is more likely to have both delayed hepatic clearance as well as inadequate intake. Other risk factors to consider in interpreting a bilirubin level are conditions that would cause increased hemolysis. Note, however, that all causes of hemolysis in a newborn do not cause the DAT to be positive (in 8%), and that some with a positive DAT may not have clinically significant hemolysis. Also it is important to determine how well the newborn is feeding, as poor breastfeeding (and hence decreased stooling) will increase the newborn's risk of hyperbilirubinemia. Additional risk factors are found in *Table 11.4*.

Table 11.4
Risk factors for the development of severe hyperbilirubinemia

Major risk factors	Minor risk factors
• Predischarge TcB or TSB in high-risk zone[a]	• Predischarge TcB or TSB in intermediate risk zone
• Gestational age 34–35 weeks[a]	• Gestational age 36–37 weeks
• DAT+ or other known hemolysis[a]	
• Jaundiced before 24 h	• Jaundiced before discharge
• Exclusive breastfeeding (especially if not well or with excessive [8–10%] weight loss)	
• Sibling received phototherapy	• Sibling with jaundice
• Cephalohematoma or excessive bruising	• Macrosomic IDM
	• Maternal age ≥25 years old
• East Asian race	• Male gender[b]

Adapted from the AAP 2004 Guideline
[a]More recent studies have consistently shown predischarge TcB or TSB and GA are most significant predictors. In general these studies have not included patients with known hemolysis
[b]Unsure clinical significance, and not included in more recent studies

Once these risk factors or the lack thereof have been determined, it is best to interpret the level based on an hour-specific nomogram. Lease and Whalen have a very thorough assessment of the current limitations and need for further studies in the interpretation of both TCB and TSB levels. The nomogram supported by the AAP's 2004 policy was developed by Vinod Bhutani in 1999. The clinician utilizing the Bhutani nomogram should be aware of its limitations: (1) it was developed with a discrete population of newborns (2,840 newborns at an urban hospital in the USA, none with a positive DAT, and none requiring phototherapy before 60 h or NICU level care), (2) most of the newborns did not have a bilirubin obtained before 18 h or after 132 h. The latest 2004 policy statement of the AAP on hyperbilirubinemia for newborns ≥35 weeks, extrapolated from this nomogram to make suggestions on when to start phototherapy and when to consider an exchange transfusion. These are very helpful tools in making decisions, but each case needs to be evaluated individually. The use of electronic versions of these tools has been shown to

help in the management, including a free Web-based program (www.Bilitool.org).

Patients who do not clearly fall in the group requiring phototherapy or in the low-risk group need a repeat level to establish a trend or ensure that dangerous level is not reached. The timing of this repeat level is again dependent on the risk factors, including gestational age and feeding, social situations, the family's ability to assess and act upon the potential signs and symptoms of worsening hyperbilirubinemia, and the risk category of the initial level with most requiring repeated testing within 1–3 days. If multiple levels have been obtained, then the rate of rise can be used in addition to all of the other clinical indicators, keeping in mind the levels of some infants will not track as predicted.

The specific management of hyperbilirubinemia will be discussed in ❯ Chap. "Neonatal Hyperbilirubinemia".

Metabolic/newborn screening: The goal of newborn screening programs is to utilize reliable testing methods to detect disease prior to the onset of symptoms, when the early detection and treatment has proven to be effective in preventing the complications of the disease. Traditionally these screening programs began as the Guthrie blood spot for phenylketonuria (PKU) testing in newborns. Subsequently, other disorders were added, including congenital hypothyroidism, hemoglobinopathies (sickle cell), biotinidase deficiency, congenital adrenal hyperplasia (21 hydroxylase deficiency), maple syrup urine disease, and classic galactosemia. In May 2006, an expert panel of the American College of Medical Genetics (ACMG) published an executive summary of their process for developing their recommended core panel of 29 different disorders and 25 secondary targets for universal newborn screening. The main criteria used in their recommendations were divided into three main categories: (1) clinical characteristics including incidence, burden of disease, and presentation in the newborn, (2) analytic characteristics of the screening test, and (3) the diagnosis, treatment, and management of the disease including the availability of health professionals with experience with the disease. Their panel is summarized in ❯ *Table 11.5*. Since these 2006 recommendations, others have put forward the addition of severe combined immunodeficiency (SCID) to the universal newborn screening panel.

Maternal/Caretaker Aspects of Care

Much of what occurs after birth during the hospital stay is teaching or anticipatory guidance for the mother and family members who will be primary caregivers. The care and education is meant to optimize the health of the newborn and well-being of the expanding family during this time of transition. The following sections are key teaching points for the general care of newborns in the hospital stay and anticipatory guidance for the first few days at home. Teaching in the birth hospital stay occurs through many different methods, one of these is in modeling the care the staff/nurses provide to the newborn.

Skin to Skin/Rooming-In

One of the earliest and most important interventions in the first few hours of life is to provide skin-to-skin (STS) contact between mother and newborn. As the newborn is most alert for the first 2 h of life, STS can occur as quickly after birth (once stabilized if resuscitation is necessary) and for as long as possible. When initiated within ½ h of life and maintained for at least 1 h, STS has been demonstrated to improve the newborn's regulation of temperature and glucose, as well as neurobehavioral benefits (less crying, more flexed movements). The STS benefits for mothers include increased demonstration of affection, more parental confidence, less breast engorgement pain, and less anxiety. Breastfeeding dyads with STS achieve effective breastfeeding twice as fast as controls, increased rates of breastfeeding at time of discharge, and longer duration of breastfeeding. Additional benefits for the dyad were found in Russia with the implementation of the World Health Organization's (WHO) Ten Steps to Successful Breastfeeding. Here, they showed that the benefits went beyond breastfeeding and found a reduced rate of infant abandonment. Step 7 of Ten Steps is to practice "rooming-in," where mother and infant are allowed to remain together 24 h a day. Studies have demonstrated that rooming-in increases milk volumes by day 4 and in some studies increased breastfeeding duration by 4 months. This early contact is theorized to better introduce the dyad to each other's cues and encourage on-demand feeding.

Feeding

Mothers should be encouraged to feed their newborns on demand. Ideally, this would mean feeding with those first early cues of hunger which include rooting, sucking on hands or lips, starting to wake and stir, before the newborn escalates to crying. It is not always possible to do this, but feedings are more successful when the infant is in a calm

Table 11.5
ACMG newborn screening panel

	Core panel (29)	Secondary targets (25)
Organic acid metabolism	Isovaleric academia (IVA) Glutaric academia type 1 (GA 1) 3-Hydroxy-3-methyglutaric aciduria (HMG) Multiple carboxylase deficiency (MCD) Methylmalonic academia (MUT) 3-Methylcrotonyl-CoA carboxylase (3MCC) Methylmalonic academia (Cbl A,B) Propionic academia (PROP) Beta-Ketothiolase deficiency (BKT)	Methylmalonic academia (Cbl C,D) Malonic academia (MAL) Isobutyryl-CoA dehydrogenase (IBG) 2-Methyl-3-hydroxybutyric (2M3HBA) 2-Methylbutyryl-CoA (2MBG) 3-Methylglutaconic aciduria (3MGA)
Fatty acid metabolism	Medium-chain acyl-CoA (MCAD) Very long-chain acyl-CoA (VLCAD) Long-chain L3 hydroxyacyl- (LCHAD) Trifunctional protein deficiency (TFP) Carnitine uptake deficiency (CUD)	Short-chain acyl-CoA (SCAD) Glutaric academia type II (GA2) Medium/short-chain l-3hydroxyacyl-CoA (M/SCHAD) Medium-chain ketoacyl-CoA thiolase deficiency (MCKAT) Carnitine palmitoyltransferase II (CPTII) Carnitine/acylcarnitine translocase deficiency (CACT) Carnitine palmitoyltransferase I deficiency (liver) (CPT IA) Dienoyl-CoA reductase deficiency (DE RED)
Amino acid metabolism	Phenylketonuria (PKU) Maple syrup urine disease (MSUD) Homocystinuria (HCY) Citrullinemia (CIT) Argininosuccinic acidemia (ASA) Tyrosinemia type I (TYR I)	Benign hyperphenylalaninemia (H-PHE) Tyrosinemia type II (TYR II) Defects of biopterin cofactor biosynthesis (BIOPT-BS) Argininemia (ARG) Tyrosinemia type III (TYR III) Defects of biopterin cofactor regeneration (BIOPT-REG) Hypermethioninemia (MET) Citrullinemia type II (CIT II)
Hemoglobin-opathies	Sickle cell (Hb SS) Hemoglobin S Beta Thal (Hb S/Beta Th) Hemoglobin S/C (Hb S/C)	Variant including Hgb E (Var Hb)
Other	Congenital hypothyroidism (CH) Biotinidase (BIOT) Congenital adrenal hyperplasia (CAH) Galactosemia (GALT) Hearing screening (HEAR) Cystic fibrosis (CF)	Galactokinase deficiency (GALK) Galactose epimerase deficiency (GALE)

Source: Adapted from Watson (2006) and the ACMG

alert state. It is very common for newborns to sleep for long periods of time in the first day and can continue to do so for a few weeks. During this time, there may be times when the mother needs to wake the newborn to feed. A healthy satisfied newborn will wake easily (or with the gentle to direct encouragement such as undressing or a diaper change), and then they will feed actively, only to quickly fall back to sleep when the feeding is complete. In general, the goal for breastfeeding would be 8–12 feedings a day, which averages out to be a rough goal of every 2–3 h. For newborns taking formula, which is not as easily digested, the feedings might be spread out longer to every 3–4 h, but then the diaper changes might not be as pleasant. The newborn's stomach is smaller than their fist (which is an estimated volume of 5–7 mL), it expands to a little less than an ounce by day 3 and to 2–3 oz by 10 days of life. Ameda has a Belly Balls Lactation Education Tool, which visually demonstrates this for mothers (volumes correspond to

marble, ping-pong ball, and extra large chicken egg). Another helpful way to help parents gauge volumes (which is more applicable for bottle feeding) is to expect up to ½ oz per feeding on day 1, and then increase feeding volume by ½ oz each day until they reach 2–3 oz each feeding by day 3–4, which many continue for the first couple of weeks.

Elimination and Weight

The adequacy of feeding can be determined by the adequacy of elimination (specifically stooling) and with daily weights. The number of wet diapers (urination) does not correlate as well with hydration or the adequacy of elimination as newborns do not concentrate their urine well. Diapers can also be weighed to strictly quantify elimination; however, this is not necessary with the otherwise well newborn. A rough rule of thumb to help evaluate the adequacy of urination would be for one wet diaper each day for every day old (e.g., one on day 1, two on day 2, three on day 3, etc. until they get to seven to eight wet diapers by a week of age). Less than that would be suggestive of dehydration, which in the newborn is usually due to inadequate intake. Most full-term newborns will pass meconium in the first 24 h (late preterm by 36 h). Those who have not should have their feeding reviewed and have careful examination of their abdomen and anus. Findings consistent with obstruction such as abdominal distention or feeding intolerance should be urgently evaluated with the concurrent initiation of intravenous fluids while the newborn is being evaluated and remains NPO. Those without evidence of obstruction can be examined and gently stimulated with a small gloved digit (inserted no more than 2 cm). If there is still no passage of meconium, then the newborn should be evaluated with an AP abdominal radiograph to evaluate for the possibility of meconium plug, meconium ileus (associated with cystic fibrosis), Hirschsprung's disease, or other lower abdominal obstruction (imperforate anus).

Normal stooling pattern is at least one good size stool a day (size of a quarter), with stool transitioning from meconium by day of life 3–4. Ideally, the newborn who is breastfeeding well will have at least three, and up to eight to ten stools a day (the gastrocolic reflex can produce stool with every feeding). Breastfeeding newborns should have this frequent stooling, but may at about 1 month of age develop their own stooling pattern which can even be less than once a day. Until that time, breastfeeding newborns should be evaluated for dehydration in the presence of decreased stooling. Newborns will make funny faces while stooling (including bearing down and getting red), which is normal as long as the stools are soft and not hard little pellets. The breastfeeding newborn's stool will transition from meconium to yellow seedy. The formula feeding newborn's stool may transition from meconium earlier (perhaps day 1–3) but the resulting texture and color is not as predictable. Weighing newborns daily in the birth hospital setting is an additional tool to evaluate the adequacy of feedings. The average breastfeeding newborn will lose about 2–3% of their birth weight each day with an expected total average loss of 6–8%. Those who lose more than 3% in a day, or who are between 8% and 9% below birth weight should have their latch and feeding history reviewed. This is a good time to make any necessary interventions, including getting lactation services involved to help with the development of a feeding plan. This could also include more frequent weights to help assess whether the feeding plan/interventions are helping. Ten percent or more weight loss would currently be considered excessive weight loss in the USA, and one would want to make sure the mother is supplementing, ideally with expressed breastmilk (EBM), and depending on the clinical scenario, possibly formula if EBM is not available. Newborns with more than 10% weight loss should have their hydration status evaluated with a clinical exam. And those clearly above 10% weight loss and not improving (especially with other findings like those readmitted with hyperbilirubinemia) should have their electrolytes (especially sodium) evaluated for hypernatremic dehydration. Prior to discharge from the birth hospital, it would be best to prove that this plan can stabilize the weight loss, if not demonstrating minimal weight gain. These dyads will need careful follow-up to make sure the feeding and weight is improving. The late preterm infant (LPTI) is even more susceptible to these feeding challenges.

Umbilical Cord Care

Topical care of the umbilical cord has many cultural or traditional variations. Some of these may have some benefit (perhaps olive oil) and others (coal, spices, cow dung, ash, machine oil, turmeric, mustard oil, and dried banana) may be harmful. It is theorized that the earlier the cord stump separation the better to reduce the risk of introducing microorganisms as the necrotic tissue of the stump is an excellent medium for bacterial growth. In addition to best cord care practices in preventing omphalitis, it is important to provide Tetanus toxoid

immunization to pregnant women, clean birthing surfaces, clean cord tying and cutting devices, thermal regulation (with skin-to-skin contact and a hat), and employ hand washing during the delivery and newborn care. Hand washing by the birth assistant and before cord care has been shown to be the most effective in preventing omphalitis in developing countries. Many have suggested that in otherwise clean conditions with good hand washing, that serial inspections or "dry" cord care is viable option. Recent literature reviews have not found a difference between topical agents (triple dye, alcohol, chlorhexidine, etc.), and most have favored dry cord care in developed countries.

The WHO has developed and is now distributing clean delivery kits (CDKs). Their program also promotes keeping the cord clean and dry. However, the feasibility and effectiveness of using topical antimicrobials in developing countries with perhaps less clean conditions or where traditional cord care methods might be harmful is currently being investigated. There is preliminary evidence from the Projahnmo Study in Nepal that cord cleansing with 4.0% chlorhexidine in the first 24 h of life could reduce neonatal infection by 87% and mortality by 34%. More data are needed to promote this as a worldwide initiative, but the preliminary results are encouraging.

Safe Sleep Environment

Newborns can spend up to 20 h a day sleeping in the first few days of life and continue to need lots of sleep each day for the first few months. Therefore, sleep positioning and the sleep environment are very important to the newborn's health. Public health interventions with the "Back to sleep" program have demonstrated a dramatic decline in the rate of sudden infant death syndrome (SIDS) in the USA. However, the uptake of this message has been variable in different ethnic and cultural groups with a variety of barriers identified. Additionally, worldwide there are a variety of cultural practices related to newborn sleep environment. Many cultures practice bed sharing between the newborn and mother without evidence of effect on infant mortality or rates of SIDS. However, these may be confounded by the fact that these mothers may be breastfeeding more with its likely protective effects against SIDS. In the USA, there is strong epidemiologic evidence that bed sharing with adults raises the risk of SIDS. This is especially so when co-sleeping in waterbeds or soft surfaces like couches or chairs, as well as when the co-sleeping adult has ingested substances that alter alertness (like alcohol, as well as prescribed, over the counter or illicit drugs). Expansion of the safe sleep educational program includes parental education about the risks of co-sleeping, smoking cessation, and modeling of the safe sleep environment of the child. It has been demonstrated that when nursery staff practice placing newborns supine in a safe sleep environment, there is better adoption of these recommendations. The safe sleep environment for a newborn should be located as close to the mother as possible to promote breastfeeding while being separate from the adult bed. The safe sleep environment should be free of loose bedding, fabric near the head, stuffed animals or pillows, bumpers, and fluffy blankets or comforters.

Injury Prevention/Shaken Baby Syndrome Awareness

Shaken baby syndrome (SBS) is a devastating condition of brain injury due to violent shaking of a newborn or young child. Symptoms of SBS include apparent life-threatening events (ALTEs), retinal hemorrhage, subdural hemorrhage, permanent brain injury, and a mortality rate of close to 40%. Identified risk factors include male infant, firstborn, twin or other multiple, prematurity, low birth weight, difficult temperament/difficult to console, in utero exposure to substances causing withdrawal, drug or alcohol use, history of domestic violence, young unmarried mother with less than a high school education, and living with nonrelated adult. Some hospital-based programs are showing promising results with educational interventions that discuss the dangers of SBS, give information about child development, and provide suggestions toward nonviolent behavior management. These management plans need to help the parent or care provider recognize their own limitations, acknowledge their stress, and develop a plan in advance of when these situations arise.

Discharge and Post Hospital Follow-Up

The pediatric care provider should make sure that the mother and family have a good understanding of the care of their newborn. This would include discussion of both issues of safety and general care of their newborn. Ideally, this is done over more than one visit in the birth hospital, as research has demonstrated that postpartum mothers do not retain as much information as other patients. It is important to tailor these instructions to

match the infant's clinical scenario and to meet the parents' educational needs. At a minimum, the following safety issue should be covered in each discussion: how and when to contact the pediatric care provider after discharge, the signs and symptoms of jaundice, omphalitis, respiratory distress, sepsis, and how to take a temperature. Additional care topics that should also be reviewed include feeding, elimination, cord care, safe sleep positioning, and if applicable car seats and circumcision care. *Table 11.6* contains a sample list of topics discussed as discharge anticipatory guidance.

The AAP recommends that every newborn gets seen by a trained professional 2–3 days after discharge from the birth hospital to minimize the risk of excessive bilirubin levels and to encourage optimal breastfeeding. This can be done either by a physician or by a physician extender/nurse specialist experienced in newborn care. This and subsequent scheduled follow-up is likely more important in preventing hyperbilirubinemia and its consequences than many other interventions. This visit establishes the medical home as an outpatient and allows the physician to assess the newborn when it is at the most risk for hyperbilirubinemia. For those newborns with additional concerns such as risk factors for hyperbilirubinemia, difficulty breastfeeding, excessive weight loss, those discharged prior to 48 h of life, the LPTI, or with concerns about either the social situation or about maternal adjustment should be seen in 24–48 h after discharge. While there are many things to assess about the physical health of the newborn at this visit, it is also great time to reinforce the strengths of the dyad as the first few nights at home may leave parents with more questions than answers.

Table 11.6
Sample topics for discharge anticipatory guidance

Safety issues:
• How to call pediatrician and first appointment in 2–3 days (time/date)
• How to take rectal temperature, availability of thermometer, temperatures to notify PMD [if <97.5°F (36.4°C) or >100.4°F (38.0°C) rectally]
• How to evaluate for jaundice, to call PMD if approaches umbilicus or symptoms of hyperbilirubinemia develop
• Safe sleep environment
• Back to sleep, safe bedding, SIDS prevention
• Car seat (backward for at least the first 2 years and minimum 20 lbs, backseat in middle), where to get checked
• Smoke detectors (check each month)
• Temperature of hot water heater (<120°F)
• Injury prevention/SBS (shaken baby syndrome)
Care issues:
• Care for umbilicus, signs of infection, and when it should fall off
• Bathing
• Feeding: breast, bottle
• Urination and defecation (expected numbers and consistency)
• Dressing
• Sibling rivalry/adjustment
Parent concerns:
• As directed by discussion, give ample time and encourage the parents to ask questions

Management of Common Newborn Problems

There are many problems that occur in otherwise well newborns. A few that occur very commonly are discussed below.

Eye Discharge

Erythema, swelling, discharge, and conjunctival injection is consistent with conjunctivitis. In the newborn, this can be due to chemical conjunctivitis or infection. Factors to consider when evaluating neonatal conjunctivitis include organisms in the maternal birth canal, identification and treatment of maternal infections during pregnancy, adequacy of ocular prophylaxis, and potential trauma to the eye. Chemical conjunctivitis occurs soon after birth, lasts between 24 and 36 h, and is a reaction to the administration of ocular prophylaxis. There may be a linear erythema of the eyelids continuing onto the face or temples due to irritation of the surrounding skin. Incidence of chemical conjunctivitis is slightly higher with silver nitrate than erythromycin ointments. The presence of purulent discharge suggests an infectious etiology with Chlamydia trachomatis, the most common cause, followed by Neisseria gonorrhoeae, and then other bacterial and viral causes. Distinguishing between chlamydial and neisserial causes can usually be made based on timing and clinical appearance. Gonococcal conjunctivitis occurs earlier usually beginning within 24–48 h of life and is marked by profuse purulent discharge and eyelid edema. Chlamydial conjunctivitis appears later, most between 5 and 7 days (but can present up to 21 days)

with discharge that is initially watery progressing to mucopurulent. Although chlamydial conjunctivitis may be self-limited, it is important to test for nasopharyngeal colonization as treatment is necessary to prevent the development of pneumonitis. Diagnosis of bacterial conjunctivitis should include bacterial cultures and direct immunofluorescent antibody testing versus chlamydia. Treatment of chlamydial conjunctivitis requires oral antibiotics. Use of oral erythromycin has been associated with infantile hypertrophic pyloric stenosis but is still recommended by the AAP for treatment of chlamydial conjunctivitis after appropriate risk counseling with the parents. Treatment of gonococcal conjunctivitis requires systemic antibiotics, and with full evaluation for systemic disease in an intensive care unit. Additionally treatment of disseminated gonococcal disease requires treatment for 7 days and one should consider Cefotaxime instead of Ceftriaxone in newborns with significant hyperbilirubinemia (*Fig. 11.11*).

Viruses specifically herpes simplex virus (most commonly Type 2 but also Type 1) can cause neonatal conjunctivitis with serous to serosanguineous discharge. These may or may not appear with characteristic vesicles surrounding the eye. Prompt evaluation for CNS and disseminated HSV disease is prerequisite for determining length of treatment. Lastly commonly occurring clear watery to slightly yellowish discharge or tearing without conjunctival injection is consistent with dacryostenosis or lacrimal duct stenosis. Treatment includes warm compress or massage from outer to inner canthal folds to "milk the duct." Occasionally, these can become secondarily infected and would need topical antibiotics. A summary of the presentation and treatment of the major causes of neonatal conjunctivitis appears in *Table 11.7*.

Jitteriness

The newborn that is jittery or has an exaggerated Moro reflex should be evaluated for hypoglycemia or, less commonly, electrolyte abnormalities. With normal serum levels, the examiner should obtain a detailed obstetrical history to include risk factors for infection and potential exposures to medications (including SSRI's, opiates, etc.), illicit drugs, tobacco, and caffeine. The newborn should have a careful exam for signs and symptoms of infection and a complete neurological exam. Newborns with specific risk factors for infection (i.e., GBS positive mother, history of HSV or concurrent infection, maternal fever, prolonged rupture of membranes, chorioamnionitis, etc.) should be evaluated for infection and those with clinical manifestations of infection should be started on systemic antibiotic therapy. In the absence of risk factors or clinical manifestations, serial examinations should occur. Those with increasing jitteriness, additional neurological findings, or change in mental status including poor feeding should be evaluated for both CNS infection as well as neuroimaging to evaluate for a potential bleed or lesion. Once the other more worrisome etiologies have been eliminated as causes, and based on exposure history, one can start to think of neonatal withdrawal as the possible cause. In the case of opiates, this is described as neonatal abstinence syndrome (NAS) but has also been associated with other more commonly occurring substances such as SSRI, tobacco, and caffeine (see Chap. 34, "Miscellaneous Disorders" for a more detailed description). Lastly, there is a small subset of newborns who are neurobehaviorally more immature, but otherwise normal. These newborns and their families benefit from a complete evaluation with an occupational therapist performing a Neonatal Network Neurobehavioral Score (NNNS), with

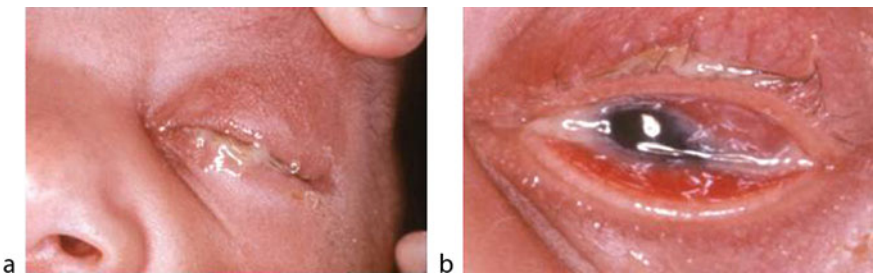

Figure 11.11
Newborn with conjunctivitis cause by Neisseria *gonorrhoeae*. (b) is a close up of the same patient in (a). In (b), note the collection of purulent eye discharge in the inner canthal region right after wiping the eye (Photograph from the patient files of James F. Padbury, MD)

Table 11.7
Summary of characteristics of common causes of neonatal conjunctivitis

Type of conjunctivitis	Agent/organism	Typical onset of symptoms	Description of discharge	Treatment
Chemical	Silver nitrate, or erythromycin prophylaxis	Birth to 1 day	Watery	Self-limited, warm compress
Bacterial	Chlamydia trachomatis	4–10 days (up to 21 days)	Watery then mucopurulent	Erythromycin PO (50 mg/kg/day in four divided doses per day for 14 days)
	Neisseria gonorrhoeae	1–4 days (up to 21 days)	Purulent and profuse, "hyper purulent"	Ceftriaxone IV or IM (25–50 mg/kg not to exceed 125 mg, once) and saline eye irrigation until resolution of discharge
	Gram positive including S. aureus, Streptococcal species, etc.	4–7 days (may be 2–21 days)	Mucopurulent (moderate)	Erythromycin 0.5% ointment topically to eyes four times a day for 3–7 days
	Gram negative including Haemophilus species, E. *coli*, etc.	5–10 days (may be 2–21 days)	Mucopurulent	Trimethoprim-polymyxin B or Gentamicin eye drops
Viral	Herpes Simplex Virus (Type 2 more common then Type 1)	6–14 days (may be up to 6 weeks of age)	Serous to serosanguineous	Acyclovir IV, (60 mg/kg in 3 divided doses per day for 14 days) and 1% trifluridine or 3% vidarabine topically to eyes

demonstration of modifications to care that would benefit their newborn. These newborn warrant close follow-up and prompt referral to early intervention services with any ongoing concerns.

Heart Murmur

Murmurs are very common in newborns, and most will resolve spontaneously. Roughly 80% of infants will have a transient murmur related to closing PDA in the first 24 h of age. The risk for pathologic murmurs/congenital heart disease (CHD) is higher in newborns with other anomalies, newborns with first-degree relatives with CHD, certain in utero exposures, and in infants of diabetic mothers (IDMs). Up to 30% of IDM newborns will have some form of CHD. Once a murmur is detected, subsequent action depends on its nature and a determination of whether it is a cause for concern. "Transitional murmurs" are common, have no clear structural basis and resolve spontaneously. Grade I–II, ejection (crescendo–decrescendo) murmurs, musical or vibratory in quality that are best heard on the left sternal border in an otherwise well newborn with normal femoral pulses, color, and capillary refill (<3 s) are usually benign. More worrisome murmurs are those associated with clinical signs or other anomalies, are harsh or blowing, holosystolic, obscure S1 or are diastolic, and grade III or higher. Transitional murmurs may start off being loud at a Grade III but then will generally decrease in intensity, sometimes even disappearing over the first 24 h. In contrast, pathological murmurs remain loud, intensify, or may develop later. In the first few days of life, murmurs may be very dynamic, due to changes in pulmonary vascular resistance.

For any worrisome murmur, or one that persists beyond 24–48 h, additional information should be obtained. The first step (when available) is to obtain a pre- and postductal pulse oximetry. The postductal SPO_2 in a full-term newborn after 4–6 h of age should be >95% on room air. Some authorities are proposing that a postductal saturation should become the fifth vital sign, or part of universal newborn screening. In general, the pulse oximetry has a good positive predictive value, and will detect about 98% of major congenital heart defects in the newborn period. However, the negative predictive value is not as good, because not all significant heart defects present with right to left shunting. The second step in evaluating the newborn's heart murmur is to obtain upper and lower extremity blood pressures. Presence of good femoral pulses does not rule out coarctation or interrupted arch, because flow across an open PDA may provide adequate systemic blood flow initially. The systolic pressures of the lower extremity should be higher than in the upper extremities (think higher pressure

downstream unless there is a dam blocking flow). Systolic pressure in the upper extremity that are ≥9–12 mmHg higher than the lower is worrisome. Blood pressure is highly state-related in the newborn, so abnormal blood pressures should generally be repeated and proper cuff sizes confirmed. If the screening SPO_2 and blood pressures are not reassuring, the newborn should be referred for cardiology evaluation and an echocardiogram. If the screening SPO_2 and blood pressures are reassuring, the newborn with a non-worrisome murmur and an otherwise normal exam can be followed with serial exams. In areas without access to cardiology or echocardiograms, additional information can be obtained from an EKG, looking primarily for right-axis deviation greater than expected for age (in the LUQ), as well as a PA and lateral chest radiograph to evaluate the cardiac silhouette for size (watch the thymus shadow which is best distinguished on the lateral), location (dextrocardia), shape (i.e., that classic "egg on a string" from transposition of the great arteries (TGA) and "boot shape" of tetralogy of Fallot (TOF)). The lung fields are assessed for pulmonary vascular markings (decreased in right-sided obstructive lesions or increased in mixing lesions with increased pulmonary blood flow). (For additional information on pediatric cardiology refer to ❯ Chap. "Pediatric Cardiology").

Omphalitis

Omphalitis or infection of the newborn's umbilical cord presents as discharge or oozing (4%), spreading erythema (6%), swelling, warmth, and tenderness (7%) of the cord stump. Redness extending more than 2 cm from the cord is generally consistent with infection. Mean time to presentation is about 2.5 days with a range from 1 to greater than 8 days. Estimates of omphalitis range from 1% to 16% of newborns depending on the criteria used in defining the diagnosis. The etiology of omphalitis traditionally includes *Staphylococcus (*both *aureus* and *epidermidis*), *Streptococcal* (group A), *Klebsiella pneumoniae*, *Escherichia coli*, *Proteus mirabilis*, and anaerobic *Bacteroides and Prevotella organisms*. With the implementation of antistaphylococcal cord care techniques such as triple dye, hexachlorophene, and alcohol, the incidence of gram-negative organisms have been increasing, although this may not be the case in developing countries. In most cases, omphalitis remains a localized infection, but complications can include neonatal sepsis and meningitis. Additionally, there can be rapid progression of the infection to the abdominal wall causing cellulitis and necrotizing fasciitis, which have a high risk of mortality. Treatment of omphalitis includes prolonged parenteral antibiotics.

Conclusion

Care of the newborn demands an attention to details, both in obtaining the maternal history and in completing the early exams as many subtle differences would be indications for adjustments in care to promote the well-being of the family and the newborn's development over time. This includes screening both in the primary or universal sense of all newborns (such as hearing and NBS programs) but also secondary screening for specific diseases (such as infection, for hypoglycemia in the IDM, and cardiac workup or screening with a murmur). Public health both nationally and internationally has its roots in maternal child care, and as such has had great impact in reducing infant mortality. Much of the care currently provided in nurseries is evidenced based only in that it has stood the test of time, and little of what is done has ever been scientifically evaluated. At present, newborn care is far from proven best practices. But we are moving toward that direction as exemplified by the work to determine the best systematic methods for screening for hyperbilirubinemia to prevent chronic bilirubin encephalopathy (kernicterus), and in evaluation of cord care techniques in real practice and developing countries. Until these and many other answers are obtained, one should continue to work toward providing the best of what is known so far, and in encouraging families to embrace the care of their newborns.

12 Birth-Related Injury

Marcia Wenner VanVleet

Birth-related injury is broadly defined as a physical injury sustained by a newborn during the process of birth. This definition places no blame or fault, but recognizes that in many cases, such injuries are unpredictable and perhaps have unavoidable outcomes. Estimates from the USA are that approximately 2.6% of births will end with some kind of injury. The severity of birth-related injury varies greatly from the minor and temporary, such as ecchymosis, swelling, or superficial lacerations, to the more serious longer lasting conditions such as brachial plexus injury, and even a fatal outcome. This chapter will describe those conditions that are most likely the result of mechanical forces on the newborn through the birth process.

Incidence

In many countries, the rate of birth-related injury has markedly decreased due to improved prenatal care, greater use of imaging, and presence of skilled attendants at deliveries with the tools necessary for intervention (both obstetrical and neonatal), including cesarean sections, fetal monitoring, and newborn resuscitation. In the USA, an estimate of overall birth-related injury indicated a rate of 37.0 per 1,000 in 1989–1990 and 29.2 per 1,000 in 1999–2000. However, birth-related injury continues to occur with the most sophisticated prenatal diagnosis, the best obstetrical practices, and even in the absence of any identifiable risk factors, occurring at times in utero. It has been suggested that despite optimal care, the birth-related injury rate will never be zero and that perhaps its low might be closer to 18 per 1,000 births as seen in normal, uncomplicated in-hospital births. This should not be surprising, as the process of birth requires the fetus to squeeze through the narrow confines of the maternal bony pelvis, propelled by the powerful contractions of the uterine myometrium and using the presenting part as a battering ram to dilate the soft tissues. However, these considerations should not prevent us from seeking to decrease birth injury as close as possible to this irreducible minimum. It should be noted that while cesarean delivery is associated with lower rates of birth trauma, it does not eliminate it.

In the USA, the reduction of infant death and injury during delivery has gained much attention including a Sentinel Event Alert from the Joint Commission in July of 2004. In an attempt to reduce the preventable injuries, the Agency for Healthcare Research and Quality (AHRQ) in the USA has developed, through expert consensus, a group of Patient Safety Indicators (PSI's) which includes seven types of birth-related injury. These include (1) subdural and cerebral hemorrhage, (2) epicranial subaponeurotic hemorrhage, (3) other injuries to skeleton, (4) injury to spine and spinal cord, (5) other cranial and peripheral nerve injuries, (6) other specified birth trauma, and (7) birth trauma unspecified. Using hospital discharge data from a 2004–2005 USA sample, Moczygemba et al. found a PSI rate of 2.45 per 1,000 and an overall birth trauma rate of 25.85 per 1,000 (*Table 12.1*). Reported rates of birth-related injury vary greatly based on the year of publication, study population (hospital-based versus larger population-based samples), the specific conditions included in the study, and geographical location. In the USA, estimates for overall birth trauma rates vary widely from 0.2 to 37 per 1,000 births. A recent robust estimate comes from a cross-sectional study using in-hospital birth discharge diagnosis codes from 2003. In this study, Sauber-Schatz found a raw data estimate of 50 per 1,000 births which, when weighted by hospital characteristics, yielded an estimate of national rate of birth-related injury of approximately 29 per 1,000 births.

International estimates of overall birth-related injury rates vary greatly based on the country and the year. Estimates from developed countries range from Salonen's multiyear estimate in Finland publish in 1990 with 31.6 per 1,000 to that of Awari's et al. in 2003 with a rate in Saudi Arabia of 6.7 per 1,000. These differences might reflect time-related changes as Zeck et al. looked at similar time periods in Austria and found a drop in incidence or birth-related injury of any sort from 24.6% (246 per 1,000 births) in 1989 to 13.2% (132 per 1,000 births) in 2000. The reduction in injury rate was not explained fully by the change in cesarean section rate. International rates for birth-related injury as defined by the AHRQ PSI from 2004 to 2006 ranged between 0.151% and 1.448%

Table compiled from data from multiple sources, most notably Moczygemba (2010) and Sauber-Schatz (2010)

(1.51–14.48 per 1,000 births) in the seven countries participating in the Organization for Economic Co-operation and Development (Austria, Canada, Germany, Spain, Sweden, UK and USA). However, the study noted that the PSI birth-related injury indicator might be unreliable for international comparison.

Sule and Onayade's review of literature from the World Health Organization (WHO), Save-the-Children,

United Nations Children's Fund (UNICEF), and other scientific sources reports that 99% of neonatal deaths occur in developing countries with a 30-fold disparity between those countries with the highest (found in sub-Saharan Africa) and lowest neonatal mortality rates. Within developing countries, estimates based on the deaths of four million newborns indicate that birth injuries at 11% was the second most common cause, behind infection, which accounted for 42%. Two hospital-based studies of birth-related injury from the country of Iran point to regional differences even within a single country and underscore the impact of sampling (denominator). Borna's study limited to singleton vaginal deliveries in 2002–2005 found incidence of 41.16 per 1,000, where Mosavat's study of all live births in 2004–2005 in Rafsanjan (south Iran) found 0.8% (or 8 per 1,000) with a relatively high cesarean delivery rate.

Overall Birth-Related Injury Risk Factors

Risk factors can be broken into three groups: those related to mother, to baby, and to delivery characteristics.

Maternal factors include: maternal obesity (BMI > 40 kg/m^2), preexisting or gestational diabetes, large weight gain, previous history of macrosomic infant, small maternal stature, and the presence of maternal pelvic anomalies.

Newborn factors include: macrosomia, prolongation of pregnancy (>42 weeks or 298 days), and abnormal (other than vertex, occiput anterior) presentation.

Delivery factors include: induction of labor, epidural analgesia, shoulder dystocia, and operative or instrumented vaginal delivery.

Specific Types of Birth-Related Injury

Skin/Soft Tissue

Superficial injury to the skin is the most common birth-related injury. Bruising, petechiae, abrasions, and even lacerations can occur on the scalp or on any other presenting part during passage through the bony pelvis, from the dilating cervix, or from instruments (including vacuum, forceps, and hands) used in delivering the newborn. Extensive bruising may predispose a newborn to jaundice peaking a little later at 5–7 days of life as reabsorption occurs. Abrasions seldom need treatment with antibiotics but should be monitored for signs and symptoms of infection (including edema, erythema, induration, warmth, or tenderness). Mild symptoms of infection can be treated topically but careful observation is necessary as cellulitis requires treatment with systemic intravenous antibiotics. Abrasions that are near the eye should prompt a careful eye examination, and any that cross the edge of the orbit should be referred to an ophthalmologist for assessment. Superficial lacerations are also rarely prone to infection, but topical antibiotics and sterile strips may aid healing. Those lacerations that are full thickness (through the epidermis) or in key anatomical locations such as the face, near the eye, or in an area with traction (over a joint) should be cleaned and then referred to a plastic surgeon (if available) for suturing in the nursery. Long-term prognoses for these superficial injuries are excellent and generally heal very quickly in the newborn.

Deeper injury to the skin and subcutaneous fat tissue leading to fat necrosis can occur rarely in any area of trauma. These usually appear on the back, buttocks, or extremities of full term infants during the first several days to weeks of life as firm, indurated and erythematous (either red to purplish-blue but occasionally fleshy colored) nodules and plaques that lack warmth but potentially may be tender. It is unclear exactly what causes fat necrosis but theories include (1) some type of mechanical trauma or pressure which induces ischemia, (2) possibly defect in fat composition with a stressful event, or (3) cold- or hypothermia-induced saturated fatty acid crystallization. After the solidification and necrosis of the fat, a granulomatous infiltrate forms increasing the extrarenal absorption of calcium. Histological examination of the tissue reveals increased levels of 25-hydroxyvitamin D3-1alpha-hydroxylase (AKA 1alpha-hydroxylase) which activates vitamin D. Subcutaneous fat necrosis is a self-limited condition resolving in about 6–8 weeks of life with some subcutaneous atrophy, but these infants can have serious alterations in their calcium levels (*Fig. 12.1*). Hypercalcemia has been reported up to 6 months after initial presentation and can rarely lead to seizures, coma, and death. Symptomatic hypercalcemia (presenting as irritability, poor feeding, etc.) should be treated in the hospital with hydration, calcium wasting diuretics, furosemide, and corticosteroids. It is recommended to check calcium levels periodically in all infants with subcutaneous fat necrosis for several months, and dietary changes would be advised in those with documented asymptomatic hypercalcemia. Thrombocytopenia, anemia, hypertriglyceridemia, and hypoglycemia have also been reported. Although presentation and history are likely enough to make the diagnosis, fine needle aspiration and punch biopsy are definitive in confirming the diagnosis. Differential diagnosis includes cellulitis, erysipelas, sclerema neonatorum, deep hemangioma, or other tumors.

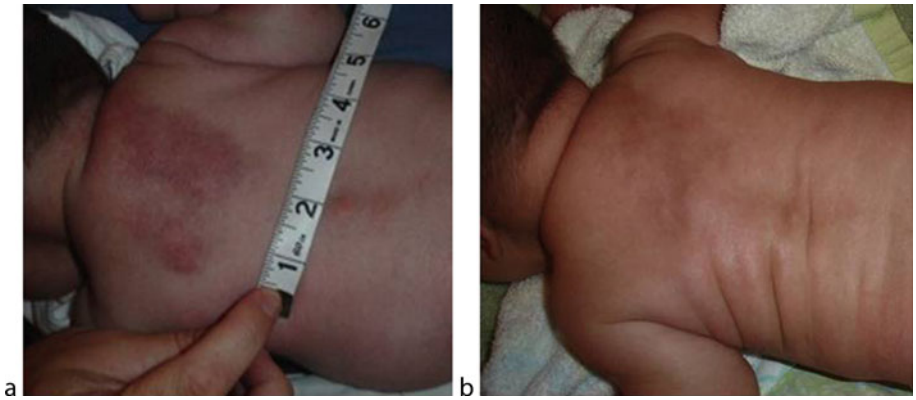

Figure 12.1
Subcutaneous fat necrosis. This large-for-gestational-age (*LGA*) newborn was born by vaginal delivery with documented shoulder dystocia. (a) Initial concern for possible midline hemangioma on day of life (DOL) 4. Note the purplish red lesions above and below the tape measure. (b) Infant referred to Dermatology at one month of life, diagnosed as subcutaneous fat necrosis (Photograph from the patient files of Tricia L. Groff, MD)

Figure 12.2
Subconjunctival hemorrhage in a newborn. (a) Taken very shortly after birth of a full-term newborn delivered by uncomplicated vaginal delivery in the occiput posterior position with no instrumentation to a gravida 2 para now 2 mother. Note the significant swelling of bilateral eyelids, and ecchymosis over most of the forehead. (b) Taken on day of life (DOL) two at the time of discharge, the swelling was nearly resolved and subconjunctival hemorrhages were now visible on the medial aspect of the left eye (Photograph by Marcia W. VanVleet, MD, MPH)

Face and Neck Injuries

Ocular Injuries

Ocular injuries can occur in up to 12% of newborns as they pass through the birth canal or with instrumentation, especially with forceps. The most common eye injury is the subconjunctival hemorrhage that appears as red bands around the iris (*Fig. 12.2*). It is usually present at birth but may not be apparent until the normal eyelid swelling/edema subsides revealing the conjunctiva over the white sclera. As with other microvascular bleeds or ecchymosis, these might appear to change color during the healing process, but usually heal spontaneously in 10–15 days. Subconjunctival hemorrhages occur as the result of elevated venous pressure in the head and neck from the increased intrathoracic pressure from passage through the birth canal. However, as they are also seen in cesarean section deliveries, it is likely that compression of the thorax/abdomen by uterine contractions, or a tight nuchal cord may have the same consequences. Other injuries to eye are more frequent when there has been

instrumentation with forceps. These can include hyphema (bleed into the anterior chamber of the eye), corneal abrasions (or vertical tears in Descemet's membrane), or orbital injuries (including fractures, and damage to the optic or oculomotor nerves). These should be referred to an ophthalmologist promptly.

Nasal Septal Dislocation

Dislocation of the nasal septum can occur in passage through the birth canal. Reports suggest that some type of usually transient nasal deformity may occur in up to 58% of births. However, the rates for nasal septal dislocation vary based on the method of diagnosis. Those relying on external exam and rhinoscopy find rates near 1.2–3.4%, whereas those that actually try to pass 2 mm struts through the nasal cavity find rates up to 14.5–25%. Reported risk factors include primiparity, breech presentation, prolonged second stage of labor, vaginal delivery, and large head circumference. Nasal septal dislocation has a clinical range of presentation based on degree of involvement, but usually presents with symptoms of airway obstruction (difficulty when feeding and mild respiratory distress). Clinical exam can include bruising and edema, but more commonly these present with just deviation of the septum or asymmetry of the nares with flattening of the affected side (Metzenbaum's sign). Further diagnostic refinement can be made 85% of the time by pressing on the tip of the nose which will, in the case of septal dislocation, worsen the deviation and flatten the nostril (Jeppesen and Windfeld test). These cases should be referred within the first 3 days of life to an ENT specialist who will confirm the diagnosis with rhinoscopy and manually reduce the dislocation. Prompt intervention is necessary to prevent long-term cosmetic deformity and potential outcomes of epistaxis, Eustachian tube dysfunction, abnormal development of the maxilla, and repeat sinusitis.

Neck/Torticollis

Torticollis defined as limitation of the lateral flexion of the neck can be the result of birth-related injury in about 10% of cases, but the majority are likely due to in utero positioning in the restricted intrauterine environment (postural asymmetry without muscular tightness). Torticollis has been associated with a maternal report of the fetus being "stuck" for more than 6 weeks prior to delivery. Many cases of torticollis (up to 40%) are due to congenital spindle-shaped mass or tumor in the midportion of the sternocleidomastoid muscle. Torticollis can be apparent at birth, but generally presents between 1 and 4 weeks of age, most commonly at 3 weeks. Careful examination of the neck includes measurements of the range of motion comparing sides and palpation of the sternocleidomastoid muscles for masses. Diagnosis is usually by clinical exam, in consultation with the occupational (OT) or physical therapist (PT). However, radiographs of the spine and ultrasonography may be helpful in confirming the diagnosis. Parents should be instructed to perform range of motion exercises, provide regularly observed prone "tummy time," and encourage the infant to look toward the non-preferred direction with the use of mirrors, pictures, etc. Most do well with stretching, but prognosis can be related to the degree of limitation. Of the cases whose range of motion is limited by more than 10°, 5% will go on to need surgical intervention. Indication for surgery includes lack of improvement in 6 months, continuation of greater than 15° of limitation, or ongoing head tilt. If left untreated, asymmetry or positional preference (either awake or asleep) strongly correlates with deformational posterior plagiocephaly at 7 weeks of age.

Head Injuries

Injuries to the head can be divided into three categories based on their anatomical location: (1) extracranial injury, (2) cranial or skull fractures, or (3) intracranial hemorrhage (*Fig. 12.3*). Although any of these injuries can occur in deliveries without instrumentation, all are more common with vacuum and forceps delivery. Any newborns with serious or massive extracranial or any intracranial hemorrhages should undergo a hematological evaluation that includes PT/PTT, fibrinogen, platelet count, and confirmation that Vitamin K has been administered.

Extracranial Injuries

Extracranial injuries are the most common type of birth-related head injury, and include caput succedaneum, cephalohematomas, or subgaleal hemorrhages.

Caput Succedaneum (or "second head" in Latin) appears first after delivery and is purely a severe form of diffuse soft tissue swelling of the scalp. Caput is thought to be the result of squeezing of the head in the birth canal or by the constriction of the cervix. They may or may not have overlying ecchymosis. These serosanguineous fluid

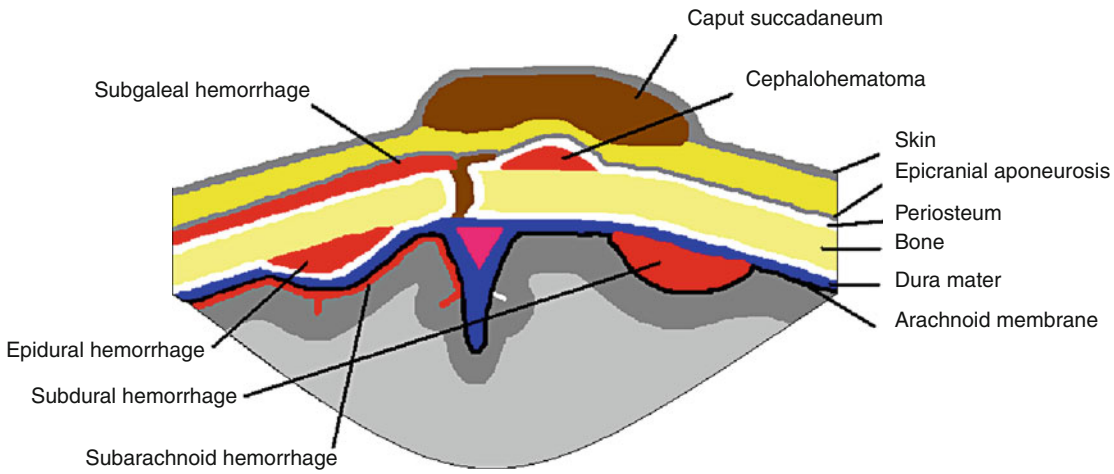

Figure 12.3
Schematic of cranial birth injuries. Diagram of location of cranial birth injuries drawn by Victoria A. VanVleet (Adapted from multiple sources including Sheikh, McKee-Garrett, Volpe)

Figure 12.4
Bilateral parietal cephalohematomas. *Arrows* point to bilateral swelling of scalp in a near-term infant nasally intubated for other reasons (Photograph from the patient files of James F. Padbury, MD)

collections occur in the plane between the skin and the epicranial aponeurosis and therefore have ill-defined margins not limited by bony landmarks. A caput can occasionally be fairly large but starts to regress quickly and usually resolves within a few days. It can mask molding or a cephalohematoma that may become more apparent as the caput resolves.

Cephalohematomas are subperiosteal collections of blood just under the outer surface of the bone (*Fig. 12.4*). They are the result of shearing friction to the bone that ruptures the bridging vessels, leading to slow bleeding. As such, they may not be apparent at the time of birth but slowly increase over the next few days. The lesions tend to become firm masses but occasionally fluctuant with distinct borders as they are limited to the edges of the bones and do not cross suture lines. This is a key distinguishing characteristic between cephalohematoma and caput. Initially, it might be difficult to distinguish between a caput and a cephalohematoma when they coexist, but over the first few days, the caput should regress and potentially reveal a cephalohematoma (or two as trauma may not be limited to just one bone of the skull). Cephalohematomas will slowly be reabsorbed over 2–3 weeks (up to 3 months) depending on size, potentially leading to increased hyperbilirubinemia as well as calcified masses. Occasionally, these create bony protuberances which can appear for many years on X-rays as cyst-like defects. Cephalohematomas may be associated with skull fractures in 5–25% of cases. Cases of infection and osteomyelitis have been reported in cephalohematomas. Cephalohematomas rarely need treatment, but often can lead to exaggerated and prolonged hyperbilirubinemia, which may require phototherapy later then physiologic jaundice.

Subgaleal hemorrhages represent the third and potentially most serious form of extracranial injuries. These rare bleeds (estimated overall at 0.8 per 1,000, and 6.4 per 1,000 of vacuum-assisted deliveries) occur between the epicranial aponeurosis and the outer periosteum of the skull bones. As such, they are not limited by bone edge and can accumulate large volumes of blood into this potential space, and even into the soft tissue of the neck. These usually result from rupture of the emissary veins, or less frequently fracture of a bone, but occasionally can be the

result of hereditary coagulopathy such as hemophilia. These can be fluctuant masses that steadily grow in size extending from the edge of the orbital ridges to the nape of the neck and to the ear and may lead to an impression of dysmorphology. The large amount of blood accumulation can cause anemia, hypovolemic shock (pallor, tachypnea, tachycardia, and hypotension), consumptive coagulopathy, and death in 12–22%. Early recognition and effective treatment is the key to a good outcome. Serial assessment of blood pressure, hemoglobin/hematocrit, and head circumference are warranted. It has been documented that an increase in head circumference of 1 cm can represent 38 mL of blood, and that subgaleal bleeds can collect 31–58% of the newborn's blood volume. Prognosis is worse for those with 25% decrease in hematocrit, shock, or evidence of asphyxia. Testing should include assessment for coagulopathy, which has been found in 30% of cases. Serial bilirubin levels should be assessed over the next few weeks of life as the hemorrhage is reabsorbed. Prognosis is good for survivors.

Cranial Injuries/Skull Fractures

Cranial Injuries/Skull fractures can occur from pressure against the maternal pubic symphysis, sacral promontory or ischial spines in vaginal deliveries, or from forceps, similar to the causes of facial nerve palsy. Most are linear fractures and are asymptomatic, requiring no treatment. The exception to this is the rare occurrence of an occipital bone fracture in a breech delivery that may be fatal due to bleeds associated with the underlying vascular sinuses. Depressed fractures (like a ping pong) are typically also asymptomatic unless there is underlying intracranial hemorrhage. Depressed fractures require brain imaging and neurosurgical evaluation.

Intracranial Injuries/Hemorrhage

Intracranial hemorrhages can occur in the epidural, subdural, subarachnoid, intraparenchymal, or intraventricular spaces.

Epidural hemorrhages (EDH) are extremely rare bleeds in newborns. They occur between the dura and the skull, often associated with a parietotemporal skull fracture. Additionally EDH may occur in association with cephalohematomas. These are arterial in source, usually from the middle meningeal artery, and can progress rapidly. Newborns with EDH present with nonspecific neurological findings (such as change in mental status or hypotonia), seizures, or symptoms of increased intracranial pressure (ICP). Diagnosis is made with CT or MRI, and serial images may need to be obtained to assess progression. Neurosurgical involvement is indicated with signs of increased ICP, and also potentially when the bleed is large, or when there is a depressed skull fracture, hydrocephalus, or a significant mass effect.

(See Resources for link to Web site with a CT Scan of a Newborn with a Cephalohematoma and Epidermal Hematoma.)

Subdural hematoma (SDH) is also a rare occurrence but is the most common intracranial hemorrhage attributed to birth-related injury. These bleeds occur between the dura mater and the subarachnoid membrane usually in the tentorial or intrahemispheric location. Some newborns remain asymptomatic, but if the volume of blood grows, they usually present in the first 24–48 h of life with apnea, respiratory distress, and/or seizure. Some may present with mental status changes such as irritability or depressed activity. The newborn skull is pliable with open sutures and fontanels; therefore, it can expand in response to the accumulated blood before the ICP rises. Rarely, when there is increased ICP, the infant can progress to increasing head circumference, tense or bulging anterior fontanel and if left untreated, progress to apnea, bradycardia, coma, and possibly death. Management of subdural hemorrhages depends on the location and symptomatology. Due to the potential for large blood loss, serial hematocrits and volume support is recommended as indicated; those with larger blood loss should be evaluated for coagulopathy. The few with increased ICP or those with bleeds located in the posterior fossa potentially causing rapid brainstem compression immediately need neurosurgical intervention/evacuation of the hematoma for decompression. The others can be conservatively managed after a period of observation.

Subarachnoid hemorrhages (SAH) result from small tears in the leptomeningeal arteries or the bridging veins and are generally asymptomatic. Usually there is no history of difficult or instrumented delivery and SAH may be more common in newborns born prematurely or with evidence of asphyxia than due to birth-related injury. Some infants develop seizures on the second day of life, and lumbar puncture may reveal red blood cells in the cerebrospinal fluid. SAH is one of the more benign etiologies of neonatal seizures and typically resolves without intervention. Rarely SAH presents with more severe neurological findings with arteriovenous malformations, and when associated with catastrophic bleeds can lead to fatality. Diagnosis is based on CT or MRI findings. Long-term course can rarely be complicated by hydrocephalus.

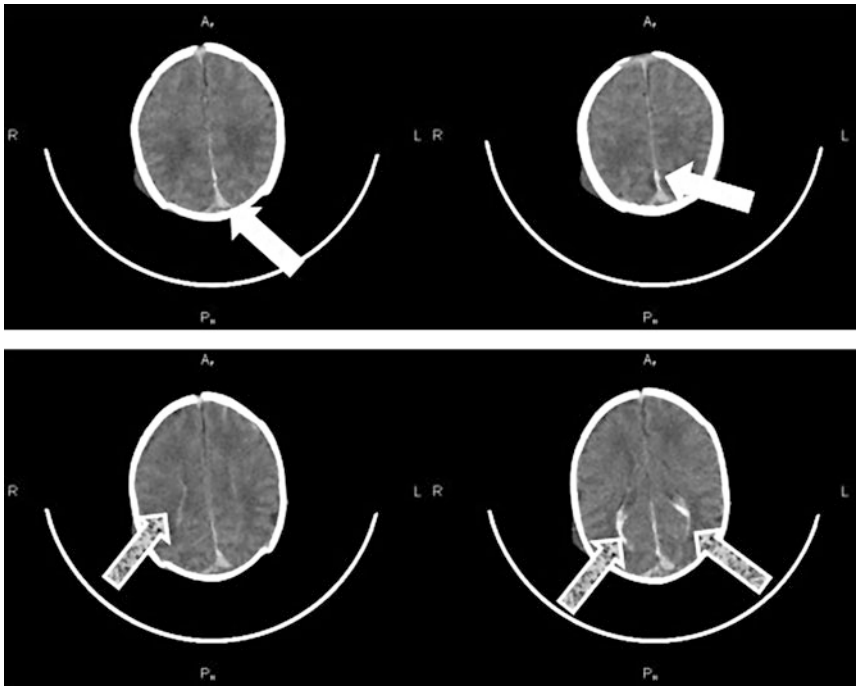

Figure 12.5
CT Scan of newborn with subtle subdural, subarachnoid, and intraventricular hemorrhages. Newborn who presented with significant soft tissue swelling on the lest (evident on CT scan) and a question of depressed skull fracture. CT scan demonstrated: A) subdural blood in the tentorium extending into the interhemispheric fissure posteriorly (white arrows), B) small amount of subarachnoid hemorrhage in the right posterior parietal region (not apparent on these images), and C) blood in the occipital horns into the lateral ventricles consistent with intraventricular hemorrhage (patterned arrows). (Image from the patient files of Marcia W. VnVleet, MD, MPH)

Intraventricular hemorrhages (IVH) can rarely occur during birth process of full-term newborn but much more commonly associated with preterm births (*Fig. 12.5*). Risk for IVH is inversely related to gestational age and birth weight. Occurrence in full-term newborns indicates a need for hematological evaluations. Otherwise, IVH is discussed elsewhere in the text (see Chap. 360, "Neonatal Neurological Disorders").

Nerve Injuries

Nerve injuries from birth-related injury can affect cranial or peripheral nerves and can be divided into three degrees of severity: (1) neuropraxia (Sunderland's class I, nerve intact but conduction blocked), (2) axonotmesis (Sunderland's class II-IV, axon not continuous but nerve is intact with increasing scarring), and (3) neurotmesis (Sunderland's class V, complete rupture of the nerve). Sunderland's five classes go from least to most severe, with the most severe cases (V) requiring surgical intervention.

Facial Nerve Injury (VII Cranial Nerve)

Facial nerve palsy has been reported to occur at a rate anywhere from 0.8 to 7.5 per 1,000 deliveries and up to 8.8 per 1,000 in deliveries with forceps. Most studies support the association with forceps-assisted deliveries; however, a recent study from Saudi Arabia spanning the years 1994–2005 found that 25% were delivered by cesarean section and the remaining 75% by vaginal delivery without forceps. Facial nerve palsy is most often caused by swelling resulting in compression due to the superficial course of the nerve as it exits the stylomastoid foramen or passes over the ramus of the mandible. This compression may be from intrauterine posture of the shoulder pushing the jaw and region in front of the ear, intrapartum compression against the maternal

boney prominences (e.g., pubic rami, ischial spines, sacral prominence) or by forceps. Clinical presentation usually involved the lower portion of the facial nerve noticeably with asymmetric cry and nasolabial folds. If there is involvement of the upper portion of the nerve, then the eye will also be involved with incomplete closure (or persistently opened) on the affected side. Differential diagnosis includes; congenital absence of the depressor anguli oris muscle (aka CULLP with isolated asymmetry with just the cry but spares the nasolabial folds), congenital facial palsy, and associated syndromes such as 22q11.2 deletion syndrome (DiGeorge or velocardiofacial with isolated asymmetric cry possibly with heart murmur), CHARGE syndrome (Coloboma, heart disease, atresia of choanae, retarded growth, genital hypoplasia, and ear anomalies within 68% are associated with cranial nerve involvement including VII), trisomy 13 or 18, Moebius (bilateral facial and abducens nerve palsy), and rarely Poland's (absence of pectoralis major muscle), or Goldenhar's. Diagnosis is generally clinical; however, imaging should be considered in cases with other paralysis suggestive of infarct or central lesions. All should be tested for hearing loss. Those newborns with associated findings should undergo chromosomal analysis, especially those with complete facial nerve palsy suggestive of 22q11 deletion.

Multiple studies report that approximately 90% of facial nerve palsies will have spontaneous recovery in 1–2 months. The House–Brackman scale has been utilized to assess the severity of facial nerve involvement. In newborns, facial injuries are usually classified on the House–Brackman scale as either mild (II with about 80% function) or moderate (III with 60% function). Treatment is generally to protect the cornea with taping, artificial tears and lubrication for those with persistently opened eyelids. Poor prognosis is associated with complete unilateral paralysis present at birth, hemotympanum, displaced temporal bone fracture, absence of movement of all facial nerve muscles by 3–5 days, or lack of improvement by 5 weeks. Treatment with corticosteroids, and especially with surgery, is controversial. Timing of surgical intervention is not uniform and some wait for a full year, but any infant with the poor prognostic factors listed should be referred at 5 weeks of age to a neurosurgeon for consultation.

Laryngeal Nerve Injury

Laryngeal nerve injury from the stretching associated with birth, usually associated with shoulder dystocia, represents 5–26% of vocal cord paralysis cases apparent at birth. Again found more commonly with forceps deliveries, laryngeal nerve injuries occur unilaterally more on the left than the right due to the longer course of the nerve on the left. Symptoms of unilateral vocal cord paralysis include hoarse, faint, or weak cry, as well as mild respiratory distress, dysphagia, aspiration, and stridor. Bilateral involvement presents sooner with more severe symptoms of respiratory distress possibly requiring intubation and tracheostomy. The differential diagnosis of bilateral paralysis includes congenital syphilis, and central nervous causes including asphyxia, hemorrhage, hydrocephalus, meningomyelocele, bulbar injury, and Arnold–Chiari malformation. For those presenting primarily with stridor, the differential diagnosis in newborns includes choanal atresia, laryngeal web, and vascular ring. Diagnosis of vocal cord paralysis is made on direct laryngoscopy. Evaluation in cases without documented birth trauma and in bilateral involvement should include imaging of the CNS and brainstem for possible etiologies. Most cases of unilateral vocal cord paralysis due to birth-related injury resolve spontaneously.

Spinal Cord Injury

Spinal cord injury is a rare but very serious form of birth-related injury, which frequently goes undiagnosed due to the critical status of the newborn. Laxity of the ligaments, muscle weakness, and incomplete mineralization of the vertebrae allow the spine to stretch to the point of pulling on the actual spinal cord. Perinatal depression with poor muscle tone probably contributes to the susceptibility to stretch injury. Higher cervical lesions are most common and associated with forceps use, while lower cervical and thoracic lesions occur during breech vaginal deliveries. Spinal injury has been reported with cesarean deliveries, especially with breech presentation. Symptoms present immediately in the labor room include decreased movements, hypotonia, areflexia, and apnea. Diagnosis can be made with MRI or bedside ultrasonography. Survival is dependent on the anatomic level and severity of the injury, but mortality rates are high (70–87%). Prognosis is poor for those requiring mechanical ventilation after 24 h of life, and long-term disabilities are common even among survivors. Surgical intervention for lower cord injuries is possible but less likely to be beneficial due to the observed delay in making this difficult diagnosis after which there is irreversible damage.

Upper Extremity Injury and Associated Conditions

There is great overlap in the etiology, pathophysiology, diagnosis, and treatment of injuries to the upper extremity including clavicular and humeral fractures, and the

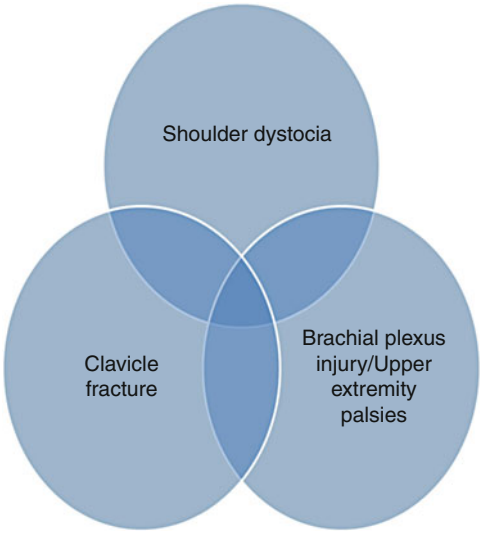

Figure 12.6
Venn diagram demonstrating relationship between shoulder dystocia, clavicle fractures, and brachial plexus injuries (Diagram by Marcia W. VanVleet, MD, MPH)

brachial plexus; therefore, these will be discussed together. There is an interrelationship between shoulder dystocia, clavicle fractures, and brachial plexus injuries that is best represented by a Venn diagram (*Fig. 12.6*).

Clavicle fractures are the most common fractures in newborn infants. Rates vary greatly partly based on study design and timing of assessment from 0.2% to 3.5% of births. Risk factors for clavicular fractures are similar to those for any birth trauma including higher gestational age, larger birth weight, and shoulder dystocia. The clinical presentation of clavicle fractures is varied as well, with up to 50% going undetected until callus formation is noted 2 weeks later. Infants often present with irritability, asymmetric arm movement, and asymmetric Moro reflex. Cases of breastfeeding difficulty only on the affected side have also been reported. The most sensitive clinical sign in the birth hospital stay is that of asymmetry of the clavicles, or difficulty palpating the margins of the fractured clavicle when compared to the normal side. Clavicle factures can be associated with injury to the brachial plexus or with a pneumothorax based on the proximity of fracture to the nerves and the apex of the lung. No active treatment is needed for a simple clavicular fracture, as the bone is quickly stabilized with callus formation and remodels without sequelae even in the presence of considerable displacement. However, the implementation of precautions is advisable to prevent injury to the brachial plexus during the healing process.

Humeral fractures is the second most common fracture in the newborn and the most common long bone fracture. It should be suspected in any newborn with asymmetric movement of the upper extremity, especially in the presence of any ecchymosis, tenderness, or swelling. It should also be actively ruled out with plain films of the arm for any infant who is not symmetrically moving the upper extremity after hospital discharge. The healing process is quick and usually does not need intervention except for wrapping the arm with a bandage to help with comfort and handling. But as with clavicle fractures mentioned above, the primary reason for intervention is to prevent secondary or recurrent trauma to the nerves that pass near the bone.

Brachial Plexus Injury (BPI) can occur alone or in conjunction with clavicular fractures. These injuries traditionally have been theorized to be the result of downward traction on the head in an effort to dislodge the anterior shoulder from under the maternal symphysis pubis and stretching of the brachial plexus roots as they emerge from the spinal cord. However, in as many as 40% of the cases, the injury occurs in the absence of shoulder dystocia and may occur even in infants delivered by cesarean section. Though BPI is one of the most common causes of malpractice allegations, its occurrence is unpredictable and not necessarily preventable. Various studies have shown links between macrosomia (>4.5 kg), shoulder dystocia, and BPI. Lispcomb reported in 1995 that out of 157 vaginal deliveries of macrosomic newborns, there were 29 cases (18.5%) of shoulder dystocia which were associated with 7 Erb's palsies, 7 clavicle fractures, and 1 humeral fractures. Gilbert in 1994–1995 found a local BPI rate of 0.15% with the following risk factors listed in order by decreasing odds ratios: Shoulder dystocia (OR 76.1), Forceps (OR 3.4), Vacuum (OR 2.7), and Gestational Diabetes Mellitus (OR 1.9), with a protective effect from prematurity and fetal growth restriction. However, the connection between shoulder dystocia and BPI is neither direct, nor constant across all birth weights. For patients with BPI weighing between 2.5 and 3.5 kg, only 22% had shoulder dystocia. While for those with BPI weighing >4.5 kg, the rate of shoulder dystocia increased to 74%. This suggests that there are different mechanisms of action for brachial plexus injury for those with lower birth weights. Additionally, as with spinal cord injuries, the depressed infant with reduced muscle tone to protect the shoulder joint may be more susceptible to stretch injury.

Brachial plexus injury will present as muscular weakness or paralysis to the affected upper extremity. In the nursery, this can be subtle with just an asymmetric Moro or grasp reflex or unequal spontaneous movements so that the affected hand does not extend above the height of the

shoulder. The exact presentation of brachial plexus injury is related to the nerve roots involved.

Erb's palsy (also called Erb-Duchenne's) presents with involvement of C5 and C6 as the arm hanging at the side, with the forearm internally rotated, extended, and pronated (*Fig. 12.7*). If C7 is involved, the wrist and fingers lose extension and are flexed/curled into the classic "waiters tip" positioning. Frequently, the hand movements and grasp will start to show improvement within hours of birth and is a good prognostic indicator; however, careful follow-up for all of these infants is imperative.

Klumpke's palsy presents with involvement of C8-T1 with weakness in the triceps, in pronation of the forearm, and in wrist flexors with the "claw-like" paralyzed hand but preserved functioning at the shoulder and elbow. Isolated injury to C8-T1 is rare and most infants present with some combination of signs of Klumpke's along with some features of Erb's palsy. A summary of these injuries can be seen in *Table 12.2* with the Narakas classification.

Careful examination would include investigating for sympathetic cervical nerve involvement with the loss of sensation on the affected side of the face, constricted pupil, and ptosis of the eyelid or "Horner's syndrome." (See Resources for link to Web site with picture of Horner's syndrome in an infant.)

Figure 12.7
Newborn with brachial plexus injury to C5-C6: Erb's Palsy: Large-for-gestational-age (*LGA*) newborn with brachial plexus injury, with absence of arm movement at the shoulder, elbow, and forearm supination. The hand lies at the side of the infant without the classic waiter's tip, thus suggesting a C5-C6 injury (Photograph from the patient files of Rebecca L. Collins, MD)

Treatment of Upper Extremity Injury

As soon as an upper extremity deficit is suspected by the nurse or any other examiner, it is important to intervene to reduce the risk of further damage. The affected side should be place on "precautions" with care taken in the handling of the newborn to protect the nerves involved. This includes making sure the arm does not dangle but is supported in all care including dressing (affected arm in shirt first and out last), and that positions for both sleep and feeding do not place additional weight or stress on the plexus. Additionally, the examiner should be careful not to elicit the Moro reflex before assessing for the presence of associated clavicular or humeral fractures.

Exam of the newborn with suspected upper extremity paralysis should include careful inspection for other injuries including symmetry of the face (facial nerve palsy), eye (Horner's syndrome with drooping eyelid, constricted pupil and sunken eye), neck for movement and masses, cry (laryngeal nerve palsy), respiratory pattern (phrenic nerve involvement), and skin for bruising, swelling, or tenderness suggestive of other muscle or bone involvement (humeral or clavicular fracture). As mentioned above, the Moro reflex should not be elicited. Instead the examiner should carefully observe the newborn's spontaneous movements including: (1) whether there is flexion of the fingers, wrist, elbow, and shoulder, (2) how far is the newborn able to spontaneously lift the hand against gravity (with a goal of symmetric above shoulder height), (3) assessment of grip strength comparing sides for symmetry, and (4) gently stroke the forearm looking for grimace and movement to assess sensory involvement.

Definitive diagnosis of a fracture of the clavicle or the humerus is based on plain radiographs (*Fig. 12.8*). For the clavicle, it is best to get two views, which will include the AP and lordotic views as the natural curvature of the clavicle sometimes obscures the site of the fracture when only seen from one view. Newborn X-rays with clavicle fractures should be also carefully examined for the presence of associated pneumothoraces, elevated hemidiaphragm, and midline posterior rib fractures.

The short-term treatment for newborns with upper extremity injury has recently changed. If there is a clavicle fracture, the current treatment is to place the arm at the newborn's side in a neutral position with a diaper or small

Table 12.2
Summary of brachial plexus injuries including Narakas classification and Sunderland lesions

Cranial nerves	Brachial plexus	Narakas group (at 3 weeks)	Percentage and newborn clinical presentation	Evidence-based recovery (S. Foad)				Probable lesion with Sunderland degree
				Biceps recovery		Complete recovery		
				@3 months	@6 months	@ 3 months	@ 6 months

C5-C6 (Erb's/ Duchene's)	Upper	1	46%: Paralysis of shoulder and biceps Absence of abduction, external rotation, elbow flexion, forearm supination	64%	68%	59%	65%	Upper trunk: I and II degree
C5-C7	Middle	2	30%: Paralysis of shoulder, biceps, and forearm extenders Group 1 with weaker wrist extension = waiter's tip					Upper trunk: II and III C7: I and II
C 8, T1 (Klumpke's)	Lower		2%: Intact shoulder and elbow but floppy hand with claw-like deformity	N/A	N/A	N/A	N/A	
C5-T1	Complete	3	20%: Complete paralysis of the entire limb Flail shoulder, absence of elbow flexion, weak extension, flexed wrist, closed fist	9%	38%	0%	14%	Upper trunk: IV and V C7: III and IV
C5-T1 with sympathetic involvement (Horner's)		4	Complete paralysis of limb with Horner's Flail extremity, half-open hand, little finger movement and constricted pupil and ptosis					Upper, middle and lower trunks: II-VI varies

Source: Adapted from Foad (2008, 2009), Narakas (1986), and Sunderland (1990)

cloth folded under the axilla to help with positioning. It is no longer recommended that the arm be pinned to the shirt to prevent movement as this places additional strain on the fracture and may lead to iatrogenic shoulder dislocations. In the case of clavicle or other bone fractures, it is important to keep the patient comfortable during care, which may include the use of oral analgesia for the first few days. After discharge from the hospital, non-pharmacological care measures should be adequate.

Prior to discharge from the hospital, the parents should be instructed by an occupational (OT) or physical (PT) therapist on how to support the upper extremity during care. And with a goal of preventing contractures and improving range of motion (ROM), the therapist will also instruct the parents on how to perform gentle ROM exercises with each diaper change (as tolerated by the newborn). Those with clavicle fractures should be advised that the bone will heal with the formation of a callus, and so a visible bump is to be expected as a sign of healing. Those with an isolated clavicle fracture should also be advised to follow up with the PT or OT specialist as an outpatient if the infant is not moving both upper extremities symmetrically above the shoulder or if there is any loss of movement. The vast majority of patients with isolated clavicle fractures do well with no long-term sequelae.

Patients with nerve involvement should be seen by the PT or OT specialist prior to discharge and then again at about 2 weeks of age to evaluate the progress, to carefully

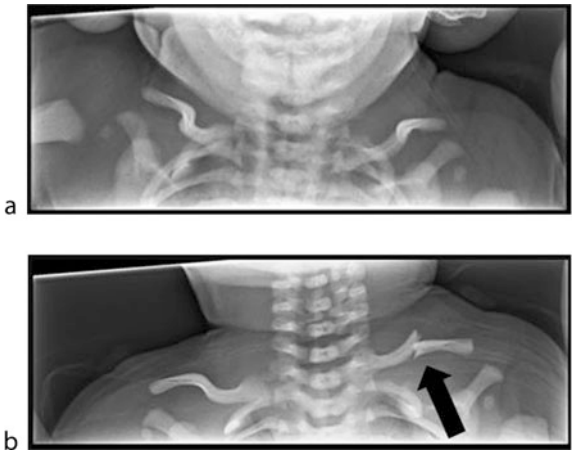

Figure 12.8
Radiograph with clavicle fracture: Patient with crepitus over the left clavicle and an otherwise normal upper extremity exam. (a) AP view without distinct fracture. (b) Lordotic view with clear mid left clavicle fracture with minimal displacement (Image from the patient files of Marcia W. VanVleet, MD, MPH)

Figure 12.9
Radiograph of newborn at 3 weeks with Callus over left healing clavicle fracture. This patient was in hospital for prolonged newborn stay as a border baby. *Arrow* points to callus which was discovered when the patient was 21 days old during the discharge examination by the attending physician. There was a palpable bump, the contour of which is visible above the *arrow*. The patient otherwise had a normal upper extremity exam (Image from the patient files of Marcia W. VanVleet, MD, MPH)

document physical movement, and to provide ongoing education to the parents. Many (originally thought to be 80–90%, but more recent statistics reveal less at 60–70%) of patients with brachial plexus injury spontaneously recover by 3 months, with the majority of those doing so in the first 3 weeks of age (*Fig. 12.9*). Those with a lack of improvement by 2–3 weeks should be investigated by exam and radiographically for the presence of a coexisting humeral fracture. If there has not been full recovery of function at one month of age, the infant should be referred to a pediatric neurologist or brachial plexus injury center. Recovery should be progressive; however, a key time point is at about 2 months when the return of biceps function is anticipated. By 2 months of time those who are not able to flex at the elbow, and sooner for those with additional nerve involvement such as phrenic or Horner's, should be confirmed that they have connected with a brachial plexus injury center or neurosurgeon specializing in brachial plexus injury treatment and repair.

Surgical treatment of BPI is evolving. At present, approximately 10% of infants with BPI will require some form of surgical intervention, either primary nerve grafting or secondary reconstruction. Key criteria for surgical intervention vary by center, but most decisions are based on biceps functioning at 3 months of age. Those with natural recovery of function before 3 months or surgical repair between 3 and 6 months do better in terms of long-term functioning than those who are delayed until after 6 months. Most of the evidence for surgical repair is from case reports and offers a 60–80% improvement in function postoperatively. After 12–18 months, most would agree that there is little benefit to primary neurosurgical intervention. At that point, surgery is indicated to reduce contractures or deformities. Also these patients will need to be screened for the development of posterior shoulder dislocation that can occur in up to 7.3%. It cannot be stressed more, how critical careful follow-up and early intervention is in effectively minimizing long-term disabilities for these newborns.

Phrenic Nerve Palsy

Phrenic nerve paralysis often coexists with brachial plexus injury and is believed to arise by similar mechanisms. Injury to the upper root of C4 which innervates the phrenic nerve (recall the mnemonic: "3, 4, 5, keeps the diaphragm alive") can present as paroxysmal breathing patterns, increased work of breathing, asymmetric chest movement or the "dancing" umbilicus, cyanosis or tachypnea due to the diaphragm paralysis. Injury to C4 should be considered with careful auscultation of the breath sounds at the bases for symmetry in any infant with Erb's palsy. Phrenic paralysis can be related to trauma but the differential diagnosis in cases of bilateral involvement also includes genetic disorders such as muscular atrophy (Werdnig–Hoffmann) and acid maltase deficiency.

Phrenic nerve involvement can be diagnosed by plain films with elevation of the affected hemidiaphragm (*Fig. 12.10*); however, ultrasonography is preferred to

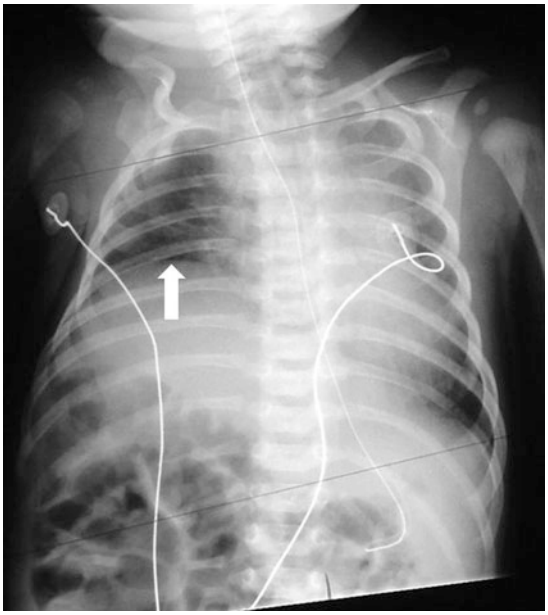

Figure 12.10
Radiograph with elevated right hemidiaphragm from phrenic nerve palsy. *Arrow* points to the elevated right diaphragm. This is a preoperative image before plication of the diaphragm on a patient admitted for feeding difficulties/failure to thrive (Image from the patient files of Joseph Bliss, MD, PHD)

analyze the pattern of movement with respirations. These newborns should be observed carefully for respiratory distress especially during their feedings as some may need additional mechanical support of respiration. Mechanical ventilation may obscure the diagnosis. Infants requiring prolonged ventilatory support need surgical evaluation as some may require plication of the affected diaphragm to correct the paradoxical diaphragmatic motion. Phrenic nerve involvement does not help in determining the prognosis of the motor recovery of the upper extremity palsy.

Lower Extremity Injury

Injury to the lower extremities from birth trauma is rare and includes femoral fracture, epiphyseal separation, joint dislocations primarily of knee and hip. Injury to the lower extremities presents as decreased movement, swelling, pain, and crepitus. Femoral fractures occur in approximately 0.13 per 1,000 births. Fracture of the femur is diagnosed by plain X-rays, but epiphyseal injury in the newborn requires ultrasonography as they are not yet ossified at birth. Long bone fractures heal well but may need to be splinted and immobilized for comfort. Proximal fractures of the femur may need spica casting or Pavlik harness to assist in immobilization. Pavlik harnesses needs to be applied carefully as an inappropriate fit may cause femoral nerve palsy and avascular necrosis. Orthopedics consult is appropriate for fractures of the femur especially with displaced fractures as these may need closed reduction and casting. Similar to other newborn fractures like the clavicle, a callus forms at the site of fracture with bone reorganization in 7–10 days.

Congenital hip dislocation is usually not a result of birth trauma but from developmental hip dysplasia, with increased incidence in newborns born breech or in breech positioning in utero late in pregnancy (estimated 35 weeks or later), female gender, and those with a family history of developmental hip dysplasia. Treatment of the subluxable hip is the same regardless of cause and includes continuous placement in the Pavlik harness and monitoring with serial ultrasound measurements of hip angles. Dislocation of the knee or hip should be referred to orthopedic surgeons for ongoing management. The subluxable or dislocated knee can be associated with other syndromes. Prognosis for these conditions is generally good.

Intra-abdominal Injury

Intra-abdominal injury from birth trauma is rare but can involve the liver, spleen, and adrenal glands. Injury is more common with prematurity, coagulation disorders, asphyxia and with hepatosplenomegaly or other organ enlargement such as of the adrenals in Beckwith–Wiedemann syndrome. Abdominal organs are relatively protected, but mechanisms of injury include direct trauma, damage from rib edges to the liver or spleen, or from chest compressions tearing ligamentous insertions into the liver or spleen. Bleeding from trauma to these organs can either be insidious, collecting in subcapsular hematomas or fulminant from frank rupture that leads to rapid clinical deterioration with shock. Postmortem examinations of early neonatal deaths reveal that 15% have some type of liver hemorrhage. The most common abdominal injury is subscapular hematoma of the liver. These can increase slowly until reaching a critical size of 4–5 cm before rupture. Splenic hemorrhage occurs one-fifth as commonly as those to the liver. Diagnosis should be suspected in any newborn with history of difficult delivery, or who presents with unexplained anemia, abdominal distention, hypovolemia, or hemorrhagic shock. Rupture of either the liver or spleen can cause scrotal swelling or discoloration as blood passes through

the patent processus vaginalis. Adrenal injury occurs in 1.9 per 1,000 births due to the larger size of the adrenal glands in the newborn. Adrenal injury can present with subtle symptoms like poor feeding, lethargy, jaundice, or irritability or may present symptoms similar to those found with injury to the liver and spleen. Palpable masses in the flank may be present. In adrenal rupture, scrotal swelling and discoloration can occur through the aforementioned mechanism with liver or spleen injuries, or directly through retroperitoneal extension. Diagnosis of abdominal injury can be made by CT but many infants are too unstable and the diagnosis will be made by ultrasonography at the bedside. For all cases, treatment starts with supportive care with special attention to volume support and fluid resuscitation as necessary. Early surgical consult is important as there can be rapid deterioration. Surgical intervention is indicated to stabilize the newborn, or stop uncontrollable bleeding. In terms of adrenal hemorrhage, damage or removal of one (or both) of the glands can result in adrenal insufficiency requiring replacement to treat hypoglycemia, hypotension, and hypernatremia. Hypertension can be a late complication of adrenal injury. As mentioned previously, the diagnosis of abdominal injury, especially to the liver or spleen, is often discovered postmortem. Prognosis is dependent on early recognition, active management of blood loss, and the ability to control the bleeding. For those who survive with preservation of the organs, the prognosis is generally good.

Conclusion

Birth-related injury is a very common occurrence that in many cases may not be avoidable. Even so, as we seek to improve medical care around the world, it is important to keep searching for methods to decrease as many of these injuries and their sequelae as possible. Fortunately, most birth injuries are superficial and self-limited. For the rare more serious injuries, it is imperative that the practicing pediatric provider recognize the risk factors and signs of these conditions, and then take action to appropriately manage them both in the short and long term.

13 The High-Risk Infant

Tonse N. K. Raju

Definitions

A "high-risk infant" is broadly defined as one who requires more than the standard monitoring and care offered to a healthy term newborn infant. Thus, infants born pre- or post-term, those with inappropriate growth for gestational age, those with manifest signs and symptoms of systemic illnesses, metabolic abnormalities, or congenital malformations requiring early evaluation and treatment are considered "high-risk infants." An important determinant of risk categorization is the overall condition of the infant, which often requires continuous monitoring, and specialized tests and treatments. Common conditions considered "high risk" in the modern neonatal intensive care unit (NICU) are listed in *Table 13.1*.

Levels of Care

The clinical condition of the infant should also determine the appropriate level of monitoring and care available in the healthcare facility. The American Academy of Pediatrics (AAP) Committee on Fetus and Newborn (COFN) Policy Statement recommends three major levels of newborn care with specific criteria outlined for each designation. The policy stems from the recognition that maternal and neonatal care should be based on matching the complexity of the illness with the availability of resources. In the mid-1970s, this concept spearheaded a nationwide movement in the USA, leading to regionalized perinatal care system in many states. Similar progress occurred in other industrialized nations, too. The regionalized perinatal system helps provide care that matches the needs of the high-risk infant, and when local resources are limited, for a timely referral to other facilities. A revised AAP policy on the levels of neonatal care is expected to be published in 2011.

Gestation Age and Postnatal Age Terminologies

Using consistent definitions to describe the duration of gestation, postnatal age, and fetal growth parameters are helpful for effective communication. Poster-size pictures of *Fig. 13.1* and *Table 13.2* in newborn units may help the staff to use consistent terminology and avoid confusion in designating gestational and postnatal age categories. For reporting purposes, a "gestational week" is assigned only after the completion of full 7 days, as explained below.

Gestational Age Terminology

Gestational age in completed weeks is the time elapsed between the first day of the last menstrual period and the day of delivery. If pregnancy was achieved using assisted reproductive technology, gestational age is calculated by adding 2 weeks to the conceptional age.

Term births are those that occur between 260th day through the 294th day, or $37^{0/4}$ through $41^{6/7}$ weeks of gestation. Because of their increased risk for morbidity and mortality (see below) some authors further categorized the first 2 weeks of term gestation (for those born between 260th through 274th day, or $37^{0/7}$ through $38^{6/7}$ weeks of gestation) as "early term" (*Fig. 13.1*).

The World Health Organization (WHO) defines "preterm birth" as delivery occurring before 37 completed weeks of gestation, or on or before the 259th day (*Fig. 13.1*). The week of the gestational age is rounded off to the nearest completed week of gestation. Thus, infants born 5 days after 35 weeks of gestation will be 35, not 36 weeks of gestation. The superscript may be used to reflect the number of days lapsed since the completed week, as $35^{5/7}$ in the above example.

The National Center for Health Statistics (NCHS) of the Center for Disease Control and Prevention (CDC) also provides data on three subcategories of preterm births. Late preterm births are those that occur between $34^{0/7}$ and $36^{6/7}$ weeks of gestation (239–259 days), moderately preterm births are those that occur between 32 and 33 weeks of gestation, and very preterm births are those that occur before 32 weeks of gestation.

"Post-term births" are those that occur on or after the 295th days, or the 42nd week of pregnancy (*Fig. 13.1*).

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_13,

Table 13.1
Conditions that determine "high-risk infant" designation

Time	Condition/diagnosis and comments
Immediate peripartum period, either in the delivery room, or in the stabilization area, usually obvious at birth, or within 10–20 min after birth	Pre- or post-term birth
	Requiring resuscitation in the delivery room
	Perinatal asphyxia
	Congenital infections (e.g., syphilis, CMV, toxoplasmosis, herpes simplex)
	Cardiopulmonary distress
	Drug withdrawal syndrome requiring monitoring
	Suspected or proven congenital malformation requiring immediate evaluation and/or treatment
	For example, congenital heart disease
	Omphalocele, gastroschisis; prune belly syndrome
	Meningomyelocele, hydrocephalus, etc
	Ambiguous genitalia
	Chromosomal anomalies, especially those with manifest distress
	Multiple congenital anomalies
Early neonatal period (The first day)	Small or large for gestational age
	Cardiorespiratory distress
	Drug withdrawal syndrome requiring monitoring
	Suspected/proven neonatal sepsis
	Seizures
	Metabolic abnormalities (e.g., hypoglycemia; hypocalcemia); anemia
First week and beyond	Jaundice requiring exchange transfusions
	Sepsis
	Necrotizing enterocolitis
	Other surgical conditions
	Bleeding diathesis and other hematological conditions

Postnatal Age Terminology

The AAP recommends precise postnatal age terminology. These concepts are explained in *Table 13.2*. Chronological age, in days, weeks, months, or years is the time elapsed from birth; postmenstrual age in weeks is gestational age plus the chronological age; corrected age in weeks or months is chronological age reduced by the number of weeks born before 40 weeks of gestation. The later term should be used only for children up to 3 years of age who were born preterm.

During the perinatal period and neonatal hospital stay, the term "postmenstrual age" is preferred to describe the age of preterm infants. After the perinatal period, "corrected age" is the preferred term. According to the AAP, one should avoid using such terms as "conceptional age," "postconceptional age," "conceptual age," and "postconceptual age," and scientific publications reporting on fetal and neonatal outcomes should clearly describe the methods used to determine gestational age.

Variations in Intrauterine Fetal Growth

With the gestational age information and anthropometric measurements (see below), infants are classified according to the appropriateness of growth for gestational ages. This is particularly important for high-risk infants, since such categorization helps identify specific risks factors.

Appropriate, Small, and Large for Gestational Age and Intrauterine Growth Restriction

Infants with a birth weight between the 10th and the 90th percentile for gestation are referred to as appropriate for gestational age (AGA). The term "average" for gestational age should be avoided, as an infant who is at the 80th percentile is appropriate for gestational age, but is well above average. Those with a birth weight below the 10th percentile are referred to as small for gestational age (SGA), and those above the 90th percentile are referred to as large for gestational age (LGA). Some experts recommend considering those with a birth weight below two standard deviations from the mean birth weight for the gestation as SGA, and those with more than two standard deviations above the mean birth weight for gestation as LGA. The latter definitions lead to considering SGA as those below the 3rd percentile and LGA as those above the 97th percentile birth weight for gestational age,

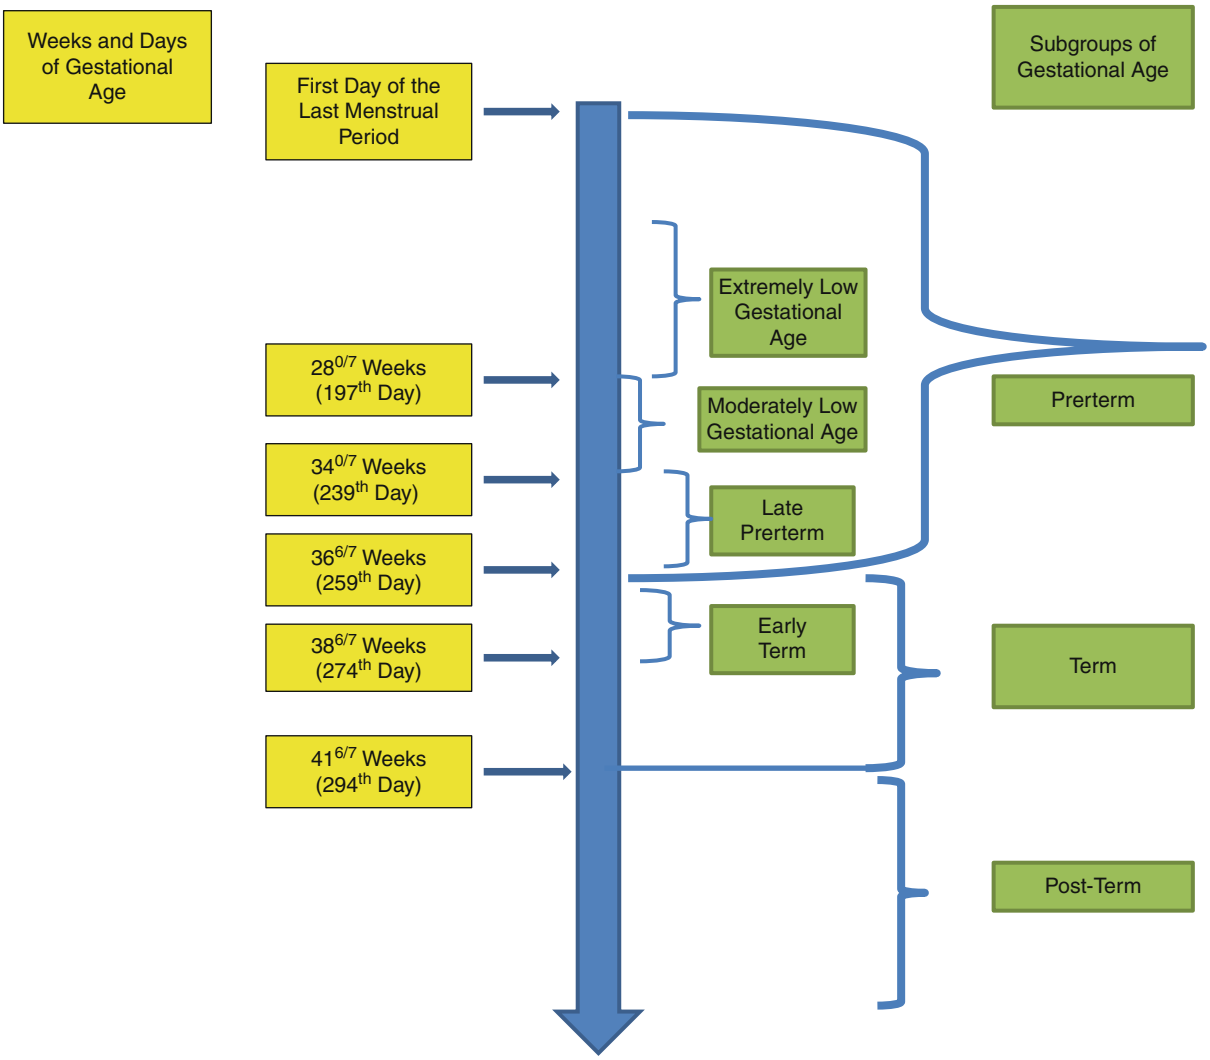

Figure 13.1
Gestational age terminology (Note: The phrase "Early term" is not universally accepted. The remainder is modified from the reporting practice of the National Center for Health Statistics, of the Centers for Disease Control and Prevention, USA. CDC web site is publicly accessible: www.http.cdc.gov)

respectively. Furthermore, such "conservative" estimates of deviations from anticipated fetal growth helps identify the subsets of SGA and LGA infants with the highest risk for neonatal mortality and morbidity.

IUGR and SGA Distinction

The terms SGA and intrauterine growth restriction (IUGR) are often used interchangeably, which is not correct. While most (not all), IUGR infants are likely to be SGA, not all SGA infants are IUGR. IUGR is due to the processes, mostly pathological, that affect the growth potential of the fetus, whereas small size for gestation is a reflection of birth weight being less than a set threshold, or "norm," based on the population distribution of birth weights. Therefore, a healthy SGA infant may be constitutionally small without any pathology.

When assessing the appropriateness of intrauterine growth, the ponderal index (weight divided by length cubed) and relative proportions of other body measurements (e.g., head circumference to weight, or femur length-to-abdominal circumference ratios) may be more useful than birth weight in distinguishing IUGR from

Table 13.2
Age terminology during the neonatal period

1.	Gestational age: (a) Days elapsed between the first day of the last regular menstrual period and the day of delivery of fetus, or fetuses (b) Count only completed weeks; any fraction thereof be shown with a superscript as described in the text
2.	Chronological age: (a) Infant's age counting from the day of birth, expressed in days, weeks, months, or years (b) Typically rounded off the completed month (e.g., 1 year and 5 months, or 17 months of age)
3.	Corrected age: (a) Chronological age minus the number of weeks or months born before 40 weeks of gestation (e.g., a preterm infant born at 28 weeks of gestation at one year of age will be of 9 months of corrected age) (b) For infants born preterm, the correction is applied only up to 3 years of age
4.	Postmenstrual age: (a) Chronological age plus the gestational age expressed in weeks (b) Usually used during the first months of hospitalization for preterm infants; or in research studies for all infants for consistency

SGA. IUGR infants tend not to gain weight to a greater extent than failure to gain in length or head circumference. Thus, their relatively large head sometimes has been referred to as "head sparing." The time course of intrauterine pathology also differentially influences growth rates of organ systems. Placental pathology early in pregnancy causes more uniform reduction in all of the growth variables (symmetric growth restriction) as opposed to pathology later in pregnancy that tends to affect weight to a greater extent than length and head size.

For further discussions on the deviations from normal fetal growth and the obstetric aspects of SGA, IUGR, and LGA, please consult other chapters in this section (Chap. 8, "Pregnancy: Intrauterine Development and Assessment").

Physical Examination and Gestational Age Assessment of the High-Risk Infant

Infants are assessed and given Apgar scores at 1 and 5 min of age (Delivery Room Stabilization). If the scores remain low, assessment is continued at 5-min intervals until the score reaches 7 or more, and the time to reach this threshold is recorded in the medical records. The infant is also assessed for general well-being, and when stable, a complete physical examination is performed as described elsewhere (Care of the Normal Newborn). For high-risk infants, when clinical conditions require, plans need to be made for continued monitoring during their hospital stay.

Routine body measurements to be obtained are birth weight, crown-heel length, and head and abdominal circumferences, which are plotted on intrauterine growth curves to facilitate infant classification. One should also calculate the ponderal index to assess growth asymmetry.

Gestational age calculated using maternal menstrual history is very helpful, especially if supported by fetal ultrasound studies done at or before 20 weeks of gestation. These estimates are accurate to ± 1 or 2 weeks. For clinical assessment of gestational age, one of several published scoring methods can be used. In the USA, the New Ballard scale is the most frequently used method. Other methods are also available, all of which provide reasonably accurate estimates of the gestational age. It is more important to develop proficiency in one method to ensure accuracy and consistency of assessment.

Two sets of clinical features are included the New Ballard scoring system. One set of physical features include, the skin texture; distribution of lanugo; the extent of the plantar crease; the thickness of the breast tissue nodule; the stiffness of the ear pinna; and the maturity of the external genitals. In male infants, the extent of the descent of the testes is assessed, and in females, the appearance and the size of the clitoris and the labia are assessed. The second set of neuromuscular features include the posture; the "square window" (the extent infant's hand can be flexed toward the wrist); arm recoil; popliteal angle; the "scarf" sign; and the heel-to-ear maneuver. The total score is then used to assign the gestational age in weeks.

The New Ballard score provides an estimation of gestational age to within 1–2 weeks accuracy. The neurological features are more stable and less variable among healthy infants. Decreased neuromuscular tone may be encountered in sick infants, affecting the neurological score. If the discrepancy between the obstetric estimate and clinical assessment exceeds 2 weeks, one needs to ascertain the accuracy of obstetric history, and reassess the gestational age, if possible by a different examiner after a period of 24 h. In preterm infants, the New Ballard score has been shown to be reliable up to 7 postnatal days.

Common Clinical Problems Associated with High-Risk Infants

Thermoregulation

High-risk infants should be cared for in a neutral thermal environment, defined as the ambient temperature and humidity settings at which the oxygen consumption required to maintain the internal body heat is at its lowest. When exposed to a cold environment, newborn infants rely upon non-shivering mechanism to generate internal heat, enhancing oxygen consumption. However, since oxygen consumption is not routinely measured, a common practice to determine the optimal ambient thermal environment is to base it on the previously developed charts and graphs, keeping in mind, the general principles of thermogenesis in high-risk infants. The hypothalamus in mature infants exposed to cold releases norepinephrine, which leads to a breakdown of brown adipose tissue to fatty acids and the oxidation of the latter generates internal heat. However, preterm, SGA, and IUGR infants are deficient in brown fat, and their neural responses to cold may be inadequate. Thus, the smaller and more immature an infant, the narrower is the required ambient neutral thermal environment.

In most modern neonatal units, sick newborn infants are cared for inside double-walled incubators or under overhead-warming intensive care beds, which are equipped with servo-controlled systems for maintaining the infant's skin temperature at 98.5 ± 0.5° F. This topic is covered in more detail in Chap. 14, "Thermoregulation/Environment".

Abnormalities of Glucose Homeostasis

The mammalian fetus relies upon placental transport of glucose and other nutrients for growth and development. Termination of this supply at birth leads to an immediate demand for maintenance of glucose homeostasis through the initiation of glucose production in the newborn. Such transitions occur smoothly in most newborn infants; but in SGA, IUGR, and LGA infants, the transition may not be smooth, leading to low plasma glucose concentrations, with or without manifest signs and symptoms.

However, since the "natural history" of the glucose changes following birth in healthy infants has not been studied using continuous, noninvasive methods, "postnatal euglycemia" remains undefined. Therefore, at present there is no universally accepted definition of clinically significant, transient neonatal hypoglycemia. An NIH expert panel concluded that, "there is neither a rational basis nor sufficient evidence to identify a specific value or a range of plasma glucose concentrations that would define hypoglycemia as a pathological entity." The complexity of postnatal homeostasis has also been discussed in other excellent reviews. Some experts recommend that plasma glucose concentrations <40–45 mg/dL after birth (which occurs in ~5–15% of normal newborn infants), may be deemed as operational threshold for supplementing glucose or additional feeding. The AAP Clinical Report on this topic is currently in print; this will provide additional guidelines on monitoring and treating altered neonatal glucose homeostasis in term and late preterm infants.

Compared to term infants, the incidence of low concentration of plasma glucose after birth (persisting for several hours, and rarely for a few days) is higher among SGA and IUGR infants. This is due to low hepatic concentrations of glycogen stores, immature hepatic enzymes (glucose-6-phosphatase), decreased ketogenesis, and increased brain-to-body mass ratio with increase in relative brain consumption of glucose in these infants. On the other hand, in LGA infants, especially those born of diabetic mothers, hyperinsulinemia is considered a major cause for drops in plasma glucose concentration after birth.

For infants at risk for hypoglycemia, early initiation of breastfeeding is an important first step. If the infant is feeding well and has no clinical symptoms, some experts recommend bedside check of glucose *after the feeds* between 1 and 4 h of age. Such tests are done immediately, when symptoms suggestive of hypoglycemia, for example, jitteriness seizures occur. If plasma glucose levels are below 35 mg/dL in asymptomatic infants, some experts recommend additional feeds or oral glucose supplements with a goal to raise the plasma glucose concentrations above 40 mg/dL.

However, repeated additional feeding (especially commercial formula or glucose solutions) may impede success rates for breastfeeding. Therefore, the WHO recommends that in asymptomatic LGA infants with no maternal history of diabetes, bedside glucose checks should be avoided during the first 4 h or longer, to prevent unnecessary interference with the normal process of breastfeeding. This is an advice especially valuable in resources-limited parts of the world. Additional details concerning hypoglycemia and its management are discussed elsewhere (Chap. 29, "Disorders of Glucose Homeostasis in the Newborn"), and a new Clinical Report from the AAP on the management of altered glucose homeostasis in term and late preterm infants is under review for publication in 2011.

Feeding and Nutritional Issues

Due to the immature sucking and swallowing reflexes, even otherwise healthy preterm infants may feed poorly. Nasogastic tube feedings may be considered using mother's expressed breast milk, or where resources permit, banked human breast milk. Human milk is to be preferred to commercial infant formula. If oral feedings are not possible because of illness, intravenous alimentation should be begun, usually within the first 24 h. Fluid and nutritional support and other medical conditions of high-risk infants are discussed elsewhere in this Section.

Late Preterm Infants: A Special Category of High-Risk Infants

Since the publication of the executive summary of a workshop on late preterm births sponsored by the NIH, and a Clinical Report on the same topic by the AAP, there has been a greater awareness that late preterm infants are indeed "high-risk." In fact, recent studies have shown that compared to those born at 39 or 40 weeks, even early term infants born at 37 or 38 weeks of gestational age are at risk for higher risks for neonatal morbidity and mortality, underscoring the dictum that maturation is a continuous process, and no single calendar date can be considered to provide assurance that all organ systems are completely mature. This is in part true because individual infants have different rates of maturation, resulting in substantial differences in physiologic maturity in infants of the same gestational age.

The NIH and AAP reports also recommended discontinuation of the phrase "near-term," because the latter implies that such infants are "almost term," requiring no special monitoring or care. Because of their growing importance and high prevalence, the section that follows provides a detailed, albeit brief, discussion on the epidemiology and clinical issues in late preterm infants.

The US preterm birth rate increased each year since 1992, reaching an all-time high of 12.8% in 2006. The rates have dropped slightly in 2007 and 2008; yet, each year more than 375,000 late preterm births (8.8% of all live births) occur in the USA. Since 75% of all preterm births are late preterm gestations, even a slight increase in the risk of illness in this group has a major impact on healthcare resources.

Possible contributing factors for increasing rates of preterm births include: increasing maternal age at first pregnancy, higher proportion of pregnancies conceived through artificial reproductive technologies (with higher risks for multi-fetal pregnancies), and increased rates of labor-inductions and cesarean births at all gestations. A recent study found that the average gestational age at term births dropped about 0.33–0.42 weeks over a 15-year period in the USA (◉ *Fig. 13.2*). The authors hypothesized that higher levels of stress or environmental pollutants may be the unmeasured causes for shortened pregnancy durations across the population. Some nonmedical reasons for increasing preterm births include parental requests, the convenience and logistical reasons of the healthcare team, and errors in estimating gestational age. However, the relative proportions of the causes leading to increased preterm birth rates have not been studied.

About 60% of preterm births are due to spontaneous onset of preterm labor, with or without rupture of the fetal membranes prior to the onset of labor, and the remainder are "indicated" preterm births due to interventions carried out because of specific medical, surgical, or obstetric conditions in the mother or the fetus (◉ *Fig. 13.3*).

A recent study found that in about 20% birth certificates of late preterm births, no specific medical, obstetrical, or fetal condition was documented as the cause for preterm birth (◉ *Fig. 13.4*). The authors implied that these might be due to nonmedical indications. Sociodemographic factors also have been etiologically linked to spontaneous onset of preterm labor, which include black race/ethnicity, maternal age <17 years or >35 years, smoking, substance abuse, and poor socioeconomic status. Note that many of these factors are interrelated and may coexist along with medical or obstetric pathological conditions.

Outcome Data for Late Preterm Infants

The neonatal and infant mortality rates, as well as cause-specific mortality rates, are much higher in late preterm infants than in term infants. Among the late preterm infants with a maternal history of hypertensive disorders of pregnancy, antepartum hemorrhage, diabetes, infections, or chronic renal, lung, or cardiac disease, the morbidity risks were 10- to 14-fold higher compared to term infants with similar history. The morbidity rates also doubled for each gestational week earlier than 38 weeks, implying an independent effect of low gestational age on morbidity. Some specific conditions leading to poor outcome in late preterm are described below.

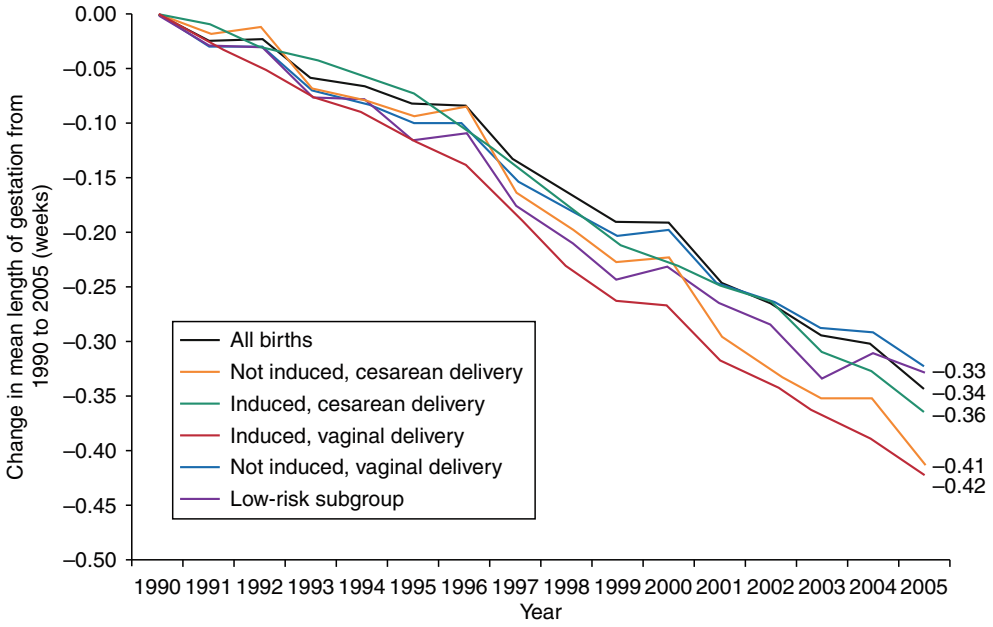

Figure 13.2

Trends in length of gestation from 1990 to 2005, according to induction of labor status and route of delivery, among 36,827,828 singletons born at 37–41 completed weeks of gestation, and among a low-risk subgroup of 502,716 singleton neonates born to mothers aged 25–29 years, of non-Hispanic white race/ethnicity, with 13 or more years of education, of married status, who received prenatal care in the first trimester, were nonsmokers, had no pregnancy complications, delivered vaginally, did not have labor induced, had a prenatal ultrasound examination, and gained 26–35 lb during pregnancy (Reproduced from Donahue SM, Kleinman KP, Gillman MW, Oken E (2010) Trends in birth weight and gestational length among singleton term births in the United States: 1990–2005. Obstet Gynecol 115 (2 Pt 1):357–364. With permission)

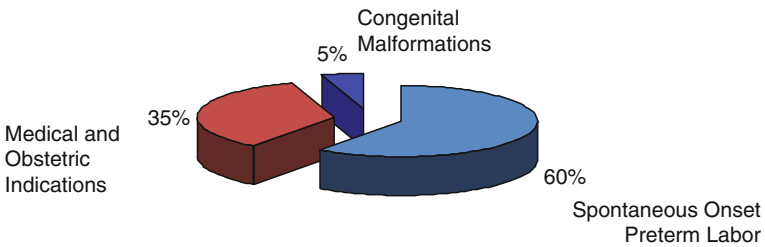

Figure 13.3

Possible causes of preterm births (Redrawn based on compilation of statistics from various publications)

Rehospitalization

For late preterm infants, the rates for readmissions to the nursery within 4 weeks of initial discharge was between 5.3% and 9.6%, compared to 3.6–4.4% for term infants, with the risk increasing threefold if the initial hospital discharge occurred at <96 h of age. Common reasons for readmission were jaundice, feeding difficulties, poor weight gain, dehydration, and apnea with apparent life-threatening events.

The risk for hospital admission is higher for late preterm infants compared to term infants throughout the

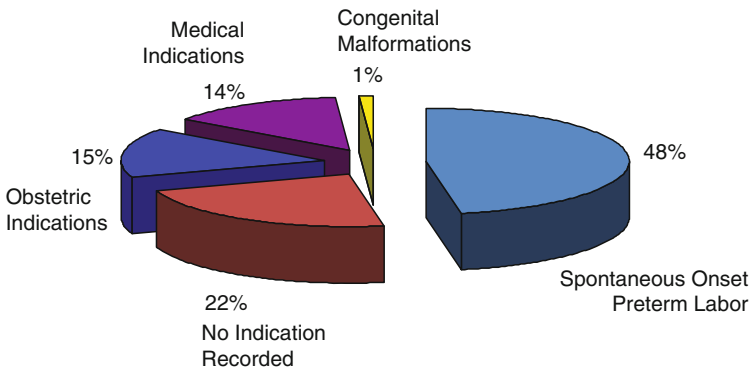

Figure 13.4
Delivery indications for late preterm births compiled using various published data sources

first year of age. A California study found that 13% of infants born at 35 weeks were readmitted at least once during the first year of age, adding $80 million to the healthcare cost.

Specific Morbidities Associated with Late Preterm Births

Hypothermia and hypoglycemia: Late preterm infants develop hypothermia and hypoglycemia far more quickly and more often than term infants. Since they generally appear normal at birth, they are likely to be left in the delivery room with their mothers or to be "rooming-in" with minimal monitoring. Of the 196 infants consecutively admitted to a newborn nursery, 48.8% were hypothermic (core temperature <36°C). Over half of the hypothermic infants were late preterm, who became hypothermic while in the delivery room. Neonatal hypoglycemia is nearly threefold higher in late preterm compared to term infants (14% vs 5.3%), because of some of the reasons noted above.

Respiratory distress: About 1–4% of late preterm infants develop some form of respiratory distress, including the classical respiratory distress syndrome (RDS). The risk for RDS is higher when there is no exposure to antenatal steroids. A failure of fetal pulmonary surfactant surge that usually occurs at 34 weeks may be one reason for RDS in late preterm infants. Maternal diabetes or planned cesarean delivery in the absence of labor increases the risk for RDS due to lack of labor-related biochemical changes that enhance fetal lung maturation and facilitate pulmonary fluid clearance. Transient tachypnea of the newborn, absorption atelectasis, and persistent pulmonary hypertension are also other causes of respiratory distress in late preterm infants.

Hyperbilirubinemia: Because of immaturity and delay in the development of hepatic bilirubin conjugation pathways, late preterm infants are more likely than term infants to develop physiological jaundice, to have higher serum bilirubin concentrations, and to have longer duration of jaundice. In addition, feeding difficulties lead to delay in the resolution of enterohepatic recirculation of bilirubin and cause an increase in the systemic bilirubin load. Immaturity of the bilirubin blood–brain barrier functions, lower circulating albumin concentrations for bilirubin-binding, and concurrent illnesses increase the risk for bilirubin-induced brain injury and kernicterus in late preterm infants.

The AAP has recommended steps to treat neonatal jaundice based on hour-specific bilirubin values in high-risk as well as term infants.

Feeding and apnea: Oro-buccal coordination and swallowing mechanisms remain immature in most late preterm infants, leading to considerable difficulty in establishing successful feeding, especially breastfeeding. Late preterm infants also have a higher frequency of gastroesophageal reflux, further reducing food intake and affecting weight gain. In some cases, this chain of events leads to dehydration and hypernatremia during the first few weeks of life and may lead to severe hyperbilirubinemia, which in turn makes feeding difficulties worse. This interruption of adequate protein and caloric intake at a critical part in brain growth and development may have significant adverse effects (discussed further below). Both obstructive and mixed apneas occur at higher frequencies in late preterm than in term infants.

Brain maturation and development: Recent imaging and pathological studies have shown that the brain remains significantly immature in late preterm relative to term infants. The external surface at 34 weeks of gestation shows fewer sulci, and the brain weight is only 65% of full-term infant's brain weight. Between 35 and 40 weeks gestation, there is also a marked increase in synaptogenesis, neuronal connectivity, and dendritic arborization. Using advanced neuroimaging studies at 9 years of age in 192 infants who were born between 32 weeks gestation and term, a recent study noted a significant reduction in cerebellar volumes in relation to earlier gestations, independent of birth weight, sex, and intracranial volume. Cerebellar injury has been recognized as an important contributor to adverse motor, language, and social–behavioral outcomes.

Taken together, the above anatomical changes, and higher prevalence of morbidities may be the underpinnings of brain injury in late preterm infants, which might explain the reasons for the reported cognitive deficits documented in late preterm infants during school age (see below).

Learning disabilities and scholastic problems and adult age outcomes: Several recent reports have raised concerns about the long-term neurological and psychological outcomes for late preterm infants. In a cohort of 970 preterm and 13,671 term infants from a longitudinal study, late preterm infants on average performed worse on reading and math tests from kindergarten through fifth grades. The requirement for special education at early grades was also higher for the late preterm group compared to the term counterpart (odds ratio, 1.4:2.1). A Norwegian study based on a national cohort found that in nearly 33,000 adults born at late preterm gestations, most psychosocial measures were 50–200% worse compared to those born at term.

Thus, the burden of short- and long-term morbidities should be a matter of great concern for those caring for late preterm infants. The AAP has made the following recommendations for the care of late preterm infants.

Prevention of non-indicated preterm births: In the absence of medical or obstetric indications, no planned, induced vaginal or planned cesarean delivery is to be conducted prior to 39 weeks of gestation.

Clinical assessment and transitional care: All infants need accurate assessment of gestational age and comprehensive clinical examination within the first hours of birth. Close monitoring of temperature and feeding patterns during the transitional period is needed to avoid delayed recognition of feeding problems, jaundice, and hypoglycemia.

Feeding adequacy and stability of vital signs: Irrespective of the method of feeding, late preterm infants should be monitored for the adequacy of feeding, age-appropriate changes in weight and well-being. An infant who is losing >3% of body weight in a single day, or a total weight loss of >7% at any time needs further evaluation for dehydration and feeding status.

Hyperbilirubinemia: Early assessment, monitoring, and implementation of treatment should be based on the AAP guidelines.

Timing and preparation for discharge: Individualized timing of discharge should be based on overall stability, feeding status, and clinical well-being. Prior to discharge, a successful pattern of breastfeeding needs to be demonstrated for at least 24 h, and that the infant must have had normal passage of at least one stool. Other predischarge requirements are those that are recommended by the AAP for all high-risk infants (see below).

Follow-up: When the infant is discharged prior to 48 h, a repeat visit needs to be planned 24–48 h after discharge. During this visit, one needs to assess the overall well-being, nutritional status, and the status of jaundice. Additional visits may be needed based on clinical course. Late preterm infants also need thorough evaluation of neurological status during all their subsequent clinic visits.

Education: Healthcare providers caring for late preterm infants throughout the pediatric age group need to be educated about the vulnerability of this cohort of infants and a need for close surveillance and comprehensive follow-up. Parents and family members should be educated about the special needs of late preterm infants during the first months of life.

Hospital Discharge Planning for All High-Risk Infants

As per the AAP Policy Statement, special attention should be given during discharge planning for all high-risk infants, since for many, medical care may be needed even after discharge. The group of infants qualifying for special consideration include all preterm infants; infants with special health care needs or dependence on technology; infants at risk because of family issues; and infants with anticipated early death. The plan should be individualized to ascertain that the infant is physiologically stable; the parents are involved and are ready for the care of their infant at home; arrangements have been made for healthcare after discharge by a physician, or other healthcare professionals with experience in the

care of high-risk infants; and an organized program for tracking and surveillance to monitor growth and development.

14 Thermoregulation/Environment

Andrew James Lyon

Children and adults maintain a constant deep body temperature over a wide range of ambient thermal conditions (homeothermic). This is achieved by physiological and behavioral responses that control the rate at which heat is produced and lost. The newborn infant is also homeothermic but control of body temperature can only be achieved over a narrower range of ambient conditions. The preterm infant has even greater difficulty in body temperature control, and the most immature infants behave at times as if they are poikilothermic – their body temperature tending to drift up and down with the ambient temperature. The aim in neonatal care is to provide a thermal environment which keeps body temperature in the normal range, and which does not stress the infant to produce or lose large amounts of heat.

The importance of thermoregulation in the newborn has been recognized for a long time. In late nineteenth century Paris, Tarnier, and Budin reduced by half the mortality of infants, under 2,000 g birthweight, by nursing them in a warming chamber they designed from an incubator used for rearing poultry. In a series of randomized controlled trials in the 1950s, William Silverman showed that keeping babies warm resulted in a 25% absolute reduction in mortality in all birthweight groups, including those under 1,000 g. Subsequent studies in the 1960s showed a significant reduction in death rate among low birthweight infants when their abdominal skin temperature was maintained at 36°C (relative risk 0.72–95% CI 0.54, 0.97). This effect was even greater among the very low birthweight infants.

Despite the lessons from these studies, there is evidence that newborn babies today are still being allowed to get cold and hypothermia, especially in the preterm infant, remains independently associated with increased mortality.

Heat Balance

Heat is produced as a by-product of cell metabolism. The basal metabolic rate is the lowest obligatory rate of heat production which occurs when an individual is starved, quiet, and resting. In the newborn, this is usually taken as the minimal rate of oxygen consumption in an infant who is lying still and asleep, at least 1 h after a feed in a neutral thermal environment. Values depend on gestation and postnatal age. Heat production must be balanced by that lost from convection, radiation, evaporation, and conduction.

The more immature the infant, the greater the difficulty in temperature control. Heat loss is related to surface area, which is relatively high in the smaller babies. There is reduced insulation due to lack of subcutaneous tissue and the poorly developed stratum corneum results in high transepidermal water loss (TEWL) and evaporative heat loss. TEWL is related to both gestational age and postnatal age. The ability to conserve heat by vasoconstriction is limited, and heat production, which is related to mass, is low. This poor response to relatively high heat losses means that hypothermia is a common problem in the immature baby.

Response to Thermal Stress

The thermoneutral environment is a range of environmental temperature over which an infant has a minimum rate of heat production and is not sweating. Within this range, small adjustments to thermal control can be made by alterations in posture, activity, and skin blood flow with deep body temperature remaining constant. The thermoneutral range is wide if the infant is mature and well insulated by clothes and bedding, but narrow in the small and naked baby. As environmental temperature falls below the lower end of the thermoneutral range, the newborn baby is unable to shiver but increases metabolic heat production. This is mainly the result of oxidation of brown adipose tissue which is distributed in the neck, between the scapulae and along the aorta. The metabolism of brown fat to produce heat is controlled by catecholamine release (non-shivering thermogenesis). A term newborn infant can double his resting heat production in this way without any increase in activity. As environmental temperature continues to decline, heat production reaches a maximum and below this point the body temperature falls. If environmental temperature rises above the upper end of the thermoneutral range, sweating occurs

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_14,

until a point is reached when the heat lost by sweating is insufficient and body temperature starts to rise.

In all infants, heat production is delayed during adaptation to extrauterine life, especially if there is asphyxia, hypoxia, or maternal sedative administration. Heat production per unit area is lower in preterm infants, particularly below 28 weeks' gestation, and the immature infant has a more prolonged impairment of non-shivering thermogenesis.

Sweating occurs from birth in infants above 36 weeks' gestation but is delayed by 2–3 weeks in the most immature infants. This is a result of neurological rather than glandular immaturity. Sweating is a relatively poor defense against overheating in the newborn because the production of sweat per unit area of skin is low compared with a child or adult. The term newborn can alter skin blood flow effectively, and hence the amount of heat lost by convection and radiation, but this is impaired in the very immature infant. Change of posture to increase or decrease the surface area available for heat loss by convection and radiation is important in thermoregulation. It occurs in the healthy term infant and to some extent in the preterm infant but not in the presence of illness.

Body Temperature and Its Measurement

The only practical method in day-to-day care for assessing the effects of the thermal environment on the baby is to measure body temperature. This is crude because it tells us nothing about the amount of energy the baby may be using to maintain its body temperature. An infant can be exposed to very significant thermal stress and still maintain a normal deep body temperature. The corollary of this is that just because a baby has a normal deep body temperature does not necessarily mean that it is in a neutral thermal environment.

In clinical practice, we need an easily measured temperature that is at least close to, and follows changes in, deep body temperature. There is, however, no such thing as a single deep body temperature. The temperature of a tissue will depend on its metabolic rate, with the brain being the highest. The temperature in mid esophagus is often used to represent deep body temperature as this measures the temperature of the blood in the great veins returning to the heart from all the tissues. However, this is invasive and difficult to use in routine care.

Rectal temperature should no longer be used routinely in infants and children as there is a significant risk of damage to the mucosa. Temperature in the rectum is an unreliable measure as it is affected by the depth of insertion of the thermometer, whether the baby has just passed a stool and by the temperature of the blood returning from the lower limbs. It is very difficult to retain rectal probes in the same position if continuous temperature monitoring is being used. The one exception is for babies who are being cooled for management of hypoxic ischemic encephalopathy when rectal probes are a reasonable alternative to continuous esophageal temperature monitoring of deep body temperature.

Tympanic temperature closely correlates with that of the brain and is commonly used for intermittent recording in children but is less practical in the newborn infant.

Axillary temperature is a reasonable guide to deep body temperature. The bulb of the thermometer should be held in the roof of the axilla with the infant's arm pressed against the side of the chest until a stable reading is obtained, usually by 3 min. The normal range is 36.3–37.0°C.

Skin temperature reflects tissue insulation and environmental conditions as well as deep body temperature. In the preterm baby, the temperature of the skin over the liver can be used to monitor trends in deep body temperature. If the infant lies on a temperature probe which is insulated on the outside, the skin under the probe cannot lose heat and so equilibrates with the deep body temperature. This is the zero heat flux temperature and is a practical method for continuous monitoring of a central temperature.

A single temperature, measured intermittently, gives limited information on the thermal state of the baby. Particularly in the sick or unstable baby, more information can be obtained from the continuous measurement and display of a central (abdominal, axillary, or zero heat flux) and a peripheral (foot) temperature. Changes in peripheral temperature can detect cold stress before the central temperature falls. The preterm baby, who appears to be comfortable in its environment, will have a central temperature, measured from a skin probe, of 36.8–37.3°C and a central-peripheral temperature difference of 0.5–1°C. An increasing central-peripheral temperature difference, particularly above 2°C, is commonly due to cold stress and occurs before any fall in central temperature. Hypovolemic babies will vasoconstrict their peripheral circulation in an attempt to maintain blood pressure. This results in a rise in central-peripheral temperature difference but, in such cases, there are other signs of hypovolemia, such as a rising heart rate and falling blood pressure. A raised and unstable central temperature, along with a wide central peripheral gap, is seen in septic babies.

Management of the Thermal Environment

At Delivery

Delivery rooms should be warm, with a minimum temperature of 25°C, and well insulated against drafts to reduce radiative and convective heat losses. Evaporation of amniotic fluid from the skin is the greatest source of heat loss following delivery. The term newborn infant should be dried at delivery, wrapped in a warm dry blanket, and given to the mother. Skin to skin contact with the mother is an effective way of maintaining body warmth but it is important to cover the baby to prevent heat loss from exposed skin on the back.

In the preterm infant, low temperature on admission to the neonatal unit has been shown to be independently associated with increased mortality. The use of heated mattresses has been shown to prevent hypothermia and in well infants skin to skin contact is effective. Evaporation is the major source of heat loss, particularly in the very immature infant, and this can be significantly reduced using occlusive dressings. Plastic wraps or bags are effective in reducing heat losses in infants <28 but were not more effective than standard care in those between 28 and 31 weeks' gestation. Clear plastic bags are easy to use and prevent hypothermia immediately after delivery. The baby can be slid into the bag, up to the neck, whilst still wet. The head is dried and covered with a hat. No blankets are used, allowing radiant heat to warm the infant through the bag. Clinical inspection and auscultation during resuscitation can be done through the bag and if vascular access is needed a small hole can be cut in the plastic. The infant can be transported while still in the bag, which is only removed once the baby is in a humidified environment.

Nursing

The healthy term newborn will maintain a normal temperature if nursed fully dressed in a cot in a warm room. Most healthy preterm babies can be managed in the same way, although comparative data between cot and incubator care are limited. Some very small infants may need to be nursed clothed in an incubator to provide a sufficiently warm ambient temperature.

- Over 2 kg: nurse clothed, with bedding in a cot, in a room temperature of about 24°C.
- 1.5–2 kg: nurse clothed with a hat and bedding in a cot, in a room temperature of about 26°C.
- Below 1.5 kg: nurse clothed with a hat, in an incubator temperature of 30–32°C.

Heated Cot

A water-filled mattress, heated to a set temperature between 35°C and 38°C, can be used to provide conductive heat to a preterm infant nursed in a cot. This can be as effective as an incubator for keeping small babies warm, resulting in similar rates of resting metabolism and growth. It is cheap, simple, and does not depend on a constant unbroken supply of electricity (because of its stored heat), so that it is particularly useful in developing countries. It is only of use if the infants are healthy and do not need to be nursed naked for observation and access. It has been effectively used as a method of rewarming cold preterm infants. Gel-filled heated mattresses are also available but are more expensive.

Incubator

The incubator provides a warm, humid environment suitable for nursing small or sick infants, particularly if they need to be naked for observation and access. Air within the canopy is warmed by a heater and circulated by a fan. The heater output can be controlled in two ways. In air mode, the incubator air temperature is set to a point between 30°C and 37°C, and the heater is thermostatically controlled to reach and maintain this temperature. In servo mode, a thermistor probe is taped to the infant's abdominal skin and the desired skin temperature is set – the heater output varies to provide an air temperature which maintains the set skin temperature. In practice, air mode control is simpler to use, safer, and results in a very constant ambient air temperature regardless of the condition of the infant and the amount of care being receiving. Servo control results in wide fluctuations in air temperature, particularly during handling, and in the preterm baby this has been associated with an increase in apnea and possibly a poorer outcome. The probe can become detached or wet, and the infant's own attempts at thermoregulation are overridden so that a fever may be disguised. For these reasons, air temperature control is preferred in most circumstances.

Suggested air temperature (*Table 14.1*) and skin temperature settings (*Table 14.2*) for the two modes of control are shown.

These are a guide only and there will be variation in individual requirements. In particular, dressed babies will need lower incubator temperatures. Monitoring of body temperature is essential to allow appropriate changes in environmental settings.

Table 14.1
Average incubator air temperatures needed to provide a suitable environment for naked, healthy infants (From Rutter N (2005) Temperature control and its disorders. In: Rennie JM (ed) Roberton's textbook of neonatology, 4th edn. Churchill Livingstone, Edinburgh)

	Environmental temperature					
Birthweight (kg)	37°C	36°C	35°C	34°C	33°C	32°C
Less than 1.0	For 1 day	After 1 day	After 2 weeks	After 3 weeks	After 4 weeks	After 6 weeks
1.0–1.49			For 10 days	After 10 days	After 3 weeks	After 5 weeks
1.5–1.99				For 10 days	After 10 days	After 4 weeks
2.0–2.5				For 2 days	After 2 days	After 3 weeks
More than 2.5					For 2 days	After 2 days

Table 14.2
Suggested abdominal skin temperature settings for infants nursed in servo-mode incubators or under radiant warmers (From Rutter N (2005) Temperature control and its disorders. In: Rennie JM (ed) Roberton's textbook of neonatology, 4th edn. Churchill Livingstone, Edinburgh)

Weight (kg)	Abdominal skin temperature (°C)
Less than 1.0	36.9
1.0–1.49	36.7
1.5–1.99	36.5
2.0–2.5	36.3
More than 2.5	36.0

The naked infant will lose heat by radiation to the cooler walls of the incubator. This loss can be reduced by raising the temperature of the nursery, and therefore of the incubator wall, raising the incubator air temperature, using a radiant heat shield within the incubator which warms to the air temperature and shields the infant from the canopy, or by using a double-walled incubator. Although radiative heat losses can be minimized, there are no data available that show an impact on outcome in low birthweight infants.

In infants below 30 weeks' gestation, especially if weighing less than 1 kg, evaporative water and heat loss is high during the first days of life and may exceed the infant's own heat production. Raising the humidity of the air around the body will reduce evaporative losses so that a normal body temperature can be achieved and fluid losses minimized. Beyond 1 week of age, the immature infant's skin has matured to such an extent that evaporative water and heat losses are less important and added humidity is rarely required. Incubators using a sealed system do not need to be run dry for part of the day and there does not appear to be any increased risk of infection when humidity is used. Evaporative heat losses can also be reduced by covering the baby with a plastic sheet. This reduces visibility and when removed to handle the baby there are high evaporative losses. The use of semipermeable nonadhesive skin dressings lowers TEWL and reduces the number of bacteria in the covered skin. Emollients have also been used to cover the skin and reduce fluid loss. They are safe and reduce excessive drying, skin cracking, and fissuring. However, the effect of these products wears off after about 3 h, necessitating repeated application.

There are few data available to help in deciding the optimum time to make the transition from incubator to cot. Traditionally, this is based on weight, with most babies able to maintain their temperature in a cot, and continue to gain weight, when they are between 1,700 and 1,800 g.

Radiant Warmer

With the use of radiant warmers, the infant lies naked on a platform with a radiant heat source above. The output of the heater is controlled by a temperature sensor in contact with the infant's skin, set to the desired temperature. The sensor should be taped to the abdomen or chest rather than a limb and must be shielded from the heat source. The normal range of abdominal skin temperature under neutral thermal conditions for infants of different size is shown in *Table 14.2*.

Heat losses by convection and radiation are high when radiant warmers are used. Evaporative water loss is also

very high even in term infants, with a mean of about 23 ml/kg/day, due to the low relative humidity in the surrounding air. These losses are all balanced by a large radiant heat gain from the heater. Wide fluctuations in heater output occur, producing a very uneven, asymmetrical thermal environment compared with an incubator. In the more immature infants, increased evaporative water loss may lead to hypernatremia and dehydration. The wide fluctuations in thermal environment and high evaporative water losses can be reduced by placing a small clear plastic canopy over the infant – radiant heat can still reach the infant but heat losses by convection, radiation, and evaporation are greatly reduced.

Overheating can occur and regular measurement of the infant's body temperature by an independent method is essential. It is important to be sure that the skin temperature probe is securely attached to the baby. If the heater is switched off, moved to one side or if something is interposed between the infant and the heat source, the infant's heat losses are very great and rapid cooling occurs. Their advantage is that they allow access to the infant for practical procedures while keeping the infant warm.

Babies nursed with similar skin temperatures have a higher basal metabolic rate when managed under radiant heaters compared with incubators. However, no study has shown any significant difference in outcome for babies nursed using either device.

Transport

The newborn, and in particular the preterm infant, is at high risk of cold stress during transport. High radiative heat losses, especially in cold weather, can be reduced by covering the incubator and using blankets around the baby. Evaporative heat loss can be reduced by placing the baby in a plastic bag. If ventilator gases are not heated and humidified, there will be high evaporative heat losses from the respiratory tract. Heated gel mattresses that can be used during transport are available, with the baby gaining heat by conduction. All units transporting babies should collect data on temperature control during transfer and use this to audit the quality of care during the transport process, because, as previously stated, admission temperature is an important predictor of outcome.

Surgery

There is a major risk of cold stress during surgery. The baby is starved and anesthetized, reducing the normal metabolic response to cold. The operating theatre is often cool and the baby may have had to travel some distance from the nursery. Exposure of the skin and moist organs increases heat loss significantly. Heat losses can be minimized by increasing the environmental temperature to 28–30°C, exposing only the minimum area during surgery and adding a supplementary heat source such as an electric heating pad or radiant heater. Careful intraoperative temperature monitoring is advisable.

Disorders of Body Temperature in the Newborn

A Low Body Temperature (Below 36°C)

Mild hypothermia (central temperature 34 –36°C) is not uncommon. In hospitals, it is most often seen following resuscitation or when infants are exposed to a cool delivery room or theatre. This is easily preventable by paying careful attention to keeping infants warm after delivery. Moderate (30–34°C) or severe (below 30°C) hypothermia due to cold exposure occur most often when infants are born outside hospital, either unexpectedly or after a concealed delivery – if the infant is small, born into a toilet, abandoned, or inadvertently exposed to cold, severe hypothermia may result.

Accidental hypothermia also occurs later in the newborn period or early infancy because of inadvertent cold exposure due to inadequate clothing or cold thermal environments. Infants with bacterial sepsis or with respiratory syncytial virus (RSV) infection are prone to mild hypothermia – so too are infants in severe heart failure or with marked cyanosis. Malnutrition predisposes to hypothermia because of poor tissue insulation and an impaired metabolic response to cold. Hypothyroidism also results in an impaired metabolic response to cold. Drugs given to the mother which cross the placenta have a similar effect on the newborn infant, particularly the long-acting sedatives such as diazepam.

Intentional hypothermia is used as an adjunct to cardiopulmonary bypass – the body temperature being lowered to about 28°C to reduce the metabolic demands of the brain. The infants tolerate this brief, acute severe hypothermia well.

Whole body or preferential head cooling with mild systemic hypothermia appear to be effective in reducing brain damage in asphyxiated animals, and trials have shown improved survival and neurodevelopmental outcome in term newborn infants following birth asphyxia.

Cooling to around 33.5°C is now a common part of the management of hypoxic ischemic encephalopathy with remarkably few adverse effects. The safety and effectiveness of therapeutic hypothermia in preterm infants has not been established.

Hypothermic infants develop symptoms when their deep body temperature falls below 34°C. They become lethargic, feed poorly, have a weak cry and reduced movements. The heart rate falls in proportion to the degree of hypothermia. If exposure to cold has been persistent, there may be peripheral oedema, sclerema, and marked facial erythema in the presence of a strikingly cold skin – these are the features of neonatal cold injury. In very severe hypothermia, there is profound bradycardia with slow, shallow respiration and the infant may appear to be dead. There are anecdotal reports of such infants being left for dead yet eventually making a full recovery. The diagnosis of hypothermia is made by recording a low rectal temperature – it is important that a low reading thermometer is used, not the standard clinical thermometer with a minimum reading of 35°C.

The treatment of accidental hypothermia is rewarming – if there is an underlying cause, this obviously needs to be treated too. There is limited information about the correct rate for rewarming cold infants but in cases of mild hypothermia this can take place fairly rapidly. In moderate or severe cases, there is concern that rapid rewarming of the infant's surface causes peripheral vasodilatation, diversion of blood from the core, and therefore hypotension. There is no evidence for the routine use of plasma expanders in these cases. Following acute accidental hypothermia, it appears to be safe to restore deep body temperature to normal over a few hours. This can be achieved using a radiant warmer, an incubator, or a heated cot. Rapid rewarming in preterm infants has been associated with increased apnea of prematurity.

Hypoglycemia may occur during rewarming and should be anticipated and prevented with an intravenous infusion of 10% dextrose. Care should be taken in interpreting blood gas results – a metabolic acidosis at 37°C is less severe at 30°C and should not be overenthusiastically treated. Abdominal distention is common as a result of ileus and feeding should not be started until a normal body temperature is achieved. NEC and hemorrhagic pulmonary edema have been described. The reported mortality rate in severe hypothermia is 25–50% but this includes infants with overwhelming sepsis or congenital abnormalities that predisposed them to cold. Most survivors develop normally.

A High Body Temperature (Above 38°C)

Most commonly an infant with a high body temperature is being overheated iatrogenically. It is important, however, to be sure that the baby is not truly febrile due to an underlying disease. An intrinsically febrile infant has a high set point temperature and behaves as if cold. He makes physiological and behavioral responses which reduce heat loss, increase heat production, and therefore raise body temperature. Although he has a raised central temperature, his central-peripheral temperature difference will be high (above 2°C).

In contrast, an overheated infant makes physiological and behavioral responses in an effort to increase heat loss and therefore lower body temperature. In this case, the central temperature will be high but the central peripheral temperature gap will be small (below 1°C). Overheated infants simply need a cooler environment, not a series of painful investigations to find a cause for the "fever."

The newborn infant may develop a raised body temperature in the presence of infection but this is usually not marked. It is not known why serious infection in a newborn seems to elicit such a mild febrile response when mild infection in a toddler is often associated with a very high body temperature. Infection is not the only cause of a raised set point temperature in the newborn; it is also caused by a severe cerebral abnormality, either congenital (holoprosencephaly, hydranencephaly, encephalocele) or acquired (birth asphyxia). Such infants have hypothalamic dysfunction leading to poor temperature control.

Overheating is less common than accidental hypothermia in the newborn. Mild degrees occur when active, large infants are overwrapped and left in a warm room, or when small infants are overheated by an incubator or radiant warmer. Severe overheating occurs when there is electrical or mechanical failure of a warming device, or when an incubator is exposed to direct sunlight (this turns it into a greenhouse). It can also occur if infants are left in closed cars exposed to direct sunlight.

Mild overheating has been suggested as a predisposing factor in apnea of prematurity but otherwise seems not to be dangerous. Severe overheating leading to hyperpyrexia (rectal temperature above 41°C) has caused sudden death in the newborn without prior symptoms.

Recent data from the therapeutic hypothermia trials indicate that overheating should be carefully avoided in infants with perinatal asphyxia, because asphyxiated infants who became hyperthermic had significantly worse neurodevelopmental outcome than similar infants who remained normothermic.

15 Respiratory System

Martin Keszler · Kabir M. Abubakar

Lung Development

The tracheobronchial airway system develops as a ventral outpouching of the primitive foregut, which leads to the formation of the embryonic lung bud. The lung bud subsequently divides and branches, penetrating the mesenchyma and progressing toward the periphery. Lung development is divided into five phases (*Table 15.1*). A variety of physical, hormonal, and other factors affect the pace of lung development and maturation. Normal lung growth and development requires adequate distending pressure of fetal lung fluid and normal fetal breathing movements – their absence leads to pulmonary hypoplasia. Lack of saccular development and surface area for gas exchange are the limiting factors for survival of infants born in the late cannalicular phase before 24 weeks of gestation.

Respiratory Physiology/Lung Mechanics/ Gas Exchange

Although basic principles of lung mechanics and gas exchange are similar to those of older children and adults, newborn infants present the clinician with a number of special challenges that are the consequence of their unique physiology and pathophysiology. This is especially true when they are born prematurely. The reader is referred to any of the major texts on respiratory physiology for in-depth coverage of the subject. The key concepts are briefly reviewed below.

Lung Mechanics

The lungs of preterm infants are relatively noncompliant (stiff), while the chest wall lacks rigidity. As a result of this disturbed balance between the tendency of the lungs to collapse due to elastic recoil and the rigidity of the chest wall that maintains lung expansion, the lungs come to rest at a lower functional residual capacity and the airways tend to close near the end of exhalation. Therefore, special attention needs to be paid to maintaining adequate lung volume during respiratory support of newborn infants. Differences between the shape of an adult versus newborn infant's chest put the infant at a mechanical disadvantage. The infant's thorax is more cylindrical than ellipsoid and the ribs are more horizontal, rather than oblique. Because of these anatomic differences, the intercostal muscles in infants have a shorter course and provide less mechanical advantage for elevating the ribs and increasing intrathoracic volume during inspiration. Because the insertion of the infant's diaphragm is more horizontal than in the adult, the lower ribs tend to move inward rather than upward during inspiration. The compliant chest wall exacerbates this inward deflection with inspiration. This results in inefficient respiratory effort, which may be manifested clinically by intercostal and substernal retractions associated with abdominal breathing, especially when lung compliance is decreased. Additionally, infants have low muscle mass and a low percentage of type 1 (slow twitch) muscle fibers compared to adults, making infants with respiratory distress prone to respiratory muscle fatigue and respiratory failure.

During expiration the main driving force is elastic recoil, which depends on the surface tension produced by the air–liquid interface, the elastic elements of lung tissue, and the bony development of the rib cage. Expiration is largely passive. Because the chest wall of premature infants is compliant, it offers little resistance against expansion upon inspiration and little opposition against collapse upon expiration.

The airways of the preterm infants are very small, resulting in relatively high airway resistance, especially as airway epithelium becomes injured during mechanical ventilation. Additionally, the small size of the trachea necessitates the use of narrow endotracheal tubes that add substantially to the airway resistance (recall that resistance to flow is inversely proportional to the fourth power of the radius). All of these factors confer a significant mechanical disadvantage to the respiratory mechanics of newborn and especially preterm infants, making them more vulnerable to fatigue and respiratory failure.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_15,

Table 15.1
The phases of lung development. There is some overlap between the phases

Embryonic phase (weeks 3–6)	Development of proximal airways. The lung bud arises from the foregut 21–26 days after fertilization
Pseudoglandular phase (weeks 6–16)	Development of the first 20 generations of conducting airways. The first eight generations (the bronchi) ultimately acquire cartilaginous walls. Generations 9–20 are the nonrespiratory bronchioles. Lymph vessels and bronchial capillaries follow the airways as they grow and develop
Canalicular phase (weeks 16–26)	Respiratory bronchioles (generations 21–23) develop. The proportion of parenchymal connective tissue diminishes. Pulmonary capillaries develop
Terminal sac phase (weeks 26–36)	Rudimentary primary saccules subdivide by formation of secondary crests into smaller saccules and alveoli, greatly increasing the surface area for gas exchange. The interstitium continues to thin out, decreasing the distance for diffusion. Capillary invasion leads to an increase in alveolar–blood barrier surface area. The surfactant system develops and matures
Alveolar phase (week 36–3 years)	Saccules become alveoli due to thinning of the acinar walls and invagination of alveoli by pulmonary capillaries with secondary crest formation. The alveoli attain a polyhedral shape

Oxygenation

As in older patients, oxygenation is a function of the fraction of inspired oxygen and optimal ventilation/perfusion (V/Q) matching. Optimal V/Q ratio occurs at normal lung volume. Atelectasis results in intrapulmonary right-to-left shunting and V/Q mismatch with resulting hypoxemia. The condition can be corrected by increasing mean airway pressure (best accomplished by raising positive end-expiratory pressure = PEEP), until oxygenation improves. Overexpansion of the lungs also results in V/Q mismatch and additionally may increase pulmonary vascular resistance by compressing pulmonary capillaries and result in extrapulmonary right-to-left shunt. Both over- and under-expansion contribute to lung injury and should be avoided. Chest radiographs, though not a direct measure of lung volume, are helpful in assessing the appropriateness of lung expansion. It is important to recognize that several factors influence mean airway pressure (MAP), including positive end-expiratory pressure (PEEP), peak inspiratory pressure (PIP), inspiratory:expiratory ratio, and, finally, the slope of the inspiratory waveform, which determines how rapidly the pressure limit is reached. Alteration of any of these variables will affect MAP and thus may alter lung expansion. Because, in addition to the effects of their excessively compliant chest wall, newborn infants commonly are surfactant deficient, special attention must be directed toward maintaining adequate lung expansion.

CO_2 Elimination

CO_2 elimination (ventilation) is relatively independent of oxygenation and requires a flux of fresh gas in and out of terminal respiratory units. With conventional respiratory rates, the gas moves by bulk flow or convection in the large and small airways with diffusion accounting for gas movement in the respiratory bronchioles and terminal air sacs. Bulk flow of gas is greatly influenced by the mechanical properties of the lungs: compliance, airway resistance, and time constants. Understanding the concept of time constants is important for optimal selection of respiratory rate, specifically inspiratory and expiratory time. Conceptually, time constants describe the length of time required for gas to get in and out of the lungs when a change in pressure is applied at the airway opening (three time constants are required to reach 95% equilibration of pressure). Mathematically, the following equation describes the phenomenon of time constants:

$$\text{Time constant(s)} = \text{airway resistance}\left(\text{cmH}_2\text{O} \times \text{L}^{-1} \times \text{s}\right) \times \text{lung compliance}\left(\text{L/cmH}_2\text{O}\right)$$

Because total compliance, not compliance/kg is used, time constants are also a function of subject size – as is intuitively obvious, the larger the lung is the longer it takes to get gas in and out.

The practical consequence of this relationship is that small infants with respiratory distress syndrome (i.e., low compliance, low resistance) have very short time constants and normally have rapid respiratory rates with little danger of air trapping, while larger infants with meconium aspiration or bronchopulmonary dysplasia (high airway

resistance) need slower respiratory rates and are more prone to air trapping, thus require longer expiratory times. Inspiratory times are normally shorter than expiratory times, because expiratory airway resistance is always higher, but should also be adjusted according to patient size and pathology. Typically, inspiratory to expiratory ratio of 1:2 is used, as this approximates normal breathing.

CO_2 elimination is determined by how effectively fresh gas is moved in and out of the terminal gas exchanging units. Total minute ventilation is the product of respiratory rate and tidal volume (V_T). Tidal volume is principally determined by lung compliance and pressure amplitude or ΔP (peak pressure – PEEP). In newborn respiratory support, pressure-limited ventilation has traditionally been used. In this mode, V_T is not set directly, but is a derived variable, which is indirectly controlled by adjusting ΔP and is affected by changes in lung compliance. An additional consideration is the fact that exhaled alveolar gas occupies the upper airway, endotracheal tube, and any additional apparatus such as a flow sensor at the end of each exhalation. Thus, with the next breath, at least a portion of this dead space gas flows back into the lungs, followed by fresh gas. Traditional physiology teaches that:

$$\text{Alveolar minute ventilation} = (\text{VT} - \text{dead space volume}) \times \text{respiratory rate}.$$

In practice, at the high flow rates seen in small infants with very short time constants, there appears to be considerable mixing of gases in the dead space volume, resulting in partial bypass of the anatomical and instrumental dead space.

Regulation of Respiration

Regulation of breathing is accomplished by a complex process involving the respiratory control center, peripheral and central sensors, and respiratory muscles. The respiratory control center consists of a group of neurons in the brainstem that receive and integrate the afferent information from the sensors and in turn send motor impulses to the respiratory muscles to regulate respiratory activity. The respiratory regulatory mechanism undergoes a significant maturation process during the neonatal period. The preterm infant's respiratory control center is immature, resulting in irregular respiratory pattern, periodic breathing, and apnea. Sleep states have the potential for profound influences on the control of respiration. In the older, awake individual, respiratory activity is under a significant degree of voluntary control. The degree to which this is true in the immediate neonatal period is unclear, but an infant's activity and emotional state clearly do influence the respiratory pattern.

A group of 150–200 neurons, known as the *pre-Botzinger complex* (PBC), located in the medullary region of the brainstem functions as the pacemaker for automatic respiratory activity. PBC neuron activity is modulated by afferent input from neurons located in the lower pons called the *apneustic center* (stimulatory effect) and inhibited by neurons in the upper pons, known as the *pneumotaxic center.* Thus, damage to various parts of the brain often manifests with abnormal respiratory pattern.

Central and peripheral chemoreceptors and a variety of mechanoreceptors provide feedback to the central respiratory controller. Central chemoreceptors located over a large area of the brain are bathed by the cerebrospinal fluid (CSF) and respond to changes in the H^+ concentration, i.e., pH. A decrease in pH concentration stimulates ventilatory activity, while an increase inhibits it. The CSF is separated from the blood by the blood-brain barrier, which is relatively impermeable to H^+ and HCO_3^- ions, but readily permeable to CO_2. A rise in $PaCO_2$ is quickly reflected in a similar rise in the CSF, resulting in a fall in CSF pH and stimulation of ventilation. It is important to understand that changes in $PaCO_2$ exert their influence on ventilation through changes in CSF pH. The CSF has much less CO_2 buffering capacity than blood because of a much lower protein concentration. This amplifies the response to CO_2, because the same change $PaCO_2$ in blood leads to a larger change in CSF pH. With a persistent elevation in $PaCO_2$, the pH of the CSF gradually normalizes as HCO_3^- equilibrates across the blood-brain barrier. Thus compensated respiratory acidosis is associated with a relatively normal CSF pH and therefore these infants do not increase their ventilatory response in response to these high levels of $PaCO_2$.

Peripheral chemoreceptors, located in carotid bodies just above the bifurcation of the common carotid arteries, and in the aortic bodies in the aortic arch primarily respond to changes in PaO_2 with hypoxia stimulating ventilation and hyperoxia having an inhibitory effect. Exposure to unnecessarily high FiO_2 may thus depress the respiratory response to CO_2, another of the many reasons to avoid hyperoxia. The carotid bodies also respond to pH irrespective of whether the acidosis is respiratory or metabolic. The effect of hypoxia and acidosis is synergistic, leading to a greater degree of stimulation by their combination than either one alone. Hypoxia is a more potent stimulus than alkalosis; therefore hypoxic respiratory drive usually leads to some degree of hyperventilation when hypoxemia persists.

Mechanical receptors provide additional input to the respiratory control center. *Stretch receptors* located within the airway smooth muscle are stimulated by lung inflation, decreasing the respiratory rate by inhibition of inspiratory muscle activity and an increase in expiratory time. This reflex is called the Hering–Breuer inflation reflex. Hering–Breuer deflation reflex stimulates inspiratory muscle activity in response to deflation of the lung. *Irritant receptors* in the airway mucous membranes are stimulated by particulate matter and other noxious stimuli, including cold air. So-called J receptors or juxta-capillary receptors located in the alveolar walls close to the pulmonary capillaries respond to pulmonary capillary engorgement, interstitial and alveolar wall edema by inducing shallow and rapid respirations and a sensation of dyspnea. *Muscle receptors* in the diaphragm and the intercostal muscles sense the degree of stretch of the muscle and control the strength of contraction. Activation of muscle receptors by excessive chest wall distortion occasioned by the very compliant rib cage may be partially responsible for the cessation of inspiration and apnea seen with airway obstruction in preterm infants. Important afferent input also originates in the upper airway and especially the laryngeal area. Superior laryngeal nerve afferents are connected to cardiac vagal neurons in nucleus ambiguus, or terminate in the nucleus of the solitary tract with inhibitory connections to phrenic motor neurons. Inhibition of phrenic and cardiac motor neurons with laryngeal stimulation is likely the mechanism of apnea and bradycardia associated with gastroesophageal reflux.

The response of the respiratory control center to chemoreceptor and mechanoreceptor input and the efficiency of the respiratory muscles are markedly altered in the preterm newborn infant, compared to older subjects. Unlike adults who have an immediate and sustained response to hypoxemia characterized by hyperventilation, the newborn exhibits a biphasic response. After an initial brief period of hyperventilation, the newborn exhibits hypoventilation and apnea in the face of sustained hypoxemia. The more premature the infant is, the more pronounced and earlier is the apneic response to hypoxemia. Neonates also have a decreased CO_2 responsiveness as measured by an increase in minute ventilation for a given increase in $PaCO_2$. This decreased chemoreceptor responsiveness and the paradoxical response to hypoxia is a key difference between the newborn and older subjects and a major contributor to their susceptibility to various forms of respiratory depression and apnea. Additionally, the inhibitory stimuli from the larynx of newborn infants appears to be more active than in older subjects and appears to play an important role in the genesis of neonatal apnea/bradycardia.

Sleep has a profound effect on respiratory control, decreasing central responsiveness to CO_2. Rapid eye movement (REM) sleep, the predominant sleep pattern in premature babies that accounts for more than 60% of the total, leads to suppression of postural muscle tone and lack of spontaneous movements. The depression of muscle tone during REM sleep has two important effects. Increased compliance of the chest wall leads to less efficient respiration and may lead to loss of lung volume (microatelectasis) with resulting hypoxemia. Relaxation of upper airway muscles cause airway obstruction and contribute to obstructive apnea.

Apnea of Prematurity

A striking feature of the resting breathing pattern of the premature newborn is its irregularity, characterized by large breath-to-breath variability accompanied by long stretches of periodic breathing and brief apnea. Clinically important apnea of prematurity is almost always associated with periodic breathing. Although the mechanisms have not been fully elucidated, it is likely that the periods of hyperpnea or hyperventilation decrease the $PaCO_2$ thus reducing the stimulus to breathe, resulting in apnea; the resulting hypoxemia may then further depress the respiratory center.

Apnea of prematurity (AOP) can be thought of as a developmental disorder that reflects physiological immaturity of respiratory control. AOP occurs in up to 85% of infants of less than 34 weeks' gestational age. AOP increases in frequency with decreasing maturity and resolves with increasing maturity. In $>$90% of infants, AOP resolves by 37 weeks postmenstrual age, but occasionally it may last until 40 weeks or beyond, especially in infants born at 24–26 weeks or those with chronic lung disease.

Clinically significant apnea is defined as cessation of breathing that lasts for at least 20 s. Shorter apneas, if associated with significant bradycardia or oxyhemoglobin desaturation, may also be considered clinically significant. Lack of airflow may occur despite continued respiratory effort in the presence of airway obstruction and may be the reason for the shorter "apneas" being associated with bradycardia and desaturation.

Brief episodes of bradycardia are common and typically not associated with desaturation.

Apnea is traditionally classified as central, obstructive, or mixed, based on the primary mechanism involved. These mechanisms can be distinguished by simultaneous measurement of chest wall movement by electrical

impedance, airflow by nasal thermistor, and heart rate by EKG. Central apnea is, as the name implies central in origin, characterized by cessation of respiratory effort and airflow and is related to immaturity of the respiratory control center. Obstructive apnea is characterized by cessation of airflow despite continued respiratory movement and is believed to be related to poor pharyngeal muscle tone, especially during REM sleep. The majority of apneas are mixed with central apnea preceded or followed by obstructive apnea. These events represent a continuum and are the result of a complex interaction of airway obstruction and central respiratory depression: central apnea leading to hypoxemia results in relaxation of the pharyngeal muscles and the resulting airway obstruction will prolong the duration of apnea. Airway obstruction in turn produces desaturation with resulting depression of central respiratory control. Most such events are self-limited and terminated eventually by arousal, but in some infants, active intervention is required when the normal arousal mechanisms fail and the infant enters a state of severe bradycardia and hypoxemia.

Treatment of apnea should be guided by an assessment of the predominant nature of the apneic events. Methylxanthines are a mainstay of therapy for central apnea. Caffeine has now been shown to be safe and in fact was associated with improved neurodevelopment and lower incidence of BPD. Adjunctive treatments include continuous positive airway pressure (CPAP), which helps maintain lung volume and counteract the REM sleep-related chest wall distortion issues, as well as reduce airway obstruction by providing distending pressure that helps maintain pharyngeal patency. Nasal cannula flow may serve the same function, though perhaps less effectively. Avoidance of hypoxemia is important in reducing central apnea, but possible benefit of higher oxygen saturation targets must be weighed against adverse consequences of oxygen exposure. Lower environmental temperature has been shown to reduce apnea in preterm infants. Although acid reflux is capable of triggering reflex apnea and bradycardia, there are no studies that have established a causative relationship between gastroesophageal reflux and apnea/bradycardia in the preterm infant and no studies that have demonstrated benefit of anti-reflux drugs.

Controversy persists regarding the question of whether the episodes of apnea/bradycardia/desaturation are associated with neurodevelopmental sequelae. Clearly, since most preterm infants experience a substantial number of such events, harm, if any, is minimal with the commonly seen brief episodes. However, alterations in cerebral oxygenation have been documented and there is substantial concern that more prolonged and profound episodes are likely to lead to some degree of cumulative harm. It is unclear whether the improved neurodevelopmental outcome seen in the caffeine-treated infants in the CAP trial reflects a decrease in such episodes or is due to the lower incidence of BPD; the frequency of apnea was not documented in that study.

Persistent apnea is often the last remaining condition that delays discharge. There is no uniform approach to judging an infant's readiness for discharge. Most clinicians rely on an apnea-free interval of 5–7 days as indicative of a safe discharge to home care without the need for home monitors. However, it has been demonstrated that only 33–50% of apnea or bradycardia events recorded by bedside pneumograms are documented by nursing staff, raising a question about the reliability of this approach. The alternative is to perform screening pneumogram recordings on all infants with history of apnea. This approach is also controversial, as most infants will continue to have some events well past the stage when clinical symptoms are apparent and these recordings have not been shown to have good predictive value. Because most apnea resolves prior to 37 weeks postmenstrual age, it is customary to discontinue methylxanthines when an infant reaches 34–36 weeks and observe. It must be understood that these are long-acting drugs that require several days to drop below therapeutic levels. If symptoms recur, pharmacotherapy is restarted and if effective, the infant may be discharged home with outpatient follow-up.

The Infant with Respiratory Distress

Respiratory distress is a common presenting sign in newborn infants with potentially life-threatening implications. In considering the approach to such infants, it is important to recognize that the underlying cause may not be limited to the respiratory tract. Respiratory distress may be a nonspecific manifestation of neurologic, cardiovascular, metabolic, hematologic, or neuromuscular disorders, as well as reflection of sepsis, drug withdrawal, and other conditions such as severe anemia (*Table 15.2*).

The diagnostic approach begins with obtaining a good medical history focusing on potential risk factors for any of the possible etiologies. Is the infant term, preterm or postmature? Was there any difficulty at birth? What was the route of delivery? When did the signs begin? Was the amniotic fluid stained with meconium or blood? Was it foul smelling? Maternal history may offer important clues to possible infection, maternal medical conditions, intrauterine medication exposure, or family history of heritable disorders. A thorough physical examination needs to focus

Table 15.2
Differential diagnosis of respiratory distress in newborn infants

Major category	Subcategory	Examples
Pulmonary	Airway	Laryngeal web, tracheomalacia, TE fistula, vascular ring
	Congenital	Hypoplasia, CDH, CCAM, sequestration, lobar emphysema
	Developmental	RDS, TTN, pulmonary insufficiency of prematurity
	Aspiration	Meconium, blood, amniotic fluid
	Miscellaneous	Pneumothorax, pulmonary hemorrhage, pleural effusion
Cardiac	Structural heart disease	Transposition, anomalous venous return, coarctation
	Pulmonary hypertension	Primary, secondary
	Myocardial dysfunction	Myocardiopathy, myocarditis, asphyxia
	Hypovolemia/shock	Hemorrhage, capillary leak, sepsis
	Congestive failure	PDA, VSD, A-V malformation, severe anemia
Infectious	Sepsis	Group B strep, *E. coli*
	Congenital pneumonia	Bacterial, viral, chlamydia
Metabolic	Hypoglycemia	Infant of a diabetic mother
	Severe acidosis	Lactic acidosis, inborn errors
	Polycythemia	
Neuromuscular	CNS depression	Anesthetic, narcotic analgesics, asphyxia
	Nerve injury	Phrenic nerve, laryngeal nerve
	Muscle weakness	Muscular dystrophy, MgSO4
	Anterior motor neuron	Werdnig Hoffman, spinal muscular atrophy
Skeletal	Asphyxiating thoracic dystrophy	Thanatophoric dwarfism
		Camptomelic dwarfism
	Rib fractures	Severe osteogenesis imperfecta

not only on the evaluation of breath sounds, but also the general appearance and activity of the infant, the nature of respiratory efforts, adequacy of the circulatory status, and coexisting physical findings in other organ systems. The history and physical exam will then guide the next steps in the evaluation, which will likely include a chest radiograph, evaluation for possible infection, a basic chemistry panel including glucose, plus additional studies based on clues from the H&P. Cardiology consultation may be appropriate if there is suspicion of cardiac anomaly based on clinical findings of a murmur, congestive failure, abnormal pulses, cyanosis out of proportion to the degree of distress, or abnormal cardiac shape on chest radiograph. Pulse oximetry now provides a quick assessment of the oxygenation status of the infant and will also detect a pre- and post-ductal saturation gradient that may be indicative of heart disease or persistent pulmonary hypertension.

While general supportive measures, including provision of supplemental oxygen when needed, thermal support, and provision of adequate fluid and calories, are common to all infants with respiratory distress, specific intervention depends on accurate diagnosis. In the majority of infants, the respiratory illness will be self-limited with full recovery, but management and outcome depend heavily on the underlying cause. The pulmonary causes of respiratory distress will be reviewed in the following paragraphs.

Specific Respiratory Disorders

Transient Tachypnea/Delayed Transition

Definition: Transient tachypnea of the newborn (TTN) is a usually benign condition associated with delayed clearance of lung fluid after birth.

Etiology/Pathogenesis: TTN typically occurs in term or late preterm infants and is greatly increased in infants born

by elective cesarean delivery. The process of lung fluid reabsorption normally begins prior to the onset of spontaneous labor and is greatly accelerated during labor. Infants who do not benefit from this normal process are at a distinct disadvantage and require a longer time to achieve adequate fluid clearance, because they have a substantially larger volume of fluid to clear and have not initiated this process in utero. The exact mechanism responsible for changing the lung epithelium from a Cl-secretory to a Na-reabsorption mode is the subject of intense study. Postnatally, lung fluid is taken up by the lung lymphatics and capillaries by a process mediated by the epithelial Na channels (ENaC). These mechanisms are less effective in the preterm infant and also vary among full-term infants, explaining the variation in the presence and extent of delayed fluid clearance.

Epidemiology: The true incidence of TTN is unknown as milder forms are often unreported. TTN account for a substantial number of admissions to NICUs, especially where the rate of cesarean section and late preterm delivery is high.

Clinical Manifestations: TTN presents with tachypnea, occasionally grunting respirations, and minimal retractions. The oxygen requirement, if any, is usually no more than 30%. The onset is shortly after birth and the signs resolve within a few hours to 2–3 days. Occasionally, TTN may be accompanied by persistent pulmonary hypertension (PPHN) with a high oxygen requirement out of proportion to the degree of lung disease and this can become a life-threatening illness, discussed further under PPHN.

Diagnosis: The presence of a compatible history, absence of infection, and a benign clinical course may be sufficient to establish the diagnosis. The chest radiograph may show hazy lung fields, but good lung expansion (as opposed to the loss of lung volume in respiratory distress syndrome), but more classically reveals streaky increased perihilar lung markings due to engorged lymphatics. The lung volume is normal or increased. Blood cultures, leukocyte counts, and other tests to rule out infection may be indicated.

Differential Diagnosis: TTN must be distinguished from respiratory distress syndrome (RDS), pneumonia, aspiration syndromes, and all the other common causes of respiratory distress.

Treatment: Treatment is supportive with provision of supplemental oxygen if hypoxemia is present, maintenance of temperature and provision of fluids/nutrition if the distress is severe enough to preclude oral feeding. There is no contraindication to breastfeeding of the tachypneic infant, as long as the distress is mild and the infant is not exhibiting desaturation during feeding. Nasogastric tube feeding is usually well tolerated. Continuous positive airway pressure is often used in these infants, but this practice is not evidence-based or physiologically sound, since the etiology of TTN is not specifically addressed by increased distending airway pressure. Antibiotics may be appropriate until infection has been ruled out.

Prognosis: The clinical course is usually benign and the signs resolve quickly. Duration and severity greater than described above should prompt a reevaluation of the diagnosis.

Prevention: Avoidance of elective cesarean delivery without labor would reduce the incidence dramatically. There are no other known prevention strategies.

Respiratory Distress Syndrome (RDS)

Definition: RDS is a specific disorder that occurs almost exclusively in preterm infants and is due to deficiency, inactivation, or dysfunction of pulmonary surfactant. It is not to be confused with "respiratory distress," which is merely a clinical sign. RDS is synonymous with the older term "hyaline membrane disease" (HMD).

Etiology: RDS results from functional deficiency of pulmonary surfactant, the surface tension lowering substance produced in type II pneumocytes.

Epidemiology: The incidence of RDS is inversely proportional to gestational age and is higher in male infants, those born by cesarean section, and in infants of mothers with diabetes. RDS is rare, but can occur in early-term infants and becomes progressively more common in late preterm, preterm and extremely preterm infants. Reported rates of RDS range from 80% in infants $<$26 weeks to 50% at 26–28 weeks, and under 30% at 30–32 weeks. RDS is the most common cause of respiratory failure in preterm infants. It is estimated that approximately 25,000 cases of RDS occur in the United States alone and it is known to occur in all races and regions of the world, though precise statistics are unavailable. Genetic variations underlying individual variation in susceptibility to RDS for individuals of the same gestational age are the subject of intense study.

Pathogenesis: Surfactant is a complex mixture of phospholipids and four types of surfactant-associated proteins. Surfactant lines the terminal air sacs and reversibly lowers the surface tension at the air–liquid interface, allowing alveoli of different sizes to coexist. In the absence of sufficient amount of functional surfactant, smaller alveoli, which require greater pressure to remain

open, will empty into larger alveoli, leading to diffuse microatelectasis. Atelectasis results in further surfactant inactivation, worsening lung compliance, increased pulmonary vascular resistance, increased ventilation/perfusion mismatch, and hypoxemia. Anatomical immaturity of the lung coexists with RDS in the very preterm infants and contributes to their respiratory insufficiency. Surfactant-associated protein B (SP-B) and to a lesser degree surfactant-associated protein C (SP-C) are necessary for adequate surfactant function. Rare mutations in SP-B and SP-C and ATP-binding cassette transporter *A3* (*ABCA3*) genes lead to severe, often fatal cases of RDS in term infants.

Clinical Manifestations: Infants with RDS present with tachypnea, cyanosis, grunting, subcostal and intercostal retractions, and nasal flaring. Oliguria with mild generalized edema may be present. Oxygen requirement may increase rapidly and is typically higher than that seen in infants with TTN. The natural course of the disease is worsening in the first 24 h, followed by stabilization and recovery by 72–96 h, usually heralded by spontaneous diuresis. In the modern era, this course is modified by therapeutic interventions.

Diagnosis: Typical clinical signs coupled with a characteristic appearance on chest radiograph of "ground glass" parenchymal opacification, air bronchograms, and decreased lung volume are sufficient to establish the diagnosis.

Differential Diagnosis: RDS must be distinguished from TTN, spontaneous pneumothorax, sepsis, and pneumonia. The clinical and radiographic presentation of RDS and group B streptococcus pneumonia are often indistinguishable. Other, less common etiologies listed previously should be considered when the clinical picture is atypical.

Treatment: Mild cases only require supplemental oxygen and supportive treatment as described above. Continuous positive airway pressure (CPAP) is helpful in preventing or reversing the diffuse microatelectasis and maintaining FRC. Surfactant replacement therapy has become standard of care in industrialized countries for infants who require mechanical ventilation and for those deemed at very high risk of RDS, namely, those below 27 weeks GA. More recently, it has been demonstrated that even very premature babies can be effectively treated with CPAP without surfactant replacement with similar results to those treated with mechanical ventilation and surfactant. This is particularly encouraging news for practitioners in resource-limited settings, as bubble CPAP can be delivered with very simple equipment. Surfactant replacement therapy, noninvasive respiratory support, and mechanical ventilation are covered in greater detail elsewhere in this Section.

Prognosis: Prognosis depends on gestational age and the presence of complications, many of which are a function of prematurity, rather than directly related to RDS, but all tend to occur more frequently in infants with RDS. Complete recovery is the rule in infants >30 weeks gestation with uncomplicated disease. In contrast, extremely preterm infants of 26 weeks or below often progress to bronchopulmonary dysplasia, discussed in more detail below. Mortality directly attributable to RDS is relatively low even in extremely low birth weight infants – more commonly, these infants succumb to sepsis, intraventricular hemorrhage, or pulmonary hemorrhage.

Prevention: Antenatal administration of betamethasone or dexamethasone at least 48 h prior to preterm birth dramatically lowers mortality and morbidity from RDS, as well as other complications of prematurity. Early application of CPAP in the delivery room and avoidance of excessive tidal volume with positive pressure ventilation can prevent inactivation of the marginal surfactant pool present in preterm newborns.

Meconium Aspiration Syndrome (MAS)

Definition: MAS refers to a clinical syndrome of respiratory distress associated with aspiration of meconium into the lungs before, during, or immediately after delivery.

Etiology: Fetal hypoxemia associated with placental insufficiency or limited fetal reserve leads to passage of meconium into the amniotic fluid prior to delivery. Subsequent gasping inspiratory effort caused by continued fetal distress leads to aspiration of meconium in utero. Rarely, aspiration of meconium present in the upper airway may occur after delivery. This only occurs in depressed infants, because vigorous infants are able to protect their airway against aspiration.

Epidemiology: Approximately 10–15% of all term deliveries have meconium stained amniotic fluid (MSAF). Passage of meconium is rare in preterm infants but occurs in as many as 33% of deliveries beyond 42 weeks gestation. Only about 5% of infants born through MSAF will have aspirated the material into their lungs and develop symptoms of MAS. A recent study from Australia and New Zealand reported an overall rate of MAS requiring mechanical ventilation of 0.43 per 1,000 live births.

Pathogenesis: Particulate meconium leads to partial or complete obstruction of the airways. Partial obstruction often results in hyperinflation, as air passes beyond the obstruction during inspiration when the airway dilates,

but it is trapped behind the obstruction on exhalation when the airway collapses around the obstruction, causing a ball-valve effect. Complete obstruction results in distal reabsorption and atelectasis. These events result in the typical radiographic picture of patchy atelectasis with areas of overexpansion. More dilute meconium that reaches the distal air spaces inactivates surfactant and leads to a picture similar to RDS with diffuse haziness and decreased lung volumes. Subsequently, the inflammatory response to the various components of meconium mediated by release of cytokines leads to alveolar and airway edema with release of protein-rich edema fluid further inactivating surfactant. Ventilator-induced lung injury may worsen the condition further, especially when aggressive hyperventilation is applied to treat PPHN, a practice no longer recommended.

Clinical Manifestations: Infants often appear dysmature with loose, peeling skin, greenish-yellow staining of the umbilical cord, nails, and skin. They present with tachypnea, nasal flaring, retractions, cyanosis, coarse rales, and rhonchi. There may be a barrel-shaped appearance of the chest related to air trapping or pneumomediastinum. Perinatal depression and PPHN often coexist as do complications of IUGR.

Diagnosis: The diagnosis is made in the presence of history of MSAF, respiratory distress, and radiographic changes. The radiographic appearance may be highly variable and changes over time. In the acute phase of MAS with particulate meconium, there is a typical patchy infiltrate with air trapping and increased lung volume, often accompanied by airleak. Where surfactant inactivation is the predominant pathophysiologic mechanism and in later stages of chemical pneumonitis, the chest radiograph may show homogeneous opacification with normal or low lung volume. Recovery of meconium from the trachea with suctioning confirms the diagnosis, but is not always present.

Differential Diagnosis: Because MSAF occurs in 10% of all deliveries, infants with other causes of respiratory distress may well have a history of MSAF. Most commonly, the dilemma is between MAS and TTN. The chest radiograph of an infant with TTN may be very suggestive of MAS; the differentiation rests on rapid clearance of the "infiltrate" in the infant with TTN, whereas meconium pneumonitis persists radiographically for many days. Other etiologies of respiratory distress, including infection, structural abnormalities of the lungs or airways, need to be considered.

Treatment: Supplemental oxygen, CPAP and mechanical ventilation may be required in that sequence if the severity of the illness is sufficient to require these steps. Avoidance of hypoxemia is important because of the propensity of these infants to develop PPHN. Hyperoxia does not offer any benefit over normoxia (PaO_2 50–70 mmHg); it may increase pulmonary artery vasoreactivity and blunt the response to inhaled nitric oxide if PPHN develops. Suctioning of the airway should be done judiciously, because each time the infant is suctioned, lung volume recruitment is lost. Saline lavage of the airways is ineffective and is not recommended. Surfactant replacement therapy is warranted because of the surfactant inactivation caused by meconium. Larger doses and repeated application may be necessary. Surfactant preparations that are more resistant to degradation by meconium may be preferred. Lung lavage with dilute surfactant may be effective, but is difficult to perform and not always well tolerated by the infant. Steroids may be effective in supressing the inflammatory and may reduce the severity of the disease process. However, their safety in this context has not been established. Antibiotics are indicated, typically for a 5–7-day course, because the aspirated material may have bacterial contamination and meconium may enhance bacterial growth. When mechanical ventilation is required, care must be taken to set an adequate inspiratory and expiratory time because infants with MAS have increased airway resistance and are thus prone to air trapping; therefore, rapid respiratory rates are to be avoided. Moderate PEEP of 4–7 cmH_2O is appropriate, despite evidence of overexpansion. This is because the distending expiratory pressure helps maintain airway diameter during expiration and decreases the ball-valve effect. When surfactant inactivation predominates and diffuse atelectasis is present, even higher PEEP of up to eight or more cmH_2O may be needed. High-frequency ventilation is widely used in infants with MAS with some objective evidence of benefit, but care must be taken to use lower frequencies to avoid air trapping. With very severe disease, especially when complicated by PPHN, rescue with extracorporeal life support (ECMO) may be required, where available – see Chap. 22, "ECMO".

Prognosis: With modern newborn intensive care, MAS is now rarely fatal, though it is occasionally associated with chronic lung disease. In a resource-limited setting MAS remains an important cause of morbidity and mortality. Associated PPHN increases mortality substantially.

Prevention: Avoidance of postmaturity is effective in reducing the number of infants at risk. Routine suctioning of the trachea after delivery is no longer recommended for vigorous infants, but remains an important preventive measure in depressed infants. Amnioinfusion has not been shown to reduce incidence or severity of MAS.

Persistent Pulmonary Hypertension of the Newborn (PPHN)

Definition: Persistent pulmonary hypertension of the newborn is a clinical syndrome, peculiar to the early neonatal period, characterized by severe arterial hypoxemia caused by increased pulmonary vascular resistance (PVR) with resultant right-to-left shunting of deoxygenated blood through fetal channels.

Etiology: Pulmonary hypertension of the newborn may be a primary disorder in infants with no associated lung disease, or secondary to a variety of disease conditions. Some of these are associated with hypoplasia of the lung parenchyma and decreased number of pulmonary arteries (i.e., pulmonary hypoplasia or CDH). Most commonly it occurs in infants with normal lung parenchyma and pulmonary vasculature because of a failure to make the normal transition at birth to decrease PVR (maladaptation). This may occur in intrapartum asphyxia, meconium aspiration syndrome, infection, and RDS. Cesarean delivery substantially increases the risk of PPHN due to maladaptation. Chronic intrauterine hypoxia causes pulmonary smooth muscle remodeling with increase in resistance across the vessels (maldevelopment). Severe polycythemia with sludging of blood in the pulmonary vessels can increase PVR. Recent evidence suggests that exposure to selective serotonin reuptake inhibitors (SSRIs) during late gestation is associated with a sixfold increase in the prevalence of PPHN. Pulmonary hypertension associated with severe bronchopulmonary dysplasia is a separate entity, but shares some of the same clinical features.

Epidemiology: Severe persistent pulmonary hypertension of the newborn affects approximately 1–2 infants per 1,000 live births, but some degree of transient pulmonary hypertension complicates the course of >10% of all neonates with respiratory failure. PPHN is typically seen in term infants with MAS, respiratory distress syndrome, sepsis, and congenital diaphragmatic hernia. Idiopathic pulmonary hypertension is responsible for only 10–20% of all infants with PPHN. Thought less common, PPHN may occur in preterm infants, especially in the presence of pulmonary hypoplasia due to prolonged preterm rupture of the membranes with prolonged oligohydramnios, CDH, or with sepsis.

Pathogenesis: High pulmonary vascular resistance (PVR) is the normal condition in utero. With the clamping of the umbilical cord at delivery, systemic vascular resistance increases and PVR begins to fall in response to alveolar expansion, clearance of lung liquid, decreasing carbon dioxide tension, and increasing oxygen tension. These changes are mediated by nitric oxide and prostacyclin pathways that cause pulmonary vascular smooth muscle relaxation. This reverses the fetal shunts and allows increasing blood flow to the lungs. The failure to achieve this normal circulatory transition is the fundamental problem in infants with PPHN.

Pulmonary hypoplasia is associated with a decrease in the number and cross-sectional area of pulmonary blood vessels with increased muscularization of pulmonary arterioles and increased vasoreactivity. Chronic fetal hypoxia induces vascular remodeling with increased smooth muscle proliferation resulting in thickening of the media and increased PVR. Premature closure of the ductus arteriosus from exposure to non-steroidal anti-inflammatory agents in the third trimester causes structural remodeling of the peripheral pulmonary vascular bed, resulting in PPHN. Maladaptation or failure to establish adequate vasorelaxation at birth from intrapartum asphyxia, meconium aspiration syndrome, and respiratory distress syndrome or release of vasoactive mediators that may contribute to pulmonary vasoconstriction as a result of infection leads to sustained high PVR and severe hypoxemia. Elective cesarean delivery without labor is associated with a slower fall in pulmonary vascular resistance and increased incidence of PPHN, because the normal process of labor leads to changes in the elaboration of mediators of vascular tone and prepares the fetus for successful transition to extrauterine life.

Clinical Manifestations: Severe hypoxemia out of proportion to the degree of lung disease is the hallmark of PPHN, often presenting as cyanosis and respiratory distress within a few hours of birth in a term or late preterm infant. Classically, there is great lability of oxygen saturation with frequent desaturation with any stimulation or stress and there may be a history of MSAF, fetal distress during labor, or antenatal ultrasound findings of CDH.

Diagnosis: The diagnosis of PPHN is suggested by the presence of cyanosis/labile hypoxemia and respiratory distress out of proportion to any lung disease that may be present. Examination of the heart sounds may reveal a harsh systolic murmur with a loud S2 secondary to tricuspid regurgitation. Pulse oximetry will demonstrate the severity of the hypoxemia. Simultaneous monitoring of pre-ductal (in the right hand) and a post-ductal (in any lower extremity) oxygen saturation may show significantly lower post-ductal saturation. This is a reflection of right-to-left shunting across the PDA, a finding also seen in neonates with a duct-dependent cyanotic heart lesion, coarctation of the aorta, or interrupted aortic arch. Consequently, pulse oximetry does not reliably differentiate PPHN from cyanotic heart disease. Additionally, if the ductus arteriosus is closed, no gradient will be seen,

because the shunting may be at the atrial level. CXR may show evidence of MAS, pneumonia, diaphragmatic hernia, or the pulmonary hypoplasia. In primary PPHN, the lung fields look clear and oligemic, similar to cyanotic heart disease with decreased pulmonary blood flow. Definitive diagnosis is made by echocardiography. This will help rule out cyanotic heart disease and identify signs of pulmonary hypertension. Echocardiogram typically shows right-to-left or bidirectional shunting across the PDA and PFO, tricuspid regurgitation, and flattening of the interventricular septum as a result of increased right ventricular pressure. By using peak velocity of the tricuspid regurgitant flow, it is possible to estimate pulmonary artery pressure. Echocardiogram is also vital in evaluating ventricular filling and ejection as sudden decompensation in neonates with PPHN can often be caused by poor myocardial function and right heart failure. Because in most infants the PVR is quite labile, the evidence of pulmonary hypertension may not be clear if the echocardiogram is done at a time the infant is responding to treatment and oxygenating well.

Differential Diagnosis: PPHN must be distinguished from cyanotic heart disease and severe parenchymal lung disease. When PPHN and severe lung disease coexist, it may be difficult to determine the relative contribution of pulmonary hypertension, in part because hypoxia and atelectasis itself increases pulmonary vascular resistance. Clinically, this may be done with the hyperoxia test. Briefly increasing the FiO2 to 1.0 will have no effect on oxygen saturation in an infant with a fixed intracardiac right-to-left shunt caused by cyanotic heart disease. A modest improvement in oxygenation is seen in infants with parenchymal lung disease and a dramatic improvement is often (but not always) seen when PPHN is the predominant cause of hypoxemia. Echocardiography will usually establish the diagnosis, but partial anomalous pulmonary venous drainage, which presents clinically with very similar findings, may be difficult to diagnose by echocardiography.

Treatment: Treatment of PPHN is focused on lowering pulmonary vascular resistance, supporting systemic blood pressure to keep it above pulmonary pressure, and providing gentle respiratory support in order to avoid complications, as the elevated PVR will eventually fall in most patients. Systemic blood pressure support can be achieved by judicious use of crystalloids (e.g., normal saline) in boluses of 10–20 mL/kg to improve circulating blood volume. This and the appropriate use of inotropic agents improve cardiac output and systemic blood pressure. Excessive use of saline can lead to volume and sodium overload. With adequate preload, the inotropic agents dopamine and dobutamine improve cardiac contractility and output. The use of epinephrine and higher doses of dopamine increase peripheral vascular tone and raise systemic blood pressure. Care should be exercised in the use of these agents, as they can be associated with tachycardia, arrhythmia, increased afterload, myocardial ischemia, and may increase PVR. Milrinone is a useful agent in PPHN, because it provides positive inotropic effect, does not cause systemic vasoconstriction, and achieves pulmonary vasodilatation because it inhibits phosphodiesterase 3, the enzyme that breaks down cyclic AMP.

Respiratory stabilization may require intubation and mechanical ventilation with the goal of providing sufficient mean airway pressure to achieve optimal lung volume, improve ventilation/perfusion matching, and lower pulmonary vascular resistance. Adequate oxygenation and avoidance of hypoxemia minimize pulmonary vascular resistance but supraphysiologic arterial oxygen tension should be avoided. Pulmonary vascular resistance only increases with PaO2 below 50 torr and no further fall in PVR is seen at PaO2 above 70 torr. Exposure to hyperoxia even for short periods of time increases oxidative stress and actually increases vasoreactivity of the pulmonary vessels and blunts response to inhaled nitric oxide (iNO). Target PaO2 therefore should be in the range of 60–80 torr. Acidosis increases PVR and should generally be avoided in patients with PPHN. Slightly alkaline arterial blood pH between 7.4 and 7.5 may be needed in some patients whose pulmonary hypertension fails to improve with more conservative ventilation and other appropriate therapies, including iNO. However, the practice of hyperventilation to achieve significant respiratory alkalosis is associated with increased likelihood of hemodynamic impairment, lung injury, chronic lung disease, and neurologic sequelae and is no longer recommended. The goal should be to maintain physiologic PCO2 between 35 and 45 torr. The use of alkali infusion (sodium bicarbonate) to increase blood pH has been used to reduce the need for respiratory alkalosis, but was associated with increased need for ECMO rescue in a large retrospective study. The choice of conventional ventilation or high-frequency ventilation (HFV) depends on availability and the underlying disease condition. HFV may offer advantages in patients with pulmonary hypoplasia, congenital diaphragmatic hernia, and airleak syndromes, and may be useful in achieving optimal lung inflation. Intravenous vasodilators have been used in the past, but lack specificity for the pulmonary circulation and generally have been ineffective. There is no sound evidence to support the widespread use of MgSO4 to treat pulmonary hypertension. Inhaled nitric oxide (iNO) has been studied extensively and is currently

the only specific pulmonary vasodilator approved for treatment of PPHN. Nitric oxide (NO) is generated by NO synthase from L-arginine. NO then activates guanyl cyclase leading to the production of cyclic GMP, which causes relaxation of the vascular smooth muscle by decreasing cytosolic calcium concentration. The use of iNO in doses of up to 20 PPM improves oxygenation and decreases the risk of death or need for ECMO by up to 50%, except in neonates with congenital diaphragmatic hernia in whom no significant benefit was demonstrated. Doses of iNO greater than 20 PPM do not result in greater efficacy but are associated with higher toxicity. iNO is most effective when the circulatory status and pH have been optimized and adequate lung expansion has been achieved. iNO in combination with HFV may be more effective than iNO used with conventional ventilation in infants with significant lung disease. Traditionally, iNO is started at oxygenation index (OI) levels of 25 or above; ($OI = [(F_IO_2 \times Paw)/PaO_2] \times 100$), where Paw is mean airway pressure and F_IO_2 is the fraction of inspired oxygen. However, when PPHN persists despite optimized ventilatory and hemodynamic support, iNO use at lower OI appears justified. Response to iNO should be evident within a short period of time when pH and perfusion have been optimized first. Treatment should be weaned as soon as possible after the FiO_2 has decreased to 70% or less by decrements of 5 PPM, down to 5 PPM, and more slowly thereafter with the goal of weaning from iNO by 3–4 days. Prolonged exposure to iNO will suppress endogenous nitric oxide production and make it more difficult to discontinue the drug. Although iNO has been shown to be safe and effective in the treatment of PPHN, it is expensive and not readily available everywhere. Sildenafil, a phosphodiesterase five inhibitor improves oxygenation in patients with PPHN. Sildenafil decreases the degradation of cyclic GMP resulting in higher concentrations of cyclic GMP locally, which in turn leads to relaxation of pulmonary vascular smooth muscles. Its lower cost and greater availability has made sildenafil very attractive to clinicians with no access to iNO. Despite the absence of definitive studies to determine the safest effective dose and to evaluate its safety profile in neonates, this drug is widely used in less affluent countries.

The general care of infants with PPHN is crucial to optimizing outcome. Correction of acidosis, glucose and other electrolyte derangements, aggressive treatment of sepsis, circulatory support, correction of coagulopathy, and institution of appropriate supportive treatments for perinatal asphyxia are vital determinants of response to treatment and survival. Minimal handling and use of adequate sedation/analgesia to avoid agitation are very important. Although routine use of paralytic agents is not recommended, at times they may be necessary to control agitation. Up to 40% of patients with PPHN and most infants with CDH do not respond to iNO. In these patients, ECMO is the ultimate rescue treatment and should be instituted while the infant has some degree of stability. It is vital for clinicians to recognize early those patients who are nonresponders to iNO and anticipate the need for ECMO where available. Institutions that do not have ECMO as a treatment option readily available should perhaps consider how nitric oxide is used and be prepared for early transfer of nonresponders to an ECMO center.

Prognosis: Prognosis in PPHN depends on the underlying diagnosis, response to treatment, and availability of rescue therapies. Mortality has been reduced to $<5\%$ with more optimal ventilatory support, iNO, and ECMO, but remains high where these advanced therapies are not available. An early and sustained response to inhaled nitric oxide is associated with clinical improvement and better outcomes. Patients with perinatal asphyxia, pulmonary hypoplasia, and CDH often have the worst prognosis. Residual chronic lung disease and/or sensorineural hearing loss have been reported to correlate with duration of hyperventilation.

Prevention: Many infants that develop PPHN exhibit signs of respiratory distress early in their course. Progression of respiratory disease with failure to establish adequate oxygenation and ventilation will impair the normal newborn transition and lead to the persistence of high PVR leading to PPHN. Recognition of infants with early respiratory disease and acting quickly to provide adequate respiratory support to maintain good oxygenation may reduce the progression to hypoxemic respiratory failure and PPHN. Many infants that develop PPHN were born late preterm via elective C-section who then exhibit signs of surfactant deficiency or retained lung fluid that can progress to PPHN. Avoiding elective delivery before 38 weeks of completed gestation will significantly reduce respiratory morbidity in this subgroup of patients. Prenatal ultrasounds are now able to readily identify infants with oligohydramnios and CDH so that delivery can occur in a tertiary center where optimal treatments can be instituted early.

Airleak Syndrome

Definition: Pulmonary airleak is defined as accumulation of air outside of the airway and alveolar space. Depending on the location of the air it may be described as a pneumothorax, pneumomediastinum, pulmonary

interstitial emphysema (PIE), pneumopericardium, or subcutaneous emphysema.

Etiology: Airleaks are caused by over-distension of alveoli or terminal bronchioles with resultant rupture and escape of air into the interstitium. Spontaneous pneumothorax can occur soon after birth due to the high pressures generated by the baby taking their first breaths. High positive airway pressure used during resuscitation may also cause airleak. Most airleaks are associated with lung diseases such as RDS, meconium aspiration syndrome, pneumonia, pulmonary hypoplasia, and congenital diaphragmatic hernia. The majority of airleaks are associated with mechanical ventilation, particularly with the use of inappropriately high inspiratory pressure or tidal volume, use of unsynchronized ventilation. Direct injury to the trachea or airway can occasionally result from suctioning through the endotracheal tube (ETT), use of introducers through the ETT for their placement, or central venous catheter placement.

Epidemiology: The overall incidence of airleaks in term infants is about 1%, although only about 10% of these are symptomatic. The incidence of airleak is significantly higher in preterm infants requiring mechanical ventilation and was reported to occur in 3–13% of infants less than 28 weeks gestation born between 2003 and 2007 from the NICHD Neonatal Research Network centers. PIE is predominantly seen in the extremely low birth weight infant with RDS on mechanical ventilation with a reported incidence of 3–5%.

Pathogenesis: The development of airleak starts with over-distension of alveoli or terminal bronchioles with subsequent rupture and escape of air into the interstitial tissue. This free air then tracks along the bronchial and vascular sheaths to the hilum of the lung. The air can escape into the mediastinum producing a pneumomediastinum or dissect through the visceral pleura producing a pneumothorax. A pneumopericardium may develop when the air dissects into the pericardial sac usually in association with a pneumothorax in ventilated infants. Free air in the mediastinal space can track into the subcutaneous tissues of the neck or chest wall as subcutaneous emphysema or into the abdomen causing a pneumoperitoneum. In ELBW infants with pulmonary interstitial emphysema, the lung connective tissue is more abundant and less dissectible, therefore the air remains in the bronchovascular sheaths splinting the alveoli in a state of inflation causing significant ventilation perfusion mismatch by impeding alveolar emptying and pulmonary blood flow.

Clinical Manifestations: The clinical presentation of airleak syndromes is varied from the asymptomatic to sudden acute decompensation depending on the amount of air that has collected and whether it is under tension compressing the lung and other intrathoracic structures. Most cases of pneumomediastinum are not associated with significant clinical symptoms because the air is usually not under tension. Subcutaneous emphysema can be recognized by a "crackly feeling" on palpation of the anterior chest wall or over the neck. Pneumoperitoneum may present with abdominal distension or rarely enlargement of the scrotum in boys. A small pneumothorax in an infant with little or no lung disease can be asymptomatic. This is typical with a spontaneous pneumothorax. Tension pneumothorax presents with respiratory distress, hypoxia, acute respiratory acidosis, and rapid deterioration. Clinical examination will show subcostal retractions, cyanosis, decrease or absence of breath sounds on the ipsilateral side, shift of heart sounds to the contralateral side due to mediastinal shift, and abdominal distention due to downward displacement of the diaphragm. There may be associated hypotension and bradycardia because of impaired cardiac output from impeded venous return. Pneumopericardium may be asymptomatic, but usually presents acute circulatory decompensation due to cardiac tamponade with distant heart sounds on auscultation. PIE is usually encountered in the ELBW infant on mechanical ventilation who has progressive worsening of respiratory status without localizing signs, unless it is unilateral.

Diagnosis: The diagnosis of airleak syndrome should be suspected in any infant with sudden respiratory deterioration particularly those with underlying lung disease on mechanical ventilation or CPAP. A pneumothorax can be diagnosed by the use of a high-intensity fiberoptic light placed firmly against the skin in the midaxillary line or anteriorly in a darkened room. Free air in the pleural space lights up the affected hemithorax. In an emergency when there is clinical suspicion of a pneumothorax thoracocentesis by aspiration of air with a syringe attached to a 23- or 25-gauge butterfly needle or an 20–22 gauge angiocatheter can be both diagnostic and therapeutic. Definitive diagnosis of all airleaks is made by chest x-ray. (Please see the paragraph on airleak in Chap. 21, "Complications of Mechanical Ventilation" for further description).

Differential Diagnosis: Pulmonary airleaks are easily recognizable on CXR although they may be confused with or coexist with other pulmonary diseases like congenital diaphragmatic hernia, cystic adenomatoid malformation, congenital lobar emphysema, and pulmonary abscess. Diminished breath sounds and mediastinal shift to the opposite side may be due to a large pleural effusion,

while diminished breath sounds with shift to the ipsilateral side may be due to atelectasis. In the delivery room, the scenario of a distressed, cyanotic infant with diminished breath sounds on one side and shift of the heart sounds to the other most often is due to a pneumothorax, but a congenital chylothorax or diaphragmatic hernia can have a similar presentation. The key difference is that with tension pneumothorax and pleural effusion the abdomen should be distended, whereas it is flat or scaphoid with diaphragmatic hernia.

Treatment: Most cases of pneumomediastinum, subcutaneous emphysema, and non-tension pneumothoraces cause few symptoms and resolve spontaneously. The patient should be observed for any sudden deterioration in clinical status suggesting worsening accumulation of air. Nitrogen washout with 100% oxygen is not recommended as the toxicity caused by high amounts of oxygen likely outweighs the problems caused by a non-tension pneumothorax. A tension pneumothorax represents a medical emergency and should be treated promptly. Immediate relief can be achieved by thoracocentesis with aspiration of air with a syringe attached to a 23- or 25-gauge scalp vein needle or an 18–22-gauge angiocatheter. Definitive treatment is by insertion of a chest tube into the anterior pleural space attached to underwater seal with continuous suction at 15–20 cm H2O. For infants on mechanical ventilation, the level of support should be evaluated to correct atelectasis by optimizing adequate but not excessive PEEP and reduce PIP/VT to the lowest value consistent with adequate CO2 elimination. High-frequency ventilation has advantages over conventional ventilation in the presence of airleak because adequate MAP can be provided with lower tidal volume and still remove CO2 efficiently. HFJV has unique benefits in the treatment of airleak, specifically PIE and bronchopleural fistula. When HFV is not available, rapid rate and short inspiratory times are preferable. Lateral decubitus positioning of the infant with unilateral PIE, placing the affected lung in a dependent position improves gas exchange and reduces mediastinal shift with faster resolution of PIE. Selective main-stem bronchus intubation is not always well tolerated, but is an effective way of resolving unilateral PIE.

Prognosis: Spontaneous resolution occurs in most infants with pneumomediastinum and pneumothoraces even when they require drainage. Tension pneumothorax is a known risk factor for intraventricular hemorrhage in preterm infants. Failure to recognize and quickly treat the acute hemodynamic compromise caused by tension pneumothorax and pneumopericardium can lead to sudden death. ELBW infants who develop PIE have substantially increased mortality and are at increased risk of developing BPD.

Prevention: Early provision of distending airway pressure in infants with respiratory distress to recruit and maintain optimal lung volume and avoidance of excessive tidal volume are the two steps most helpful in reducing the risk of airleak. Surfactant replacement therapy also reduces airleak. The infant with respiratory distress and progressive atelectasis that is not treated early is more likely to develop an airleak when subsequently placed on positive pressure support because most of the distending pressure will now be delivered to the compliant parts of the lung making them more prone to over-distension and airleak. Therefore early administration of surfactant in preterm infants with RDS and subsequent support with CPAP or mechanical ventilation as appropriate will maintain more uniform lung volume and reduce alveolar injury. Avoidance of hyperventilation with inappropriately high tidal volumes and peak airway pressure will lessen the likelihood of developing airleak. Although PEEP is generally lung protective and helps to achieve more uniform lung inflation, the optimal pressure required to maintain good lung volume should be reassessed frequently by checking lung expansion on CXR and lowering PEEP if the FiO2 is close to room air, as inappropriately high lung volumes can lead to alveolar rupture at peak inspiration and produce airleak. It is not clear that avoidance of mechanical ventilation with the use of noninvasive modes of ventilation reduces airleak; increased rate of airleak was reported in the CPAP arm of the COIN trial. Both volume-targeted ventilation and high-frequency ventilation have been shown to reduce airleak.

Pulmonary Hemorrhage

Definition: Pulmonary hemorrhage is assumed to be present when there is appearance of bloody fluid from the upper respiratory tract or the endotracheal tube (ETT).

Etiology: What is commonly referred to as pulmonary hemorrhage may be true hemorrhage originating in the lung parenchyma or the airways, but much more commonly is actually hemorrhagic pulmonary edema. Risk factors for the development of pulmonary hemorrhage include: extreme prematurity, surfactant treatment of RDS, left to right shunt through a patent ductus arteriosus (PDA), fluid overload, intrauterine growth restriction, hypoxic insults, and generalized coagulopathy.

Epidemiology: The overall incidence of pulmonary hemorrhage is reported to be 1/1,000 live births, but in ELBW infants with RDS it is as high as 4–7%.

Pathogenesis: True hemorrhage may result from trauma or coagulopathy. The more common hemorrhagic pulmonary edema occurs as a result of acute left ventricular decompensation leading to increased pulmonary capillary pressure. Many factors may contribute to acute decompensation, but most commonly this results from increased pulmonary blood flow caused by left to right shunting through a PDA. The association with surfactant therapy is thought to be due to rapid improvement of lung compliance and fall in pulmonary vascular resistance, allowing greater left to right shunt. The preterm myocardium has limited reserve and does not cope effectively with a large volume overload. Hypoxia and acidosis may also lead to decreased left ventricular function with resultant acute increase in pulmonary capillary pressure. Because of this increase in pressure, capillary ultrafiltrate leaks into the pulmonary interstitial space. The fluid is initially drained via the lymphatics, but as these get overwhelmed the fluid ruptures through the alveolar epithelial walls. As the leak worsens red cells and plasma escape into the alveolar space leading to hemorrhagic pulmonary edema. The fluid initially has a frothy bloody appearance and a hematocrit of about 10% but may progress to frank hemorrhage into the lungs. Coagulopathy is usually not present with hemorrhagic pulmonary edema, but does play a part in frank pulmonary hemorrhage in term infants.

Clinical Manifestations: The clinical presentation of pulmonary hemorrhage is usually sudden and catastrophic. Patients are usually ELBW infants on mechanical ventilation for RDS following surfactant therapy and usually have an underlying large left to right shunt via a PDA. Symptoms most commonly appear around the second or third day of life with sudden deterioration in the infant's condition manifested as acute fall in oxygen saturation, loss of chest wall excursion, respiratory acidosis, hypotension, and bradycardia. The appearance of bloody fluid in the ETT may accompany the sudden deterioration, but sometimes is only evident upon suctioning.

Diagnosis: The diagnosis of pulmonary hemorrhage is usually obvious from the clinical presentation and sudden appearance of bloody fluid in the ETT. Chest radiograph will typically show diffuse opacification or a complete "white out." The presence of the usual predisposing factors supports the diagnosis. Air bronchogram may not be seen, however, since the airways may be filled with hemorrhagic fluid.

Differential Diagnosis: Hemorrhagic pulmonary edema must be differentiated from local bleeding due to mucosal trauma. In this instance, the volume of blood is usually small, it does not appear frothy, and is typically not associated with the sudden deterioration seen in hemorrhagic pulmonary edema. The distinction is of critical importance, because the treatment is very different. True pulmonary hemorrhage is much less frequent, but may present with a large amount of almost pure blood in the trachea in the setting of coagulopathy or very high ventilator settings in a larger infant. Obtaining a hematocrit may help differentiate the two conditions, but is usually not necessary.

Treatment: Treatment of hemorrhagic pulmonary edema requires aggressive resuscitation starting with maintenance of adequate gas exchange. The urge to continuously suction blood from the ETT should be resisted, as any loss of distending airway pressure would worsen the hemorrhage. The fluid has low viscosity and will not clot in the airways. The use of PEEP as high as 10–12 cmH2O is the most effective means of stabilizing the patient and reversing the outflow of hemorrhagic fluid. This approach mitigates the left to right shunt through a PDA, promotes uptake of fluid into the pulmonary lymphatics and capillaries, clears the fluid from the airways, and improves lung compliance. Peak pressure adequate to achieve desired tidal volume or chest wall movement should be selected. High-frequency ventilation is often used, because clinicians are more comfortable using higher mean airway pressure with high-frequency devices. However, because of the acute nature of the crisis, changing ventilators may not be optimal; sufficient PEEP will achieve similar results with conventional ventilation. Inotropic support may be beneficial to optimize myocardial contractility, but aggressive volume expansion is contraindicated, because the infant is usually *not* hypovolemic and excessive volume administration may worsen the ventricular failure. Appropriate ventilator management limits intravascular volume loss and the need for replacement. An echocardiogram should be obtained if available and a significant PDA should be treated. Coagulopathy is usually not an issue, but, if present, should be corrected with the use of fresh frozen plasma and/or cryoprecipitate to supply clotting factors as needed. After stabilization, infants may benefit from surfactant replacement, as the hemorrhagic alveolar edema inevitably leads to inactivation of surfactant and secondary surfactant deficiency.

Mucosal bleeding usually subsides spontaneously with avoidance of further trauma. If persistent, coagulopathy/thrombocytopenia should be sought and corrected. Local administration of epinephrine via the endotracheal tube and lavage with iced saline are traditional therapies, although their value is unproven. These measures have *no place* in the treatment of hemorrhagic pulmonary edema.

Prognosis: Pulmonary hemorrhage has traditionally been associated with high mortality of up to 80%. With better understanding of the underlying pathophysiology and more appropriate therapy, the mortality rate has declined to <50%. However, these infants are usually the smallest and sickest, and are at high risk for long-term pulmonary morbidity (chronic lung disease) between 60% and 80% and an increased risk of developing intraventricular hemorrhage and retinopathy of prematurity.

Prevention: The use of prenatal steroids before preterm delivery has reduced pulmonary morbidity significantly including pulmonary hemorrhage. Timely recognition and treatment of a significant PDA will reduce the likelihood of hemorrhagic pulmonary edema, particularly in infants with history of hypoxia and poor left ventricular function.

Pulmonary Hypoplasia

Definition: Pulmonary hypoplasia refers to impaired growth and development of lung tissue and the pulmonary vascular bed.

Etiology: Pulmonary hypoplasia can result from (1) lack of adequate space for the lung to grow either from intrathoracic space occupying lesion, longstanding pleural effusion, or extrathoracic compression (asphyxiating thoracic dystrophies); (2) reduction in fetal breathing movements; and (3) decreased amniotic fluid volume. Rarely, pulmonary hypoplasia may be associated with Trisomy 21 due to reduced numbers of alveoli and a smaller alveolar surface area.

Epidemiology: The true incidence of pulmonary hypoplasia is unknown because many infants with severe pulmonary hypoplasia die in utero, during labor or at birth. The frequency of pulmonary hypoplasia is related to the incidence of underlying causes. In cases of premature rupture of membranes at 15–28 weeks gestation, the reported incidence of pulmonary hypoplasia ranges from 9% to 28%. The occurrence of congenital diaphragmatic hernia (CDH) is estimated at 1/2,500–3,000 live births and cystic adenomatoid malformation (CCAM) 1 per 25,000–35,000 pregnancies. Adding to the difficulty in estimating the frequency is the wide spectrum of severity and presentation.

Pathogenesis: Lung development starts with the ventral outpouching of the primitive foregut to form the lung bud which then subsequently divides and branches through several phases to form the airways and lung parenchyma. Pulmonary vasculature develops in parallel with lung parenchyma. Any physical limitation to the space available for lung growth may impair lung development. This may result from intrathoracic compression (CDH, CCAM, large pleural effusion secondary to hydrops or congenital chylothorax) or extrathoracic compression secondary to skeletal abnormalities (asphyxiating thoracic dystrophy). Fetal lung growth is also dependent on adequate distension of the lung by fetal lung fluid and on fetal breathing movements, which are impaired or absent in conditions such as fetal akinesia syndromes, congenital myopathies, and phrenic nerve agenesis. The fetal kidney produces proline which together with several growth factors found in amniotic fluid aid in lung collagen and mesenchyme formation. As fetal lung liquid pressure is slightly higher than amniotic fluid pressure any decrease in amniotic fluid volume will be associated with loss of lung liquid and a decrease in the distending pressure to the developing lung. Fetal urine is an important component of amniotic fluid and renal agenesis/dysplasia or complete urinary tract obstruction (e.g., posterior urethral valves) is associated with oligohydramnios leading to pulmonary hypoplasia. The severity of lung hypoplasia depends on the timing of the insult in relation to the stages of lung development. The earlier the insult in gestation, the more severe the degree of lung hypoplasia. Physical and histological examination of the hypoplastic lung will show reduced lung weight, fewer generations of airways, decreased number of alveoli with delayed epithelialization, as well as paucity and maldevelopment of the corresponding pulmonary arteries.

Clinical Manifestations: The clinical presentation of infants with pulmonary hypoplasia depends on severity of disease and the underlying cause. In the severe forms, respiratory distress, hypercapnia, and hypoxemia are universal together with signs and symptoms of associated conditions. Infants with CDH may have a scaphoid abdomen and decreased breath sounds on the affected side. Infants with severe oligohydramnios may present with a small chest, contraction deformities such as arthrogryposis, and "Potters facies." Severe hypotonia with a small chest compared to the rest of the body may indicate an underlying central nervous system abnormality. Pulmonary hypertension commonly accompanies pulmonary hypoplasia.

Diagnosis: Most conditions associated with pulmonary hypoplasia can be identified through antenatal ultrasound and magnetic resonance imaging (MRI). The presence of pulmonary hypoplasia should be expected with any of the underlying associated conditions. Chest x-ray after birth will show an underdeveloped "bell shaped" rib cage with decreased lung expansion in patients with history of oligohydramnios or underlying neurologic disease.

Conditions where there is restriction of lung growth from external compression are often unilateral and can be identified on x-ray with the ipsilateral lung affected more than the contralateral lung. Definitive diagnosis of pulmonary hypoplasia requires pathologic examination of the lung to determine lung weight, perform radial alveolar counts, and measure the total lung DNA. Hypoplastic lungs have a decreased number of airway generations, with fewer and smaller peripheral airspaces and decrease in the number and cross-sectional area of pulmonary vessels.

Differential Diagnosis: The degree of pulmonary hypoplasia, if any, may be difficult to determine in milder cases and also when associated with other conditions. Severe RDS with poor lung expansion in a premature infant is difficult to differentiate from pulmonary hypoplasia radiographically. If the lung fields are relatively clear but with very low lung volume, hypoplasia is more likely.

Treatment: Recognition of conditions associated with pulmonary hypoplasia and instituting appropriate resuscitative measures are key to early management. Infants with CDH require immediate intubation with avoidance of facemask ventilation and rapid decompression of the stomach (see ❯ section on CDH). Infants with pulmonary hypoplasia have severely decreased lung compliance requiring higher airway pressure to achieve adequate gas exchange. This, together with the underdeveloped lung parenchyma, places these patients at increased risk of developing an airleak syndrome. Pulmonary hypertension from decreased pulmonary vascular development requires specific therapy as discussed in the section on PPHN. It should be noted that excessive expansion of the hypoplastic lungs will worsen PPHN due to compression of the pulmonary capillaries. Distending pressure should therefore be used with caution. High-frequency ventilation can provide better support with its ability to remove CO2 more efficiently and to treat or mitigate airleak syndromes better than conventional ventilation. In most patients with pulmonary hypoplasia, surfactant replacement therapy has not been shown to be beneficial unless the infant is also premature. Inhaled nitric oxide therapy may only show a transient improvement. Caution should be exercised in considering patients with severe pulmonary hypoplasia as candidates for ECMO, as the degree of lung hypoplasia and pulmonary vascular underdevelopment may not be reversible.

Prognosis: The outcome of infants with pulmonary hypoplasia is dependent on the degree of lung underdevelopment and the nature of the underlying disease. Conditions that hinder lung development early in gestation are associated with more severe hypoplasia and have the worst prognosis. Most infants with severe pulmonary hypoplasia die in utero, during labor, or soon after birth. Associated conditions with poor prognosis include: renal dysplasia, asphyxiating thoracic dystrophy, congenital myopathies, and other neurologic conditions. Surviving patients may go on to develop chronic pulmonary insufficiency requiring long-term care.

Prevention: There are no proven methods of prevention for most of the conditions leading to pulmonary hypoplasia. Animal and human studies have shown that tracheal occlusion in utero will reverse pulmonary hypoplasia but because of the high incidence of preterm deliveries related to this intervention, it has not been widely accepted and remains experimental. In utero placement of pleuroperitoneal shunt to treat pleural effusion and vesicoperitoneal shunt to relieve bladder outlet obstruction has met with mixed success as well.

Congenital Diaphragmatic Hernia (CDH)

Definition: CDH refers to herniation of abdominal contents into the chest through a defect in the diaphragm and the associated pulmonary hypoplasia present at birth.

Etiology: CDH is a developmental abnormality of the diaphragm resulting in a defect with resulting herniation of abdominal viscera into the chest. The diaphragmatic defect occurs when some of the structures making up the fetal diaphragm fail to develop adequately or to fuse by the eighth week post conception. Abnormalities in the retinoic acid signaling pathway may be important in the maldevelopment of the diaphragm early in gestation and may independently contribute to pulmonary hypoplasia.

Epidemiology: CDH occurs in 1/2,500–3,000 live births with a slight preponderance of males (1.5:1 male to female ratio). Recurrence risk for future pregnancies is approximately 2%. Worldwide incidence appears to be the same as that in the United States: 85–90% occur on the left side, 10% and a small number are bilateral. There are two types of diaphragmatic hernias: the posterior Bochdalek hernia accounting for about 95% of the total and the anterior Morgagni hernia for the remaining 5%.

Pathogenesis: In the fetus with CDH, the bowel, sometimes stomach, spleen, or liver herniate into the chest impairing lung development. Lung hypoplasia is thought to be secondary to the in utero compression of the fetal lung. Both the ipsilateral and contralateral lungs are involved, because the herniated abdominal contents cause mediastinal shift. The degree of hypoplasia is often severe on the ipsilateral side with only a minute lung seen in the apex of the chest at surgery. The severity of pulmonary hypoplasia roughly correlates with the size of the

defect, which may range from a small posterior opening to complete agenesis of the hemidiaphragm. Lung hypoplasia involves not just a decrease in lung parenchyma, but a dramatic decrease in the number and cross-sectional area of the pulmonary blood vessels. Additionally, there is abnormal muscularization of the pulmonary arterioles and increased vasoreactivity, which often leads to associated refractory PPHN.

Clinical Manifestations: The severity of respiratory distress is highly variable. Most infants present in the delivery room with cyanosis, retractions, and tachypnea. Breath sounds are decreased on the affected side with shift of the breath sounds to the opposite side – all signs consistent also with the more common problem of spontaneous tension pneumothorax. The key differentiating factor is that the abdomen is distended in the presence of pneumothorax, while it is flat or scaphoid with CDH. Bowel sounds are rarely heard in the chest, but this sign is diagnostic, if present. Some infants have minimal signs initially and may not be recognized for some time. The clinical status often remains reasonably stable for the first 12–24 hours, a period referred to as the "honeymoon," followed by development of severe pulmonary hypertension.

Diagnosis: In industrialized countries, the majority of cases are diagnosed by antenatal ultrasound. Postnatal diagnosis is based on clinical presentation and radiographic confirmation. Initial chest films may not show the classical bowel pattern in the chest, if air has not yet filled the bowel, but may instead just show a water density mass with mediastinal shift.

Differential Diagnosis: CDH must be distinguished from eventration of the diaphragm, pulmonary sequestration, pleural effusion, or cystic adenomatoid malformation involving the lower lobes of the lung. Acutely, it must be distinguished from tension pneumothorax.

Treatment: Immediate intubation with avoidance of facemask ventilation is critical to avoid filling the bowel with air and causing further lung compression. A naso- or oro-gastric tube is rapidly placed for gastric decompression. Muscle relaxation is advocated by some to prevent the infant from swallowing air, but this is not usually needed when effective gastric decompression. Nasal CPAP or high-flow nasal cannula are to be avoided. Pulmonary hypertension is triggered or aggravated by pulmonary overexpansion; therefore distending airway pressure is applied cautiously. Gentle ventilation with either conventional or high-frequency ventilators, allowing moderate permissive hypercapnia and accepting just adequate oxygenation, appears to improve outcome, compared to the more aggressive traditional treatment, even when PPHN is present. Exogenous surfactant does not appear to be beneficial (unless the infant is premature) and was associated with worse outcomes in a large retrospective study. Infants with CDH and PPHN do not usually respond well to inhaled NO, but many show a modest transient improvement.

CDH is no longer considered a surgical emergency, since it is now well recognized that the fundamental problem is the pulmonary and pulmonary vascular hypoplasia, which is not reversed by removing the herniated contents from the chest. In fact it is now clear that early surgery at the time of greatest physiologic instability and highest pulmonary vascular resistance often makes matters worse. The surgical approach now is to await improvement in pulmonary status and delay surgery for 3–7 days or until the infant is on low ventilator settings and FiO_2. In unstable patients ECMO, where available, is offered prior to surgical repair. ECMO remains the treatment of last resort, but survival remains only about 50% in infants sick enough to require this rescue therapy.

Prognosis: Prognosis depends on the presence or absence of other anomalies, severity of the defect, and availability of state of the art treatment. Associated anomalies, especially chromosomal, portend a poor prognosis. Polyhydramnios, presence of liver in the chest, and low lung-to-head ratio (LHR) are poor prognostic factors. The LHR, is a ratio of the visible lung on the contralateral side to fetal head. MRI volumetry has been proposed as a better tool, but requires validation. Echocardiography is utilized to detect associated fetal cardiac anomalies. Various estimates of left ventricular mass and pulmonary artery diameters appear to be good indicators of pulmonary hypoplasia. Survival depends on the denominator used in the calculation. Many CDH pregnancies end in elective termination, spontaneous abortion, or stillbirth, especially when associated anomalies are found. A substantial number of live born infants succumb in the delivery room. Therefore, reported survival statistics from tertiary centers include only a selected group of infants who reached the center alive. This "hidden mortality" not seen at the tertiary center accounts for large differences in reported survival. When all CDH pregnancies are counted, survival may be as low as 25%. Infants reaching tertiary centers have a 60–80% survival with the most advanced care, but continue to have long-term sequelae, including growth failure, severe gastroesophageal reflux, and developmental delays. Late death may occur after apparently successful treatment from recurrent pulmonary hypertension.

Prevention: There is no known prevention for CDH, but in utero fetal therapy has been a subject of intense study. It has been shown that the lung hypoplasia can be reversed by fetal tracheal occlusion, but improved survival

has been difficult to demonstrate, in part due to high rate of preterm delivery associated with this procedure. The treatment remains experimental.

Bronchopulmonary Dysplasia (BPD)

Definition: Bronchopulmonary dysplasia is defined as lung injury in preterm infants resulting from oxygen and mechanical ventilation. Various definitions have been used since its initial description in 1967. Oxygen requirement at 36 weeks postmenstrual age has been the most widely used definition. Current definition has been modified to define severity of BPD and differentiate between infants of different gestational age. This definition, based on the NIH consensus conference in 2001, is shown in *Table 15.3*.

Etiology: BPD is believed to result from the combination of oxygen-mediated injury and exposure to mechanical ventilation in immature lungs with limited antioxidant defenses.

Oxygen exposure impairs secondary crest formation and alveolar septation, leading to a "simplified lung," which lacks adequate surface area and sufficient pulmonary capillaries in close proximity to the saccules. Mechanical ventilation results in disruption of cellular structures, release of inflammatory mediators, chemokines, and influx of activated neutrophils, beginning a sequence of injury, inflammation, and repair that eventually results in the clinical picture of BPD.

Epidemiology: The Neonatal Research Network study of 1,598 inborn survivors 501–1,249 g born between 2000 and 2002 showed that 31% received oxygen or ventilatory assistance at 36 weeks. Prematurity is the single most important predisposing factor for BPD; in one study, the incidence of BPD using the 36 weeks postmenstrual age definition was 42% for infants weighing 501–750 g, 25% for 751–1,000 g, and 11% for infants 1,001–1,250 g. Data from the Israeli National VLBW database showed that 19% of 3,689 VLBW infants met the definition of BPD. BPD is the most common form of chronic lung disease in infants in the United States with an estimated 7,000–10,000 new cases occurring each year.

Pathogenesis: Tissue stretch associated with mechanical ventilation results in disruption of airway epithelial and alveolar cells with early interstitial and alveolar edema which progresses to persistent structural changes, persistent inflammation, and fibrosis in the lung that ultimately result in significant effects on lung mechanics, gas exchange, and pulmonary vasculature. It is a heterogeneous condition and its manifestations vary. In some infants it is characterized primarily by arrest of normal lung development, resulting in a "simplified lung," which has decreased number of larger alveoli, paucity of pulmonary capillaries in close proximity to the saccules, and decreased total surface area for gas exchange (the "new BPD"). Various degrees of interstitial fibrosis and elastin deposition in alveolar walls may be associated with the more severe forms of BPD, as a result of the complex sequence of lung injury, inflammation, and remodeling. These infants typically have significant airway disease as part of their clinical picture with increased airway resistance, mucosal thickening, ongoing inflammation, increased mucus production, and varying degrees of airway smooth muscle hyperplasia.

The pathogenesis of PBD is complex and multifactorial. The role of inflammation is increasingly recognized with both prenatal and postnatal infection contributing substantially to the development of BPD. It has been shown that the rate of histologic chorioamnionitis is

Table 15.3
Diagnostic criteria for BPD

Gestational Age	<32 weeks	≥32 weeks
Time of assessment	36 weeks PMA or discharge, whichever comes first	28–56 days postnatal age or discharge, whichever comes first
	Treatment with oxygen >21% for at least 28 days, *plus*	Treatment with oxygen >21% for at least 28 days, *plus*
Mild BPD	Breathing room air at 36 weeks PMA or discharge, whichever comes first	Breathing room air by 56 days
		PMA or discharge, whichever
Moderate BPD	Need[a] for <30% oxygen at 36 weeks PMA or discharge, whichever comes first	Need[a] for <30% oxygen at 56 days of age or at discharge, whichever comes first
Severe BPD	Need[a] for <30% oxygen and/or positive pressure (PPV or NCPAP) at 36 weeks PMA or discharge, whichever comes first	Need[a] for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 56 days of age or discharge, whichever comes first

PMA postmenstrual age, PPV positive pressure ventilation, NCPAP nasal continuous positive pressure ventilation

[a]Need should ideally be defined by physiologic criteria, e.g., need to maintain SPO2 >90%. The optimal SPO2 targets are not yet well defined

inversely proportional to gestational age. Other contributing factors include excessive fluid intake, presence of patent ductus arteriosus, and exposure to high FiO2 and large tidal volume ventilation. Infection with Ureaplasma Urealyticum is associated with a high incidence of BPD, but its postnatal eradication does not appear to improve outcome. There is considerable variation in susceptibility to BPD and the underlying mechanisms for the genetic basis of this are under intense investigation.

Clinical Manifestations: BPD evolves insidiously when the initial RDS fails to resolve. The infant will have persistent or increasing oxygen requirement, tachypnea, and retractions with increased secretions noted in intubated infants. Some VLBW infants may have little or no RDS initially, but then gradually develop increasing oxygen requirement and classical features of BPD. Chest radiographs initially show diffusely hazy lungs with good lung expansion and this may progress to the more patchy, hyperinflated lung fields associated with classical BPD. The increased airway resistance is in part due to the poorly supported small airways with tendency to airway collapse at low lung volume. There is airway mucosal edema with increased secretions, but usually there is no active bronchoconstriction in the first few weeks of life. In later stages of BPD, reactive airway disease may develop. Severe cases of BPD may be associated with pulmonary hypertension and this is occasionally fatal.

Diagnosis: There is no single diagnostic test. The condition evolves over time, beginning within days of birth, but the formal diagnosis is based on oxygen or positive pressure ventilation requirement at 28 days or beyond. Radiographic changes are no longer a requirement for the diagnosis, but are typically present.

Differential Diagnosis: The main distinction is between BPD and chronic pulmonary insufficiency of prematurity (CPIP), related to insufficient rigidity of the chest wall leading to diffuse microatelectasis and consequent oxygen requirement. The differentiation is best made on chest radiographs. In both instances, there is increased opacification of the lung fields, but the lung expansion is normal or increased in BPD and reduced with CPIP. When respiratory status is deteriorating during the second or third week of life in a ventilated preterm infant, evolving BPD needs to be differentiated from ventilator associated pneumonia. This is not always easy, as endotracheal tube cultures and gram stains only indicate colonization, not necessarily infection. The chest x-ray may not be helpful, as diffuse pulmonary opacities are seen in both conditions. Acute deterioration is more likely to represent infection. Presence of leukocytes on gram stain of ET secretions and changes in peripheral white count support the diagnosis of infection. Recurrent aspiration pneumonia may contribute to or mimic BPD – evidence of gastroesophageal reflux should be sought in infants whose BPD is worsening over time.

Treatment: Treatment is primarily supportive with optimization of ventilator support and aggressive nutritional support. The ventilator settings need to reflect the longer time constants resulting from increased airway resistance. Therefore, inspiratory and expiratory time need to be sufficiently long. Overexpansion and air trapping are often seen in these infants. The common response to this is lowering of the PEEP setting, which is actually counterproductive. Air trapping typically results from airway closure at low lung volume and is made worse at low PEEP. This can be seen on the flow-volume loop with pulmonary function testing. Increasing the PEEP setting until the flow limitation at low lung volume resolves is helpful. Optimal oxygenation targets remain the subject of intense study. Higher targets appear to increase lung injury in the majority of infants. However, lower oxygen tension may over time lead to increased pulmonary vascular resistance and increase the risk of serious pulmonary hypertension. Current practice is to limit oxygen exposure until PMA of about 34–35 weeks by targeting SPO2 of 85–93% and to use somewhat higher targets beyond that period. In infants with documented pulmonary hypertension, SPO2 should be maintained in mid to high 90 s. The role of diuretics remains controversial. There is good evidence of short-term benefit in lung mechanics, but the diuretics often lead to electrolyte imbalance and their impact on ultimate outcome is unproven. Thiazides and spironolactone are most widely used for treatment of BPD. Furosemide is associated with more severe adverse effects, including osteopenia, rib fractures, and renal calculi. Bronchodilators are commonly used without evidence of long-term benefit. The elevated airway resistance in early BPD is not due to bronchoconstriction, therefore unlikely to be affected by bronchodilators. Later on, there may be a place for bronchodilators in selected infants, but lack of tools to measure airway resistance in non-intubated infants hampers rational use of these drugs. Methylxanthines are widely used and probably beneficial, although this may be more related to increased CO2 responsiveness and increased diaphragmatic contractility than bronchodilation.

Postnatal steroids were once used liberally and at high doses lasting up to 6 weeks. This practice was later recognized as increasing the incidence of abnormal neurologic outcome especially when started in the first week of life. Steroids are now used much more. Short courses Dexamethasone at doses of 0.15 mg/kg/d, divided q12 h appear to be effective and is thought to be safer than the much

higher cumulative doses used previously. Inhaled corticosteroids are widely used, but evidence of benefit is scant. No sound evidence exists to guide the treatment of pulmonary hypertension when it develops. The use of iNO has become widespread and it has at least transient benefits in most infants. Transition to an oral agent such as sildenafil, a phosphodiesterase 5 inhibitor appears warranted. Higher oxygen saturation targets and avoidance of hypercapnia are thought to be beneficial.

Prognosis: A small proportion of infants fail to wean from mechanical ventilation and go on to worsening lung disease with progressive pulmonary hypertension and death. Most infants ultimately outgrow the disease and become symptom free by early childhood. However, they remain at increased risk of lower respiratory tract infections, especially with respiratory syncytial virus, require more frequent rehospitalization, and are more likely to develop asthma. These infants may fail to thrive and are at risk of significant post-discharge morbidity and mortality. Careful pulmonary function testing at school age and beyond shows continued subtle abnormalities, but these are generally not functionally limiting. Infants with BPD have worse neurodevelopmental outcome compared to infants of similar gestational age without BPD.

Prevention: Prevention of BPD is the ultimate goal of care, but an elusive one. Antenatal corticosteroids, avoidance of injurious ventilation, use of noninvasive respiratory support, and surfactant administration are all important in limiting lung injury. Recent trials of HFV have failed to show clear benefit over lung-protective conventional ventilation. Vitamin A has been shown to reduce BPD, but requires frequent intramuscular injection. Early and continued treatment with caffeine reduces the risk of BPD by a similar amount and is much less onerous. Avoidance of excessive fluid intake is advisable. It is unclear whether early treatment of PDA reduces the incidence of BPD. Prophylactic use of iNO may be an effective strategy for BPD prevention when initiated at 1–2 weeks of life and administered for several weeks, but despite very strong laboratory evidence of efficacy, the clinical data are conflicting. Prevention of prematurity is the only definitive way of preventing BPD.

16 Oxygen Therapy

Maximo Vento

Introduction

Aerobic Metabolism

Highly energized electrons liberated in the mitochondrial tri-carboxylic cycle are transported to the electron transport chain, and finally captured by oxygen. In this process known as oxidative phosphorylation, ADP is transformed into ATP and ground molecular di-oxygen is reduced by four electrons, and combining with protons intruded through the ATP synthase pump forms water. Remarkably, aerobic metabolism (i.e., with the concourse of oxygen) is 20 times more efficient than anaerobic metabolism thus providing sufficient energy for cell growth, development, and reproduction (e.g., 1 molecule of glucose forms 34 molecules of ATP through the aerobic pathway and 4 through the anaerobic). Of note is that specific cells such as neurons are unable to accumulate energy and are only able to survive for few minutes under hypoxic conditions rendering oxygen indispensable for central nervous system survival.

Each oxygen molecule has two unpaired electrons in its outer shell that prevent it from forming new chemical bonds. Partial reduction of oxygen with just one electron at a time will lead to the formation of reactive oxygen species (ROS) such as anion superoxide (O_2^-), hydroxyl radical (OH●), and hydrogen peroxide (H_2O_2). Some of these chemicals will be highly reactive species known as free radicals. Free radicals are atomic or molecular species capable of independent existence that contain one or more unpaired electrons in their molecular orbits. They are able, therefore, to oxidize cellular membranes, structural proteins, enzymes, and nucleic acids.

Oxygen Free Radicals

In the presence of nitric oxide, these oxygen free radicals will react forming reactive nitrogen species (RNS) such as peroxynitrite (ONOO–) (*Fig 16.1*). ROS and RNS are potent oxidizing and reducing agents with an extremely short half-life that will damage any nearby cellular structure.

Antioxidant Defenses

Biologic systems using aerobic metabolism have been able to survive the deleterious effects of free radicals because a large number of enzymatic and non-enzymatic antioxidants has evolved. The antioxidant enzymes are represented by the family of superoxide dismutases (SOD) formed by Cu-Zn SOD or soluble SOD1 located in the cytosol, Mn-SOD or SOD2 located in the mitochondria, and extracellular or SOD3. In addition, catalase, glutathione peroxidases, and glucose 6-phosphate dehydrogenase altogether constitute the most relevant enzymatic defense against free radicals. The major non-enzymatic intracellular antioxidant is glutathione (GSH), a ubiquitous tri-peptide formed by γ-glutamine, L-cysteine, and glycine. GSH is able to reduce free radicals by establishing a di-sulfur bond with another GSH molecule forming oxidized glutathione (GS=SG) and thus providing one electron. Oxidized glutathione is reduced again to its reduced form (GSH) by the action of glutathione reductase (GSH-reductase) with the electrons provided by NADPH. Other relevant non-enzymatic antioxidants are proteins that bind transition metals such as transferrin and ceruloplasmin, or molecules that quench free radicals such as uric acid and bilirubin.

Oxidative Stress

This concept refers to the imbalance between the formation of free radicals and the capability of the biologic system to neutralize them. In order to evaluate oxidative stress different biomarkers have been used. They may directly reflect a pro-or-antioxidant status such as GSH/GSSG quotients, one of the most reliable and employed oxidative stress markers. Other biomarkers may reflect direct damage to the cell structures. Hence, for lipid peroxidation, malondialdehyde or *n*-aldehydes (e.g., 4-hydroxy-nonenal) have been widely employed. Nucleic acid damage is generally reflected by guanosine base oxidation products such as 8-oxo-dyhydro-guanosine. Isoprostanes and isofurans have evolved as one of the most reliable markers of oxidative stress and reflect

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_16,

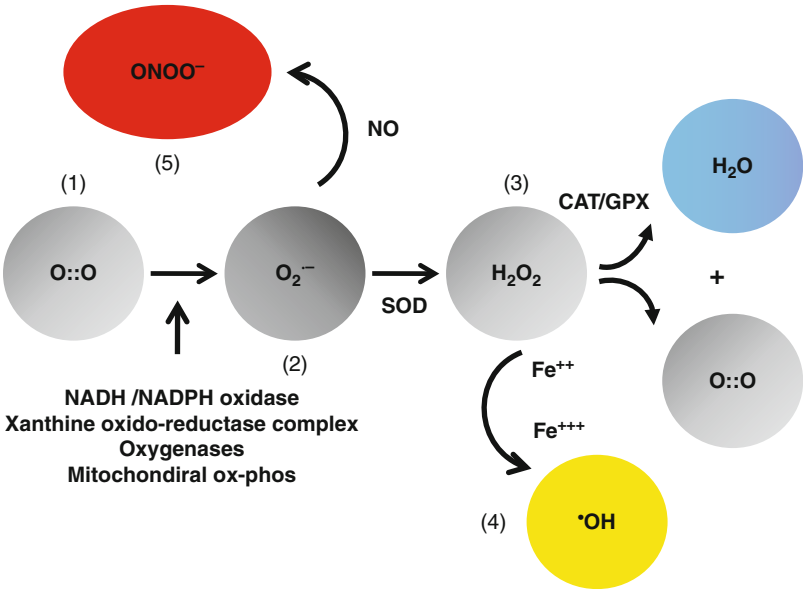

Figure 16.1

Oxygen (1) is partially reduced by the action of a series of enzymatic complexes to anion superoxide (2). Anion superoxide is dismutated by superoxide dismutases (*SOD*) to hydrogen peroxide (3), which in turn is transformed into water and oxygen by the action of catalases (*CAT*) and glutathione peroxidase (*GPX*). In the presence of transition metals (e.g., iron, copper), hydrogen peroxide can be transformed into hydroxyl radical (4). Moreover, in the presence of nitric oxide (*NO*), anion superoxide can also be transformed into peroxynitrite (5)

non-cyclo-oxygenase peroxidation of polyunsaturated fatty acids (PUFA) and intriguingly have important vaso-active properties. Oxidation of proteins can be measured by the action of free radicals on specific amino acids such as phenylalanine. As a consequence of the attack by hydroxyl radicals, phenylalanine is converted into orto-tyrosine (o-tyr). Other markers of protein oxidation are known as carbonyl compounds (C=O), which have been closely correlated when found in the lung alveolar lavage fluid with development of chronic lung disease.

In addition to causing oxidative damage to cell structures, ROS and RNS are capable of triggering inflammatory response in the cells triggering the transformation of I-κB into NF-κB, a transcription factor for multiple inflammation related genes. ROS and RNS are also capable of activating the tumor necrosis factor alpha (TNFα) essential in the inflammatory response as well as in the activation of apoptosis.

Fetal to Neonatal Transition

Fetal life develops in an environment that is relatively hypoxemic as compared to the extra uterine; hence, arterial partial pressure of oxygen (P_aO_2) in utero is of 25–35 mmHg. Immediately after birth, with the initiation of spontaneous respiration and alveolar-capillary gas exchange P_aO_2 rises to 50–70 mmHg in the first 5–10 min of life. This abrupt change causes a physiologic oxidative stress necessary to trigger the expression of a number of significant genes necessary for postnatal adaptation. The first studies of fetal pulse oximetry (SpO_2) during labor revealed that normal values were approximately 58 ± 10%. Studies performed in term newborn infants have shown that SpO_2 does not reach stable values ≥85% until 5 min after birth have elapsed, and some normal newborn infants need even more time especially if they are born by cesarean section. In addition, preterm infants especially extremely low birth weight infants will not reach an SpO_2 of ≥85% at least after 10–15 min after birth.

Arterial Oxygen Saturation Nomogram

In a large prospective observational study a total of 468 newly born infants covering gestational ages from 25 through 42 weeks of gestation and who did not need

resuscitation maneuvers in the delivery room were recruited (Fig. 16.2). SpO_2 using advanced technology with maximum sensitivity was measured in the right wrist thus representing pre-ductal oxygen saturation during the first 10 min after birth. Two graphs have been developed from the data set for babies between 32 and 36, and between 37 and 42 weeks gestation, respectively. It took a median of 7.9 (interquartile range (IQR): 5.0–10.0) min to reach $SpO_2 > 90\%$, and preterm infants needed significantly more time to reach this saturation.

Oxygen Administration in the Delivery Room

In experimental and clinical studies, it has been shown that the use of room air (21% oxygen) offers substantial advantages over the use of 100% oxygen as had been traditionally recommended in the resuscitation of depressed newborn infants. Meta-analysis of the published evidence has concluded that the use of room air significantly reduces mortality in term neonates. Moreover, air-resuscitation also shortens the time needed to initiate spontaneous respiration, improves Apgar score, and

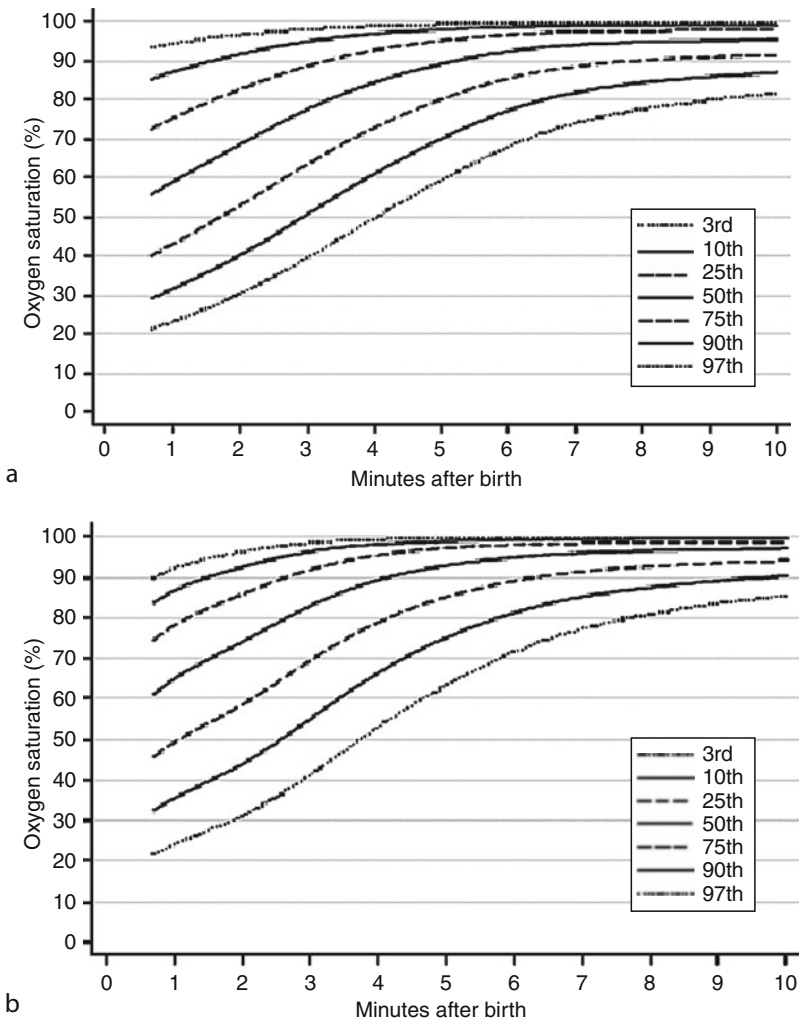

Figure 16.2

Panel a: Third, 10th, 25th, 50th, 75th, 90th, and 97th SpO_2 percentiles for preterm infants at 32–36 weeks of gestation with no medical intervention after birth. Panel b: Third, 10th, 25th, 50th, 75th, 90th, and 97th SpO_2 percentiles for infants at <32 weeks of gestation with no medical intervention at birth (From Dawson JA et al (2010) Pediatrics 125:e1340–e1347. With permission)

reduces oxidative stress and oxidative damage to vital organs such as myocardium and kidneys. As a consequence, 2010 international guidelines recommend the use of air as the initial gas admixture for the depressed neonate. Moreover, both pulse oximetry monitoring of SpO_2 and titration of the inspiratory fraction of oxygen (FIO_2) to avoid hyper-or-hypoxic damage are also encouraged.

Preterm babies do not frequently suffer from birth asphyxia; however, they experience difficulties in adapting to extra uterine due to lung and thoracic cage immaturity. Hence, a significant proportion of preterm infants will need proactive interventions in the delivery room. Positive pressure ventilation is the cornerstone of preterm resuscitation. Initial ventilation is performed in spontaneous breathing neonates with continuous positive pressure ventilation (CPAP) applying 4–8 cmH_2O. Available studies have shown that it is feasible to start resuscitation even in the most preterm infants using an initial FIO_2 of 21–30%. Regardless of whether high or low oxygen concentration was used initially, on average, the infants were on similar FiO_2 of 30–40% within 5–10 min of life with no difference in SPO_2, heart rate, Apgar scores, or acid–base status. While more studies are needed, many clinicians now opt to initiate resuscitation with 30% oxygen in preterm infants in whom normal lung function cannot be assumed. Immediately after birth, pulse oximeter probe should be adjusted to the right wrist. Reliable pre-ductal readings will be obtained in 60–90 s. Once readings are available FIO_2 should be titrated against SpO_2 readings in the pulse oximeter adjusting the air/oxygen blender to keep SpO_2 within saturation nomogram (*Fig. 16.2*). Changes should be performed every 30–60 s allowing infant's response in the form of increase/decrease in SpO_2. Abrupt changes in heart rate or saturation may be a consequence of mask leakage or incorrect endotracheal tube position. End tidal CO_2 detectors are useful in these circumstances. Once the baby is stable and maintains an adequate heart rate and SpO_2, he/she can be transferred to the NICU. Using lower oxygen load in the resuscitation process it has been shown that oxidative stress biomarkers are significantly reduced and there is less need for oxygen supplementation, and less tendency toward developing chronic lung disease.

Oxygen During Neonatal Care in Premature Infants

The conundrum regarding the establishment of upper and lower limits of oxygen saturation especially in extremely low birth weight (ELBW) infants is still open (*Fig. 16.3*). ELBW infants are very sensitive to both hyperoxia, which may lead especially to lung and retinal damage, and to hypoxia, which may cause white matter injury. Studies that have compared different limits for SpO_2 have concluded that neonatal units maintaining ELBW infants within low saturation limits (85–92%) have significantly lower incidence (~50%) of retinopathy of prematurity (ROP) and bronchopulmonary dysplasia (BPD) than those units allowing SpO_2 within higher limits (>95%). This has been confirmed in the SUPPORT trial, the only randomized study published to date. Although some concerns have been raised in relation to a small

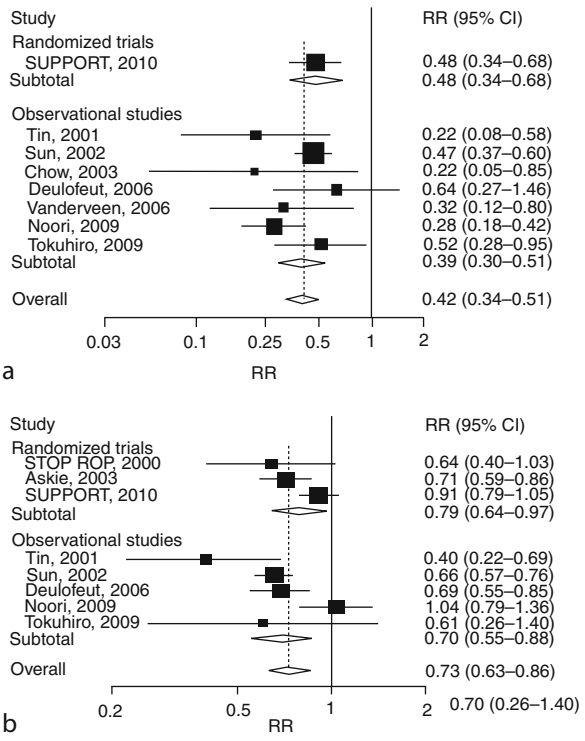

Figure 16.3

Panel a: Relative Risk (*RR*) and 95% Confidence Interval (*CI*) for randomized studies and observational studies as well as overall estimate in eight studies examining the effect on ROP of high versus low SpO_2 in preterm infants. A RR < 1 favors low SpO_2. Panel b: RR and 95% CI for randomized studies and observational studies as well as overall in eight studies examining the effect on BPD and/or lung problems of high versus low SpO_2 in preterm infants. An RR < 1 favors low SpO_2 (From Saugstad OD et al (2011) Neonatology 100:1–8. With permission)

increase in mortality in the low saturation group, there is no conclusive evidence and 85% as lower saturation limit seems to be safe. Several other clinical trials are underway with close monitoring of the mortality rate by their data safety monitoring boards. Until these studies are published, definitive recommendations are difficult. However, majority of NICUs in the USA and Europe appear to have adopted the range of 85–92% in preterm infants, and anecdotal evidence supports the decreased incidence of ROP.

Of note, studies have suggested the establishment of two different periods with different oxygen saturation targets. Preterm infants below 32 weeks postmenstrual age would benefit from lower SpO_2 limits (e.g., 85–95%). In a phase of rapid vascular growth and extreme tissue sensitivity to oxygen due to an immature antioxidant defense system, the use of higher oxygen limits would lead to oxidative stress and inflammation in the lung, intestine, or brain leading to BPD, necrotizing enterocolitis (NEC), or intra-periventricular hemorrhage (IPVH). However, older neonates (>32 weeks postmenstrual age) with a more mature antioxidant system and a tendency toward hyper-proliferation of the vascular bed of the retina due to a relative hypoxia of the retinal tissue might benefit from higher SpO_2 ranges (98–99%). This latter approach is intended for infants with pre-threshold ROP, but its benefit has not been conclusively established. Further, the potential benefit on the retina must be weighed against the apparent adverse effects on the lungs as suggested by the STOP ROP study. Perhaps, in addition to pulse oximeter monitoring levels of growth factors such as insulin-like growth factor (IGF), vascular endothelial growth factors (VEGF) and others should be closely monitored aiming to advert the initiation of ROP 2 phase that would prompt the use of higher oxygen saturation limits to avoid retinal vessel overgrowth.

Oxygen Therapy in the Term Infant

Term infants with meconium aspiration syndrome, pneumonia, or other conditions may have pulmonary hypertension and often also require respiratory support. Traditionally, clinicians were less concerned about hyperoxia in view of their more mature antioxidant defenses and often used high FiO_2 in infants with or at risk for pulmonary hypertension (PPHN). More recently, it has become clear that hyperoxia and exposure to high FiO_2 is not only unnecessary in terms of treating PPHN, but actually increases pulmonary vasoreactivity to hypoxia and decreases response to inhaled nitric oxide. Many infants with meconium aspiration and/or PPHN have a history of perinatal asphyxia and are uniquely vulnerable to oxygen radical injury to the brain. Additionally, prolonged exposure to high FiO_2 will cause lung injury even in term infants. Therefore, the current recommendations are to target normoxia (PaO_2 60–80 s) and avoid PaO_2 over 90 mmHg. The upper limit of SPO_2 should be set no higher than 99%, because when SPO_2 is >99%, the PaO_2 may well be over 100 mmHg.

17 Noninvasive Respiratory Support

Peter Davis

Neonatal Respiratory Support in the Modern Era

Assisted ventilation of infants was first reported in the modern era in 1953 by Donald and Lord. Initially, this was provided in the form of intermittent positive pressure ventilation via an endotracheal tube. Adult techniques and equipment were adapted with disappointing results. Survival rates did not improve and adverse effects such as air leak appeared more frequent. In response to the high mortality rates, particularly of newly born very low birth weight infants, Gregory developed a technique of continuous positive airway pressure (CPAP).

Initially CPAP was delivered via an endotracheal tube, but soon after, other interfaces were developed to avoid the complications associated with endotracheal intubation. Ahlström used a face chamber to deliver up to 15 cm of water pressure. Using a tight-fitting face mask, Rhodes showed that CPAP enhanced survival compared to conventional therapy with warmed humidified oxygen. Pressure effects from these devices, as well as problems accessing the mouth and nose for suctioning and feeding, led to the development of nasal interfaces.

Noninvasive ventilation grew in popularity because of the perception that it reduced the risks of trauma to the larynx and trachea, infection, and chronic lung disease. The debate over the specific roles of endotracheal intubation and noninvasive methods of support continues, but there is general agreement that the duration of endotracheal intubation, when required, should be as brief as possible.

Problems Associated with Noninvasive Ventilation

Although portrayed as simpler and easier to administer than ventilation via an endotracheal tube, noninvasive ventilation is not without its own difficulties. Nasal prongs rarely fit tightly into the nostrils. Gas can leak around the prongs or from the mouth, leading to a variable reduction of pressure delivered to the pharynx. The nasal septum and alae nasi are frequently damaged by nasal prongs and injuries including inflammation and laceration are reported. Graham described an association between NCPAP and late-onset gram-negative sepsis. Others have described a similar association between nasal trauma and coagulase negative staphyloccal infection. Airleak was found to be more prevalent in the earliest randomized trials of CPAP. An increased rate of pneumothorax was also described in preterm infants managed with CPAP compared with endotracheal intubation and surfactant. The success of noninvasive ventilation depends on the expertise of the nursing staff. Attention to detail, gentleness, and careful monitoring are as important for care of infants on CPAP as they are for those managed with an endotracheal tube.

The Physiology of Continuous Positive Airway Pressure

Surfactant deficiency, muscle hypotonia, delayed clearance of lung fluid, and a compliant chest wall combine to make it difficult for a preterm infant to establish and maintain adequate lung volumes. By assisting expansion of the lungs and preventing lung collapse at the end of expiration, CPAP helps maintain aeration. In addition, CPAP reduces the protein leak associated with atelectasis and reexpansion, thereby conserving surfactant. CPAP also helps splint the upper airway, which is very compliant and prone to collapse. In doing so, it reduces obstruction and apnea.

Types of Interfaces

There are a variety of interfaces for delivering CPAP. Endotracheal tubes are no longer recommended because they have a high resistance and increase the work of breathing. Gregory developed a head chamber with a tight seal and a pressure release valve. Subsequently face chambers and face masks were tried. Problems establishing a good seal without causing damage to the head led to the development of nasal prongs. These had the additional advantage of allowing easier access to the infant's nose and mouth.

There are at least four types of nasal CPAP device. A long nasopharyngeal tube, passed through one nostril

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_17,

with its tip lying just above the epiglottis is an inexpensive, readily available interface. However, these tubes have a high resistance and therefore a large reduction in delivered pressure and high work of breathing. A single, short nasal prong fashioned by cutting down an endotracheal tube is simple and easy to use. The problems with this interface are the leak of gas through the other nostril and the high resistance of the tube relative to double nasal prongs. Short bi-nasal prongs provide a low resistance to gas flow and good delivery of pressure to the airway. Double prongs are more effective in managing infants after extubation than single prongs. Nasal masks have been developed in an attempt to reduce the nasal trauma seen with prongs. There is little published information on their effectiveness compared to nasal prongs, and studies addressing the issue of trauma report similar rates of nasal damage, albeit at different sites.

Types of Pressure Generators

Bubbly bottle: Bubble CPAP is a simple, inexpensive technique, whereby pressure is generated by placing the distal limb of the circuit under a known depth of water. Continuous underwater bubbling occurs once sufficient flow is delivered and correct prong position with minimal leak is achieved. Operators are alerted to prong displacement by disappearance of the bubbling. It has been suggested that oscillations produced in the circuit by the bubbling may enhance gas exchange. In a preterm lamb model, Pillow et al. found that bubbling appeared to improve blood gases compared to CPAP delivered from a conventional ventilator. However, a short-term crossover human study comparing fast bubbling with minimal bubbling found no difference in blood gases.

Ventilator: CPAP may be generated using the PEEP valve of a conventional ventilator. This is a reliable way of delivering CPAP, as the pressure generated is independent of flow until the leak at the nose is large. For some, the use of a neonatal ventilator for the simple task of generating CPAP represents an unacceptable cost when alternative methods are available.

Variable flow devices (including Infant Flow Driver): These devices have an integrated nasal interface and pressure generator. Pressure is determined by altering the gas flow through the circuit. The nasal interface delivers a jet of gas into the nose, which responds to the infant's respiratory efforts. Claimed advantages include enhanced stability of pressure and decreased work of breathing. Studies of this technique have produced conflicting results. In a randomized trial, Mazzela reported that infants managed with the Infant Flow Driver (IFD) had better oxygenation and lower respiratory rates than those managed with a single nasopharyngeal prong. This result may be due, at least in part, to the high resistance of the single nasopharyngeal tube as discussed above. In a recent randomized trial, Gupta et al. showed that the underwater bubbling system was at least as effective as the IFD for the post-extubation management of preterm infants. In the subgroup of infants ventilated for less than 14 days, infants randomized to bubble CPAP were more likely to be successfully extubated than those managed on the IFD.

Nasal Intermittent Positive Airway Pressure (NIPPV)

NIPPV is a form of respiratory support characterized by the provision of CPAP augmented by mechanical inflations, and delivered in neonates using nasal prongs. The operator sets a peak inspiratory pressure, an end expiratory pressure, a rate, and an inspiratory time. The technique was used with success in adults and applied to neonates in the 1980s. A survey of neonatal units in the UK in 2006 found that 48% of regional nurseries were using NIPPV. Proposed mechanism of action of NIPPV include induction of Head's paradoxical reflex, increased mean airway pressure, increased alveolar recruitment, pharyngeal dilation, and increased pharyngeal pressure.

NIPPV has been used in a number of clinical settings: post-extubation care, primary therapy for respiratory distress syndrome, and treatment of apnea. Its use in post-extubation care is the most thoroughly evaluated. Meta-analysis of three studies comparing NIPPV with NCPAP showed that infants managed with NIPPV were more likely to be successfully extubated than those receiving NCPAP. There are small studies that suggest NIPPV may have a role in initial management of respiratory distress syndrome, but more evidence is required before NIPPV is used routinely in this patient group. Evidence for the use of NIPPV for apnea is limited, but it is now commonly used in this group of patients when NCPAP fails.

The RCTs evaluating NIPPV in the post-extubation setting all used a ventilator capable of synchronizing ventilator inflations with the infants own breathing efforts. These used an abdominal sensor. Synchronized NIPPV is now less widely available, and many units now use ventilators that do not attempt to provide synchronized inflations. Recently, Moretti et al. have described the use of a promising device for delivering NIPPV which used a flow sensor to trigger ventilator inflations synchronized with the infant's own breaths. It appears that NIPPV has

an important role to play in neonatal respiratory support. More research is required to determine the best devices and settings when using this technique.

High-Flow Subnasal Oxygen (High-Flow Nasal Cannula)

Although proven to be effective, NCPAP and NIPPV have important problems. Infants managed with nasal prongs often appear uncomfortable, and nasal trauma is an ongoing concern. Nasal cannulae have increased in popularity in the past decade as clinicians seek for a system that is easier to use and more comfortable for babies. These cannulae are used in conjunction with humidified high gas flow, and studies have shown that the technique improves lung compliance and reduces work of breathing. The mechanism of action of high-flow subnasal oxygen is unclear. Locke measured oesophageal pressure in infants treated with 2 L/min of flow through 0.3 cm prongs and showed that this device produced a mean-positive end-distending pressure of 9.8 cmH_2O. They and others have warned that delivered pressures are variable and potentially higher than commonly used CPAP levels. Pressures depend not only on the flow through the cannulae but also on the leak from the nose. This may vary considerably depending on nasal secretions. Trials are currently underway testing the safety and efficacy of high-flow nasal cannulae in this patient group. Widespread application should wait until the results of these trials are known.

Indications for Noninvasive Ventilation

Post-extubation care: Infants are intubated and ventilated for respiratory failure due to conditions, including hyaline membrane disease, sepsis, and apnea. By extubating as soon as possible, clinicians seek to avoid the complications associated with an endotracheal tube. Atelectasis, respiratory failure, and apnea are frequent, and re-intubation may be required. Noninvasive ventilation is often used in an attempt to maintain lung volumes and enhance stability. A systematic review comparing CPAP with supplemental oxygen for post-extubation care identified nine randomized trials addressing this question. Infants treated with CPAP had a reduction in the need for increased respiratory support [Relative risk (RR) 0.62 (0.51, 0.76)] with a number needed to treat of six to prevent one extubation failure. This review suggested that if resources were limited, CPAP could be reserved for use in infants who were failing supplemental oxygen. A subgroup analysis of trials in this review according to the CPAP pressure used showed no benefit in trials using <5 cmH_2O and a significant benefit for infants treated with > 5 cmH_2O CPAP.

Respiratory distress syndrome: In the presurfactant era, a series of randomized trials compared noninvasive ventilation in the form of facemask CPAP and negative pressure ventilators with headbox oxygen. Although now largely of historical interest only, meta-analysis of the trials showed continuous distending pressure (CDP) reduced the overall rate of mortality and the rate of the combined outcome of death or need for assisted ventilation [RR 0.52 (0.32, 0.87)]. However, the rate of pneumothorax was increased in infants managed with CDP [RR 2.36 (1.25, 5.54)]. A more recent trial by Buckmaster showed that the use of CPAP reduced the need for transfer of babies with respiratory distress to intensive care units.

CPAP vs *intubation in the Delivery Room*: Standard treatment of very preterm infants over the past three decades has included intubation and ventilation in the delivery room. Similarly, early administration of exogenous surfactant has become routine treatment. A small number of units reported that use of CPAP instead of an endotracheal tube was associated with reduced rates of bronchopulmonary dysplasia without increasing mortality or other morbidities. Morley et al. conducted a RCT comparing early intubation with CPAP from 5 min of life. They found that although there was no difference in the primary outcome, death or the need for supplemental oxygen at 36-week corrected age [odds ratio 0.80 (0.58, 1.12)], babies commenced on CPAP spent fewer days on an endotracheal tube. Pneumothorax rate was however increased in the CPAP group. The authors concluded that CPAP is an effective alternative to endotracheal intubation in the delivery room.

Optimum Settings

The choice of the best CPAP pressure is based more on expert opinion than evidence. Traditionally, a pressure of 5 cmH_2O has been used. Some units use this level for all infants, irrespective of disease severity and claim good results. Others have argued for allowing higher pressures. As noted above, the use of CPAP levels of 5 cmH_2O and above appears to be more effective than pressures of less than 5 cmH_2O for post-extubation care. Elgellab et al. reported that a pressure of 8 cmH_2O was associated with higher end-expiratory lung volumes, greater tidal volumes, and lower respiratory rates. Probyn et al., in an animal model, found that alveolar–arterial gradients fell

with increasing PEEP up to 8 cmH_2O. Importantly, no evidence of cardiovascular compromise was found at higher pressure levels. It seems logical that infants with hyaline membrane disease and non-compliant lungs which are prone to collapse may need higher levels of pressure than infants with normal or mildly effected lungs. Assessment of respiratory distress and oxygen requirement may help clinicians "titrate" the CPAP pressure to match the infant's requirements.

Weaning

Deciding when an infant should have CPAP pressures reduced or CPAP stopped is similarly more an art than a science. Several strategies have been tried. Gradually increasing periods of time spent off CPAP (or cycling) has not been shown to be more effective than stopping CPAP and recommencing if symptoms of apnea or respiratory failure occur. In a randomized trial, weaning pressure rather than increasing time spent off CPAP led to a shorter duration of weaning. Reducing CPAP pressure to 5 cmH_2O and discontinuing when the oxygen requirement falls below 30% appears to be a reasonable strategy with recommencement if oxygen requirements or frequency of apneas increase.

18 Surfactant Replacement Therapy

Richard Plavka

Surfactant therapy has changed neonatal respiratory care over the past two decades and dramatically improved neonatal outcome. Pulmonary surfactant is a complex mixture of phospholipids and proteins that reduce surface tension at the air–liquid interface of alveoli. The origin of its name is a collocation of the capitals from the compound lexeme "SURFace ACTive AgeNT".

In 1929, Kurt von Neergard suggested the presence of pulmonary surfactant in newborn lungs to be followed almost 25 years later by the contributions of R. Pattle, J. Clements and C. Macklin to our understanding of the physiology of pulmonary surfactant. In 1959, M.E. Avery and J. Mead reported that preterm neonates *dying from hyaline membrane disease* had surfactant deficiency. First successful use of bovine surfactant in preterm newborns with respiratory distress syndrome (RDS) was published by T. Fujiwara in 1980. Since then, a number of randomized trials of different natural and synthetic surfactants clearly demonstrated *reduction in neonatal mortality and air-leak syndrome.*

Composition

The basic composition of human surfactant is shown in Fig. 18.1. Surfactant contains about 85% phospholipids, 5% neutral lipids and 10% proteins. The main phospholipid component is phosphatidyl choline (PC, 70%), further 7% is phosphatidyl glycerol (PG), and 8% other phospholipids like phosphatidyl inositol (PI), phosphatidyl serine (PS), and phosphatidyl ethanolamine (PE). Saturated PC containing two palmitic acids is called *dipalmitoil phosphatidil choline (DPPC).* DPPC is hydrophobic and is oriented to the gas phase; the unsaturated PC is hydrophilic and is in contact with the liquid phase. It is able to generate a monolayer, thereby *lowering surface tension* in the alveolar space. DPPC is a principal surface-active component of surfactant and is responsible for the low surface tension at end-expiration. Surfactant-associated *proteins A, B, C, and D* (SP-A, SP-B, SP-C, and SP-D) are the most important protein components of surfactant. The two hydrophobic surfactant proteins, SP-B and SP-C, are important for the adsorbtion and spreading of surfactant in a monolayer film at the air–liquid interface, therefore responsible for the biophysical properties of the lungs. The hydrophilic SP-A and SP-D play an important role in innate immunity and immunomodualtion of the lungs.

Metabolism, Turnover and Quantity

Surfactant is synthesized in type II pneumocytes, where it is also transported and secreted into the alveolus. The cell pool of potentially active surfactant is collected in lamellar bodies (large aggregates) which are able to release the final active form by exocytosis; this form is called tubular myelin that creates finally a monolayer in the alveoli and effectively lowers surface tension. The inactive and damaged surfactant (small aggregate) can be recycled and reused for new synthesis. This cycle of surfactant metabolism requires adequate maturation and is insufficient in preterm and especially in extremely preterm infants. Defective pulmonary surfactant metabolism results in RDS with its attendant mortality and morbidity.

Surfactant amount in alveoli differs in preterm and term newborns. The preterm newborn has a lesser amount and different composition of surfactant, which leads to inefficient function, such that more surfactant is needed to effectively lower surface tension. The conversion from active to inactive forms is more rapid in preterm infants and the sensitivity to inhibition caused by lung injury is high. Term newborns have about 100 mg/kg and preterm infants only about 10 mg/kg of phospholipid. Physiologically, surfactant is under the ontogenetic maturation process. The less mature the infant, the more common and severe RDS can be anticipated. The acute biophysical effects of surfactant on lung function and gas exchange result in *better functional residual capacity* as well as increase in total lung capacity and are accompanied by improved oxygenation, better compliance and decreased work of breathing.

Balance Between Synthesis and Inactivation

End-expiratory stability resulting from the intraalveolar surfactant monolayer is the result of a balance between

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_18,

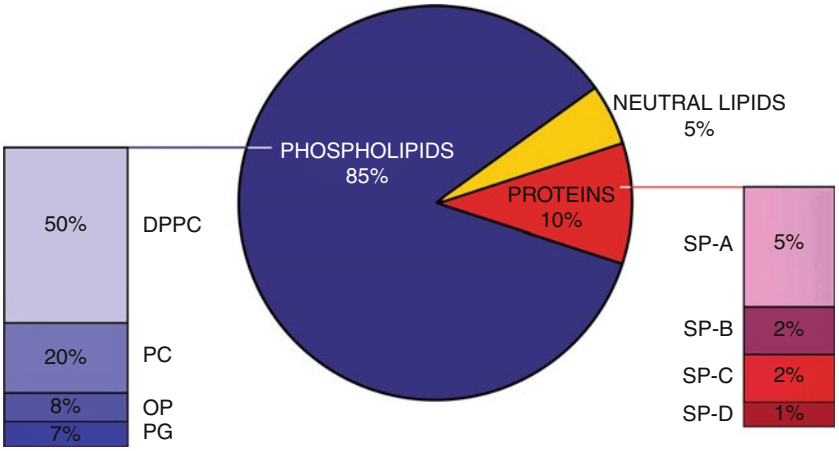

Figure 18.1
The composition of human surfactant legend: DPPC, dipalmitoil phosphatidil choline; PC, phosphatidil choline; OP, other phospholipids; PG, phosphatidil glycerol. SP-A, B, C, D, surfactant proteins A, B, C, D

the synthesis/release and inactivation or inhibition of surfactant. The main promoters of synthesis are antenatal steroids, thyroid hormones, beta adrenergic agents, and estrogens. On the other hand, inhibitors such as proteins, meconium, blood and neutrophils with inflammatory enzymes inactivate surfactant. Ventilatory strategies during mechanical ventilation, which do not minimize alveolar collapse (atelectrauma) and use high volumes (volutrauma) cause protein influx into the alveoli with inactivation of surfactant. If the balance shifts in favor of inactivation and inhibition and the respiratory properties of lungs worsen, exogenous surfactant instillation should be considered by the clinician. It should be kept in mind that factors that inactivate endogenous surfactant also inactivate exogenous surfactant. Therefore, steps must be taken to avoid injurious ventilation strategies, in addition to surfactant replacement therapy (*Fig. 18.2*).

Surfactant Preparations

The available surfactants can be divided into three main groups according to their composition: (1) old synthetic and protein free, (2) natural surfactants (animal derived or human amnionic fluid extract, (3) new synthetic surfactant with protein analogues (*Table 18.1*).

A systematic review of ten randomized trials comparing the effects of old protein-free synthetic and natural surfactants confirmed that treatment with natural surfactants results in a further decrease of air-leaks and mortality and that natural surfactants have a more rapid onset of action. Both old protein-free surfactant preparations have largely disappeared from clinical use, one having been withdrawn completely. In contrast, the new, SP-B mimic containing synthetic surfactant Surfaxin appears to be as safe and effective as the most widely used animal-derived natural surfactant and superior to synthetic, protein-free surfactant. However, as of this writing, it is not yet approved for clinical use. Venticute, the recombinant SP-C-based synthetic surfactant, has not been studied in infants. Studies in ARDS failed to show improved outcome.

Indications for Surfactant Therapy and Recommended Doses

The main indication for surfactant replacement therapy (SRT) with proven long-term benefit is RDS in premature newborns. Administration of surfactant leads to rapid improvement of oxygenation accompanied by an increase of functional residual capacity and lung compliance. Because of this, there is a risk of inadvertent hyperventilation when peak inspiratory pressure is not reduced quickly enough when using pressure limited ventilation, and hyperoxia may result if FiO_2 is not adjusted appropriately. Pulmonary blood flow improves as the ventilation–perfusion mismatch decreases and oxygenation improves. Both prophylactic SRT in preterm infants at high risk for developing RDS and early rescue within 2 h of birth in symptomatic infants decreases mortality and air leaks significantly (*Table 18.2*).

Other potential indications and recommended doses for SRT are listed in *Table 18.2*. In these indications, the short-term effect on gas exchange has been dominant, without demonstrated long-term benefits. Despite lack of definitive evidence of long-term benefit, surfactant is widely used in infants with these diagnoses.

Repeated administration of surfactant is generally accepted in clinical practice despite the modest evidence that subsequent doses improve long-term outcomes. Persistent or worsening signs of RDS are the usual criteria for surfactant retreatment. The balance between synthesis and inactivation of surfactant may be shifted in favor of inactivation, even in late preterm or term infants and therefore SRT is indicated when signs of RDS are present. The newer animal-derived surfactants have higher SP-B content and appear to require retreatment less frequently, compared to Survanta. Re-treatment is usually considered if the infant still requires mechanical ventilation with $FiO_2 > 0.30$.

Technique and Method of Surfactant Administration

Initial attempts at surfactant replacement were via aerosol administration, but were unsuccessful. Therefore, surfactant is administered as a liquid instillate, relying on its

Table 18.2
Proven and potential indications for surfactant replacement therapy

unique properties to spread relatively uniformly throughout the lungs. There are 250,000 binary airway branch points leading to 500,000 distal airways ending in terminal saccules. There is inevitably some degree of maldistribution, more so if the lungs are atelectatic prior to administration. The maldistribution is to some degree mitigated by the large (sometimes supraphysiologic) dose given. The distribution of instilled is influenced by the physical variables, such as volume and speed of instillation, gravity depending on position of lungs, fluid content in lungs and by surfactant properties like adsorption and spreading. Available data suggest that surfactant should be instilled as rapidly as tolerated, because slow administration results in greater maldistribution.

Timing of Surfactant Administration

Both early rescue treatment (within a few hours after delivery) of RDS or prophylactic use (within minutes) have been shown to decrease mortality, air-leaks and possibly even the incidence of bronchopulmonary dysplasia in preterm infants requiring mechanical ventilation.

There is no clear evidence that prophylactic administration is superior to early rescue treatment in spontaneously breathing very preterm infants on nasal CPAP. The criteria for selection of very preterm infants who might benefit from prophylactic administration have not been established. Surfactant should be administered as soon as practical in extremely premature infants who need to be intubated in the delivery room and artificially ventilated. There is no advantage to administering surfactant before the first breath, therefore resuscitation efforts should never be delayed for the sake of surfactant administration.

Adverse Effects of Surfactant Instillation

Transient hypoxemia and bradycardia are common during surfactant administration and are caused by obstruction of the small airways or the endotracheal tube. Transiently, higher inspiratory pressures may be needed to overcome the added resistance. Transient hypercapnia commonly develops following surfactant administration and may be later followed by hypocapnia as airway obstruction clears and compliance improves. The use of volume-targeted ventilation techniques, such as volume guarantee may be effective in reducing these adverse effects. A transient decrease in blood pressure is described immediately after administration and usually recovers within a few minutes. Decreased cerebral blood flow velocities, oxyhemoglobin concentration and depression of amplitude-integrated encephalographic record are also reported in several papers. The relationship of surfactant treatment and cerebral ischemia or intraventricular hemorrhage has not been confirmed in systematic reviews. Increased incidence of "pulmonary hemorrhage" has been associated with surfactant administration. This entity is actually hemorrhagic pulmonary edema that results from left ventricular volume overload due to rapid fall in pulmonary vascular resistance and increased left to right shunting through the ductus arteriosus.

Practical Issues

Surfactant should be administered rapidly, using the recommended volume/dose with the infant in the supine position or in equal aliquots in the right and left lateral position. Prior to administration, care must be taken to

ensure that the endotracheal tube is not in one of the mainstem bronchi. Different manufacturers have various recommendations regarding positioning of the infant during administration, based on how the drug was delivered during the pivotal trials. These methods were not evidence based; rather, they were consensus decisions of investigators planning the various clinical trials. Nonetheless, deviation from the recommended method of administration could theoretically alter the effectiveness of the drug. In practice, it appears that surfactant spreads remarkably effectively, regardless of the infant's position. The most common method is to administer one half of the dose with the infant in right lateral position and the other half in the left lateral position, but administering the entire dose in the supine position is also quite acceptable. Brief gentle positive pressure ventilation with adequate levels of PEEP and PIP following quick intratracheal instillation may aid distribution and clear the substance from the ETT and the large airways. Administration via a sideport adapter or dual lumen endotracheal tube rather than feeding tube inserted into the endotracheal tube, which requires disconnecting from the ventilator appears to lead to fewer dosing problems. Close continuous monitoring of heart rate, oxygen saturation, and pattern of breathing with extent of chest movement are essential for adjustment of ventilatory parameters appropriately. Hyperoxygenation and volutrauma should be avoided scrupulously as well as hypoxia and atelectasis.

Combination of Nasal CPAP with Surfactant

Widespread use of antenatal steroids, antibiotic treatment of mothers with chorioamnionitis, and less-invasive stabilization and resuscitation approach in the DR with controlled positive pressure, provision of early CPAP, and controlled FiO_2 have improved the clinical status of preterm infants. Majority of even extremely preterm infants 24–28 weeks' gestation can breathe spontaneously and even cry after delivery. Despite lack of definitive evidence from controlled trials, it is generally accepted that reduction of intubation and mechanical ventilation can improve the long-term outcome of these infants.

To reduce the duration of endotracheal intubation and mechanical ventilation, less-invasive techniques have been introduced into clinical practice. Brief intubation to administer surfactant followed by extubation as soon as possible to nasal CPAP called INSURE (INtubation-SURfactant-Extubation) technique is now widely used. Other even less-invasive techniques, such as surfactant administration with a fine thin gastric tube or nebulization in spontaneously breathing infants are under investigation with the goal of avoiding intubation and positive pressure ventilation completely. The author's criteria for surfactant administration to reduce need for intubation and duration of mechanical ventilation are summarized in *Table 18.3*.

Inherited Surfactant Disorders

Life-threatening or lethal surfactant deficiency may result from rare inherited disorders. There are three single-gene lung diseases that exhibit Mendelian inheritance and cause SP-B, SP-C and ABCA3 surfactant protein deficiency. In the early stages, it may be difficult to distinguish genetic causes of surfactant deficiency from transient neonatal surfactant deficiency. Infants with hereditary SP-B deficiency are typically full term and present with classic signs of severe RDS. The respiratory failure is usually severe and they respond to SRT with only a modest, transient

Table 18.3
Criteria for surfactant administration in combination with CPAP in preterm newborns at First Faculty of Medicine, Charles University, Prague

	Selective prophylaxis	Very early rescue treatment	Early rescue treatment

improvement followed by return to severe RDS. There is no effective treatment and the disease is ultimately fatal. Lung transplantation has been used for some of these infants, but 5-year survival is only about 30%. Expression of hereditary SP-C deficiency is much more variable and symptoms resemble the picture of interstitial chronic pneumonitis. ABCA3 deficiency is the most recently recognized genetic defect associated with surfactant production. The clinical phenotype resembles that of SP-B deficiency with a fatal outcome within 3 months of life.

Polygenic Surfactant Variations

RDS of prematurity is a complex of disease with multiple factors influencing susceptibility and outcome. A greater degree of prematurity, white ethnicity, male gender, and monozygotic twins are some of the risk factors for more sever RDS. A number of polymorphisms have been identified in the various surfactant genes associated with RDS of prematurity.

Conclusion

Surfactant replacement therapy is an effective intervention in newborn infants with surfactant deficiency or dysfunction. SRT substantially improves survival and decreases complication in infants with RDS. The indications for SRT continue to expand as our understanding of the role of surfactant inhibition in a variety of conditions other than RDS of prematurity increases. The development of effective synthetic surfactants may eventually substantially reduce the current high cost of treatment and expand indications for its use.

19 Conventional Mechanical Ventilation

Martin Keszler · Colin J. Morley

Introduction

Despite a shift to noninvasive respiratory support, mechanical ventilation remains an essential tool in the care of critically ill neonates. In industrialized countries, respiratory support has improved to the point where few infants now die of acute respiratory failure; early mortality is now predominantly from other complications of extreme prematurity, such as infection and hemorrhage or to congenital anomalies. While improving survival remains a challenge in less developed countries, the focus in industrialized countries has shifted from simply improving survival to reducing the incidence of chronic lung disease and neurodevelopmental sequelae, which remain high in extremely premature survivors. Preterm infants are more vulnerable to respiratory failure because of unfavorable chest wall mechanics and limited muscle mass and endurance. Ventilatory support of preterm infants is made more difficult by their small size, rapid respiratory rates with short inspiratory times, high resistance of small endotracheal tubes (ETT), and variable leak of gas around uncuffed ETT. Immature respiratory control, problems associated with the transitional circulation, and patency of the ductus arteriosus add to the challenges. These are the reasons why "universal" ventilators designed primarily for adult patients do not perform optimally in preterm newborn infants.

Indications for Mechanical Ventilation

Mechanical ventilation should be reserved for infants who are exhibiting signs of respiratory failure or have inadequate spontaneous respiratory effort. There is no weight limit below which premature infants should be automatically intubated and mechanically ventilated. However, the most immature infants are more likely to fail trials of continuous positive airway pressure (CPAP) often because of intractable apnea not responsive to caffeine and require mechanical ventilation. In some NICUs, infants below a certain gestational age (typically 26–27 weeks) are routinely intubated for the purpose of surfactant replacement therapy, followed by some period of ventilation. Mechanical ventilation may also be needed after a surgery or because of congenital anomalies. The diagnosis of respiratory failure in the preterm infant is somewhat subjective. In general, severe respiratory acidosis with pH <7.20 is considered an indication for mechanical ventilation. High work of breathing and excessive oxygen requirement despite optimization of CPAP therapy is generally viewed as an indication for intubation and surfactant administration with some period of mechanical ventilation. The FiO_2 at which this decision is made varies, but there is evidence that earlier intervention at FiO_2 of ≥ 0.40 may be associated with fewer complications. Infants with persistent pulmonary hypertension may benefit from mechanical ventilation even when their pH is otherwise acceptable, because even modest degree of acidosis may contribute to elevated pulmonary vascular resistance.

Synchronized Mechanical Ventilation

The most basic form of mechanical ventilation is intermittent mandatory ventilation (IMV). This is a time-cycled, pressure-limited mode that provides a set number of "mandatory" mechanical breaths. The patient breathes spontaneously between mechanical breaths, using the fresh gas flow in the ventilator circuit that also provides positive end-expiratory pressure (PEEP). With simple IMV, the random respiratory rate of the baby frequently leads to asynchrony between the infant and the ventilator, resulting in high airway pressures, poor oxygenation, and large fluctuations in intracranial pressures. Heavy sedation and muscle paralysis are needed to prevent the baby from "fighting the ventilator," resulting in more dependence on respiratory support, lack of respiratory muscle training, generalized edema, and inability to assess the neurologic status. The advantages of synchronizing the infant's own effort with the ventilator instead of using muscle relaxants are obvious and include better oxygenation and ventilation and easier weaning from ventilatory support (*Table 19.1*). Synchronization can be achieved by a variety of ways, each with its own advantages and disadvantages. The ideal trigger device will have rapid response time, high sensitivity, and be immune from

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_19,

autotriggering caused by leak artifact. Table 19.2 lists available trigger systems and their characteristics. Currently, flow triggering is the standard trigger mode; the susceptibility to autotriggering has been overcome by the use of effective leak compensation in some devices. The terminology used to describe various modes of respiratory support can be quite confusing. Device manufacturers often use different terms to describe essentially identical modes. In basic terms, ventilator breaths can be time- or flow-cycled (onset of inspiration and expiration), pressure or volume-limited. Breath initiation can occur at a fixed rate (controlled ventilation) set by user or variable rate determined by the patient (assisted ventilation). The basic modes that are primarily used in newborn infants with their definitions, advantages, and limitations are described in Table 19.3.

Table 19.1
Documented and generally accepted benefits of synchronized mechanical ventilation

Eliminates asynchrony
Avoids muscle paralysis
Decreases need for sedation/analgesia
Reduces airway pressures
Decreases risk of volutrauma
Decreases risk of IVH
Allows respiratory muscle training
Facilitates weaning

Table 19.2
Comparison of triggering methods

Method	Advantages	Disadvantages
Pressure	No added dead space	Poor sensitivity
	Unaffected by leak	Long trigger delay
		High WOB
Airflow	Good sensitivity	Added dead space
	Rapid response	Leak sensitive
Surface capsule	Rapid response	Positioning is critical
	No added dead space	May trigger out of phase
	Unaffected by leak	Not currently available
EADi	Very good sensitivity	Limited availability
	Very rapid response	Expensive probe
	No added dead space	Careful positioning needed
	Unaffected by leak	Invasive

WOB work of breathing, *EADi* electrical activity of the diaphragm

Volume-Controlled Versus Pressure-Limited Ventilation

Pressure-limited ventilation has been the standard mode in newborn respiratory support, because early attempts to use traditional volume-controlled (VC) ventilation showed it to be impractical in small preterm infants. With VC ventilation, volume is the primary control variable with pressure in the system rising passively in inverse proportion to lung compliance and the breath is terminated when the set volume is delivered. VC delivers a set tidal volume (V_T) into the ventilator circuit, but in small infants with uncuffed endotracheal tubes, there is a large and unpredictable loss of V_T to gas compression in the circuit, stretching of the tubing and variable ETT leak. Pressure-limited ventilation remains the primary mode of ventilation in newborns because of its relative simplicity, ability to ventilate effectively despite large ETT leak, improved intrapulmonary gas distribution due to the decelerating gas flow pattern, and the presumed benefit of directly controlling PIP as the primary control variable. The disadvantage is that the V_T is a dependent variable and can change rapidly with changes in lung compliance. The availability of independent flow and volume monitoring makes it possible to manually adjust the set V_T of VC ventilation to target an appropriate exhaled V_T at the airway opening, but this is cumbersome, time consuming, and difficult with variable ETT leak. A more practical alternative is pressure-limited ventilation with volume-targeting, described later in this chapter.

Choice of Synchronized Ventilation Modes

No clear consensus exists regarding the relative merits of assist/control (AC) and synchronized intermittent mandatory ventilation (SIMV), the two most common types of synchronized ventilation. Short-term clinical trials have demonstrated smaller and less variable V_T, less tachypnea, more rapid weaning from mechanical ventilation, and smaller fluctuations in blood pressure with AC, when compared to SIMV. In very premature infants with small

Table 19.3
Available modes of synchronized mechanical ventilation with their key features and limitations

	Key features	Set variables	Advantages	Limitations
SIMV	Time-cycled, pressure-limited mode. Set number of breaths are supported	IMV rate, PIP, PEEP, T_I, FiO_2 rise time/ flow rate	Familiar, simple to understand	High WOB, high deadspace: V_T ratio Larger mechanical V_T
AC	Time-cycled, pressure-limited mode. Every breath is supported	Backup rate, PIP, PEEP, T_I, FiO_2, rise time/flow rate	Lower WOB, faster weaning, smaller V_T, smaller BP fluctuations	Lack of control of RR, autocycling can cause excessive RR
PSV as stand-alone	Flow-cycled, pressure-limited mode. Every breath is supported	Backup rate, PIP, PEEP, T_I limit, FiO_2, rise time/flow rate	Lower WOB, faster weaning, smaller V_T, smaller BP fluctuations, better synchrony	Lack of control of RR, autocycling can cause excessive RR
PSV + SIMV	Flow-cycled, pressure-limited mode. Every breath beyond SIMV rate is supported	As in SIMV plus positive pressure above PEEP	Avoids most problems of SIMV alone, faster weaning	More complex, not available on all ventilators

SIMV synchronized intermittent mandatory ventilation, *AC* assist/control, *PSV* pressure support ventilation

endotracheal tubes, the high airway resistance for unsupported spontaneous breaths results in ineffective rapid shallow breathing, high work of breathing, and exhaustion. Nonetheless, many clinicians still prefer SIMV, especially for weaning from mechanical ventilation based on the flawed assumption that weaning of ventilatory rate is necessary prior to extubation. However, experience with high-frequency ventilation demonstrates that lowering pressure amplitude and leaving the rate unchanged is an effective way of reducing ventilator support to the point of extubation. It has been clearly demonstrated that lung injury is most directly caused by excessive V_T, irrespective of the pressure required to generate that V_T. Because the mechanical breaths of SIMV must compensate for the ineffective spontaneous breaths in small infants, significantly larger tidal volume is needed to maintain adequate alveolar minute ventilation. Thus, it would be reasonable to accept that a larger number of smaller breaths with AC is probably less injurious. Many also believe that supporting every breath results in lack of respiratory muscle training. This concern stems from a failure to recognize that during synchronized ventilation the delivered tidal volume is the result of the combined negative inspiratory pressure of the patient and the positive pressure generated by the ventilator. This combined effort (the baby "pulling" and the ventilator "pushing") results in the transpulmonary pressure, which determines the V_T delivered at a given compliance of the respiratory system. Thus, as ventilator pressure is decreased during weaning, the infant gradually assumes a greater proportion of the work of breathing and in the process achieves training of the respiratory muscles. Ultimately, the ventilator pressure is decreased to the point of merely overcoming the added resistance of the ETT and circuit, at which point the infant is achieving a normal level of work of breathing and is ready for extubation. The limitations of SIMV can be mitigated by provision of pressure support for the spontaneous breath, when this mode is available. Pressure support ventilation (PSV) can also be used as a stand-alone mode (without SIMV), when it is very similar to AC (including a backup apnea rate on the specialty neonatal ventilators), with the difference being that PSV is flow-cycled, rather than time-cycled.

Volume-Targeted Ventilation

Recognition that volume, not pressure, is the critical determinant of ventilator-induced lung injury, along with clear evidence that hypocarbia is associated with neonatal brain and lung injury has made direct control of V_T more desirable. Modifications of time-cycled, pressure-limited ventilation have evolved that are designed to target a target tidal volume by microprocessor-directed adjustments of peak pressure or inspiratory time. Each of the available modes has advantages and disadvantages. The most widely available modes of volume-targeted ventilation (VTV) are briefly described in *Table 19.4*. All forms of volume-targeted ventilation depend on accurate measurement of V_T and are adversely affected by large leak around uncuffed endotracheal tubes. Volume guarantee (VG) is the most extensively studied form of volume-targeted ventilation. It is an option available on the Draeger Babylog 8000-plus and the newer

Table 19.4
Various forms of volume-targeted ventilation (VTV)

	Controls	Adjusts	Based on
PRVC (Servo 300, Servo i)	V_T to circuit	Inspiratory pressure	Exhaled V_T
VAPS (VIP Gold, Avea)	V_T to circuit	Inspiratory time/flow	Inspiratory V_T
VL (Bear Cub 750, Avea)	V_T to circuit	Inspiratory time	Inspiratory V_T
TTV (SLE 5000)	V_T to circuit	Inspiratory time	Inspiratory V_T
VV+ (Puritan Bennett 840)	V_T to circuit	Inspiratory time/flow	Inspiratory V_T
VG (Babylog 8000, VN500)	V_T to patient	Inspiratory pressure	Exhaled V_T

PRVC pressure-regulated volume control, *VAPS* volume-assured pressure support, *VL* volume limit, *TTV* targeted tidal volume (essentially same as VL), *VV* volume ventilation+, *VG* volume guarantee. V_T to circuit = control of V_T is based on volume measurement at the ventilator end of the circuit (affected by circuit compliance), V_T to patient = control of V_T is based on proximal (accurate) V_T measurement. Exhaled V_T = V_T is controlled based on previous breath

VN500 (Dräger, Lübeck, Germany) that may be combined with any of the basic ventilator modes (AC, SIMV, and PSV). The user chooses a target V_T and a pressure limit up to which the inspiratory pressure (the working pressure) may be adjusted. The microprocessor compares the V_T of the previous breath, using exhaled V_T to minimize possible artifact due to airleak, and adjusts the working pressure of the next breath up or down to achieve the target V_T. The PIP increase from breath to breath is limited in order to avoid over-correction leading to excessive V_T. This means that with rapid changes in compliance or patient inspiratory effort, several breaths are needed to reach target V_T. A volume limit function based on inspiratory tidal volume is a secondary safety feature to minimize the risk of excessively large V_T. The microprocessor opens the expiratory valve, terminating inspiration if the delivered V_T exceeds 130% of the previous breath. The servoregulation of inspiratory pressure makes VG a self-weaning mode. Because weaning occurs in real-time, rather than intermittently in response to blood gases, VG has the potential to achieve faster weaning from mechanical ventilation. The documented benefits of volume guarantee are listed in *Table 19.5*.

Table 19.5
Documented benefits of volume guarantee ventilation in comparison to traditional pressure-limited ventilation

Same or lower PIP	Cheema 2001, Abubakar 2001, Herrera 2002

Novel Modes of Respiratory Support

Proportional assist ventilation has been available on the Stephanie ventilator (Stephan GmbH Medizintechnik, Gackenbach Germany) for a number of years. It is a modality that modulates inspiratory pressure in proportion to tidal volume and inspiratory flow, providing elastic and resistive unloading. It is a form of positive feedback delivering support in proportion to patient effort and as such, it assumes mature respiratory control. It therefore may not be suitable for premature infants. The common problem of periodic breathing would be accentuated by the ventilator, with less support being generated with hypopnea and excessively high level of assist provided when the infant becomes agitated. Also, because the system responds to inspiratory flow and volume, a large leak around the ETT would be interpreted as a large inspiration and supported by correspondingly large inspiratory pressure, potentially leading to dangerously large V_T.

Neurally Adjusted Ventilator Assist (NAVA) is an interesting approach that uses the patient's own respiratory control to drive the ventilator. Bipolar electrodes mounted on a nasogastric tube and positioned at the level of the diaphragm sense the diaphragm's electrical activity to trigger and adjust the level of support in proportion to the inspiratory effort. NAVA is still

experimental in newborn infants. As a trigger, the concept is attractive, because it is not affected by leak around endotracheal tubes. However, like PAV, it utilizes a positive feedback scheme and assumes that the respiratory control center is mature, an assumption that is clearly not valid in the preterm infant.

Clinical Application

As discussed above, the choice of SIMV or AC is, to some extent, a matter of personal preference and practice style. In reality, there is little difference between the two in the acute phase of respiratory failure, especially when the infant has little or no respiratory effort of their own. Under these circumstances, simple IMV is provided, regardless of the ventilator mode selection. However, the differences between SIMV and AC/PSV become more pronounced during weaning and are especially important in the smallest infants with narrow endotracheal tubes. Prolonged ventilation with low SIMV rates without pressure support should be avoided in these infants, as it imposes an undesirably high work of breathing.

Standard Synchronized Ventilation Modes

As with all pressure-limited, time-cycled ventilators, the operator must chose inspiratory and end-expiratory pressure (PIP and PEEP), inspiratory time, ventilator rate (either directly or by separately adjusting inspiratory and expiratory time), inspiratory flow rate or rise time, and FiO_2. The initial steps are common to all forms of synchronized ventilation.

Initial Settings

The starting **PIP** is selected based on severity of lung disease and adequacy of chest rise and should then be adjusted to achieve an appropriate V_T, typically 4–7 ml/kg, measured at the airway opening. Contrary to widely held beliefs and numerous published tables, the requirement for PIP is *not* related to the baby's size, but to severity of illness. The misconception arose from the fact that larger babies cope with poorly compliant lungs more effectively because of their greater strength and endurance. Consequently, respiratory failure occurs at lesser degrees of illness severity in the smaller infant. However, even small preemies may have very stiff lungs and may, at times, require fairly high pressures. On the other hand, the term infant with normal lungs who is ventilated for non-respiratory reasons will only need PIP of 12–14 cmH_2O to achieve a normal V_T. Beware of rapid improvement in compliance following surfactant administration or lung volume recruitment! When tidal volume measurement is not available, the clinician must rely on assessment of chest rise, air entry on auscultation, and blood gas determination.

The use of adequate **PEEP** to achieve a well-aerated "open lung," along with avoidance of excessive V_T, is central to the prevention of ventilator-associated lung injury. PEEP should be set in proportion to the oxygen requirement, because, except when extrapulmonary right-to-left shunting is present, hypoxemia is a reflection of ventilation/perfusion imbalance and intrapulmonary right-to-left shunting, a reflection of atelectasis and low lung volume. With few exceptions, high oxygen requirement can be corrected by adequate PIP to open atelectatic alveoli, and sufficient PEEP to maintain lung volume. PEEP of 5 cm H_2O is usually adequate if the FiO_2 is 0.25–0.35, PEEP should be increased to 6 cm H_2O with oxygen requirement between 0.35 and 0.50 and 7–10 cm H_2O if FiO_2 remains >0.60. Selection of the level of PEEP can additionally be guided by lung expansion on chest X-ray.

Selection of **inspiratory time** ($\mathbf{T_i}$) should reflect the infant's time constants, a measure of how rapidly gas can get in and out of the lungs; mathematically the product of resistance and compliance. Small preterm infants with respiratory distress syndrome (low compliance, low resistance) have very short time constants and should be ventilated with Ti of 0.3 s or less. Large infants or those with increased airway resistance (e.g., chronic lung disease, meconium aspiration) have longer time constants and require longer Ti, up to 0.5 s, occasionally more. Prolonged Ti as a means of improving oxygenation is now rarely used, because it is associated with greater risk of airleak.

Ventilator rate should reflect the severity of illness and the infant spontaneous respiratory effort. Infants with severe lung disease and little or no respiratory effort need a fairly rapid rate of 50–60 breaths/min. Spontaneously breathing infants with less severe disease can be supported with rate of around 40 breaths/min, allowing them to trigger the ventilator. It is important to keep in mind the need to allow sufficient expiratory time to avoid air-trapping due to incomplete exhalation. Therefore, rates >60/min in larger infants or those with increased airway resistance and >80 in small preemies should be avoided. Adequacy of inspiratory and expiratory time can be verified by observing the flow waveform and making sure that flow returns to zero (baseline) before each expiration and inspiration begins.

Some ventilators have continuous flow through the circuit that remains constant throughout the breath cycle; others have demand flow that provides additional gas flow over a low baseline available for spontaneous breathing. Continuous flow devices need the user to choose **inspiratory flow rate** (usually 4–10 l/min, depending on patient size). Demand flow devices require the user to select a **"rise time"** which is a reflection of how rapidly the circuit is pressurized. Currently, there is little evidence available to guide the setting of optimal rise time, but most clinicians elect to use 50–75% rise time.

Subsequent Adjustments

When the infant begins to generate spontaneous respiratory effort, ventilator rate should be lowered to just below the normal breathing rate, to allow the infant to take over some of the work of breathing; an excessively rapid rate will override the infant's own effort and defeat the purpose of synchronized ventilation, i.e., the infant and the ventilator working together. Similarly, low $PaCO_2$ will suppress the infant's respiratory drive and is equally undesirable.

It is important to understand clearly how different ventilator variables affect gas exchange and how they interact with the underlying pathophysiology. ***Oxygenation*** is controlled by adjustments in FiO_2 and mean airway pressure, as discussed above. The goal should be to optimize lung volume and ventilation/perfusion matching and lower FiO_2 to <0.35 ("open the lung and keep it open"). PEEP is the most important determinant of mean airway pressure (Paw) with PIP, inspiratory time and rise time (how quickly plateau pressure is reached) being the other factors. ***Ventilation*** (CO_2 elimination) is controlled by adjusting ventilatory rate and V_T. In standard pressure-limited ventilation, V_T, is determined by lung compliance and the ΔP or pressure amplitude (difference between PIP and PEEP). Thus, increasing PIP will improve ventilation as well as oxygenation, through its effect on V_T and Paw. Increasing PEEP and/or lowering PIP will decrease V_T, if all other factors remain equal. However, if the increased PEEP results in recruitment (normalization) of lung volume, this will lead to better lung compliance and may actually improve ventilation, sometimes quite dramatically and lead to inadvertent hyperventilation (this can be avoided by the use of volume-targeted ventilation). Excessively high PEEP will cause overexpansion of the lungs with resultant hemodynamic compromise and incomplete exhalation (lower V_T), resulting in hypercapnia. Lowering PEEP in such situations will improve ventilation. It is important to recognize that as the patient's lung disease evolves major changes in compliance and resistance will occur. Therefore, the appropriateness of all settings needs to be reevaluated frequently. For example, PEEP of 6 or 7 cm H_2O, which would be quite appropriate early in the course of RDS when the lungs are stiff will become excessive as compliance and lung volume improve. Oxygen requirement is the best bedside tool to assess adequacy of lung volume. If FiO_2 is <0.25, PEEP should be no higher than 4–5 cm H_2O.

Weaning

With SIMV, weaning is accomplished by reducing PIP as well as ventilator rate. In general, rate should not be reduced substantially until PIP is down to relatively low values ($<$16–20 cm H_2O) that signify improved lung compliance. Weaning the rate while the lungs are still quite stiff would impose a high work of breathing and may require excessively large V_T for the machine breaths to compensate for ineffective spontaneous breaths that may do little more than rebreathe the anatomical dead space. The rate should not be reduced to $<$10 breaths/min, especially in small infants, because of the high work of breathing associated with small ETT. As a rule, infants who are able to generate adequate V_T and gas exchange with PIP of 15–18 cm H_2O and rate of 10 breaths/min are ready for extubation. Tachypnea and retractions suggest that the infant is not tolerating the weaning and needs a higher level of support.

With AC and PSV, the infant controls the ventilator rate, therefore there is little impact of lowering the set rate, which only acts as backup in case of apnea. Weaning is accomplished by lowering the PIP, thereby decreasing the amount of support for each breath and transferring gradually the work of breathing to the infant. The infant should be extubated when PIP is reduced to 10–14 cm H_2O in small preemies and 15–20 cm H_2O in larger infants and there is a sustained spontaneous effort without excessive work of breathing. In very premature infants, the backup rate should be reduced to 15–20 breaths/min for a few hours prior to extubation to uncover inconsistent respiratory effort/periodic breathing that may be masked by a higher backup rate.

Volume-Targeted Ventilation

VTV is best implemented soon after initiation of mechanical ventilation, as this is the time when most rapid changes in lung mechanics are likely to occur. Success

with volume-targeted ventilation (VTV) depends on the appropriate choice of target V_T. Exhaled V_T of 4–5 ml/kg during the acute phase of the illness in term and preterm infants with homogeneous lung disease is appropriate. Infants with heterogeneous lung disease and/or lung overinflation have increased physiologic dead space and need larger V_T (as much as 6–8 ml/kg). When changing from simple pressure-limited mode, the easiest approach is to start with a V_T similar to what was generated on the pressure-limited mode, assuming the $PaCO_2$ was normal. Appropriate pressure limit should be selected to minimize the potential for excessive V_T delivery. The unique characteristics of each VTV mode must be considered when selecting specific settings. The site of V_T measurement is critical – accurate measurement can only be obtained by a flow sensor at the airway opening. The "open lung concept" is central to optimizing the impact of volume-targeted ventilation: Its benefits cannot be realized without ensuring that this tidal volume is distributed evenly throughout the optimally aerated lungs. With improving lung compliance and patient respiratory effort, the ventilator pressure will come down with volume guarantee, referred to as self-weaning. However, with the volume limit type of VTV, the effective inspiratory time is what is reduced if the set PIP is kept unchanged, resulting in an abnormally short Ti with the airways being exposed to high PIP. Therefore, with volume limit modes, the PIP needs to be lowered manually to generate a V_T close to the target volume. Regardless of VTV mode, the target V_T should not be lowered below a normal physiologic value of about 4 ml/kg – doing so would only impose an excessive workload on the infant and impair weaning.

Conclusion

Avoidance of mechanical ventilation by means of early CPAP with or without surfactant administration may be the most effective way to reduce the risk of chronic lung disease, but the smallest and sickest infants continue to require mechanical ventilation. A host of new modalities and techniques have been made available for the treatment of respiratory failure. The understanding of how to optimally use these devices, while improving constantly, remains somewhat behind the pace of technological innovation. Each ventilator functions differently and it is critical that the user becomes familiar with the specific features of their device. The reader is referred to user manuals of their respective devices for further guidance. A ventilator is only a tool in the hands of the clinician; a tool that can be used well, or not.

20 Mechanical Ventilation: HFV

Anton H. van Kaam · Martin Keszler

Basic Principles

Like with any other mode of mechanical ventilation, the basic goal of high-frequency ventilation (HFV) is to deliver oxygen to and clear carbon dioxide from the blood, while minimizing ventilator-induced lung injury (VILI) as much as possible. In order to achieve this goal, a constant pressure, often referred to as mean airway pressure or continuous distending pressure (CDP), is applied to the lungs. This CDP stabilizes airways and alveoli/saccules. Superimposed on this CDP are small pressure swings, usually at a frequency of 6–15 Hz or 240–900 cycles/min, resulting in small volume changes of approximately 1–3 ml/kg. Despite the fact that these volume changes are sometimes smaller than the anatomical dead space, HFV is very efficient in clearing carbon dioxide from the lungs. Some of the mechanisms responsible for adequate gas exchange during HFV are coaxial flow, asymmetric velocity profiles, the pendelluft effect and molecular diffusion.

High-Frequency Modalities

There are three types of HFV available for clinical use. Although similar in the basic principles of ventilation, each HFV modality has its own unique characteristics. During *high-frequency oscillatory ventilation (HFOV)*, gas within the airways is moved in and out (oscillated) by an in-line piston or diaphragm (so-called piston oscillators) or an intermittent expiratory venturi jet (non-piston oscillators). The key feature of HFOV is that at 1:1 inspiratory: expiratory ratio, the negative pressure deflection is equal to the positive deflection, therefore both the inspiration and expiration phases are active. Examples of piston oscillators are the Sensormedics 3100A & 3100B, the Humming V, the Flowline Dragonfly, the Leoni plus, and the Stephan SHF 3000. Contemporary non-piston oscillators include the SLE 5000, the Drager Babylog 8000+, and the Babylog VN 500.

High-frequency jet ventilation (HFJV) delivers short pulses of pressurized gas directly into the upper airway via a special endotracheal tube containing a HFJV injector port. In contrast to HFOV, exhalation is passive, resulting in somewhat lower optimal operating frequencies. The mean airway pressure is primarily generated by applying positive end-expiratory pressure via a conventional ventilator used in tandem, sometimes combined with very low-rate conventional mechanical ventilation to provide periodic sigh as a means of lung volume recruitment.

High-frequency flow interruption (HFFI), also known as *high-frequency percussive ventilation,* is usually delivered by hybrid ventilators, also capable of delivering conventional mechanical ventilation. These devices generate short bursts of gas delivered directly into the ventilatory circuit without the narrow injector cannula used in HFJV. For many years, the Infant Star 950 ventilator was widely used in the USA, Europe, and elsewhere. It is no longer manufactured, but remains in use in many parts of the world. In this device, a venturi system on the exhalation valve assists the return of pressures to expiratory baseline and results in a modest negative deflection, facilitating expiration. However, the negative deflection is much smaller than the positive deflection leading to air trapping and increased risk of air leak. The Bronchotron, a pneumatically powered high-frequency flow interrupter developed in the 1980s, is gaining popularity as a neonatal transport ventilator because of its light weight, low gas consumption, and ability to function as both conventional and high-frequency ventilator. The Volumetric Diffusive Respirator – VDR 4 – is a time-cycled, pressure-limited, pneumatically driven high-frequency flow interrupter device similar to the Bronchotron, but more complex and designed for hospital use.

Animal studies have shown that mechanical ventilation can lead to VILI and identified alveolar overdistension (volutrauma) and collapse (atelectrauma) as important risk factors. As previously mentioned, by design, HFV uses very small tidal volumes, which can potentially reduce VILI (less volutrauma) during mechanical ventilation. Animal studies comparing HFV to conventional mechanical ventilation have indeed shown that HFV attenuates lung injury but only when combined with an optimal lung volume or open-lung ventilation strategy (less atelectrauma).

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_20,

High-Frequency Ventilation: The Open Lung Strategy

The primary goal of the open-lung strategy is to avoid both alveolar overdistension and collapse. To achieve the latter, collapsed alveoli need to be actively recruited and thereafter stabilized with sufficient airway pressure (CDP). *Figure 20.1* shows the pressure-volume (P/V) relationship of a single alveolus. After a critical opening pressure is reached, the collapsed alveolus pops open, immediately resulting in a large volume increase. As follows by the law of LaPlace, which states that the pressure (P) necessary to keep a spherical structure opened is two times the surface tension (γ) divided by the radius (r), the critical closing pressure of the alveolus will be lower than the opening pressure (increased radius). The P/V curve of the entire lung reflects the cumulative volume changes of all alveoli during incremental (inflation limb) and decremental (deflation limb) airway pressure steps (*Fig. 20.2*). Comparable to the behavior of a single alveolus, the lung volume gained during incremental pressure steps can be maintained at a lower airway pressures, a phenomenon called *lung hysteresis*. Placing HFV on the deflation limb of the P/V curve will optimize lung volume and compliance at the lowest possible airway pressure.

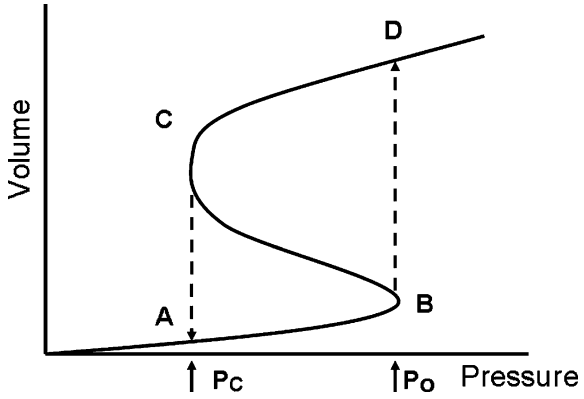

Figure 20.1
Schematic drawing of the pressure-volume relationship of a single alveolus during inspiration and expiration (solid line). At the start of the inspiration, (A) the alveolus is collapsed. At point B, the pressure increase has reached the critical opening pressure (Po), leading to an immediate volume increase (dashed line) as the alveolus is recruited (D). As the pressure is slowly decreased, there is little volume loss until the critical closing pressure (Pc) is reached at point C. The alveolus immediately collapses to point A. Note that Pc is lower than Po due to the law of LaPlace

Although the importance of an open lung strategy during HFV is well recognized, there is currently no validated, easy to use, bedside tool to measure changes in lung volume in newborn infants. Most clinicians have therefore adopted oxygenation as an indirect tool to measure changes in lung volume. Increases in airway pressure that result in alveolar recruitment will reduce intrapulmonary shunt and improve oxygenation. In theory, optimal recruitment will reduce intrapulmonary shunt to <10%, allowing for adequate oxygenation without supplemental oxygen. However, most clinicians use a target fraction of inspired oxygen (FiO_2) ≤ 0.30 to define optimal recruitment. *Figure 20.3* shows a schematic overview of the recruitment procedure. First, the CDP is stepwise increased over time until oxygenation no longer improves or the $FiO_2 \leq 0.30$, whichever comes first (opening pressure). Next, the CDP is stepwise reduced until oxygenation deteriorates (closing pressure). Finally, the CDP is briefly increased to the opening pressure in order to recruit the collapsed alveoli and is then set 2 cmH_2O above the closing pressure (optimal pressure). A recent study in preterm infants with respiratory distress syndrome (RDS) showed that this approach resulted in an optimal recruitment ($FiO_2 \leq 0.30$) in 96% of the included infants. The association between lung volume and oxygenation can be compromised by extrapulmonary right-to-left shunting (congenital heart defect, persistent pulmonary hypertension) and reduced pulmonary diffusion capacity (pneumonia, aspiration syndromes).

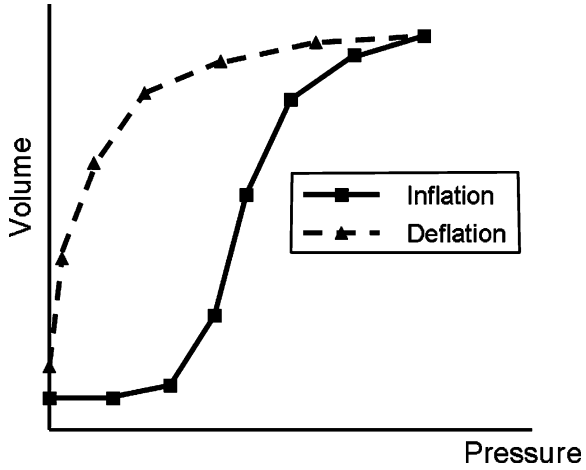

Figure 20.2
Pressure–volume relationship of the lung showing the inflation (solid line) and the deflation limb (dashed line). Note the clear difference in lung volume between both limbs at identical pressures (*hysteresis*)

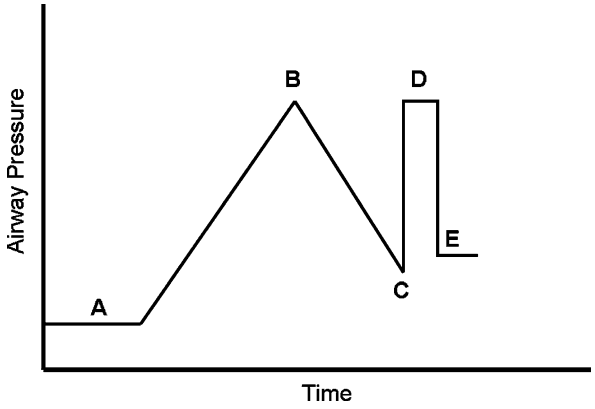

Figure 20.3

Schematic presentation using oxygenation to optimize lung volume in preterm infants with RDS. At the start, (A) airway pressures is low and FiO_2 is high, indicating a high degree of atelectasis and intrapulmonary shunt. Over time, airway pressures are stepwise increased, resulting in alveolar recruitment, a reduction in intrapulmonary shunt, and an improvement in oxygenation. The latter will allow a stepwise reduction in FiO_2, thus preventing hyperoxia. Airway pressures are increased until FiO_2 is below 30% or oxygenation no longer improves (B). The pressure level at point B is called the opening pressure. Airway pressures are stepwise reduced until FiO_2 starts to increase, indicating alveolar derecruitment (C). This pressure level is called the closing pressure. After reopening collapsed alveoli (D), airway pressure is set to 2 cmH_2O above closing pressure to ensure a stabilization of lung volume (E)

Based on the encouraging results from experimental reports, showing less VILI compared to conventional mechanical ventilation, HFV was also investigated in newborn infants. Most of these studies were conducted in preterm infants with RDS, and only a few studies explored the use of HFV in other causes of neonatal respiratory failure.

HFV in RDS

Starting in 1989, to date, 17 randomized controlled trials have compared HFV to conventional positive pressure ventilation as a primary treatment in preterm infants with RDS. Most of these trials used mortality and/or bronchopulmonary dysplasia (BPD) as the primary outcome parameters. Meta-analysis of the trial results showed, at most, a modest but inconsistent reduction in the incidence of BPD in favor of HFV. Some of the suggested reasons for this disappointing effect of HFV on the incidence of BPD are changes over time of the conventional ventilation strategy (more lung protective), and the fact that in the majority of trials that intended to apply an open-lung strategy during HFV were probably not successful. Primary HFV may be beneficial in a subgroup of preterm infants with RDS but only when combined with an open-lung strategy. HFV is used most often in infants with RDS as an early rescue rather than as a primary modality. Infants are transitioned to HFV if they are showing early signs of air leak, or if they are judged to be at high risk of complications, because they are requiring relatively high inspiratory pressure to achieve adequate gas exchange. Most clinicians experienced in the use of HFV will begin HFV if infants with birth weight $<$1,000 g are requiring PIP of 25 cmH_2O and slightly higher in larger infants. The greatest benefit of HFV may be the relative ease with which lung volume recruitment can be achieved. Animal studies have suggested that the same benefits as with HFV can be achieved when conventional ventilation is used with the open lung strategy.

HFV in Other Causes of Respiratory Failure

Animal studies have shown that when combined with an open-lung strategy, HFV improves gas exchange and attenuated VILI compared to conventional mechanical ventilation in a model of *meconium aspiration syndrome* (MAS). Two randomized controlled trials in infants with MAS suggested that both HFOV and HFJV improve gas exchange, compared to conventional ventilation, and may reduce the need for more invasive therapies. However, there were no differences in mortality and long-term morbidity. Because of the longer time constants in term infants in general and those with airway obstruction due to MAS in particular, lower frequencies should be used with both HFJV and HFOV. Similar results were also reported for other aspiration syndromes and in *pneumonia*.

HFV has also been investigated in infants with *air leak syndrome (ALS)*. One cohort study reported a successful resolution of the ALS during HFOV. A larger, prospective randomized trial showed higher success rate and faster resolution of *pulmonary interstitial emphysema* with HFJV. When crossover was taken into account, HFJV improved survival. No long-term effects were reported. It appears that HFJV is uniquely suited for the treatment of air leak because of its extremely short inspiratory time and the nature of the compact streaming of gas down the center of the larger airways. HFJV has been shown also to be effective in the treatment of *bronchopleural* and *tracheoesophageal fistulae.*

The use of HFV in patients with *congenital diaphragmatic hernia* (CDH) and *lung hypoplasia* have mainly been reported in case reports and series. Compared to historical controls, most of these reports showed an improved survival after adopting HFV in the management of CDH/lung hypoplasia. To date, no randomized controlled trials have explored effect of HFV on long-term outcome parameters.

In summary, HFV can potentially improve gas exchange and mortality in other causes of neonatal respiratory failure, but the randomized evidence on these outcomes is limited and the effect on long-term morbidity needs to be established.

Recommended initial settings and subsequent adjustments are briefly outlined in ❯ *Table 20.1*.

High-Frequency Ventilation: Complications

HFV has been associated with several adverse effects. Some of the earlier trials on HFV reported an increased risk for severe intraventricular hemorrhage and

Table 20.1
Suggested initial settings and subsequent adjustments for HFOV and HFJV in infants with various diagnoses

Diagnosis	HFOV	HFJV
RDS		
Initial settings	Freq 10–15 Hz, MAP 8–10 cmH_2O (or 2 cmH_2O > than on CV), power/amplitude sufficient to cause adequate chest vibration. 1:2 I:E ratio, if available.	Rate 400–450, PIP sufficient to cause adequate chest movement (or same as on CV), PEEP 6–8 cmH_2O. Ti 0.02 s.
Subsequent adjustment	Increase Paw in increments of 1–2 cmH_2O if FiO_2 > 0.30. Once oxygenation improves, decrease Paw to find point just above critical closing pressure. Adjust amplitude in response to $PaCO_2$, changes in chest vibration. Adjust Paw in response to SPO_2, PaO_2.	Increase PEEP in increments of 1–2 cmH_2O if FiO_2 > 0.30. Once oxygenation improves, decrease PEEP to find point just above critical closing pressure. Adjust PIP in response to $PaCO_2$, changes in chest vibration. Adjust PEEP in response to SPO_2, PaO_2.
Air leak		
Initial settings	Freq 10–12 Hz, MAP 8–10 cmH_2O (or 2 cmH_2O > than on CV), power/amplitude sufficient to cause just adequate chest vibration. Accept moderate hypercapnia, higher FiO_2, avoid aggressive recruitment.	HFJV is preferred, if available. Rate 380–420, PIP sufficient to cause just adequate chest movement (or 2 cm <CV), PEEP 6–7 cmH_2O. Accept moderate hypercapnia, higher FiO_2, but avoid atelectasis by using enough PEEP.
Subsequent adjustment	Adjust amplitude in response to $PaCO_2$, changes in chest vibration. Adjust Paw in response to SPO_2, PaO_2.	Adjust PIP in response to $PaCO_2$, changes in chest vibration. Adjust PEEP in response to SPO_2, PaO_2.
MAS		
Initial settings	Freq 6–8 Hz, MAP 10–14 cmH_2O (or 2 cmH_2O > than on CV), power/amplitude sufficient to cause adequate chest vibration. Accept mild hypercapnia, higher FiO_2.	Rate 280–360, PIP sufficient to cause adequate chest movement (or same as CV), PEEP 7–10 cmH_2O. Accept mild hypercapnia, higher FiO_2. Avoid atelectasis and air trapping by using enough PEEP.
Subsequent adjustment	Adjust amplitude in response to $PaCO_2$, changes in chest vibration. Adjust Paw in response to SPO_2, PaO_2. If PPHN is present, iNO may be indicated.	Adjust PIP in response to $PaCO_2$, changes in chest vibration. Adjust PEEP in response to SPO_2, PaO_2. If PPHN is present, iNO may be indicated.
CDH		
Initial settings	Freq 10–12 Hz, MAP 8–10 cmH_2O (or 1 cmH_2O > than on CV), power/amplitude sufficient to cause just adequate chest vibration. Accept mild hypercapnia, higher FiO_2, avoid aggressive recruitment.	Rate 360–420, PIP sufficient to cause adequate chest movement (or same as CV), PEEP 6–8 cmH_2O. Accept mild hypercapnia, higher FiO_2.
Subsequent adjustment	Adjust amplitude in response to $PaCO_2$, changes in chest vibration. Adjust Paw in response to SPO_2, PaO_2. Avoid lung overexpansion.	Adjust PIP in response to $PaCO_2$, changes in chest vibration. Adjust PEEP in response to SPO_2, PaO_2. Avoid lung overexpansion.

periventricular leucomalacia. It has been suggested that these adverse effects were caused by the use of a low volume HFV strategy and/or these trials were not successful in avoiding hypocapnia. More recent studies in extremely preterm infants did not report an increased risk of the aforementioned adverse effects. Studies with the Infant Star HFFI in aggregate showed increased incidence of air leak. There have been concerns that the relatively high airway pressures applied during open-lung HFV can compromise the hemodynamic status. However, two recent cohort studies showed that open-lung HFV when applied correctly did not compromise heart, blood pressure, and systemic blood flows. It must be understood that once lung-volume recruitment is achieved, the lungs become more compliant, and mean airway pressure must be reduced to a point just above the critical closing pressure in order to avoid hemodynamic compromise. Finally, several early animal studies reported increased inflammation of the tracheal and bronchial mucosa (necrotizing tracheobronchitis) after HFV, which can cause airway and endotracheal tube obstruction. However, this problem is not unique to HFV and appears to have been caused by high airway pressure with systemic hypotension with HFOV and inadequate humidification of inspired gases with early prototype HFJV devices. The clinical relevance of these studies today appears limited.

Conclusion

High-frequency ventilation is a valuable, often life-saving treatment modality in infants who are not responding well to conventional ventilation. Its role as a primary treatment modality in infants with uncomplicated RDS remains controversial, although it is used with considerable success in select NICUs. The benefits of HFV as a primary mode have become more difficult to demonstrate more recently as the nature and severity of RDS have evolved due to greater use of antenatal steroids, effective, rapidly acting surfactants and more sophisticated, gentler, conventional ventilation modes have become available. Knowledge of the unique characteristics of each HFV (or conventional) device is critical to optimal use. Careful attention to accurate assessment of the underlying disease process and tailoring the ventilation strategy to address the predominant pathophysiology are vital to achieving the best results. The recognition of the importance of the open-lung approach is probably the single most important development in mechanical ventilation.

21 Complications of Mechanical Ventilation

Kabir M. Abubakar

Even though mechanical ventilation provides lifesaving support for infants with respiratory failure, it can be associated with a variety of complications. Adverse effects associated with mechanical ventilation range from events related to endotracheal intubation, airway and tracheal injury, air-leak syndromes, volutrauma/bronchopulmonary dysplasia, hemodynamic compromise, and neurologic injury.

Complications of Endotracheal Intubation

The process of introducing a laryngoscope to visualize the larynx and vocal cords and insertion of the endotracheal tube (ETT) produces significant stress to the infant, very often leading to periods of bradycardia and oxygen desaturation. Premedication with several pharmacologic agents either alone or in combination including atropine, fentanyl, muscle relaxants, benzodiazepines, and other agents has been shown to facilitate the procedure (fewer attempts and shorter times), reducing potentially harmful physiological fluctuations and pain. Tracheal injury can lead to tracheal perforation, which is associated with significant mortality. Subglottic stenosis, although now rare (1–2%), can occur in intubated neonates (sometimes in association with subglottic cysts) primarily as a result of friction injury from the endotracheal tube. Palatal deformities can develop with resultant grooves and a high-arched palate that can lead to significant feeding and speech problems. The presence of the ETT is an important portal for infection leading to ventilator-associated pneumonia (VAP). The frequency of VAP is directly related to duration of mechanical ventilation and can be minimized by prompt extubation as soon as possible.

Mechanical complications associated with endotracheal intubation can be minimized by a skillful technique, premedication for elective intubation, use of appropriate size endotracheal tubes, and avoidance of intubation by using less invasive modes of respiratory support where possible.

Air-Leak Syndromes

Pulmonary air-leak syndromes are a cause of significant mortality and morbidity in ventilated neonates, particularly extremely low birth weight infants. Air-leak syndromes can present as *pneumothorax* (Fig. 21.1), *pneumomediastinum*, or *pulmonary interstitial emphysema* (PIE). Occasionally they may present as a *pneumopericardium* and *subcutaneous emphysema.*

Air-leak complications generally occur in infants with significant lung disease undergoing mechanical ventilation, but can occur spontaneously or in infants receiving continuous positive airway pressure (CPAP). In general, their incidence parallels the severity of lung disease, but inappropriate ventilator settings can cause air leak even in infants who are less ill. Poor lung compliance and extensive atelectasis increase the risk of alveolar rupture. Prolonged inspiratory time, high peak inspiratory pressure, excessive tidal volume, and air-trapping due to insufficient expiratory time all increase the risk of airleak during mechanical ventilation. All air leaks start with overdistension of alveoli or terminal bronchioles with resultant rupture and escape of air into the interstitium. The air then tracks along the peribronchovascular sheaths to the hilum and into the mediastinum producing a pneumomediastinum or dissects through the visceral pleura producing a pneumothorax. With pulmonary interstitial emphysema, the air remains in the interstitial space.

Pulmonary interstitial emphysema is predominantly seen in the extremely low birth weight infant with RDS on mechanical ventilation with a reported incidence of 3–5% in that category of infants. The lung connective tissue in these infants is more abundant and less dissectible; therefore, the air remains at this site and splints the alveoli in a state of inflation by impeding alveolar emptying in the distal alveoli while causing compression atelectasis of adjacent alveoli. Because of the perivascular location of this air, it also impedes pulmonary blood flow causing significant ventilation perfusion mismatch.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_21,

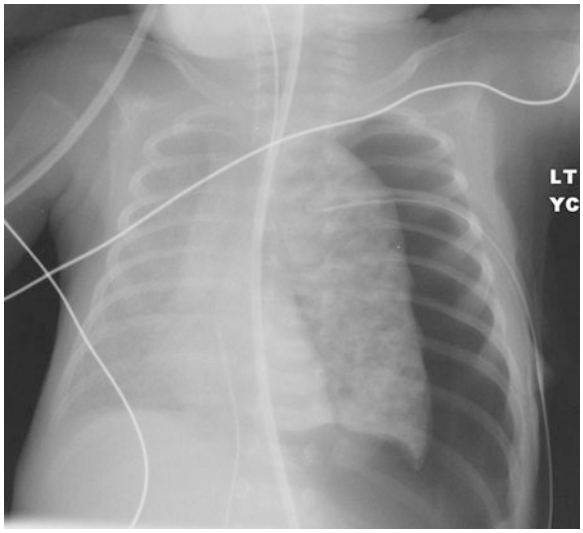

Figure 21.1
Left-sided tension pneumothorax with chest tube in place. Note how the left lung is compressed by pleural air, the mediastinal structures are shifted to the right and both lungs have become atelectatic

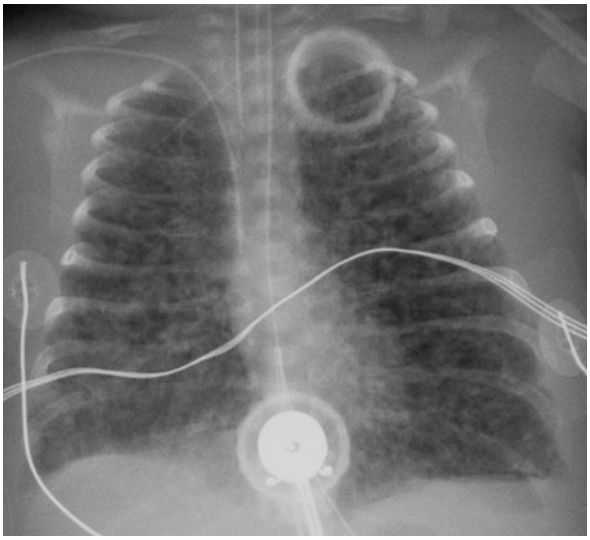

Figure 21.2
Bilateral pulmonary interstitial emphysema. Note the heart has been squeezed in the middle of the thorax by the over-expanded lung fields. The circular shadows at the top and bottom of the image are made by transcutaneous carbon dioxide sensors placed on the baby's skin

On x-ray, this appears as overexpanded lung fields with small round or branching lucencies of air interspersed with areas of atelectasis. The branching pattern may cause it to be confused with air bronchograms. PIE, unlike a pneumothorax, is not amenable to external drainage (*Fig. 21.2*). Management of an infant with PIE can present a special challenge and it is important to remember that in spite of the air leak, adequate MAP/PEEP is required to keep the unaffected alveoli open and maintain oxygenation. To this end, high-frequency ventilation has been shown to be better than conventional ventilation in these infants because adequate MAP can be provided with a lower lung volume and still remove CO_2 more efficiently. High-frequency jet ventilation has been shown to lead to faster and more frequent resolution of PIE in a multicenter randomized clinical trial. Oscillatory ventilation is also used with apparent success, though evidence for its benefit is anecdotal. PIE is often unilateral making management even more difficult. In those situations, use of selective main stem bronchial intubation/occlusion has been reported with varying success. Lateral decubitus positioning of the infant with the affected lung in a dependent position has been reported to be beneficial in unilateral PIE possibly because it causes plugging of dependent airways and improves oxygenation of the nondependent lung.

Pneumomediastinum is rarely associated with significant clinical symptoms because the air is usually not under tension and causes little respiratory compromise. Radiological appearance of pneumomediastinum can be varied but an area of hyperlucency in the superior retrosternal space can usually be seen and often the air elevates the lobes of the thymus producing the classic "sail sign." When large amounts of air are present, the thymus can be pushed to the apex of the lung, a finding often confused with atelectasis, or it can overlie the heart to be confused with a pneumopericardium. Pneumomediastinum is classically seen in infants with meconium aspiration syndrome because of the ball valve effect of particulate meconium. Because the air is usually not under tension, external drainage of a pneumomediastinum is usually not required. Air from a pneumomediastinum can track into the subcutaneous tissues of the neck and anterior chest wall producing subcutaneous emphysema or into the abdomen causing a *pneumoperitoneum.*

A pneumothorax is commonly associated with respiratory distress syndrome, meconium aspiration syndrome, and pulmonary hypoplasia, although it can occur spontaneously in nonventilated infants particularly term or late preterm infants with retained lung fluid born after elective cesarean section. Pneumothorax is seen more frequently

in immature infants requiring mechanical ventilation and was reported to occur in 3–13% of infants less than 28 week gestation born between 2003 and 2007 from the NICHD Neonatal Research Network centers.

Pneumothorax appears on chest x-ray as an area of hyperlucency lateral to the lung with no lung markings beyond the demarcation line. It can be unilateral or bilateral. On an anteroposterior film, the air may layer anteriorly and the noncompliant RDS lung may not collapse, making diagnosis more difficult. Greater lucency of one lung field with a very sharp heart border may be the only clue to the presence of an anterior pneumothorax. Lateral decubitus film is helpful in clarifying the diagnosis. Smaller collections of pleural air in a pneumothorax can be only mildly symptomatic and require observation/conservative management. The practice of nitrogen washout with 100% oxygen is strongly discouraged as the toxicity caused by hyperoxia likely outweighs the benefit of a slightly more rapid resolution of a non-tension pneumothorax. When a large amount of air collects in the pleural space under pressure it causes a "tension pneumothorax" leading to alveolar collapse and shift of the mediastinum to the contralateral side, compromising gas exchange as well as cardiac output. This presents acutely with a sudden decrease in oxygen saturation, hypotension, and bradycardia and represents a medical emergency requiring rapid evacuation of the air to allow lung reexpansion, adequate ventilation, and restoration of venous return/cardiac output. Bedside detection can be aided by use of a focused bright light to "transilluminate" the air in the pleural space. Rapid evacuation of the air can be achieved quickly with a 22–25 gauge needle inserted over the superior aspect of the rib in the midclavicular line and attached to a three-way stop cock and a syringe. Definitive evacuation of a pneumothorax may require chest tube drainage. Tension pneumothorax increases the risk of intracranial hemorrhage, likely by several mechanisms. The increased intrathoracic pressure from tension pneumothorax impairs venous return and at the same time reduces cardiac output, reducing cerebral perfusion and increasing venous back pressure. Following resolution, there may be a surge in cerebral blood flow as cardiac output is restored and enters the cerebral circulation rendered pressure-passive by hypoxia induced loss of autoregulation.

Pneumopericardium develops when there is dissection of air into the pericardial sac and is seen almost excusively in ventilated infants and is commonly in association with a pneumothorax. Some cases are asymptomatic, but if sufficient air accumulates, it will cause cardiac tamponade requiring urgent drainage. The infant presents with acute circulatory collapse, decreased pulse volume, and inaudible or distant heart sounds. The diagnosis is confirmed by lucency all the way around the heart on x-ray (*Fig. 21.3*) or by recovery of air and immediate improvement in the patient's condition after pericardiocentesis. This complication is now uncommon, but is still associated with a high mortality if immediate drainage is not accomplished.

Hemodynamic Compromise

Normal respiration generates negative pressure in the thorax, which facilitates venous return from the superior and inferior vena cavae. Mechanical ventilation by its nature delivers positive pressure to the lungs during all phases of respiration. This increase in intrathoracic pressure impedes venous return and therefore decreases ventricular filling, cardiac output, and pulmonary and systemic blood flow.

Systemic venous return depends on a pressure gradient between the peripheral veins and intrathoracic or right atrial pressure. This gradient is increased by spontaneous respiration because it generates a negative intrathoracic

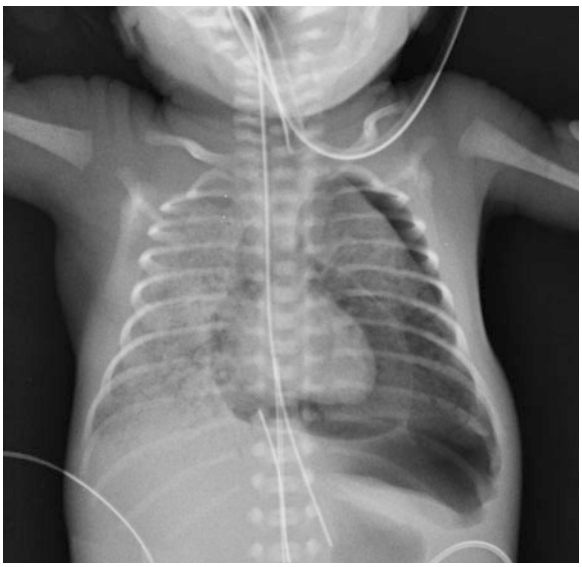

Figure 21.3
Pnemopericardium with tension pneumothorax. Note that the air completely surrounds the heart, including the infracardiac space. This clearly distinguishes this as pneumopericardium, rather than bilateral pneumomediastinum

pressure, therefore right ventricular filling and stroke volume will both increase during spontaneous inspiration. Positive pressure ventilation on the other hand increases both intrathoracic and right atrial pressures reducing right ventricular filling and preload. The use of PEEP prevents the intrathoracic pressure from returning to atmospheric levels, and the positive intrapleural pressure throughout the respiratory cycle leads to some degree of circulatory compromise with all forms of positive pressure ventilation. The transmission of airway pressure to the mediastinum is limited when the lungs are poorly compliant and increases when the airway pressure is excessive relative to lung compliance and leads to overexpansion of the lungs (*Fig. 21.4*). These effects are exaggerated in the presence of hypovolemia and decreased peripheral vascular tone as seen in patients with septic shock. In addition, the relative compliance of the chest wall and the lungs determines the amount of pressure transmitted to the pleural space. The relationship is described by the following equation:

$$\mathbf{P_{PL} = AWP \times (C_L/C_L + C_{CW})},$$

where P_{PL} is pleural pressure, AWP is mean airway pressure, C_L is compliance of the lungs, and C_{CW} is compliance of the chest wall. It can be seen that in situations of good lung compliance but poor chest wall compliance, transmission of pressure to the pleural space and hemodynamic compromise are increased. This is often seen in cases of increased intraabdominal pressure impairing diaphragmatic motion, or with massive chest wall edema.

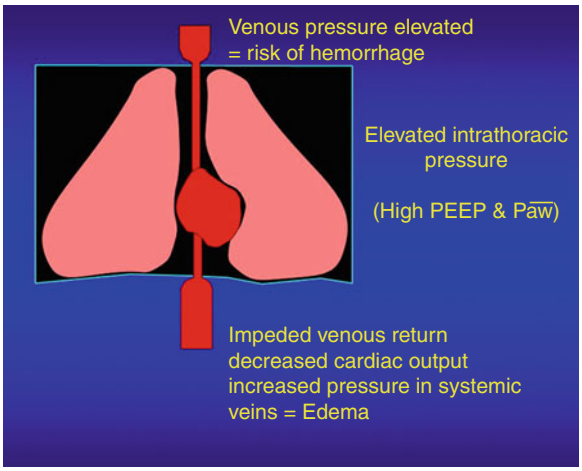

Figure 21.4
Schematic representation of impairment of venous return in the presence of excessive intrathoracic pressure

Changes in lung volume also affect pulmonary vascular resistance and right ventricular afterload. At excessive lung volumes, the alveolar vessels become directly compressed as a result of alveolar overdistension. Low lung volumes with atelectasis leads to collapse of intrapulmonary veins and hypoxic vasoconstriction, both leading to increased pulmonary vascular resistance. Aiming to maintain optimal lung volume at near FRC is essential to minimize the hemodynamic consequences of mechanical ventilation.

Bronchopulmonary Dysplasia

The use of both high inflating pressures and high tidal volumes has been shown to cause lung injury. But it has now become clear that large tidal volumes are the primary cause of lung injury regardless of pressure used (volutrauma). Excessive alveolar stretch causes epithelial injury, influx of inflammatory cells and protein leakage into the alveolar space, hyaline membrane formation, changes in lymphatic flow, and disruption of surfactant activity. Even very few large breaths immediately after birth can alter lung compliance and surfactant function. Although excessive tidal volume can lead to alveolar injury, suboptimal lung inflation and alveolar collapse with inadequate use of PEEP has been shown to have deleterious effect on the lungs (atelectotrauma) and should be avoided.

The use of mechanical ventilation is associated with the development of bronchopulmonary dysplasia since it was first described by Northway in preterm infants who were mechanically ventilated for RDS. Ample studies have demonstrated the association of BPD and mechanical ventilation, but avoidance of mechanical ventilation by using noninvasive modes of respiratory support such as CPAP have not clearly reduced the risk of BPD. The most important determinant of the risk of BPD remains gestational age. In those infants who still require mechanical ventilation, several lung protective strategies have been suggested to decrease BPD including the use of volume-targeted ventilation to avoid excessive tidal volumes, adequate PEEP to maintain lung volume and minimize atelectotrauma, permissive hypercapnia, and the judicious use of supplemental oxygen to minimize oxygen toxicity. The use of antioxidants, such as vitamin A, appears to offer some benefit. Because the etiology of BPD is multifactorial, none of these strategies by themselves may show demonstrable decrease in BPD. The ideal mode of respiratory support should maintain adequate lung volume at minimal pressures and reduce work of breathing.

Neurologic Injury

Although it may not be immediately obvious, the use of mechanical ventilation can be associated with significant neurologic morbidity. Cerebral blood flow in the preterm infant is poorly regulated due to the relatively narrow window of effective autoregulation of immature cerebral vessels. Therefore, changes in systemic blood flow are easily reflected in the cerebral vascular system. Systemic hypotension caused by decreased cardiac output as a result of increased intrathoracic pressure can lead to decreased cerebral blood flow and cerebral ischemia particularly in the periventricular regions of the immature brain. Subsequent return of normal or increased blood pressure can then lead to a reperfusion injury that can contribute to intracranial hemorrhage. By the same token, impedance of venous return from the superior vena cava as seen with tension pneumothorax can lead to venous congestion in the brain possibly contributing to intracranial hemorrhage.

Several events during mechanical ventilation can result in rapid changes in cerebral circulation. Endotracheal intubation and suction are painful procedures associated with surges in blood pressure followed by periods of bradycardia and oxygen desaturation that can affect cerebral blood flow. Patient ventilator asynchrony between spontaneous and mechanically delivered breaths is associated with a "valsalvar-like maneuver" during which excessive intrathoracic pressures can be generated. This used to require administration of sedative and paralytic agents to prevent the patient from "fighting the ventilator." Now this can be mitigated by the use of synchronized ventilation, which allows the machine to breathe with the baby thereby avoiding asynchrony and obviating the need for paralysis and excessive sedation. The use of synchronized ventilation is associated with more stable blood pressures, stable cerebral perfusion, and a lower incidence of intracranial hemorrhage.

The development of air-leak syndromes such as pneumothorax can very quickly increase intrathoracic pressure impeding venous return and decreasing blood pressure. Rapid evacuation of the pneumothorax with return of systemic and cerebral blood flow has been implicated in the development of intraventricular hemorrhage (IVH). In the same way, lung overdistention either as a result of inappropriately high tidal volume, high mean airway pressure, or PEEP will decrease venous return and impair cerebral blood flow.

Arterial blood pH, carbon dioxide concentration, and oxygen levels all have significant effects on neonatal cerebral blood flow. Hypocapnia decreases cerebral blood flow whereas hypercapnia causes cerebral vasodilation, increases CBF in premature infants, and may contribute to the development of IVH. Several studies report a strong association between PaCO2 levels less than 25–30 mm Hg and an increased incidence of cystic periventricular leukomalacia (PVL) IVH and cerebral palsy in preterm infants. Prolonged exposure to PaCO2 values less than 25–30 mm Hg is also associated with hearing loss in term and near-term infants. Inadvertent hyperventilation and the previous practice of hyperventilation in patients with PPHN to achieve pulmonary vasodilatation is strongly discouraged. Earlier concerns about the association of high-frequency ventilation with increased incidence of IVH and PVL appears to be related to inadvertent hyperventilation in those patients. Permissive hypercapnia, even though promoted within reasonable limits to minimize the development of BPD should be used with caution as rapid increases in CO_2 are associated with loss of cerebral autoregulation in very low birth weight infants. Exposure to high $PaCO_2$ during the first few days of life in preterm infants has been associated with increased risk of severe intraventricular hemorrhage.

Mechanical ventilation is an important lifesaving tool in our hands. Like all tools, it can be used optimally or not and have more or fewer adverse effects, depending on how well that tool is used. Awareness of the possible deleterious effects related to mechanical ventilation will help the clinician in adopting ventilation strategies to minimize these complications and the ability to recognize them promptly when they do occur. Some complications are inherent to mechanical ventilation, but careful attention to all aspects of neonatal care particularly the effects of positive pressure ventilation and the physiologic derangements associated with it can help improve outcomes.

22 ECMO (Extracorporeal Membrane Oxygenation)

Martin Keszler

Introduction

Extracorporeal membrane oxygenation (ECMO) is an effective, but costly and invasive rescue therapy for term and late preterm infants with reversible heart and/or lung failure unresponsive to maximal conventional therapies. These include less invasive newer technologies, such as, high-frequency ventilation, surfactant replacement therapy, and inhaled nitric oxide (iNO). ECMO is the application of modified extracorporeal bypass technology for a period of days to weeks to provide temporary life support allowing the injured lungs and/or heart to recover. The first successful clinical application in infants was reported by Bartlett in 1976 and the treatment began to be adopted widely in the mid to late 1980s. ECMO has been shown to significantly improve mortality in a randomized controlled trial and has been the standard of care in industrialized countries for over 20 years. Availability in less-developed countries is limited due to its high expense, need for sophisticated equipment and training, and limited patient volume (relatively low cost-effectiveness in resource-limited countries). ECMO utilization peaked in the 1990s and has steadily declined over the past 10–12 years with the availability of iNO and adoption of less-aggressive ventilation strategies.

Indications

The most common conditions requiring ECMO support are meconium aspiration syndrome, congenital diaphragmatic hernia, sepsis/pneumonia, severe RDS or airleak syndrome. Typically, these are complicated by persistent pulmonary hypertension of the newborn (PPHN). Severe airleak syndrome may also necessitate ECMO to allow lung rest and resolution of the lung injury. Less commonly, PPHN of the primary or idiopathic variety may lead to ECMO (*Table 22.1*). Transient causes of myocardial failure, such as perinatal asphyxia or viral myocarditis can also be effectively supported with ECMO. Oxygenation index > 40 despite optimal respiratory support remains the most widely used indication of poor likelihood of survival and the need for ECMO. However, some infants require ECMO for impending cardiac failure without reaching the traditional ECMO criteria. Because of improvements in mechanical ventilation techniques and the effectiveness of iNO, fewer infants now require ECMO, but those who do are more often suffering from multiorgan dysfunction, sepsis, and circulatory failure. As a result, traditional ECMO criteria are no longer adequate as a sole basis for the decision to initiate ECMO and more attention needs to be given to assessing the adequacy of myocardial function.

Technique

ECMO differs from cardiopulmonary bypass as performed in the operating room (OR) in three important ways: (1) ECMO is partial, not complete bypass; some amount of blood continues to flow through the heart and lungs. Unlike OR bypass, diversion of blood into the extracorporeal circuit begins and ends gradually, not all at once. (2) Because ECMO is only partial bypass, the patient's arterial oxygen saturation reflects not only the values in the ECMO circuit, but primarily the proportion of oxygenated blood returning from the oxygenator vs. that of the desaturated blood that shunted through the patient's nonfunctioning lungs. (3) ECMO is performed for much longer periods; therefore, anticoagulation must be carefully titrated to avoid serious bleeding complications.

Traditional venoarterial ECMO utilizes a 10–14Fr. cannula placed in the external jugular vein for drainage and an 8–12Fr. cannula inserted into the common carotid artery and advanced just to the junction with the arch of the aorta. The venous cannula has many side holes in the final 5 cm of its length to improve drainage and is advanced into the body of the right atrium. Blood is drained from the right atrium by gravity, is pumped through an artificial lung where gas exchange takes place, rewarmed to body temperature in a heat exchanger and returned into the aorta. Most centers use a bubble detector between the oxygenator and heat exchanger to minimize the risk of air embolism.

Table 22.1
Survival rates and primary diagnoses of Neonatal ECMO cases according to the Extracorporeal Life Support Organization Registry, Jan 2010

Primary diagnosis	Number of cases	Survival (%)
Meconium aspiration syndrome	7584	94
Congenital diaphragmatic hernia	5929	51
Persistent pulmonary hypertension	3870	78
Sepsis	2617	75
Respiratory distress syndrome	1484	84
Other	2383	63

Patients with adequate cardiac function can be supported with veno-venous ECMO, utilizing a double-lumen cannula inserted into the right atrium via the internal jugular vein. Adequate gas exchange can be maintained with this approach, although oxygen delivery is less efficient due to recirculation of blood in the right atrium and a longer period is required to stabilize the patient.

The effectiveness of ECMO depends on the ability to drain a sufficient volume of blood to meet the oxygen demand of the infant. Typically, this requires bypassing about 70–85% of the available venous return, or about 100 ml/kg/min. Oxygenation is controlled by adjusting ECMO pump flow while CO_2 elimination is regulated by adjusting the composition and flow rate of gases ventilating the oxygenator. The standard silicone rubber membrane oxygenator remains the most widely used device, but newer hollow fiber oxygenators have improved resistance to plasma leak and are increasingly finding their way into long-term bypass with ECMO.

Once on bypass, the ventilator settings are rapidly reduced to achieve lung rest. Originally, this was done by reducing ventilator rate, inspiratory pressure, and end-expiratory pressure to very low values. However, this approach leads to severe atelectasis, which increases patient dependence on bypass and prolongs the duration of ECMO. Many centers now employ a lung rest strategy with high end-expiratory pressure that has been shown to shorten duration of ECMO and minimize deterioration of lung function.

Inotropic support can be weaned rapidly once on VA bypass, since cardiac support is provided, but is continued with VV bypass. Deterioration of cardiac function known as myocardial stun is sometimes seen with VA ECMO, but is always transient. Management of circulating blood volume is often complicated by capillary leak, renal insufficiency, and volume shifts between infant and circuit.

Table 22.2
ECMO mechanical complications (Adapted from the Extracorporeal Life Support Organization Registry, Jan 2010)

Complication	Incidence	Associated survival
Oxygenator failure	5.9%	53%
Circuit disruption	0.9%	67%
Pump malfunction	1.7%	66%
Clots: oxygenator	17.5%	65%
Clots: bridge	10.2%	67%
Clots: bladder	15.4%	68%
Clots: other	8.7%	54%
Air in circuit	4.9%	70%
Cannula problems	11.5%	68%

Anticoagulation must be carefully monitored and frequent adjustments made to the rate of heparin infusion to minimize the risk of clotting and bleeding. Activated clotting time is a rapid bedside tool utilized by most ECMO programs and is usually maintained at about 1.5–2 times normal values (160–220 s). Platelets counts are monitored closely and are kept >100,000 by means of transfusion as needed.

Optimal nutritional support is important for recovery and is usually provided by parenteral nutrition. Enteral feeding is feasible, but used infrequently in these critically ill infants. Electrolyte shifts and oliguria are common and edema is always present, in part due to capillary leak. Hemofiltration is widely used to aid fluid management, but overly aggressive fluid removal will lead to hypovolemia and jeopardize renal recovery. Diuretics are often needed in order to help mobilize fluid. Resolution of the severe edema often seen in ECMO patients is a prerequisite for successfully coming off ECMO.

Once cannulation is completed, the patient is allowed to be awake and moving. Spontaneous respiration is encouraged. Careful neurologic assessment is performed frequently to detect significant change that might signal intracranial bleeding. Seizures are fairly common in infants with history of perinatal asphyxia. Cranial ultrasound is done daily at least initially for early detection of intracranial hemorrhage, which would necessitate discontinuation of ECMO.

Complications

The majority of ECMO patients do not experience serious complications, but the potential for catastrophic events is ever present, because patients are, for a period of time,

Table 22.3
ECMO patient complications (Adapted from the Extracorporeal Life Support Organization Registry, Jan 2010)

Complication	Incidence	Survival
Cannulation site bleeding	6.9%	65%
Surgical site bleeding	6.3%	44%
Central nervous system hemorrhage	6.8%	45%
Pulmonary hemorrhage	4.5%	44%
Gastrointestinal hemorrhage	1.7%	45%
Hemolysis	1.0%	65%
Disseminated intravascular coagulation	2.4%	40%
Seizures	10.8%	60%
CNS infarction	7.7%	54%
Hemofiltration/Dialysis required	19.7%	51%
CPR required	2.3%	43%
Myocardial stun	5.1%	59%
Cardiac arrhythmia	4.0%	53%
Hypertension requiring vasodilators	12.5%	72%
Cardiac tamponade	0.7%	36%
Pneumothorax requiring treatment	6.0%	59%
Culture proven infection	6.1%	53%
Hyperbilirubinemia (> 2 direct or > 15 total)	7.5%	65%

completely dependent on extracorporeal support with significant potential for life-threatening complications and mechanical failure. Minimizing such problems requires meticulous attention to detail, careful maintenance of the equipment, close monitoring of the patient and circuit, and continuous staff training. Mechanical or electrical failure, air embolization, thrombus formation with embolization, and massive hemorrhage from circuit disruption are the main circuit-related complications (*Table 22.2*). The most serious patient complication of ECMO is internal hemorrhage, especially intracranial hemorrhage. Renal insufficiency, edema, hypertension, conjugated hyperbilirubinemia, and metabolic disturbances are common, but typically are transient (*Table 22.3*). Neurologic manifestations usually reflect pre-ECMO events, such as perinatal asphyxia or severe hypoxemia, rather than being caused by the procedure.

Outcomes

Survival depends on underlying diagnosis, patient condition at the start of the procedure and on occurrence of complications, if any. Patients with congenital diaphragmatic hernia have the lowest survival (51%), whereas those with meconium aspiration syndrome have survival >90% (*Table 22.1*). Overall survival rates have been declining since they peaked at 82% in the late 1980s, because only the more severely ill patients now require ECMO and because the patient mix is shifting to diagnoses with lower survival rates. In the past few years, survival has dropped to around 65%. Neurodevelopmental outcome in infants treated with ECMO is similar to those who were comparably ill but did not require ECMO. Severe neurodevelopmental impairment is present in only about 10% of survivors.

Preamble

The management of the hemodynamic status of neonates, particularly premature infants, poses many challenges. There is currently a lack of clarity on the subject of whether therapeutic intervention should be based on arterial pressure or systemic blood flow. What is clear, however, is that the subject of neonatal hemodynamics is highly complex and influenced by developmental, transitional, and pathological factors. The approach to therapeutic intervention does not lend itself toward any directive or strict protocol, but must be individualized based on maturity, disease, and response to intervention. It is likely that a composite approach based on blood flow and arterial pressure is required, with careful consideration of the influence of preload, afterload, and myocardial performance in the context of individual patient. Serial echocardiography may better facilitate this decision-making process. This chapter will deal with these issues and provide a comprehensive assessment and management pathway for infants with hemodynamic instability.

Hemodynamic Compromise in the Neonate

Introduction

The adaptive process for the preterm circulation, particularly those less than 30 weeks gestation, may be complex and if abnormal may result in compromise to vulnerable organs such as the brain, bowel, and kidneys. Persistence of the ductus arteriosus, delay in the normal postnatal fall in pulmonary artery pressure, and failure to increase cardiac output all contribute to the delay in the normal postnatal transition. The reasons for this maladaptation are unclear. The potential determinants of cardiovascular compromise may include immaturity of the myocardium and blood vessels, poor tolerance of afterload, hypovolemia, high volume shunts through the ductus arteriosus or foramen ovale, adverse consequence of positive pressure ventilation, or other treatments with cardiovascular consequences. These factors may all play a role in reducing systemic blood flow and oxygen delivery to vital organs potentially leading to irreversible damage.

Fetal Physiology of the Cardiovascular System

Fetal cardiac output rises from 50 ml/kg/min at 18 weeks gestation to 120 ml/kg/min at term reflecting the growing

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_23,

demand on the myocardium to supply vital organs in the developing fetus. Cardiac function is dependent on a variety of factors: *Preload* (amount of blood present in the ventricle at end diastole) which is dependent on the intravascular volume status of the infant and diastolic compliance of the ventricle. *Afterload* (resistance against which the ventricle muscle must contract) which depends on vascular resistance, blood viscosity, and ventricular outflow tract obstructions. *Myocardial performance* (the intrinsic ability of the myocardium to contract) and *heart rate* are the other two determinants. The fetal heart is usually subjected to a low afterload due to the low-pressure system of the placenta; therefore, the myocardium is subjected to very little wall stress antenatally. This low-pressure system suits the immature myocardium as it is unable to adapt when subjected to additional stresses.

Transitional Changes in the Premature Neonate

In the early postnatal period, the patent ductus arteriosus (PDA) and the patent foramen ovale (PFO) play a vital role in determining cardiac output and systemic perfusion. The PDA in premature neonates is unpredictable and poses different hemodynamic influences depending on whether it is persistent, closed, or initially constricted followed by patency. Contrary to previous belief, the shunt across a PDA is predominantly left to right. Similarly, an atrial shunt is usually present and is left to right in direction. These early shunts dramatically increase pulmonary blood flow and reduce systemic blood flow due to short-circuiting of blood in the lungs. This may lead to increased ventilator dependence, pulmonary edema and hemorrhage, and poor end organ perfusion leading to ischemia, anaerobic metabolism, and loss of function.

Myocardial Function

The problem of low systemic blood flow in the early transitional period is further compounded by the universally poor myocardial function in preterm neonates. In mature myocardium, surface L-type calcium channels cause a small amount of interstitial calcium molecules to enter the myocytes following depolarization; these in turn lead to more intracellular calcium release from intrinsic stores called the sarcoplasmic reticulum leading to effective myofibril shortening and muscle contraction. Conversely, the preterm heart muscle relies on L-type calcium channels as a source of calcium contraction. Furthermore, the immature myocytes have a higher surface area-to-volume ratio to compensate for the lack of the T-tubule system necessary for effective calcium entry into the cell. These developmental differences drastically reduce the functional reserve of the premature heart in the face of postnatal stresses (◉ *Fig. 23.1*). The neonatal myocardium is poorly tolerant of increased afterload compared to older children. Furthermore, the immature myocardium contains a higher proportion of noncontractile collagen and an inefficient process of calcium extrusion from the myocytes. This leads to impaired relaxation and ventricular filling during diastole and contributes to diastolic dysfunction. The immediate postnatal period following the loss of the low-pressure system of the placenta and postoperative period following PDA ligation represent two clinical situations in which the neonatal myocardium is subjected to afterload stress. The net effect is impaired myocardial systolic performance and consequential poor systemic blood flow due to low cardiac output, oftentimes despite a normal systemic blood pressure. This problem is further compounded by any potential stressors such as hypoxia, anemia, and mechanical ventilation, which reduces venous return and causes pressure on the myocardium preventing effective contraction.

Ventricular Afterload

As mentioned earlier, the sudden increase in systemic vascular resistance immediately after birth poses a major afterload challenge to the preterm infant, which may limit its ability to support cardiac output with resultant compromise to organ blood flow. After the transitional period, vascular tone may fall in certain clinical circumstances such as sepsis. Vascular smooth tone muscle is controlled by a balance between vasoconstrictors, for example, thromboxane, vasopressin, and vasodilators, for example, nitric oxide and prostaglandins. Immaturity of the central nervous system may also impact on transitional vascular changes. The clinical situation of systemic hypotension but normal or high cardiac output is oftentimes missed as these patients may appear pink and well perused. Targeted neonatal echocardiography is likely to be useful in this situation to guide choice of cardiovascular intervention.

Nitric oxide (NO) is produced by actions of nitric oxide synthase (NOS), present in abundance in smooth muscle tissue and acts via cyclic guanosine monophosphate (cGMP) on calcium-sensitive potassium channels and myosin light-chain phosphatases to cause smooth muscle relaxation. Endotoxins and cytokines such as tumor necrosis factor alpha (TNF-α) and a variety of

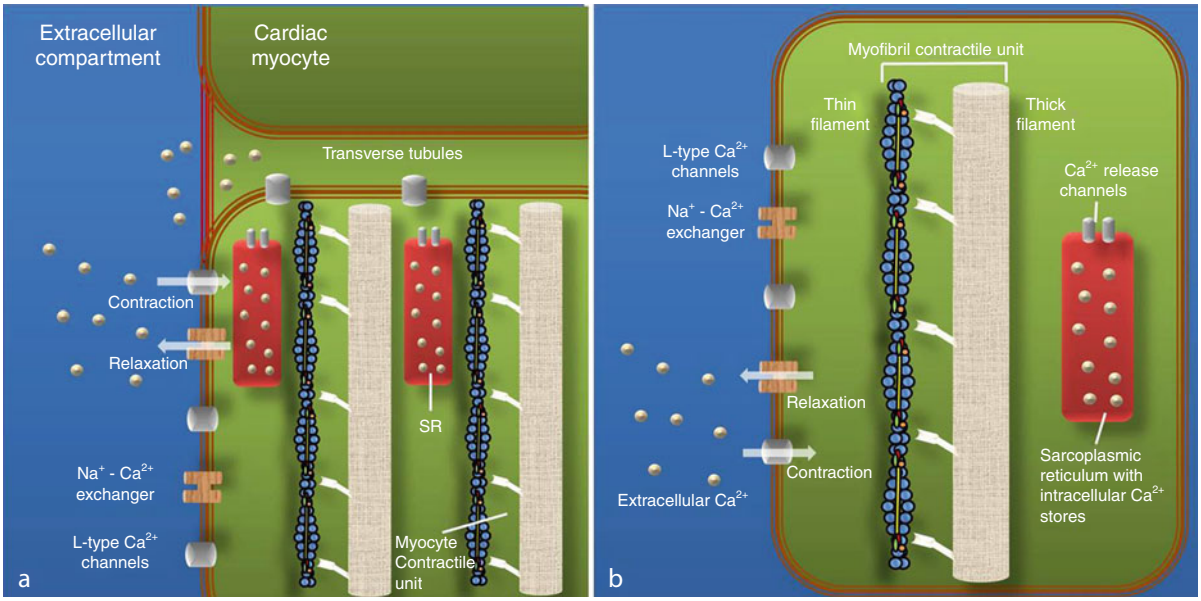

Figure 23.1

Diagram of a myocyte in the adult (a) and preterm infants (b). **In normal adult myocytes, extra cellular calcium (*white circles*) enters the cell via L-type calcium channels. This in turn activates the release of large amounts intracellular calcium stored in the sarcoplasmic reticulum (SR) into the cytosol. This results in contraction of the myofilament. This whole process is facilitated by the proximity of the SR to the L-type Ca channels and by the presence of transverse tubules, which are invaginations of the myocyte cell wall into the cytosol. Relaxation is a result of active reuptake of cytosolic calcium into the SR. The small amount of calcium that entered the cell via L-type calcium channels is transported back to the extracellular compartment via Na^+-Ca^{2+} exchanger. In preterm infants, the SR is physically separated from L-type Ca channels (diagram b), the transverse tubules are absent, and the myocyte has a greater surface area to volume ratio. Consequently, contraction is dependent on extracellular calcium influx into the cells**

interleukins can induce NOS and NO synthesis leading to profound dilatation and a reduced systemic blood flow in the presence of sepsis. In addition, excess NO leads to formation of free oxygen radicals leading to vascular wall damage.

Vasopressin plays an important role in regulating vascular tone postnatally. It increases vascular tone via vasopressin (V1) receptors in many organs, excluding the lung, brain, and heart, which in turn increase calcium release from the sarcoplasmic reticulum, upregulate adrenaline receptors on smooth muscle walls, and reduce NO synthesis. Its implication in shock has been studied in adults. Initially, vasopressin levels increase in response to shock to maintain vascular tone; however, as shock progresses, vasopressin stores are depleted and vascular tone is therefore compromised.

Prostaglandins are eicosanoids derived from cell membrane arachidonic acid by the actions of cyclooxygenase enzymes and play an important role of regulation of vascular tone. Prostaglandin E2, a vasodilator, and Thromboxane A2, a vasoconstrictor are both implicated in the early regulation of vascular tone and may have a role in the pathogenesis of hypovolemia associated with shock.

Adrenal Insufficiency

Low-birth-weight infants have an immature hypothalamic–pituitary–adrenal axis. This immaturity was highlighted by Ng et al. who showed an exaggerated pituitary response with cortisol deficiency in the presence of severe hypotension. Corticosteroids regulate vascular tone by upregulating adrenergic receptors on vascular smooth muscle wall. Sick preterm neonates cannot increase glucocorticoid production in response to stress; this may be due to the lack or immaturity of enzymes necessary for synthesis. This may explain the poor cardiopulmonary status in sick newborns. Furthermore, inotrope-resistant preterm neonates have low cortisol levels.

Arterial Pressure and Systemic Blood Flow

The thresholds for consideration of a stable or compromised circulation pose to be an ongoing challenge for neonatologists. Systemic low blood flow states in neonates have been associated with mortality. In addition, hypotension has been associated with the development of intraventricular hemorrhage, periventricular leukomalacia, and adverse neurodevelopmental outcome. The goal of therapy is to counteract or minimize the evolution of these morbidities. The prevalence of systemic hypotension in preterm infants is around 40%. There are no data to show that correction of low arterial pressure leads to a reduction in adverse neurodevelopmental outcomes. Studies investigating the association between hypotension and acute brain compromise or injury have documented both an association and a lack of an association. The study by Martens et al. sheds important light on the topic. In a cohort of over 200 babies, they found an association between hypotension and adverse neurological outcome; however, when they controlled for postnatal steroids and intrauterine growth retardation, the association no longer existed suggesting that hypotension was merely a marker of potential neurological compromise but this was not a cause-and-effect relationship.

A common misconception among clinicians is that arterial pressure is a reliable surrogate and correlates well with systemic blood flow implying that a normal mean arterial pressure confirms the adequacy of blood flow to essential organs. This conceptual framework fails to consider the third determinant of blood pressure and flow, which is peripheral vascular resistance. Several studies have confirmed that the relationship between arterial pressure and cardiac output was found to be loose at best. As arterial pressure is a product of systemic blood flow and peripheral vascular resistance, it follows that blood pressure is partly determined by resistance. A normal mean arterial pressure in the setting of a high-resistance systemic circulation can only be explained by reduced systemic blood flow. This, in part, explains why premature neonates suffer from low systemic blood flow in the first 24 h of life. Conversely, a low blood pressure in the setting of low peripheral vascular resistance may imply normal or high systemic flow. In addition to vasoactive hormones and maturity of the sympathoadrenal system, core body temperature, arterial carbon dioxide, sepsis, and a patent ductus arteriosus (which exposes the left ventricle to combined systemic and pulmonary resistance) all impact on systemic blood flow.

There is emerging evidence to support the influence of systemic vascular resistance on cardiac output. Some groups have demonstrated reciprocal relationships between cardiac output and systemic vascular resistance in preterm neonates. The relationship between cardiac output, blood pressure, and systemic blood flow needs to be examined beyond the first few days of life. In the preterm infant, further problems arise. The presence of a PDA, with systemic to pulmonary shunting, will lead to an elevated left ventricular output not translated to improved flow. The presence of a PFO, with left-to-right flow, will falsely elevate right ventricular output. Reliance on arterial pressure and ventricular output alone will not provide a complete representation of the adequacy of systemic blood flow and organ perfusion. Nevertheless, serial evaluation of cardiac output and arterial pressure in tandem may provide more insights regarding need for intervention, therapeutic agents of choice, and long-term consequences.

Superior Vena Caval (SVC) Flow

SVC flow measurement as a marker of systemic perfusion has recently come to light. Blood returning from the SVC reflects blood supply to the brain (80%) and the upper body (20%) and is not influenced by the presence of a PDA or atrial shunting. Doppler volumetric measurements of SVC flow are feasible and have been described and validated with normal ranges established. Low SVC flow is defined as a value less than 30 ml/kg/min at 6 h or a value less than 46 ml/kg/min at 48 h. Low systemic blood flow was found to be common in preterm infants, with over a third having at least one measurement below the established thresholds. Low SVC flow was commonly associated with low gestational age, high systemic vascular resistance, PDA, mechanical ventilation, and a high mean airway pressure. The limitation of blood pressure as a measure of systemic blood flow are further emphasized by the weak correlation between mean blood pressure (BP) and SVC flow. Furthermore, low systemic blood flow assessed by SVC flow is independently associated with late intraventricular hemorrhage (IVH) which occurs as flow improves. This may be explained by fragility of cerebral blood vessels upon exposure to prolonged periods of ischemia with loss of cerebral autoregulation and secondary reperfusion intracranial hemorrhage. Neurodevelopmental outcome at 3 years has also shown to be adversely influenced by early low SVC flow states. This method has been superior to middle cerebral artery flow velocity measurements in predicting neurological outcome.

Although SVC flow measurement is useful, caution should be exercised regarding its everyday applicability to neonatal intensive care. SVC venous return reflects blood supply to the brain and upper body and therefore no information regarding blood supply to the liver,

kidney, and gut can be derived. SVC return may not be reflective of inferior vena cava (IVC) return especially when a PDA is present as the carotid arteries arise preductally and are therefore not subjected to diastolic steal in the presence of a large left-to-right shunt. Secondly, cerebral blood flow is subjected to intrinsic autoregulatory mechanisms (see below) that may directly alter SVC flow, independent of myocardial performance. Thirdly, SVC flow estimation relies on measurement of the diameter of the vessel as it enters the right atrium. The latter is subject to a high degree of operator-dependent variability, particularly in the setting of lung hyperinflation, which may compromise its reliability.

Cerebral Blood Flow and Autoregulation

Cerebral blood flow is important in determining oxygen delivery to the brain. It is determined by perfusion pressure, systemic blood flow, and resistance in the cerebral circulation. Cerebral autoregulation is an intrinsic mechanism which ensures constant cerebral blood flow in the setting of varying blood pressure, flow, and resistance. Unfortunately, studies examining the relationship between cerebral blood flow and mean blood pressure are conflicting. Cerebral autoregulation appears functional in normotensive preterm infants with mean BP above 30 mmH with a suggestion that sick neonates (particularly neonates with IVH) lose the autoregulation mechanism resulting in passive circulation independent of pressure and resistance making brain tissue more vulnerable to fluctuations in blood pressure and hypotension. On the contrary, there is alternative evidence documenting a lack of change in cerebral perfusion across a wide range of mean blood pressures (23–40 mmHg). This is further complicated by the observation that cerebral fractional oxygen excretion is unaffected by hypotension but inversely proportional to left ventricular output. This supports the concept of left ventricular output being the major determinant of cerebral blood flow.

Clinical Assessment of the Adequacy of the Preterm Circulation

The determination of an adequate circulation cannot be made on the basis of any one variable. It is a composite appraisal of clinical indices such as arterial pressure, heart rate, urinary output, laboratory parameters such as arterial pH, lactate and plasma troponin, and echocardiography markers such as cardiac output or SVC flow, which reflect the adequacy of tissue oxygenation. The value of these parameters is likely to be best when used in combination and longitudinally to document trends or response to therapeutic intervention. Therapeutic decisions should not be made on the basis of any one parameter. In addition, the decision to intervene is likely to depend on the underlying disease process.

Arterial Pressure Measurement

There are no set criteria to define true hypotension in neonates. Studies correlating blood pressure with tissue perfusion are lacking. Furthermore, as explained earlier, systemic resistance is an important determinant of systemic blood flow. Therefore, treatment remains a dilemma with many physicians still relying on blood pressure alone to guide management as it is the most readily available measure of cardiovascular performance. In general, there are two definitions of hypotension in widespread use. The first is based on data stating that a mean BP < 30 mmHg is associated with cerebral injury (with white matter damage and IVH) and a reduction in cerebral blood flow measured by spectroscopy. The second definition uses the gestational age as a guide for the cutoff for treatment. Little attention is paid to blood pressure components such as the systolic and diastolic arterial pressures, when adjudicating circulatory stability or selecting a cardiovascular intervention. Normative population-based data for systolic arterial pressure are available, but rarely used in practice. Systolic arterial pressure is a useful surrogate of the adequacy of cardiac output whereas diastolic arterial pressure reflects preload and systemic vascular resistance. The nature of low mean arterial pressure, whether it reflects systolic or diastolic pressure compromise, is likely to be helpful in better selection of cardiovascular treatments.

Heart Rate

A heart rate greater than 160 can be a physiological response to hypovolemia. However, there are several other causes of tachycardia in the neonate. This includes pain, sepsis and fever, hyperthyroidism, catecholamine excess, drugs (caffeine), hypoglycaemia, anemia, and neonatal arrhythmias.

Capillary Refill Time

A capillary refill of >5 s correlates weakly with low flow states. In addition, cool extremities, acrocyanosis, and pallor are all early signs of peripheral vasoconstriction and redirecting of blood to vital organs.

Laboratory Markers

Surrogate markers of poor systemic perfusion in neonates include a rising lactate, reduced urine output, and a rising urea and creatinine.

Cardiac Output Measurement

In pediatric and adult intensive care units, catheter-derived measurements of cardiac output give a quick and continuous monitoring of systemic blood flow. In neonatal intensive care, pulmonary artery catheterization of preterm infants is not feasible. Doppler-derived measurements of cardiac output are possible and have been validated. The normal range for preterm neonates, as reported in the literature, is between 150 and 300 ml/kg/min per ventricle. Evaluation of cardiac output requires comprehensive echocardiography skills but these may be acquired by the neonatologist after a period of sufficient training. It should be recognized that these calculations may be inaccurate in the presence of intra- and extracardiac shunts.

Causes of Hypotension in the Newborn

There are many causes of neonatal hypotension and shock. Therapy must be specifically directed at the underlying cause. It should be noted that hypovolemia is not a common cause of hypotension and shock in the preterm neonate soon after birth, but more common later:

1. Cardiogenic shock
   (a) Asphyxia
   (b) Arrhythmia
   (c) Congenital heart disease
   (d) Cardiomyopathy and myocarditis
2. Impedance of venous return
   (a) Pneumothorax
   (b) High intrathoracic pressure secondary to positive pressure ventilation
3. Sepsis and septic shock
4. Hemodynamically significant patent ductus arteriosus
5. Large systemic A-V malformation
6. Drug induced: opiates, vasodilator drugs, for example, milrinone
7. Adrenal insufficiency
   (a) Extreme prematurity
   (b) Adrenogenital syndromes
   (c) Adrenal hemorrhage
8. Hypovolemia
   (a) Placental blood loss
   (b) Feto-maternal hemorrhage
   (c) Twin–twin transfusion
   (d) Birth trauma
   (e) Ruptures spleen/liver
   (f) Disseminated intravascular coagulation

Treatment of Preterm Circulatory Compromise

Despite the high prevalence of hypoperfusion states, the treatment remains controversial. Treatment of low blood pressure does not necessarily translate into an improvement in systemic blood flow as many cardiotropic agents, for example, high-dose dopamine act by increasing systemic vascular resistance but at the expense of cardiac output which falls. The use of regimented protocols, which usually recommend the use of volume administration followed by dopamine, dobutamine, and epinephrine, should be avoided. This approach does not take into account the maturity of the infant, the underlying cause, the presumed physiology or other potential iatrogenic influences on systemic blood flow including other medication, mechanical ventilation in the presence of a PDA. There is limited evidence supporting the use of current therapeutic agents. However, understanding the mechanisms of action of the various available agents will aid in their selection to address the various situations. The ultimate goal of treatment is to maintain adequate oxygen delivery and tissue oxygenation to ensure normal cellular metabolism. Other factors influencing the adequacy of cellular oxygen delivery include hemoglobin, oxygen saturation, as well as factors influencing myocardial performance. Oxygen consumption should also be minimized by ensuring adequate sedation if necessary, pain control, and normothermia (*Fig. 23.2*).

Volume Expansion

The benefit of using crystalloids or colloids to treat hypotension has not been established. In hypotensive normovolemic neonates, volume expanders generally do not improve arterial pressure. They do however increase left ventricular output in the short term. There are no studies examining whether this rise is maintained beyond the immediate period. Liberal administration of fluid is not recommended as there are no data to suggest benefit. Indeed, some data suggest a detrimental effect in preterm

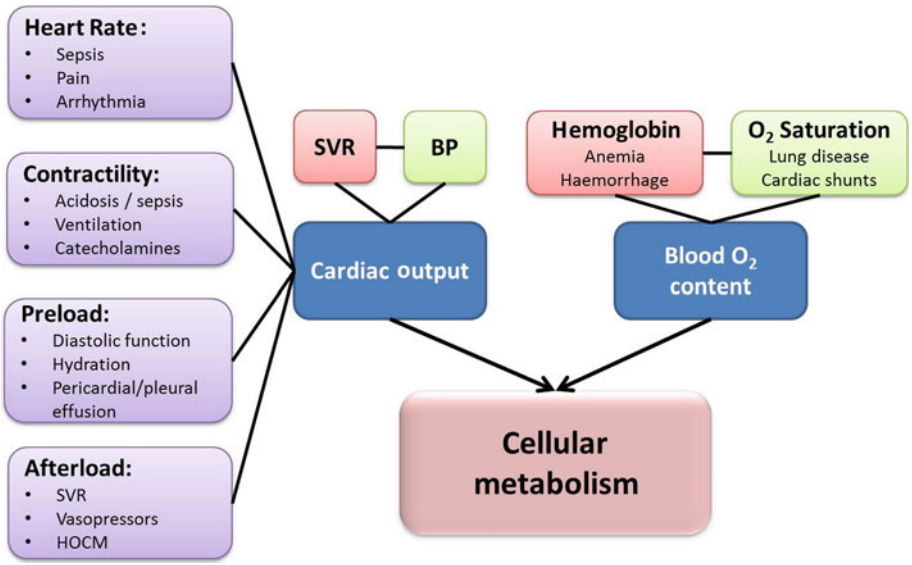

Figure 23.2
***Factors affecting cellular metabolism, cardiac output and blood oxygen content*. See text for details**

neonates with a higher incidence of PDA, necrotizing enterocolitis (NEC) and death. This may be due to the inability of the premature myocardium to cope with the extra preload, which may lead to increased heart rate. In addition, volume loading of asphyxiated babies with a damaged myocardium may cause ventricular wall stress and circulatory compromise. The use of volume expanders in hypovolemic neonates may be beneficial as it restores intravascular volume; however, this has not been adequately studied. The subpopulation of neonates with high insensible losses or transepithelial losses such as gastroschisis, malabsorptive syndromes are likely to benefit from increased fluid administration. The presence of sepsis, capillary leak, or unrecognized perinatal blood loss must however be considered as potential causes of hypovolemia. Clinical assessment of intravascular volume status is difficult. Targeted neonatal echocardiography can be helpful in assessing ventricular filling when doubt exists regarding intravascular volume status.

Hypotension and Inotropes

Arterial pressure thresholds, which commonly form the basis for treatment, are not based on systemic blood flow. As highlighted earlier, the assumption that pressure and flow are proportionate is not true. Future studies need to examine the effect of inotropes on systemic blood flow. A Cochrane review of literature on dopamine versus dobutamine showed that dopamine was more reliable in increasing arterial pressure. *Dopamine* is a synthetic amine and is the most commonly used vasoactive agent. It has mixed β1 and α-adrenergic effects depending on the dose. There is some evidence of improved left ventricular performance at levels of 2.5 μg/kg/min. Vasoconstricting effects can occur at levels as low as 6 μg/kg/min leading to increased systemic vascular resistance (SVR) and potentially reducing cardiac output and organ perfusion. *Epinephrine* is an endogenous catecholamine with β1 effects at low doses and α-adrenergic effects at levels of 0.3 μg/kg/min. It is an effective vasopressor and is usually reserved as a rescue agent but may be beneficial in cases of septic shock and NEC. Prolonged treatment may be associated with myocardial ischemia and dysfunction. Epinephrine is equally effective as dopamine in increasing arterial pressure but no data exist regarding its effects on systemic blood flow, intraventricular hemorrhage, or neurodevelopmental outcome. *Dobutamine* acts by improving left ventricular output and systemic blood flow with a marginal increase in arterial pressure; it may in fact reduce systemic vascular resistance. It has predominant β1 effect with marginal effects on systemic vascular resistance. High doses, however, may lead to hypotension through its action on vascular β receptors. *Milrinone* is a phosphodiesterase III inhibitor that acts through increasing the bioavailability of cyclic adenosine monophosphate (cAMP). It is a systemic and pulmonary vasodilator with positive inotropic and lusitropic

properties. It is used in infants following cardiac surgery to prevent low cardiac output syndrome and reduce mortality. There is also evidence of benefit in neonates with pulmonary hypertension. In addition, it has been used in preterm infants following PDA ligation to prevent low cardiac output states and subsequent clinical and respiratory deterioration. *Vasopressin* use in preterm and term infants with refractory hypotension is gaining interest. It is a nine-amino acid structure synthesized in the pituitary, commonly known as the antidiuretic hormone. Its acts via V1 receptors leading to systemic vasoconstriction through phospholipid-mediated calcium release and pulmonary vasodilatation through modulation of nitric oxide release. It may be beneficial in infants not responding to conventional inotropes and/or hydrocortisone, or in infants with pulmonary hypertension. It must be used with caution, however, as evidence of safety is lacking; in some patients it may cause oliguria and renal failure or liver necrosis secondary to compromised splanchnic perfusion. Infants with septic shock, high cardiac output, and low diastolic arterial pressure are likely to benefit from a vasopressor, for example, dopamine, vasopressin. Conversely, infants with cardiogenic shock, low cardiac output, and low systolic arterial pressure may benefit from and inodilator agent, for example, milrinone (◉ *Table 23.1*).

Corticosteroids

A small proportion of preterm neonates may suffer from a relative adrenal insufficiency leading to a poor response to stress, which may manifest as refractive hypotension. Steroid administration to these neonates can improve arterial pressure and reduce the need for inotropes. Their use has been associated with NEC and intestinal perforation, especially when combined with indomethacin. Prophylactic administration of hydrocortisone cannot be recommended in the first days of life due to the potential harmful side effects.

Role of Targeted Neonatal Echocardiography (TnECHO) in Guiding Therapy

The lack of a reliable measure of systemic blood flow as highlighted in this section is one example of a clinical situation which has prompted neonatologists to perform echocardiographic examinations. Clinical signs such as heart rate, blood pressure, and capillary refill time, which traditionally physicians have relied upon, provide limited insight into the adequacy of systemic blood flow and organ perfusion. Targeted neonatal echocardiography (TnECHO) is increasingly used by neonatologists in the intensive care setting to support clinical decisions. It provides hemodynamic information, which may provide novel insights regarding actual physiology and nature of cardiovascular disease. The technology may be applied to evaluation of cardiac output and systemic blood flow. The provision of real-time information on cardiovascular performance and systemic hemodynamics, the noninvasive nature of the technique, the rapidity of data acquisition, and ability to perform longitudinal functional assessments have all contributed to the increased utilization of functional echocardiography by neonatologists in the neonatal intensive care.

Summary

Premature infants, in the immediate transitional period, are at increased risk of cardiovascular compromise manifested as low systemic blood flow or hypotension, which relates to afterload stressors; therefore, dobutamine may be the best first line option as it reduces SVR and improves cardiac output. Dopamine or epinephrine in high doses should be avoided as these vasoactive agents act by increasing SVR which imposes an additional afterload stress on the preterm myocardium leading to reduced blood flow. Measures of blood flow, in addition to blood pressure, should be used to assess treatment success. If mean or diastolic arterial pressure is very low (there are no definitive cutoffs), then dopamine or adrenaline may be used. A hemodynamically significant ductus arteriosus should also be considered in early hypotension, as vasoactive agents may increase the volume of the ductal shunt. Volume expansion is indicated when there is clear evidence of hypovolemia, for example, hemorrhage, capillary leak, gastroschisis, and dehydration. Functional hypovolemia induced by high intrathoracic pressure requires volume expansion to allow adequate ventricular filling. There is no evidence that routine volume augments cardiac output. Crystalloid fluid is as effective as colloid in volume expansion, but hypotonic fluids, such as dextrose solutions, should not be used for volume expansion.

In persistent pulmonary hypertension of the newborn, inhaled nitric oxide reduces right ventricular (RV) afterload leading to enhanced right ventricular performance, improves ventilation–perfusion matching, and increases left heart preload. The net effect is improved systemic blood flow. Dopamine is not recommended in

Table 23.1
Drug used in the cardiovascular support of the neonate

Agent	Dose	Mechanism of action	Indications	Clinical considerations
Inodilator agents				
Dobutamine	5–20 [μ]g/kg/min	β: Increased myocardial contractility and SBF. Higher doses lead to a fall in SVR and PVR	Low CO states including early preterm transitional period, asphyxia, PPHN, and in low SBF stated such as PDA	Dobutamine is effective at improving SBF. BP may not improve. Monitor response clinically (blood gas, urine output, etc.) and TnECHO
Milrinone	0.75 [μ]g/kg/min loading dose over 30 min 0.33–0.99 [μ]g/kg/min maintenance dose	Phosphodiesterase III inhibitor. Increases availability of cAMP. Leads to improved contractility, and a fall in SVR/PVR. Net effect is increased SBF	Low CO states in early transitional period, infants with PPHN, post PDA Ligation to reduce the risk of post ligation low cardiac output syndrome	May result in a fall in BP. Volume support could be used in conjunction with milrinone. No long term data available
Vasopressor agents				
Dopamine	2–10 [μ]g/kg/min	β: Increases contractility at low doses (2.5 [μ]g/kg/min) α: At doses of >6 [μ]g/kg/min leading to increased SVR/PVR. Vasoconstircting effects have been reported at doses <6 [μ]g/kg/min	Septic shock, refractory hypotension in the setting of adequate myocardial performance. Can be used in conjunction with dobutamine in low CO/low BP states	Higher doses have a negative effect on systemic blood flow and may compromise contractility due to increased afterload. Should be avoided in infants with PPHN and after PDA ligation. Dopaminergic effects on renal blood flow have not been established in neonates
Epinephrine	0.05–0.5 [μ]g/kg/min	β: Increases contractility at low doses (<0.3 [μ]g/kg/min). Will have α effects as well. May improve SBF α: At doses of >0.3 [μ]g/kg/min leading to increased SVR/PVR with a negative effect on SBF	Consider as a rescue therapy or in cases of septic shock. Can be used in conjunction with dobutamine in low CO/low BP states	High doses may lead to myocardial ischemia due to increased oxygen demand. May lead to profound increase in systemic and pulmonary vascular resistance. Should be avoided in PPHN
Vasopressin	0.0001–0.002 units/kg/min	V1: Increase SVR and decrease PVR. No effect on contractility. May reduce splanchnic circulation	Refractory hypotension. PPHN no responding to NO (experimental). Cardiovascular copromise secondary to ventricular hypertrophy states, e.g., infant of diabetic mother, cardiomyopathy	Use not established in clinical practise but promising observational data in neonates with PPHN

SBF systemic blood flow, *SVR* systemic vascular resistance, *PVR* pulmonary vascular resistance, *BP* blood pressure, *CO* cardiac output, α alpha adrenergic receptors, β beta adrenergic receptors, *PPHN* persistent pulmonary hypertension of the newborn, *TnECHO* targeted neonatal echocardiography

persistent pulmonary hypertension of the newborn (PPHN) due to its potent vasoconstricting effects, particularly in the setting of a hypoxic inflammatory environment. Dobutamine is a more desirable agent in this setting due its vasodilator properties and ability to enhance right ventricular performance. Epinephrine has been shown to increase pulmonary vascular resistance (PVR) and SVR equally, in both animal and human studies. In inotropes-refractory cases, intravenous steroids should be considered.

Patent Ductus Arteriosus in the Preterm Infant

Introduction

The diagnosis and management of a patent ductus arteriosus (PDA) in preterm neonates poses a major challenge. It is the most common cardiovascular abnormality of prematurity occurring in about a third of infants below 30 weeks gestation and up to 60% of infants less than 28 weeks. There is little consensus to guide management, and treatment policies vary among centers depending on the expertise, presence of on-site echocardiography, and ease of access to a surgical center. Timing of treatment remains controversial as there is no clear long-term benefit to prophylactic and early treatment based on clinical and conventional echocardiographic parameters.

Physiology and Pathophysiology of the Ductus Arteriosus

The ductus arteriosus (DA) connects the main pulmonary artery to the descending aorta and is necessary for fetal survival. In the fetus, the left ventricle delivers oxygenated blood returning from the placenta and shunting through the foramen ovale to vital organs. The right ventricle delivers deoxygenated blood returning from the SVC via the ductus arteriosus to the placenta as the lungs are bypassed. Following birth, as the lungs expand and become the oxygen-exchange organ, the DA is no longer needed and it normally closes.

Ductus arteriosus patency and closure is influenced by a multitude of factors. In utero, low systemic oxygen tension and elevated circulating prostaglandins are important in maintaining ductal patency. Functional closure of the ductus arteriosus begins within a few hours after birth and is usually complete by a week of age in preterm infants. This is partly due to the increase in oxygen tension and the falling prostaglandin levels postnatally. Anatomical closure is achieved due to hypoxia-ischemia in ductal tissue resulting in cell apoptosis leading to the transformation of ductal tissue to a non-contractile element.

Prostaglandin E_2 is the most important factor in the regulation of DA tone during fetal development. It is generated through the actions of cyclo-oxygenase 1 and 2 (COX 1 and 2) on arachidonic acid. Animal models demonstrate that COX-2 expression plays a major role in maintaining fetal DA but the emphasis is switched to COX-1 after birth. The inhibition of COX-1 leads to reduced PGE_2 levels and ductal constriction. The low oxygen tension in the fetus is important to maintain ductal patency. After birth, increased oxygen tension leads to ductal closure. This oxygen-mediated constriction is facilitated by a mechanism intrinsic to the DA. Potassium voltage channels (Kv Channels) present on the ductal smooth muscle cells function to keep the cells in a hyperpolarized state. The presence of oxygen leads to depolarization which in turn activates L-type calcium channels allowing an influx of calcium into the smooth muscle cells causing constriction. Levels of inflammatory mediators, namely, TNF-α and prostaglandins, are elevated in the presence of infection associated with late ductal opening. Therefore, late-onset sepsis may be an important contributing factor to ductal reopening, especially when anatomical closure is not achieved in preterm infants. Once functional DA closure is achieved, the smooth muscle cells migrate from the media to the subendothelial layer. This results in an interruption of the vasa vasorum blood supply to the innermost layer resulting in hypoxia and cell death. In term infants, the DA wall thickness exceeds the distance which allows nutrients to travel by passive diffusion (500 μm). In premature infants, tissue hypoxia may not occur as the inner layers may effectively be supplied by blood flow through the ductal lumen rendering these cells resistant to local hypoxia thereby delaying anatomical ductal closure and predisposing the duct to reopening.

Hemodynamic and Clinical Effects of a PDA

Pulmonary Effects of a PDA

Left-to-right shunting across the PDA leads to important hemodynamic changes. As pulmonary arterial resistance falls, the degree of shunting across the duct becomes more significant leading to increased pulmonary blood flow and compromised systemic blood flow. The nature of the volume of the transductal shunt is dependent on the size of the vessel and transductal pressure differential. A ductal diameter greater than 1.6 mm is associated with high pulmonary blood flow and increased incidence of pulmonary hemorrhage (hemorrhagic pulmonary edema). Increased pulmonary flow may contribute to increased oxygen dependency and pulmonary edema. The presence of a PDA has been shown to be a risk factor for chronic lung disease (CLD) due to altered pulmonary mechanics and arrested alveolar development. Pulmonary vasculature overload may also lead to pulmonary hemorrhage and eventually the development pulmonary vascular disease.

Cardiovascular and Systemic Effects of PDA

One of the consequences of a high order of magnitude left-right transducal shunt is increased left ventricular output (LVO) secondary to increased pulmonary venous return and augmented left ventricular (LV) systolic performance. This increase in cardiac output does not translate into improved systemic perfusion, as the left-to-right shunt continues to short-circuit blood flow back into the lungs. The net effect is higher LVO, increased pulmonary blood flow, but lower systemic blood flow. In addition, increased left heart preload leads to left atrial dilatation, stretching of the foramen ovale, increased left-right trans-atrial flow, and increased left ventricular diameter reflecting volume loading of the heart.

Shunting from the systemic to the pulmonary circulations is referred to as ductal steal and results in systemic hypoperfusion (*Fig. 23.3*). The clinical consequences include hypotension, oliguria, abdominal distension, and metabolic acidosis. Although systolic, diastolic, and mean arterial pressure may fall in the most immature patients, systolic pressure may be maintained in older or more mature patients through augmentation of cardiac output. A hemodynamically significant PDA is associated with lower blood flow volumes in the abdominal aorta with retrograde flow in diastole reflecting a severe shunt leading to diastolic steal. In addition, compromised arterial flow, predominantly during diastole, to the celiac, superior mesenteric, renal, and cerebral arteries despite a rising LVO may indicate a decompensated state. These biological effects support the association between PDA and NEC, renal dysfunction, and IVH.

Diagnosis of a PDA

Clinical Diagnosis

Prior to the advent of routine echocardiography, the diagnosis of a PDA was reliant on the evolution of clinical signs including: a pansystolic, or a continuous systolic/diastolic (machinery-like) murmur, increased precordial activity, and bounding peripheral pulses. In some patients, a difference of greater than 20 mmHg between the systolic and diastolic arterial pressure may also occur, as described earlier. Bounding pulses and a murmur

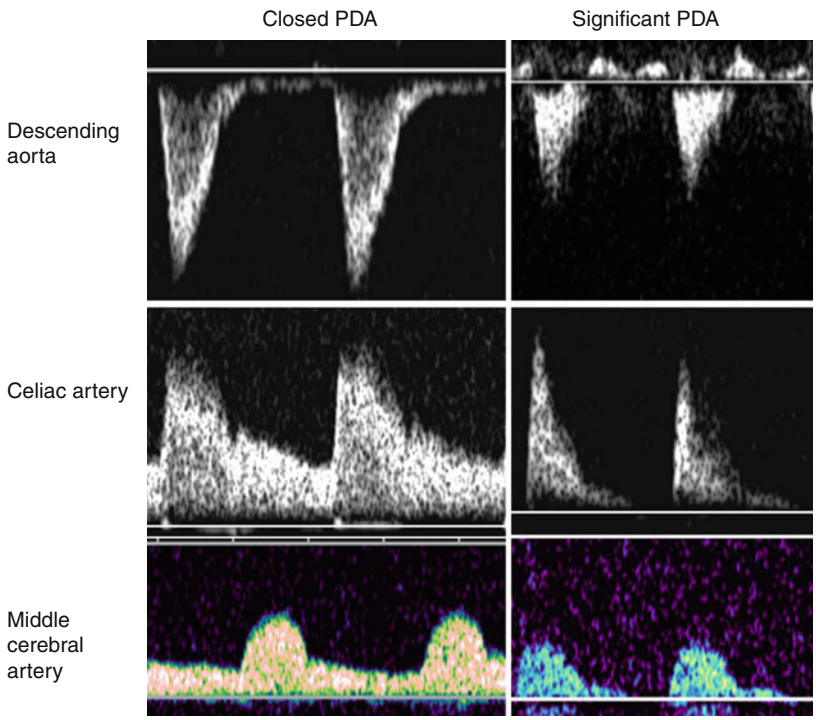

Figure 23.3
***The effect of a significant PDA on systemic blood flow*. Note the reduced systolic velocity and absent or reversed diastolic flow in all three blood vessels**

may be absent in up to 20% of infants with a PDA. Chest radiograph finding include increased pulmonary vascular markings, pulmonary edema, a large cardiac silhouette, and a splayed carina due to a large left atrium moving the left main bronchus superiorly. The development of a significant PDA by echocardiography precedes the development of clinical signs by a mean of 2 days. Correlation between physical signs and the presence of a PDA by echo in the first week of life is poor. Therefore, Doppler echocardiography remains the gold standard for PDA diagnosis.

Echocardiographic Assessment of PDA

In most centers, the adjudication of hemodynamic significance is made on the basis of a 2D or color Doppler measurement of the internal ductal diameter (*Fig. 23.4*). The rationale is that a diameter greater than 1.5 mm is predictive of persistence of the ductus arteriosus. The value of a single point estimate of transductal diameter is questionable as it does not consider architectural variability of the ductus arteriosus, temporal changes in ductal size, or provide any information about the magnitude of the ductal shunt. The traditional focus on transductal diameter has contributed to consideration of the ductus arteriosus as a binary variable or "all or none phenomenon." The determinants of transductal flow are the size of the vessel and the transductal pressure differential. Although the volume of the transductal shunt may not be quantified by conventional echocardiography, the physiologic or hemodynamic effects on pulmonary and systemic blood flow caused by left-to-right shunting can be demonstrated by various echocardiographic measures (*Table 23.2*). Left atrial to aortic ratio (LA:Ao) uses the fixed diameter of the aorta to assess the degree of left atrial volume loading. LA:Ao ratio correlates significantly with increased pulmonary flow due to a duct, and optimal cutoff point is $\geq$1.4 to predict a significant PDA. Furthermore, diastolic blood flow velocity in the left pulmonary artery is also a useful indicator of ductal significance with a high-end diastolic velocity representing a large left-to-right shunt and increased pulmonary perfusion. Turbulent pulmonary arterial flow at the level of the pulmonary valve also implies a more significant shunt. Left ventricular output usually rises in the presence of a patent ductus. Transmitral Doppler flow measurement may be a useful marker of left atrial pressure/volume loading. A phenomenon referred to as pseudo-normalization of the Doppler pattern is seen in infants with a significant PDA.

A hemodynamically significant PDA is associated with lower blood flow volumes in the abdominal aorta and lower mean blood flow velocities in the celiac, superior mesenteric, and renal arteries despite a rising LVO. Superior vena cava (SVC) flow measurement has been recently described and advocated as a marker of systemic blood flow. The effect of a PDA on the systemic circulation may be quantified by comparing LVO to superior vena caval flow (LVO: SVC). Infants without a PDA have an LVO: SVC of 2.4 (SVC return account for 40% of LVO). In the presence of a significant PDA, LVO: SVC increases to 4.5 (SVC return accounts for 22% of LVO) indicating a compromised upper body circulation. Low SVC return is associated with an increased incidence of late IVH and may be one factor in the causal pathway of impaired preterm neurodevelopmental outcome. Comparing celiac artery blood flow to LVO may give an accurate quantitative measure of the degree of ductal steal and lower systemic body flow. Volumetric analysis of celiac artery flow (CAF) shows that it receives approximately 20% of LVO at 12 h of life regardless of the presence of a PDA. In other words, the ratio of celiac artery blood flow to left ventricular output (CAF: LVO) is 0.2. The lack of influence of a PDA and its diameter on the flow parameters and CAF: LVO at the 12 h may demonstrate the lack of a significant pressure gradient between the systemic and pulmonary circulations during the early transitional period. Flow across the PDA at this stage may not be hemodynamically significant. At 48 h, the pulmonary artery pressure drops and shunting across

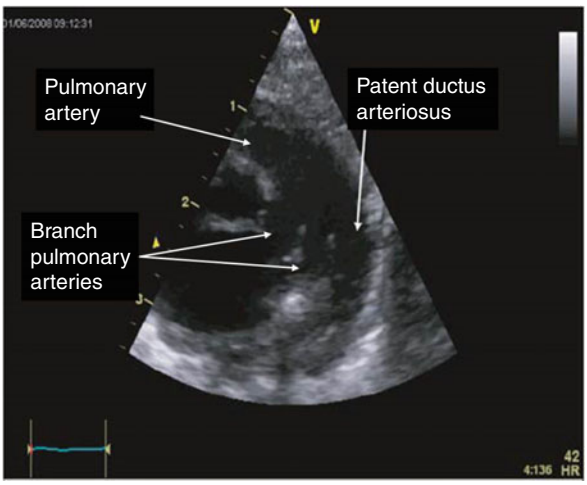

Figure 23.4
Echocardiographic image of the PDA

Table 23.2
Echocardiographic markers of ductal significance

Measurement	Modality and sample gate	Moderate PDA	Large PDA
Ductus arteriosus			
Diameter (mm)	High parasternal ductal view	1.5–3.0	>3.0
Ductal velocity (m/s)	PWD at ductal view (PA)	1.5–2.0	<1.5
PA diastolic flow (m/s)	PWD at left PA	0.3–0.5	>0.5
Pulmonary overcirculation			
LA: Ao ratio	M-mode: long axis view	1.5–1.8	>1.8
E wave to A wave ratio	Doppler: transmitral view	0.8–1.2	>1.2
IVRT (ms)	PWD between MV and AV	35–45	<35
Systemic hypoperfusion			
Left ventricular output (ml/kg/min)	PWD at LV outflow tract	300–400	>400
Diastolic descending Ao flow (%)	PWD at beyond PDA	30–50	>50
LVO/SVC ratio	PWD of flow at SVC	<2.4	>2.4
Celiac artery flow: LVO ratio	PWD at celiac artery	0.10–0.15	<0.10
Celiac, renal or middle cerebral diastolic flow		Absent	Reversed

See text for abbreviations and details

the PDA increases. As a result, the celiac artery receives proportionately less of the LVO in infants with a PDA compared to infants with spontaneous ductal closure at 48 h (11% vs 19%) showing a reduction in systemic perfusion.

The Use of Biomarkers in the Diagnosis of PDA

B-type natriuretic peptide (BNP) is a 32-amino acid ring structure. The ventricles of the heart are the main site of BNP synthesis and release in response to volume loading, pressure loading, and ventricular stress. BNP causes diuresis, natriuresis, arterial and venous vasodilatation, and antagonizes the renin-angiotensin system. The net effect is a reduction of intravascular volume, ventricular preload, and afterload. N-terminal-Pro-BNP (NTpBNP) is the inactive by-product of BNP resulting from the cleavage of the parent peptide Pro-BNP. In the presence of a PDA, BNP and NTpBNP levels rise significantly and fall following treatment. They may be used as screening tools for the presence of a PDA and in monitoring treatment response, though their value and reliability is not yet clearly established.

Cardiac troponin T (cTnT) is another useful marker of DA significance and associated myocardial ischemia secondary to diastolic steal. cTnT is significantly higher in infants with hemodynamically significant PDA compared to controls in a study of 80 preterm infants. cTnT levels also correlated significantly with echocardiographic markers of PDA significance. Following successful treatment of the PDA group, cTnT fell significantly to levels comparable to the control group. McNamara et al. have proposed that ductal steal due to left-to-right shunting may also affect coronary arteries leading to myocardial ischemia and a resultant rise in cTnT. cTnT may identify infants at risk of PDA-associated myocardial ischemia and therefore warrant PDA treatment. The associated fall in cTnT levels following successful PDA closure may reflect the resolution of ductal steal from the coronary arteries.

Targeted Treatment of PDA: The Use of Echocardiography and Biochemical Markers

Conventional echocardiographic markers such as ductal diameter and left atrial to aortic ratio (LA:Ao) applied at 48 h of life do not predict outcome associated with a PDA. In addition, treatment based on these parameters has not led to improved neurodevelopmental outcome at 2 years in preterm infants. Biochemical markers may prove to be a useful adjunct to a recent clinical and echocardiographic

PDA staging system proposed by McNamara et al. Medical therapy for PDA has well-recognized adverse effects and neither prophylaxis nor treatment on the basis of clinical and echocardiographic signs has been shown to improve long-term outcomes. Accurately identifying infants with PDA who are at highest risk of poor outcome using biomarkers may allow more successful trials of targeted medical therapy of PDA.

Management of the Preterm PDA

Once a PDA is diagnosed, the clinician faces multiple management challenges including whether or not to treat, and the timing and method of treatment. Nonsteroidal anti-inflammatory drugs are the first-line medical treatment. Indomethacin and more recently ibuprofen are used in prophylactic and early treatment of a PDA. Ibuprofen does not appear to confer a net benefit over indomethacin for the effective treatment of a PDA. However, ibuprofen reduces the risk of oliguria but may increase the risk for CLD and pulmonary hypertension. Surgical ligation of a PDA is usually only undertaken following failure of medical treatment as there is no evidence it confers any benefit over medical treatment when used as first-line therapy.

Conservative Management of a PDA

Most centers implement systematic treatment of a PDA using medical therapy. However, controversy still exists about the optimal timing for starting treatment. The ductus arteriosus will close in 40–60% of preterm infants spontaneously by 48 h of life. Conservative PDA management has been advocated as an alternative or an interim measure. In addition, there is concern in infants with NEC or severe IVH, that instituting medical therapy with nonsteroidal anti-inflammatory drugs (NSAIDS) may exacerbate the preexisting conditions due to their antiplatelet and vasoconstrictive properties. Little attention has been paid to strategies that may modulate transductal flow by controlling pulmonary or systemic vascular resistance. These include permissive hypercapnia, judicious use of oxygen, and avoidance of high arterial PaO_2, increasing the positive end-expiratory pressure (PEEP) on the ventilator, and avoidance of vasopressor drugs, for example, dopamine which may increase systemic vascular resistance (*Fig. 23.5*). Cardiotropic agents such as dobutamine are preferable in the setting of circulatory compromise by nature of its ability to augment cardiac output with negligible effects on vascular resistance. Severe fluid restriction and diuretic use are not

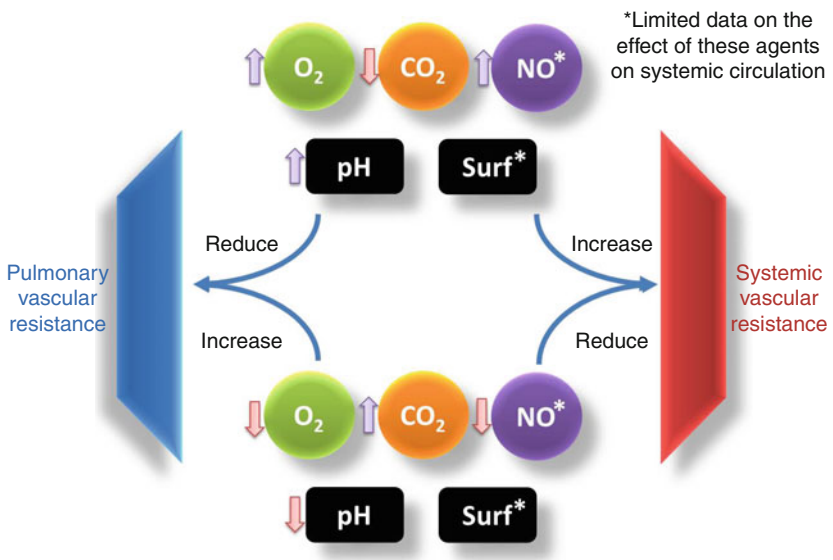

Figure 23.5

***Biological effects of vasoactive mediators on the systemic and pulmonary circulations*. O_2: oxygen; CO_2: carbon dioxide; NO: nitric oxide, Surf: surfactant**

recommended as they may lead to further compromise of systemic blood flow, electrolyte derangement, and impaired growth. In addition, the promoting effect of frusemide (furosemide) on renal prostaglandin production is counterintuitive.

Medical Treatment of a PDA

Indomethacin has been the mainstay of medical PDA treatment to date and successfully closes around 90% of PDAs. Indomethacin is a nonspecific prostaglandin inhibitor and therefore causes ductal closure by reducing prostaglandin levels. This effect, however, is also responsible for the range of well-recognized side effects including oliguria, hyponatraemia, reduction in systemic blood flow, gastrointestinal bleeding, and decreased splanchnic perfusion potentially leading to NEC and perforation. Ibuprofen is another NSAID with similar antiprostaglandin properties to indomethacin and has recently emerged as an alternative agent. It is a nonselective COX inhibitor which causes a reduction in circulating prostaglandin levels. Compared to indomethacin, ibuprofen does not significantly reduce mesenteric and renal blood flow velocity in a study of 17 preterm infants. It also causes less cerebral blood flow disturbances.

Prophylactic Treatment of a PDA

The optimal timing of PDA treatment remains controversial. The Trial of Indomethacin Prophylaxis in Preterms (TIPP) randomized 1202 ELBW infants to receive either placebo or prophylactic indomethacin soon after birth. There was no difference in death, or a composite of death and cognitive delay, cerebral palsy, blindness, or hearing impairment between the treatment and placebo group. The prophylactic use of indomethacin reduced the incidence of grades III/IV IVH (from 13% to 9%, $p = 0.02$), the incidence of PDA (from 50% to 24%, $p < 0.001$), the need for later closure with indomethacin (from 46% to 17%, $p < 0.001$), and the need for surgical ligation (from 12% to 7%, $p = 0.001$). There was no difference in the incidence of NEC or pulmonary hemorrhages between the groups. In addition, outcome at 2 years was not affected by prophylactic treatment. Further review of the TIPP data shows that prophylactic indomethacin increased oxygen dependency in the first 7 days of life and increased the incidence of CLD among infants who did not develop a PDA but received indomethacin (43% vs 30%, $p = 0.015$) . It was postulated that this was a result of the drug's oliguric properties leading to pulmonary edema. Adult studies show that indomethacin augments lung inflammation and fibrosis by increasing elastase activity and fibronectin concentration.

A recent Cochrane review of four trials comparing prophylactic ibuprofen to placebo found it effective in reducing the incidence of PDA on day 3, reducing the need for rescue treatment and the need for surgical ligation. There was no difference in ventilator dependence, urine output, IVH of any grade, periventricular leukomalacia (PVL), CLD, NEC, or other gastrointestinal complications, or duration of hospital stay. There are no trials comparing prophylactic ibuprofen versus indomethacin. There is some evidence suggesting that prophylactic use of ibuprofen may precipitate pulmonary hypertension. Giving ibuprofen early probably prevented the natural decrease of pulmonary vascular resistance as prostaglandins play a role in regulating pulmonary vasculature in the first hours of life. Secondly, micro-emboli due to ibuprofen precipitation may have explained this phenomenon. The preparation used by this group was ibuprofen–tromethamine but most other groups use L-lysine ibuprofen. Recently, a case report of severe pulmonary hypertension following administration of L-lysine ibuprofen on day 3 of life to a premature infant of 32 weeks gestation was reported.

Early Treatment of PDA

There is no difference in mortality or other outcomes such as NEC or CLD when an echo-patent duct was treated at day 3 of life, although there was less need for later PDA treatment. This possibly indicates that treatment on day 3 may be too late. These studies however are limited by the early introduction of backup treatment soon after initial randomization, and therefore conservative versus active treatment was not adequately tested. In the TIPP trial, all PDAs were either medically or surgically treated by day 5. The lack of changes on outcome may relate to the homogenization of the problem and lack of consideration of variability of ductal effect. Attribution of hemodynamic significance based on a single-point estimate of ductal diameter, without consideration of its systemic and pulmonary effects, is a hemodynamic oversimplification which may lead to incorrect treatment choices. A better definition of significance as highlighted earlier will lead to more streamlining of patients according to illness severity, and a better identification of infants responding to treatment.

Surgical Treatment of PDA

Surgical ligation of a PDA is influenced by availability and ease of access to a pediatric cardiothoracic center. In addition, in some centers, surgery may be considered the

first-line treatment in infants with NEC, severe IVH, and pulmonary hemorrhage, in view of the potential adverse effects associated with NSAIDs. There is currently no evidence in the literature supporting surgical over medical treatment as a first-line approach. Perioperative complications include pneumothorax, accidental ligation of the thoracic duct leading to chylothorax, intraoperative bleeding, and hemodynamic instability. There is substantial late mortality and a high incidence of morbidity in the survivors. Low cardiac output syndrome (LCOS) is now a recognized postoperative complication with potentially harmful effects. After PDA ligation, there is an initial acute deterioration followed by an improvement in global cardiac function. Recently, PDA ligation has been associated with poorer neurosensory outcomes compared with medical treatment alone.

The postoperative course after PDA ligation is variable and unpredictable, with about 30% of infants requiring initiation of inotropes for hypotension. Recent publications have demonstrated echocardiographic evidence of poor myocardial contractility and low cardiac output which precedes the development of hypotension and respiratory failure. The impact of postoperative cardiorespiratory instability and poor systemic blood flow is the subject of recent debate due to the reported association of surgical ligation and adverse neurodevelopmental outcome. Whether the latter relates to prematurity, magnitude of ductal illness, or is a complication of surgical ligation remains unknown. In addition, an association between surgical ligation and the development of chronic lung disease, independent of immaturity or/and ductus arteriosus–related variables, has been reported. These findings add to the growing uncertainty about the benefits and risks of surgical ligation during the neonatal period.

Conclusion

The management of a patent ductus arteriosus has become a subject of much controversy and debate. The current definition of a hemodynamically significant PDA is probably too simplistic as it considers the problem to be a binary variable requiring a dichotomous approach to therapeutic intervention. It is not surprising that all trials to date have failed to demonstrate a benefit of therapeutic intervention due to such homogenization of the patient population. In addition, the focus to date has been on ductal size, rather than the volume or magnitude of the ductal shunt. Echocardiography may facilitate a better understanding of the hemodynamic effects of a PDA and the magnitude of the shunt. A more comprehensive appraisal of echocardiography markers may optimize the definition of hemodynamic significance, enhance selection of patients who may benefit from therapeutic intervention, and facilitate longitudinal monitoring of response to therapeutic intervention. The association between cTnT and NTpBNP with severe IVH and death in infants with a PDA suggests that it may also facilitate stratification of neonates with a PDA into high-and low-risk groups allowing more focused early targeted treatment. Future randomized trials of targeted PDA treatment require an enhanced definition of hemodynamic significance and should stratify patients according to echocardiography markers, and biomarkers such as cTnT and NTpBNP. This may allow identification of those patients who may benefit from therapeutic intervention.

The Approach to an Infant with Suspected Congenital Heart Disease

Introduction

Congenital heart disease (CHD) occurs in 8 per 1,000 live births and is a major cause of morbidity and mortality in the neonatal population. Fifteen percent infants with CHD have potentially life-threatening lesions. Up to 35% on infants with congenital heart disease have low birth weight (<2,500 g). The incidence in the preterm population is around 12 per 1,000. The preterm population are at an increased risk of adverse outcome due to composite and additive effects of morbidities attributable to prematurity and the specific cardiac defect, or their treatment. Therefore, premature infants with CHD represent a highly vulnerable population who constitute a major challenge to daily management. This section will review the approach to the management of neonates with congenital heart disease. Detail of specific lesions is covered elsewhere.

Clinical Features and Assessment of CHD in Neonates

Antenatal diagnosis of most major cardiac lesions is now possible with the improvement in fetal ultrasound technique and the increasing expertise. Detection rates vary widely however, depending on operator experience, the gestational age of infants, fetal position, and the type of defect. A thorough history is important in identifying maternal conditions that increase the risk of CHD.

Maternal diabetes is associated with transient hypertrophic cardiomyopathy, transposition of the great arteries, and ventricular septal defects. Mothers with connective tissue disease (see later) are at an increased risk of congenital heart block. Congenital infection and maternal intake of certain drugs will also predispose to CHD. Examples include pulmonary or aortic stenosis in fetal hydantoin syndrome, Epstein's anomaly with lithium treatment, and septal wall defects with fetal alcohol syndrome. A family history of CHD also leads to a slight increase in CHD presence in the fetus. Clinical assessment of the neonate and certainly the preterm infant for symptoms of CHD is difficult, and many findings may be lacking before discharge. Early diagnosis of even major cardiac defects may be challenging as the typical clinical features, for example, hypotension, hypoxemia, and metabolic acidosis may be attributed to prematurity.

The physician should be extra vigilant in looking for the following symptoms: poor or slow feeding, frequent vomiting, tachypnea at rest or with feeds, cyanosis or pallor, persistent couch or unexplained wheeze, sweating, lethargy, irritability, decreased activity, and poor weight gain. These symptoms may be absent in up to 75% of infants in the early newborn period and are, unfortunately quite nonspecific. Cyanosis is an important sign of CHD but may be very difficult to assess in the first 24–48 h of life, particularly in dark pigmented infants. As a result, pulse oximetry screening has recently been advocated in all infants prior to discharge from hospital. Postductal oxygen saturations below 95% have a sensitivity and specificity of 75% and 88% for the detection of congenital heart disease, respectively.

The hyperoxia test is useful in distinguishing cardiac and pulmonary causes of cyanosis. In this test, arterial oxygen tension is measured in the right radial artery (preductal) and in a lower extremity artery while the patient breathes 100% oxygen (postductal). In clinical practice, a preductal blood gas will suffice, particularly in premature infants where sampling is more challenging. A transcutaneous oxygen monitor can be used to assess whether arterial oxygen tension rises in response to the increased inspired oxygen concentration, thereby avoiding arterial puncture for blood sampling but is generally not recommended if an arterial sample may be obtained. Lung disease is more likely than CHD in cyanotic patients whose postductal arterial PaO_2 increases to >150 mmHg in a hyperoxia test. Patients with cyanotic lesions such as TGA or severe pulmonary outflow obstruction typically have $PaO_2 < 50$–60 mmHg during hyperoxia. In lesions with intracardiac mixing and increased pulmonary blood flow such as trunks arteriosus, PaO_2 may increase to 75–150 mmHg.

Approach to Management

Early identification of CHD, and in particular a duct-dependant lesion, allows the opportunity for focused cardiac interventions, which may ultimately improve patient outcomes. The yield from clinical assessment in preterm infants is low but the possibility of a CHD should be entertained in all neonates who present with cyanosis, systemic hypoperfusion, pulmonary congestion, or heart failure. Occasionally, CHD is suspected after abnormal findings on a chest x-ray or electrocardiogram (ECG). The clinical course is often altered by comorbid pathophysiologic processes normally associated with prematurity, for example, respiratory distress syndrome. The gold standard for diagnosis is two-dimensional echocardiography. The approach to management of a preterm infant with CHD is dependent on two important physiological considerations: *first*, whether the lesion is duct dependent, and *second*, whether there is single ventricle type physiology. In the latter situation, the DA controls blood supply to both the pulmonary and systemic circulation. Hypoplastic left-heart syndrome and pulmonary atresia with a hypoplastic right ventricle are two examples of duct-dependant lesions with single ventricle physiology. The term single ventricle type physiology (SVP) refers to the anatomic anomalies that result in a single ventricle supporting both pulmonary and systemic circulations. In these lesions, there is complete mixing of both systemic and pulmonary venous return; and as a result, the pulmonary arterial saturation equals systemic arterial saturation.

Echocardiography and Preterm CHD

The role of echocardiography in the care of preterm neonates is twofold: First, to establish the anatomical diagnosis and second to monitor patency of the DA, myocardial performance, and pulmonary arterial pressures. Serial echocardiography is often necessary prior to surgical intervention to monitor cardiovascular health and the effects of the CHD on pulmonary arterial pressures.

Management of the Preterm Neonate with a CHD

The care of the preterm neonate with a CHD should take into account the morbidities specific to this population as well as those related to the particular CHD. The approach in the initial postnatal period is often predominantly medical.

Surgical interventions or other invasive procedures are usually delayed until the neonate reaches a maturity and weight at which the risks of an expectant approach outweigh the risks of the specific intervention. Management of the premature infant with a CHD requires expertise to ensure both focused cardiovascular and neonatal care, neither of which is mutually exclusive. It is only by ensuring excellence in each that outcomes will be improved.

Focused Cardiovascular Care: Medical Management

Prostaglandin Treatment

Neonates with a duct-dependant CHD require continuous intravenous prostaglandin E_1 therapy to sustain patency of the DA. In the early stabilization phase, the dose required may range from 0.01 to 0.2 μg/kg/min. For neonates with an antenatal diagnosis, the lowest dose should be prescribed immediately after birth since this is usually sufficient to maintain ductal patency; however, in those presenting with acute hypoxemia or circulatory collapse, high doses are often required. Once clinical and hemodynamic stability has been achieved, the intravenous prostaglandin E_1 dose is usually weaned to the lowest effective dose in order to avoid excessive pulmonary vasodilatation. This is particularly relevant for neonates with SVP where a profound or sustained fall in PVR leads to excessive pulmonary blood flow at the expense of systemic perfusion. In many cases, prostaglandin therapy is required for several weeks or months while awaiting surgical intervention. This increases the risks of complications related to prostaglandin administration including apnea, hyperthermia, hypotension, gastric outlet obstruction secondary to gastric foveolar hyperplasia, and cortical hyperostosis.

Cardiovascular Monitoring

This is particularly relevant in premature infants with single ventricle type physiology because acute physiologic changes in arterial oxygen or carbon dioxide content or common neonatal treatments, for example, increased ambient oxygen, surfactant replacement therapy, or inhaled nitric oxide may affect pulmonary and/or systemic vascular resistance (Fig. 23.5). The consequences may include altered ventricular afterload, transductal, pulmonary, or systemic blood flow. As pulmonary vascular resistance falls in the immediate postnatal period, increased pulmonary blood flow may occur at the expense of systemic perfusion thereby leading to end-organ compromise and suboptimal tissue oxygenation. Arterial $PaCO_2$, pH, and FiO_2 should be carefully monitored and controlled therefore to prevent excessive pulmonary vasodilatation and consequential overcirculation

Hemodynamic stability and the adequacy of either pulmonary or systemic blood flow may be evaluated both clinically and biochemically. Signs of circulatory compromise include tachycardia, hypotension, and decreased urinary output. Biochemical markers of the efficacy of oxygen delivery include: plasma lactate, arterial pH, base deficit, and mixed venous oxygen saturation. Lactic acidosis, metabolic acidosis, or falling mixed venous oxygen saturation are suggestive of suboptimal systemic perfusion and tissue oxygenation. Arterial access is an essential prerequisite of the care of these patients, particularly in the first 1–2 weeks of life, when major changes in transductal vascular resistance are most likely. The ratio of pulmonary to systemic blood flow (Qp: Qs) is another useful tool to evaluate the adequacy of systemic oxygen delivery. The Qp: Qs ratio is calculated as follows: SaO_2–$SmVO_2$/$SpVO_2$–$SpAO_2$ (where SaO_2 aortic oxygen saturation, $SmVO_2$ mixed venous oxygen saturation, $SpVO_2$ pulmonary venous oxygen saturation, and $SpAO_2$ pulmonary arterial oxygen saturation). In patients with single ventricle physiology, $SpAO_2$ can be assumed to be equal to SaO_2 since blood supply to both great vessels is from the same ventricle. $SpVO_2$ can be assumed to be 100% in the absence of lung parenchymal disease. $SmVO_2$ is obtained from a central venous catheter placed in the SVC. A normal SaO_2/$SmVO_2$ difference is 25–30%. Using these assumptions, the optimal Qp: Qs ratio is thought to be 0.5–1. Both circulations are balanced and the aortic arterial saturation tends to range from 75% to 85%. An aortic arterial saturation of 95% is therefore indicative of pulmonary blood flow five times that systemic.

Cardiotropic Support

There is a paucity of data describing physiologic norms for blood pressure and indices of systemic perfusion in the premature population. The goal of treatment is to ensure that blood pressure is maintained within a range that sustains adequate systemic perfusion. As indicated earlier, monitoring heart rate, urinary output, arterial pH, and lactate are essential components of the stabilization and ongoing care of neonates with CHD. Treatments options should be selected based on the underlying pathophysiology and the likelihood of the intervention to correct the abnormal physiologic state. Therapeutic options include volume

expansion with crystalloids, the use of inodilators like dobutamine and milrinone, and in special circumstances pressor agents, for example, dopamine, epinephrine, and vasopressin. Volume expansion is useful in neonates with abnormal right ventricular performance to support pulmonary blood flow. Milrinone has been shown to reduce both mortality and low cardiac output syndrome in postoperative cardiac patients. In many centers, milrinone is routinely administered to all neonates after complex cardiovascular surgery as the first-line cardiotropic agent. High-dose dopamine and epinephrine are rarely recommended in premature infants because of their adverse effects on both myocardial performance and vascular resistance.

Catheterization Procedures

Cardiac catheterization is occasionally performed in preterm infants. There are some reports in the literature of successful balloon dilation of the pulmonary valve in neonates at a weight of less than 750 g. Balloon atrial septostomy can be performed in neonates with Transposition of the Great Arteries or other conditions dependant on a transatrial shunt. Surgical intervention in premature neonates with single ventricle physiology is challenging. To avoid the risks of cardiopulmonary bypass and the need for chronic prostaglandin administration in this highly vulnerable population, a new technique called the "Hybrid procedure" has been developed to replace the first stage of the Norwood procedure. The procedure is performed in the cardiac catheterization laboratory and involves the placement of a stent in the DA to ensure both pulmonary and systemic blood flow. Pulmonary arterial bands are placed to reduce excessive pulmonary blood flow. This procedure has been performed on a number of premature neonates and early results are encouraging; however, long-term data are not yet available. The age and weight thresholds for performing these procedures are likely to vary significantly between neonatal cardiac centers.

Surgical Procedures

Determining the optimal time for surgical intervention in the preterm population has proven to be a challenge because of technical issues related to both low birth weight and the comorbidities inherent within this population. Typically, an expectant approach has been employed with a view to intervention at a higher weight, although this is oftentimes a moving target with little consistency between centers and cardiovascular surgeons. Delaying surgery until a predetermined weight is achieved is not without risks which include:

1. Prolonged exposure to abnormal physiology and hypoxia
2. Failure to thrive
3. Prolonged need for central venous access and total parenteral nutrition administration and the attendant risks of infection, thrombosis, and cholestasis
4. Prolonged volume overload and its possible contribution to the development of pulmonary hypertension and the progression of chronic lung disease

Corrective Surgery

Total anatomic correction is possible in neonates with transposition and anomalous pulmonary venous drainage or coarctation of the aorta. Several studies have demonstrated a more favorable outcome in patients greater than 1,500 g at the time of surgical intervention. For this reason a weight $\geq$1,800 g has been widely accepted as the target weight for intervention; particularly in light of the challenges of cardiopulmonary bypass, the potential need for postoperative extracorporeal life support and the risks to the developing organs especially the brain. In most centers, the average weight at surgery is between 2,000 and 2,500 g, although with modified techniques of cardiopulmonary bypass surgical intervention is attempted at less than 1,800 g.

Palliative Surgery

Palliative surgical interventions refer to procedures where total anatomic correction is not possible and blood flow is controlled by natural or artificial shunts and a single ventricle. Neonates with hypoplastic left heart syndrome, pulmonary atresia, or tricuspid atresia undergo a three-stage surgical repair called the "Norwood or single ventricle" track. These patients will have lower oxygen saturation than normal, limited exercise capacity and significant periods of hospitalization during this time period. The final step in this staged approach results in the complete separation of pulmonary and systemic circulations by the fashioning of a Fontan circulation whereby inferior and superior venous blood flow is directed to the pulmonary artery while the single ventricle supplies the systemic circulation. Mortality rates associated with these procedures have improved over the past 10 years; however, significant acute and long-term morbidity remains a reality.

Focused Preterm Care

Preterm neonates with congenital heart disease should ideally be cared for in tertiary neonatal intensive care units with a critical mass of preterm neonates with CHD and in close proximity to pediatric cardiology services. There are no published data or guidelines on best practice for the management of preterm neonates with congenital cardiovascular malformations. Most of the current practices extrapolate from evidence for the care of term neonates with CHD. Close collaboration between neonatology and pediatric cardiology is recommended to optimize the quality of care delivered to these patients, which ensures the needs of prematurity and cardiovascular care are met.

Assisted Mechanical Ventilation

Routine intubation of all neonates when prostaglandin E_1 is administered is not necessary. Intubation is recommended in the presence of respiratory failure, clinical signs of cardiogenic shock, the need for cardiotropic support, profound metabolic or lactic acidosis, gestational age less than 28 weeks, and an associated airway disorder. In general, patients should be ventilated to maintain a $PaCO_2$ of 40–50 mmHg and an arterial pH of 7.25–7.35 to avoid excessive pulmonary blood flow in those patients with single ventricle type physiology. The provision of optimal positive end-expiratory pressure may have the additional benefit of limiting left-to-right shunting across a patent ductus arteriosus and may therefore be useful in controlling transductal flow. One of the most challenging aspects of management is supporting those neonates with evolving chronic lung disease and pulmonary hypertension secondary to pulmonary vascular remodeling. Episodic apnea and/or hypoxemia occur frequently in these patients necessitating therapeutic intervention. Oxygen therapy is normally administered to preterm neonates when the oxygen saturation falls below 88% although the optimal saturation for preterm neonates remains controversial. An oxygen saturation range of 75–85% is normally targeted in neonates with duct-dependant CHD, particularly if single ventricle type physiology exists. This range has been chosen to minimize an excessive decline in pulmonary vascular resistance in an attempt to maintain satisfactory systemic perfusion. At the same time, the risk of tissue hypoxia and adverse neurodevelopmental outcome must be taken into consideration and judicious oxygen administration may be required. Neuroimaging studies of neonates report a high incidence (>50%) of periventricular leucomalacia after cardiac surgery. Arterial $PaO_2 < 40$ mmHg and diastolic hypotension were two of the most important risk factors associated with the evolution of brain injury. There are limited studies addressing the relationship of CHD or oxygen saturations to abnormal respiratory outcomes in premature infants and the mechanism of lung injury.

Other Respiratory Interventions

The administration of prophylactic surfactant to preterm neonates with an antenatal diagnosis of a duct-dependant systemic circulation may result in an excessive fall in PVR leading to excessive pulmonary blood flow at the expense of systemic perfusion. A recent prospective evaluation of delivery room surfactant demonstrated increased transductal diameter, decreased cardiac output, and increased Qp:Qs. This may be particularly hazardous for neonates with hypoplastic left heart syndrome in whom the systemic circulation tends to be extremely tenuous. The radiological confirmation of a diagnosis of respiratory distress syndrome is recommended for these neonates before surfactant administration.

Neurological Care

The risk of an adverse neurological event is significantly increased in neonates with a CHD requiring cardiopulmonary bypass or postoperative extracorporeal life support due to the fragility of the developing brain, particularly in premature infants. Intracranial hemorrhage and non-hemorrhagic infarction are the most common adverse events in the immediate postoperative period. There is, however, increasing evidence that neurological damage may occur preoperatively and perhaps in utero. Neonates with congenital heart disease have an increased incidence of structural central nervous system and neurobehavioral abnormalities. The incidence of microcephaly was 24–36% in one series. Infants with hypoplastic heart disease have also been reported to have an increased incidence of holoprosencephaly, agenesis of the corpus callosum, and abnormalities of the operculum in other series. Magnetic resonance image evaluation preoperatively in newborns with congenital heart defects has revealed periventricular leukomalacia in 16–28% . It has been reported that more than 50% of infants with congenital heart disease have poor state regulation and abnormalities of tone preoperatively. There is a strong correlation between these findings and preoperative

arterial PaO_2 and blood pressure. Preoperative neurological abnormalities portend a poor neurodevelopmental outcome. In addition, the presence of perioperative hyperthermia or seizures, coexisting genetic abnormalities, or associated organ defects also increase the risk of neurological morbidity. The preterm neonate is even more vulnerable to the effects of chronic hypoxaemia and intermittent periods of systemic hypoperfusion on the developing brain because of poor cerebral autoregulation. There are limited published data on the neurodevelopmental outcome of premature infants with CHD.

Nutritional Support

The risk of necrotizing enterocolitis is significantly increased in neonates with a CHD. This is most likely to be related to intestinal hypoperfusion and/or chronic hypoxaemia. Extreme immaturity, higher doses of prostaglandin treatment, and episodic low cardiac output syndrome are also strong predictive factors. These newborns required a focused approach to nutrition that balances the risks of prematurity within the context of a fragile circulation. Wherever possible, guidelines should be developed that focus on the unique needs of preterm neonates with cardiac disease. While growth is paramount to achieve target surgical weights, these newborns should be fed cautiously. Expressed breast milk is recommended, and feeds should be increased slower compared to their gestational age counterparts, although there are few supporting data for the latter in currently published literature.

Miscellaneous

The risk of anemia is likely to be increased in this population due to more frequent blood sampling. Although the threshold for transfusion in preterm neonates remains unclear, it is probably advisable to implement a lower more liberal transfusion policy for transfusion to maintain oxygen-carrying capacity. This is particularly relevant for neonates with single ventricle type physiology who are at greater risk of tissue hypoxia. Plasma hemoglobin should probably be maintained > 100 g/dl but during periods of instability the level should be maintained > 120 g/dl.

The risk of infection is higher in preterm neonates with CHD; for this reason vigilance is required and that possibility entertained in the presence of hemodynamic instability.

Due to the challenges of clinical assessment of preterm neonates for dysmorphism or genetic abnormalities, routine karyotype analysis as well as screening for 22q microdeletion is recommended.

Outcome

Mortality rates for preterm infants with CHD of 10–43% have been reported by various studies. Few of these studies however take into account the heterogeneity of the cardiovascular malformations. With advances in antenatal diagnosis and postnatal management, there has been a trend toward improved survival in patients with CHD. As a result, the focus has shifted toward evaluating the long-term neurodevelopmental outcome of these infants. Annette Majnemer et al. examined the neurodevelopmental outcome of 131 term neonates with CHD who underwent surgical intervention at Montreal's Children's Hospital between 1994 and 1998. Evaluation of the patients at 12–18 months revealed global delays in 25%; delays in speech and hearing in 34%; locomotor 26%; hand-eye coordination 24%; personal/social 17%; and abnormal neurological exam in 41%. Dittrich et al. investigated the neurodevelopmental outcome at 1 year of age of 90 infants who had surgical repair of various congenital heart defects. Mean developmental quotient was statistically significantly lower in test subjects than controls (who were infants with minor or no congenital heart defect). Thirty-two percent of the index patients had neurological abnormalities compared with 5% of the controls. In each of these scenarios, outcome was worse for those patients offered palliative surgery compared with patients who underwent corrective surgery. There is a paucity of data on long-term outcome in the premature population, however. Additionally, outcome data for specific lesions are lacking. This makes accurate counseling of the parents of affected newborns a challenge.

Summary

With an improvement in the survival rates for neonates with CHD over the past 10–15 years, the high incidence of cognitive and neurodevelopmental impairment have become a cause for concern. The care of the preterm neonate with a CHD poses a significant challenge for neonatal intensivists attempting to stabilize a vulnerable circulation within the context of organ immaturity. A multidisciplinary approach with collaboration between neonatal intensivists and cardiologists with careful

attention to the issues peculiar to this population is of paramount importance. Prospective research evaluating the physiological and hemodynamic impact of acute therapeutic and surgical interventions on morbidity, mortality, and neurodevelopmental outcome are urgently required to further guide and shape the optimal approach to management.

Common Neonatal Arrhythmias

Introduction

The incidence of serious neonatal arrhythmias is not well defined as the problem is relatively rare. Benign arrhythmias, such as premature atrial beats, are common and often cause concern when frequent, leading to "irregular heartbeat." Tachyarrhythmias represent the most common form of dysrrhythmias, of which supraventricular tachycardia (SVT) occurs most frequently. Ventricular arrhythmias are usually a complication of metabolic disturbances, illness severity. Bradyarrhythmias may also occur and range from relatively benign sinus bradycardia to complete heart block most commonly associated with maternal systemic lupus erythematosus (SLE). The majority of neonatal arrhythmias occur in a structurally normal heart. However, infants with congenital heart disease, particularly in the postoperative period, are at a higher risk of developing arrhythmias. This chapter will review the two commonest pathological neonatal arrhythmias, namely, SVT and complete heart block.

Supraventricular Tachycardia

Introduction

SVT can be defined as an abnormally fast regular heart rhythm originating above the ventricle with a narrow QRS complex. The heart rate usually ranges from 230 to 250 beats per minute (and up to 300) during an SVT episode. It is characterized by a sudden onset of a regular fast rhythm with no beat-to-beat variability and a narrow QRS complex. The p wave is often absent but may be seen after the QRS wave. These features distinguish SVT from sinus tachycardia, which is characterized by a gradual onset with beat-to-beat variability and rate between 180 and 240. The incidence was previously quoted at 1 in 25,000 infants. However, with increased index of suspicion and improved detection modalities, the incidence has increased to 1 in 250.

Pathophysiology and ECG Features

The normal cardiac impulse originates from the sinoatrial (SA) node in the right atrium and travels through the atria to the atrioventricular (AV) node. The impulse is then delayed to accommodate the completion of atrial contraction. Further impulse propagation occurs through the AV node and spreads to the right and left ventricles through the bundle of His. Normal conduction from atria to ventricles only occurs though the AV node (Fig. 23.6).

Atrioventricular reentry tachycardia (AVRT): This is the commonest form of SVT in neonates and accounts for about 70% of cases. Mechanistically, the AV node usually acts as the antegrade pathway (from atria to ventricles) and an accessory pathway acts as a retrograde pathway leading to impulse reentry into the atria. This is referred to as orthodromic AV reciprocating tachycardia and results in a circular pathway of the impulse leading to a tachycardia. Occasionally, the accessory pathway serves as the antegrade and AV node serving as the retrograde course of conduction. This is called antidromic AV reciprocating tachycardia. The ECG is characterized by a narrow complex QRS, an inverted P wave that may be seen following a QRS complex, and a PR longer than an RP interval. In 10–50% of the cases, ventricular preexcitation may occur resulting in the formation of a short PR interval and a delta wave. This is caused by early antegrade propagation of the impulse through the accessory pathway leading to early depolarization followed by delayed antegrade impulse conduction through the AV node completing the depolarization of the ventricles. This is referred to as Wolff–Parkinson–White (WPW) syndrome.

AV nodal reentry tachycardia (AVNRT): This is the second most common form of SVT and accounts for about 15% of cases. There are two pathways within or adjacent to the AV node. Typically, the impulse is conducted slowly through one pathway to the ventricles with a rapid retrograde conduction back to the atria (slow-fast AVNRT). The ECG is characterized by a narrow QRS, with the P wave often not visible (within the ORS). Atypical AVNRT is characterized by fast antegrade flow and slow retrograde flow (fast-slow). The ECG may show a P wave after the QRS with a PR shorter than the RP interval.

Atrial Tachycardia (AT): This is the third most common form of SVT in neonates (15%). AT includes atrial

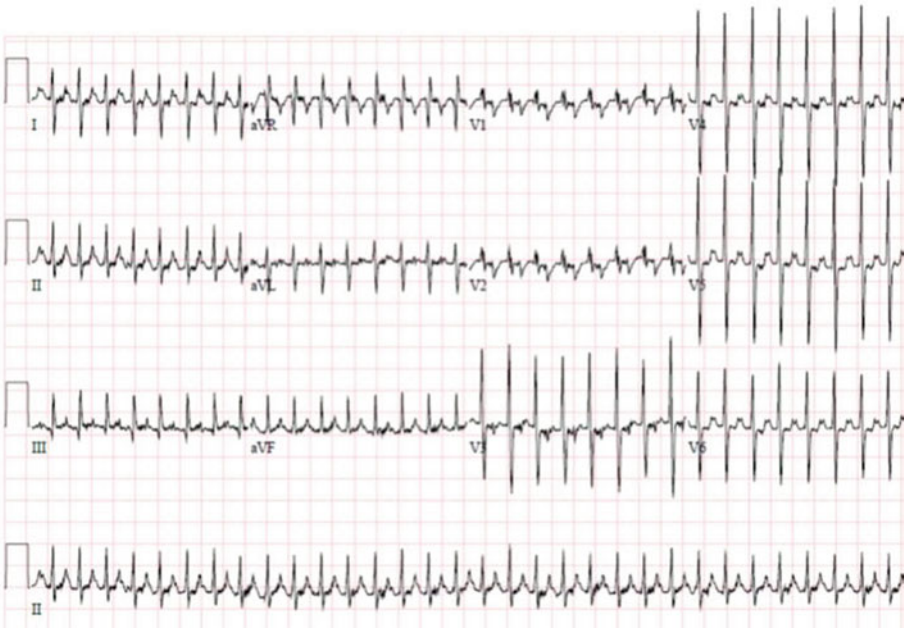

Figure 23.6
***SVT* (Courtesy of Dr. Gil J. Gross)**

flutter and atrial ectopic tachycardia (AET). Atrial flutter occurs due to accessory pathways within the atrial muscle leading to atrial rates of up to 600 beats per minute. The ECG shows flutter waves and varying ratios of conduction via the AV node. AET results from ectopic foci within the atria with automaticity with a rate of firing higher than the SA node. There is a period of gradual heart rate escalation preceding AET. The ECG shows abnormal P wave morphology, a short PR interval, and varying degrees of conduction to the ventricles via the AV node. AV node is not a part of this arrhythmia.

Clinical Features

Fetal SVT may be identified in utero upon routine ultrasound examination of the heart beat and may lead to hydrops fetalis. SVT in neonates is usually paroxysmal in nature with a sudden onset and resolution. Episodes usually occur at rest and may last from minutes to hours. They may go undetected in neonates. Hemodynamic instability is relatively rare. Infants with sustained SVT lasting greater than 24 h may present with signs and symptoms of heart failure, such as poor feeding, respiratory distress, sweating, lethargy, irritability, and restlessness. Syncope and ventricular fibrillation is rare in neonates. Sudden death is very uncommon in neonates. Chronic tachycardia will lead to ventricular dilatation. This cardiomyopathy may be reversible if the arrhythmia is terminated. However, cardiac injury from untreated SVT may be permanent leading to myocardial dysfunction and ventricular arrhythmias.

Management of SVT

Infants presenting with SVT need a comprehensive evaluation aiming to identify the cause and the type of SVT. Electrolytes associated with the development of SVT should be checked including sodium, calcium, potassium, and magnesium. The presence of peripherally inserted central catheters (PICC) or umbilical catheters should be noted as they may act as a trigger if the tip is in the right atrium. A 12-lead ECG with a rhythm strip is essential to assess the heart rate and identify the type of arrhythmia. An echocardiogram should be done to assess cardiac anatomy once the infant is stable. *Adenosine* can be used to both terminate and help diagnose the type of arrhythmia. Adenosine acts directly on the AV node to terminate conduction; therefore, it will terminate AVRT and AVNRT but not AET as the latter has the arrythmogenic

focus in the atria. Consultation with the cardiology service is essential in providing ongoing management.

In a stable infant, a graded approach is utilized. Vagal maneuvers such as applying an ice pack on the face and nose for 10–20 s will trigger the diving reflex (peripheral vasoconstriction and a vagal discharge). This maneuver is successful in around 60% of cases. Eyeball pressure, carotid message, and immersion in water *are not recommended* in the neonatal population.

Adenosine may be used if vagal maneuvers are unsuccessful. A rapid intravenous bolus of 0.05 up to 0.3 mg/kg may be used followed by a saline flush with continuous ECG monitoring. It can terminate SVT in up to 90% of cases. Adenosine has a very short half-life of 15 s, and repeat administration may be used for resistant SVTs. Side effects include bronchospasm, and premature atrial and ventricular contractions. It may also cause varying degrees of AV block.

Esmolol is a beta blocker with class II antiarrhythmic properties. It has a very short half-life and may be used in resistant SVTs, including AETs to achieve ventricular rate control. It acts by increasing the refractory period of the AV node and interrupting the reentry circuit. It is administered as a continuous infusion of 50 to 100 μg/kg/min following a bolus of 100–500 μg/kg/min. It may cause profound hypotension and bradycardia, and therefore, its use should be guided by a pediatric cardiologist. Further, heart rate control and management should be done in consultation with the cardiology services and the choice of drug will be dependent on local experience and preference. Amiodarone, flecanaide, and procainamide are alternative agents that are sometimes used, although amidorone is now contraindicated in the newborn period. Digoxin should be avoided in WPW syndrome as it only slows conduction on the AV node and not the accessory pathway.

If the infant shows signs of cardiovascular compromise, immediate *synchronized* cardioversion is needed. The starting dose is 0.5 J/kg increasing to 1 J/kg if no response. Cardioversion will only restore (and not maintain) cardiac rhythm and therefore, pharmacological therapy is needed to maintain sinus rhythm. Intravenous (IV) access should be instituted as soon as the infant is stable, preferably in a vein in close proximity to the heart such as the right or left antecubital fossa.

Prognosis

The majority of infants (50–70%) with a normal heart will be free of SVT by 1 year of age, and up to 85% are SVT-free by 5 years of age. Infants with early persistent SVTs, infants requiring multiple drug therapy, and those with structural heart defects are at greater risk of developing recurrence particularly during the teenage years. These infants may need radiofrequency ablation of the accessory pathways.

Congenital Heart Block

Incidence and Etiology

Congenital heart block (CHB) is defined as a neonatal bradycardia of 40–80 beats per minute. It occurs in around 1 in 20,000 live-born infants. The majority of cases are secondary to maternal SLE antibodies that cross the placenta and cross-react with the AV node, accounting for up to 90%. The remainder are caused by myocarditis, congenital heart disease (particularly AV and VA discordance), some hereditary disorders, and polysplenia.

Pathophysiology

In neonatal lupus, maternal anti-Ro/SSA and anti-La/SSB antibodies cross the placenta and bind to fetal cardiac tissue, particularly the AV node; a site is rich in La/SSA and Ro/SSB antigen. This antibody–antigen interaction leads to AV nodal fibrosis and inhibition of calcium channel activation thereby preventing impulse propagation from the SA node to the ventricles. Occasionally, the SA node may be involved as well. CHB occurs in 2% of women with these antibodies.

Clinical Features and Prognosis

CHB usually presents in utero by ultrasonic detection of fetal bradycardia usually at 18–24 weeks gestation. Fetal echocardiography can estimate the PR interval and assess the anatomy of the heart. The degree of heart block is variable and can start as second-degree heart block later progressing to third-degree heart block. Ninety-five percent of cases detected in utero are due to maternal antibodies. Hydrops fetalis, endocardial fibroelastosis, pericardial effusion, and fetal demise may all arise. Death can occur in 5–20% of cases. Early mortality is high with CHB with up to 25% of affected infants dying in the first 3 months of life. Infants born with first- or second-degree heart block can also progress to complete heart block.

The cardinal sign in neonates is the detection of a slow heart rate soon after birth. Infants usually tolerate the low

Figure 23.7
Congenital heart block **(Courtesy of Dr. Gil J. Gross)**

heart rate well in the initial period. Heart failure will develop in untreated infants. Other signs include canon waves in the neck, and a first heart sound varying in intensity. The ECG shows a narrow QRS due to the junctional or AV origin of the escape rhythm (*Fig. 23.7*), and complete p wave dissociation.

Management

Antenatal management includes steroid administration in an attempt to arrest the progression to complete heart block. The mainstay of treatment is pacemaker insertion either soon after birth or when symptoms arise. The indications for pacemaker insertion include the following: symptomatic bradycardia, ventricular dysfunction, wide QRS escape rhythm, ventricular rates <55, and complex ventricular ectopic beats.

Neonatal Cardiomyopathies

Introduction

Cardiomyopathy is an intrinsic myocardial disease. These rarely present in neonates, with the exception of asphyxia cardiomyopathy. Primary cardiomyopathies are disorders confined to the heart and have no systemic disease. Secondary cardiomyopathies are associated with other disease states. A detailed description of the various disease states is outlined elsewhere.

Etiology

The following are causes of cardiomyopathies that may present in the neonatal period. This is not an exhaustive list:

- Primary Causes
  - Endocardial fibroelastosis
  - Familial hypertrophic/dilated cardiomyopathies
  - Noncompaction of the left ventricle
- Secondary Causes:
  - Neonatal asphyxia
  - Cor pulmonale: following chronic lung disease
  - Genetic syndromes: Beckwith–Wiedemann, Noonan, neurofibromatosis I
  - Infectious myocarditis: congenital viral infections, syphilis
  - Inflammatory: SLE, peripartum myocarditis
  - Myocardial insufficiency: tachyarrythmias, anomalous left coronary artery origin
  - Metabolic: infants of diabetic mothers, inherited disorders of metabolism (e.g., glycogen storage disease), pheochromocytoma, thyroid disease, mitochondrial disease
  - Toxic: alcoholic myopathy, cocaine use, cyclophosphamides

Clinical Approach to Neonates with Suspected Cardiomyopathies

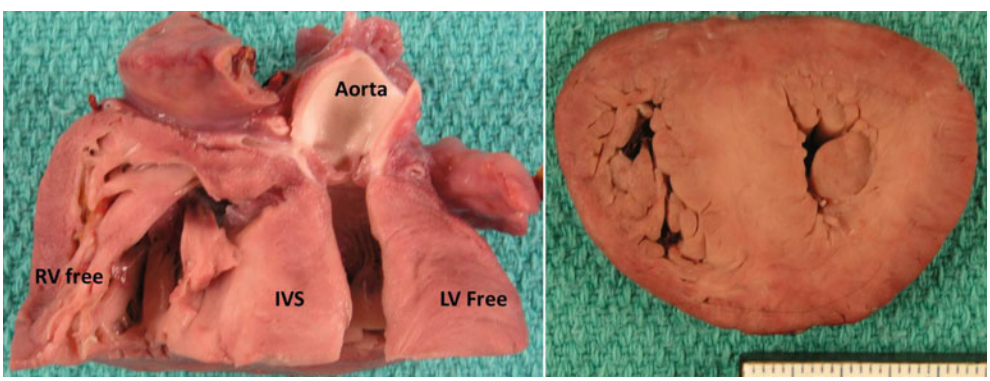
As the causes of neonatal cardiomyopathies are many, a focused history, physical examination in addition to laboratory and imaging modalities may narrow down the diagnosis. A history of stillbirths or cardiomyopathies in the family or siblings may be indicative of a familial cause; in addition, a maternal history of diabetes or autoimmune disease (such as SLE) may provide further clues. A history of antenatal and postnatal events needs to be completed. Clinical examination of the cardiovascular status looking for signs of heart failure or a low cardiac output state is necessary. In addition, dysmorphic features often give clues toward a diagnosis. Hypotonia and encephalopathy may lead to a diagnosis of mitochondrial disease. Chest radiographs and echocardiogram will provide supporting evidence of heart failure and distinguish hypertrophic from dilated types. Laboratory investigations will be exhaustive and include basic tests such as full blood counts, electrolytes, and basic metabolic screens. Further testing will depend on initial investigations and advice from other consultative services. Prognosis is varied and depends on the underlying pathology.

Infants of Diabetic Mothers

Infants of diabetic mothers (IDM) are at an increased risk of developing transient hypertrophic cardiomyopathy (HCM). It occurs in around 5% of infants with mothers with gestational diabetes. The incidence is higher in mothers with type 1 and 2 diabetes where 25–50% of infants are at risk of developing HCM (◉ *Fig. 23.8*). Hypertrophy of the cardiac myocytes develops as a result of fetal hyperinsulinemia secondary to impaired glucose metabolism in the mother. This leads to increased synthesis and deposition of fat and glycogen in the myocardial cells. It is more common in mothers with poor glycemic control, but can occur in mothers with diabetes and good glycemic control throughout pregnancy. The condition may be identified on antenatal scans. Severe cases could be associated with third trimester polyhydramnious, severe ventricular hypertrophy, and pericardial effusion.

The majority of infants are asymptomatic at birth. About 10% of infants are symptomatic with signs of respiratory distress and poor cardiac output. Heart failure could also develop. The heart will appear large on chest radiographs. Echocardiography is the gold standard for diagnosis. The heart usually appears hypertrophied, with prominent thickening of the interventricular septum. The ventricular chambers are usually small in size and may be associated with left ventricular outflow tract obstruction. This may be aggravated by anterior systolic motion of the mitral valve.

HCM is usually transient and resolves as insulin levels fall. Symptomatic infants, however, may need cardiovascular support. This includes administration of intravenous fluids and the judicious use of propranolol. Inotropes are generally contraindicated as they may further increase afterload, decrease ventricular size, and further obstruct outflow. Intravenous vasopressin should be



◉ **Figure 23.8**
***Pathology specimen of an infant with hypertrophic cardiomyopathy*. Note the thickened left ventricular free wall and the intraventricular septum. There is also evidence of left ventricular outflow tract obstruction**

considered as it will increase myocardial preload with negligible direct effects on myocardial performance. Diuretics are absolutely contraindicated, as a reduction of preload will be detrimental to ventricular filing and systemic blood flow.

General Principles

This chapter aims to inform the reader of the underlying principles that guide the day-to-day assessment and management of fluid and electrolyte therapy in newborn infants. A good history, consideration of the clinical context, careful examination of the baby, and review of charts are essential and should precede laboratory or other investigations. Case histories and common clinical scenarios are described to illustrate the application of these principles.

Changes in Body Water During Normal Postnatal Adaptation

All newborn infants lose around 10% of total body water after birth. This is from the extracellular compartment and includes pulmonary interstitial fluid. Loss of extracellular fluid is a component of normal postnatal adaptation to a gaseous environment. The size of the extracellular compartment reduces with increasing gestational age. At birth, it is around 65% of body weight at 26 weeks gestation and has fallen to 40% by full term. Loss of extracellular fluid is marked clinically by postnatal weight loss, the extent of which is variable and reflects the loss of body water as well as the balance of loss and gain of body solids that is in turn a reflection of nutritional support provided. It is therefore unhelpful to suggest a specific target for postnatal weight loss, but in the majority of newborn babies provided with adequate nutritional support, this should not exceed 10% of birth weight. Delay in the loss of body water, marked clinically by delayed postnatal weight loss, is associated with increased respiratory morbidity in all babies, regardless of gestational age. This is because postnatal extracellular fluid loss appears triggered by a rise in circulating atrial natriuretic peptide, induced by the fall in pulmonary vascular resistance, rise in pulmonary blood flow, and increase in left atrial venous return and atrial distension, resulting in an acute natriuresis and accompanying loss of body water. Sodium and water balance during this period of postnatal adaptation will consequently be negative. Antenatal steroids and postnatal surfactant have altered the natural history of classical respiratory distress syndrome, and delayed postnatal loss of extracellular fluid does not pose the major problem it did previously. Nonetheless, it is important to recognize that clinical management must be directed at avoiding interventions that adversely affect postnatal extracellular fluid loss; in particular, the administration of sodium in maintenance intravenous fluids should be delayed until postnatal weight loss is underway. This is especially relevant in preterm babies that have not received antenatal steroid therapy to promote pulmonary maturation, and in term babies with respiratory problems.

Case history: *An infant is delivered at 37 weeks gestation by elective Cesarean section. The baby weighs 3.500 kg and is in good condition at birth, but he rapidly develops signs of respiratory distress with grunting, tachypnea, and intercostal recession. He is admitted to the neonatal unit and placed on CPAP. Baseline blood biochemistry results are serum sodium 134 mmol/l, potassium 4.5 mmol/l, and creatinine 64micromol/l. What fluids would you prescribe?*

This baby most likely has transient tachypnea of the newborn characteristic of delivery without exposure to labor. However, at this stage, the precise diagnosis and the time scale of resolution are unknown. The differential diagnosis includes respiratory distress syndrome, and Group B streptococcal infection. Loss of extracellular fluid will be delayed until there is improvement in respiratory status. Hence, only glucose-containing fluid should be prescribed; no intravenous sodium is necessary. Glucose 10% at 60 ml/kg/day is prescribed.

At 4 h of age, chest x-ray shows an air bronchogram and a ground-glass appearance. Serial arterial blood gas measurements show worsening respiratory acidosis; by 7 h, the oxygen requirement has risen to 60%. The baby is intubated and positive pressure ventilation commenced. Surfactant is administered. The oxygen requirement falls to 30%, but at the age of 12 h, the baby suddenly desaturates. Examination suggests a tension pneumothorax, confirmed on chest x-ray. A chest drain is inserted. At 24 h of age, repeat blood biochemistry values are serum sodium 129 mmol/l,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_24,

potassium 4.3 mmol/l, and creatinine 76 micomol/l. Blood glucose measurements have been normal and stable. Urine output has not been monitored, but his weight has risen to 3.540 kg. What would your day 2 fluid prescription be?

By this stage, a small quality of fresh maternal colostrum should be available and may be administered by nasogastric tube. Transepidermal water loss will be no more than 15 ml/kg/day, and glucose 10% at 60 ml/kg/day is sufficient to maintain hydration. However, the baby has not lost weight, indicating positive water balance and the serum sodium has fallen; urine output is unknown.

Examination reveals good peripheral perfusion, a core–peripheral temperature gap of 1°C, and a capillary-refill time of 1.5 s. No bladder is palpable. Mean arterial blood pressure is 45 mmHg. The baby's respiratory requirements have not reduced.

The likely diagnosis is mild dilutional hyponatremia (see section below). Monitoring of urine output is begun and the intravenous infusion rate reduced to 40 ml/kg/day with no added sodium.

Over the next 4 h, the baby's urine output increases from 1.2 ml/kg/h to 3 ml/kg/h. Respiratory requirements fall. Ventilator settings are weaned and he is extubated at 48 h of age. The next set of blood biochemistry results are serum sodium 132 mmol/l, potassium 3.8 mmol/l, and creatinine 70 micomol/l. What would your fluid prescription be for day 3?

Following extubation, he is placed at the breast, and over the next 12 h, suckling progressively improves while he continues to receive nasogastric milk feeds. The intravenous infusion of 10% glucose is discontinued. By day 4, he has shown a 2% weight loss. He is discharged on day 5, exclusively breastfeeding.

Renal Function

Fetal urine production begins at around 8–10 weeks gestation. Nephrogenesis proceeds centrifugally with the deep cortical juxtamedullary zone developing first, and those in the superficial cortex, last. Nephrogenesis continues through most of the third trimester and is completed by a gestational age of around 34–36 weeks. The increase in renal mass during infancy and childhood is due to tubular growth as nephrons that die are not replaced. Renal function in healthy preterm and term newborn babies should be regarded as immature, not abnormal. Although often described as "low" or "reduced" in the newborn, the glomerular function rate (GFR) is adequate for need.

Tubular function is immature, and the preterm baby has a narrower capacity to conserve and excrete sodium than the term infant; hence, preterm newborns are highly susceptible to both sodium depletion and sodium overload. Many tubular functions are upregulated by antenatal glucocorticoid therapy. In newborns, in comparison with older subjects, a smaller proportion of filtered sodium is absorbed in the proximal tubule and a larger proportion delivered distally where sodium reabsorption is regulated by the renin-angiotensin-aldosterone-system (RAAS). The retention of approximately 1 mmol/kg per day of sodium is necessary for growth in preterm and term neonates. Healthy, mature breast-fed neonates achieve this by excreting virtually sodium-free urine; limited sodium conservation in preterm babies of less than 32 weeks gestation requires that they receive an intake of at least 4 mmol/kg per day. Intestinal absorption is an important route for sodium conservation but is also reduced.

Babies receive nutrition only in liquid form and must therefore be able to sustain a high urine flow rate to maintain water balance. This is achieved by reduced proximal tubular reabsorption of filtered water, with a correspondingly greater fraction delivered to the distal nephron. Here water moves across the tubular membrane following an arginine vasopressin (AVP)-dependent increase in water permeability brought about through the insertion of water channels, principally acquaporin 2 (AQP2), from intracellular vesicular reservoirs into the apical membranes of cells of the collecting ducts. The capacity of the healthy term and preterm baby to dilute urine matches that of adults in that a minimum urine osmolality of 50 mOsmol/kg H_2O is achievable. The clinical implication is that impaired water excretion should not be attributed to limited diluting ability.

Urinary concentrating capacity increases with postnatal age. In adults, maximum urine concentration is around 1200–1400 mOsmol/kg water. The capacity to concentrate urine in neonates is lower at around 600–800 mOsm/kg because of the low urea concentration and low tonicity of the medullary interstitium of the anabolic, rapidly growing infant, and reduced expression of AQP2. Antenatal glucocorticoid therapy enhances concentrating ability as does high protein feeding leading to an increased urea production rate. In the first postnatal days, very immature babies with extremely limited concentrating ability may become dehydrated while continuing to pass dilute urine.

Nonrenal Influences on Fluid Balance

The skin is an important organ of water balance particularly in extremely preterm babies. Although keratinization of the stratum corneum commences at around 18 weeks

gestation, the epidermis remains very thin until the third trimester. Water loss through the skin, transepidermal water loss, may be considerable, even exceeding urine volume. Excessive transepidermal water loss is the cause of hypernatremic dehydration in extremely preterm babies, as sodium is not lost through the skin. The evaporation of each milliliter of water from the skin also results in the loss of 560 cal of heat. This is the rationale for placing extremely preterm babies in plastic bags at delivery, and for maintaining a high-humidity environment around them in the neonatal unit. Unlike nephrogenesis, which proceeds along a predetermined and fixed time scale, skin maturation is accelerated by birth. Hence, transepidermal water loss at birth is dependent on gestational age; thereafter, it falls exponentially with postnatal age. After 32 weeks gestation, water loss through the skin in an ambient humidity of 50%, falls to around 12 ml/kg/day. The extent to which transepidermal loss can be reduced is an index of the quality of nursing and medical care. Insensible water loss can be reduced to less than 40 ml/kg/day even in infants weighing less than 1000 g if ambient humidity is maintained above 90%. Babies must be protected from draughts, and care taken to maintain skin integrity and reduce excoriations using nonabrasive tape. Concern about increased infection and difficulty in fixing electrodes has limited the use of water-impermeable barrier ointments and soft paraffin to reduce transepidermal water loss. As radiant heat increases transepidermal water loss considerably, humified incubator care is preferable for the most immature infants. An effective, low cost option is to use a plastic sheet or a humidified body box to achieve a high-humidity microenvironment immediately around the baby.

The Principles of Constructing an Intravenous Fluid Prescription

As neonates receive nutrition only in fluid form, fluid balance and nutritional support are closely interrelated. The clinician must be careful to distinguish the demands of fluid balance and hydration, from those of nutrition. The volume required for nutritional support is determined by the energy density and composition of the fluid used. Put simply, 150 ml/kg of 10% glucose will deliver 60 kcal/kg purely as carbohydrate; this volume of parenteral nutrition could be constituted to deliver around 120 kcal/kg as a balanced intake of carbohydrate, protein, and lipid. The volume required to maintain hydration is determined by insensible water loss, urine output, and any other sources of substantial loss such as stoma output. In preterm babies, the fluid requirement to maintain hydration *falls* with postnatal age, as transepidermal water loss decreases. Hence, a stepwise daily *increase* in intravenous intake is illogical. Each neonatal service should establish guidelines for immediate fluid administration to preterm babies based on their ability to provide a high-humidity environment. Given present day care and ability to provide an ambient humidity in excess of 50%, this equates to around 80–100 ml/kg/day for babies below 32 weeks gestation. The higher the humidity, the lower the volume required to maintain hydration. It may be helpful to prescribe a higher volume during the few initial hours of stabilization when arterial and intravenous lines are being inserted when it can be difficult to maintain a high-humidity environment around the baby. This is particularly helpful in the most immature babies, below 26 weeks gestation. Once a stable high-humidity environment is established, the intravenous flow rate may be reduced. It is important to realize that the initial fluid prescription is a "best estimate," based upon a judgment regarding likely transepidermal water loss, renal function, and rate of postnatal adaptation. The adequacy of this estimate must be assessed within 6–8 h. Traditionally, glucose 10% has been used as the initial intravenous fluid, but with recognition of the importance of good immediate nutritional support, many centers now commence with an amino acid/glucose solution. If glucose tolerance is unstable, as is not uncommon in extremely immature babies, the use of 5% and 50% glucose solutions delivered through a Y connection allows the glucose delivery and fluid volume to be altered independently. After the period of postnatal adaptation, the volume of fluid administered should be based on the volume required to deliver the desired nutritional intake. If parenteral nutrition is delivered by central venous line, a concentrated solution can be used. Administration by peripheral line requires an isotonic solution and hence a larger volume. Milk feed volume is determined by enteral tolerance. The justification for "restricting" fluid intake must be considered very carefully as this will compromise nutrition. Meta-analysis of studies suggesting that "high" fluid intake leads to increased ductal patency and necrotizing enterocolitis have not taken into account the failure to control sodium intake, so that an increase in total fluid volume was in fact an increase in both sodium and water. Preterm babies with intact renal function tolerate abrupt changes in intravenous volume from 95 to 200 ml/kg/day without adverse effect, if sodium intake remains constant. Delaying maintenance intravenous sodium administration until postnatal weight loss is underway is associated with reduced respiratory

1	Estimate insensible water loss	Based on gestational age, postnatal age and humidification
2	Assess gastrointestinal and respiratory fluid losses	Unless there is gastrointestinal pathology, or stoma losses, these will be minimal; respiratory losses will also be minimal if inspired gases are adequately humidified
3	Assess urine output	If the baby has just been born, estimate this as 40ml/kg.day
4	The sum of steps 1, 2, and 3 above represents the volume of fluid required to maintain hydration (H)	
5	Determine what nutrition you wish to provide and by what route	Are you providing fluid enterally, or by central or peripheral intravenous line?
6	The energy density of this fluid will determine the volume required to deliver the required amount of nutrition (N)	
7	If transepidermal water loss, or other fluid losses are high, H may exceed N; if there is need to restrict fluid intake (e.g. in renal or heart failure), H is likely to be less than N	Healthy preterm and term neonates can safely tolerate up to 200ml/kg.day intravenously after the period of postnatal adaptation is over, as long as sodium intake does not exceed maintenance requirements (Coulthard and Hey 1985)

Figure 24.1
Key steps in developing a fluid prescription

morbidity. Key steps in developing a fluid prescription are set out in *Fig. 24.1*.

Case History

A 25-week gestation infant weighing 620 g was delivered following spontaneous preterm labor. Her mother had received a full course of treatment with antenatal steroids. The baby was in good condition at birth and was immediately placed in a plastic bag. She became apneic at 1 min, was intubated, and received surfactant prior to transfer to the neonatal unit. A peripheral intravenous line was sited and 10% glucose at 120 ml/kg/day commenced. Umbilical venous and arterial lines were inserted and chest x-ray and cranial ultrasound scan performed. At 4 h of age, the initial glucose infusion was replaced with Vamin-glucose (an amino acid–containing solution) at 90 ml/kg/day. By the second day, her weight had fallen to 605 g and ventilator requirements were minimal. The Vamin-glucose infusion rate was increased to 120 ml/kg/day with the addition of lipid, delivering approximately 100 kcal/kg/day. Trophic feeds of expressed breast milk at 15 ml/kg/day were commenced. By day 12, she was tolerating 150 ml/kg/day of expressed breast milk. Parenteral nutrition was discontinued, and next milk feeds gradually increased over the following week to 200 ml/kg/day.

Monitoring Renal Function

Formal measurement of GFR is not usually made in the newborn though the plasma or serum creatinine (SCr) is widely used as a proxy. Serial measurement of SCr is recommended over blood urea for assessment of renal function as the latter is influenced by many nonrenal factors. Sequestered blood in the gastrointestinal tract as well as an excessive protein intake will result in a rise in blood urea despite unaltered renal function. The SCr at birth reflects the maternal value. SCr falls with postnatal age at a rate influenced initially by the magnitude of the maternally derived load and subsequently, as creatinine is derived from the turnover of phosphocreatine in muscle, the balance between creatinine production, dependent on muscle mass and clearance, dependent on GFR. Hence in the newborn, failure to observe the expected postnatal fall

in SCr, or a sustained rise, is indicative of reduced GFR and impaired renal function. In term newborns, the SCr at birth is around 70–90 micromol/l (about 1 mg/dl), falling to about 30 micromol/l (0.3 mg/dl), range of 15–40 micromol/l (0.17–0.45 mg/dl), by 1 week and remaining at this level up to the end of the first month.

The urine flow rate is important clinical index. Urine can be collected into adhesive urine bags, or into pre-weighed nappies. Catheterization is practicable even in very small babies and is preferable in critical care situations. Healthy breast-fed infants usually excrete urine approximately isotonic to plasma at a rate of about 3 ml/kg/h. A urine osmolality that lies between 200 and 400 mOsm/kg suggests that fluid intake is satisfactory. The minimum acceptable urine flow rate, beyond which solute retention would occur, is widely accepted as around 1 ml/kg/h. This value is based on a maximal urine concentration of 600 mOsm/kg, and the need to achieve a urine flow rate of 25 ml/kg.24 h (1 ml/kg/h) in order to excrete a renal solute load of approximately 15 mOsm/kg/day. The maximal urine flow rate achievable by babies below 30 weeks gestation is around 7 ml/kg/h, rising to around 12 ml/kg/h in mature infants.

Fluid balance monitoring is the responsibility of both medical and nursing staff. The aim of monitoring is to detect problems early, in particular to avoid a potentially reversible situation such as prerenal failure becoming irreversible. At a minimum, fluid balance monitoring for babies receiving intensive care requires that serum sodium, potassium, creatinine, and body weight are measured daily; urine output should also be monitored. A useful adjunctive measure particularly in babies that are very ill or unstable, and in the postoperative period, is continuous monitoring of core–peripheral temperature gap. Satisfactory management is marked by a urine flow rate of at least 0.5–1 ml/kg/h on the first day, rising to 2–3 ml/kg/h thereafter, daily weight loss of the order of 1–2%, followed by weight gain once a balanced energy intake greater than 100 kcal/kg/day has been achieved, a progressive fall in serum creatinine, and Na and K concentrations within the normal range.

Oligo-anuria

Around 7% of healthy term neonates do not pass urine in the first 24 h. In babies receiving intensive care, a fall in urine output below 1 ml/kg.h should lead to prompt assessment and investigation of possible acute renal impairment. The spectrum extends from a reversible reduction in glomerular filtration, mild tubular dysfunction to tubular or cortical necrosis and established glomerular injury. Recovery may be complete or partial, or failure may be irreversible. The clinical history and context are as important as the clinical examination and investigations. The immediate goal is to establish if the cause is due to impaired renal perfusion (prerenal), established renal failure (renal), or obstruction to urine flow (postrenal).

Maternal antenatal treatment with ACE inhibitors, angiotensin receptor blockers, and cyclo-oxygenase (COX) inhibitors may present as renal impairment in the newborn. Impaired renal perfusion accompanies dehydration, hypovolemia, shock and as a consequence of high dose administration of the vasoconstricting inotropes dopamine and epinephrine. The nonselective COX inhibitors, indometacin and ibuprofen, used to promote closure of the ductus arteriosus, reduce GFR and may also reduce urine flow rate through stimulation of the AVP V2-receptor. The COX inhibitors inhibit prostaglandin synthetase, and the effect on glomerular filtration is believed to reflect the dependence of the preterm infant on renal prostaglandins to maintain renal blood flow in the face of high RAAS activity. Ensure the baby is not dehydrated at the start of treatment with indometacin or ibuprofen as this will potentiate renal toxicity. On starting treatment, reduce fluid intake by a third, and monitor daily weight, serum sodium, and urine output. If the baby gains weight, serum sodium falls, or urine output declines acutely, reduce intake volume further. If oliguria persists, it may be necessary to miss a dose until renal function has recovered. The response to COX inhibitors is variable and cannot be predicted with certainly.

Established renal injury may result from failure to recognize and treat preexisting prerenal impairment. Other well-recognized antecedents are perinatal hypoxic-ischemic injury, acute blood loss as in major feto-maternal hemorrhage, systemic sepsis, and hypovolemia arising during surgery. There can be major loss of fluid into the intestinal tract in necrotizing enterocolitis, volvulus, and other intestinal emergencies. Causes of acute renal impairment are shown in *Table 24.1*.

Failure to void in an otherwise healthy newborn baby boy should give rise to suspicion of a diagnosis of posterior urethral valves though this diagnosis is usually now made at antenatal screening. Acute urinary retention is not uncommon in the immediate postoperative period.

Oliguria of antenatal origin, and hence oligohydramnios, is associated with Potter's syndrome (pulmonary hypoplasia and respiratory insufficiency, talipes and joint contractures, low-set ears and flattened nasal bridge). Clinical examination should include abdominal palpation for presence of renal masses and evidence of

Table 24.1
Renal impairment: causes and common clinical situations

Prerenal (*if untreated may progress to established renal failure*)
Dehydration (e.g., high transepidermal losses; unreplaced intraoperative losses; gastrointestinal losses)
Hypovolemia (feto-maternal or other hemorrhage)
Decreased effective intravascular volume (heart failure, lung over-inflation during high-frequency oscillatory ventilation, systemic sepsis)
Cyclo-oxygenase inhibitors (indometacin, ibuprofen)
Intrinsic Renal Disease
Acute tubular necrosis (hypoxic-ischemic insult, aminoglycoside induced, hemoglobinuria, rhabdomyolysis)
Acute cortical necrosis (hypoxic-ischemic insult)
Renal artery/venous thrombosis)
Intrauterine exposure to angiotensin-converting enzyme inhibitors
Congenital renal disorders (cystic dysplasia, autosomal dominant/autosomal recessive polycystic renal disease, congenital nephritic syndrome, renal hypoplasia)
Pyelonephritis
Postrenal obstruction
Unilateral or bilateral uteteral obstruction
Posterior urethral valves
Drug induced (spinal anesthesia)

a distended bladder, assessment of perfusion, measuring capillary-refill time, toe-core temperature gap, and blood pressure. In mature infants, reduced skin turgor, a sunken anterior fontanelle, and excessive weight loss are indicative of dehydration. Poor perfusion is indicated by a core–peripheral temperature gap exceeding 2°C and a capillary-refill time exceeding 2 s. Clinical signs are less reliable with increasing immaturity. Renal function in the neonate is not at steady state, but alters with gestational and postnatal age. Therefore, unlike other age groups, there can be no fixed definition for ARF in the newborn. Renal impairment should be considered if the SCr does not decline with postnatal age or remains above 1.5 mg/dl (about 130 micromol/l). Renal artery or venous thrombosis, and cortical necrosis should be considered when oliguria is accompanied by thrombocytopenia, macroscopic or microscopic hematuria, and hypertension.

In prerenal failure, the avid stimulus to retain sodium and water results in urine with high osmolality (greater than 350 mOm/l), high urea and creatinine, and low sodium concentration (less than 30 mmol/l). This is the basis for attempting to distinguish prerenal from established renal failure from the fractional excretion of sodium (Fe_{Na}), calculated as:

$$FE_{Na}(\%) = \frac{U_{Na} * S_{Cr}}{S_{Na} * U_{Cr}} \times 100$$

where U_{Na} = urine sodium, S_{Na} = serum sodium, U_{Cr} = urine creatinine, and S_{Cr} = serum creatinine. With intact tubular function, sodium reabsorption continues, the Fe_{Na} will be less than 2.5% in mature infants. However, the Fe_{Na} and other similar indices such as the renal failure index ($U_{Na} * S_{Cr} / U_{Cr}$) are unreliable in extremely preterm babies.

Ultrasound examination of the renal tract will identify congenital abnormalities, obstructive lesions, bladder distension and the large, swollen kidneys of renal venous thrombosis. Radionuclide studies are unhelpful in acute renal failure in the newborn.

Prompt recognition is crucial for restoration of renal perfusion and avoidance of progression to overt renal failure. Equally, recognition of established renal failure is essential for optimal management of fluid balance. If prerenal impairment is suspected, administer an initial intravenous volume of 0.9% NaCl, 15–30 ml/kg, over 30–60 min, followed by a single intravenous dose of 2 mg/kg furosemide. As the scant pharmacokinetic information available indicates that the half-life of furosemide is prolonged, exceeding 24 h in healthy preterm infants below 32 weeks gestation, avoid repeated doses as this will result in accumulation and progressive risk of ototoxicity. If restoration of intravascular volume does not result in an increase in urine flow rate, a diagnosis of established renal failure must be made.

Clinical Management of Established Renal Failure

The principles of immediate management are to maintain stable fluid and electrolyte balance, avoid catabolism, support growth, and await recovery. Fluid requirements are calculated as the sum of estimated transepidermal water loss, and measured urine and gastrointestinal losses. In term babies, fluid intake should be restricted to 30 ml/kg/day plus gastrointestinal losses. Central venous access is recommended for the infusion of hypertonic glucose or parenteral nutrition. Intravenous sodium and potassium should be avoided. The intravascular compartment should be supported with infusions of 0.9% NaCl administered as necessary as a bolus over 1 h. Red cell transfusions may be required to maintain an

adequate hemoglobin concentration. Milk feeds are recommended if the baby's condition permits but parenteral nutrition is often required. An energy intake adequate to avoid catabolism and hence hyperkalemia, hyperphosphatemia, and acidosis is desirable. Dietary sodium should not exceed 1 mmol/kg/day and may be given as sodium bicarbonate if metabolic acidosis is present. Hyperphosphatemia is managed by the addition of oral calcium carbonate to feeds. This binds phosphate, rendering it insoluble, thereby reducing intestinal absorption.

Unproven therapies include furosemide by infusion (0.1 mg/kg/h), low-dose dopamine (2–5 μg/kg/min), and low-dose theophylline (8 mg/kg per dose). Dopamine has several effects that potentially affect renal function. Inotropic actions may improve renal perfusion, though vasoconstrictor effects may be detrimental. Dopamine is also a proximal tubular diuretic, increasing the presentation and reabsorption of chloride by the ascending limb of the loop of Henlé, an effect that may increase medullary oxygen consumption and exacerbate medullary ischemia. The direct renal actions of dopamine include inhibition of renal Na^1/K^1-ATPase and Na^1H^1 exchange and attenuation of aldosterone and AVP. In critically ill adult patients, low-dose dopamine does not protect against renal dysfunction.

Except in situations such as overwhelming sepsis and multiorgan failure, the majority of babies in acute renal failure can be maintained in stable condition for several days and even weeks. Elevation in serum creatinine is not an indication for dialysis. Dialysis is indicated when there is inability to meet the baby's nutritional needs because of limitation in the amount of fluid that can be given, intractable metabolic acidosis, volume overload, and severe electrolyte disturbance. A discussion of dialysis techniques is beyond the scope of this chapter. The prognosis of acute renal failure depends on the underlying etiology. Acute cortical necrosis has a poorer prognosis than acute tubular necrosis. Mortality is highest when renal failure is part of a spectrum of multiorgan failure.

Case History

A baby boy weighing 3.0 kg is delivered by emergency Cesarean section following placental abruption at 37 weeks gestation. His heart rate is 40/min, he has no respiratory effort, and he is pale and limp. He receives full cardiopulmonary resuscitation, infusion of 20 ml/kg 0.9% NaCl, and is transferred ventilated to the neonatal unit. The first arterial blood gas at 20 min age shows a profound metabolic acidosis; the pH is 6.95 and the blood lactate 16.9 mmol/l. His mean arterial blood pressure is 32 mmHg. What fluid would you prescribe?

This infant has had a profound hypoxic-ischemic insult. He is shocked and a further infusion of 20 ml/kg 0.9% NaCl is indicated in view of the low blood pressure, aiming to restore renal perfusion. As he is a full-term baby, transepidermal water loss will be less than 15 ml/kg/day. He is at high risk of acute tubular necrosis and fluid overload. A urinary catheter is inserted. Glucose 10% at 30 ml/kg/day is prescribed. However, this will deliver a glucose infusion rate of only 2 mg/kg/min. Careful monitoring of blood glucose is indicated.

Umbilical and venous and arterial catheters are inserted. At 4 h of age, the blood glucose is noted to be 1.9 mmol/l. He receives a glucose bolus.

To increase the glucose delivery to 5 mg/kg/min using 10% glucose would require an increase in infusion volume to 70 ml/kg/day. The fluid prescription is changed to glucose 5% (2.2 ml/h) with glucose 50% (1.6 ml/h) administered through a Y connection by umbilical venous catheter. This delivers a glucose infusion rate of 5 mg/kg/min in a total volume of 30 ml/kg/day. Further infusion of 0.9% NaCl is required, with dobutamine, for blood pressure support.

Over the first 24 h, the urine flow rate averages 0.6 ml/kg/h. By day 2, the baby's weight has risen to 3.2 kg. The SCr has risen from 75 microl/l to 110 micromol/l; serum sodium and potassium are within normal limits. The gain in weight is predictable as total fluid intake over the first 24 h has been 90 ml/kg (270 ml); urine output has been 42 ml. Assuming an insensible water loss of 12 ml/kg/day (36 ml), this would leave him in positive balance of 192 ml. Over the second 24 h, urine output gradually increases.

Trophic milk feeds are commenced at 15 ml/kg/day. His general condition improves. By day 3, his weight has fallen to birth weight. Urine output continues to improve. Milk feeds are increased, blood glucose values stabilize, and the glucose delivery rate is reduced maintaining total intravenous infusion volume at 30 ml/kg/day.

Electrolyte Disturbances

Hypernatremia and Hyponatremia

Sodium is the principal electrolyte of extracellular fluid, and disorders of sodium balance are common in the newborn. It is important to recognize that changes in the serum sodium concentration primarily reflect changes in water balance. In both hypernatremia and hyponatremia, total body sodium may be increased,

decreased, or unchanged. Hypernatremia (serum sodium >145 mmol/l) is an indication that there is an absolute or relative deficit of water in relation to body sodium. Conversely, in hyponatremia (serum sodium <135 mmol/l), there is relative or absolute excess of body water.

When confronted with hyponatremia or hypernatremia, consider the clinical history and assess the change in body weight. Hypernatremia with weight loss suggests dehydration; hyponatremia with weight loss or inadequate weight gain suggests sodium depletion. Hyponatremia in a sick neonate is usually accompanied by water excess; the diagnostic challenge is to establish if whole body sodium is depleted, normal, or increased. In otherwise healthy, stable preterm babies receiving feeds of expressed breast milk, whole body sodium depletion should be suspected if there is poor weight gain despite an intake of 180–200 ml/kg/day. The serum sodium concentration will initially be normal, but the urinary sodium concentration will be less than 20 mmol/l. Chronic sodium depletion is associated with poorer long-term neurodevelopmental outcome.

Appropriate and Inappropriate ADH Secretion

A rise in serum osmolality triggers the release of ADH (AVP) from the posterior pituitary increasing the reabsorption of water. ADH also has vasoconstrictor effects relevant to blood pressure regulation. Hypovolemia and hypotension stimulate baroceptors in the heart and great vessels leading to a rise in circulating ADH. Under experimental conditions, a rise in ADH occurs when intravascular volume falls by about 10%. Pain is known to provoke an antidiuresis, and this may contribute to impaired free water excretion in the sick newborn baby. The syndrome of inappropriate ADH secretion (SIADH) is rare in the newborn baby and should only be made when hyponatremia exists with normovolemia, normal blood pressure, normal renal and cardiac functions, evidence of continuing sodium excretion, and urine that is not maximally dilute. In the newborn, SIADH has been described in acute brain injury and central nervous system infection and following maternal substance abuse. Elevated ADH and hyponatremia are common in acutely ill infants, but this is most likely attributable to reduced intravascular volume that is all too often unrecognized. In the face of hypotonicity and intravascular volume depletion, defense of the latter will take precedence. This effect, namely an ADH response *appropriate* to intravascular volume status, probably underlies the impaired water excretion seen in ill infants. The assessment of adequacy of intravascular volume in babies is not easy. Precipitate cord clamping at birth can result in a reduction in blood volume by as much as 50% when compared with late clamping. The normal range for blood pressure is wide. Blood pressure correlates poorly with blood volume and cannot be relied upon to detect hypovolemia. The core–peripheral temperature difference correlates with circulating AVP; this is useful simple, low cost index ideal for longitudinal monitoring in neonatal intensive care.

Common Clinical Scenarios Leading to Hypovolemia-Induced ADH Secretion

Unrecognized postoperative hypovolemia is a common cause of ADH-driven impairment in free water excretion. Thoracic air trapping in severe chronic lung disease, pneumothorax, and overdistension of the lungs during high-frequency oscillatory ventilation may compromise central venous return with similar effect. Use glucose in 0.9% NaCl, not glucose 5% or 10% alone for intraoperative and postoperative fluid support.

Central Nervous System Effects of Hypernatremia and Hyponatremia

The regulation of cell volume in response to changes in extracellular tonicity is effected through the accumulation or loss of inorganic ions and organic solutes. Acute alterations in tonicity result in cell swelling or shrinkage. Compensation is initially brought about by the movement of electrolytes out of or into the cell. With a hypertonic stimulus, there is cell shrinkage, followed by rapid movement of electrolytes and accompanying water, into the cell, restoring cell volume. If the hypertonic stimulus persists, the concentration of intracellular organic osmolytes rises. With correction of the hypertonic state, loss of organic osmolytes occurs more slowly than movement of electrolytes out of the cell. The persisting intracellular hypertonicity, in the face of falling extracellular tonicity, results in continuous movement of water into the cell, cell swelling, cerebral edema, occlusion of blood flow, and cell death. Conversely, an acute fall in serum sodium concentration and extracellular hypotonicity will lead to intracellular influx of water, edema, and brain swelling. Over a period of time, the intracellular osmolyte concentration decreases to favor the movement of water out of the cell. If extracellular hypotonicity is corrected rapidly after these slow

compensatory changes have occurred, the continuous movement of water out of the cell will result in acute brain shrinkage.

Common Clinical Scenarios

Hypernatremia in the extremely preterm baby is almost always due to excessive transepidermal water loss. Hypernatremia in an otherwise healthy, breast-fed, full-term neonate is well described. It results from inadequate lactation and the baby is dehydrated and sodium depleted. The classic picture is that of an exhausted mother and a hungry baby. Rarer causes of hypernatremia are excessive, injudicious, or accidental administration of sodium bicarbonate or hypertonic sodium chloride. Hypernatremia due to salt poisoning is distinguished by a high fractional excretion of sodium and absence of weight loss.

Treatment

Hypernatremia

Mild hypernatremic dehydration in a mature baby may be corrected with milk feeding. If intravenous rehydration is necessary, the initial fluid should be 0.9% NaCl with glucose 5% or 10%, followed by 0.45% saline with glucose 5% or 10%. Do not use hypo-osmolar salt-poor fluid. Milk feeds should be continued except where a specific contraindication exists. The intravenous infusion rate (ml/h) may be calculated as:

$$[M + D/T]/24$$

where: M = Daily maintenance volume (ml); D = total Deficit (ml); T = Time over which to correct deficit (days).

Serum electrolytes and blood glucose must be monitored closely. If the serum sodium falls at a rate exceeding 0.5 mmol/l/h, reduce the rate of infusion. Though the exact time scale over which the neonatal brain adapts to alterations in tonicity is unclear, correction must be tailored to the duration of the imbalance. If hypernatremia develops over a period of hours, as with excessive transepidermal water loss, reducing the serum sodium by 1 mmol/l/h is believed to be safe. In all other circumstances, the rate of reduction should not exceed 0.5 mmol/l/h. Too rapid correction can cause cerebral edema, convulsions, and permanent brain injury. Extremely severe hypernatremia (serum sodium >200 mmol/l) requires correction by peritoneal dialysis.

Hyponatremia

Restriction of water intake to correct dilutional hyponatremia should not obviate the need to treat the underlying cause. Acute severe hyponatremia (serum sodium <120 mmol/l) is rare in neonatal medicine. If associated with neurological signs, the intravenous infusion of 3% sodium chloride (sodium content approximately 0.5 mmol/ml) is justified but should never exceed 1 ml/kg/h and should be stopped before the serum sodium has normalized. A sodium deficit requires correction, but once body stores have been replenished, intake must be reduced to maintenance requirements. Sodium depletion in babies fed exclusively with expressed breast milk is likely to require an oral sodium supplement of 2–4 mmol/kg/day until a postmenstrual age of 32 weeks is reached.

Potassium Balance

Potassium is the principal electrolyte of intracellular fluid. The normal serum potassium concentration is 3.5–5 mmol/l. The kidney is the primary regulator of potassium balance. More than 60% of filtered potassium is reabsorbed in the proximal tubule; reabsorption continues along the thick ascending limb of the loop of Henlé so that only around 10% is delivered to the distal tubule and collecting ducts. Here potassium is exchanged for sodium driven by Na+K+ATPase. Aldosterone and acute respiratory and metabolic alkalosis stimulate potassium excretion. In children and adults, the major component of dietary potassium is reabsorbed in the small intestine, with fine-tuning in the colon.

Hypokalemia

Common causes of hypokalemia in the neonate are insufficient intake, metabolic or respiratory acidosis, and treatment with loop diuretics. Preterm neonates fed intravenously require a potassium intake of 2 mmol/kg/day, commencing within 48 h of birth if urine output and renal function are normal.

Hyperkalemia

Spurious hyperkalemia is common in neonatal intensive care when blood sampling is difficult and samples are hemolysed. True hyperkalemia results from renal failure and is a medical emergency when severe, with the risk of

death from ventricular fibrillation. The classical ECG changes of peaked T-waves, PR prolongation, of P-wave flattening, and QRS widening are not usually evident in extremely preterm babies until the serum potassium exceeds 8 mmol/l. Values exceeding 6 mmol/l should be checked in a free-flowing blood sample. If confirmed, immediate measures that promote a shift in potassium from the extracellular to intracellular compartment are indicated. These include administration of intravenous (4 mcg/kg over 5 min) or nebulized (2.5–5 mg) salbutamol (albuterol), intravenous glucose and insulin by infusion (12 units soluble insulin in 100 ml 25% glucose; 5 ml/kg given over 30 min), intravenous sodium bicarbonate 1 mmol/kg (2 ml/kg 4.2%) and 10% calcium gluconate (0.1 ml/kg) by intravenous injection over 10 min. The blood glucose should be monitored closely. Sodium bicarbonate is effective even if the baby is not acidotic but should not be administered through the same line as calcium gluconate because of the risk of precipitation. Oral/rectal cation exchange resins (calcium polystyrene sulfate) remove potassium. To reduce the risk of bowel obstruction, administer rectally and remove prior to the next dose by gentle saline lavage.

Acid-Base Disturbances

Acidosis (or acidemia) is defined as an arterial pH below 7.35 and alkalosis as a pH exceeding 7.45. This normal pH range for extracellular fluid corresponds to an H^+ concentration of 35–45 mEq/l. Acidosis and alkalosis may be metabolic, respiratory, or mixed in origin. Regulatory responses to acid-base disturbances involve immediate buffering, respiratory and renal compensation, in order of speed of onset. Bicarbonate is the most important buffer, illustrated by the classic equation, $CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$ where CO_2 clearance is regulated by respiratory function, and HCO_3^- regeneration by the kidneys. In the face of an acid challenge, the equation is pushed to the left. In healthy individuals, respiratory rate increases, carbon dioxide is eliminated, and equilibrium is restored. Renal compensation involves the formation of carbonic acid from carbon dioxide and water. This dissociates into H^+ and HCO_3^- in the proximal tubular cells. H^+ is actively pumped into the renal tubular lumen to combine with filtered bicarbonate to form carbonic acid, which dissociates into water and CO_2. The CO_2 diffuses back into the tubular cell to repeat the cycle, regenerating one bicarbonate ion for each hydrogen ion excreted. In adults, bicarbonate is regenerated so as to maintain a plasma concentration of about 25 mmol/l. Preterm babies have a lower threshold. Hydrogen ions are excreted along the nephron and combine with other base-buffers, chiefly phosphate, sulfate, and ammonia in the tubular fluid, when bicarbonate reabsorption is complete. Newborn infants can acidify urine to the same extent as healthy adults.

Interpretation of Blood Gas Results

In an otherwise normal subject, a fall in pH will stimulate hyperventilation, shift the carbonic acid equation to the left, and increase CO_2 elimination. The features of acute metabolic acidosis are a low bicarbonate, normal PCO_2, and low pH; the features of compensated metabolic acidosis are a low bicarbonate, low PCO_2, and normal pH. Infants with both respiratory disease and a metabolic acidosis will show a mixed picture, with a high PCO_2, low bicarbonate, and low pH. In a ventilated infant, acute respiratory acidosis is managed by increasing the tidal volume or respiratory rate to lower the PCO_2. Once compensatory changes have taken place, lowering the PCO_2 will lead to a respiratory alkalosis, hence the importance of recognizing if compensation has taken place and in this case, targeting ventilation management upon achieving a normal pH, and not a normal PCO_2. The best measure of metabolic acidosis is the Standard Base Excess (SBE) as this is independent of PCO_2. Changes in arterial blood in acid-base disturbances are shown in *Table 24.2*.

Table 24.2
Changes in arterial blood in acid-base disturbances

	pH	PaCO2	$HCO3^-$
Metabolic acidosis, acute	↓	→	↓
Metabolic acidosis, compensated by increased ventilation	→	↓	↓
Respiratory acidosis, acute	↓	↑	→
Respiratory acidosis, compensated by increased renal $HCO3^-$ retention	→	↑	↑
Metabolic alkalosis, acute	↓	→	↑
Metabolic alkalosis, compensated by decreased ventilation	→	↑	↑
Respiratory alkalosis, acute	↓	↓	→
Respiratory alkalosis, compensated by increased renal $HCO3^-$ excretion	→	↓	↓

Metabolic Acidosis

Renal excretion is the only route for the elimination of acids generated by oxidative metabolism. Metabolic acidosis arises from increased production (or administration) of acids, decreased excretion, or reduced bicarbonate regeneration. Acid gain may arise from respiratory or metabolic disorders. The commonest causes in neonatal intensive care are tissue hypoxia and renal failure. Parenteral nutrition amino acid intolerance and inborn errors of metabolism are well recognized but rare causes. Proximal and distal renal tubular acidosis are rare disorders that usually present beyond the neonatal period. Hypovolemic situations are characterized by lactic acidosis. If the cause of a metabolic acidosis is unclear, measurement of the anion gap (AG) may be helpful. This is the difference between the sum of the serum sodium and potassium concentrations and the sum of chloride and bicarbonate, $AG = (Na^+ + K^+) - (Cl^- + HCO_3^-)$. In practice, the K is often ignored and the simplified formula $AG = Na^+ - (Cl^- + HCO_3^-)$ may be used. The normal AG is 12–20 mmol/l and reflects unmeasured anions, albumin, phosphate, and small amounts of lactate and other organic anions. Modern blood gas analyzers provide a measure of lactate. A wide AG should raise suspicion of the possibility of an inborn error of metabolism. Management should be directed toward restoring tissue perfusion; as this improves, the acid load is eliminated. Treatment with base, as sodium bicarbonate or THAM, is probably employed far more often than is necessary. If treatment with base is considered, bear in mind that commonly used formulae to calculate the "dose" to be administered are imprecise. The widely used formula "0.3 × body weight × base deficit" to estimate the full correction requirement is based on adult extracellular volume (20% of body weight) increasing the factor 0.2 – 0.3 as administered base equilibrates in part with the intracellular compartment. The extracellular compartment is larger in the neonate, and in most neonatal intensive care situations, the rate of acid accumulation is uncertain. Recent evidence does not support any benefit for acute correction of base deficit. Acute administration of base may actually exacerbate intracellular acidosis; care should be directed toward addressing the underlying cause of the acidosis.

Respiratory Acidosis

This arises in respiratory failure, when carbon dioxide elimination is impaired, pushing the equation $CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$ to the right. As a result, the $PaCO_2$ and blood HCO_3 rise and pH falls. The renal response involves increased H^+ excretion and bicarbonate regeneration, leading to gradual compensation over many days.

Metabolic Alkalosis

A metabolic alkalosis is caused by gain of base, as in the injudicious use of sodium bicarbonate or from loss of acid. A common cause is loss of gastric acid and chloride in high intestinal obstruction, vomiting or failure to replace gastric aspirates. In the distal tubule and collecting duct, sodium is reabsorbed in exchange for either potassium or hydrogen ions, under the influence of aldosterone. If intracellular H^+ is low, potassium is preferentially lost and vice versa, explaining the association between alkalosis and hypokalemia. Hypokalemia is both a cause and a consequence of metabolic alkalosis. Chronic diuretic therapy results in metabolic alkalosis through multiple mechanisms and is commonly seen in infants with chronic lung disease who are receiving diuretics. Other causes of metabolic alkalosis are Bartter's syndrome, a tubulopathy caused by mutations in membrane transporters in the thick segment of the ascending limb of the loop of Henlé that result in failure of reabsorption of sodium, potassium, and chloride, increased salt delivery to the distal nephron, and salt loss, volume depletion, hyperaldosteronism, hypokalemia, and metabolic alkalosis. Polyuria may be evident antenatally. Similar biochemical findings can occur due to transcutaneous electrolyte loss in cystic fibrosis and intestinal loss in congenital chloride-losing diarrhea. Treatment consists of potassium supplements and indometacin (up to 3 mg/kg/day in divided doses). Sodium supplementation may also be required.

Respiratory Alkalosis

This results from hyperventilation; the PCO2 will be low. The commonest cause in the neonatal unit is iatrogenic and occurs during assisted ventilation, particularly high-frequency oscillatory ventilation. This is dangerous because of the consequent reduction in cerebral blood flow. Spontaneous hyperventilation may be a feature of neurologically damaged infants.

Long-Term Renal Sequelae of Extremely Preterm Birth

Preterm birth is emerging as a risk factor for higher blood pressure and hypertension in adult life, though whether this is renal or vascular in origin is unclear. Plausible contributors to impaired third trimester nephrogenesis are nephrotoxic medications, ischaemic injury and poor nutrition. The concern is that nephron deficit may lead to compensatory hyperfiltration, glomerulosclerosis, deteriorating renal function, and elevated blood pressure in adult life. To-date assessment of renal function in preterm cohorts has not identified consistent alteration in renal function. As the earliest of these cohorts are still in early adulthood, continued follow-up is essential.

25 Gastrointestinal System and Neonatal Nutrition

Christopher Young · Maka Mshvildadze · Josef Neu

Introduction

The intestine is one of the most active and complex organ systems in the body. As an example of its complexity, it is notable that the system contains neural tissue equivalent to the entire spinal cord. The intestine is involved in important endocrine and exocrine roles and also serves as the largest and most active immune organ of the body. In addition to the intestine itself, the luminal microbiota and its interactions with the intestinal mucosa and submucosa are becoming increasingly recognized as critical in postnatal development and lifelong health and disease. In addition to these seemingly newfound GI tract functions, its classic role in digestion and absorption of nutrients remains of utmost importance in health and needs to be understood in order to optimize nutrition during these highly critical windows of development.

Dramatic events in gastrointestinal (GI) system development begin in the 3rd week of fetal development. Gastrulation, organ formation, growth, herniation, rotation, and retraction complete the major anatomic features of normal fetal GI system development over the first 12 weeks. During this time, a complex mixture of neurologic, vascular, endocrine, exocrine, and immune tissue development also occurs, which will postnatally provide not only nutritive, but also immune, barrier, endocrine, and other critical functions. The goal of this chapter is to provide an overview of some of the salient features of physiology and development of the GI tract and how it relates to neonatal nutrition and other aspects of neonatal and subsequent health.

Gastrointestinal System Development

Beginning around the 3rd week of gestation, gastrulation begins the complex process of GI system development. By the end of the first week of gastrulation, the newly formed gut tube is nearly closed and development of the liver, gallbladder, and pancreas has begun as evaginations from the endoderm. At about 4 weeks of gestation, the human esophagus can be identified as a distinct structure. The fetal stomach begins to develop at 13 weeks and characteristic anatomical features can be identified by the 14th week. This is important in that failure to identify the fetal stomach by ultrasound in the second trimester indicates the possibility of esophageal atresia, and an enlarged stomach may herald the presence of duodenal atresia or a gastric outlet obstruction. The liver begins its development as a diverticulum which emerges from the caudal foregut, distal to the stomach, at about the 4th week of gestation. Morphogenesis of the pancreas begins at about 30 days of gestation, and at around 20 weeks of gestation, enzyme activity is detectable. By the 13th week, organogenesis of the human intestine is complete (*Table 25.1*).

The three major arteries supplying the GI system, the celiac, and superior and inferior mesenteric arteries, have also begun to form and help establish further growth and development. With establishment of the vascular system, growth proceeds rapidly with the continued expansion and rotation of the primordial GI tract. By the 5th week, growth has produced herniation of the gut tube into the umbilical cord. Beginning at week 7, rotation of the intestine begins and continues until about the 11th week, at which time retraction occurs, and the process is completed by the 12th week with the establishment of neural innervations. The fetus starts to swallow amniotic fluid at 16 weeks, which plays an important role in intestinal growth and differentiation.

The fetal GI lumen is bathed in the nutrient rich milieu of amniotic fluid and extracellular matrix. Unless there is an intra-amniotic infection or other major insult, the fetal GI system remains primarily in growth mode, preparing for the extrauterine environment. Once birth occurs, the GI system's functions accelerate in its roles as a nutritional, endocrine, and immunologic organ. It is also almost immediately exposed to external microbes, most of which are incorporated into a symbiotic relationship. It takes over the conduit role of the mother and the umbilical cord for food digestion, absorption, and assimilation. Most of the required GI physiologic mechanisms to achieve this nutritive function are mature at term birth;

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_25,

Table 25.1
GI tract developmental milestones

Event	Timing
Gastrulation begins	Week 3
Liver and pancreatic buds develop, esophagus established	Week 4
Organogenesis complete	Week 13
Stomach has identifiable anatomic features	Week 14
Fetus begins to swallow amniotic fluid	Week 16
Pancreatic enzyme secretion detectable	Month 5

however some, such as bilirubin conjugation and hepatic drug metabolism, only mature in the postnatal period. Other mechanisms, such as esophageal motility and sphincter function, gastric acid and bile salt synthesis and secretion, glucose absorption, and bile salt absorption continue to develop well after birth. One notable example is that pancreatic exocrine function is only completely developed after 6 months postnatal age. The normal growth, development, and subsequent maturation of this complex organ system establish one of the most important systems of the body.

Gastrointestinal System Function

Barrier Function

The GI system performs many physiologic functions, as mentioned previously. As the largest surface area of the body that is exposed to trillions of microbes and a large mass of food antigens, the intestine requires a barrier mechanism that provides for selective entry of luminal constituents. There is only a single cell layer, the intestinal luminal epithelial surface, covered by a thin layer of mucus, which separates the extremely sensitive immunoreactive submucosa from potentially immunogenic substances in the lumen. This epithelial layer comprises a large surface area in the adult, encompassing approximately 200 m^2, through the formation of crypts, villi, and microvilli throughout the length of the small intestine. The epithelial surface has a rapid turnover: it is completely replaced every 2–5 days as cells migrate from the crypts to the tips of the villi, eventually dying, and being sloughed into the intestinal lumen. About 20–50 million cells per minute are shed in the small intestine, and 2–5 million cells per minute are shed in the colon. These cells are continuously replaced by dividing multipotent stem cells, which replace each cell lost with cells of the same lineage.

Much like the epithelial lining of the skin, the luminal epithelial layer of the GI system provides an important boundary with the external environment. This single-cell layer has many defense mechanisms, however, to help ward off invasion from offending exogenous agents. Tight junctions located intercellularly form complexes that regulate molecular transport both into and out of the intestinal lumen. This also adds a protective feature to the GI system, being the apparatus by which the intestine can secrete large amounts of chloride and water to flush exogenous toxins and pathogens. This layer also contains specialized mucin-producing goblet cells that provide a thick protective mucous layer to protect and lubricate the cells of the intestinal epithelium. Other cell types, such as Paneth cells, secrete defensive antimicrobial peptides into the lumen of the GI system to help modulate pathogenic bacterial content. Breakdown of this barrier has been related to several pathologic processes including neonatal sepsis and subsequent autoimmune and allergic diseases. It is becoming increasingly recognized that commensal bacteria play an integral role in the process of epithelial repair and barrier integrity, and that disruption of these microbes could have deleterious consequences.

Digestive–Absorptive Function

The process of digestion starts in the mouth and continues throughout the GI system (*Fig. 25.1*). It is important to note that this complex process is more involved than the purpose of this chapter, so a physiology text would be best for full details. Here, the salient features are summarized for clinical application.

Starting with the mouth, mechanical and chemical breakdown are initiated; mechanically through the process of mastication, and chemically with the presence of primary reducing enzymes in the saliva. For neonates and infants, the initial steps in the process are obviously dependent on the type of feeding the baby is receiving. The simpler the starting food source, the easier the process of digestion will be.

In the mouth, enzymes, such as amylase, begin the process of digesting relatively complex carbohydrates into simple sugars for subsequent absorption (*Table 25.2*). Mastication allows the food to be mechanically broken apart and provides more surface area for the action of these digestive enzymes.

As the food passes to the stomach, acids are released from the parietal lining which further the process of breakdown in addition to the mechanical action of the stomach with churning and mixing. Lipases derived from

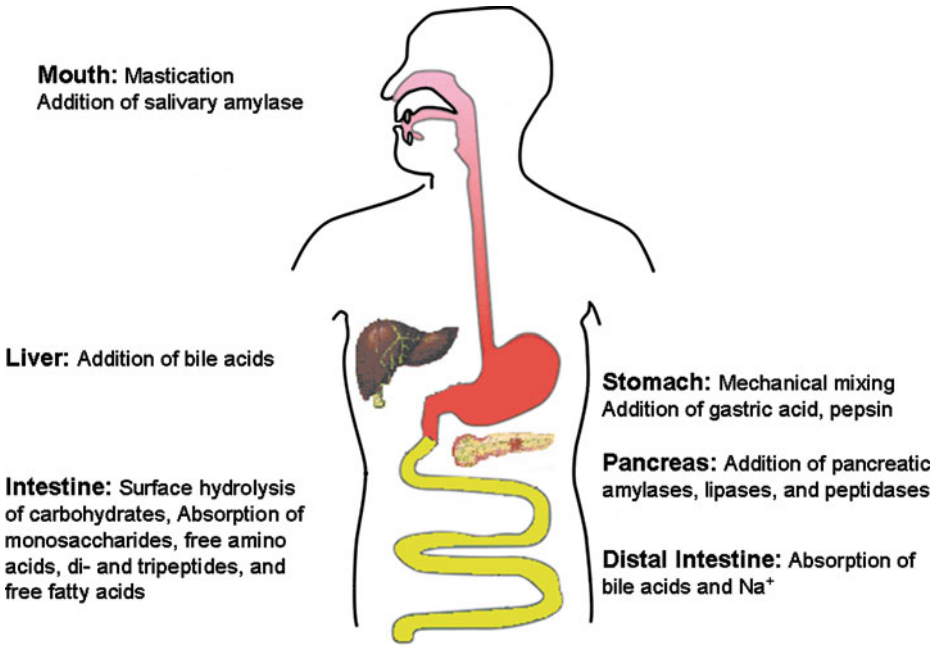

Figure 25.1
Overview of digestion and absorption

Table 25.2
Digestive enzymes and functions

Location	Digestive enzyme	Function
Mouth	Amylase	Breaks down simple sugars
Stomach	Stomach acids	Mechanical action of the stomach and addition of acids aids in digestion
Small intestine	Lipases, pancreatic enzymes, bile, pepsin, proteases	Continues the process of digestion as the food passes through to the colon

breast milk and from lingual, gastric, and pancreatic origins are added to the mixture and digestion proceeds as the food passes from the stomach into the small intestine. Pancreatic enzymes, bile, pepsin, proteases, and many other digestive enzymes continue the process of digestion as the food passes through the small intestine.

As food passes through the digestive system and is broken down, absorption of the nutrients occurs at the level of the microvillus (brush border) membrane. Among the several cell types that comprise the intestinal mucosa, the differentiated villus enterocyte, at the mid villus to the tip regions, are the most specialized for absorptive purposes.

Neonatal Nutrition

In order to understand the intricacies of neonatal nutrition, it is vitally important to understand the processes through which the different nutritional components are digested and absorbed. By understanding these key processes and combining them with an understanding of fetal and neonatal growth, it is easier to understand the nutritional requirements and feeding methods used for neonates. The following sections will describe these processes and how they relate to neonatal nutrition.

Carbohydrate Digestion and Absorption

The simplest process involves the breakdown of simple and complex carbohydrates. For complex carbohydrates, they must first be broken down into their main components, the oligosaccharides, by digestion via salivary amylase in the mouth and stomach, and pancreatic enzymes added in the upper small intestine (*Table 25.3*). For absorption, the oligosaccharides must be hydrolyzed into

Table 25.3
Carbohydrate digestion and absorption

Location	Digestive entity	Function
Digestion of carbohydrates		
Mouth	Amylases derived from the saliva (and colostrum)	Hydrolyze starches and complex carbohydrates into oligosaccharides
Small Intestine	Pancreatic amylases	Hydrolyze carbohydrates into oligo- and monosaccharides
Distal intestine	Bacteria	Hydrolysis of undigested sugars into short-chain fatty acids
Absorption of carbohydrates (oligosaccharides must be hydrolyzed into monosaccharides)		
Intestinal epithelial brush border	Maltase	Cleaves maltose into two molecules of glucose
	Lactase	Cleaves lactose into glucose and galactose
	Sucrase	Cleaves sucrose into glucose and fructose

monosaccharides, a process which occurs primarily at the intestinal epithelial brush border by hydrolytic enzymes such as lactase, sucrase, and maltase (*Table 25.3*). Dietary lactose, sucrose, and maltose come in contact with the surface of absorptive epithelial cells covering the villi where they engage with brush-border hydrolases performing the following functions:

- Maltase cleaves maltose into two molecules of glucose
- Lactase cleaves lactose into a glucose and a galactose
- Sucrase cleaves sucrose into a glucose and a fructose

The process of absorption of each of these monosaccharides is different. Glucose and galactose are taken into luminal enterocytes by a transport mechanism involving sodium cotransport. Fructose, on the other hand, is taken up by enterocytes by facilitated diffusion (passive transport) (*Fig. 25.2*).

For the purposes of neonatal nutrition, this process is vitally important. Depending on the starting carbohydrate composition of the infant's primary food source, the process of carbohydrate digestion can be affected by many factors, including the maturity of the infant's pancreatic function, the presence and functionality of the intestinal hydrolytic enzymes, and whether or not the infant is breast-fed.

Breast-feeding, for the purposes of carbohydrate metabolism, is important in that the breastmilk of mothers with babies born preterm actually contains an enzyme, α-amylase, that aids in oligosaccharide digestion. This is important, because even in babies born at term, there are lower levels of amylase from both salivary and pancreatic sources than at adulthood. As the baby matures, these enzymes increase in quantity, but their low levels in the neonatal period are important to remember when administering any complex carbohydrates to these infants.

For these reasons, most preterm and some term formulas contain partially hydrolyzed carbohydrates. This helps aid in digestion by providing a simpler and easily accessible source of sugars, but also increases the osmolality of the formula. It has not yet been established whether the hydrolyzed starch formulas have any advantage over those containing lactose or other disaccharides. Whether lack of salivary or pancreatic amylase plays a significant role in premature infants is questionable, since the major carbohydrate in human milk is lactose. Also, many premature babies are fed by tube in neonatal intensive care units; thus the food partially bypasses the action of the salivary amylase and appears to be digested without problem in healthy infants.

The majority of the carbohydrate contained in standard cow's milk formulas and in human milk is lactose. Lactase activity is relatively low in preterm infants but increases with maturity. This concept has led to many formulas being produced that contain carbohydrates other than lactose. However, bacteria in the lumen of the intestine have the ability to ferment lactose into short-chain fatty acids, which can then be salvaged via absorption into the distal intestine and utilized for energy production and other important roles. Thus, the use of lactose-containing formulas or human milk feedings in preterm infants is not contraindicated, especially since feedings in these infants are advanced slowly and do not exceed the theoretical thresholds for enzymatic capability.

Protein Digestion and Absorption

The protein composition of feedings provided to neonates is largely dependent on either the composition of the

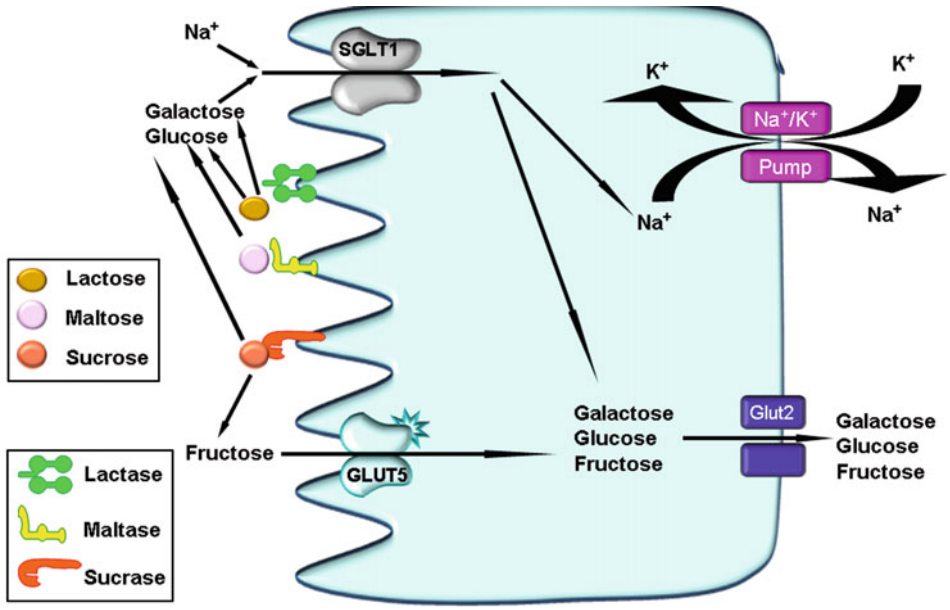

Figure 25.2
Digestion and absorption of carbohydrates

maternal breastmilk or that of the infant formula chosen for the baby. Understanding the process of protein digestion and absorption should help with the choice of feeding provided to infants.

The process of protein digestion begins in the stomach as the food enters the acidic environment (*Table 25.4*). The mechanical forces of the stomach ensure mixture of the food with gastric acid and the proteolytic enzymes that begin the digestive process. As the food enters the intestine, pancreatic enzymes, including proteases and peptidases, are added and the digestive process continues. It is important to note that, in most instances, the proteins must be digested into their amino acid components, or at least into smaller peptides, to be absorbed by the intestinal enterocyte.

Proteolysis occurs through the actions of pepsinogen, which is converted in the stomach by the acidic environment into pepsin, and the other pancreatic peptidases, including trypsin. Through the action of these enzymes, the proteins are broken down into shorter oligopeptides (di- or tripeptides). These oligopeptides can then generally be absorbed into the cells. This occurs through a cotransport mechanism with hydrogen ions (*Fig. 25.3*).

Once the oligopeptides have entered the cell, they are then further hydrolyzed by intracellular peptidases into their individual amino acids, which can then be assimilated into the bloodstream. Only a few of the oligopeptides enter the blood without having been hydrolyzed into individual amino acids.

An important aspect of the neonatal absorptive process is that early in the newborn period, some proteins are allowed to pass into the cells from the intestinal lumen without being broken down. This is important in the passing of maternal antibodies (passive immunity) to the infant. This ability is rapidly lost, so feedings with colostrum in infants whose mothers intend to breast-feed should be initiated as soon as possible after birth. This also, in part, describes why it may be important to limit the intake of certain highly antigenic proteins (such as peanuts, eggs, and shellfish) during this hyper-permeable period.

Just as with the hydrolytic enzymes needed for carbohydrate digestion, the proteolytic enzymes are present in much lower concentrations in neonates than in adults. This is especially true in the premature infant. Peptic activity is low and is in proportion to the degree of maturity. As was true of the formulas containing hydrolyzed carbohydrates, some formulas also contain hydrolyzed proteins as well as different proportions of casein and whey. The use of these formulas is still an area of much debate.

For clinical correlation, it is important to note that there is a large amount of protein present in the amniotic

Table 25.4
Protein digestion and absorption

Location	Enzyme	Function
Digestion of proteins		
Stomach	Stomach acid	Food is mixed well with the stomach acid and proteolytic enzymes
	Pepsinogen – converted to pepsin by the acidic environment	Proteolysis – proteins are broken down into shorter oligopeptides
Intestine	Pancreatic enzymes – proteases, peptidases, trypsin	Proteolysis continues
Absorption		
Enterocytes	Hydrogen ions	Amino acids are taken into the cell by a cotransport mechanism
	Intracellular peptidases	Hydrolyzed into their amino acid building blocks, they can then enter the bloodstream

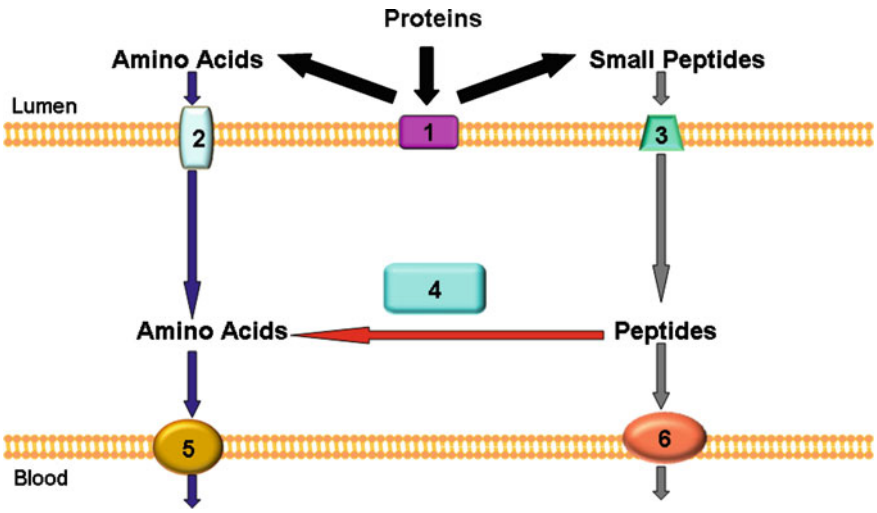

Figure 25.3
Protein absorptionProtein absorption in the small intestine: *1* brush-border membrane peptidases; *2* brush-border membrane amino acid transporters; *3* brush-border membrane di- and tripeptide transporters; *4* intracellular peptidases; *5* basolateral membrane amino acid carriers; *6* basolateral membrane di- and tripeptide carriers

fluid. Each day, approximately 50% of the amniotic fluid volume is swallowed by the fetus. Thus, the fetus at or near term ingests about one fifth of its daily protein from the amniotic fluid alone. Once the amniotic membranes rupture or if the baby is born prematurely, this important source of protein is removed. In the fluid, a fairly wide spectrum of proteins are obtained which include human serum albumin, immunoglobulin (Ig) G, IgA, chorionic gonadotropin, and growth hormone. It is important to note that the protein requirements for preterm infants are significantly higher than in those infants delivered at term.

Another clinical consideration should be that there is lower acid secretion in the stomach of the premature infants. Studies suggest that critically ill premature infants treated with H_2 blockers have a higher incidence of nosocomial infections and necrotizing enterocolitis. It is speculated that with the already limited hydrogen ion production in the stomach of the preterm infant, additional reduction further diminishes the acid barrier and

allows for a higher load of potentially pathogenic bacteria to reach the more distal regions of the intestine.

Lipid Digestion and Absorption

There are many different types of lipid molecules that comprise the food that we eat. Most of them are neutral lipids or triglycerides, but they are also made up of phospholipids, sterols, and fat-soluble vitamins. An understanding of their digestion and absorption is vital in order to optimize infant nutrition.

The process of lipid digestion occurs in two major steps and requires bile acids and lipases (*Table 25.5*). The first step involves the breakdown of large globules of lipid into smaller particles via micellar emulsification. This is a process that allows for greater fat-mucosal interaction at the absorptive surface and allows for more efficient absorption. Bile acids, through their amphipathic properties, form a micelle, which is a circular structure with a hydrophilic exterior and hydrophobic interior that leads to emulsification of the larger lipid globules. The triglycerides in the emulsified micellar particles are then de-esterified into their main components, 2-monoglyceride and free fatty acids, via the action of lipases and are then are transported into the enterocyte (*Fig. 25.4*). Most of the primary lipases are derived from the pancreas but there are several other lipases that are thought to be important, including human milk–derived bile salt stimulated lipase, lingual lipase, gastric lipase, and intestinal epithelial cell–derived lipases.

Once inside the enterocyte, the process takes different pathways depending on the chain length of the free fatty acid. Longer chain fatty acids and 2-monoglycerides are transported to the Golgi apparatus where they are resynthesized into triglycerides and packaged into chylomicrons. The chylomicrons are packaged into vesicles which are exocytosed into the lymphatic system, which

Table 25.5
Lipid digestion and absorption

Steps	Enzyme/structure	Function
Digestion of lipids		
Micellar emulsification of fat globules	Bile acids	Formation of micelles – provide a larger charge-specific surface area for the enterocytes to uptake the fatty acids and monoglycerides
Triglyceride hydrolysis	Lipases	Formation of absorbable 2-monoglycerides and free fatty acids
Transport into the enterocytes	Poorly understood transport processes	Transport of the 2-monoglycerides and free fatty acids into the intestinal epithelial cell
Absorption		
Golgi apparatus processing	Golgi apparatus	Monoglycerides resynthesized into triglycerides and packaged into chylomicrons
Lymphatic system	Chylomicrons	Chylomicrons are packaged into vesicles, exocytosed into the lymphatics, and rapidly enter the blood

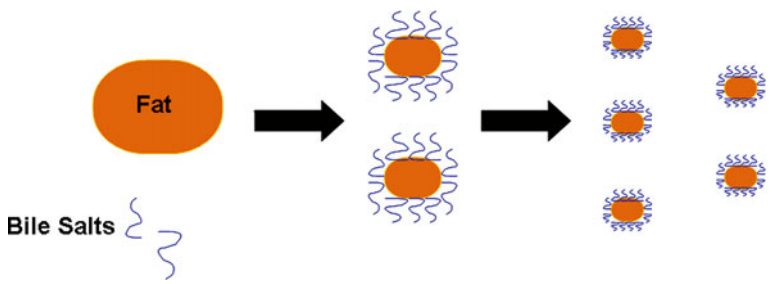

Figure 25.4
Digestion of lipids-micellar emulsification

rapidly flows into the blood. The blood carries these chylomicrons throughout the body where they are broken down and used for energy or stored.

Medium-chain fatty acids are processed differently. Once they enter the enterocyte, instead of being reprocessed, they are able to directly enter the portal venous system. This process is important to understand for instances where the lymphatics are obstructed or severed, such as in a chylothorax. Feeding those infants with long-chain fatty acid rich formulas is not recommended, but using a formula with medium-chain fatty acids would be helpful.

Another developmentally important aspect of lipid digestion and absorption is that in the preterm neonate, bile acid formation and reabsorption are limited, so the use of large amounts of fat in their formulas could lead to undigested and unabsorbed fat passing through the intestines. The use of medium-chain triglyceride lipids that do not undergo such complex processes of digestion and absorption should lead to better growth. However, comparative benefits of routinely using the medium- versus long-chain triglycerides in the nutrition of premature infants have not been firmly established.

Fat absorption from breast milk increases slightly during the first month in infants born at term. In total, this increase results in absorption values reaching close to 90%. Surprisingly, the absorption of fat in premature infants is close to that of full-term infants. This is due to the fact that although long-chain fatty acid absorption is lower during the first 6 weeks of life, medium- and short-chain fatty acids are absorbed quite efficiently in premature infants soon after birth.

The long-chain polyunsaturated fatty acids (LCPUFAs), such as docosahexaenoic acid (DHA), are critical in the formation of the structural components of the central nervous system. They are found in relatively high concentrations in human milk, especially in mothers who live in marine coastal areas who also eat a diet rich in fish. These have recently been added to many commercial formulas, but are not present in routinely used intravenous lipid solutions. Whether the addition of these LCPUFAs to formulas results in improved neurodevelopment remains the subject of current intense investigation.

Other Aspects of the Infant GI System

As mentioned in the introduction to this chapter, the gastrointestinal system is one of the most complex and integral organ systems in the body. It is considered to be one of the largest immune structures in the body. The luminal surface is constantly being exposed to bacteria and other antigens, essentially the external environment. The infant GI system is responsible for protecting the infant against pathogens, establishing a healthy relationship with commensal organisms, and preventing the development of autoimmunity, among other important tasks.

The development of this system is vitally important to set the infant up for a life of health and proper nutrition. One important aspect of the development of the GI tract is the colonization by bacteria. The steps that initiate this process begin almost immediately as the gut tube is formed early in gastrulation. It has previously been held as convention that the amniotic fluid that the fetus swallows in utero is sterile. However, recent studies have found, using non-culture-based techniques, that there are bacteria present in the amniotic fluid that may not have been detected by standard culture-based techniques. There has also been research performed that shows the fetal GI tract can produce a systemic inflammatory response. Further studies have shown a link between these bacteria and an inflammatory response that may lead to preterm labor. Postnatally, in premature infants, an inflammatory process likely related to aberrant intestinal microecology has also been shown to be important in the pathogenesis of necrotizing enterocolitis, and there is currently a great deal of research being performed to help diagnose this devastating condition.

The colonization of the infant with commensal, or "good," bacteria however helps to establish the GI tract as a healthy, protective system. Studies show that if kept in a sterile environment, animals had an increased susceptibility to infections, decreased digestive enzyme activity, decreased smooth muscle thickness, and reduced vascularity when compared with animals that had a normally developed intestinal microbiota.

Therefore, the composition of the intestinal flora has been determined to be important in both health and disease states. In this context, it can be seen that excessive use of antibiotics is likely to have adverse consequences on the bowel intestinal microbiota. Further, it is important to keep this delicate balance in mind when considering the use of nutritional adjuncts such as pre- or probiotics. There has been a recent trend toward the addition of these supplements to infant formulas and in the treatment of infants; however, there is still not enough data to promote their regular use in the neonatal population. By altering the delicate balance of the intestinal flora, the use of these and other supplements could alter the natural state of immune tolerance in the GI tract and potentially lead to autoimmunity, atopy, serious infections, or other disease states.

Summary

The theme presented throughout this chapter is that developmental stages of intestinal development relate to our capabilities to provide different nutrients. Colonization of the intestine by microbes is also important for the infant in establishing a life of good nutrition and health. When this process is disrupted, disease states can easily follow. For this reason, there is currently intense investigation ongoing in the areas of the neonatal intestinal microbiota and neonatal nutrition. As research emerges, optimization of feeding guidelines, composition of both enteral and parenteral formulations for premature infants, and many other aspects of neonatal and infant care will be in flux. As evidence arises, this should be used to provide a strong foundation upon which to help neonates and infants develop a healthy GI system which will set them up for a lifetime of health.

26 Hyperbilirubinemia

William J. Cashore

Jaundice is the most common condition leading to medical evaluation, treatment, and follow-up in otherwise healthy newborns. Average neonatal bilirubin levels are 6–8 mg/dL (100–135 micromol/L) in term infants, predominantly unconjugated or indirect-reacting, and slightly higher in breast-fed than in formula-fed infants. Peak bilirubin levels in the blood are usually found at about 3–5 days of postnatal age, although a minority of cases peak later or last longer.

Unconjugated bilirubin is poorly soluble in water. Water solubility and biliary excretion are facilitated by glucuronide conjugation in a two-step process, followed by apical excretion of conjugated bilirubin into the biliary system and proximal G.I. tract. In fetal life, these steps are bypassed in favor of placental return of fetal unconjugated bilirubin to the maternal circulation. For several days after birth, neonatal bilirubin conjugation (and sometimes biliary excretion) remain somewhat downregulated, with a modest elevation of unconjugated bilirubin (and occasionally of conjugated bilirubin as well) to levels that are "physiologic" for the newborn, but which would be considered abnormal at any other age. Developmental implications of this postnatal delay may include (1) an antioxidant function for bilirubin during neonatal adaptation to an oxygen-rich environment, and (2) avoidance of a dead-end pathway for bilirubin in the bowel prior to the onset of feeding.

Bilirubin levels may be exaggerated in the newborn period by overproduction of bilirubin due to hemolysis, inefficient conjugation/excretion of bilirubin due to underlying genetic or metabolic disorders, or hepatic injury, e.g., due to infection, ischemia, or intoxication.

Premature infants may have any or all of the above, leading to exaggerated levels or longer duration of jaundice.

This writer prefers the term "neonatal jaundice" for the expected mild, generally short-lived, and benign elevation of plasma bilirubin noted in most if not all newborns, with the term "hyperbilirubinemia" reserved for cases in which jaundice appears earlier, lasts longer, reaches higher levels than expected for age, or has a recognized pathologic cause.

Hemolytic Jaundice

Overproduction of bilirubin can occur with immunologically mediated maternal-fetal blood group incompatibility, sepsis with hemolysis, G6PD deficiency with an oxidative triggering event, resolving bruises or hematomas, or red cell structural defects such as hereditary spherocytosis.

Common features of neonatal hemolytic disorders include early onset of jaundice, sometimes present even at birth; often, an abrupt unexpected increase in plasma bilirubin level; and an overall rate of increase more rapid than expected for age, often several times greater than the usual upper limit of hour-specific increase at 0.2–0.25 mg/dL/h. A rate of increase in plasma bilirubin equal to or greater than 1 mg/dL/h is nearly always indicative of hemolytic jaundice, although milder cases of hemolysis may show slower rates of increase than that. Hepatosplenomegaly may or may not be present.

The most common presentation of neonatal hemolytic jaundice is with maternal-fetal ABO blood group incompatibility. Group O mothers have preformed anti-A and anti-B immunoglobulins capable of crossing the placenta and attaching to fetal A or B cellular antigens. Although 20–25% of pregnancies are ABO incompatible, only 10% of potentially exposed infants show clinical evidence of hemolytic disease (therefore, the overall risk of ABO hemolytic disease in newborns is about 2–3%). The anemia associated with this disorder is usually mild. Jaundice appears early, and some infants have splenomegaly. Many cases self-resolve in 3–5 days. Some show jaundice appearing early enough or progressing rapidly enough to require early treatment, usually phototherapy. "False positive" anti-A or anti-B antibody tests may be found in 75–80% of infants with no clinical evidence of hemolytic disease.

Fifteen to thirty percent of Caucasian mothers and, approximately, 2–10% of mothers in "other" ethnic groups lack the "Rh D" antigen on their red cells and are, thereby, classified as "Rh negative" Since "race" is often not a reliable genetic or medical classification, all pregnant women should be screened for their major (ABO) and minor blood types.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_26,

Parturition for an Rh positive baby by an Rh negative mother is often accompanied by maternal trans-uterine exposure to Rh positive cells, with a maternal antibody response which is recalled and exaggerated in subsequent Rh positive pregnancies. The exposed fetuses and infants can have a severe, prolonged reaction to the maternal antibodies, with jaundice and profound anemia at or even before birth, a rapid postnatal increase in plasma bilirubin, and a prolonged course of anemia and jaundice if treatment is not early and adequate.

Rh negative mothers should be screened for anti-Rh antibodies as well as major and minor (Rh) blood groups, past history of transfusions, and personal and family history of newborns requiring transfusions or treatment for jaundice. During pregnancy, the mother has serial testing for presence and titer of anti-Rh antibodies. Prophylactic Rh immune antiglobulin is given in midpregnancy (27–28 weeks) and at delivery.

Neonatal treatment of Rh hemolytic disease is presented later in this chapter.

The X-linked gene for G6PD deficiency is associated with an increased risk of hyperbilirubinemia in two apparently different ways. First is the rare but potentially severe event of an acute hemolytic crisis in a male infant exposed to an oxidant agent such as fava beans or naphthalene. The patient may be well at birth and may not be noticeably jaundiced until exposure. Post exposure, which may not occur until after discharge, there is an abrupt decrease in hematocrit and an abrupt increase in bilirubin, sometimes to potentially hazardous levels. As the oldest red cells are preferentially hemolyzed, the underlying enzyme deficiency may be masked during recovery by near – normal enzyme levels in a new population of red cells. Despite carrier rates for G6PD deficiency of 10% or more in some minority populations, hemolytic crises are uncommon in the newborn period and, often, unexpected and difficult to diagnose when they do occur.

A second pattern of jaundice associated with the gene mutation for G6PD deficiency is an increase in average neonatal bilirubin levels and in clinically apparent hyperbilirubinemia without evidence of hemolytic disease. This pattern shows itself even in hemizygous female infants, who have a normal gene for G6PD production and are not at apparent risk for hemolytic crises. The single gene defect for G6PD deficiency in this otherwise asymptomatic group of infants appears to act in concert with heterozygous mutations or polymorphisms in the gene for bilirubin glucuronyl transferase. The most common of these gene variants is an odd, rather than an even number of TATA repeats in the promoter region for glucuronyl transferase. Perhaps this group of patients combines a slight but subclinical increase in bilirubin production from red cells with an inefficient production or function of the conjugating enzyme in the newborn period.

Sepsis may contribute to neonatal jaundice by accelerating red cell breakdown with increased bilirubin production or by endotoxin-mediated hepatocellular toxicity.

Structural defects in red cell membranes, such as hereditary spherocytosis or elliptocytosis, may be associated with increased bilirubin production. Splenomegaly is common with red cell membrane defects, and may be an early clue to the need for a detailed hematologic evaluation.

Hemoglobinopathies, such as classic sickle cell disease and Beta-thalassemia, may not present with neonatal jaundice because of the predominance of fetal hemoglobin in the perinatal period. Some variants of alpha thalassemia may be associated with neonatal hyperbilirubinemia, but homozygous alpha thalassemia usually presents with profound anemia and hydrops before the clinical onset of jaundice.

Defects in Bilirubin Conjugation/ Excretion

As noted above, bilirubin glucuronyl transferase is relatively downregulated and not fully functional in newborns until several days or even several weeks after birth. In addition to perinatal "physiologic" downregulation of the enzyme, more than 50 polymorphisms in the gene for glucuronyl transferase have been described, some with significant negative effects on production or function of the enzyme. Briefly, several classes of deleterious mutations can be described:

1. An odd number of TATA repeats in the promoter region of the gene, rather than the usual number of 6. The efficiency of enzyme synthesis is limited by these mutations, with exaggerated or persistent jaundice in the newborn period followed by recurrent mild indirect hyperbilirubinemia (often termed Gilbert's Disease) in later childhood and adult life. The associated neonatal jaundice is often severe enough to require treatment, and in adult life, mild jaundice is prone to recur during acute illness or with metabolic stress, such as prolonged fasting.
2. Single amino acid substitutions in the enzyme protein are relatively common and vary from almost negligible to moderately severe in their clinical effects. These substitutions may alter rates of enzyme

synthesis and protein stability, binding and stereospecificity of the enzyme, or both. Hyperbilirubinemia may be limited to the newborn period or may persist into adulthood. Clinical phenotypes may be described as Crigler–Najjar Type 2 Syndrome or as a variant of Gilbert's Disease, with considerable overlap between the two clinical syndromes.

3. A nonsense or "stop" mutation may inhibit synthesis of the enzyme or severely truncate its carboxy terminal so that no functioning enzyme is produced. This condition, clinically known as Crigler–Najjar Syndrome Type 1, is associated with severe lifelong unconjugated hyperbilirubinemia, and with eventual development of signs of bilirubin encephalopathy in most cases.

Although specific genetic tests are seldom indicated for neonatal jaundice which is time-limited and responsive to treatment, mutations and polymorphisms in glucuronyl transferase with mild or minor clinical consequences may explain many instances of family histories with recurrent cases of neonatal jaundice, some cases of "breast milk" jaundice, and some individual cases of severe or prolonged nonhemolytic jaundice in newborns.

Certain metabolic disorders and dysmorphology syndromes are associated with nonhemolytic neonatal hyperbilirubinemia. Infants of diabetic mothers, infants with congenital hypothyroidism, and those with galactosemia are at increased risk for hyperbilirubinemia. The pediatric and medical literature describe an increased frequency of conjugated or direct hyperbilirubinemia with galactosemia or hypothyroidism, but affected infants may first present with indirect hyperbilirubinemia as newborns.

The most common form of toxic hyperbilirubinemia in newborns at present is probably that associated with prolonged parenteral nutrition. Infants at particular risk are very low-birth-weight infants receiving total or partial parenteral nutritional support, and surgical patients receiving total parenteral nutrition (TPN) for long periods of bowel rest. Most such infants have a mixed presentation of elevated conjugated as well as unconjugated hyperbilirubinemia, often with the conjugated fraction predominating. The exact etiology of this TPN-related cholestasis is unknown with both fat and protein components variously believed to be responsible. The condition is usually self-limited and resolves with resumption of enteral feeds.

Conjugated hyperbilirubinemia secondary to intracellular liver disease or extracellular hepatobiliary obstruction usually presents later or persists longer than the newborn period, and is beyond the scope of this chapter. The author, however, has seen numerous cases of neonatal indirect hyperbilirubinemia with concomitant mild elevations of their direct-reacting fractions, both resolving simultaneously with treatment. This appears to be the result of increased bilirubin load that is progressively more effectively conjugated by the hepatocytes with the active transport of conjugated bilirubin into the hepatic canaliculi becoming the rate-limiting step and leading to some accumulation of conjugated bilirubin.

Breast-Feeding Jaundice

The cause of increased unconjugated bilirubin levels in breast-fed newborns is not clearly known. Some breast-fed infants may have exaggerated physiologic jaundice in their first few days because of low milk intake, mild dehydration, lack of stooling, and hemoconcentration. Others appear to have decreased rates of bilirubin conjugation, increased enteric reabsorption of bilirubin from the proximal small bowel, or both. Family histories of breast-feeding jaundice are possibly associated with mutations in the gene for glucuronyl transferase, as noted above. Most elevations of plasma bilirubin in breast-fed infants are within or only slightly above the physiologic range (but above average levels compared to formula-fed infants). Most cases of breast-feeding jaundice are benign and eventually self-correcting, although a minority of cases are severe or persistent enough to require diagnostic intervention and treatment. Withholding of breast milk is not indicated, but if dehydration is significant, supplementation may be necessary. Severe unconjugated hyperbilirubinemia may occur in the late preterm infant who is exclusively breast-feeding and not able to achieve adequate intake. This, in combination to their more immature liver function, is associated with increased risk of hospital readmission and, in rare instances, has led to kernicterus.

Assessment and Diagnostic Evaluation of Hyperbilirubinemia

The appearance of cutaneous or scleral jaundice in newborn infants should be documented with the nursing assessment of skin color as part of the infants' daily vital signs. The observations should be made under adequate light and preferably against a neutral color background. Although visual assessment does not always correlate well with actual plasma bilirubin levels, visual recognition of jaundice should be taught and learned as a simple initial screening tool, and in some settings, the only tool

immediately available. The observations may be structured in several ways:

1. By intensity – Is the jaundice barely discernible, faint but obvious, or intensely orange-yellow?
2. By location – Is the jaundice facial only, does it include the face and trunk, or does it also reach the extremities? For this assessment, scleral jaundice is part of facial jaundice, and not by itself a good sign of intensity or severity.
3. By age – visible jaundice on Day 1 should never be considered normal. The earlier jaundice appears, the more likely it is to be a sign of hemolysis or significant hepatic dysfunction. Widely disseminated or very intense cutaneous jaundice at any age is probably above the average levels for age, requiring further assessment.

Semiquantitative or quantitative screens can be accomplished by skin photometry, or by age-specific serum bilirubin measurement at the time of metabolic screening or on the day of discharge. The numerical results obtained by either method can be plotted against postnatal age in hours and compared to reference data graphed by percentile or risk assessment for age. Many of these numerical screens, whether based on bedside colorimetry or laboratory measurement, require a subsequent age-specific follow-up measurement by the same technique or by laboratory measurement if the instrumental measurement of skin color is above the average range. Transcutaneous screening should incorporate a threshold for laboratory determination if the transcutaneous value is above the expected normal range for age.

Screening for jaundice in many nurseries also incorporates a nurse-generated order to the laboratory for serum bilirubin measurement if certain threshold criteria are met (e.g., jaundice on the first day or a transcutaneous value in a high percentile for the patient's age). This strategy can generate an early warning for subsequent evaluation and treatment, can give the pediatrician useful information at the time of daily assessment, and can facilitate the timing of discharge and scheduled follow-up if the laboratory value is normal.

Bilirubin level may still be rising at the time of an "early" discharge (<48 h).

Therefore, reassessment for jaundice (and overall state of health) by a trained provider is recommended within two working days of discharge for normal vaginally delivered newborns, and within three working days for those delivered by cesarean section. If clinic or office hours or other limits on provider availability (e.g., multiple sites for one provider) preclude follow-up at the exact recommended intervals, a follow-up visit should be arranged for as soon as possible thereafter.

Early jaundice should be assessed for hemolysis, including:

- Assessment for anemia – RBC dysmorphology, reticulocytes, nucleated RBC count, Hemoglobin, hematocrit, RBC indices
- Comparison of maternal and neonatal blood types and antibody screens
- Examination for hepatosplenomegaly
- Family history
- A plan for age-specific periodic reassessment if treatment is not required immediately

Persistent or later jaundice should be assessed in the context of family history, feeding, adequacy of hydration, any laboratory findings known at the time or later requested, and follow-up bilirubin measurements based on age, rate of increase, and need for treatment. Some cases of mild persistent jaundice readily responsive to phototherapy or self-resolving may be followed only with repeat bilirubin measurements at intervals suitable to verify that the problem is correcting itself. This is especially so for otherwise well breast-fed infants without evidence of blood group incompatibility or other significant risk indicators.

Treatment

The major goal of treatment is to control plasma bilirubin concentration in order to keep accumulated bilirubin from reaching potentially neurotoxic levels. Concomitant treatment for associated conditions such as sepsis or anemia from severe hemolysis may also be part of the treatment of neonatal jaundice.

Cases of congenital hemolytic disease of the newborn or occasional hemolytic crises may require prompt or even prospective intervention with tranfusion and/or cardiorespiratory support. Most cases of hyperbilirubinemia evolve within a postnatal time frame, allowing for observation, evaluation, and non-emergent treatment. For these as well as for hemolytic disorders which are not life-threatening, phototherapy is the first line of treatment.

Intravenous immunoglobulin (IVIG), when used as early as possible in cases of severe alloimmune hemolytic jaundice has been shown to significantly decrease the need for exchange transfusion, as well as significantly reduce the length of phototherapy and hospitalization. The exact mechanism of action is unknown, but it is thought to inhibit hemolysis by blocking antibody receptors on red blood cells.

How Phototherapy Works

Bilirubin is a slightly asymmetric tetrapyrrole, rendered largely nonpolar by internal hydrogen bonding. Blue light excites a central carbon bond between two paired sets of pyrrole groups, breaking the hydrogen bonds to form bilirubin isomers of identical molecular weight and primary structure, but with their polar groups now exposed.

"Photobilirubin" is more water soluble than the parent compound, Bilirubin IX – alpha, and therefore more readily excretable into the biliary tract. The photochemical reaction occurs in the skin and subjacent capillaries, and its effectiveness is proportional to the light intensity in the blue spectral region and the area of skin exposed. Isomerization takes place within the first hour of light exposure, and the subsequent excretory phase is probably rate-limiting if the dose of light is adequate. Once excreted, the isomers gradually revert to the parent structure if they are retained in the biliary tree and proximal small bowel. This reversion and reabsorption of bilirubin partly explains the "rebound" in plasma bilirubin concentration after phototherapy.

Indications for Phototherapy

The 2004 recommendations of an American Academy of Pediatrics expert committee for evaluation, treatment, and follow-up of neonatal hyperbilirubinemia have largely been adopted in pediatric primary care, with some individual and local variations based on resource availability, community or institutional past experience, and the presence of certain high-risk groups in the population. These guidelines apply to term (equal to or greater than 38 weeks) and late preterm (35–37 weeks) infants. Guidelines for newborns less than 35 weeks are less uniformly established and more likely to reflect individual or institutional preferences.

The AAP guidelines for treatment are based on stratification of risk according to hour-specific percentile rankings for serum bilirubin levels and comorbidities such as prematurity or blood group incompatibility. The hour-specific rate of physiologic increase up to the 95th percentile of bilirubin concentration for age is generally within 0. 2–0.25 mg/dL/h. Approximate 95th percentile values are 8 mg/dL at 24 h, 13 mg/dL at 48 h, and 17–18 mg/dL at 72–96 h. Percentile value for age is not by itself considered a strict indication for treatment, for several reasons:

- Early-appearing jaundice in the absence of severe hemolysis may begin to self-resolve as early as the second or third hospital day. In these cases, a rapid initial rate of increase will be seen to slow itself with subsequent bilirubin measurements.
- Transient plasma bilirubin levels <20–22 mg/dL do not have a high risk of neurotoxicity for otherwise well infants. Plateau values of 15–18 mg/dL at 3–5 days may be observed for self-resolution if they do not continue to rise.
- Disruption of breast-feeding by treatment at 15–18 mg/dL or lower may not be in the best interests of the mother–baby pair.
- The early age-specific percentiles are partial predictors of continued and potentially progressive hyperbilirubinemia, rather than reliable predictors for risk of kernicterus.

Practical Guidelines for Phototherapy

Hospitals should invest in the best affordable blue-light phototherapy equipment to gain maximal therapeutic effectiveness and reduce hospital length of stay.

Undress the baby except for a small mask over the eyes and, if desired, a small bikini-style diaper (such as a surgical mask).

Measure light intensity at the bed surface. An intensity of at least 30 μWatts/cm^2 is recommended.

Expose a maximum area of skin for an optimal rate of photoconversion. Multidirectional light sources, "top and bottom" LED sources, reflecting devices, and turning the baby periodically may all be helpful. Partially dressed babies do not gain full advantage.

Set a goal, including a clinically meaningful decrease in bilirubin within 6–12 h and an overall decrease to 50–60% of the starting bilirubin value, or less.

Ignore small rebounds of <2 mg/dL. These are to be expected after the lights are off.

Arrange a follow-up appointment, with or without a scheduled bilirubin measurement, for 1–3 days after hospital discharge.

Exchange Transfusion

Exchange transfusion is now an uncommon procedure, generally performed by experienced operators in specialty centers. Phototherapy is usually performed as a preliminary or concomitant treatment, and should

always be continued while preparations for the exchange transfusion are underway. Each center should develop a locally applicable set of policies/procedures for exchange transfusion.

The principal indications are:

Hemolytic disease with early or perinatal anemia and/or a rate of bilirubin increase of 0.5–1.0 mg/dL/h or greater.

Potentially toxic bilirubin levels not promptly responsive to intensive phototherapy.

The approximate levels of risk for CNS toxicity are 25–30 mg/dL for previously "well" term infants, 20–25 mg/dL for term infants with hemolytic disease, and approximately15–20 mg/dL for premature infants of 33–34 weeks gestation or less. The last of these "threshold" values, for preterm infants, are based more on historical and customary practices than on current evidence. An exchange transfusion threshold based on birth weight in kilograms × 10 is widely used but lacks sound scientific basis.

The procedure usually requires reconstitution of irradiated packed RBC's with compatible plasma. The target volume for exchange of 85–90% of the infant's blood is 2× the estimated neonatal blood volume of 80 mL/kg, or 160 mL/kg of exchange blood.

For a one-vessel technique (usually the umbilical vein), the "push–pull" volumes per exchange can approximate 5 mL/kg, withdrawn and replaced in a 1 min cycle.

A two-vessel technique of simultaneous withdrawal and infusion can be accomplished in 30–45 min, depending on catheter diameter, pump capacity, and patient condition.

Bilirubin, hematocrit, glucose, and electrolytes should be monitored at beginning and end of the procedure. The bilirubin level may fall by more than half the initial value, but return of extravascular bilirubin from the tissues to the blood may create a substantial post transfusion rebound. Transient hypocalcemia occurs during the procedure in nearly half of the infants if blood anticoagulated with citrate phosphate dextrose (CPD) is used for the exchange transfusion. Metabolic acidosis and thrombocytopenia are seen in 25–30% of infants following exchange transfusion. The infant should be made NPO for the procedure because necrotizing enterocolitis has been associated with exchange transfusion. The reported incidence of serious complications was nearly 24% in a recent review. Careful monitoring of vital signs and of blood volume withdrawn and infused are essential safety precautions.

The Small Premature Infant

For premature infants of very low birth weight, the evidence base for risk assessment, early treatment, and the relative contribution of bilirubin to adverse outcomes is not well established. There is no known safe bilirubin level in very preterm infants. This is largely because the blood brain barrier, which keeps albumin-bound bilirubin from entering the CNS, is frequently rendered open by hypoxia, acidosis, and other events commonly seen in critically ill extremely low-birth-weight infants. Most tertiary centers have adopted strategies to control bilirubin concentrations within low levels in these infants. This strategy may be counterproductive based on the following concerns:

1. A possible contribution of prophylactic or very early phototherapy to excess mortality in the lowest-birth-weight group of infants in a large randomized trial.
2. Blue light applied to thin non-jaundiced skin may predispose to excessive insensible water loss or to photochemical injury in the absence of bilirubin to absorb most of the photons from the light exposure. Intuitively, a firm indication for early phototherapy should entail that at least some cutaneous jaundice is present as a "target" for treatment.
3. Bilirubin is also an important antioxidant and a transient rise in bilirubin during a period of increased oxidative stress may be an important defense mechanism, with which early phototherapy may interfere.

Levels of 13–15 mg/dL or greater in VLBW prematures may be associated with increased risk of hearing loss and motor delay, but without the characteristic findings of subsequent choreoathetosis and cranial nerve motor damage associated with "classic" kernicterus in older newborns.

Prudent current advice for VLBW and ELBW infants would seem to be to avoid gratuitous prophylactic phototherapy but to use phototherapy early enough in most such infants to constrain bilirubin concentrations in the range of 5–10 mg/dL. Additional clinical trials of treatment and follow-up appear necessary to clarify the indications and contraindications for phototherapy in VLBW infants.

27 Infections of the Fetus and Newborn

Joseph M. Bliss

The far-reaching impact of microbes on the human condition cannot be overestimated. The microbial species are vast, diverse, and present in virtually every ecosystem on earth. A single gram of human feces, for example, is estimated to contain 10^{11} bacteria, which is equivalent to 10–50% of all the human cells in the body, and is nearly two orders of magnitude higher than the total number of people on the planet. Humans have therefore evolved elaborate and elegant defense mechanisms to maintain health in a microbe-rich environment. Nowhere are these mechanisms more important for the overall health of the species than in pregnancy and childbirth, and in the vast majority of cases, host defense mechanisms provide for healthy infants. A very small subset of microbes have developed ways to subvert host defense and cause infections in pregnancy or the perinatal period that are damaging to the fetus and/or infant, and these infections cause substantial morbidity and mortality throughout the world. These microbes and the diseases that they cause are the focus of this chapter.

The clinical manifestations of infection during gestation or surrounding birth vary depending on the properties of the infectious agent, the timing of the infection, and the extent of inflammation resulting from the host's response to the infection. The microorganisms that cause disease in this period include viruses, bacteria, protozoa, and fungi. They can be further divided into agents that are acquired during pregnancy and lead to symptomatic infection in the fetus prior to birth (congenital infection), and those acquired in the perinatal period, either during or shortly after delivery. Although useful from a conceptual point of view, this classification is somewhat artificial, as considerable overlap exists between these groups. This chapter will focus on those microorganisms that are well recognized to lead to disease in the fetal and neonatal period and have serious impact in terms of prevalence and severity of symptoms. An exhaustive review of all possible infections in the neonatal period is beyond the scope of this chapter, and readers are referred to specialty texts devoted exclusively to neonatal infections that provide additional breadth and depth.

Congenital Infections

Exposure to infectious agents during pregnancy is unavoidable, and the majority of infections in pregnant women lead to self-limited respiratory or gastrointestinal illnesses that resolve without specific intervention or with antimicrobial therapy. However, a subset of infectious agents is capable of infecting the placenta and fetus with potential adverse consequences. Risk of infection in the fetus and newborn varies with each infectious agent and depends on timing of maternal exposure in pregnancy (summarized in *Table 27.1*). Prompt and accurate diagnosis of these infections in the fetus and newborn is complicated by the fact that maternal infections with many of these agents are asymptomatic or cause minor, nonspecific symptoms.

The classic pneumonic for microbes that lead to congenital infections is "ToRCH", referring to *Toxoplasma gondii*, rubella, cytomegalovirus (CMV), and herpes simplex virus (HSV). However, equally important causes of congenital infection are not reflected in this acronym, including syphilis, parvovirus, varicella-zoster virus (VZV), and human immunodeficiency virus (HIV), which seriously limits its utility. Further, the clinical features, diagnostic studies, and sequelae related to these infections differ depending on the unique aspects of each disease. Thus, the concept of a "ToRCH workup" in the setting of a fetus or neonate with signs that may be related to congenital infection is an oversimplification that should be avoided. This section will focus on the clinical aspects that are characteristic of infection with each of these agents.

Toxoplasmosis

Etiology

Toxoplasmosis is caused by infection with the protozoan parasite, *Toxoplasma gondii*. The life cycle of this organism is relevant to understanding its transmission, and has three stages: tachyzoite, bradyzoite, and sporozoite. Domestic and feral cats are the definitive host for the sexual stage of

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_27,

Table 27.1
Disease manifestations of congenital infections based on timing of maternal exposure

Infectious disease	Timing of maternal infection/fetal exposure	Disease manifestations*
Toxoplasmosis	First Trimester – 10–25% transmission	More severe
	Third Trimester – 60–90% transmission	Less severe
Rubella	First trimester – 85% transmission	Congenital rubella syndrome
	Second trimester – 25% transmission	
Cytomegalovirus	First trimester	More likely severe
Herpes Simplex	In utero – rare	CNS damage
	Primary infection close to delivery	SEM, CNS, or disseminated disease
Syphilis	14 weeks through term	Congenital syphilis
Parvovirus B19	First half of pregnancy (13–20 weeks)	Highest risk of hydrops
Varicella	First half of pregnancy (13–20 weeks)	Congenital varicella syndrome (rare)
	5 days prior to 2 days after delivery	Perinatal varicella
Hepatitis B	In utero – rare	Fulminant or chronic HBV
	At delivery	
HIV	In utero – less than half of cases	Congenital HIV
	At delivery – most common	
	Breast feeding – well documented	

*See text for additional details

the organism, and generally acquire the infection by feeding on infected animals such as mice or from uncooked meats. The sexual stage occurs at the intestinal mucosa and results in unsporulated, and therefore noninfectious, oocysts that are excreted in the feces. The oocysts then sporulate (sporozoites) and become infectious within one day to several weeks, depending on climate. Infectious oocysts are then ingested by humans or other animals and become tachyzoites in the acute stage of infection where they can invade the heart, muscles, liver, spleen, and central nervous system. In immunocompetent hosts, the acute infection is controlled and latent infection is established, characterized by bradyzoites in tissue cysts. In humans, ingestion of oocytes can occur through contact with cat litter, contaminated soil encountered through gardening or unwashed vegetables, or contaminated water supplies. Humans can also become infected by the ingestion of undercooked infected meat or uncooked foods that have come into contact with raw meat. Finally, reactivation of latent infection can occur in the setting of immune compromise from HIV, chemotherapy, or organ transplantation. Infection of the fetus occurs by transplacental transmission in the setting of acute maternal infection during pregnancy. The fetus is also at risk in the setting of reactivation due to maternal immunosuppression during pregnancy. Infection of the fetus in most likely when maternal infection occurs during the third trimester (60–90% transmission vs. 10–25% in the first trimester), but the consequences of infection are more severe when it occurs early in gestation.

Epidemiology

Infection with *T. gondii* is common and is estimated to be present in up to one-third of the world's population. It has its highest prevalence in tropical areas and prevalence decreases with distance from the equator. In Europe, for example, seroprevalence is 54% in Southern European countries but only 5–10% in northern Scandinavian countries. *T. gondii* infection is common in South America and Africa, while seroprevalence is lower in most Asian countries. In the United States, approximately 11% of women of childbearing age are seropositive and congenital infection is estimated to occur at a rate of 1 in 1,000 to 1 in 10,000 live births.

Clinical Manifestations

Infection during pregnancy is most often asymptomatic for the mother. Infants who were congenitally infected are also asymptomatic 70–90% of the time. However, the majority of these infants (up to 80%) will go on to develop manifestations of infection such as learning disabilities or impaired

vision months to years later. In infants who are symptomatic at birth, signs of congenital infection include hepatomegaly, splenomegaly, thrombocytopenia, generalized lymphadenopathy, and a maculopapular rash. Infection of the central nervous system and the accompanying inflammation account for the most severe consequences of intrauterine infection, both in the short and long term. These include the classic triad of congenital toxoplasmosis: chorioretinitis, microcephaly, and intracranial calcifications. Other signs of CNS infection include meningoencephalitis, hydrocephalus, seizures, and deafness. Indeed, CNS calcifications, microcephaly, and/or hydrocephalus on prenatal ultrasound can be the first clues of infection in the developing fetus. Manifestations of toxoplasmosis in the premature infant can include CNS and ocular disease in the first 3 months of life, while infants born at term tend to have milder disease with hepatosplenomegaly and lymphadenopathy in the first 2 months of life.

Diagnosis

Diagnosis of acute infection with *T. gondii* during pregnancy is based on specific antibody detection in the maternal serum, but the interpretation of these tests can be difficult. IgG and IgM levels are detectable within 1–2 weeks of infection. Detection of IgG alone documents past infection with the organism, but cannot distinguish between recent infection and infection sometime prior to pregnancy. Since the risk to the fetus is associated with acute, active infection, this distinction is paramount. The presence or absence of IgM is helpful in this regard. The lack of *T. gondii*-specific IgM in the presence of IgG is indicative of infection more than 6 months prior to obtaining the test. However, the fact that IgM antibody can persist up to 18 months following infection and false positives are also known to occur complicates the interpretation of positive IgM serology. Therefore, consultation with a reference laboratory is recommended in cases where acute infection is likely and IgM is positive. Additional testing available through reference laboratories includes IgG avidity testing and tests for *T. gondii*-specific IgA and IgE which can help to determine timing of infection and risk to the fetus. If acute infection is likely, fetal infection can be assessed by PCR-based techniques on sampled amniotic fluid or fetal blood as well as serial by serial ultrasound examinations.

Treatment

Treatment for pregnant women with a confirmed case of acute *T. gondii* infection is recommended with spiramicin. The goal of treatment is to prevent transmission to the fetus. However, fetal transmission is thought to occur quickly after maternal infection and institution of maternal treatment probably needs to occur within 2 weeks of infection. As such, there is little evidence that treatment in pregnancy impacts maternal-fetal transmission, and spiramicin does not treat the fetus in utero. If fetal infection is confirmed or maternal infection is documented in the third trimester, the combination of pyrimethamine and sulfadiazine should be considered, but only after the 17th–18th week of gestation due to toxicities of these agents. Additionally, folinic acid should be given to offset the bone marrow toxicity associated with pyrimethamine. There is some evidence that maternal treatment may decrease the severity of manifestations of fetal infection. Combined therapy with pyrimethamine and sulfadiazine is recommended for treatment of both symptomatic and asymptomatic congenital infection, generally for the entire first year.

Prevention

Education relating to the risks of exposure and infection with *T. gondii* during pregnancy is the mainstay of prevention and should focus on avoiding contamination from contact with meat, soil, and cats. Pregnant women should avoid raw or undercooked meats and ensure that meat is cooked to a safe temperature prior to consumption. Fruits and vegetables should be thoroughly washed or peeled before eating. Hands and utensils that come into contact with meat or unwashed vegetables during their preparation should be carefully cleaned. Gloves should be worn in gardening. Cat owners should be encouraged to keep their cats inside and cats should be fed commercially canned or dried cat foods, avoiding raw meats. Pregnant women should avoid contact with cat feces or litter boxes or wear gloves when handling them. Clearly, avoiding infection during pregnancy is by far the best way to reduce morbidity and mortality related to congenital infection.

Rubella

Etiology/Epidemiology

Also known as "German measles," rubella is caused by infection with rubella virus. It is found only in humans and is transmitted through either direct or droplet contact with the nasopharyngeal secretions of an infected person. Prior to widespread vaccination programs, rubella was endemic worldwide and occurred in 6–9 year cycles with children infected most commonly. With the approval and

widespread usage of rubella vaccine, the virus is no longer endemic in the United States, and the virus has essentially been eliminated from some industrialized countries. Cases in these countries have become exceedingly rare and occur primarily among women born in areas with poor vaccine coverage. In developing countries with limited vaccination, 15–20% of women of childbearing age are susceptible to rubella, with higher rates in rural areas and in island communities. In 2003,>100,000 infants were estimated to be affected by congenital rubella syndrome worldwide. Attention from the World Health Organization has improved vaccination rates, such that as of 2005, 117 of 214 countries and territories have included rubella in national vaccine programs.

Clinical Manifestations

Symptoms of rubella infection tend to be milder in children than in adults. Infections are subclinical in 20–50% of cases, depending on the population. After an incubation period of 14–23 days, symptoms include a characteristic erythematous maculopapular rash that starts on the face and then becomes generalized, lymphadenopathy that may precede the rash, low-grade fever, headache, sore throat, cough, and conjunctivitis. Polyarthritis and polyarthralgia are uncommon in children, but more common in adolescents and adults, particularly in females. Encephalitis and thrombocytopenia are rare complications. Congenital rubella syndrome (CRS) occurs when a susceptible pregnant woman is infected, with early gestation being the most critical time period. CRS results in 85% of cases in which infection occurred before 12 weeks gestation, and multiple defects are most likely before 8 weeks. Spontaneous abortion occurs in 20% of fetuses affected in this time period. The risk to the fetus declines rapidly after 12 weeks, with estimates of 54% during 13–16 weeks and 25% during the second trimester. The most common manifestations of CRS are summarized in ❯ *Table 27.2*.

Table 27.2
Clinical manifestations of congenital rubella syndrome (CRS)

Organ System	Signs
Ophthalmologic	*Cataracts (33%, 50% bilateral)
	Pigmentary retinopathy
	Microophthalmos
	Glaucoma
Cardiac	*Patent ductus arteriosus (30%)
	Pulmonary artery stenosis/hypoplasia
Auditory	*Sensorineural or central auditory deafness
Neurologic	Microcephaly
	Meningoencephalitis
	Mental retardation
	Psychomotor retardation
	Language delay
Other	Low birth weight, Growth restriction, Failure to thrive
	Hepatosplenomegaly
	Interstitial pneumonitis
	Thrombocytopenia
	Radiolucent bone disease
	Dermal erythropoiesis (Purpura; "Blueberry Muffin" lesions)

*Classic abnormalities

Diagnosis

Congenital rubella can be diagnosed by the presence of rubella-specific IgM in serum or oral fluid of an infected infant. The test is most reliable when it is obtained before 3 months of age and reliable detection of IgM decreases thereafter (85% of symptomatic infants between 3 and 6 months; > 30% at 6–12 months). Stable or increasing titer of rubella-specific IgG after 6 months of age also supports the diagnosis. Culture of rubella virus from throat or nasopharyngeal swabs is also useful to establish a diagnosis, and PCR-based tests on throat swabs or urine specimens are available as well. A diagnostic evaluation of pregnant women with symptoms of rubella (fever, rash, joint pain) should also be undertaken. A positive rubella IgM is strongly suggestive, but subsequent samples should be drawn to confirm the result and document a rising IgG titer. False positives are common with this testing, particularly in areas with low disease incidence, and referral to reference laboratories for supplemental testing is useful before decisions regarding possible pregnancy termination are made.

Treatment and Prevention

There are no antiviral chemotherapeutic agents available to treat CRS or deter transmission to the fetus. Human immune globulin may reduce clinically apparent

infection, viral shedding, and viremia in exposed, susceptible women and may theoretically reduce transmission to the fetus. Its use can be considered in susceptible women who are rubella exposed early in pregnancy, but its efficacy is not well understood. Vaccination is therefore the mainstay of prevention, and has been remarkably safe and effective. The vaccine is generally administered in combination with measles vaccine (MR), measles and mumps vaccine (MMR), or measles, mumps, and varicella vaccines (MMRV). In many countries, rubella immune status is screened during pregnancy, and women who are not immune are offered vaccination in the immediate postnatal period. Because it is a live vaccine, vaccination during pregnancy is contraindicated due to the theoretical risk of harm to the fetus. However, in studies of women who inadvertently received the vaccine during pregnancy, only a small percentage of their infants had evidence of infection, and none had congenital defects.

Cytomegalovirus

Etiology/Epidemiology

Cytomegalovirus (CMV) is a ubiquitous DNA virus and is a member of the herpesvirus group. Numerous strains have been identified and, like other herpes viruses, primary infection is followed by life-long latency in infected hosts. Reactivation and viral shedding can occur years after primary infection. The virus is shed in secretions, including saliva, semen, cervical secretions, breast milk, and urine, and is transmitted by close person-to-person contact. Transmission has no seasonal variation and can also occur through blood transfusion and organ transplantation. Infection is common during childhood and well documented to occur at child care centers. Rates of seroprevalence vary significantly based on varied living conditions, hygiene practices, breast feeding rates, and socioeconomic factors and range from 35% to 95%. Infection among children in the first years of life is therefore less common in industrialized countries and high socioeconomic groups, resulting in higher rates of susceptibility among women in childbearing years in these populations.

Clinical Manifestations

Primary infection with CMV is most frequently asymptomatic, although a mononucleosis-like syndrome with malaise, fever, and mild hepatitis can occur in a small number of adolescents and adults. Approximately 1% of all live born infants are infected with CMV and shed virus at birth, making this infection the most common congenital viral infection. However, manifestations of the infection and subsequent sequelae vary dramatically depending on timing of infection. Transmission of CMV to a fetus or infant can occur in three settings. The fetus can be infected in utero by passage of virus from the mother across the placenta, by contact with cervical secretions or maternal blood during delivery, or from breast milk after delivery. Transmission can occur in the setting of primary infection or with reactivated disease, but transmission is much more common in primary infection. Approximately 1–4% of seronegative women acquire primary CMV infection during pregnancy and the risk of transmission is estimated at 30–40%, while reactivation occurs in 10–30% of seropositive women during pregnancy with a transmission risk of 1–3%.

Among the 1% of infants who are infected with CMV at birth, approximately 10% are symptomatic. Manifestations of symptomatic congenital CMV include growth restriction, microcephaly, intracerebral calcifications, retinitis, hepatosplenomegaly, jaundice, and purpura. These infants have a mortality rate of approximately 30%, generally secondary to liver failure, and the survivors are at the highest risk for neurodevelopmental sequelae. Severe consequences of CMV infection are most likely to occur when primary infection occurs in the mother in early pregnancy. The central nervous system is particularly susceptible to these insults. Infection early in pregnancy can alter neural migrational patterns in the brain and lead to polymicrogyria and microcephaly. Later in pregnancy, effects on the cortex are less pronounced while the white matter remains susceptible. Sensorineural hearing loss is the most common later manifestation of congenital CMV infection, making CMV the most common nongenetic cause of hearing loss in children. Hearing loss is more common and more severe in symptomatic than in asymptomatic congenitally infected infants, but asymptomatic infants still carry a 10% risk of progressive hearing loss. Further, hearing loss may not be apparent in the first months of life. Therefore, infants known to have congenital CMV should have careful audiologic follow-up throughout their early childhood as hearing loss can fluctuate and be progressive.

Infection from cervical secretions or blood during birth or from breast milk after birth is most commonly asymptomatic, although interstitial pneumonia has been reported in this setting. Preterm infants, however, are at higher risk for symptomatic infection than full term infants as well as neurodevelopmental sequelae.

Diagnosis

The most common method used to diagnose congenital CMV is through detection of the virus in urine samples using tissue culture techniques. PCR-based assays are also available, particularly for cerebrospinal fluid. Detection of CMV-specific IgM in the newborn can also support a diagnosis, but can only be detected in 70% of infected infants at birth. Diagnosis of primary infection in a pregnant woman is more difficult because of frequent reactivation of the virus, infection of a seropositive woman with a different strain, and the tendency for development of an IgM response with reactivation. Seroconversion of CMV-specific IgG between paired samples when available is the most reliable means to identify primary infection in pregnancy. Fetal infection can be evaluated in these cases by viral culture and PCR of an amniotic fluid sample. The sensitivity of amniotic fluid testing is highest when it is obtained after 21 weeks gestation and at least 5 weeks after the onset of infection. Still, the risk of neurodevelopmental consequences in an individual infected fetus is difficult to predict.

Treatment

Ganciclovir is used to treat CMV in the setting of retinitis or other end-organ manifestations in immunocompromised patients and prophylactically in organ transplant recipients. Data concerning the use of this drug in neonates are limited. However, in symptomatic congenitally infected infants with CNS disease, 6 weeks of intravenous ganciclovir therapy may protect against hearing deterioration and improve developmental outcomes at 1–2 years of age. Its use is limited by toxicity and the high rate of neutropenia in infants on this regimen. Preterm infants with symptomatic disease and evidence of end-organ damage have also been treated empirically, but ganciclovir has not been studied in this population.

Prevention

Because of the ubiquitous nature of this virus and the absence of a vaccine, prevention is centered on education, particularly in industrialized countries with high rates of seronegative women of childbearing age. Because reactivation of infection with viral shedding is commonplace, avoiding contact with the virus is difficult. However, daycare and child care centers, particularly with children under 2 years of age, are very frequent sources of exposure. Women in these settings should focus on frequent hand washing to reduce exposure, particularly after contact with saliva or changing diapers.

Herpes

Etiology/Epidemiology

Two species of herpes simplex virus infect humans. Infection with type 1 (HSV-1) generally involves the face and skin above the waist while infection with type 2 (HSV-2) generally involves the genitals and skin below the waist. However, either virus can lead to genital infection. Approximately 75% of neonatal infections are caused by HSV-2. Like other herpes virus infections, infection with HSV is characterized by latency after primary infection with intermittent reactivation and viral shedding. Current estimates in the United States are that 25–60% of pregnant women are infected. Infants born to mothers with genital HSV infection are at risk of acquiring the infection either before birth or after delivery, but the majority of neonatal HSV is acquired at delivery from active viral shedding in cervical secretions. Infection prior to delivery is rare. Postnatal acquisition of HSV can come from health-care workers or family members as well as the mother and is almost always due to HSV-1. Depending on the population studied, estimates of incidence of neonatal HSV range from 1 in 12,500 to 1 in 1,700 live births. Because of the severe morbidity and mortality associated with neonatal infection, these rates represent a substantial disease burden that is as high as or substantially higher than that associated with other congenital infections. Primary genital HSV infection in women is very commonly asymptomatic and therefore frequently undiagnosed. The risk to the infant is substantially higher in the setting of primary infection during pregnancy (25–60% incidence) than in reactivated disease with viral shedding (1–2% incidence), likely due to the absence of protective maternal antibodies in the former. As a result the majority of neonatal HSV infections (50–80%) occur in babies born to women who acquired primary HSV-1 or HSV-2 genital infection close to term and are unaware of their HSV status.

Clinical Manifestations

In the rare cases of in utero acquisition of HSV, the central nervous system is susceptible to damage leading to microcephaly and hydrocephalus. Chorioretinitis can also be seen. The much more common acquisition through

exposure at delivery can manifest in one of three ways: skin, eye, mouth disease (SEM), central nervous system disease (CNS), or disseminated disease. Each type of infection has distinct clinical features, response to therapy, and prognosis. Evidence of HSV infection typically presents within the first month. Infants with SEM and disseminated disease present somewhat earlier, in the first 1–2 weeks, while those with CNS disease typically develop symptoms between 2 and 3 weeks.

SEM disease accounts for approximately 45% of neonatal HSV infection. These infants develop vesicular lesions of the skin, eyes, and/or mucus membranes without involvement of the CNS or other organ systems. There is little to no mortality in this category and with treatment, neurodevelopmental outcomes are normal. However, skin lesions commonly recur, and those that do frequently in the first 6 months can be associated with CNS sequelae. Infection of the CNS occurs in approximately 30% of cases. Skin and mucosal lesions may or may not be present. Infants with CNS disease may present with poor feeding, lethargy, and seizures. Timely initiation of therapy improves the outcomes of these infections and reduces later sequelae, but because the signs are nonspecific, diagnosis can be delayed. Antiviral therapy improves mortality from 50% to 6%, but sequelae such as epilepsy, blindness, and developmental delay remain common, particularly with HSV-2. More than half of these children have moderate to severe neurodevelopmental problems. Disseminated disease occurs in approximately 25% of cases and involves other organ systems in addition to the CNS, particularly liver and lungs. The presentation of these infants is identical to bacterial sepsis and skin lesions are absent in approximately 40% of cases. Thus, diagnosis requires a high index of suspicion for timely initiation of therapy, and HSV should be considered in any infant with culture negative sepsis and severe hepatic dysfunction. Mortality occurs in approximately 30% of patients, even with treatment. Survivors have a somewhat better neurodevelopmental prognosis than in CNS disease.

Diagnosis

Available diagnostic tests for HSV include culture, direct fluorescent antibody (DFA) staining, and PCR. Cell culture methods are sensitive and specific, and can be positive in as little as 1–3 days. DFA is much more rapid, but slightly less sensitive. PCR to detect viral DNA is quite sensitive, and is particularly useful for neonatal CSF specimens where culture is usually negative. Any infant with signs of possible HSV infection or with suspicious skin lesions should be evaluated. Swabs of the mouth, nasopharynx, conjunctivae, and rectum, and specimens of blood, CSF, and any skin vesicles should be obtained for culture. Any positive culture from these sites obtained more than 12–24 h after delivery is highly suspicious for neonatal infection. PCR should also be obtained on CSF. DFA or enzyme immunoassays can be useful for rapid confirmation on scrapings from skin lesions. Although not useful in neonates, serologic testing is available for adults and can distinguish between antibodies to HSV-1 and HSV-2. These antibodies develop between 2 and 12 weeks after primary infection and persist indefinitely. Serologic testing can therefore be useful in distinguishing recent from past infection and in identification of discordance among sexual partners of uninfected women. Such testing can therefore be useful to inform the risk of infection in an individual infant.

Treatment

Treatment of infants infected with HSV with IV acyclovir (20 mg/kg every 8 h) has dramatically reduced mortality from these infections. Because infants with SEM disease can have progression to the CNS, any infant diagnosed with HSV should be treated with IV acyclovir. Treatment is recommended for 14 days for SEM disease and 21 days for disseminated and CNS disease. Longer-term suppressive therapy and treatment of recurrent disease are the subject of current investigation. Management of the exposed infant who is asymptomatic is controversial. Because of the high rates of perinatal infection, some experts recommend treatment for 14 days in asymptomatic infants born vaginally to mothers who acquire primary HSV late in pregnancy. However, distinction between primary infection and reactivation can be difficult. Others recommend cultures of mouth, nasopharynx, conjunctivae, and rectum between 12 and 24 h after birth, with either empiric therapy initiated after cultures are obtained or awaiting culture results with completion of the evaluation (hepatic transaminase measurement, CSF PCR) and therapy if positive.

Prevention

A number of strategies to reduce the risk of neonatal HSV have been discussed, including serologic testing of women and their partners to identify those at risk of acquisition during pregnancy, counseling of pregnant women to avoid unprotected intercourse or oral-genital contact in late

pregnancy, and rapid testing for HSV shedding in mothers at delivery. The effectiveness of such strategies is currently unknown. During labor, all women should be asked about recent or current signs or symptoms of herpes infection and should be examined for lesions. Current guidelines recommend cesarean delivery for any woman with genital herpes lesions and this approach decreases the risk to the neonate. The use of antiviral agents for suppression of viral shedding in infected women late in pregnancy has also been suggested and may reduce the rates of cesarean delivery, but the safety of this approach and whether such treatment reduces neonatal infection is unknown. In most cases, this approach targets recurrent disease which is much less commonly the source of neonatal infection. In any case, HSV infection of the neonate remains a prevalent and severe problem with considerable need for research to identify effective preventive strategies and the optimal identification and management of the exposed newborn.

Syphilis

Etiology/Epidemiology

Syphilis is caused by the bacterial spirochete, *Treponema pallidum*. Features of this organism, such as having humans as its only natural host and its inability to be cultured on artificial media, have limited progress in understanding its biology for decades. It has a worldwide distribution, and its incidence varies dramatically based primarily on the local resources available for screening and treatment. Screening programs in industrialized countries have made congenital syphilis a rare disease, although resurgence has been detected in recent years. In the United States, for example, the rate of congenital syphilis increased by 23% from 2005 to 2008. Current estimates of the rate of congenital syphilis in the United States and in Europe range from 1.9 to 10.1 cases per 100,000 live births. Rates are much higher and potentially underappreciated in developing countries where limited resources make screening programs difficult to achieve. Rates of syphilis in pregnant women are estimated to be below 5% in Asia, 5–10% in the Caribbean and Latin America, and as high as 17% in sub-Saharan Africa. Estimates from the World Health Organization indicate that approximately 1,000,000 pregnancies are affected by syphilis annually worldwide, resulting in 460,000 infants who are stillborn or die in the perinatal period; 270,000 infants born preterm or with low birth weight, and 270,000 infants with stigmata of congenital syphilis.

Clinical Manifestations

The stages of acquired syphilis in adults are well known and have been extensively discussed elsewhere. In the setting of maternal syphilis, the fetus can acquire the infection transplacentally from about 14 weeks of gestation, with increasing rates of infection as pregnancy progresses. The potential short- and long-term impacts of fetal infection are numerous and profound, and recognition and treatment of syphilis early in pregnancy makes these manifestations almost entirely preventable. The chance of fetal transmission from an untreated pregnant woman is approximately 70%, and about 40% of pregnancies in untreated women result in stillbirth, hydrops fetalis, and/or perinatal death. Infected infants who are live born may be entirely asymptomatic (about two-thirds) or may be born prematurely or with low birth weight. Manifestations of congenital syphilis may occur early or later in life, regardless of symptoms at birth, and are summarized in *Table 27.3*. Treatment of early infection prevents the development of late manifestations.

Diagnosis

In the absence of the capacity to culture the organism, diagnosis of syphilis infection relies primarily on serologic testing. Microscopy can be used for secretions and tissues,

Table 27.3
Clinical manifestations of congenital syphilis

Early ($\leq$ 2 years)	Late ($>$ 2 years)
Nasal discharge ("snuffles")	*Interstitial keratitis (5–20 years)
Maculopapular rash	*8th cranial nerve deafness (10–40 years)
Hepatosplenomegaly	*Hutchinson teeth (peg-shaped, notched central incisors)
Lymphadenopathy	Mulberry molars
Edema	Saber shins (anterior tibial bowing)
Pneumonia	Frontal bossing
Osteochondritis with pseudoparalysis	Saddle nose
Hemolytic Anemia	Clutton joints (painless swelling of knees)
Thrombocytopenia	Rhagades (linear scars around mouth/nose)

*Hutchinson's triad

but requires darkfield examination or *T. pallidum*-specific fluorescent antibody staining. Serologic tests can be classified as nontreponemal and treponemal, and both are necessary to establish a diagnosis with the least ambiguity. Nontreponemal tests can yield false positive results in the setting of some viral and autoimmune conditions, and treponemal tests remain positive long after effective treatment is instituted and can be positive with other spirochete infections. The commonly used nontreponemal tests are the rapid plasma reagin (RPR) and the Venereal Disease Research Laboratory (VDRL) slide test. They have the advantage of being inexpensive and easy to perform, and they provide quantitative results that can be used to measure disease activity and response to therapy. Positive nontreponemal tests should be confirmed with treponemal tests to exclude a false positive result. Treponemal tests include fluorescent treponemal antibody absorption (FTA-ABS) and *T. pallidum* particle agglutination (TP-PA) tests. All pregnant women presenting for prenatal care should receive a nontreponemal screening test early in pregnancy. Although the utility of additional screening varies based on prevalence, in women at high risk or in areas with high prevalence of syphilis, the test should be repeated at 28–32 weeks gestation and at delivery. Additionally, any woman that delivers a stillborn infant after 20 weeks gestation should be screened for syphilis. In the setting of a positive screen, a treponemal test should be done to confirm the diagnosis and treatment initiated. Infants born to mothers who are seropositive should also receive a quantitative nontreponemal test, preferably of the same type that the mother received and ideally at the same laboratory, as relative titers can inform the likelihood of infection versus passive transfer of maternal antibody only.

Treatment

Definitive diagnosis in the neonate born to a seropositive mother is challenging because many infants are asymptomatic at birth and there is no diagnostic test that yields an unambiguous result in this setting. In spite of this difficulty, identifying infected infants is paramount, because early treatment is effective and prevents much of the severe sequelae that can present later in life. As such, algorithms have been developed that utilize conservative strategies to identify and treat infants who have either proven or suspected disease, while excluding as many infants as possible who are uninfected and therefore will not benefit from treatment. One such algorithm endorsed by the American Academy of Pediatrics is depicted in *Fig. 27.1*. Follow up of treated infants is important to ensure that therapy was effective. Positive syphilis serology generally clears by 6 months of age with effective treatment. Testing serologic titers with a nontreponemal test at 1, 3, 6, 12, and 24 months following treatment should document a fourfold decrease by 6 months post therapy and should be nonreactive by 12 and 24 months. Titers that increase or fail to fall are concerning for treatment failure or reinfection and these infants should be reevaluated and treated. Infants that had congenital neurosyphilis on the basis of a positive CSF VDRL or abnormal CSF parameters should undergo repeat lumbar puncture every 6 months until it normalizes. Abnormal CSF parameters or a continued positive VDRL is an indication for further treatment.

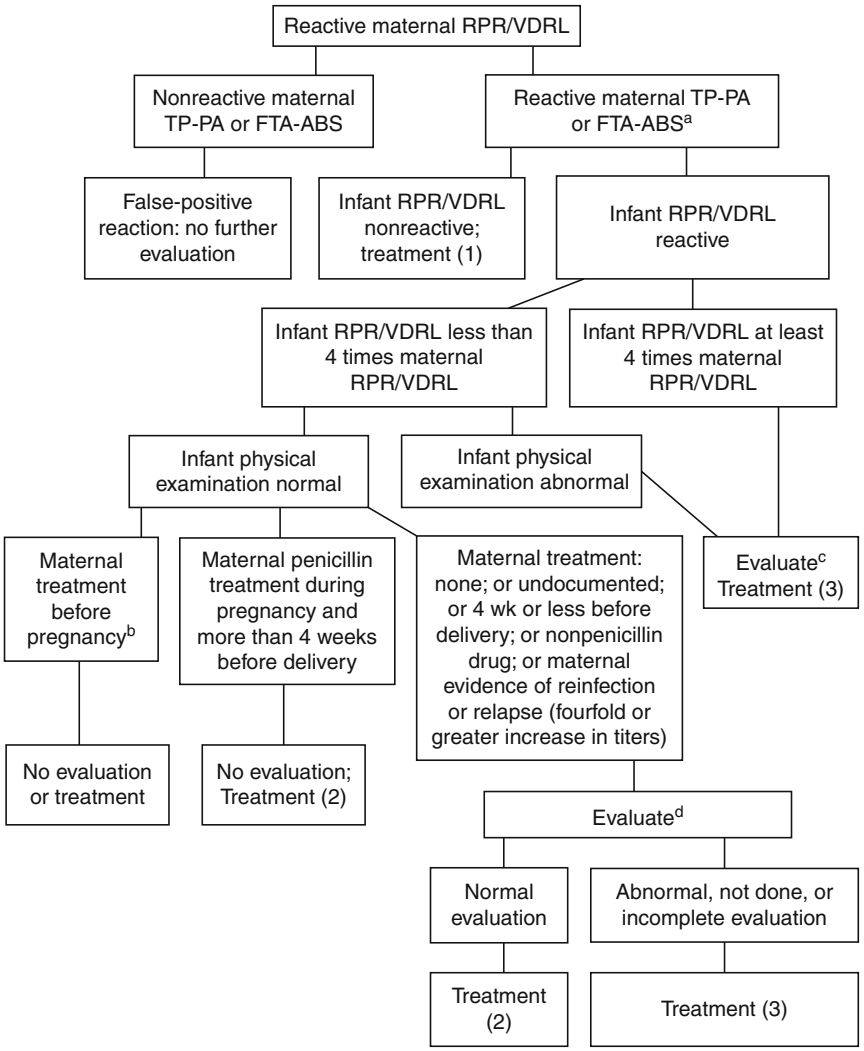
Prevention

The complications of untreated congenital syphilis can be avoided by optimal identification and treatment of patients at risk. Education regarding the benefits of syphilis screening and treatment and the importance of early prenatal care is important, as well as education about avoidance of high-risk sexual behaviors and the benefits of condom use. Case reporting to local public health agencies with investigation, testing, and treatment of all sexual contacts is important and effective at limiting spread of the disease. Confirmation of maternal serologic screening should be documented on all newborn infants before discharge from the hospital. With due diligence and appropriate resources, the significant burden of congenital syphilis could be drastically reduced.

Parvovirus B19

Etiology/Epidemiology

Parvovirus B19 has worldwide distribution and humans are its only known host. It replicates exclusively in erythroid precursors through recognition of its receptor, the P-antigen. Infections peak in late winter/early spring and epidemics tend to occur every 4 years. It is transmitted by contact with infected respiratory secretions or through blood products. Seroprevalence increases with increasing age; ranging from 2% to 15% in children under age 5, 15–60% at ages 6–19, 30–60% in adults and>90% among the elderly. Women of childbearing age are seronegative about 40% of the time. When infection occurs during pregnancy,



RPR indicates rapid plasma reagin (test); VDRL, Venereal Disease Research Laboratory (test); TP-PA, *Treponema pallidum* particle agglutination (test); FTA-ABS, fluorescent treponema antibody absorption (test).

[a]Test for human immunodeficiency virus (HIV) antibody. Infants of HIV-infected mothers do not require different evaluation or treatment.

[b]Women who maintain a VDRL titer 1:2 or less (RPR 1:4 or less) beyond 1 year after successful treatment are considered serofast.

[c]Evaluation consists of complete blood cell (CBC) and platelet count; cerebrospinal fluid (CSF) examination for cell count, protein, and quantitative VDRL. Other tests as clinically indicated; long-bone and chest radiographs, neuroimaging, auditory brainstem response, eye examination, liver function tests.

[d]CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL; long-bone radiography.

TREATMENT:

(1) If the mother has had no treatment, undocumented treatment, treatment 4 weeks or less before delivery or evidence of reinfection or relapse (fourfold or greater increase in titers) AND the infant's physical examination is normal, THEN treat infant with a single intramuscular (IM) injection of benzathine penicillin (50 000 U/kg). If these criteria are not met, no treatment is required. In both scenarios, no additional evaluation is needed.

(2) Benzathine penicillin G, 50 000 U/kg, IM 1 dose.

(3) Aqueous penicillin G, 50 000 U/kg, IV, every 12 hours (1 week of age or younger), every 8 hours (older than 1 week), or procaine penicillin G, 50 000 U/kg, IM, single daily dose, 10 days.

Figure 27.1

Algorithm for evaluation and treatment of infants born to mothers with reactive serologic tests for syphilis. transmission to the fetus occurs in one-third to one-half of cases, and estimates of adverse fetal outcome are 10%.

Clinical Manifestations

Infection with parvovirus B19 can be asymptomatic but classically causes "Fifth Disease" or erythema infectiosum, characterized by mild malaise with or without fever and a subsequent facial rash with a "slapped cheek" appearance and circumoral pallor. A diffuse maculopapular, pruritic rash may also occur. Arthralgia and arthritis occur uncommonly in children but are much more common in adults and especially women. Infection during pregnancy places the fetus at risk for infection, with the greatest risk associated with the first half of pregnancy. The overall risk of hydrops is 4% in the setting of maternal infection during pregnancy. The maximum risk is when infection occurs between 13 and 20 weeks gestation and is estimated to be 7%. Infection of the fetus can result in a lytic infection of fetal erythrocyte precursors that leads to anemia. When anemia is severe, high output cardiac failure can occur, leading to nonimmune hydrops fetalis and ultimately intrauterine fetal death. Infection of the fetus has not been associated with specific congenital anomalies. In the setting of fetal hydrops, a maternal condition termed "mirror syndrome" can also develop that is similar to preeclampsia and manifests with hypertension, proteinuria, edema, and anemia.

Diagnosis

In the setting of exposure to parvovirus B19 in a pregnant woman, serologic testing is a sensitive and specific means to diagnose new infection. Parvovirus B19-specific IgM can be detected 7–10 days after infection and rapidly decreases by 2–3 months after infection. IgG antibodies are detected later and rise more slowly. When IgM titers exceed that of IgG, recent infection is likely and the fetus should be closely monitored for signs of anemia. Because of the delay in detectable IgM, if the contact is too recent diagnosis can be missed. Likewise, because of the delay between maternal infection and the development of hydrops, a negative or low IgM does not exclude parvovirus infection as the etiology. Serological testing of fetal or infant blood is much less reliable, and confirmation of infection should be confirmed by PCR based methods. Cell culture methods for parvovirus B19 are not currently available. When a fetus is determined to be at risk for congenital infection, regular ultrasound examination should be undertaken to look for signs of fetal anemia and hydrops. Because of the low viscosity and high cardiac output that accompanies anemia, changes in middle cerebral artery peak systolic velocity are detectable by Doppler examination and provide a sensitive method to diagnose fetal anemia. Hydrops can be detected by abnormal fluid accumulation in two or more fetal body compartments. In the setting of anemia, the first changes notable are ascites and thickening of the fetal heart. Pericardial effusion, skin edema, and placental edema will ensue if untreated.

Treatment

Intrauterine fetal transfusion is the mainstay of therapy in the setting of severe fetal anemia and hydrops. Unlike immune-mediated hemolytic anemia, a single transfusion is usually sufficient for fetal recovery. The precise indication and timing for intervention is somewhat controversial, based in part on reports of spontaneous resolution of symptoms in the setting of fetal anemia and even hydrops. Most clinicians use the results of hemoglobin level on percutaneous umbilical blood sampling to guide their decision regarding transfusion. The prognosis for infants surviving fetal anemia and or hydrops after intrauterine transfusion is generally quite favorable.

Prevention

Avoiding exposure to parvovirus B19 is complicated by the fact that many cases are asymptomatic, and among those that develop symptoms, infectivity precedes the development of symptoms attributable to the virus. Women who are exposed to children at home or at work are at increased risk of exposure, but community outbreaks generally coincide with these exposures and further complicate measures to avoid infection. Pregnant women who are known to be seronegative can be educated about the risk of infection and general means to decrease that risk through frequent hand washing and avoidance of sick contacts, but these measures may have limited efficacy for this particular virus. Pregnant women with known exposure can be counseled about the relatively low potential risk of infection and serologic testing offered with ultrasound monitoring as indicated. Candidate vaccines have also been described, but the relative infrequency of severe intrauterine infection casts doubt on the cost-effectiveness of immunization strategies on a population basis.

Varicella

Etiology/Epidemiology

Varicella zoster virus (VZV) is a member of the herpesvirus group and is present throughout the world. Like other herpes viruses, primary infection is followed by latent infection that can reactivate at a later time. Primary infection with VZV is recognized clinically as varicella (chicken pox), and reactivation leads to herpes zoster. The virus is transmitted through respiratory droplets or direct contact with skin lesions. Because the virus is highly infectious, childhood acquisition is common and most individuals acquire immunity by adulthood. An effective vaccine against VZV has been available since 1995, and has dramatically reduced rates of natural infection with this virus while maintaining high levels of immunity in areas with effective vaccination programs. There is considerable geographic variation in VZV incidence. In temperate climates, infections peak in winter and spring and >90% of children become infected by age 15. In tropical climates, the infections tend to occur less frequently and therefore at an older age. The majority of infections lead to benign, self-limited illness, but pregnant women and newborn infants are at considerably higher risk for complications from this disease. Because rates of immunity are very high among adults in most populations, infection during pregnancy is fortunately uncommon.

Clinical Manifestations

Primary infection with VZV generally manifests with prodromal flu-like symptoms in approximately 50% of older children and adults and less frequently in young children. The prodrome is followed by a characteristic vesicular rash ("dew drops on a rose petal") that can be diffuse and is intensely pruritic. Complications of varicella are more common in adults than children and pregnant women are at higher risk. Varicella pneumonia is the complication that leads to the majority of morbidity and mortality. Mortality rates of 20–45% have been reported, but these rates have been significantly reduced with current respiratory care and antiviral agents. Infection during pregnancy can also lead to infection of the fetus, and like many infections, the timing during pregnancy determines the likelihood of adverse outcomes for the infant. Spontaneous abortion, intrauterine fetal demise, and premature birth have all been reported in the setting of varicella in pregnancy, but these complications are rare. Likewise, the majority of infants born to mothers with varicella during pregnancy are healthy, although some have been reported to have zoster in infancy. Congenital varicella syndrome (CVS) is an uncommon complication that occurs primarily in infants whose mothers had varicella in the first half of pregnancy, with the highest risk between 13 and 20 weeks gestation, but the overall incidence is approximately 1%. The primary manifestations of CVS involve the central nervous system (CNS) including the eye, the musculoskeletal system, and the skin. CNS manifestations include microcephaly, cortical atrophy, seizures, and cognitive impairment. Autonomic dysfunction is also seen, leading to esophageal dilation, severe reflux and aspiration pneumonia. Horner syndrome, neurogenic bladder and hydroureter are other autonomic manifestations. Cataracts, chorioretinitis, ptosis, microophthalmia, and nystagmus are typical eye findings. Hypoplasia of limbs, muscle, and digits can occur and cicatricial lesions or cutaneous defects are skin findings. The prognosis of CVS is poor.

A more common severe manifestation of varicella exposure during pregnancy results from acquisition in the perinatal period. The highest risk period for the infant is when maternal infection occurs within 5 days prior to delivery to 2 days after delivery. The basis for severity in this window is that there is insufficient time for protective maternal IgG to be generated and transferred to the fetus. Estimated rates of perinatal infection range from 17% to 30% with a risk of mortality of up to 30% in those infected. The availability of varicella zoster immune globulin (VZIG) has improved these outcomes (see Treatment). Infants with perinatal varicella are generally well appearing at birth and subsequently develop the characteristic rash. Because of their impaired immune status and the absence of maternal protective antibody, disseminated viral infection can occur with significant end-organ damage. Pneumonia, hepatitis with coagulopathy and liver failure, encephalitis, and thrombocytopenia are typical.

Diagnosis

The diagnosis of varicella infection during pregnancy can often be made on clinical grounds with a history of exposure and development of the characteristic rash. Laboratory tests are also available for confirmation when necessary. Vesicles contain abundant virus, which can be unroofed and scraped for culture or direct staining. Antibodies are available for direct fluorescent antigen staining of scrapings from lesions which has high sensitivity and specificity. VZV PCR tests are also available and offer even

higher sensitivity. Culture is highly specific but less sensitive and requires more time for results. Unlike many of the other infections in pregnancy, there is very little role for serologic testing in varicella. Serial ultrasound examination of the fetus after maternal varicella can be used to detect evidence of CVS. Amniotic fluid testing is of limited value, because detection of VZV DNA by PCR in amniotic fluid is not indicative of whether active fetal infection has occurred and has a poor predictive value for fetal disease or disease severity.

Treatment

Acyclovir and valacyclovir are antiviral agents with activity against varicella and other herpes viruses. The United States Food and Drug Administration has designated acyclovir as a category B drug in pregnancy. In the setting of uncomplicated varicella in pregnancy, some experts recommend oral acyclovir treatment, particularly in the second and third trimester when the risk of the drug to the fetus is likely to be low but the risk of maternal complications is higher. IV therapy is recommended should any signs of pneumonia develop. Acyclovir should also be given to any infant with signs of perinatal varicella infection, and must be given IV secondary to poor oral bioavailability.

Passive immunization with immune globulin preparations is also an effective strategy for prevention of severe sequelae. VariZIG is an immunoglobulin preparation with high titers of varicella-specific antibody and can be administered IM. IV immune globulin (IVIG) preparations also contain varicella-specific antibody and are an acceptable substitute, but must be administered IV. If a varicella-susceptible pregnant woman has close contact with an infected person, prophylaxis should be administered within 72–96 h of exposure. Infants born to women who develop varicella infection in the perinatal period should also receive passive immunization with VariZIG or IVIG if VariZIG is unavailable. They should also be monitored closely for any signs of varicella infection and treated with IV acyclovir promptly if signs are detected.

Prevention

The availability of a VZV vaccine has significantly altered the epidemiology of these infections. Ideally, the immune status of women should be determined before pregnancy. A history of disease or receiving two doses of varicella vaccine is indicative of immunity. If neither is present, VZV IgG testing can be performed and vaccination offered if negative. Because it is a live vaccine, immunization during pregnancy is contraindicated because of the theoretical risk of adverse effects on the fetus. However, there have been no reports of congenital varicella in infants whose mothers were inadvertently exposed to vaccine during or immediately prior to pregnancy. Vaccination is safe in the immediate postpartum period and breast feeding is not a contraindication.

Hepatitis B

Etiology/Epidemiology

The hepatitis B virus (HBV) is distributed worldwide and can lead to acute hepatitis that is sometimes fulminant, chronic hepatitis, liver cirrhosis, or liver cancer. It is transmitted efficiently through blood and body fluids, and exposure to infected maternal blood during delivery is a highly efficient route of transmission. Those with chronic HBV infection are the primary source of new infections, and the prevalence varies dramatically by region. Prevalence is as high as 10–20% in Asia, Africa, and Southern Europe, while North America and Northern Europe have a prevalence of approximately 0.1%. In areas where prevalence is high, the majority of new infections occur in infancy, whereas in places with lower prevalence, transmission occurs primarily in adolescents and adults through high risk sexual or drug abuse behaviors or among health-care workers. Implementation of vaccination programs has successfully reduced the transmission rates, particularly in the perinatal period, and therefore prevalence is decreasing.

Clinical Manifestations

Acute infection with HBV can be symptomatic or asymptomatic. Asymptomatic infection is more common in younger people, but even in older children and adults acute infection is accompanied by symptoms only 30–50% of the time. Symptoms can be nonspecific and mild such as anorexia and malaise, but can also include clinically apparent hepatitis and jaundice or fulminant hepatitis. The risk of developing chronic HBV infection, marked by the persistence of hepatitis B surface antigen (HBsAg), varies markedly based on the age of acquisition. When infants are infected perinatally, more than 90% will develop chronic infection. Children infected between 1 and 5 years of age progress to chronic infection 25–50% of the time, whereas the rate

is 2–6% in older children and adults. Hepatitis B e antigen (HBeAg) is a marker for active viral replication, and patients who are HBeAg-positive generally have high levels of HBV DNA is their serum. These patients are more likely to transmit infection. In fact, in the absence of prophylaxis, the risk of perinatal transmission in a mother who is HBsAg and HBeAg positive is estimated at 70–90%, whereas the risk in a mother who is positive for only HBsAg is 5–20%. Intrauterine transmission has also been documented to occur, but is fairly uncommon. The majority of perinatally acquired HBV remains asymptomatic, however infants can develop fulminant hepatitis between 6 weeks and 6 months of age. This clinical course occurs most commonly in infants infected from HBsAg-positive, HBeAg-negative mothers, and the mortality is high in this setting (approximately 67%). Among infants and children that acquire chronic infection with HBV, an estimated 25% will develop hepatocellular carcinoma or cirrhosis later in life.

Diagnosis

Tests for HBV-specific antigens and antibodies are commercially available, including HBsAg, HBeAg, anti-HBs, anti-HBe, and anti-hepatitis B core antigen (anti-HBc). Molecular methods are also available to detect HBV DNA. HBsAg is detectable in acute and chronic infection, and is also the antigen used in HBV vaccine. Anti-HBs is seen in both resolved infection and in vaccine recipients. Anti-HBc is present in acute, chronic, and resolved infections, but not in vaccine recipients. Detection of HBeAg is indicative of a higher risk of transmitting the virus, whereas presence of anti-HBe is associated with lower risk. Tests for HBeAg and HBV DNA can guide the use of antiviral therapy and monitor response to treatment.

Treatment

Agents that are used to treat HBV include interferon-α and the nucleoside analogue, lamivudine. Treatment is not recommended in infants during the neonatal period or in children with chronic infection and normal transaminase levels.

Prevention

Immunization is a safe and very effective strategy for preventing HBV infection and has been an area of focus for the World Health Organization. HBV immunization had been integrated into the Expanded Program of Immunization in 155 countries by 2005, leading to a current coverage rate of approximately 50% of newborn infants worldwide. Infection rates are low and continue to decrease in countries where implementation of vaccination programs has led to near universal coverage. Immunoprophylaxis at birth achieves the primary goal of decreasing prevalence of chronic HBV-infection and related chronic liver disease as well as decreasing acute HBV infection. HBV immune globulin (HBIG) provides passive immunity for 3–6 months, while HBV vaccine can prevent perinatal infection in many and provides lifelong immunity. There are several strategies for prophylaxis that are used throughout the world, depending on the incidence and resources available. In Taiwan, where prevalence is historically high, pregnant women are screened for HBsAg and HBeAg. Infants born to mothers positive for both receive HBIG, while all infants receive the HBV vaccine series initiated shortly after birth. In the USA, a similar strategy is employed, except that screening for HBsAg only is performed during pregnancy, and HBIG is given regardless of HBeAg status. Finally, some countries with fewer resources and/or low prevalence have no maternal screening program and use the vaccine series starting at birth only. The vaccine should be administered within 12 h of birth for maximum efficacy. The combination of HBV vaccine and HBIG in exposed infants is highly effective at preventing transmission. Efficacy for vaccine only without HBIG has also been demonstrated, albeit to a more modest degree.

Human Immunodeficiency Virus (HIV)

Etiology/Epidemiology

Two types of human immunodeficiency virus (HIV), HIV-1 and HIV-2, cause disease in humans. These RNA-containing retroviruses undergo reverse transcription of their genome to double-stranded DNA followed by incorporation into the host genome where it persists as a provirus. Persistent virus has been detected in peripheral blood mononuclear cells, as well as in the brain, bone marrow, and genital tract. Transmission of infection has been documented through exposure to blood, semen, cervicovaginal secretions, and breast milk. Of all the infectious agents discussed in this chapter, vertical transmission of HIV to newborn infants is by far the most common neonatal infection with severe consequences worldwide. In 2008, an estimated 1,200 children became infected with HIV daily. Children account for 14% of new infections with HIV globally and nearly 20% of annual

deaths from AIDS. The tragedy in these data is that vertical transmission of HIV is almost entirely preventable with current prophylactic strategies. In countries with adequate resources, the rate of new HIV infections in children continues to decline, with an estimated 300 cases in Western and Central Europe in 2005. Likewise, the estimated number of perinatally acquired infections in the United States is 141 in 2008, among the 37 states with HIV reporting.

Clinical Manifestations

Transmission of HIV from mother to infant can occur in utero, at delivery, or postnatally through breast feeding. Estimated rates of transmission from an HIV-positive mother to her infant in the absence of preventive measures range from 12% to 40%. Less than half of the transmission is believed to occur in utero, and may occur through infection of the placenta or exposure to virus in amniotic fluid. Infection in the perinatal period is the most common and can occur through exposure to maternal blood during labor and delivery or ascending infection from the genital tract to the amniotic fluid surrounding membrane rupture. The most relevant predictor of risk for perinatal transmission is maternal viral load. Primary HIV acquisition during the third trimester of pregnancy is particularly high risk, because viral load is high in this setting with insufficient time to generate an immune response that could protect the fetus. Other risk factors for transmission include prolonged membrane rupture, vaginal delivery, cervicovaginal viral load, low maternal $CD4^+$ T-lymphocyte count, advanced maternal disease, chorioamnionitis, prolonged labor, and prematurity. Postnatal transmission through breast feeding is also well documented and is estimated to account for 30–50% of transmission to infants worldwide.

In the absence of treatment, manifestations of perinatally acquired HIV infection generally occur within 12–18 months of age, but the distribution is bimodal with both rapid and slow progression. Approximately 20% of infants develop symptoms early and die before the age of 4 with a medium age of death at 11 months. The remainder have much slower disease progression, remaining asymptomatic for 5 years or more. Early manifestations can be nonspecific and include fever, lymphadenopathy, hepatosplenomegaly, hepatitis, recurrent diarrhea, failure to thrive, parotitis, or recurrent invasive or opportunistic infections. Multiple infectious agents and malignancies have been described. The natural history of the disease has been substantially modified by current therapeutic strategies.

Diagnosis

Serologic and nucleic acid detection based tests are available for the diagnosis of HIV infection. Because infants born to seropositive mothers will acquire maternal antibody, serological tests are not useful in the newborn period and are generally not recommended until after 18 months of age. The HIV-1 DNA PCR test is widely used in infancy and has excellent sensitivity and specificity. A positive result before 48 h of age occurs in 30–40% of infected infants and generally signifies in utero transmission. By 2 weeks of age, 93% of infected infants are positive and by 1 month of age, 95% are positive. Diagnostic testing is recommended in infants born to HIV-positive mothers at 14–21 days of age, and if negative, repeated at 1–2 months and again at 4–6 months. Some experts recommend testing within the first 48 h as well. An infant is considered infected in the setting of two separate positive tests. In non-breast-feeding infants less than 18 months of age, infection is considered to be excluded with (1) at least two negative nucleic acid tests obtained after 1 month of age with at least one obtained after 4 months of age, (2) at least two negative HIV antibody tests obtained at 6 months of age and older, and (3) no other laboratory or clinical evidence of HIV infection.

Enzyme immunoassays (EIA) are the most widely used tests for HIV antibody testing. They have high sensitivity and specificity, but confirmation of a positive test by Western blot is required. Rapid tests that can provide results within 20 min are also available and are used primarily to screen mothers of unknown HIV status when in labor. Confirmation is still required. Because identification and prophylactic treatment of HIV-positive women is so effective at reducing perinatal transmission, some areas have implemented universal screening algorithms for pregnant women. In these scenarios, HIV testing is routinely recommended to pregnant women when they present for prenatal care on an "opt-out" basis. In the setting of presentation in labor in the absence of prenatal care, rapid testing is performed on the mother at presentation. Should maternal testing be declined, universal testing of the infant at delivery is then performed. In areas where this strategy has been implemented, screening rates during pregnancy have risen dramatically, with the expected drop in perinatal transmission rates.

Treatment

Treatment of patients infected with HIV is an area of active investigation and as such is rapidly evolving. Involvement

of experts in pediatric HIV disease is strongly recommended to ensure that patients receive the maximum benefit from treatment. Current US treatment recommendations are available online at http://aidsinfo.nih.gov. The use of highly active antiretroviral therapy (HAART) began in 1996 and has been associated with marked improvement in survival and quality of life in patients infected with HIV. Multiple categories of drugs are available that target various aspects of the viral infectious cycle. The categories include Nucleoside Reverse Transcriptase Inhibitors (NRTIs), Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs), Protease Inhibitors (PIs), Fusion Inhibitors, Entry Inhibitors, and HIV Integrase Strand Transfer Inhibitors. The goals of therapy are to suppress viral replication, preserve immune function, reduce morbidity and mortality, maintain normal growth and development, and improve quality of life, while minimizing drug toxicity. Although indications for antiretroviral (ARV) therapy vary based on clinical status in older children, HIV-infected neonates should receive therapy regardless of symptoms or status, because of the risk of rapid disease progression in these patients. In general, at least three drugs are included when ARV therapy is initiated, most often including two NRTIs plus either a PI or a NNRTI. Viral genotyping can be used to assess resistance to ARV agents and guide therapy.

Prevention

As mentioned above, screening for HIV infection during pregnancy with application of prophylactic measures and modified obstetrical practices has dramatically reduced the rates of perinatal HIV transmission in resource-rich countries. This reduction has come about primarily through optimizing ARV therapy during pregnancy, complete avoidance of breast feeding, and planned cesarean section prior to onset of labor and membrane rupture. The first documentation of the success of ARV therapy in prevention of perinatal transmission came from a study in which zidovudine (AZT) was given to HIV-positive pregnant women beginning at 14–34 weeks' gestation and continued for the remainder of pregnancy, given IV during labor until delivery, and then given orally to the infant for the first 6 weeks. Perinatal transmission was reduced by two-thirds in this study. Currently in the United States, most HIV-positive pregnant women receive combination ART, as there is some suggestion that this approach is more effective than AZT alone. Many questions related to the optimal type, timing, and duration of HAART in pregnancy, the potential for toxicity to exposed infants, as well as the best prophylaxis strategies for these infants remain and are the target of ongoing investigation. AZT is then given with the ART drugs during labor and delivery, and the infants receive 6 weeks of therapy. From an obstetrical standpoint, any procedure that is likely to increase exposure of the infant to maternal blood or secretions (instrumented delivery, scalp electrodes, episiotomy, etc.) should be avoided. Delivery by cesarean section prior to labor or rupture of membranes is recommended for women with plasma viral loads greater than 1,000 copies/ml or those with unknown viral loads at term. The baby should be bathed promptly and postnatal prophylaxis should begin within 12 h. Breast feeding is associated with approximately double the risk of HIV transmission, and the risk persists as long as breast feeding continues. These findings are the basis for the recommendation that breast feeding is contraindicated in countries where alternative feeding methods are available that are safe, affordable, and culturally acceptable. In countries where alternatives are not available that meet these criteria, exclusive breast feeding is recommended for 6 months, with introduction of supplemental food sources after 6 months. Given the dramatic potential to reduce perinatal transmission and therefore overall disease burden using preventive strategies, successful implementation of these strategies in resource-poor countries would have a profound impact on world health.

Neonatal Sepsis

Etiology/Epidemiology

Current estimates indicate that infections cause approximately a third of the four million neonatal deaths each year worldwide. Although the most robust epidemiologic data have come from studies in industrialized countries, by far the highest burden of neonatal sepsis is in the developing world, particularly in South Asia and sub-Saharan Africa. Precise knowledge of the true disease burden in these regions is very difficult to quantify on a population basis because many deliveries occur outside of health-care facilities and reporting is limited. Irrespective of these difficulties in epidemiological assessments, however, the global burden of neonatal sepsis is tremendous and strategies to reduce its impact are clearly needed.

Neonatal sepsis is conceptually divided into two categories based on timing of infection after birth, but the definitions are somewhat varied in the literature. Early-onset disease generally occurs within the first 72 h after birth, although the first 7 days has been used as a cutoff in

some studies, particularly with Group B *Streptococcus* (GBS). Late-onset disease is therefore defined as sepsis occurring after day 4 or day 8, through day 28. Infections after day 28 are sometimes also considered late-onset neonatal sepsis, particularly in neonatal intensive care units caring for premature infants who have not yet attained a post-menstrual age of 44 weeks. The distinction between early-onset and late-onset sepsis is useful because it reflects differences in acquisition and risk factors. Early-onset sepsis is generally caused by pathogens to which the infant is exposed during delivery and is associated with maternal risk factors, while late-onset disease is generally from a hospital or community acquired pathogen.

The organisms associated with early-onset neonatal sepsis vary over time and also by region. *Streptococcus pneumoniae* and Group A *Streptococcus* were prevalent in the United States in the 1930s and 1940s. These have sharply declined in incidence, being largely replaced in recent years by GBS and *Escherichia coli*. Sepsis caused by *Listeria monocytogenes* is considerably less common, but is also unique to the neonatal period and seems to be predominant in developed countries. This is primarily an early-onset pathogen, but is also less commonly associated with late-onset sepsis and/or meningitis. Although data on etiologic agents in developing countries are more limited because of challenges in methodology, GBS sepsis seems to be less prevalent in these areas for reasons that are not well understood, whereas *Klebsiella* species and *Staphylococcus aureus* appear to be more common. Late-onset sepsis is associated with many of the same organisms, but coagulase-negative *Staphylococcus* becomes increasingly prevalent in this setting, particularly in premature infants. Generally speaking, infections with Gram-positive organisms are most common in premature infants and are not associated with increased mortality. Gram-negative infections are less frequent than Gram-positive infections in this population, but fulminant infections with high mortality are considerably more common with these organisms. Infections with *Pseudomonas* sp. are well known to have a frequently fulminant course with high mortality.

Premature infants are also uniquely susceptible to disseminated fungal infection. The vast majority of these are with *Candida* species. These infections are the second most common cause of infection-related death in extremely low birth weight infants and are associated with high rates of neurodevelopmental impairment among survivors. The susceptibility of these patients to *Candida* infections relates to their immature immune system as well as to well-described risk factors including the use of third-generation cephalosporins and foreign bodies such as central venous catheters and endotracheal tubes. Rates of invasive candidiasis differ dramatically among centers throughout the world. Centers with high incidence have successfully reduced their rates of invasive disease by instituting prophylaxis of at-risk infants with fluconazole. Widespread application of this strategy, particularly where rates of disease are low, is controversial secondary to concerns of increased drug resistance.

Other infectious complications rarely seen in resource-rich settings are also problematic in developing nations. Neonatal tetanus occurs in areas where maternal tetanus vaccination is not universal and hygienic practices surrounding labor and delivery are suboptimal. Estimates from the WHO indicate that 180,000 neonatal deaths were attributable to tetanus in 2002. Infections of the umbilical cord (omphalitis) can lead to peritonitis and bacteremia, but these infections are also uncommon in settings with clean cord care and hygienic birth practices. Estimates of rates of omphalitis in resource-poor settings range from 55 to 197 cases per 1,000 live births where cord care is not optimal, such as the common use of unsterile instruments to cut or tie the cord. Mortality from omphalitis has been reported as high as 15%.

Clinical Manifestations

The term "sepsis" as applied to neonates is essentially a set of nonspecific clinical features characteristic of disseminated bacterial infections, including temperature instability (fever or hypothermia), lethargy, irritability, poor feeding, apnea, respiratory distress, vomiting, and jaundice. These features overlap with other conditions such as encephalopathy from noninfectious causes and prematurity, making accurate estimates of sepsis rates due to bacterial infection difficult, particularly in areas that lack sophisticated microbiology laboratories. The strictest definition of sepsis includes the presence of blood culture documented bacteremia. These infections may also be accompanied by pneumonia, meningitis, and urinary tract infections. Because positive cultures of cerebrospinal fluid have been well documented in the setting of negative blood cultures, including a lumbar puncture in the evaluation for presumed sepsis is encouraged. However, since meningitis is more common with late-onset disease, a lumbar puncture is sometimes not included in sepsis evaluations performed shortly after birth, although this practice is controversial and subject to ongoing debate. Similarly, urine cultures are often omitted in early sepsis evaluations. Pneumonia should be considered in infants with respiratory symptoms such as grunting, tachypnea, nasal flaring, retractions, and hypoxemia. However, many

of these signs are also present in the setting of sepsis, and radiographic findings are likewise nonspecific.

Factors that increase the risk for sepsis in neonates are well established. For early-onset disease, many of these risk factors are maternal, including chorioamnionitis, maternal fever, prolonged rupture of membranes, and bacteriuria during pregnancy. Prematurity and low birth weight also increase risk. For late-onset disease, low birth weight, prematurity, mechanical ventilation, use of central venous catheters and total parenteral nutrition all increase risk. Rates of late-onset sepsis increase dramatically as birth weight decreases below 1000 g. These factors should be considered in the evaluation of symptoms potentially attributable to sepsis.

Diagnosis

Although a positive blood culture is considered the gold standard for diagnosis, even where laboratories are available blood cultures are relatively insensitive. Maternal treatment with antibiotics likely reduces the utility of blood cultures, and the amount of blood that can be sampled in neonates further limits sensitivity of the test. As mentioned above, cultures of cerebrospinal fluid are quite useful and should be obtained. Urine cultures are also recommended, but should be obtained in a sterile fashion; either by clean catheterization or suprapubic aspiration from the bladder. Adjunctive laboratory tests are also frequently obtained to aid in the diagnosis of sepsis in a symptomatic infant or when maternal risk factors are present. These include complete blood count, platelet count, absolute neutrophil count, calculation of the immature to total neutrophil ratio, C-reactive protein, and erythrocyte sedimentation rate. Although routinely obtained, these tests lack positive predictive value. The negative predictive value of normal results is considerably better and can be reassuring. In the absence of laboratory tests that are completely sensitive and reliable in distinguishing symptoms attributable to sepsis from other etiologies, many infants are treated with extended courses of antibiotics in the absence of positive cultures. Although this practice results in antibiotic use that may not be needed, the clinician must weigh the risk of therapy against the risk of a poor outcome due to an undetected and untreated infection.

Treatment

Because of the nonspecific symptoms and potential difficulties in establishing a diagnosis, recognition and treatment of neonatal sepsis requires a high index of suspicion. Empiric treatment is frequently indicated in the setting of risk factors and/or signs of infection. However, antibiotic use is far more prevalent than culture-proven neonatal sepsis due to this same combination of factors. The most common choice for empiric therapy is ampicillin and an aminoglycoside. This combination is efficacious against both Gram-positive and Gram-negative organisms and covers the most common etiologic agents. In late-onset disease, substitution of an agent with better staphylococcal activity for ampicillin such as oxacillin or vancomycin is recommended by some. However, such recommendations are controversial from an antibiotic stewardship point of view as resistance continues to emerge and become increasingly problematic worldwide. When candidiasis is suspected or confirmed, amphotericin B is recommended as first line therapy in the neonate. In any case, empiric antibiotic therapy should be based on the local epidemiology of common causative organisms and appropriately tailored to the organism involved when positive blood cultures are available to guide therapy.

Prevention

Strategies to prevent neonatal sepsis begin in the prenatal period and extend through labor, delivery, and postpartum care of the infant. Routine prenatal care is common in developed countries and can have a positive impact on infections in the newborn. Screening for and treatment of maternal sexually transmitted infections, urinary tract infections or asymptomatic bacteriuria, and administration of tetanus vaccine can mitigate risk of infection in the newborn. Delivery in a setting that allows a skilled attendant to be present and provide hygienic birth practices further reduces risk. Antibiotic treatment for preterm prolonged rupture of membranes as well as for maternal chorioamnionitis may reduce neonatal sepsis by as much as a third. In the postnatal period, the benefits of exclusive breast feeding in preventing infection are well established. The inexpensive and practical intervention of increasing breast feeding rates could provide an extremely cost-effective and far-reaching impact on neonatal infection rates. Ensuring good hand hygiene and the availability of clean water with sanitary disposal of waste are additional interventions that reduce disease burden. For preterm infants, many of these same strategies are important. Strict adherence to routine hand washing procedures is well documented to effectively reduce late-onset sepsis in premature infants. Additionally, utilization of best practices for placement and maintenance of central venous catheters while minimizing their use as much as possible is an important means to reduce one of the most important risk factors

for sepsis. Early introduction of enteral feedings and provision of breast milk are also well-established interventions that reduce infection rates. Evidence is also accumulating that provision of "kangaroo care," including frequent if not exclusive skin-to-skin contact with the mother and frequent breast feeding has a number of benefits for the preterm infant including lower infection risk.

Early-onset GBS sepsis is the best example demonstrating the potential for well-designed preventive strategies to decrease rates of neonatal sepsis. In the United States, GBS emerged as the leading cause of early-onset sepsis in the 1970s. Approximately 10–30% of women are colonized with GBS in the vagina or rectum, and in the absence of intervention, 1–2% of infants born to these mothers will develop early-onset GBS infection. Consensus guidelines were developed by the Centers for Disease Control and Prevention, the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics in 1996 with revisions in 2002 and 2010. Current recommendations include universal screening for GBS colonization by recto-vaginal culture of all pregnant women at 35–37 weeks gestation. Colonized women should receive intrapartum antibiotic prophylaxis with penicillin or ampicillin. Women who have GBS bacteriuria at any point during pregnancy or those with a previous infant with invasive GBS disease should also receive intrapartum prophylaxis. Because GBS colonization occurs rarely in the absence of labor with intact membranes, prophylaxis is not recommended for those women who undergo cesarean section before onset of labor when membranes are intact. When GBS colonization status is uncertain, prophylaxis is recommended for those at highest risk, including prematurity (gestational age less than 37 weeks), rupture of membranes for 18 or more hours, or maternal temperature during labor greater than 38°C. Before preventive strategies were implemented, the early-onset GBS sepsis rate was estimated at 1.7 per 1,000 live births. In recent years, the rate has dropped 80% to 0.34 per 1,000 live births. Ongoing study and surveillance is utilized to identify barriers to compliance with guidelines, strategies to further reduce infection rates, and the potential emergence of other pathogens or altered resistance patterns in the era of widespread prophylaxis.

Conclusion

The human newborn is uniquely susceptible to a host of infectious pathogens that have a substantial impact on morbidity and mortality worldwide. Their risk is impacted by innumerable factors including the immaturity of their immune mechanisms; the general health and exposures of their mothers; the prenatal, intrapartum, and postnatal health-care practices where they are born; and the local economic resources available for treatment and prevention. Tremendous progress has been made in decreasing the impact of these infections, but a tremendous need for improvement remains on a global scale. Extending the best practices available to the regions with the least resources remains a major challenge of this century.

28 Common Endocrine Problems in Neonatology

Jose Bernardo Quintos

Congenital Adrenal Hyperplasia

Definition/classification: Congenital adrenal hyperplasia (CAH) is a family of autosomal recessive disorders of adrenal steroidogenesis characterized by impaired cortisol synthesis. CAH results from a deficiency of one of the enzymes necessary for normal steroid synthesis (Fig. 28.1). Ninety five percent of all CAH cases are caused by 21 hydroxylase deficiency. There are two forms of 21 hydroxylase deficiency: classic and nonclassic CAH (late onset). Classic CAH includes the salt-wasting form (cortisol deficiency and aldosterone deficiency) and simple virilizing form (cortisol deficiency without aldosterone deficiency). Patients with the classic form have severe enzyme deficiency and prenatal onset virilization while the nonclassic form patients have mild enzyme deficiency and postnatal hyperandrogenism and are not virilized at birth.

Etiology: The most common form of CAH is caused by mutations in CYP21A2, the gene encoding the adrenal steroid 21-hydroxylase enzyme (P450c21). The steroid 21-hydroxylase enzyme converts 17-hyrdroxyprogesterone (17-OHP) to 11-deoxycortisol and progesterone to deoxycorticosterone, which are precursors of cortisol and aldosterone, respectively. In 21-hyroxylase deficiency, there is deficient cortisol synthesis impairing cortisol-mediated negative feedback of ACTH secretion leading to accumulation of cortisol precursors that are shunted to the sex hormone (androgen) pathway.

Epidemiology: The incidence of CAH in the general population, as shown by newborn screening, ranges from 1 in 5,000 live births in Saudi Arabia to as low as 1 in 21,270 live births in New Zealand. The newborn screening incidence in the United States and Canada is 1 in 14,203 live births, Brazil 1 in 1,863 live births, Japan 1 in 18,827. A high frequency of CAH exists among Yupik Eskimos from western Alaska at 1 in 282 live births.

Clinical Manifestations: The cardinal feature of classic CAH in newborn females is ambiguous genitalia (Fig. 28.2).

Neonates with classic salt-wasting CAH exhibit salt-wasting crisis during the first 1–3 weeks of life but it may occur as late as few months of age. This manifests as poor feeding, vomiting, loose stools, weak cry, failure to thrive, dehydration, and lethargy. The biochemical hallmark of salt-wasting crisis is hyponatremia, hyperkalemia, metabolic acidosis, and hypoglycemia. Without treatment, circulatory collapse, arrhythmias from hyperkalemia, and death may occur within days or weeks. In females with classic CAH, genital ambiguity ranging from clitoromegaly to complete virilization occurs while internal genitalia (uterus and fallopian tubes) are normal (Fig. 28.3). Boys with classic CAH do not manifest ambiguity at birth but can have subtle scrotal hyperpigmentation because of ACTH hypersecretion or phallic enlargement because of excessive adrenal androgens in utero. Postnatally in untreated boys and girls, excessive adrenal androgen secretion leads to rapid growth, bone age advancement, progressive penile or clitoral enlargement, and premature appearance of pubic hair, axillary or facial hair, and acne. Without treatment, early epiphyseal closure occurs and result in short adult height.

Diagnosis: CAH is the most common cause of ambiguous genitalia in the newborn period. The physician is obliged to make timely diagnosis to prevent sex misassignment and initiate immediate treatment to prevent salt-wasting crisis in the salt-wasting form of CAH. Karyotype will identify chromosomal sex and pelvic ultrasonography will help identify mullerian structures (ovaries and uterus). Consultation with an endocrinologist should be sought. Adrenal steroids should be measured by blood sample on day 2–3 of life. A markedly elevated level of 17-OHP in a virilized 46, XX female with nonpalpable gonads is most likely due to CAH. In affected females, androstenedione and testosterone levels are high. In males, testosterone is usually elevated because of minipuberty in the first 6 months of life and is thus not helpful. ACTH levels are high but are not needed for diagnosis. In salt-wasting CAH, plasma renin is elevated and serum aldosterone is inappropriately low for the renin level. Diagnosis of 21 hydroxylase deficiency

is most accurately established by measuring 17-hydroxyprogesterone before and 30 or 60 min after intravenous injection of 0.25 mg of Cosyntropin (ACTH1-24). Basal and 60 min 17-OHP are plotted on a nomogram and distinguish normal and patients with nonclassical and classical CAH.

Differential Diagnosis: The result of physical exam, karyotype, and adrenal steroids will narrow differential diagnosis into four categories: (1) chromosomal or gonadal disorders (e.g., 45X/46 XY), (2) 46, XX patients with adrenal insufficiency, (3) 46, XY patients with adrenal insufficiency, and (4) 46, XY patients without adrenal insufficiency with testosterone biosynthesis defect or action.

Treatment: Cortisol deficiency is treated with glucocorticoids. Glucocorticoid treatment also suppresses excessive adrenal androgens preventing rapid somatic growth and early epiphyseal fusion. Hydrocortisone tablets at a dose of 10–15 mg/m^2/day in 2–3 divided doses is the preferred treatment. Infants with CAH require higher doses 50 mg/m^2/day during the first few weeks of life to suppress ACTH hypersecretion. Patients with salt-wasting CAH require mineral corticoid replacement with Fludrocortisone 0.05–0.3 mg daily in 1–2 divided doses and Na CL supplementation 1–3 g/day. NaCL tablets are available and one tablet is equivalent to 17 meq of NaCL. Stress dosing (2-3X maintenance dose) is needed in febrile illness (>38.5°C), gastroenteritis with dehydration, surgery accompanied by general anesthesia, and major trauma. For infants, parenteral dose of Solucortef (Hydrocortisone sodium succinate) 25 mg IM or IV could be given for severe vomiting, diarrhea, surgical stress, or severe trauma. Surgery for significantly virilized females (urogenital sinus and severe clitoromegaly) is usually done between 2 and 6 months of age and performed by an experienced surgeon. The need for clitoral recession for severe clitoromegaly should be individualized and discussed with family.

Prognosis: Untreated salt-wasting CAH can lead to circulatory collapse, arrhythmia, and death. Untreated nonclassical and simple virilizing CAH can lead to excessive adrenal androgen secretion and cause rapid bone age advancement and ultimate short adult stature.

Prevention: Since CAH is common and potentially fatal, it is a disease that is ideal for newborn screening. As of 2009, all 50 states in the United States and 12 other countries screen for CAH. Early recognition and treatment can prevent morbidity and mortality. CAH is an autosomal recessive condition. If a mother has a previously affected child with CAH and is pregnant with the same father, the fetus has a one in four chance of having CAH. Prenatal treatment of 21 hydroxylase deficiency with dexamethasone has been used since 1984 to prevent virilization should the fetus be an affected female. Dexamethasone is preferred because it is not bound to cortisol binding globulin in the maternal blood, and the placenta which has 11β-hydroxysteroid dehydrogenase enzyme cannot metabolize dexamethasone the way it metabolizes hydrocortisone. Dexamethasone crosses the placenta from the mother to the fetus and suppresses ACTH secretion. Dexamethasone at a dose of 20 mcg/kg/day in three divided doses is administered to pregnant mother before 10 weeks gestation. Prenatal therapy is considered experimental and should be pursued through protocols approved by Institutional Review Boards at specialized centers.

Adrenal Insufficiency

Definition/classification: Adrenal insufficiency is divided into congenital forms or acquired. Congenital adrenal insufficiency consists of group of disorders including (1) defects of adrenal development; (2) hypothalamic or pituitary dysfunction leading to ACTH deficiency and adrenocortical insufficiency; (3) inborn defects of steroidogenesis; and (4) degenerative, metabolic, or immune disorders affecting the adrenal glands (which are rare conditions in the neonatal period).

Etiology

1. *Defects of adrenal development*: Cytomegalic Adrenal hypoplasia congenita. (SF-1 and DAX1 deficiency).
   (a) SF-1 Deficiency: Steroidogenic Factor-1 (SF-1, NR5A1) belong to the family of nuclear hormone receptor. SF-1 is a transcription factor required for adrenal and gonadal development. The classic phenotype of SF-1 loss of function gene mutation is 46 XY sex reversal (female internal and external genitalia, complete gonadal dysgenesis (streak gonads), and primary adrenal failure). Given that SF-1 is a key regulator of adrenal and reproductive development and function, other phenotype of SF1 mutation include 46 XX primary adrenal failure, 46 XY Disorder of Sex Development (DSD), hypospadias, anorchia, male factor infertility, and primary ovarian insufficiency in women.
   (b) DAX 1 deficiency: DAX1 (NROB1) Human mutation of DAX-1 (dosage sensitive sex reversal adrenal hypoplasia congenital (AHC), critical region on the X chromosome), causes the

cytomegalic form of AHC, the most common variant of congenital adrenal insufficiency. Male 46 XY patients with DAX1 mutations typically present with hypogonadotropic hypogonadism and adrenal insufficiency.

2. *Abnormal hypothalamic-pituitary development*: ACTH deficiency may be isolated or may be a part of multiple pituitary hormone deficiency (MPHD).
   (a) Isolated ACTH insufficiency due to TPIT mutations: Tpit is a T box transcription factor important for terminal differentiation of pituitary propiomelanocortin-expressing cells. Patients with loss of function Tpit mutations present with low cortisol with undetectable or inappropriately low ACTH level, neonatal hypoglycemia associated with seizures in half of the cases, cholestatic jaundice, and occasionally hepatomegaly. Symptoms of adrenal insufficiency as well as cholestatic jaundice disappear after hydrocortisone treatment.
   (b) Multiple pituitary hormone deficiency (MPHD): ACTH deficiency may be part of multiple pituitary hormone deficiency caused by abnormal hypothalamic-pituitary development caused by mutations in transcription factors HESX1, LHX4, SOX3, PROP1, and OTX2.

Figure 28.4
Baby boy with (a) cleft lip and palate associated with hypopituitarism; (b) micropenis associated with hypopituitarism

3. *Inborn defects of steroidogenesis*: The most common cause of adrenocortical insufficiency in infancy is the salt-wasting form of 21 hydroxylase deficiency. Almost 75% of 21 hydroxylase deficiency is due to salt losing form. Congenital lipoid adrenal hyperplasia (StAR deficiency) in newborns, a rare disorder due to mutations in steroidogenic acute regulatory protein (StAR) which is required for cholesterol delivery to the mitochondria, leads to inability to convert cholesterol to pregnenolone, preventing synthesis of all steroids (cortisol, aldosterone, and androgens). Genetic males present with normal female genitalia, signs and symptoms of adrenal insufficiency, and salt loss. Infants with deficiency of 3β-hydroxysteroid dehydrogenase manifest salt losing symptoms in the newborn period.
4. *Adrenoleukodystrophy*: Neonatal ALD is a rare autosomal recessive disorder associated with neonatal seizures, psychomotor retardation, developmental regression, and impaired adrenocortical function.

Clinical Manifestations: Clinical signs and symptoms of hypopituitarism in neonates include hypoglycemia, poor feeding, apnea, jitteriness, temperature instability, recurrent sepsis, prolonged jaundice, conjugated hyperbilirubinemia, lethargy, and electrolyte abnormalities (hyponatremia without hyperkalemia). Physical exam findings suggestive of hypopituitarism include micropenis, bilateral undescended testes, cleft lip and palate (◉ *Fig. 28.4*), nystagmus, anophthalmia, and microphthalmia.

Diagnosis: Patients with primary or secondary adrenal insufficiency present with signs and symptoms of hypoglycemia in the newborn associated with low cortisol level with undetectable or inappropriately low or normal ACTH level in ACTH deficiency (secondary adrenal insufficiency) or low cortisol with high ACTH level in primary adrenal insufficiency.

Treatment: Treatment with hydrocortisone, NaCL, fludrocortisone is needed for inborn errors of steroidogenesis. Hydrocortisone alone is needed for patients with isolated ACTH deficiency. Hydrocortisone, Levothyroxine, growth hormone, and DDAVP is needed in neonates with panhypopituitarism.

Prognosis: Hypoglycemia should be treated aggressively to prevent adverse neurocognitive sequela. Growth and development should be monitored closely.

Prevention: Genetic counseling to families of affected patients is needed to discuss risk of having another affected child in future pregnancies.

29 Disorders of Glucose Homeostasis in the Newborn

William Oh

Normal glucose homeostasis in the newborn is maintained by adequate intake of glucose or glucose-producing substrates and appropriate balance of hormones that regulate glucose production and utilization. Insulin is the primary hormone while glucagon, glucocorticoid, epinephrine, and growth hormones are the counter-regulatory hormones. Inadequate or excessive intake of glucose or improper balance of insulin and the counter-regulatory hormones will produce abnormally low or high blood glucose values resulting in hypoglycemia and hyperglycemia respectively. Both conditions can cause clinical signs that require prompt management to avoid undesirable short- and long-term outcomes.

Neonatal Hypoglycemia

Definition

The definition of neonatal hypoglycemia is based on the normative blood glucose values and the 95th% confidence intervals. Hypoglycemia is defined as blood glucose falling below the 95th percentile of the normal values. The normative value is gestational and postnatal age dependent. Based on the data published by Srinivasan and Cornblath (*Figs. 29.1* and *29.2*), blood glucose values of <30 mg/dL is considered hypoglycemic for term infants during the first 24–48 h of life. In preterm infants, a value of <20 mg/dL is considered hypoglycemic during the same postnatal age period. There are several reasons for the lower values in preterm infants: (1) they have lower glycogen reserve, (2) less efficient gluconeogenesis, and (3) they are more likely to have lower enteral intake. The latter is often modified by early parenteral nutrition which is a common practice in the care of these infants. During the third day through the first week of life, hypoglycemia is defined as blood glucose <40 and 30 mg/dL for term and preterm infants respectively. Beyond the first week, <50 and <40 mg/dL are considered hypoglycemic for term and preterm infants respectively. It should be noted that the normative data for preterm infants were collected in the 1960s when very preterm and extremely preterm infants did not survive and the normative data are primarily obtained in the larger preterm infants. Thus, it is quite likely that the definition we use may "over-diagnose" the condition among very or extremely preterm infants. Nevertheless, while there are considerable debates and controversies on the precise values for the definition of this disorder, most clinicians consider the definition clinically acceptable.

A common clinical practice in the management of hypoglycemia is to screen for this condition at the point of care using heel stick to obtain a small amount of blood for glucose determination using a reflectance meter. The procedure has the advantages of being simple, requiring a small amount of blood and having a quick turn-around time for the result. The distinct disadvantage is that there is a relatively poor correlation between the values obtained by this technique when compared with those obtained by standard laboratory measurements. This phenomenon is particularly true in the high and low range of the blood glucose values. Because of this limitation, it is important that when a screening value suggests the possibility of hypoglycemia, the diagnosis should be confirmed with a standard laboratory determination.

Infants at Risk for Neonatal Hypoglycemia

The following are the conditions that put an infant at risk for hypoglycemia:

- Infants of diabetic mothers
- Intrauterine growth restriction
- Perinatal asphyxia
- Extreme prematurity
- Beckwith–Wiedemann Syndrome
- Severe Rh erythroblastosis
- Inborn error of metabolism
- Glycogen storage disease

Infants of diabetic mothers are at risk because of fetal hyperinsulinemia resulting from exposure to episodic

maternal hyperglycemia in a poorly controlled diabetic state. The episodic fetal hyperglycemia stimulates the pancreatic islet cells and produces an increased amount of insulin. Hypoglycemia occurs during the first few hours of life when the placental glucose supply is terminated by birth due to the sustained effect of hyperinsulinemia. Intrauterine growth restriction (IUGR) is associated with increased incidence of neonatal hypoglycemia because of decreased glycogen reserve and impaired gluconeogenesis. The association is particularly common in IUGR due to placental insufficiency as in the cases of maternal preeclampsia and/or pregnancy-induced hypertension. Perinatal asphyxia is associated with increased risk of hypoglycemia because of increased metabolic demand when the infant is ill from ischemic hypoxia. Extreme prematurity is associated with decreased glycogen reserve since fetal glycogen storage occurs in late gestation. The prematurely born infants are deprived of the glycogen accretion leading to reduced glucose production during early neonatal life. Beckwith–Wiedemann syndrome, a relatively uncommon condition characterized by macrosomia, macroglossia, and umbilical hernia, is prone to hypoglycemia because of pancreatic beta cell hyperplasia and hyperinsulinemia.

Although rare nowadays because of successful prevention by administration of Rhogam (anti Rh antibodies), severe Rh erythroblastosis has been shown to have an increase incidence of hypoglycemia because of inhibitory effect of glutathione, a by-product of hemolysis.

Clinical Signs and Manifestations

During the first 24–48 h of life, the infant with hypoglycemia is often asymptomatic despite the fact that glucose is the main source of energy for brain metabolism. This is due to the fact that a newborn infant has an abundance of alternative substrate in the brain that can provide the energy for metabolism in the presence of low glucose supply. If the condition is undetected or untreated, the infant will eventually exhaust the alternative substrates and become symptomatic. This is the reason that hypoglycemia needs to be treated promptly despite the absence of clinical signs. The signs relate primarily to the central nervous system with jitteriness, tremor, apnea, bradycardia, and, in the worst scenario, seizure. Seizure is the worst sign because it signals severe brain cell dysfunction and has been shown to result in poor developmental outcomes at a later age.

Management

When diagnosis of hypoglycemia is established, the condition should be treated promptly even if the infant is asymptomatic. Intravenous glucose infusion at a rate of 4–5 mg/kg/min will approximate the fetal glucose intake and will maintain adequate glucose concentration and delivery to the brain. Concentrated glucose bolus infusion should be avoided in infants whose hypoglycemia is a result of hyperinsulinemia because such infusion may result in rebound hypoglycemia that may lead to persistent hypoglycemia.

Early enteral feeding is encouraged to promote early onset of gluconeogenesis. Feeding can be in the form of breast milk or infant formula. If infant is stable at the time of birth, breast feeding soon after birth in the delivery room is encouraged. This practice has been shown to improve glucose homeostasis and reduce the incidence of hypoglycemia.

Neonatal Hyperglycemia

Definition

Neonatal hyperglycemia occurs primarily in very and extremely low birth weight infants. The lack of normative data in this population makes it difficult to provide a blood glucose value for such definition. In the absence of a universally accepted definition, most clinicians consider blood glucose values of >125 mg/dL or plasma glucose >150 mg/dL as hyperglycemic.

Risk Factors and Mechanism

There are several risk factors for neonatal hyperglycemia: low gestational age, intrauterine growth restriction, excessive glucose and lipids intakes, sepsis, and use of glucocorticoids. It is well known that neonatal hyperglycemia is very common among extremely low birth weight infants. There is good evidence that insulin resistance in the peripheral tissues is the main reason for elevation of blood glucose values. Moreover, these infants often received a large amount of parenteral glucose and lipids in an attempt to meet their nutritional requirements. The combination of large substrate intakes and diminished ability to utilize the glucose because of insulin resistance results in the elevation of blood glucose. *Figure 29.3* shows the direct relationship between glucose infusion load and plasma glucose levels for infants at two birth weight groups. The smaller infants (birth weight 500 g) have a higher plasma glucose value at a similar glucose load than infants with higher birth weight (900 g). The data illustrate the interaction between maturity and glucose load, which is an important concept in understanding the inverse relationship in gestation and degree of insulin resistance and the effect of large glucose load in considering the strategy of management. The increased risk of IUGR infants for hyperglycemia has been well documented. However, the mechanism for such association is poorly understood. Sepsis is a risk factor primarily because of stress produced by such conditions. Similarly, the administration of glucocorticoid for clinical indication (such as blood pressure support or bronchopulmonary dysplasia) results in enhanced glucose production and elevation of blood glucose value if utilization is impaired by insulin resistance.

Clinical Manifestations and Complications

Hyperglycemia per se does not usually produce any symptom. However, when the degree of hyperglycemia is severe (e.g., >300 mg/dL of blood or plasma glucose levels), osmotic diuresis occurs because the blood/plasma glucose levels exceed the renal glucose threshold. Marked water loss and potential development of dehydration often occur

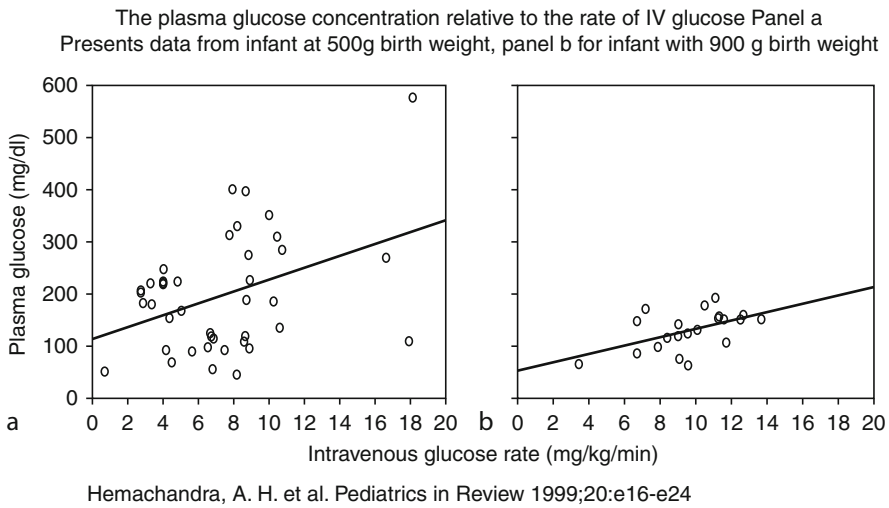

Figure 29.3

The plasma glucose concentration relative to the rate of IV glucose. Panel a presents data from infant at 500 g birth weight, Panel b for infant with 900 g birth weight (From Hemachandra AH et al (1999) Pediatr Rev 20:e16–e24)

if fluid balance is not maintained. A very high plasma osmotic level can also result in water shift in the brain increasing the risk of CNS injury including intracranial hemorrhage. Thus, it is important that the condition is treated to avoid these complications.

Management

The first step in the management of infant with hyperglycemia is to consider the cause. If the condition is due to administration of medication such as glucocorticoid, consideration should be made to discontinue the treatment, balancing the risk of such approach against the harm of not continuing the medication. Because the adverse effect of glucocorticoids is dose related, lowering the dose may reduce the hyperglycemia. If the infant has signs of sepsis, use of appropriate antibiotics to treat the sepsis will usually result in amelioration of hyperglycemia. If immaturity and large doses of glucose and lipids are the causes of hyperglycemia, the glucose and intravenous lipid doses should be reduced to meet the minimum nutritional requirement. The usual approach is to reduce the glucose infusion rate at 1 mg/kg/min and intravenous lipid at 1 g/kg/24 h while monitoring the blood glucose at the point of care. The approach should be balanced with the maintenance of adequate nutrient intakes providing at least 60 kCal/kg/day to maintain a protein sparing state and minimal metabolic requirement.

If the above procedures do not result in abatement of hyperglycemia, continuous low-dose insulin infusion will often produce the desirable outcomes. The usual dose of insulin is 0.02–0.05 U/kg/h. Since the response may be rapid with potential development of hypoglycemia, point of care monitoring of blood glucose at 4–6 h interval is essential.

30 Infant of Diabetic Mother

William Oh

Basic science and clinical research during the past several decades have significantly enhanced our understanding of the various perinatal morbidities and childhood problems relating to infants of diabetic mother (IDM). These morbidities include congenital anomalies, hypoglycemia, respiratory distress syndrome, macrosomia, fetal distress, neonatal depression and asphyxia, polycythemia/hyperviscosity, hyperbilirubinemia, shoulder dystocia, birth injury, hypocalcemia, childhood obesity, and metabolic syndrome. With the exception of congenital anomalies, the etiology of which is still unknown, the pathophysiology of these morbidities are accounted for by various events that stem from poor maternal diabetic control. The pathophysiologic basis of these morbidities are for the most part evidence based (*Fig. 30.1*) and discussed below.

When the maternal diabetes is poorly controlled, episodic hyperglycemia occurs. Since there is a constant gradient (maternal blood glucose level is 10% higher than the fetal), episodic fetal hyperglycemia ensues, which results in fetal hyperinsulinemia. The latter accounts for the higher risk of neonatal hypoglycemia and respiratory distress syndrome (RDS). In vitro studies have shown that insulin is a potent inhibitor of surfactant synthesis in fetal pulmonary type II cell explaining the increase risk of RDS in IDM. Enhanced fetal growth is a result of abundance of substrate and hyperinsulinemia since insulin is a significant fetal growth factor. Enhanced fetal growth will in some cases result in fetal macrosomia, which increases the risk of shoulder dystocia and birth injury. There is also good evidence that macrosomia is associated with increased risk of childhood obesity and metabolic syndrome. Increased fetal growth will require an increase fetal metabolic demand. If placental oxygen transfer does not meet the increased demand, a relative fetal hypoxemia ensues leading to fetal hypoxia/distress and neonatal depression/asphyxia. Fetal hypoxia will stimulate the synthesis of erythropoietin, which is a hormone that promotes erythropoiesis. This accounts for the increased risk of neonatal polycythemia and hyperviscosity as well as hyperbilirubinemia. It is apparent that if maternal diabetes is well controlled, these morbidities would likely not occur. Unfortunately, there are multiple reasons why we still see these problems in the clinical setting, including lack of adequate prenatal care and lack of patient compliance. In some cases, the severity of the diabetes is so high that it defies optimal control during gestation.

Congenital Malformation

Infants of a diabetic mother have significantly higher incidence of congenital malformation than normal newborn population. The incidence is estimated to be between 5% and 10% for major malformations in contrast to the usual 1–2% among normal newborn population. The prevalence rate appears to be related to types, severity, and level of control of diabetes particularly with reference to hyperglycemia. The incidence is higher among infants of type I diabetes than those born to mothers with gestational diabetes, probably because the onset of insulin-resistant glucose intolerance occurs around 24–28 weeks of gestation which is well past the period of embryogenesis (first 12 weeks of gestation). The anomalies usually affect cardiovascular and gastrointestinal systems, although other organ systems are not spared. The more common anomalies are listed in *Table 30.1*.

The pathogenesis of congenital malformations in IDM is not known. However, based on indirect evidence that tight control of blood glucose level during preconception and early embryogenesis periods results in marked reduction in its incidence, it is likely that hyperglycemia may well be the main culprit for the malformations.

Neonatal Hypoglycemia

Neonatal hypoglycemia is the most common metabolic disorder in the newborn and IDMs are at higher risk. Because glucose is transported from the mother to the fetus by facilitated diffusion, episodic maternal hyperglycemia (reflected by high hemoglobin A_1C) in poorly controlled diabetic state will result in episodic fetal hyperglycemia. The latter will stimulate the beta cells of the fetal pancreatic islet cell with release of insulin resulting in fetal hyperinsulinemia.

When the infant is delivered and the maternal placental supply of glucose is interrupted, the fetal

hyperinsulinemia will precipitate a rapid fall in blood glucose during the first hours of life. In contrast to the full-term newborn of the nondiabetic mothers, the fall in blood glucose value and duration of low blood glucose are exaggerated in IDM because of the hyperinsulinemic state which may last beyond the first few hours of life. The latter suppresses endogenous production of glucose by gluconeogenesis and glycogenolysis accounting for a delay in recovery of blood glucose value during the immediate postnatal period. It is a common practice that bedside or point of care determination of blood glucose values are done using reflectance meter because of ease in performing the measure and immediate availability of results. The screening is generally done every 30–60 min during the first 2 h to evaluate the trend and the rate of fall in blood glucose. When the level is in the hypoglycemic range, the infant is managed accordingly. Since reflectance meter for screening is not precise, it is advisable to obtain a blood glucose measurement by regular laboratory technique to confirm the diagnosis. If the blood glucose screening showed a normal range during the first 2–3 h, or if treatment results in normal values, the frequency of screening can be extended to every 3–6 h during the first 24 h and every 12 h in the second and third day of life.

There is considerable controversy on the biochemical definition of hypoglycemia and current number used by clinicians is arbitrary. Most clinicians consider values <30 mg/dL for term and 20 mg/dL for preterm infants as diagnostic of this condition. When the blood glucose reached normal levels (generally considered as 50 mg/dL or higher), hypoglycemia is considered resolved.

Newborn infant's brain uses glucose as the main substrate for metabolism. However, there is evidence that the developing brain is capable of using alternative substrates for metabolism. This may explain why most infants with hypoglycemia in the first hours of life are asymptomatic. If the hypoglycemia is not corrected, the infant may

eventually become symptomatic when alternative substrate is exhausted. Thus, it is important that the hypoglycemia be treated even in the absence of clinical manifestations. The signs are usually nonspecific and may include jitteriness, tremor, apnea, feeding intolerance, and seizures.

If the infant is stable and without respiratory distress, early enteral feeding (first 6 h of life) is recommended for IDM to minimize the risk of hypoglycemia. The initial feeding can be in the form of 10% glucose solution or formula. If the mother intends to breast-feed, breast-feeding should commence in the delivery room when the infant is stable. It has been shown that delivery room breast-feeding improves glucose homeostasis in gestational IDM with lower incidence of hypoglycemia than those who were not nursed. Intravenous glucose infusion should be initiated if the infant is hypoglycemic. Intravenous glucose infusion at a rate of 4–5 mg/kg/min in the form of 10% glucose at a dose of 60–70 mL/kg/day will often maintain euglycemia. Concentrated glucose bolus infusion should be avoided because it tends to provide a very high dose of glucose over a short period of time which may trigger an abrupt rise in serum insulin level followed by a rebound fall in blood glucose values. The rebound hypoglycemia may require further bolus infusion, which may result in persistent hypoglycemia that may require other forms of treatment, such as the use of glucocorticoid.

Respiratory Distress Syndrome

In 1974, Smith et al. showed that insulin inhibits the production of lecithin in rat type II cell fibroblasts. Robert et al. subsequently showed that at matched gestational age, the IDM has a higher incidence of RDS than their non-IDM counterparts (*Fig. 30.2*). Subsequent studies showed that the insulin inhibitory effects involved other classes of phospholipids in the surfactant specifically the phosphotidyl glycerol (PG) resulting in part from the delay in structural development of fetal lung type II cells. Another measure that has been proven useful in predicting fetal lung maturity is the TDx-FLM assay. This is a technique that measures total lamellar body counts in the amniotic fluid. The presence of more than 70 mg/dL is an assurance of lung maturity with none of cases with such number has respiratory distress syndrome. Close monitoring of fetal well-being by noninvasive means and maintaining the pregnancy to as close to term as possible is probably the best approach in avoiding the complication of neonatal disorders in this population. Although there are no data in the use of antenatal steroids to accelerate fetal lung maturation and surfactant synthesis for IDM who develops respiratory distress syndrome, it is probably safe to state that such usage is likely to be effective.

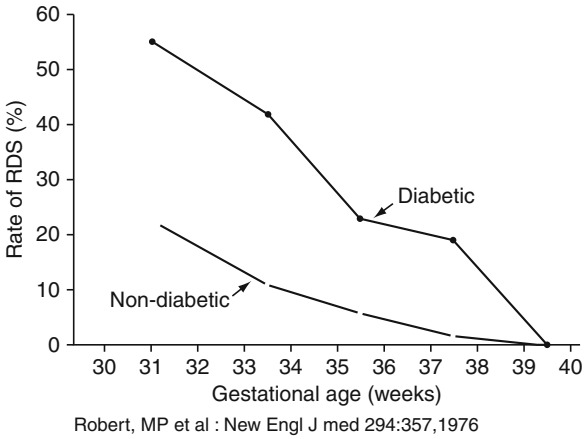

Figure 30.2
Incidence of respiratory distress syndrome in infants of diabetic mothers (From Robert MR, Neff RK, Hubbell, JF et al (1976) Association between maternal diabetes and the respiratory-distress syndrome in the newborn. N Engl J Med 294:357–360)

Macrosomia

Macrosomia or large for gestational age is defined as birth weight exceeding the 95th percentile of the intrauterine growth curve. A birth weight of >4.5 kg at term or close to term will likely fall under this category. The enhanced fetal growth in IDM is due to a combination of fetal hyperinsulinemia and the presence of abundance of substrate. The acceleration in fetal growth usually occurs at around 32–33 weeks of gestation reaching its peak at term. However, it should be noted that macrosomia is not all due to maternal diabetes; other factors can cause macrosomia, including maternal obesity without diabetes and constitutional statures of the parents.

The morbidity rate of macrosomia in IDM is similar to macrosomic infants without a history of maternal diabetes. Thus, surveillance for potential problems related to macrosomia should disregard the diabetic status of the mothers.

Prenatal diagnosis of macrosomia is feasible by fetal ultrasound conducted during the accelerated fetal growth phase at around 32–33 weeks of gestation. Such serial assessment is an important part of the management of diabetic pregnancy because early identification of

macromia will allow for serial assessment of fetal well-being. Macrosomia has been shown to increase the risk of fetal hypoxia and related neonatal morbidities including low 5-min Apgar score, seizure, hypoglycemia, polycythemia and, meconium aspiration syndrome. The reason for the association is that macrosomia is associated with increased metabolic rate that results in an increase in fetal oxygen consumption. If the placenta cannot accommodate this increased demand, relative fetal hypoxia can occur leading to fetal distress and all the subsequent adverse fetal and neonatal events.

Other perinatal complications related to macrosmia include shoulder dystocia resulting in difficult labor and delivery and often requires cesarean delivery, birth injury including fracture of clavicles, Erb's palsy, and paralysis of the diaphragm due to phrenic nerve injury. In an observational cohort study comparing the neonatal mortality rate of marosomic infants with reference to mode of delivery, Boulet et al. showed that the hazard ratio (demonstrating advantage of cesarean delivery) was 1.4, 1.3, and 0.8 for infants weighing 4.0–4.5 kg, 4.5–5.0 kg, and >5 kg, respectively, suggesting that cesarean delivery is most beneficial for extremely large infants (>5.0 kg) but debatable among infants weighing between 4.0 and 5.0 kg.

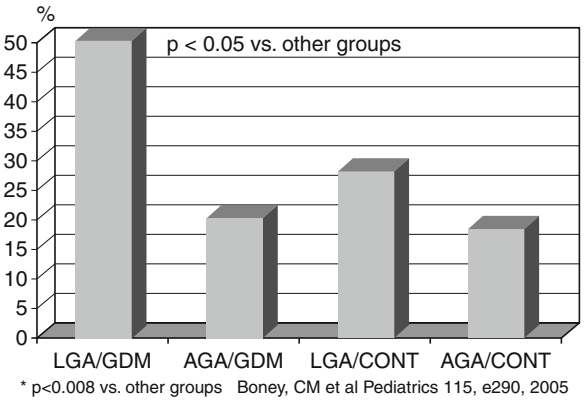

Figure 30.3
Prevalence of metabolic syndrome in macrosomic infant of gestational diabetes (From Boney CM, Verma A, Tucker R et al (2005) Metabolic syndrome in childhood: association with birth weight, maternal obesity, and gestational diabetes mellitus. Pediatrics 115:e290–e296)

Childhood Obesity and Metabolic Syndrome

There is evidence that macrosomic infants, particularly those born to mothers with gestational diabetes, are at increased risk of childhood obesity and metabolic syndrome. In a long-term follow-up program of 207 gestational diabetic mothers, Boney et al. showed that the macrosomic (LGA) infants of gestational diabetes have a 50% prevalence of metabolic syndrome during late childhood. The metabolic syndrome was defined as having two or more of the following conditions: obesity (BMI > 85th percentile), hypertension (systolic or diastolic BP > 95th percentile), high triglyceride (>95th percentile for age), and low HDL (<5th percentile for age). The LGA (macrosomic) infants of nondiabetic (control) mothers also have a higher prevalence of metabolic syndrome but not as high as the LGA infants of gestational diabetic mothers (*Fig. 30.3*). The data are consistent with those found in animal models in which the macrosomic pups of streptozotocin-induced diabetic pregnant rats remain macrosomic at later age with development of glucose intolerance. The data emphasize the importance of anticipatory guidance in regard to diet and exercise for children who were macrosomic infants born to gestational diabetic mothers, to minimize the risk of metabolic complications and obesity that may lead to cardiovascular and other metabolic syndrome-related diseases during adulthood.

Polycythemia and Hyperviscosity

Polycythemia is defined as venous hematocrit value exceeding 65%. The condition is of clinical significance because this level of hematocrit may result in hyperviscosity. The latter may cause circulatory sludging, which may in turn result in dysfunction of the organs supported by the circulation. Complete blood counts are often obtained by heel puncture providing hematocrit values of the capillary blood. In interpreting the hematocrit values in making the diagnosis of polycythemia, it is important to keep in mind that the capillary hematocrits are 10% higher than the simultaneously obtained venous hematocrits. If the capillary hematocrit is high (>65%) and polycythemia is suspected, a venous hematocrit should be obtained to confirm the diagnosis.

In IDM, polycythemia is a result of hypoxia-induced erythrocytosis. In fetal monkey model, Susa et al. showed that hyperinsulinemia induced by fetal implantation of an insulin pump resulted in marked increase in erythropoietin levels and histologic evidence of increased hepatic erythropoietic activities. In human IDM, Widness et al. provided evidence of increased erythropoiesis with higher cord serum erythropoietin levels than in non-IDM. Other

than a ruddy appearance, most infants with polycythemia are asymptomatic. When symptomatic, the signs are nonspecific and may involve various organ systems including CNS and gastrointestinal and respiratory systems. Tachypnea, feeding intolerance, and jitteriness are common signs. These signs are indistinguishable from such conditions as sepsis and metabolic problems such as hypoglycemia. Management is by performing a partial exchange transfusion in which the infant's blood is removed to achieve a normal hematocrit level. The formula used for calculation of blood to be removed and replaced with normal saline or equivalent is as follows:

Blood to be removed and replaced with saline = infant's current hematocrit (%) − desired hematorit (55%) × 80 (infant's estimated blood volume) × body weight ÷ infant's current hematocrit.

The indication of doing the partial exchange transfusion is somewhat controversial because of lack of evidence that such treatment will assure good outcome. The empiric approach is to perform the procedure if the infant is symptomatic and the hematocrit is greater than 70%. If the infant is asymptomatic, the indication of such procedure is less definite, unless the hematocrit is exceedingly high (e.g., 75% or higher).

Hyperbilirubinemia

In IDM, this condition is often associated with polycythemia. The reason is that excess red cell volume results in increased break down of red blood cells and bilirubin production. If the infant's bilirubin conjugating and elimination capacity are immature, bilirubin accumulation will occur leading to hyperbilirubinemia. The degree of bilirubin elevation is often modest and the infant will respond promptly to phototherapy. Exchange transfusion is rarely required.

Hypocalcemia

This is another common metabolic problem in newborn and the IDM is at higher risk than non-IDM. The reason for an increased risk is not entirely clear. One hypothesis is that in the presence of fetal or neonatal hypoxia, the calcitonin level may be elevated. The latter is a hormone that can act in opposite direction as parathyroid hormone accounting for the fall in serum calcium levels.

The diagnosis of hypocalcemia is based on serum calcium level of < 7 mg/dL in term and 6 mg/dL in preterm infants. It should be noted that data for this definition were derived from the studies conducted in the era when the very low or extremely low birth weight infants were not surviving and thus not included in the survey for normative values. Since serum calcium levels have been shown to directly correlate with gestational age, it is likely that lower cutoff level for serum calcium levels in very low and extremely low birth weight infants are lower than the 6 mg/dL. Clinical signs of hypocalcemia are nonspecific and similar to those listed for hypoglycemia. The most serious sign is seizure. Hypocalcemia can be treated readily with parenteral calcium administration given as constant infusion. The prognosis for this condition is good.

In summary, infants of diabetic mother are at risk for various fetal, neonatal, and childhood morbidity due to maternal episodic hyperglycemia and concomitant fetal hyperglycemia and hyperinsulinemia. It is apparent that good control of maternal diabetes will markedly reduce the risk of the infants' morbidities with benign neonatal course and at lower risk for late childhood obesity and metabolic syndrome.

31 Neonatal Hematology

Eric Werner

Introduction

From fetal life to infancy, through childhood and adolescence, the cellular and plasma components of the blood undergo dramatic change. This is especially true in the first few months of life as the infant transitions from the protected, hypoxic intrauterine environment to extrauterine life. In this chapter, many aberrations of the blood in the neonatal period are briefly discussed. There are several textbooks that cover the topic of neonatal hematology to which the reader can refer for more in-depth discussion of these disorders.

Red Cell

The site of erythropoiesis migrates in the fetus from the yolk sac to the liver to the marrow. During this time, the predominant hemoglobin also changes from the early embryonic hemoglobins Gower 1 (ε_4 or $\zeta_2\varepsilon_2$) and Gower 2 ($\alpha_2\varepsilon_2$) to Hb Portland ($\zeta_2\gamma_2$). By the beginning of the second trimester, Hb F ($\alpha_2\gamma_2$) is the predominant Hb, while Hb A ($\alpha_2\beta_2$) synthesis begins in utero and increases in the third trimester. At birth, the median Hb F fraction for the term and preterm infant is 68% and 75% Hb F, respectively. By 6 months of age, these decrease to a median of 5% for the term and 9% for the preterm infant. The mean Hb of cord blood is 16.5 g/dL, higher than at any other time in life, but quickly decreases to 11.2 g/dL by 2 months of age. From that point on, the hemoglobin increases to a mean value of ~12.6 g/dL at 6–12 months. The reference range for Hb concentration for the term and preterm infant are shown in ❯ *Table 31.1*.

Anemia, usually defined as a hemoglobin or hematocrit level more than two standard deviations below the mean for age, can be due to blood loss, accelerated red blood cell destruction (hemolysis), or decreased erythrocyte production. Hemolysis typically presents with an elevated reticulocyte count and may have elevated indirect bilirubin, aminoaspartate transferase, and lactate dehydrogenase levels. Serum haptoglobin levels are generally low but are unhelpful in the neonatal period. Hypoplastic anemias usually have a low reticulocyte count. Occasionally, hemolytic disorders will present with a low reticulocyte count due to bone marrow suppression as occurs with parvovirus B19-induced aplastic crises.

Site and Timing of Collection

The hematocrit value is usually higher from capillary blood specimens such as those obtained by heelstick as compared with venous specimens in the first several weeks of life. Hematocrit values increase with delayed clamping of the umbilical cord at birth. There is also a slight increase in hematocrit in the first few hours of age, but by 24 h of age, the values are similar to cord blood levels.

Red blood cell production dramatically decreases at the end of the first week of life. Over the first few months of age, as the neonate adapts to the extrauterine environment, the hemoglobin decreases with a trough level of approximately 11 g/dL at 2 months of age. This is commonly called the physiologic anemia of infancy. As discussed below, this effect is more exaggerated in the preterm infant, where symptomatic anemia can result.

Neonatal Anemia

Blood Loss

Placental Blood Loss

Blood loss from the fetal side of the placental circulation can occur leading to anemia in the newborn. The most common causes are placental bleeding as occurs in placenta previa, placental abruption or rupture of the umbilical cord, feto-maternal bleeding, and twin–twin transfusion syndrome.

While the majority of the blood loss with placental bleeding is maternal, the risk of neonatal anemia increases with the severity of the maternal bleeding. The Apt test can be used to test vaginal blood for fetal hemoglobin. Umbilical cord rupture may occur with traumatic delivery or the presence of placental/cord anomalies such as a velamentous cord insertion. Surgical laceration of the

placenta may occur with C-section or rarely with traumatic amniocentesis or cordocentesis.

Feto-maternal Blood Loss

While a small amount of fetal blood crosses into the maternal circulation with most deliveries, in 0.1–0.3% of pregnancies, this volume can exceed 20–30 mL and can lead to significant or even fatal neonatal blood loss. On occasion, chronic feto-maternal bleeding can lead to hydrops fetalis. The diagnosis of feto-maternal hemorrhage is made by examining maternal blood for fetal erythrocytes using the Kleihauer-Betke stain or flow cytometry. Disorders where there is a high percentage of Hb F in maternal erythrocytes such as hereditary persistence of fetal hemoglobin can lead to false positive results.

The infant who has suffered acute hemorrhage can present with signs of hypovolemia such as hypotension, pallor, and tachycardia. The hemoglobin measurement obtained at birth may not accurately demonstrate the amount of blood loss as equilibration has not yet occurred. In addition, capillary hemoglobin values are especially higher than those obtained centrally in the acidotic newborn. Treatment usually begins with volume expanders and red cell transfusion may be indicated.

Twin–Twin Transfusion

Twin–twin transfusion syndrome (TTTS) occurs when there is unbalanced blood flow between diamniotic, monochorionic, monozygotic twins via placental vascular anastomoses. The donor twin becomes hypovolemic with oliguria, while the recipient twin has polyhydramnios. The older criteria of a >5 g/dL difference in neonatal Hb concentration and a >20% difference in birth weight are no longer used. Fetal diagnosis currently is based on sonographic criteria. Obstetric management may include serial amnioreduction or laser ablation of the anastomoses. There may be multiple complications for survivors of TTTS, including cardiac hypertrophy, hyperviscosity, and vascular occlusion in the recipient, and renal failure, severe anemia, neutropenia, and cutaneous erythropoiesis in the donor twin.

Hypoplastic Anemia

Anemia of Prematurity

Physiologic Anemia of Infancy

Adaptations to intrauterine life include the increased oxygen affinity of fetal hemoglobin due to the decreased sensitivity of Hb F to the ability for 2–3 DPG to modulate the oxygen sensitivity and the relatively high hemoglobin of the fetus. After delivery and exposure to extrauterine oxygen content, red cell production in the neonate decreases for several weeks, demonstrated by a low reticulocyte count at the end of the first week of life and a gradual decrease in Hb concentration from a mean of 16.6 g/dL at birth to 11.2 g/dL at 8–9 weeks of age. As Hb A becomes the predominant Hb, red cell production again increases gradually, and the Hb increases to a mean of ∼12.6 g/dL at 6–12 months of age. This expected decline in red cell production during the first 3 months of age is referred to as physiologic anemia of infancy.

Several factors make this phenomenon more pronounced in the premature infant. The premature infant has a smaller red blood cell mass at birth, often requires iatrogenic blood loss for monitoring in the hospital, and there is a relative insensitivity of the erythropoietin response. Hb concentrations can fall below 8 g/dL and cause clinical symptoms including poor growth in these infants. Erythropoietin treatment has generally not been shown to be effective in the prevention of this anemia of prematurity.

Nutritional

Iron

While iron deficiency remains the most common form of anemia in children worldwide, it is rarely seen in the newborn because the fetus is particularly good at extracting iron from the mother. Iron deficiency at birth is usually caused by chronic fetal blood loss.

The peak age for iron deficiency begins in late infancy with some evidence that the risk for severe iron deficiency is highest in the second year of life after the use of iron fortified formulas is discontinued. Other risk factors in this age group include prematurity, blood loss, use of non-iron fortified formulas, and lead intoxication. Exclusively human-milk-fed infants usually receive adequate iron intake in the first 6 months of age, but then may become iron deficient if additional sources of iron are not supplied.

Clinical manifestations: Typically, iron deficiency or iron deficiency anemia is discovered by screening studies. More severe cases may present with pallor, decreased activity, and tachycardia. Often, a sallow appearance is appreciated. Pica is often described in children who are mobile. In the developing child, there is concern that iron deficiency can lead to permanent neurodevelopmental effects.

Diagnosis: There are a number of laboratory tests which can indicate the presence of iron deficiency, including the hemoglobin concentration, red cell distribution of width (RDW), iron saturation ratio (serum iron/total iron binding capacity), serum ferritin, serum transferrin receptor level, and reticulocyte hemoglobin content. None of these tests in and of themselves are pathognomonic for iron deficiency as false positives and false negatives may occur. Thrombocytosis is common in iron deficiency anemia, while thrombocytopenia may be seen especially with severe cases. Iron deficiency can be present in the absence of anemia. Most recommendations for replenishing iron stores apply to either the presence of iron deficiency or iron deficiency anemia.

Treatment: The best approach is prevention. Formula-fed infants should receive iron-supplemented formulas, and iron supplementation should begin in infants fed human milk by 6 months of age, earlier for high-risk infants such as premature infants. Screening for iron deficiency is now recommended at the end of the first year of life and again at 18 months of age. For children with iron deficiency or iron deficiency anemia with intact intestinal systems, oral treatment with iron preparations containing the ferrous form of iron is appropriate. The usual dose is 3–6 mg/kg/day of elemental iron/day. Failure to respond to oral iron therapy may be due to noncompliance, the presence of *Helicobacter pylori* infection, ongoing blood loss, or inability to absorb iron. Parenteral iron sucrose infusions have been used in children with a high degree of safety.

Folate and Cobalamin

Folate is found in both animal products and leafy vegetables, but can be destroyed with heat. The addition of mandated folate supplementation of cereal-grain products in the USA and Canada has increased the American daily folate to over 400 μg/day.

Cobalamin is found in only animal products. Cobalamin has a slow turnover, so deficiency tends to take months to develop upon removal of cobalamin from the diet. The adequate vitamin B12 intake for infants <6 months of age is 0.4 μg/day and for those 6–12 months of age is 0.6 μg/day.

Folate deficiency is common in undeveloped countries but is relatively rarely seen in developed countries. It is very uncommon in the neonatal population. In addition to poor diet, a number of disorders can lead to folate deficiency. Goat's milk has very low folate content and infants fed with goat's milk are prone to deficiency. Intestinal disorders such as celiac disease, tropical sprue, and jejunal resection are causes. Disorders with increased cell turnover such as hemolytic anemias can lead to an increased folate requirement. Anticonvulsants and other medications may cause folate deficiency.

Cobalamin deficiency in infants is rare and usually due to these infants receiving exclusive human milk nutrition from cobalamin-deficient mothers as a result of a vegan diet, gastric bypass, pernicious anemia, or other disorders. As it takes many months to deplete cobalamin stores, deficiency is rarely recognized in infants who are born with adequate amounts of this vitamin. Cobalamin

deficiency can be caused by short-gut syndrome or removal of the distal ileum as can occur as a complication of necrotizing enterocolitis. Long-term use of antacids or H2 blockers has also been associated with cobalamin deficiency. Two rare congenital disorders, intrinsic factor deficiency and Imerslund–Gräsbeck syndrome, a defect in the ability of enterocytes to absorb the cobalamin-intrinsic factor complex, can lead to severe cobalamin deficiency early in childhood.

In addition to inadequate folate or cobalamin levels due to dietary or absorptive problems, there are several metabolic derangements in folate and cobalamin metabolism that can have profound neurodevelopmental effects. Not all of these cause anemia and some may be found newborn screening.

Hematologically, patients with cobalamin or folate deficiency may present with the typical signs of anemia such as pallor and fatigue. Ineffective erythropoiesis may lead to an elevated bilirubin and mild clinical jaundice. Neutrophil function defects have been described in cobalamin deficiency.

Neuropathy is seen in children with severe cobalamin deficiency as well as defects in cobalamin metabolism. Folate treatment may mask some of the features of cobalamin deficiency but will not treat the neurologic manifestations. Hence, proper diagnosis is necessary to prevent permanent neurologic damage.

Diagnosis: The classic hematologic feature of folate or cobalamin deficiency is anemia with an elevated mean cell volume (MCV). This may be accompanied by neutropenia and/or thrombocytopenia. The peripheral blood film can show macrocytes, misshapen red blood cells, and often hypersegmented neutrophils defined as >5% of neutrophils with five clearly distinct lobes or the presence of any neutrophils with six clear lobes. When performed, bone marrow findings include dyserythropoiesis, giant bands, and metamyelocytes. There is also a relative decrease in the late hematopoietic precursors due to ineffective hematopoeisis. As previously noted, serum bilirubin and lactate dehydrogenase can be elevated.

Diagnosis of folate deficiency is usually confirmed by demonstrating low levels of either serum or red blood cell folate levels. Cobalamin levels are useful, but there is often overlap between clinical deficiency and the documented reference range due to the effect of holotranscobalamin I, which is metabolically inactive. In such instances, levels of methylmalonic acid and homocysteine, which are elevated in cobalamin deficiency, can be helpful. In addition, these may be increased and lead to a diagnosis in the rare disorders of cobalamin metabolism. Reference ranges for neonates have been published.

Treatment of folate deficiency is initiated by giving large doses of folic acid for 4 months. Continued folate supplementation is continued if the underlying condition causing folate deficiency cannot be reversed. Annual check of serum cobalamin levels is advisable to avoid masking of unsuspected cobalamin deficiency. Prophylactic folic acid is often given to children with severe hemolytic anemias, e.g., sickle cell anemia, thalassemia major or intermedia, and severe autoimmune hemolytic anemia. When they are old enough to practically receive the medication.

Cobalamin deficiency treatment is usually initiated with a series of intramuscular or subcutaneous injections of hydroxocobalamin, at least until it is clear that the absorptive mechanisms are intact. Prophylactic cobalamin therapy is given to patients with an ileal resection or total gastrectomy. The management of children with metabolic derangements of folate or cobalamin is beyond the scope of this chapter. Where possible such children should be referred to centers with the requisite expertise.

Vitamin E Deficiency

Vitamin E is a natural antioxidant with an important protective effect from lipid peroxidation of the erythrocyte membrane. Unsupplemented premature infants are at risk for vitamin E deficiency in the first few months of age. The anemia of vitamin E deficiency is hemolytic and disappears rapidly with treatment. Most at-risk infants currently receive supplementation of this vitamin in the nursery.

Other Nutrient Deficiencies

Deficiencies of other vitamins, minerals, and nutrients may also result in anemia. The clinician should consider in these instances whether multiple deficiencies coexist. Riboflavin and pyridoxine deficiency can cause anemia.

Copper deficiency can cause anemia and neutropenia and may be due to decreased intake, especially in infants and children on total parenteral nutrition.

Bone Marrow Infiltration

Malignant disorders that involve the bone marrow inhibit erythropoiesis leading to anemia. Two of the most common malignancies in infants, neuroblastoma, and leukemia can involve the marrow. Following diagnosis, usually confirmed by a bone marrow aspirate and/or biopsy,

the treatment includes management of the underlying malignancy. Often red blood cell transfusion will be a component of therapy. Irradiated and CMV safe blood products should be used in the setting of immunosuppressive therapy.

Inherited Bone Marrow Failure Syndromes

There are many inherited syndromes associated with bone marrow failure. Some, such as Fanconi Anemia cause pancytopenia, while others such as Diamond–Blackfan Anemia (DBA) are usually restricted to a single cell line. The reader is referred to reviews of this topic for detailed information, and this chapter will only briefly discuss Fanconi Anemia (FA) and DBA in this section, Thrombocytopenia with Absent Radii in the platelet section, and Severe Congenital Neutropenia in the white blood cell section.

Fanconi Anemia

The underlying defect in Fanconi Anemia (FA) is in the ability to repair breaks in double stranded DNA. Causative mutations have been identified in >13 genes. Over 2,000 cases of FA have been described in the medical literature and a registry of patients (http://www.rockefeller.edu/labheads/auerbach/clinresearch.php) has provided information regarding recognized patients. FA often presents with aplastic anemia in childhood but can be identified in adults, some of whom are asymptomatic. While the median age at diagnosis is 6.5 years, the disorder can be identified in neonates, especially those with consistent physical stigmata of the disorder. Physical abnormalities are present in approximately 60% of individuals reported in the literature, especially short stature, café-au-lait spots, and hyper- and hypopigmented areas. Abnormalities of the thumbs with or without radial ray anomalies are seen in 35% and 20–25% have microcephaly, micropthalmia, structural renal anomalies, or hypogonadism. In addition to aplastic anemia, there is a markedly elevated risk for malignancy, both hematologic and solid tumors.

Diagnosis: FA should be considered in anyone with aplastic anemia, especially a young person. The diagnosis is confirmed by an assay of chromosomal breakage using peripheral blood T cells exposed to a DNA cross-linking agent such as diexpoxybutane or mitomycin C. A few specialized laboratories perform this assay. Testing of asymptomatic family members should be entertained, especially when they are being considered as possible stem cell donors for transplantation.

Management: Comprehensive management for FA requires a multispecialty group of health care professionals to address the many physical, hematologic, and health maintenance needs for these children. Guidelines for management are available online at http://www.fanconi.org/index.php/publications/guidelines_for_diagnosis_and_management.

Diamond–Blackfan Anemia

Diamond–Blackfan Anemia (DBA) or congenital pure red cell anemia is a rare inherited disease caused by a defect in ribosome biosynthesis that causes the erythroid precursor to be prone to early apoptosis. Over 90% present in the first year of life. Congenital anomalies such as short stature, low birth weight, microcephaly, cardiac, genitourinary, and thumb abnormalities are common but not universal.

Hematologic findings usually demonstrate a macrocytic anemia with an elevated Hb F. These may overlap with the relatively high MCV and Hb F levels of the newborn in the first months of life. The diagnosis is usually made by bone marrow examination, which demonstrates normal cellularity with an absence of red blood cell precursors. In most patients, the red blood cell adenosine deaminase levels are elevated. Ribosomal gene mutations have been identified in approximately 50% of patients and can be used for diagnosis in asymptomatic family members. A registry for DBA patients is located at http://www.dbar.org/.

Management of infants and children with DBA is not fully defined and should be done, where possible, in a center with expertise in the disorder. The anemia often responds to corticosteroid treatment, and some patients who respond achieve complete remissions with the ability to discontinue the medication, although relapses can occur. Transfusion therapy is indicated for those who do not respond and possibly as an alternative to corticosteroids in infants, but long-term transfusion therapy causes iron overload. Individuals with DBA have a lifelong increased risk for malignancy.

Hemolytic Disorders of Infancy

Hemolysis, by definition, is a shortened red blood cell life span. The life span of the neonatal erythrocyte is about 80 days, slightly shorter than the 120 day survival seen later in childhood and in adults. It is even shorter in premature infant. Causes of hemolytic anemia include

disorders of the erythrocyte membrane, hemoglobin, enzyme pathways, and extra-erythrocytic disorders such as infection or antibody formation.

Immune

Maternal sensitization, from exposure to fetal blood passed transplacentally in a prior pregnancy or possibly other blood product exposure, can lead to alloantibody formation. During pregnancy, maternal IgG crosses transplacentally to the fetus and can attach to antigens on the fetal erythrocyte leading to hemolysis. In the past, the Rh antigen was the most common cause of severe hemolytic disease of the newborn, but in one of the great medical triumphs of the last century, this is now a quite uncommon disorder. ABO incompatibility occurs more commonly, but the severity of hemolysis is generally less than for Rh disease. There are several other antigens, referred to as minor group antigens such as c, C, e, E, Kell, and others, which can occasionally lead to significant hemolytic disease in the neonate. Of note, previously transfused women account for 50% of the mothers of infants with non-Rh antibody hemolytic disease of the newborn.

Severe fetal hemolytic disorders can present with hydrops fetalis identified by the obstetrician. Screening of maternal blood can identify the causative antibody and intrauterine transfusion may be necessary. The pediatric service should be consulted prenatally in cases of identified maternal sensitization. In the newborn, hemolysis often presents with early-onset hyperbilirubinemia. Cord blood is routinely screened for blood type and antibody on the neonatal erythrocyte via the direct antiglobulin test also called the direct Coomb's test. Due to the low density of many antigens on the neonatal erythrocyte, on occasion, it is necessary to use the indirect antiglobulin test that looks for unattached antibody in plasma to identify antibody.

Management includes treating the hyperbilirubinemia with phototherapy and, when indicated, exchange transfusion and treating the anemia with transfusion if necessary. In some cases, additional modalities such as intravenous gammaglobulin are indicated. Parents of children with neonatal alloimmune hemolysis should be counseled about the potential for future affected infants. Infants with Rh disease who receive intrauterine transfusion may have a prolonged effect and require red cell transfusion postnatally until the antibody levels decline.

T-Antigen Activation

The T antigen is a usually hidden galactosyl residue present on the erythrocyte membrane and exposed by cleavage of sialic acid residues by neuramidase during major bacterial infections, especially *Clostridium perfringens* and *Streptococcus pneumoniae*. Most adults have IgM antibodies against the T-antigen. Infected infants may develop severe hemolysis upon exposure to adult plasma. Neonates with necrotizing enterocolitis appear to be especially at risk for T-activation hemolysis. Its presence should be suspected when marked hemolysis is present after transfusion and often spherocytes are seen on the peripheral blood smear. It can be confirmed in the blood bank by the demonstration of agglutination in vitro when donor serum and patient red blood cells are mixed. If further transfusion is necessary, washed blood products to eliminate the antibody can be used.

Hemoglobinopathy and Thalassemia Syndromes in the Newborn

Hemoglobin molecules all consist of four globin chains connected to a heme moiety. The globin chains vary to create the different hemoglobin forms, while the heme moiety remains the same. Hb A contains 2 α and 2 β chains, while Hb F consists of 2 α and 2 γ chains. The common genetic hemoglobin abnormalities are either decreased production of normal hemoglobin molecules, known as thalassemia syndromes, or the production of abnormal hemoglobins that are called hemoglobinopathies. There are hundreds of identified hemoglobin abnormalities that affect the α, β, or γ chains. In the heterozygous state, most are asymptomatic and identified usually by newborn screening. However, in the homozygous or double heterozygous state, they may produce a wide variety of problems, including hemolysis, sickling, altered oxygen affinity, and methemoglobinemia. The interested reader is referred to multiple resources on this topic.

Thalassemia

The thalassemia syndromes are named for the affected hemoglobin chain, alpha, beta, gamma, or a combination of two or three (e.g., gamma-beta-delta). Thalassemias present with a hypochromic, microcytic anemia of variable severity as described below. In addition

to specific management, genetic counseling is appropriate with all of the identified thalassemia syndromes. There are four alpha chain genes located on the short arm of chromosome 16 and four gamma chain genes, two delta chain genes and two beta chain genes on chromosome 11.

Gamma-Beta-Delta Thalassemia

Rare, large deletions within the β globin gene cluster may affect the γ, β, and δ genes, leading to gamma-beta-delta thalassemia. In the newborn, this may present with a moderate, hypochromic, microcytic anemia that usually evolves into a phenotype consistent with β thalassemia trait with the exception that the Hb A_2 is not elevated. In the homozygous state, these gene deletions would be fatal.

Alpha Thalassemia

Most alpha gene abnormalities are gene deletions, and alpha thalassemia is very common worldwide, particularly in Africa, Asia, and the Mediterranean. The four alpha thalassemia syndromes are defined by the number of functioning genes. With each nonfunctional alpha gene, there is a greater imbalance in the ratio of beta or gamma to alpha chains within the erythrocyte. These excess beta or gamma chains form abnormal hemoglobins, Hb H (β_4) or Hb Barts (γ_4) which are unstable, precipitate out in the cytoplasm, to cause hemolysis. Many of these abnormal erythrocytes do not leave the bone marrow (ineffective erythropoiesis). There are four alpha thalassemia syndromes and other multiply heterozygous conditions that may present similarly such as Hb Constant Spring described below.

Silent Carrier (–α/αα). When one alpha gene is defective, there are minimal or no hematologic consequences. In the neonate, small amounts of Hb Barts may be identified.

Alpha Thalassemia Trait. (−α/−α) or (–/αα). With two defective alpha genes, there is usually a mild anemia. In the neonate, this also usually presents with 3–10% Hb Barts and an MCV <100 fL. In older children, anemia is generally quite mild with a low MCV. Of note, the genotype of individuals with alpha thalassemia trait can be with the deletions occurring in the cis position, i.e., on the same chromosome (–/αα) or in the trans position on the opposite chromosome (−α/−α). While phenotypically these appear identical, genetically there are significant differences as only the cis abnormalities that are found commonly in the Southeastern Asian population will lead to the more severe alpha thalassemia syndromes described below. The trans deletions are common in the African-American population.

Hb H disease (–/−α). Loss of three alpha genes causes a moderately severe anemia with excessive Hb Barts in the neonatal period and Hb H after that. Splenomegaly may develop and hemolysis may be accentuated by infection or exposure to oxidative agents as described for G6PD deficiency. Intermittent transfusion may be indicated and occasionally splenectomy is indicated. Treatment includes folic acid supplementation and counseling of the parents regarding signs/symptoms of anemia.

Hydrops Fetalis (–/–) Deletion of all four alpha genes prevents the formation of both Hb A and Hb F and is generally not compatible with extrauterine life. Some fetuses can survive in utero perhaps due to the presence of the embryonic Hb Portland, but the infants are prone to multiple problems and pregnancy complications such as toxemia appear to be increased. Intrauterine transfusions may be helpful for fetuses diagnosed prenatally. Postnatally, chronic transfusion therapy and/or stem cell transplantation are possible for the surviving infants.

Hb Constant Spring. Hb CS is caused by a mutation that prevents the normal termination of the alpha chain leading to an elongated variant. While this is actually a hemoglobinopathy, Hb CS is produced at a very low rate and functionally produces a thalassemia phenotype. For unclear reasons, Hb CS only occurs in conjunction with a normal alpha gene on the same chromosome. Heterozygous Hb CS ($\alpha^{CS}\alpha/\alpha\alpha$) may be asymptomatic or have an alpha thalassemia trait phenotype. Homozygous Hb CS ($\alpha^{CS}\alpha/\alpha^{CS}\alpha$) or double heterozygous Hb CS/alpha thalassemia trait ($\alpha^{CS}\alpha/-$) would have more of a Hb H phenotype. Homozygous Hb CS typically has a mild anemia, splenomegaly, a normal MCV, marked basophilic stippling and continues to produce Hb Barts after infancy.

Beta Thalassemia

Unlike the alpha chain, there are only two beta genes. Hence, the two potential phenotypes are beta thalassemia minor (heterozygous) and beta thalassemia major (homozygous). In addition, beta thalassemia genes can lead to the production of no beta chains (β^0) or a variably decreased rate of beta chain production (β^+) with significantly different phenotypes. Of note, since beta chain

production does not become the predominant non-alpha chain until after the neonatal period, usually beta gene abnormalities are not symptomatic until that point. Major abnormalities may be identified on newborn hemoglobin screening, however. In addition, co-inheritance of a beta thalassemia gene with an abnormal hemoglobin gene on the other chromosome can lead to a symptomatic hemoglobin disorder.

Beta thalassemia minor. Affected children have a mild hypochromic, microcytic anemia, and no clinical symptoms. Often, these children are diagnosed with iron deficiency and repeatedly treated with therapeutic doses of iron. As iron absorption can be increased in these children, iron overload can result. Therefore, in addition to genetic counseling, affected children and their parents should be advised that iron therapy is only indicated if iron studies have demonstrated a deficiency. Diagnosis is usually made by exclusion of iron deficiency and documentation of an elevation in Hb A_2 ($\alpha_2\delta_2$). As Hb A_2 does not reach adult levels until toward the end of the first year of life, testing can be deferred until that point.

Beta thalassemia major (Cooley's Anemia). Homozygous β^0 thalassemia presents in infancy with marked anemia, signs of extramedullary hematopoiesis such as hepatomegaly and splenomegaly, and markedly abnormal erythrocytes on the peripheral smear with numerous normoblasts. In the past, this disorder was managed with lifelong transfusion therapy and the complications of iron overload were often fatal. Recently, the availability of iron chelation therapy and stem cell transplantation has dramatically improved the outcome for affected individuals. Homozygous β^+ thalassemia usually has a milder phenotype with moderately severe anemia and may not be transfusion dependent. Co-inheritance of Hb E (β 26 Glu $\rightarrow$ Lys), the second most common hemoglobinopathy, with β^0 thalassemia leads to a more severe phenotype that may be as severe as homozygous β^0 thalassemia.

Hemoglobinopathies

Because Hb A only accounts for a minority of the hemoglobin at birth, disorders of the β chain, such as sickle cell, rarely present clinical problems in the newborn but can be identified by newborn screening techniques. More recent techniques such as isoelectric focusing or HPLC have been very good at identifying abnormal hemoglobin molecules. It should be remembered that cellulose acetate hemoglobin electrophoresis (pH 8.6) does not separate Hb A from Hb F well making it hard to distinguish sickle trait from sickle cell disease. In the newborn, often citrate agar electrophoresis is used in addition to cellulose acetate to better separate these hemoglobins.

In the newborn, gamma chain disorders can cause significant hemolysis. However, because of their rapid disappearance, they are infrequently identified. For example, Hb F Poole is an unstable hemoglobin due to a mutation in the gamma gene. Alpha chain disorders can and do occasionally cause neonatal hemolytic anemia. For example, Hb Hasharon is an unstable hemoglobin due to a mutation in the alpha chain gene. Unstable hemoglobins precipitate within the erythrocyte causing hemolysis. They are usually identified by unstable hemoglobin preparations using techniques such as isopropyl alcohol or heat sensitivity that can identify these abnormal erythrocytes with subsequent hemoglobin identification in specialized laboratories. The number of laboratories with expertise in these techniques is small, and use of reference laboratories may be necessary.

Sickle Cell

Sickle hemoglobin (β 6 Glu $\rightarrow$ Val) is the most common hemoglobin variant with a worldwide distribution. As the heterozygous state is believed to offer protection from malaria, it is very common in central Africa, the Near East, Mediterranean, and parts of India. While numerous variants are described, in practice, the most common sickle syndromes are homozygous Hb SS and heterozygous Hb SC and Hb $SB^{thalassemia}$. Sickle trait (Hb AS) is generally asymptomatic, and other than parental counseling, no specific intervention is indicated in infancy. After the transition from Hb F to Hb A occurs in infancy, examination of the peripheral blood smear can demonstrate sickle cells in Hb SS and Hb $SB^{thalassemia}$. The smears from patients with Hb SC disease show large numbers of target cells with an occasional sickle form. Diagnosis can be proven by any of the hemoglobin analysis techniques currently available, including hemoglobin electrophoresis, isoelectric focusing, high-performance liquid chromatography, immunologic techniques, or DNA analysis. Hemoglobin solubility tests are of limited use as false negative tests occur, and they do not distinguish Hb AS from Hb SS or other clinically significant sickle cell syndromes. False normal tests are especially common in the presence of Hb F. Genetic counseling is indicated for parents of identified children and for the affected individuals themselves when they reach childbearing age.

Sickle cell disease syndromes develop over the first year of life. A discussion of the complications of the disorder and

their management is beyond the scope of this chapter, the reader is referred to some excellent discussions of the topic. Guidelines have also been developed and are available online (http://www.nhlbi.nih.gov/health/prof/blood/sickle/sc_mngt.pdf). Two complications, bacterial sepsis and splenic sequestration are especially problematic in infancy, and the parents should be counseled on the importance of immediate medical attention with fever, pallor, splenomegaly, pain, or ill appearance.

Membrane Defects

The red cell membrane consists of a lipid bilayer, an underlying protein cytoskeleton, and many integrated proteins that serve as transportation channels and other functions. Disorders of this red cell membrane, especially the cytoskeleton, cause morphologic changes to the erythrocyte that generally lead to decreased deformability and a decreased life span.

Spherocytosis

Hereditary spherocytosis is one of the more common membrane disorders with a frequency of 1 in 2,500–4,000 in Northern European populations. Inheritance is autosomal dominant in 67–75% of cases and recessive in the rest. Defects in the cytoskeleton proteins Band 3, α spectrin, β spectrin, ankyrin, and palladin have been identified as causing HS. The degree of hemolysis can vary quite widely, from minimal hemolysis indicated by a mild elevation in reticulocyte count to severe, transfusion-dependent anemia. Red cell destruction takes place in the relative hypoxic splenic environment. In most instances, splenectomy normalizes or nearly normalizes the red cell life span.

The diagnosis is often suspected by a positive family history. In the author's experience, sometimes the affected parent is unaware of their diagnosis but is aware that she/he had splenectomy in childhood. In addition to the usual features of hemolysis, the peripheral blood film demonstrates an increased number of small, dense spherocytes. The MCHC is usually elevated. A hemolytic anemia with the classic morphology in the presence of a history of the disorder in the parent can be sufficient for diagnosis, especially if immune hemolysis is excluded. The standard confirmatory diagnostic test is an osmotic fragility that demonstrates the increased sensitivity of the spherocyte to hypotonic conditions. In the neonate, controls must also come from newborns, so this may be harder to accomplish. Red cell membrane cytoskeleton protein analysis can be formed in some highly specialized laboratories.

Management: Most children with HS do well with minimal intervention. However, anemia may be more pronounced in the first few months of life, and red cell transfusion may be necessary in this time. Such infants should be followed relatively closely until the severity of their anemia becomes clear. Folate supplementation can be used to prevent deficiency, especially with severe hemolysis. Parents should be counseled regarding signs and symptoms of anemia as may occur with parvovirus B19 infection-induced aplastic crisis, where the transient decrease in erythropoiesis induced by this virus can cause a severe decrease in hemoglobin concentration due to the shortened red cell life span. Spleen size should be monitored and counseling to avoid splenic trauma is appropriate. Splenectomy may resolve the hemolysis, but the decision whether to proceed with this surgery needs to be individualized as there are significant short and long-term complications. Immunization, especially against encapsulated organisms, should be done. Unless absolutely necessary, splenectomy should be delayed until after 5 years of age to decrease the risk of fatal bacterial sepsis, especially due to *Streptococcus pneumoniae*.

Elliptocytosis

Abnormalities of several cytoskeletal protein abnormalities, including protein 4.1, α spectrin, β spectrin, Band 3, and glycophorin, give rise to the hereditary elliptocytosis (HE) phenotype. There is an increased prevalence noted in malarial areas of Africa and SE Asia. The inheritance of the common HE is usually autosomal dominant. Hemolysis is generally mild, with morphologic changes showing elongated red blood cells on the peripheral blood smear. For most patients with HE, treatment is unnecessary. As noted below, in the neonatal period and occasionally with infection, more severe hemolysis may occur transiently.

Hereditary Pyropoikilocytosis

HPP is a rare, recessively inherited hemolytic disorder with severe hemolysis and distinctive morphology. It is now recognized that HPP is a variant of HE, where often both parents have HE. Alternatively, one parent may be

a silent carrier for HE or carry another mutation that contributes to the phenotype.

Patients with HPP generally have a lifelong moderate hemolytic anemia. Splenomegaly may develop. The diagnosis can be made by review of the peripheral blood smear. Osmotic fragility may be increased. Red cell cytoskeleton protein analysis may be useful to confirm the diagnosis, and DNA mutation analysis may be used for prenatal diagnosis. Treatment is much the same as outlined for HS.

HE can present with more severe hemolysis in the neonatal period. This infantile pyropoikilocytosis may require transfusion or even exchange transfusion and red cell morphology identical to HPP. Over the first 3–12 months of life, the rate of hemolysis lessens and the red cell morphology transitions to that of HE. As it is not possible to distinguish infantile pyropoikilocytosis from HPP in the first few months of life, these infants should be observed closely.

Enzymopathy

The red blood cell utilizes glucose to produce ATP via the Embden–Myerhoff pathway and to a lesser degree to create NADPH, which is involved with the protection of the erythrocyte from oxidative damage. While disorders of the glycolytic pathway are well described, with the exception of glucose-6-phosphate dehydrogenase (G6PD) deficiency, which is the gateway into the hexosemonophosphate shunt, they are all quite rare.

Glucose-6-Phosphate Dehydrogenase Deficiency

The red blood cell is protected from oxidative damage by the glutathione system that requires NADPH to regenerate reduced glutathione. G6PD deficiency can lead to a defect in this pathway, allowing for hemolysis especially at times of infection or exposure to potential oxidants.

The gene for G6PD is located on the X-chromosome. Hundreds of variant enzymes have been described with varying degrees of clinical manifestations. Over 400 million people are affected worldwide. Hemizygous males with G6PD deficiency account for the majority of symptomatic individuals, but females can also be affected if they have homozygous or double heterozygous gene defects or via the Lyon hypothesis, where the normal gene is inactivated in an imbalanced manner. Over 400 variants of the G6PD enzyme have been described, and a classification system has been developed based on the severity of the deficiency. Class I, the most severe G6PD variants can cause a chronic hemolytic anemia and can affect leukocyte function. Class II variants, such as the common $G6PD^{Mediterranean}$, has $<10\%$ residual activity but typically presents with hemolysis, which while intermittent can be quite severe. Class III variants, such as the $G6PD^{A-}$, seen in 10–15% of the African-American population causes hemolysis upon exposure to infection or drugs. In this variant, the erythrocyte G6PD activity falls off more quickly than normal as the red cell ages.

Clinical manifestations of G6PD deficiency are typical for acute hemolysis, usually upon exposure to infection or oxidants. Broad or fava beans and naphthalene are common offending agents. Patients develop pallor, jaundice, and dark urine. The peripheral blood smear often shows "bite cells" and polychromasia. The diagnosis can be confirmed with a quantitative G6PD enzyme test, but this test can miss the diagnosis if there are a large number of reticulocytes, especially with the $G6PD^{A-}$ variant.

Neonatal hyperbilirubinemia, including severe hyperbilirubinemia, has been well described with G6PD deficiency and is more common with the $G6PD^{Mediterranean}$ than the $G6PD^{A-}$ variant, and may be caused by oxidant exposure in the nursery and/or maternal fava bean ingestion. Despite the hemolysis and hyperbilirubinemia, anemia is not always present.

Management begins with counseling the family on the signs/symptoms of anemia and medications and foods to avoid. The handling of a particular episode of hemolysis depends upon the severity of the anemia. Exposure to the offending agent should be removed if possible, bacterial infection treated, and transfusion may be indicated. If transfusion is given prior to testing, the quantitative G6PD assay should be deferred until the transfused red cells are gone – usually approximately 3 months. Hyperbilirubinemia should be managed as per established guidelines.

Other Hemolytic Diseases in the Neonate

Infantile Pyknocytosis

Infantile pyknocytosis is a rarely recognized hemolytic disorder identified in infancy. The pyknocyte morphologically appears as an irregularly contracted, dense cell with irregular projections. The etiology is unknown, but as transfused cells can acquire the pyknocytic morphology, it is presumably caused by an extra-erythrocytic factor.

Clinical features are similar to other hemolytic disorders: hyperbilirubinemia, pallor, and, occasionally, hepatomegaly and splenomegaly. The laboratory features are also typical of hemolytic disease, including an elevated reticulocyte count, elevated indirect bilirubin, and elevations in the aspartate aminotransferase and lactate dehydrogenase enzymes. Diagnosis is usually made by examination of the peripheral blood smear and exclusion of other disorders that can occasionally have a similar appearance such as G6PD deficiency, pyruvate kinase deficiency, vitamin E deficiency, and other Heinz body producing anemias. Infantile pyknocytosis is usually a transient disorder with resolution in the first few months of life, but other disorders that may have a similar appearance may be lifelong. Management involves treatment of hyperbilirubinemia as necessary and occasional red blood cell transfusion for severe anemia.

Microangiopathic Disorders

While thrombocytopenia and coagulopathy are the more often clinically relevant problems with microangiopathic disorders such as DIC, red cell destruction with prominent schistocytes on the peripheral blood film is common. Mechanical hemolysis can occur with congenital heart disease, ECMO, and cavernous hemangiomas. In addition to a schistocytic hemolytic anemia, hemoglobinuria is often present and may lead to the diagnosis. Management is dependent upon the severity of the anemia but should include the recognition that chronic mechanical hemolysis can lead to iron deficiency.

Infection

Congenital infections often can cause hemolysis. This includes intrauterine infections such as TORCH and enterovirus, as well as postnatal infections with cytomegalovirus.

Methemoglobinemia

Methemoglobin is formed when the iron in the heme moiety is oxidized from the usual ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Methemoglobin is unable to carry oxygen and high levels interfere with oxygen delivery to the tissues. The erythrocyte enzyme NADH-methemoglobin reductase acts to keep methemoglobin levels below 1%, and another enzyme, NADPH-methemoglobin reductase, can function under certain conditions in this activity. Exposure to oxidizing agents such as nitrites, aniline dyes, nitrous oxide among others can trigger methemoglobinemia. Intrinsic factors such as the presence of M hemoglobins that are particularly susceptible to oxidation or deficiency of NADH-methemoglobin reductase increase the risk of the disorder and cause chronic methemoglobinemia.

There are several reasons that the neonate is particularly susceptible to methemoglobinemia. Hb F is more prone to oxidation, and neonatal levels of NADH-methemoglobin reductase are lower than adult levels. Sick neonates may be exposed to nitric oxide that is known to trigger methemoglobinemia.

The principal clinical manifestation of methemoglobinemia is cyanosis. A screening test is done with a drop of blood on filter paper waved in the air. With methemoglobin, the color of the blood does not change upon exposure to air as it should when cyanosis is due to deoxyhemoglobin. Cyanosis is apparent with methemoglobin levels about 10% (1.5 g/dL). Diagnosis can be confirmed via use of a co-oximeter. Symptoms caused by interference with oxygen delivery usually do not appear until the methemoglobin level is in excess of 30%. Asymptomatic individuals with chronic methemoglobinemia do not usually need treatment, especially if the level is $<30\%$. Treatment begins with removal from exposure to any offending agent. Methylene blue can reverse methemoglobinemia in individuals who do not have M hemoglobins but requires a functioning NADPH-methemoglobin reductase system, so it will not be effective in individuals with G6PD deficiency.

Thrombocytopenia

The reference range for platelet counts in the newborn is considered to be the same as for adults, 150,000–450,000/μL. While neonatal thrombocytopenia is defined as a platelet count $<150/000/\mu L$, platelet counts of 100,000–150,000/μL are more common in the newborn than in the adult and, do not necessarily indicate a disease state. Neonatal thrombocytopenia occurs in 22–35% of infants admitted to neonatal intensive care units with the higher frequencies occurring in the more premature infants.

While there are a large number of potential etiologies for neonatal thrombocytopenia, important clues can be determined from the perinatal history, the physical appearance of the infant, the timing, and the

severity of the thrombocytopenia. The more common causes of neonatal thrombocytopenia are shown in *Table 31.2*.

Table 31.2
Causes of neonatal thrombocytopenia

Feto-maternal unit
Pregnancy-induced hypertension
Maternal diabetes mellitus
Immune thrombocytopenia
Maternal autoimmune
Neonatal alloimmune
Infection
Neonatal sepsis
Intrauterine infection
Neonatal illness
Disseminated intravascular coagulation
Necrotizing enterocolitis
Thrombosis
Inherited thrombocytopenia syndromes
Thrombocytopenia with absent radii
Thrombocytopenia with radiosynostosis
Congenital amegakaryocytic thrombocytopenia
Macrothrombocytopenias
Bernard–Soulier syndrome
Grey platelet syndrome
Paris-Trousseau-Jacobsen syndrome
Montreal platelet/type 2b von Willebrand disease
MYH9-related Thrombocytopenia
May–Hegglin anomaly
Epstein syndrome
Fechtner syndrome
Sebastian syndrome
Other bone marrow failure syndromes
Fanconi anemia
Dyskeratosis congenita
Chromosomal anomalies
Trisomy 13
Trisomy 18
Trisomy 21
Others
Noonan syndrome
Bloom syndrome
Turner syndrome
Gaucher type 1

Infection

Neonatal sepsis needs to be considered in any infant with thrombocytopenia, whether this occurs in the first few days of life or later. Such infants usually appear quite ill with respiratory symptoms and/or hemodynamic instability.

Disorders of the Fetal-Maternal Unit

The most frequent cause is chronic fetal hypoxia as is seen in infants with intrauterine growth delay, maternal diabetes, or maternal hypertension. The platelet count is usually not severely depressed (e.g., >50,000/μL) and usually recovers to normal levels within 10 days. This thrombocytopenia appears to be due to decreased production and is often accompanied by neutropenia and increased numbers of nucleated red blood cells. Some causes of this problem include:

Maternal Hypertension

Maternal hypertension is one of the more common causes of thrombocytopenia in the neonate, especially in the neonatal intensive care unit. The platelet count in these children is usually just moderately reduced to 50,000–100,000/μL. As discussed in the below section, neutropenia may coexist in these infants. The mechanism of this thrombocytopenia appears to be decreased production. In most instances, the platelet count returns to normal within 7–10 days of birth.

Maternal Diabetes

Infants of mothers with gestational diabetes may have low platelet counts at birth. The platelet count may decrease over the first few days of life. As with maternal hypertension, the thrombocytopenia tends to be mild to moderate. The etiology is unclear as well but may be similar to that of maternal hypertension and other placental insufficiency syndromes. Thrombosis, especially renal vein thrombosis, has also been seen in these infants and should be considered strongly in any child born to a diabetic mother who has a flank mass or hematuria. In most instances, this thrombocytopenia is short lived and recovers within the first 2 weeks of age.

Maternal Medications

In the unusual case of a mother who receives chemotherapy during pregnancy, myelosuppression may affect the newborn. Infants of such mothers should have an initial CBC, and if thrombocytopenia is present, be monitored until it has recovered. Rarely, other medications administered to mothers may suppress platelet production. Maternal medications, such as aspirin, may decrease platelet function without affecting platelet count. When necessary, platelet transfusion may be given to manage bleeding complications or severe thrombocytopenia.

Intrauterine Infection

Several intrauterine infections including the TORCH (Toxoplamosis, Other, Rubella, Cytomegalovirus, and Herpes Simplex) infections, enterovirus, and HIV may result in neonatal thrombocytopenia. The mechanisms involved may differ between these infections but may include viral suppression of platelet production, splenic sequestration, maternal medications, antiplatelet antibody (as with maternal HIV infection), and consumptive coagulopathy as may occur with perinatal enterovirus infection. Cytomegalovirus infection when it occurs early in gestation may cause intrauterine growth restriction, multiple congenital anomalies, and extramedullary hematopoiesis, presenting as a blueberry muffin rash. In contrast, perinatal CMV infection may be less clinically obvious but can present with thrombocytopenia.

The management of infected children depends upon the underlying infection and is beyond the scope of this chapter. The reader should refer to sections on these specific infections.

Immune Thrombocytopenia

Immune thrombocytopenia usually presents with the well-appearing child with the exception of petechiae and/or purpura. A careful maternal history is very important to determine the cause in such infants.

Maternal Autoimmune Thrombocytopenia

Mothers with autoimmune thrombocytopenia generally have a low platelet count at the time of delivery, although on occasion the mother has undergone splenectomy for the disorder, and while she still has circulating antiplatelet antibody, she may no longer be thrombocytopenic. The incidence of thrombocytopenia in pregnancy is 7–8% and in addition to maternal ITP, can have a number of causes, including pregnancy-induced hypertension, DIC, HELLP, TTP/HUS, and medications, although the most common cause is gestational thrombocytopenia. The history of thrombocytopenia predating pregnancy, other autoimmune disorders such as systemic lupus erythematosis or earlier treatment for ITP can lead to the correct diagnosis for the neonate.

The IgG antiplatelet antibody can cross the placenta and affect the fetus. Fortunately, 85–90% of infants born to mothers with ITP have a platelet count $>50{,}000/\mu L$ and <1–5% have a platelet count $<20{,}000/\mu L$. No reliable predictors of severe fetal thrombocytopenia have been identified; however, the history of maternal splenectomy, severe thrombocytopenia, or a prior pregnancy with a severely affected newborn has been associated with lower platelet counts with this child. Prenatal or fetal scalp platelet counts are not generally recommended during the pregnancy; however, a cord blood platelet count should be obtained after delivery.

The platelet count can decrease from cord blood levels over the first few days of life. Few infants will need intervention other than monitoring of the platelet count over this period of time. Infants with severe thrombocytopenia or hemorrhage should be managed as described for neonatal alloimmune thrombocytopenia.

Neonatal Alloimmune Thrombocytopenia (NAIT)

With a mechanism analogous to Rh disease for red blood cells, a mother can be sensitized to platelet antigens that do not occur on her own platelets. Genetic polymorphisms in the major platelet surface glycoproteins account for the antigenic differences are defined serologically and given a designation as human platelet antigen (HPA) number. The most common antigens to cause NAIT are HPA (human platelet antigen) 1 and 5, except in women of Asian descent, where it is HPA-4. There is a recommendation to screen HPA 1, 3, and 5 (and HPA-4 in women of Asian descent) in cases of NAIT. In most cases, maternal serum, and if available, both parents' platelets are sent for analysis. It is important to utilize a laboratory with expertise in studying women for NAIT.

Despite the analogy with Rh disease, there are significant differences between NAIT and red cell

alloimmunization. These include the finding that the first pregnancy can be affected, pregnancies are not screened for NAIT (except in Norway or in the presence of a prior history), only a small percentage of women with platelet antigen mismatch become sensitized and when the disorder is diagnosed, treatment is often given to the mother prenatally. Obviously, the bleeding manifestations of NAIT, including intrauterine intracranial hemorrhage, are very different than the anemia and hyperbilirubinemia caused by Rh incompatibility.

NAIT usually presents with a platelet count $<50{,}000/\mu L$. While helpful if present, only a minority of cases have a history of a prior affected pregnancy. Hemorrhage may occur in utero, at delivery, or postpartum. Intracranial hemorrhage occurs in 11–21% of clinically recognized cases of NAIT and may be higher in infants whose mother had a prior severely affected pregnancy.

The management of pregnancies known to be at risk or affected should be done by obstetricians familiar with the disorder and is beyond the scope of this chapter. It is important to monitor the affected neonate's platelet count over the first few days as it often falls from cord blood levels. Treatment depends upon the presence of bleeding and the platelet count. An urgent head ultrasound should be obtained. Platelet transfusion has been recommended if the asymptomatic term infant's platelet count is $\leq 30{,}000/\mu L$, although some have recommended transfusion for platelets $\leq 50{,}000$ for all cases of NAIT, especially those with HPA-5b incompatability. A threshold of $50{,}000/\mu L$ may be appropriate in the presence of prematurity, birth asphyxia, or other factors predisposing to ICH, and $100{,}000/\mu L$ if ICH or other significant bleeding is present. Of note, recent studies have demonstrated that random donor platelet transfusions are often effective in infants with NAIT. IVIg, 1 g/kg daily for 1–2 days can be given if the initial platelet count is low, especially in the first day of life, or in conjunction with platelet transfusion. Corticosteroids have also been used, preferably for a very short course due to the risk of infection. For infants who do not responds to random donor platelets, HPA 1 and 5 negative platelets (HPA-4 for mothers of Asian descent) can be tried if available. Maternal platelets were previously recommended but are problematic, in that immediately postpartum women are not ideal platelet donors, they have high levels of antiplatelet antibody, and platelet washing damages the platelets. If maternal platelets are used, they should be volume-reduced to decrease the amount of antibody infused and irradiated to prevent graft-versus-host disease.

In most instances, NAIT resolves completely within 2 weeks of birth. Infants should be followed until it has resolved, and if thrombocytopenia persists, evaluation should be done for alternative diagnoses.

Congenital Disorders

Trisomy 13, 18, and 21 can all be associated with early-onset thrombocytopenia. Infants with Down's syndrome can develop transient myeloproliferative disorder, also called transient abnormal myelopoiesis, that presents with leukocytosis, peripheral blasts, hepatosplenomegaly, and, occasionally, pulmonary or pericardial effusions. While this usually resolves spontaneously, some infants do require treatment for hepatic, renal, pulmonary, or cardiac insufficiency. Of note, about 20–30% of these infants develop acute myelogenous leukemia in the first few years of life.

Bone Marrow Failure Syndromes

As discussed above, thrombocytopenia may be the presenting finding for Fanconi Anemia and other marrow failure syndromes. Two syndromes in particular can present in the newborn with isolated thrombocytopenia.

Thrombocytopenia with Absent Radii (TAR)

Infants with TAR are identified either by prenatal ultrasonography or at birth by their radial defects. Of note, the thumbs are present in children with TAR. In addition to the radial ray anomalies and thrombocytopenia, which is present at birth, other anomalies may be present, including other skeletal defects (ulnar, humeral, knees, hips), microcephaly, capillary hemangiomata, cardiac defects, and short stature. Radial ray defects are not specific for TAR as other syndromes may present with this skeletal defect.

The etiology of TAR is not completely understood. Thrombocytopenia is hypoproductive with bone marrow examination documenting decreased and abnormal megakaryocytes. Serum levels of thrombopoietin are elevated, consistent with decreased megakaryopoiesis. Inheritance appears to be autosomal recessive in most cases with autosomal-dominant inheritance described as well. Recently, abnormalities in chromosome 1q21.1 have been identified in patients with TAR and unaffected family members, suggesting that this gene defect is contributory

but not sufficient to cause TAR. In addition to the thrombocytopenia, some evidence for platelet functional abnormalities in TAR has also been described.

The platelet count usually increases in the first year of life, and while mild to moderate thrombocytopenia may persist, the risk of bleeding decreases at that time. In addition to the thrombocytopenia, other issues for children with TAR exist. There appears to be an increased incidence of lactose intolerance and GI bleeding may be problematic, especially in infancy. Bleeding may in turn lead to anemia for which iron supplementation is indicated. Orthopedic anomalies need long-term attention. Procedures to address the radial ray and functional hand defects are currently available. Other limb defects such as genu varum need to be monitored and managed. Children with TAR have an increased incidence of leukemia and long-term follow-up is necessary. However, aplastic anemia does not appear to occur in TAR.

Management for TAR consists of platelet transfusion support. As noted, usually the need for platelet transfusion decreases after the first year of life, occasional platelet transfusion may still be necessary if the platelet count falls with infection or a higher platelet threshold is necessary for surgical procedures. Long-term follow-up is also indicated to look for the development of leukemia.

Congenital Amegakaryocytic Thrombocytopenia (CAMT)

CAMT may also present with bruising, petechiae, and thrombocytopenia in the newborn. Unlike the radial ray abnormalities of TAR, there are no diagnostic physical anomalies in children with CAMT, but anomalies are present in about half the cases, including skull, cardiac, renal, optic nerve, and other skeletal defects. GI and other mucous membrane bleeding can occur as can more severe internal and CNS hemorrhage. CAMT may progress to myelodysplastic syndrome and aplastic anemia. Additional long-term complications include the cardiac, renal, skeletal abnormalities, and some who have psychomotor retardation.

Like TAR, the thrombocytopenia of CAMT is hypoproductive with elevated TPO levels and decreased bone marrow megakaryocytes. Defects in the thrombopoietin receptor gene c-MPL have been identified and are causative in most cases. An additional form of CAMT with radioulnar synostosis due to defects in the HOX-A11 gene has been described.

Management in the immediate newborn period is supportive, but long-term management is best done with hematopoietic stem cell transplantation. There is a high frequency of aplastic anemia and leukemia development long-term.

Wiscott–Aldrich Syndrome (WAS)

WAS is an X-linked disorder that affects more than platelets. The classic triad includes thrombocytopenia, immunodeficiency, and eczema. The defect lies in the Wiscott–Aldrich associated protein (WASp), the responsible gene for which is located on Xp11.23. A more complete description of this disorder and its immunologic complications is reviewed in Chap. _____.

Infants with WAS often present with perinatal bleeding. A striking feature of the thrombocytopenia is the small platelet size. These small, misshapen platelets may be sequestered in the spleen. Splenectomy may improve the platelet count in most patients, but this may be problematic due to the immune deficiency in these children. While corticosteroids have increased the platelet count in some children with WAS, intravenous gammaglobulin therapy does not appear to be helpful for the thrombocytopenia. Platelet transfusion may be necessary. The long-term management of WAS is hematopoietic stem cell transplantation where available. This addresses the immune deficiency as well as the thrombocytopenia.

X-linked thrombocytopenia is disorder related to WAS. These patients also present with thrombocytopenia and small platelets and may have eczema. The degree of immunodeficiency is less than that in WAS, but immunologic disturbances may increase over time.

Qualitative Platelet Disorders

In addition to thrombocytopenia, platelet function disorders can and do present in the neonatal period. The most common are probably disorders caused by medications that inhibit platelet function such as cyclo-oxygenase inhibitors. These are rarely diagnosed. Rare but severe platelet function disorders such as Glanzmann's thrombocythemia and Bernard–Soulier syndrome may present in the neonatal period. Infants treated with extracorporal membrane oxygenation (ECMO) may have both thrombocytopenia and acquired platelet function abnormalities.

Late-Onset Thrombocytopenia

Consumptive Coagulopathy and Thrombosis

Disseminated intravascular coagulation (DIC) appears to occur fairly commonly in sick neonates. DIC can be triggered by sepsis, necrotizing enterocolitis, hypotension, hypoxia, congenital enterovirus infection, and other causes. While bleeding symptoms are usually apparent to the clinician, intravascular thrombosis is the underlying pathology and thrombotic complications of DIC can occur. The most important component of management is to treat the underlying cause. Blood product support, such as platelets or fresh frozen plasma, may be necessary to manage bleeding episodes. DIC is discussed more completely in the hemostasis chapter.

Infection

Late-onset sepsis can cause thrombocytopenia in the newborn and should be strongly considered in an infant who develops this finding.

Thrombosis

Thrombocytopenia can also be caused by thrombosis within the infant; therefore a search for a blood clot can be revealing, especially in the older infant with unexplained thrombocytopenia. In infants with central venous catheters, Doppler ultrasound studies may demonstrate the clot. Neonatal thrombosis is discussed in the hemostasis chapter.

Neutropenia

Several factors can affect the reference range for neutrophil counts in the neonate. Manroe et al. first published a reference range for neonates in 1979 when survival of very low birth-weight infants was rare. In 1994, Mouzinho et al. published neutrophil counts from VLBW infants demonstrating a lower limit below that of Manroe. Infants born at high altitude have higher absolute neutrophil counts. Schmutz et al. published data on neutrophil counts from >30,000 infants born at high altitude. These three studies have had somewhat different results. For infants >36 weeks gestational age at delivery, the reference range lower limits were 3500/microliter (Schmutz) or 1800/microliter (Manroe) while these levels were 2700/microliter and 3000/microliter respectively at hours 72-240. For infants 28-36 weeks gestational age, the lower limits of the reference range at delivery were 1000/microliter (Schmutz) and 2100/microliter (Mouzinho) and these values were 800/microliter and 1100/microliter respectively at 72-240 hours of age. Finally, for infants <28 weeks gestational age at delivery the lower limit of neutrophil counts were 500/microliter (Schmutz) and 2100/microliter (Mouzinho). These authors had similar lower neutrophil counts at 72-240 hours of 1100-1300/microliter. While these reference ranges show a lower limit that may be as high as 8,200/μL, it is not clear that infants whose absolute neutrophil count (ANC) is above 1,000/μL are at increased risk for infection. Hence, mild neutropenia, where the ANC remains above 1,000/μL, may not need extensive evaluation. In addition, preanalytic specimen degradation can affect the neutrophil count, so it is often wise to repeat the CBC in a well-appearing child who is found to have unexpected neutropenia.

The evaluation of the infant with neutropenia can be directed by the timing and the severity of the neutropenia, the clinical picture the infant presents with and other findings on the CBC and peripheral blood smear. The presence of a left shift with metamyelocytes and band forms on the peripheral blood smear suggests that there is intact neutrophil production. A bone marrow test is occasionally indicated in the work-up of such infants but is not commonly performed in the infant and usually requires an individual with expertise with the procedure.

In this section, some of the more common causes of neutropenia are discussed (*Table 31.3*). There are several excellent discussions available on the topic for additional information.

Infection

Infection is probably the most common cause of neonatal neutropenia. Such infection can be bacterial, viral, fungal, or other, and severe neutropenia can be a sign of overwhelming septicemia. There may be an increased percentage of immature granulocytes such that the ratio of bands to segmented neutrophils is elevated (increased I/T ratio). Examination of the peripheral blood smear may also demonstrate toxic granulation, vacuoles, and Döhle bodies within the neutrophils.

Usually, the infant with infection-induced neutropenia is clinically ill. The work-up should be directed at identifying the underlying cause of the neutropenia. Management is focused on treating the underlying cause, usually with empiric antimicrobial therapy.

Table 31.3
Causes of neutropenia in newborns

Infection
Necrotizing enterocolitis
Medication induced
Maternal fetal unit
Pregnancy-induced hypertension
Rh incompatibility
Twin–twin transfusion
Maternal medications
Immune
Maternal autoimmune neutropenia
Neonatal alloimmune neutropenia
Inherited disorders
Severe congenital neutropenia
Schwachman–Diamond syndrome
Glycogen storage type 1b
Reticular dysgenesis
Osteopetrosis
Cartilage-hair hypoplasia
Cyclic neutropenia
X-linked agammaglobulinemia
Bone marrow failure syndromes, e.g., Fanconi anemia
Chronic benign neutropenia

Transient Neonatal Neutropenia

Infants of Hypertensive Mothers

Neutropenia is commonly found in infants of hypertensive mothers. While the ANC can be quite low, studies of infection rates in these infants have yielded conflicting results, and it is unclear if such infants have an increased risk for serious infection. The neutropenia is hypoproductive but usually lasts only a few days postdelivery. Management can be supportive with little evidence to date that in the absence of clinical symptoms, these infants require either empiric antibiotics or the use of growth factors such as filgrastim.

As with infants of mothers with pregnancy-induced hypertension, infants with Rh incompatability or survivors of twin–twin transfusion may be born with a transient neutropenia. In most cases, the neutropenia is self-limited, and the clinical approach to these infants may be similar to that for pregnancy-induced hypertension.

Immune Neutropenia

As for red cells and platelets, alloimmune and isoimmune neutropenia may occur. The neutropenia in such infants is present at birth and may last for several weeks depending upon the maternal titers of anti-neutrophil antibody.

In isoimmune neutropenia, the mother has autoimmune antibody formation and may have a low ANC herself. In alloimmune neutropenia, the mother is sensitized against antigens on the neonate's neutrophils that she does not carry.

The diagnostic work-up usually begins with the maternal history and examination of her CBC results. The history of a previously affected sibling is very helpful but may not be present. The diagnosis can be confirmed by sending anti-neutrophil antibody studies to a specialized reference laboratory with expertise in this area.

Management of immune neutropenia depends upon clinical symptoms, degree of neutropenia, and cause. For severe, persistent neutropenia, infants should be monitored closely for the development of infection. Recombinant granulocyte stimulating factor has been demonstrated to be effective in increasing the ANC and is often used in these infants; however, the long-term effects are unknown, and there are no controlled trials to demonstrate improved outcomes. Other therapies, such as corticosteroids, have not been demonstrated to be beneficial. The long-term outlook is good and the neutropenia should resolve within several weeks without recurrence.

Congenital Neutropenia Disorders

Severe Congenital Neutropenia (SCN)

SCN is a rare, inherited disorder characterized by persistent, severe neutropenia (ANC $< 500/\mu L$), and recurrent severe infections. Infants usually present within the first few months of age with infection. Monocytosis and eosinophilia often accompany the neutropenia. The diagnosis can be confirmed by bone marrow examination which typically demonstrates an arrest of myeloid differentiation at the promyelocyte/myelocyte stage. Abnormal, vacuolated promyelocytes can be seen.

Inheritance can be autosomal dominant, autosomal recessive, or X-linked. A slight majority is caused by mutations in the neutrophil elastase gene ELA2 and demonstrates autosomal dominant inheritance. Interestingly, defects in this same gene are thought to be responsible for cyclic neutropenia. Another form of SCN, caused by mutations in the mitochondrial protein gene HAX1, has an autosomal recessive inheritance. Defects in the glucose

6 phosphate dehydrogenase catalytic subunit three gene have recently been shown to cause autosomal recessive SCN. X-linked SCN can be caused by mutations in the WASP protein also associated with Wiscott–Aldrich Syndrome. Barth Syndrome is an X-linked recessive neutropenia due to defects in the tafazzin gene. There are other forms of SCN caused by other identified and as yet unidentified gene defects.

The immediate management of infections in infants with severe neutropenia includes a search for the etiology of the infection and empiric broad spectrum antibiotics. Additional management of fever and neutropenia and fever in infants is discussed in Chap. 38, "Disorders of Organic Acid and Amino Acid Metabolism".

The development of an SCN registry (http://depts.washington.edu/registry) has provided a good deal of information regarding the management and long-term complications for SCN. Most children with SCN respond to G-CSF therapy with the dosage adjusted to maintain the absolute neutrophil count above 1,000/μL. The dose can vary widely, but an analysis of the SCN registry showed the median dose to be approximately 5 μg/kg/day and that most children could be effectively maintained at this level with doses <25 μg/kg/day. For children whose neutrophil count does not respond to G-CSF treatment, hematopoietic stem cell transplantation is recommended.

Children with SCN have an increased risk of development of myelodysplastic syndrome or leukemia with a cumulative incidence of 21% at 10 years. Children who require higher doses of G-CSF may be more at risk for leukemic development. Neurologic abnormalities have been identified in children with HAX1 defects, cardiac and urogenital defects in children with glucose 6 phosphate dehydrogenase catalytic subunit 3 gene, and organic aciduria, dilated cardiomyopathy, and distal muscle weakness in Barth Syndrome.

Other Inherited Neutropenia

Many other congenital syndromes may be associated with neutropenia, including glycogen storage disease type 1, Schwachman–Diamond syndrome, reticular dysgenesis, X-linked agammaglobulinemia, cartilage-hair hypoplasia, and others.

32 Neonatal Neurology

Matthias Keller · Elke Griesmaier

Introduction

In neonatology the physicians are faced with numerous challenges in the field of neonatal neurology. In this chapter the most prominent and challenging conditions are discussed complementary to the section of Neonatal Neurology in the Pediatric Neurology chapter.

Most important to note is that the brain of term infants is not the same as of preterm infants and even within preterm born infants there is a clear difference depending on gestational age. Therefore, insults like hypoxia and ischemia will have a different effect depending on the stage of brain development. This has also consequences for treatment. Treatments shown to be protective in term newborns are not necessarily protective in preterm infants.

In order to understand these particularities, it is mandatory to know the key aspects of brain development. It can be separated into structural and functional. Structural brain development is characterized by the proliferation of neural cells in the subventricular zone and migration of glia and neuronal cells to the cortex. Functional brain development is characterized by organizational events, which occur over a time period spanning from the fifth month of gestation to several years after birth. Key features of functional brain development include attainment of proper alignment, orientation and layering of cortical neurons, elaboration of dendritic and axonal ramifications, establishment of synaptic contacts, and cell death as well as selective neuronal/synaptic elimination. Development of the functional neuronal network depends mainly on the establishment of afferent input and synaptic activity. The timing and spacing of an adequate level of stimulation is thereby essential for normal brain development. This phase is reflected by a tremendous growth of the brain from 70 g at 24–350 g at 40 weeks of gestation (term). During this period up to 40,000 synapses per second are established. Furthermore this phase is characterized by a high level of neurotransmitter receptor expression which surpasses levels in adults. In addition the function of neurotransmitter receptors is developmentally regulated. The GABA receptor known to act inhibitory in adults acts excitatory in the developing brain. The development of functional neural networks is susceptible to changes in neurotransmitter signaling. It has been shown that inhibition of activating receptors causes neuronal cell death and impacts on brain development. In summary, it is important to note that (1) the preterm brain is not comparable to the adult brain and not even to the mature newborn brain, (2) that any factor which modifies neurotransmitter signaling might potentially disturb brain development, and (3) that drugs shown to have beneficial effects in the adult brain might have other, potentially negative effects in the developing brain.

Developmental Brain Injury in the Preterm Infant

Premature birth itself affects brain development at a very early stage of neuronal network development, leading to lifelong sequelae. Depending on the gestational age and birth weight there is an increased risk of lifelong disabilities such as cerebral palsy and cognitive disorders. This poses a serious burden to the children, their families and to the healthcare system and therefore to society in general. Besides severe impairments such as cerebral palsy, it has been shown that several cognitive dysfunctions have a higher incidence in formerly preterm children. Even in premature infants without severe neurodevelopmental impairments, the risk of attention deficit hyperactivity disorder (ADHD) is increased 2.6–4.0 times in early childhood. Some of these difficulties persist into adolescence and early adulthood. Magnetic resonance imaging (MRI) studies of ex-premature infants less than 32 weeks of gestation revealed reduced brain volumes and cortical folding, delayed maturation, and disturbed myelination, all of which result in an impaired neurological development. It is important to take into account that also the so-called "late preterm infants," born at a gestational age >32 weeks of gestation, are at a higher risk of cerebral palsy and connectivity disorders such as ADHD and psychiatric disorders in childhood and even adulthood.

From Periventricular Leukomalacia via White Matter Disease to Encephalopathy of Prematurity

Within the last 10 years major progress has been made in understanding the pathophysiology of perinatal brain injury in preterm infants. The classic description of developmental brain injury in preterm newborns is periventricular leukomalacia (PVL). The term periventricular leukomalacia describes injury of the white matter around the lateral ventricles, which mainly involves fibers that come from or lead to the cerebral cortex. Therefore, the corticospinal tract, associating fibers and the optic and acoustic radiation are mainly affected. Infants who suffer from PVL often develop motor disabilities, cognitive, visual, or acoustic impairment.

A condition called "Little´s disease" was described by Little in 1853. He related this condition with its prominent features – limb contractures, diplegia, and mental retardation – to preterm birth and asphyxia at birth. In 1867 a disease called "congenital encephalomyelitis" was first described by Virchow. As many of the children´s mothers suffered from smallpox or syphilis, he related the disease to acute infection. Examination of the brains post mortem showed pale softened zones within the periventricular white matter, glial hyperplasia, and evidence of necrosis. In this context, infarction and hemorrhage was connected by Parrot, proposing that white matter damage was the result of nutritional and circulatory disturbances during development. In 1962 Banker and Larroche first introduced the term "periventricular leukomalacia," describing cardiopulmonary diseases or abnormalities, placental abnormalities, or a severe anoxic period prior to or shortly after birth as risk factors for PVL.

The histopathology of PVL is characterized by a chronological sequence of astrocytosis, microglial reactivity, and swollen axons to astrocytic proliferation and capillary hyperplasia, followed by microglial proliferation and accumulation of lipid-laden cells within 7 days after the insult. Cavitation emerges within 3–4 weeks. According to the histopathological distribution, three types of PVL are distinguished: focal, diffuse, and widespread. The focal type is located deep in the cerebral white matter and characterized by localized necrosis of all cellular elements and progression to cyst formation. The diffuse type mainly affects oligodendrocyte precursors and thus seemed to be cell specific. The prognosis for the diffuse is better than for the focal type. In the last decade the incidence of the cystic form of PVL is declining, presumably because of improvement of perinatal and neonatal care.

Pathophysiology of Developmental Brain Injury

The pathogenesis of PVL is complex and not yet completely understood. One major factor is hypoxia-ischemia. The preterm brain is prone to low oxygen delivery, due to the immature vascularization resulting in so-called watershed areas in which perfusion is marginal and to the lack of proper autoregulation of cerebral blood flow in preterm infants. Furthermore, precursor cells of the white matter in these periventricular regions are particularly sensitive to hypoxia. In addition to hypoxia-ischemia, inflammation plays a major role in the pathophysiology of developmental brain damage. Inflammation *per se* causes injury not only to the white but also to the cortical gray matter. Inflammation sensitizes the developing brain toward hypoxia-ischemia, causing an aggravation of brain injury. Although inflammation and hypoxia-ischemia are seen as major factors for brain injury, it has been shown that also so-called environmental factors like premature exposure to high levels of oxygen (hyperoxia), pain, and drugs contribute to disturbances of brain development. *Figure 32.1* summarizes the current knowledge about the pathophysiology of PVL.

Recent MRI studies of infants with very low birth weight (VLBW) have revealed that not only white matter injury occurs but that also cortical gray matter volume is affected and reduced. Consequently, in the last decade the term PVL has been modified and expanded to "white matter disease" and "encephalopathy of prematurity" or "developmental brain injury of the preterm infant."

Diagnostic Approach

An early diagnostic test to detect developmental brain injury is not yet available. Cysts and enlargement of the lateral ventricles as a consequence of white matter loss occur around 3–4 weeks after the damaging insult. Current state-of-the-art diagnostic approaches are cranial ultrasound and MRI as described in the section Neonatal Neurology in the Pediatric Neurology chapter. Especially in very high-risk infants, cranial ultrasound should be performed at regular intervals, e.g., 24, 72 h, and 7 days after birth and subsequently weekly. In resource-limited settings cranial ultrasound can be obtained at the end of the first week looking for early hyperemic changes in the periventricular region and again at 4–6 weeks, at which time cystic changes would be detectable, if present.

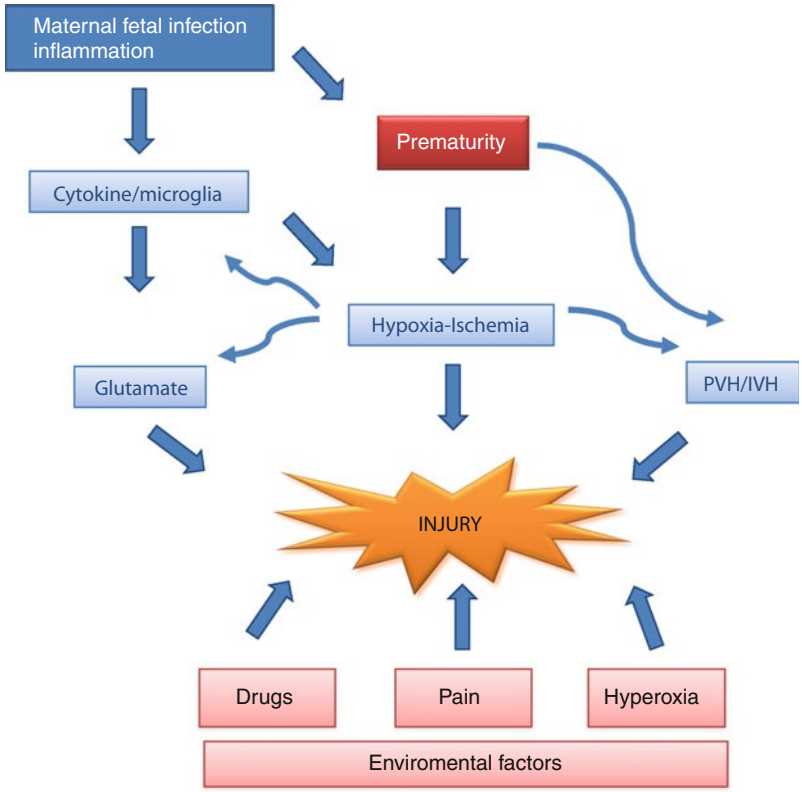

Figure 32.1

Inflammation is a major cause of preterm birth. Preterm birth per se is associated with a greater risk for hypoxia-ischemia and can also result in intraventricular hemorrhage, causing an increase in oxidative stress and excitotoxic cell death by increased levels of glutamate. In addition inflammation per se triggers microglial cell activation, sensitizes to hypoxia-ischemia and also contributes directly to cell death. In addition to hypoxia-ischemia environmental factors like hyperoxia, drugs and pain can cause cell death and can induce developmental brain injury

Therapeutic Strategies

Several therapeutic interventions have been evaluated, but up to now no treatment is available for clinical application. Promising strategies are, e.g., postnatal administration of high-dose erythropoietin or melatonin. The neuroprotective effects of these drugs are currently being investigated in controlled-randomized clinical trials. However, at present the best neuroprotective strategy is excellent peri- and neonatal care. In particular, factors such as hypocapnia and hypotension that are known to be associated with increased risk of PVL should be avoided. The overall principle is "do not harm the infant" by reducing pain and stress and by avoiding any potential harmful interventions, drugs, and unnecessary negatively impacting environmental factors.

Intraventricular Hemorrhage

One important factor contributing to neonatal neurological morbidity and often also mortality in preterm infants is intraventricular/periventricular hemorrhage (IVH/PVH). As described in *Fig. 32.1* intraventricular/periventricular hemorrhage is a major contributing factor to PVL. A detailed description of the classification as well as the pathophysiology is given in the section Neonatal Neurology in the Pediatric Neurology chapter.

Most hemorrhages occur when the preterm newborn is younger than 72 h, with 50% occurring on the first day of life. However IVH/PVH can also occur when the individual is older than 3 days, especially as a result of a significant life-threatening disease. Clinical symptoms of IVH/PVH are often subtle. They can include a sudden

drop in hematocrit by more than 10%, metabolic acidosis, glucose instability, apnea, hypotonia, and sometimes seizure activity. Because these symptoms are often nonspecific, cranial ultrasound screenings for IVH/PVH should be performed on a regular basis within the first 7 days in very high-risk infants (e.g., day 1, 3, 7 of life). Early cranial ultrasound may be helpful in decisions regarding limitation of care in the most immature infants. Otherwise, it may be sufficient to obtain a study at 3 and 7 days, since there is no active intervention available. If significant hemorrhage is found, subsequent studies are needed to monitor for possible development of ventriculomegaly. The major risk factor for IVH/PVH is prematurity itself. However, the incidence of severe IVH/PVH is declining despite constant or even increasing numbers of preterm infants, presumably due to the increased knowledge of the risk factors and subsequent improvement of perinatal and neonatal care. Major risk factors described so far are the use of catecholamines, occurrence of hypertension, bradycardia, hypocapnia, rapid volume expansion, and infusion of hypertonic solutions like sodium bicarbonate. Additional risk factors are pneumothorax, hypoxic-ischemic insults, but also improper care-giving such as tracheal suctioning and frequent handling causing stress and pain. Severe hypercapnia in the first few days of life and large swings in $PaCO_2$ have also been linked to increased risk of severe IVH. Since no effective treatment of IVH/PVH is yet available, the most effective neuroprotection remains excellent, gentle, and least aggressive neonatal care. Beside the impact of IVH/PVH on the development of encephalopathy of prematurity, IVH/PVH can lead to the development of posthemorrhagic hydrocephalus by a decreased absorption of CSF secondary to obstruction of the arachnoid villi by blood and debris or the development of obliterative arachnoiditis or as a consequence of the obstruction of the CSF circulation. In some cases subsequent interventions like regular tapping of cerebrospinal fluid (CSF) or the insertion of an intraventricular reservoir, which can be tapped, or ventriculo-peritoneal shunt are needed.

Pain in the Neonate

Newborns admitted to the neonatal intensive care unit (NICU) may experience prolonged pain and repeated painful procedures as part of their medical treatment. Several hundreds of invasive procedures may be performed in extremely preterm infants during their stay in neonatal intensive care units, particularly during the first weeks after birth. The most frequent procedures include heel sticks for blood sampling, endotracheal suctioning during mechanical ventilation, and intravenous line insertion. As described above, pain is one negative environmental factor which contributes to developmental brain injury. Repeated or prolonged pain in the newborn period causes adverse neurological cognitive outcome, adverse behavioral and neuroendocrine responses, and alterations in somatosensory perception (both hypo- and hypersensitivity). Pain may also lead to an increase in blood pressure and fluctuations in the cerebral blood flow, which can lead to the development of intracranial hemorrhage in the preterm infant. Therefore, regular pain assessment, prevention of pain, and adequate treatment is mandatory.

Pain Assessment

Clinical signs of pain in preterm and term born infants include behavioral and physical responses, like an increase in the heart rate and drop in oxygen saturation. Behavioral responses in healthy full-term infants include vigorous facial behavior and crying responses to procedural pain such as blood collection. Pain scales based on these observations have been established and adopted to prematurely born infants. Currently used pain scores are the "Premature Infant Pain Profile" (PIPP) and "Neonatal Infant Pain Scale" (NIPS). In addition "Behavioral Indicators of Infant Pain" (BIIP) have been developed particularly for use in preterm infants.

Pain Treatment

The American Academy of Pediatrics and the Canadian Pediatric Society recommend that each health care facility that treats neonates establishes a neonatal pain control program. These recommendations include (1) the routine assessment for the detection of pain, (2) to reduce the number of painful procedures, (3) to prevent/reduce acute pain from invasive procedures performed at the bedside, (4) to anticipate and treat postoperative pain following surgery, and (5) to avoid chronic pain/stress during neonatal intensive care.

The overall principle is to reduce the number of painful interventions. Preemptive analgesia before and during elective painful procedures should be provided to all neonates. Analgesia should be performed in a stepwise manner with increasing analgesia as the degree of anticipated procedural pain increases and by the use of a combination of non-pharmacologic and pharmacologic techniques.

Non-pharmacologic interventions can effectively reduce pain arising from minor procedures in neonates. These include pacifier use (non-nutritive sucking), breastfeeding, administration of sucrose or glucose solutions, skin to skin contact (kangarooing), swaddling, facilitated tucking, etc. These approaches are more effective when used in combination, depending on the extent of pain induced. They may eliminate the need for pharmacologic use or at least reduce the drug dosage or the frequency of doses required, and thus the risk of pharmacologic side effects. Anesthetics being infiltrated or applied topically can reduce procedural pain in neonates. Systemic pharmacologic agents that have been used in neonates to reduce pain and stress include nonsteroidal anti-inflammatory agents, non-opioid analgesics, and opioid analgesics. Opioids are the most effective therapy for moderate to severe pain in patients of all ages. They provide both analgesia and sedation, have a wide therapeutic window, and attenuate physiologic stress responses. Morphine and fentanyl are the most commonly used opioids in neonates, including preterm infants.

Perinatal Asphyxia and Hypoxic-Ischemic Encephalopathy

Perinatal asphyxia is a worldwide problem and a leading cause of morbidity as well as mortality in the neonatal period, causing around one million deaths each year. Approximately 5–10% of newborns require some kind of assistance to start breathing after birth, and approximately 1% need more extensive interventions. Despite declining incidence of hypoxic-ischemic encephalopathy (HIE) following asphyxia, still approximately one per 1,000 newborns, and in developing countries as many as 5–10 per 1,000, suffer from moderate or severe HIE, with at least a 25% risk of permanent neurological impairment. Perinatal asphyxia and its long-lasting consequences are a huge burden to the child, family, and produce a worldwide burden of disability.

Pathophysiology of HIE

Hypoxia-ischemia is associated with two phases – primary and secondary energy failure – that culminate in brain injury. Perinatal hypoxia-ischemia can cause primary neuronal injury and cell necrosis as a response to low cerebral blood flow, low energy substrates (adenosine triphosphate, phosphocreatine) which is termed primary energy failure (◉ *Fig. 32.2*).

Impaired mitochondrial function and energy failure are followed by an impairment of ion pump activity, hypopolarization of cell membranes, and ensuing opening of voltage-dependent ion channels. This in turn sensitizes neurons toward glutamate stimulation by releasing the magnesium sulfate blockade of the NMDA receptor. NMDA receptor activation leads to a massive influx of calcium, followed by activation of the neuronal nitric oxide synthase (nNOS), translocation of proapoptotic genes to the mitochondria, mitochondrial dysfunction, release of cytochrome *C* into the cytosol, activation of caspases, and subsequent cell death. After recovery from primary energy failure and a short period of normal energy and cell status a second interval of energy failure occurs timely remote from the initial injury. This second wave process of cell destruction can continue over several days and weeks. The hypoxic-ischemic insult as well as reperfusion elicit an inflammatory response with increased levels of pro-inflammatory cytokines and delayed brain injury. The continued generation of free radicals is contributing to the ongoing cell destruction. The short interval between primary and secondary energy failure, called "therapeutic time window," offers the possibility for therapeutic interventions to protect the neonatal brain from further injury. The beginning of treatment during this latent phase has been shown to be successful in several animal models in reducing the injury. The exact duration of this therapeutic time window in humans is still unknown, but it has been shown to be about 6 h in animal studies using near-term fetal sheep.

Treatment: Induced Hypothermia as Standard of Care

Until recently, therapy has been limited to preventive approaches and supportive strategies such as avoidance of hypocapnia, hypotension, metabolic disturbances (acidosis, electrolyte imbalance, hypoglycemia), and treatment of seizure activity, if present. The first established neuroprotective strategy to reduce HIE in full-term infants is induced hypothermia by either total body cooling or selective head cooling. Both methods of induced hypothermia minimize the continuation of neuronal injury, improve mortality, and reduce subsequent neurodevelopmental disability at 18 months of age. Immediate identification of affected infants after delivery, initiation of cooling as soon as possible, and, equally important, no active re-warming and subsequent transfer to a center that provides hypothermia therapy is necessary

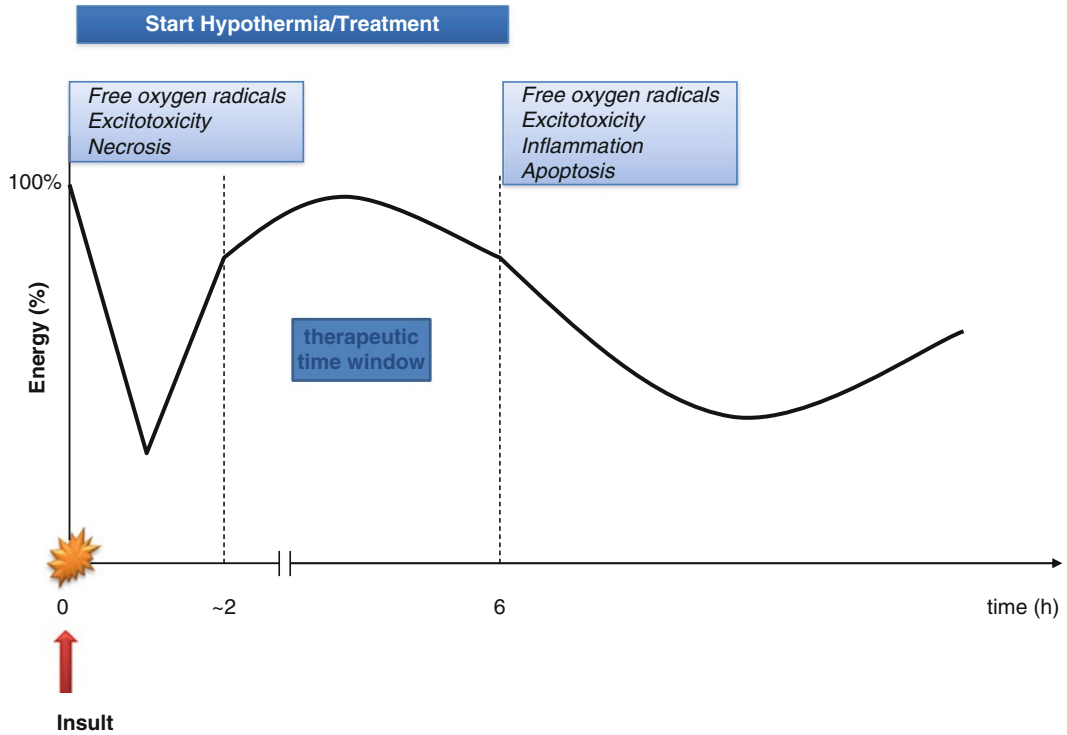

Figure 32.2
Pathophysiology of HIE

to maximize the potential of this therapeutic intervention. A delay of more than 6 h in initiating hypothermia reduces the neuroprotective potential. On the other hand, the earlier the therapy is initiated, the higher the protective effect. In regions where infants must be transported over long distances, initiating cooling during transport has been shown to be feasible and relatively safe. Standard whole body cooling protocol involves cooling to 33.5 degrees Centigrade for 72 h with gradual re-warming over 6 h. Studies are under way to determine if longer period of cooling or cooling to a lower temperature improves therapeutic efficacy. Co-treatment with other potentially neuroprotective agents, such as erythropoietin, is also being investigated.

Diagnosis

The diagnostic criteria for hypoxic-ischemic encephalopathy in term newborn infants require (1) signs of perinatal or postnatal asphyxia: obstetrical causes of hypoxia-ischemia, as well as clinical condition at birth such as low Apgar score, large base deficit, elevated blood lactate values, low cord pH, and the need for resuscitation, and (2) signs of encephalopathy characterized by abnormal neurological scores (Sarnat or Thompson score) and presence of seizure activity. When available, electroencephalographic evidence of abnormal cerebral function by means of the amplitude-integrated or ten-lead standard EEG is helpful in establishing the diagnosis (◉ *Fig. 32.3*). However currently used diagnostic procedures still require refinements. A combination of neurological scores (in particular the Thompson score), continuous electroencephalographic assessment by aEEG and neuroimaging methods (MRI) are providing the most accurate predictive power regarding neurological outcomes.

Seizures in the Neonate

Neonatal seizures occur in 2–4 per 1,000 live births in full-term newborns, with an even higher incidence in preterm infants, most of them occurring in the first days of life.

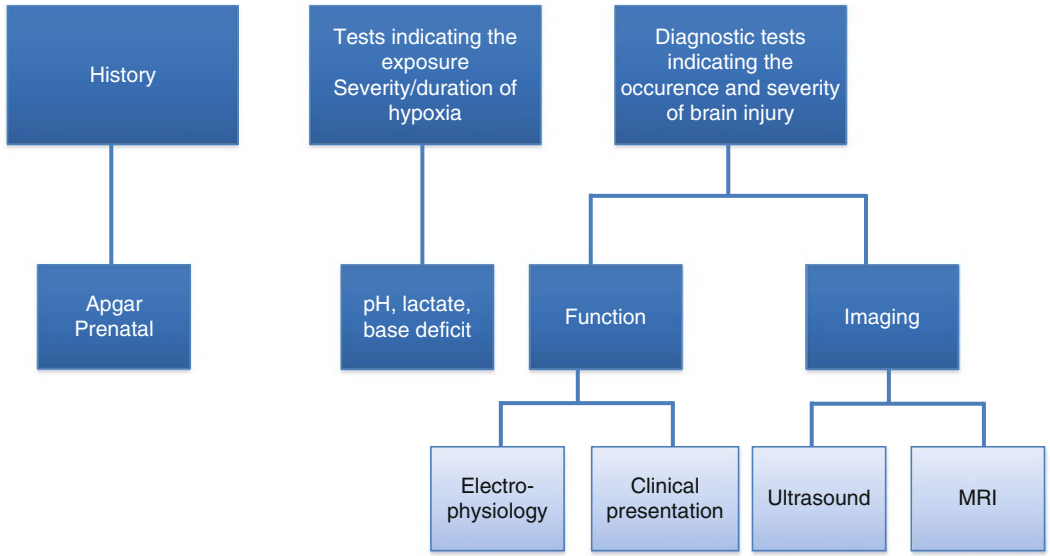

Figure 32.3
Diagnosis of HIE

Table 32.1
Challenges in neonatal seizures

• Seizures in term versus preterm infants
• Electrographic versus clinical seizures
• Impact of seizures on neurological outcome
• Potential harmful effects of anticonvulsants for the developing brain
• Uncoupling by anticonvulsant treatments

Table 32.2
Key messages of neonatal seizures

• Monitor infants at risk
• Ensure diagnosis using EEG and/or CFM before initiation of treatment
• Ensure proper electrolytes, ventilation, and blood glucose before anticonvulsant therapy
• Avoid combinations of anticonvulsants
• Before adding an additional drug, ask yourself whether you have the right diagnosis
• Monitor the "treated" brain

Diagnosis and treatment of neonatal seizures are one of the most challenging issues in neonatology. *Table 32.1* summarizes the major challenges. They include the differentiation between seizures occurring in term versus preterm born infants, the difference between clinical and electrographic seizures, and the challenge of uncoupling by anticonvulsant treatments. An additional important challenge is that currently used anticonvulsants like phenobarbital (PB), benzodiazepines, and phenytoin potentially cause brain injury because of their interference with neurotransmitter signaling impacting brain development.

Causes of Seizures in the Neonate

Seizures in the newborn always indicate some form of brain injury, as they occur with hypoxic-ischemic injury (HIE), stroke, intracranial infection, hypoglycemia, inborn errors of metabolism, and brain malformations (see also *Table 32.2*). A long debate has been ongoing whether seizures per se damage the brain since the answer would determine whether seizures in the newborn should be treated or not. However, currently evidence is emerging that neonatal seizures occurring as manifestation of existing brain injury are a very bad prognostic sign and per se harmful. The consequences of seizures at different stages of brain development differ substantially. Seizures can cause neuronal cell death in term infants. Seizures in the immature brain may in addition alter neuronal circuitry, resulting in impaired learning and memory and enhanced susceptibility to further seizures.

Diagnosis

The diagnosis of neonatal seizures is challenging, since the clinical manifestation of ongoing seizure activity might be very mild and subtle and in many cases is even absent. In addition some normal physiological movement patterns in the neonate mimic seizure activity. Even for experienced neonatologists and trained neonatal staff it might be difficult to identify the patient suffering from seizures. Therefore adequate diagnosis using standard EEG and/or amplitude-integrated EEG (CFM) with or without display of raw EEG is important to avoid overtreatment of patients on one hand and missing patients with seizures on the other hand. A particular challenge in diagnosis is "electric uncoupling," as anticonvulsant treatment might reduce clinical seizures while electrographic seizures are ongoing, warranting continuous monitoring of cortical activity by CFM, also after clinical seizure activity ceased due to treatment. Besides the diagnosis of seizures per se, it is of uttermost importance to diagnose the underlying cause of seizure activity. ❯ *Figure 32.4* summarizes causes of neonatal seizures according to their classical day of presentation.

Clinical Management

Clinical management of seizures in the newborn has remained unchanged in spite of almost 10 years of evidence that medications commonly used in newborns are not very effective and potentially neurotoxic by inducing apoptotic neurodegeneration in the developing brain. International surveys indicate that phenobarbital (PB) is by far the most commonly used first line antiepileptic agent in neonatology. PB is the oldest antiepileptic drug available and is widely used for treatment of seizures in preterm and full-term born infants during the neonatal period. However, it has been shown that PB induces apoptotic neurodegeneration in the developing brain and causes decrements in spatial learning tasks, increases aggression and locomotor activity. Therefore, other medicaments are increasingly used, such as Lorazepam, Levetiracetam, and Bumetanide. In case of ongoing continuous seizures activity the use of Lidocaine seems to be particularly effective. Clinical trials investigating anticonvulsant treatment regimens against neonatal seizures are ongoing and hopefully new knowledge about the best treatment will be gained. In addition to controlling seizure activity, it is of utmost importance to treat the underlying cause of seizure activity if treatment is available. The length of treatment with anticonvulsants is another area of controversy. Many newborns without identifiable brain lesions on imaging studies will not have recurrent seizures, but many are sent home on prolonged anticonvulsant medications that may have profound detrimental effects.

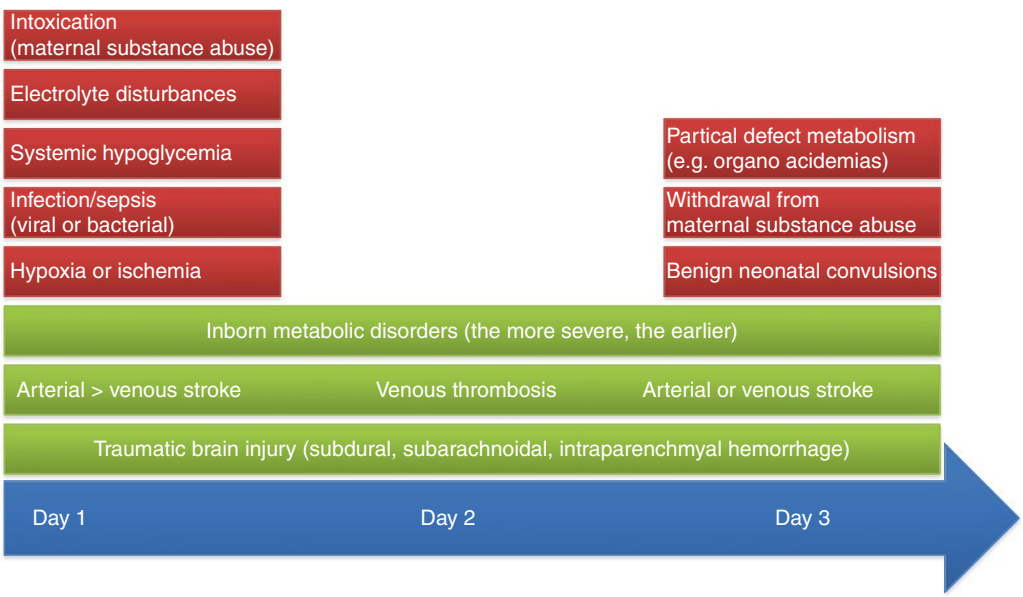

Figure 32.4
Causes of neonatal seizures

The Floppy Newborn: The Neonatal Workup

The "floppy newborn" represents a diagnostic challenge for the neonatologist. Frequently the term "floppy infant" is used to describe a condition caused by neurological or neuromuscular disorders. However this does not cover the entire spectrum of disorders that present as floppy newborn infant. Newborns can present with hypotonia due to central or peripheral nervous system abnormalities, myopathies but also because of genetic disorders, endocrinopathies, metabolic diseases, and acute illness like sepsis and hypoxic-ischemic encephalopathy. *Table 32.3* provides an overview of the differential diagnosis of the floppy newborn. Central causes are sepsis, hypoxic-ischemic encephalopathy, chromosomal disorders, congenital syndromes, inborn errors of metabolism, and neurometabolic diseases. Peripheral disorders include abnormalities in the motor unit (e.g., spinal muscular atrophy), peripheral nerve (e.g., myasthenia), neuromuscular junction, and the muscle. As highlighted in *Table 32.3* the central causes in particular HIE account for the majority of floppy newborns. The most common neuromuscular causes, although still rare, are congenital myopathies, congenital myotonic dystrophy, and spinal muscular atrophy.

Diagnostic Approach

The diagnostic approach in the newborn is based on thorough medical history and physical examination. Particular attention should be paid to the maternal and family history with assessment of pre-existing disease(s) of the mother as well as in the family, such as genetic disorders and inborn errors of metabolism; e.g., transient maternally acquired myasthenia gravis can be diagnosed by the maternal history. The prenatal history should include information on reduced or absent movements of the fetus, the existence of poly- or oligohydramnion, as well as maternal exposure to toxins, drugs, or infections. An examination of the mother might also bring new information in the case of heritable diseases, e.g., the diagnosis of myotonic dystrophy in a floppy newborn is suggested by a history of uterine dystonia as well as by examination of the handshake of the mother, who demonstrates an inability to relax her hand. The perinatal history includes the mode of delivery, since breech delivery or brow presentation is associated with cervical spinal cord trauma. Perinatal depression with low Apgar scores might be due to HIE; however, a respiratory insufficiency is also often seen in myotonic dystrophy. An infant who was born initially healthy and becomes hypotonic the first days of life should be considered septic until proven otherwise. In addition an inborn error of metabolism should be considered.

Physical Examination

The physical examination of the newborn should focus on the cardiovascular status, need for ventilation despite of good pulmonary function (compliance and oxygenation normal), signs and symptoms of sepsis and HIE, and evidence of malformations, dysmorphic features, or organomegaly. Since many heritable disorders are associated with hypotonia, the more common syndromes should be considered with the initial evaluation. Pertinent clinical features (e.g., the presence of fixed deformities) need a comprehensive neurologic evaluation. The neurological clinical examination is summarized in the neonatal neurology section in the Pediatric Neurology Chapter. Key clinical features of central hypotonia are abnormal depressed level of consciousness or seizures. Newborns with central hypotonia do not track visually and appear lethargic. They instead show abnormal eye movements in addition to apnea or exaggerated irregular breathing patterns. Dysmorphic features and malformations of other organs are also frequently present. The degree of muscle weakness is usually mild and the tendon reflexes are normal or hyperactive.

Causes of peripheral hypotonia are usually not associated with malformations of other organs, except deformities of bones or joints. In contrast to central hypotonic newborns, peripheral hypotonic newborns are alert, have a normal level of consciousness, respond appropriately to surroundings, and show normal sleep-wake patterns. Muscle weakness and hyporeflexia or areflexia are usually present, in addition to muscle atrophy.

Investigations

After assessing the history and the clinical examination a targeted approach toward a rational diagnostic should be chosen according to the clinical presentation of the infant. The initial laboratory evaluation of the hypotonic newborn is directed at ruling out systemic disorders. This includes an evaluation for sepsis with complete blood count, C-reactive protein, IT-ratio, blood culture, urine, and cerebrospinal fluid culture. In addition, measurement of serum electrolytes, glucose, parameters of liver functions, and creatinine should be taken as primary workup.

Table 32.3
Causes of a floppy newborn

Differential diagnosis of the floppy newborn		Prevalence	Central/peripheral hypotonia
Anterior horn cell disorders	Acute infantile spinal muscular atrophy		Peripher
	Traumatic myelopathy		
	Neurogenic arthrogryposis		
	Infantile neuronal degeneration		
Congenital neuropathy	Hypomyelinating neuropathy, congenital or non-congenital	1.4%	Peripher
	Charcot-Marie-Tooth disease		
	Dejerine-Sottas disease		
	Hereditary sensory and autonomic neuropathy		
Neuromuscular junction disorders	Transient acquired neonatal myasthenia	0.4%	Peripher
	Congenital myasthenia		
	Magnesium toxicity		
	Aminoglycoside toxicity		
	Infantile botulism		
Congenital myopathy	Nemaline myopathy	5%	Peripher
	Central core disease		
	Myotubular myopathy		
	Congenital fiber type disproportion myopathy		
	Multicore myopathy		
Muscular dystrophy	Dystrophinopathy	2%	Peripher
	Congenital muscular dystrophy (with or without merosin deficiency, with brain malformations)		
	Walker-Marburg disease		
	Muscle-eye-brain disease		
	Fukuyama disease		
	Congenital muscular dystrophy with cerebellar atrophy/ hypoplasia, with occipital agyria		
	Early infantile facioscapulohumeral dystrophy		
	Congenital myotonic dystrophy		
Metabolic and multisystem disease	Disorders of glycogen metabolism	3%	Central
	Glycogen storage disease Typ II (Pompe)		
	Acid maltase deficiency		
	Severe neonatal phosphofructokinase or phosphorylase deficiency		
	Debrancher deficiency		
	Primary carnitine defect		
	Peroxismal disorders		
	Neonatal adrenoleukodystrophy		
	Cerebrohepatorenal syndrome		
	Disorders of creatine metabolism		
	Mitochondrial myopathies		
	Cytochrome-c oxidase deficiency		

Table 32.3 (Continued)

Differential diagnosis of the floppy newborn		Prevalence	Central/peripheral hypotonia
Genetic/chromosomal syndromes	Down syndrome	31%	Central
	Prader-Willi-Syndrome		
	Fragile X syndrome		
	Trisomy 18		
	Trisomy 13		
	22q11.2 deletion syndrome		
	Cri-du-Chat syndrome		
	Wolf-Hirschhorn syndrome		
	Sotos syndrome		
Others	Hypoxic-ischemic encephalopathy	19%	Central
	Teratogens	1%	
	Brain tumors	0.4%	
	Sepsis		

Primary investigations for inborn errors of metabolism should be performed by determination of serum lactate, ammonia, and blood gases in particular pH, base deficit and urine analyses for ketone bodies. Particularly in intrauterine growth retarded newborns, a urine drug screen should be performed, since up to 4% of pregnant women in the United States use illicit drugs (marijuana, cocaine, ecstasy, amphetamines, and heroin). If the hypotonia is considered and dysmorphic features are present, analyses of the karyotype as a detailed molecular genetic testing might be indicated.

In case of any evidence of intrauterine infection like intracranial calcifications, thrombocytopenia and hepatosplenomegaly, titers for toxoplasmosis, rubella, cytomegalovirus infection (CMV), and herpesvirus should be determined and urine analyses for CMV (culture, PCR) should be performed. Thyroid function tests should be considered if the newborn suffers also from other signs of hypothyroxinemia. Determination of serum creatinine kinase (CK) should also be performed in suspicion of neuromuscular disease. However, at an early stage soon after birth this might not add new information, since increased levels of CK can be observed several hours to days after birth in normal infants. Imaging of the brain using cranial ultrasound and MRI is also a valuable tool for further diagnostics to detect nervous system analyses and metabolic diseases and can be easily performed in newborns. After these initial assessments additional tests like nerve conduction studies, electromyography, and muscle or sural nerve biopsy might be necessary.

33 Eye Disorders of the Newborn

Rosemary D. Higgins

There are multiple eye disorders that can present in the neonatal period, with which the pediatrician should be familiar. Some are isolated to the eye; others have systemic manifestations. The primary care pediatrician must recognize the signs of serious eye disorders, which if undetected and untreated can lead to blindness in the case of cataracts and to death in the case of retinoblastoma. A thorough eye examination with, at a minimum, visual inspection of the external eye structures plus elicitation of a red reflex is essential. Eye findings may also provide clues to a number of genetic disorders where these findings are peripheral to the overall condition. This chapter covers the common eye observations and diseases seen in the neonatal period, including an abnormal red reflex, cataracts, infections, retinopathy of prematurity (ROP), and retinoblastoma.

Abnormal Red Reflex

An uncommon but urgent finding in newborns is an absent or decreased red reflex. This is usually a sign of serious eye or possibly systemic disease. Proper workup involves a slit lamp examination. If normal, evaluation of the fundus for retinoblastoma, infection, or coloboma is warranted.

The most common cause of absent or diminished red reflex in newborn infants is congenital cataract. Cataracts can occur unilaterally or bilaterally. It is critical to properly diagnose congenital cataracts because failure to treat could result in amblyopia (central loss of vision from disuse).

Cataracts

The incidence is about 2–5/10,000 births in the Western world and substantially higher in the developing world. About half are unilateral. The evaluation of congenital cataracts requires a thorough history and physical examination. There are multiple causes of congenital cataract, listed in *Table 33.1*. Bilateral cataracts are more likely to be associated with systemic disease or infection. If the examination, other than presence of congenital cataract, is normal workup may be limited, but an urgent referral for ophthalmologic evaluation is essential to preserve vision. Treatment usually involves surgical removal of the cataracts. If there are systemic findings, detailed further assessment is warranted and may include a search for evidence of infection, neuroimaging, and genetic and metabolic workup.

Infection

Chlamydia

Chlamydia conjunctivitis can present in the newborn period. It is characterized by ocular discharge, edema, and congestion. Chlamydia conjunctivitis typically presents a few days to several weeks after birth and lasts 1–2 weeks. The causative agent is *Chlamydia trachomatis* and it is acquired via vertical transmission from the genital tract of infected mothers to the infant. The conjunctivitis can occur in conjunction with *Chlamydia pneumonia*.

Diagnosis of Chlamydia conjunctivitis can be made by isolation of the organism in tissue culture and by nucleic acid amplification (NAA). Treatment of Chlamydia conjunctivitis is with oral erythromycin base or ethyl succinate for 14 days. Topical treatment is ineffective. Efficacy of oral treatment is 80% and a second course may be needed; so a follow-up is recommended for infected infants.

Infants born to untreated mothers with Chlamydia infection are at high risk for infection. Efficacy of prophylaxis is unknown, therefore not indicated. Newborn infants should be monitored clinically and treated if they develop signs of Chlamydia infection.

Gonorrhea Ophthalmitis

Gonorrhea ophthalmitis is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus. Eye involvement (ophthalmia neonatorum) is the typical infection in newborn infants with gonococcal infection. Infants can have concurrent scalp abscess (associated with internal fetal monitoring) or disseminated infection. Diagnosis is

Table 33.1
Causes of congenital cataracts. There are many others besides the examples given

General classification	Example
Genetic – single gene disorders	Oculocerebrorenal syndrome, many others
Genetic – aneuploidy	Trisomy 21, Trisomy 18, Trisomy 13
Congenital infection	Rubella, toxoplasmosis, CMV, herpes
Metabolic	Galactosemia
Idiopathic	No identifiable cause

made by culture of the appropriate bodily fluid including eye discharge, blood, and sites to include cerebrospinal and joint fluid. The organism requires antibiotic testing to determine sensitivity due to the prevalence of penicillin and tetracycline resistant strains. Other sexually transmitted diseases should be tested for as well as hepatitis B in the mother and her partner(s).

Control measure for routine prophylaxis includes 1% solution of silver nitrate, 1% tetracycline ointment, or 1% erythromycin ointment into each eye within an hour following birth. For infants born to mothers with known gonococcal infection, a single dose of ceftriaxone (1 mg IV or IM for term infants, 25–50 mg/kg for preterm and low birth weight infants) is recommended to avoid gonococcal ophthalmitis and disseminated disease.

TORCH Infections

Some of the TORCH (toxoplasmosis, "other," rubella, cytomegalovirus, and herpes) can have ophthalmologic manifestations as part of their clinical presentation and diagnosis. If a diagnosis of toxoplasmosis, rubella, or cytomegalovirus is being considered, ophthalmologic consultation can be helpful.

The ocular finding in toxoplasmosis is chorioretinitis. *Toxoplasma gondii*-specific IgG or IgM antibodies should be looked for in the serum to confirm the diagnosis.

Congenital rubella syndrome can have several ocular manifestations including cataracts, pigmentary retinopathy, microophthalmos, congenital glaucoma, and chorioretinitis. Rubella-specific IgM or increasing serum concentrations of rubella-specific IgG over several months are confirmatory for the diagnosis.

Cytomegalovirus can be transmitted to infants by in utero transplacental passage of maternal virus, vertically at birth through the genital tract, or postnatally by ingestion of CMV-positive breast milk. Diagnosis can be made by serology or direct virus culture. Ocular manifestations include retinitis.

Retinopathy of Prematurity

ROP is a serious vasoproliferative disorder affecting preterm infants who have immature retinal vasculature. Normal development of the retinal vasculature in utero occurs at a lower oxygen tension than the prematurely delivered infant is exposed to as a result of preterm birth. Immediately following preterm birth, the retina is exposed to a higher oxygen tension resulting in a delay in the maturation of retinal blood vessels. This is also known as the vaso-obliterative phase of ROP. Over time, the retina grows in thickness and the distance for diffusion of oxygen and nutrients increases and retinal hypoxia ensues. Hypoxia at the tissue level in the retina results in an increase in hypoxia-inducible factor 1 (HIF-1) and vascular endothelial growth factor (VEGF); both growth factors result in retinal vasoproliferation and the development of ROP. ROP can lead to visual impairment, blindness, amblyopia and strabismus.

Risk factors for ROP include low birth weight, gestational age, and oxygen exposure. Infants born at less than 25 weeks have an 18–28% rate of severe ROP. Retinal screening on infants with a birth weight $<$1,500 g or gestational age $\leq$32 weeks is recommended, as well as selected infants with birth weight 1,500–2,000 g or gestational age $>$32 weeks with an unstable clinical course including those requiring cardiorespiratory support.

Diagnosis of ROP is made by retinal screening examination following pupillary dilation with indirect ophthalmoscopy and described using the international classification of ROP. The examination has several components including location of the disease, extent (clock hours) of disease, stage, and presence or absence of plus or pre-plus disease. The location of ROP is described by zone 1–3. Zone 1 is the innermost zone, which extends from the optic disc to twice the distance from the center of the optic disc to the macula. Zone I disease carries the greatest risk of visual impairment. Zone II is the area of the retina extending from the edge of zone I to the nasal ora serrata. Zone III is the remaining crescent of retina anterior to zone II. The extent of ROP, if present, is quantified in clock hours, or 30° segments.

Severity of ROP can be classified as one of five stages. Stage 1 is a demarcation line, which is a visible line of abnormally branching blood vessels at the vascular and

avascular border. Stage 2 is characterized by a ridge at the junction of the vascular and avascular retina. Stage 3 refers to extraretinal neovascularization extending from the ridge into the vitreous. Stage 4 is divided into extrafoveal (stage 4a) and foveal (stage 4b) of partial retinal detachments. Stage 5 refers to total retinal detachment and results in complete loss of vision.

ROP is also characterized by presence or absence of pre-plus and plus disease. Pre-plus disease refers to posterior pole arterial tortuosity and venous dilatation, not yet severe enough to be classified as plus disease. Plus disease is defined as venous dilatation and arteriolar tortuosity of posterior retinal vessels. There may be vascular engorgement, poor pupillary dilatation, and vitreous haze. Presence of plus disease denotes a more severe form of ROP and is considered an indication for laser therapy.

If the retinal vasculature is mature at the initial exam, there is no need for further evaluation. If the retinal vasculature is immature or there is evidence of ROP, the follow-up examination is warranted depending on the presence or absence of ROP, stage, zone, and presence or absence of plus disease. Follow-up guidelines are published by the American Academy of Pediatrics, American Academy of Ophthalmology, and the America Association for Pediatric Ophthalmology and Strabismus (ICROP).

Treatment of ROP was nonexistent until the advent of cryotherapy, validated by the CRYO-ROP study. Currently, laser surgery is used for ROP. Treatment involves retinal ablation to destroy tissues (hypoxic tissue) that is the source of growth factors. Treatment should generally be performed within 72 h of reaching treatment criteria (zone 1 ROP, any stage with plus disease; zone 1 ROP, stage 3; zone II or III ROP with plus disease) to minimize the risk of retinal detachment.

Infants who have a history of ROP, unresolved ROP prior to hospital discharge, immature retinal vasculature prior to hospital discharge, or ablative treatment or other procedures including vitrectomy, scleral buckle, or other ophthalmologic intervention should have appropriate ophthalmologic follow-up. Children with ROP are at risk for strabismus, amblyopia, cataract, and late retinal detachment.

Retinoblastoma

Retinoblastoma is the most common eye tumor in children, occurring in 1/15,000 live births and usually presents with leukocoria (absent red reflex). It can also present with strabismus or hyphema. Retinoblastoma can occur unilaterally or bilaterally and can be inherited in an autosomal-dominant pattern. The hereditary form is usually bilateral and multifocal, whereas the nonhereditary form is generally unilateral and unifocal. For small tumors, local therapy of thermal ablation or irradiation can be performed. For larger tumors, enucleation of the eye may be required. Investigation of metastatic disease including spinal tap and bone marrow aspiration are indicated. The prognosis for infants with retinoblastoma depends on the size and extent of the tumor. When confined to the eye, treatment is usually curative. The prognosis for survival is poor when the tumor has extended into the orbit or along the optic nerve.

Benign Conditions Affecting the Newborn Eye

Conjunctival hemorrhages are readily apparent and frequently occur during birth. No treatment is necessary, as they are resorbed spontaneously without consequence. Less commonly, a collection of blood is seen in the anterior chamber of the eye (*Hyphema*) and is usually associated with the rigors of passage through the birth canal, although rarely can be associated with retinoblastoma. No intervention is typically required. Parental reassurance is all that is necessary. Remnants of the *pupillary membrane* (anterior vascular capsule) are sometimes seen with the ophthalmoscope, appearing as cobweb-like lines crossing the pupil, especially in preterm infants. Superficial *retinal hemorrhages* are occasionally found in newborn infants soon after birth. These are usually absorbed promptly and normally do not have any permanent effect. The majority of birth-related retinal hemorrhages resolve within 2 weeks. *Lacrimal duct stenosis* (dacryostenosis) is a common finding that presents with crusting of the eyelids in newborn infants. It is distinguished from conjunctivitis by the absence of associated redness of the conjunctiva. Warm compress and gentle massage are the recommended treatment of this self-limited disorder. Occasionally, superimposed infection develops and requires treatment.

In summary, there are several eye disorders that can present in the newborn and early infancy period. Most eye problems can be diagnosed by ophthalmology referral. Prompt diagnosis and treatment can preserve visual function.

34 Miscellaneous Chapter

Mara G. Coyle

This chapter deals with those issues not well ascribed to a particular organ system or single diagnosis. The first section will focus on nonimmune hydrops, a nonspecific finding occurring as a common final pathway due to a multitude of reasons, many of which carry a grave prognosis, the minority of which are amenable to therapeutic intervention. The second section will focus on the effect of maternal substance use on the fetus and newborn. Both licit and illicit drug use will be described as both have implications for fetal and newborn well-being.

Hydrops Fetalis

Hydrops fetalis was first described by Ballantyne over 110 years ago, and over 60 years later by Potter, who described nonimmune hydrops. Hydrops is defined by the presence of fluid accumulation in the fetal extravascular space and body cavities. It is characterized by greater than 5 mm of generalized skin thickening, with associated pericardial or pleural effusions, ascites, or placental enlargement. While in the 1970s over 80% of cases were due to maternal isoimmunization against rhesus or other red cell antigens, these immune hydrops cases today are extremely rare, due to improved antenatal interventions. Today, 85–90% of hydrops cases are nonimmune-mediated. As such, the remainder of this discussion will focus on nonimmune hydrops.

The incidence of nonimmune hydrops ranges from 1:1,500 to 1:3,800 births, although this may represent an underestimation, as a majority of fetuses die in utero or are electively terminated, and are not always included in analysis. Given improved ultrasound capabilities, the diagnosis is usually made prior to delivery. In a series of 82 cases limited to fetuses after 20 weeks, all were diagnosed by ultrasound before delivery. Despite improved diagnostic capabilities, the perinatal mortality remains high, particularly if the diagnosis is made before 24 weeks gestation. In a series by McCoy, the overall mortality was 86.6%. Fetuses diagnosed prior to 24 weeks had a perinatal morality of 95% with nearly one-third having an abnormal karyotype. In some case series, survival is notably greater (69%) when only those cases felt to be amenable to intrauterine therapies are included.

Hydrops is not a diagnosis but rather a nonspecific finding, which occurs as the final common pathway for a multitude of disorders of the fetus, umbilical cord, and placenta, which lead to deranged fluid homeostasis. The underlying pathophysiology for hydrops is not clearly understood, although the majority of cases are felt to be due to one or more of the following mechanisms, all of which lead to generalized edema.

High Central Venous Pressure

The pathway through which cardiac failure is responsible for edema is high right atrial pressure or volume overload, which leads to increased central venous pressure and heart failure. Alternatively, obstruction of venous or arterial flow or inadequate diastolic filling as seen in rhythm disturbances, intrathoracic masses, or cardiomyopathies will lead to increased central venous pressure and edema. It should be noted that while there is a large list of cardiac disorders associated with nonimmune hydrops (*Table 34.1*), they are not all necessarily causal. The hematologic disorders known to cause hydrops all lead to anemia, resulting in high-output cardiac failure, increased umbilical venous pressure, and extramedullary hematopoesis. Portal hypertension can develop in severely affected fetuses, which leads to liver dysfunction. Resultant hypoxia and acidosis will ultimately predispose the fetus to capillary epithelial damage, which will foster loss of fluid into the extravascular space. Rapidly occurring anemia is often fatal whereas chronic blood loss can lead to hydrops.

Reduced Plasma Oncotic Pressure

Those disorders that lead to compromised liver function and reduced protein synthesis, or disorders leading to excessive protein loss will result in a reduction of intravascular oncotic pressure and interstitial edema. Congenital nephrotic syndrome, for example, will lead to excess protein loss whereas high-output failure will lead to hepatic congestion, decreased function, and

hypoalbuminemia. Inborn errors of metabolism, hematologic disorders, infections, and certain cardiac disturbances can all lead to hepatic congestion, dysfunction, and hypoproteinemia.

Reduced Lymph Flow

Lymphatic vessel dysplasia can lead to fluid imbalance with resultant hydrops due to the low output failure of the lymphatic system. In addition to lymphatic dysplasia, those disorders that lead to severe loss of fluid into the interstitial compartment due to low osmotic pressure that can only partially be reabsorbed by the lymphatic system will exacerbate intravascular fluid loss and lead to hydrops.

Diagnoses Associated with Hydrops

While most categories of diagnoses (*Table 34.1*) can be explained by one or more of the above pathophysiologic mechanisms, in a large cohort of 5,437 hydropic cases, 15.8% were felt to be idiopathic, and not easily assigned to a specific cause. In addition, the ability to assign a patient into a category may not guarantee that the cause of the hydrops is well understood. This is particularly true of the syndromic/chromosomally anomalous patient, which comprised 17.8% of the aforementioned cohort. For example, while Trisomy 21 patients can be born with hydrops, the cause may not be the congenital heart malformation, but rather isolated lymphangiectasia. As such, as many as 33.6% of cases from this cohort were not easily assigned to one of the pathophysiologic mechanisms. While the list of diagnoses associated with nonimmune hydrops is extensive, the following categories represent the more common diagnoses. Attempts to establish an etiology are essential, as several diagnoses are amenable to intrauterine therapies.

Genetic Disorders

Hydrops diagnosed prior to 24 weeks gestation is usually associated with aneupliody, which, as the most common genetic etiology of hydrops, represents 10% of all cases. The most common chromosomal abnormality linked to hydrops is monosomy X (i.e., Turners syndrome), which accounts for 42–67% of aneuploid cases. Trisomy 21, 13, 18, and 12 as well as tetraploidy, triploidy, and rare deletions and duplications have also been seen. While the mechanism behind hydrops in these cases is not always clear, explanations include congenital heart disease, and incomplete formation or obstruction of the lymphatic system leading to lymphatic dysplasia. A mechanism for hydrops associated with other genetic nonchromosomal disorders is fetal akinesia, as is seen with arthrogryposis multiplex congenital, congenital myotonic dystrophy, and Pena Shokeir and Neu Laxova syndromes. Skeletal dysplasias that present with thoracic involvement can result in hydrops due to insufficient venous return and cardiac tamponade. Examples would include short rib polydactyly syndromes, camptomelic dysplasia, lethal chondrodysplasia, thanatophoric dysplasia, and homozygous achondrodysplasia. Prognosis is usually poor when hydrops is present in association with these genetic lesions.

Autosomal recessive metabolic storage diseases account for 1–10% of nonimmune hydrops cases. These disorders usually occur because of an enzyme defect leading to an accumulation of metabolic products in the lysosome, which leads to cell death, and organ dysfunction, particularly of the liver, heart, brain, and kidneys. While death is common, making a diagnosis is important given the recurrence risk as high as 25% with future pregnancies.

Cardiovascular Disorders

Disorders of the heart are responsible for up to 40% of cases of nonimmune hydrops. These include arrhythmias, structural defects, and vascular anomalies.

Cardiac arrhythmias, felt to be suitable to fetal intervention, represent 25–50% of treatable hydrops cases in several series. Both tachyarrhythmias and bradyarrhythmias can lead to hydrops. Many of the bradyarrhythmias are associated with structural abnormalities, particularly at the AV node. Others are due to damage to the fetal bundle of His and Purkinje fibers by maternal IgG antibodies related to maternal autoimmune disease.

Blood flow velocity in the descending aorta drops significantly at cardiac rates of 230–250 beats per minute, with the development of pericardial effusions within 24 h. Treatment for tachyarrhythmias, the most common of which is SVT, includes maternal administration of antiarrhythmic agents, which pass to the fetus via the placenta. Transplacental drug therapies include digoxin, verapamil, amiadarone, and flecanide, the latter of which has been demonstrated to be superior to the other antiarrhythmic agents. While effective, these agents are less successful in achieving cardioversion and cardiac recompensation when hydrops has already occurred, due to poor placental passage of the drug. Maternal side effects may also preclude this approach to therapy. Alternative treatment modalities include administration of antiarrhythmic agents into the fetal intravascular, intraperitoneal, or intramuscular space. Careful monitoring of both the fetus and mother is essential.

The common structural heart lesions associated with hydrops include hypoplastic left and right heart, atrioventricular canal defects, and less commonly tetralogy of Fallot and premature closure of the ductus arteriosus. When hydrops develops in the context of these disorders, the prognosis is poor, with mortality reaching 100%. High-output failure from arteriovenous shunting can result from vascular abnormalities, including arteriovenous malformations (most commonly seen in the brain and liver), large (>4 cm) placental chorioangiomas, sacrococcygeal teratomas, neuroblastomas, hemangiomas, and large aneurysms. Fetal endoscopic laser coagulation therapy has been reported, but carries risks of bleeding, exsanguination, and death.

Anatomic Abnormalities

Chylothorax accounts for half of the thoracic lesions associated with nonimmune hydrops. Other lesions in order of frequency include congenital cystic adenomatoid malformation, diaphragmatic hernia, pulmonary sequestration, bronchogenic cyst, and least commonly, the aforementioned skeletal dysplasias. The mechanism for the hydrops is obstruction of venous return due to increased intrathoracic pressure, which leads to peripheral venous congestion. The overall prognosis depends upon the timing of the development of pleural effusions as well as whether the effusions are isolated, or in conjunction with hydrops. Accumulation prior to 20 weeks is associated with a poor prognosis due to associated pulmonary hypoplasia, the extent of which cannot be well ascertained by fetal ultrasound. When pleural effusions develop as part of hydrops, the outcome is usually worse.

Fetal management of pleural effusions includes the placement of a pleuro-amniotic shunt to decrease intrathoracic pressure and promote lung growth. In a systematic review of the literature including 99 cases of primary chylothorax complicated by hydrops, the survival rate was 66% with shunting versus <25% with expectant management. The main complication of this procedure was preterm rupture of membranes and premature delivery. The outcome is generally worse when the pleural effusions are due to something other than a chylothorax. In addition, the literature is limited mostly to case series, and to date, no randomized trials have been performed. Needle aspiration of pleural effusions is usually limited to diagnostic testing, as fluid generally re-accumulates within 48 h. Ex utero intrapartum treatment (EXIT) with thoracentesis as an alternative to fetal shunting has been reported, but this therapy is not available in all treatment centers.

Urinary tract and gastrointestinal anomalies rarely cause nonimmune hydrops. Posterior urethral valves associated with prune belly syndrome or urethral atresia likely cause hydrops by obstructing venous return or mechanical tamponade. Congenital nephrosis leads to hydrops because of hypoproteinemia, which can also be seen with hepatic tumors, volvulus, and meconium peritonitis. Isolated abdominal wall defects causing lymphatic obstruction can also lead to hydrops.

Lymphatic Disorders

Primary congenital pulmonary lymphangiectasia is an abnormality of lymphatic development leading to thoracic duct obstruction. Secondary forms of this disease occur due to thoracic duct obstruction by masses, total anomalous pulmonary venous return, or as a component of a discrete syndrome. The resultant chylothorax can be treated with mid gestation pleuro-amniotic shunting to avoid resultant pulmonary hypoplasia. Generalized lymphangiectasia occurs because of systemic lymphatic vessel ecstasies. In addition to chylothorax, these patients develop subcutaneous edema and hepatic, pancreatic, and

renal lymph edema. These disorders can occur spontaneously or by autosomal recessive inheritance.

Anemia

Fetal anemia, accounting for 10–27% of hydrops can result from a variety of causes including abnormal hemoglobin formation, red blood cell destruction or defective production, and hemorrhage. Regardless of the cause, anemia can result in high-output failure and hydrops. Unlike in the Caucasian population, the major cause of hydrops in Southeastern Asia is homozygous alpha-thalassemia-1 or Bart's hemoglobin. This gamma-4 tetramer, while having a high affinity for oxygen, is unable to release it to the tissues, resulting in anemia, profound hypoxia, acidosis, hydrops, and fetal death.

Feta-maternal hemorrhage, which can be diagnosed by the Kleihauer-Betke test, can present as hydrops if the anemia is chronic. Monochorionic twins are at increased risk of anemia due to twin–twin transfusion. The anemia seen in Parvovirus B-19, (see below) can be transient, as erythroid bone marrow aplasia can resolve in 7–10 days. In these cases, spontaneous resolution of the hydrops can be seen. If severe anemia persists, intrauterine transfusions are performed. Aggressive management is suggested, as the general outcome for these fetuses is good, particularly if the diagnosis is made after the first trimester.

Infectious Diseases

There are multiple infectious organisms responsible for nonimmune hydrops, of which parvovirus B-19 (Fifth Disease) is the most common. Other associated organisms include the TORCH pathogens (toxoplasmosis, cytomegalovirus, rubella, and herpes) as well as varicella, syphilis, and coxsackie. Unlike with other infectious agents where the mechanism of hydrops is not well understood, fetal anemia, hepatitis, and myocarditis can develop with parvovirus B-19, because the virus affects the bone marrow, hepatic, and myocardial tissues. As the disease is self-limited, the prognosis is good if the fetus receives red cell transfusions until the anemia resolves. The presentation of the TORCH and other organisms is one of multisystem organ failure, as the infection affects the myocardium, bone marrow, and vascular endothelium, leading to heart failure, fetal sepsis, anemia, and hypoalbuminemia with resultant anoxia, endothelial damage, increased capillary permeability, and hydrops. Interventional therapy, if the diagnosis is made prenatally, can include hyperimmune globulin for the mother and fetus in the case of CMV, or Gancyclovir for the newborn if the diagnosis of CMV is made after birth (see chapter on infectious diseases).

Maternal Presentation

While hydrops is a fetal condition, maternal morbidities can complicate the presentation. Hydrops occurs more commonly in mothers who have had a previous stillbirth or hydropic infant or twin pregnancies, particularly monochorionic twins. Additional maternal complications such as polyhydramnios/oligohydramnios, preeclampsia, preterm labor/delivery, and anemia have all been described. In an attempt to compensate for fetal hypoxia, the placenta enlarges and can penetrate deeper into the myometrium. As such, additional complications can arise after birth including retained placenta and postpartum hemorrhage.

Mirror syndrome, first described by John Ballantyne in 1892 (Ballantyne's syndrome), refers to a maternal condition of generalized edema that mirrors the edema of the hydropic fetus and placenta. This "triple edema" syndrome (mother, fetus, and placenta) can present with both immune and nonimmune-mediated hydrops. While the pathogenesis is unknown, postulated hypotheses include a systemic inflammatory response from increased shedding of trophoblastic debris into the maternal blood. A proposed mediator of this response is soluble fms-like tyrosine kinase, which has been associated with the development of preeclampsia. Mirror syndrome can present similarly to severe preeclampsia, although, unlike with preeclampsia, the maternal hematocrit is usually low, amniotic fluid volume is usually high, and the fetus is always hydropic. Delivery will usually reduce maternal symptoms, although persistence of symptoms into the postpartum period can occur. If the cause of the fetal hydrops is reversed, reversal of maternal symptoms can be seen. Additionally, if the fetal hydrops resolves spontaneously, or if the fetus dies, spontaneous resolution of maternal symptoms can occur.

Diagnosis

The diagnosis of hydrops is established with prenatal ultrasound. It is defined by the presence of fluid accumulation in the fetal extravascular space and body cavities. Polyhydramnios, defined as an amniotic fluid volume (AFI) of greater than 24 cm or a vertical pocket greater than 8 cm, is present in 40–75% of pregnancies complicated by nonimmune hydrops. An early sign of ascites is the outlining of the intraabdominal organs by a thin rim of fluid. It is important to distinguish this from pseudoascites, in which the abdominal wall muscles appear as a hypoechoic band. As ascites worsens, the bowel may appear compressed, with its walls accentuated due to the excess fluid allowing for increased ultrasound transmission. Significant pleural effusions that develop

prior to 20 weeks gestation, can prohibit normal lung growth and development, and result in pulmonary hypoplasia, a cause of death in many hydropic infants. The fetal heart should carefully be visualized for congenital defects as well as for the presence of pericardial fluid, with the knowledge that the presence of a small amount of fluid in the pericardial sac may be physiologic. Venous Doppler sonography can be a useful tool in the evaluation of the hydropic fetus as changes in velocimetry have corresponded to alterations in cardiac function.

Skin edema is a late sign of fetal hydrops. It is considered pathologic if the subcutaneous tissue on the chest or scalp measures greater than 5 mm. Attention should be paid to avoid including fat in this measurement. Placentomegaly, defined as a thickness of greater than 4 and 6 cm, may occur due to intravillous edema. However, if the polyhydramnios is profound, the placenta may be compressed.

The first site to demonstrate excess fluid can vary depending on the cause of the hydrops. In a series of 100 hydropic patients, those with a chromosomal disorder developed soft tissue swelling around the head and chest, with minimal limb swelling. Those patients with anemia or cardiovascular disease tended to have more evenly distributed fluid throughout multiple sites.

As hydrops is the final common pathway for multiple disease states, understanding the etiology can be difficult. A careful evaluation to assess for diagnoses amenable to treatment should be pursued. A detailed evaluation for structural anomalies as well as fluid assessment, placental thickness, and Doppler blood flow studies are considered part of the initial evaluation. Measurement of the fetal middle cerebral artery peak systolic velocity is a noninvasive tool for predicting fetal anemia. A careful personal and family history should be obtained to look for ethnic, genetic, or heritable disorders associated with hydrops. Alpha-thalassemia is the most common cause of nonimmune hydrops in Southern China and Thailand. Knowledge of recent exposure to infectious agents, as well as noting the time of year, may help identify parvovirus, the most common infectious etiology of hydrops. Suggested maternal laboratory testing includes a complete cell blood count with red blood cell indices, blood type, serologies, and the Kleihauer-Betke test.

Based on the initial evaluation, it may be appropriate to undertake further invasive testing in order to arrive at a fetal diagnosis. Amniocentesis or cordocentesis can be performed for karyotype although cordocentesis has the advantage that results are generally available sooner, and fetal hemoglobin and blood grouping can be obtained as well. Either fetal blood or amniotic fluid should be tested for TORCH pathogens specifically CMV, toxoplasmosis, and parvovirus B19. Amniotic fluid can be saved for additional testing should baseline studies be unrevealing and rare metabolic disorders considered.

Management

Despite improved diagnostic techniques, mortality for nonimmune hydrops remains high. The management depends on timing of diagnosis and etiology. Those cases diagnosed prior to 20 weeks, are often aneuploid and will be complicated by pulmonary hypoplasia, both poor prognostic signs. The temptation to deliver a sick fetus before term should be avoided given the added complications anticipated from the prematurity. Options for the family include termination of the pregnancy, therapeutic intervention in specific instances, and close monitoring of the mother and her fetus. Amniocentesis or aspiration of pleural or ascitic fluid before delivery can make the delivery less traumatic, and can facilitate resuscitation. There is not evidence that mode of delivery has a marked effect on outcome, although most fetuses are delivered by cesarean section, many because of dystocia and nonreassuring heart rate patterns. Antenatal consultation with appropriate neonatal and pediatric subspecialty teams, as well as planned delivery at a tertiary care center is recommended.

Antenatal diagnosis can allow for delivery to occur in a controlled setting. The neonatal team should ensure the availability of O negative blood cross matched against the mother, full monitoring capability and availability of equipment to perform an exchange transfusion. Initial resuscitation may be difficult for three main reasons. Pulmonary hypoplasia can complicate a majority of cases due to lung compression by pleural fluid, gross abdominal ascites, or a mass. Intrapartum asphyxia may complicate the delivery, and endotracheal intubation may be challenging due to the hydrops and laryngeal edema. The infant may require high positive pressure as well as thoracentesis and/or abdominal paracentesis before adequate gas exchange can be ensured. As peripheral venous access will be difficult due to skin edema, there should be a low threshold for the placement of an umbilical catheter. If associated anomalies are identified or, if despite these interventions the infant is unable to maintain a stable heart rate and ability to oxygenate/ventilate, this may be an appropriate time to discuss with the family the discontinuation of support.

If the infant is stillborn or dies in the immediate newborn period, continued evaluation should be considered including the consent for an autopsy in order to assist in counseling of the family with regard to future

pregnancies. If the parents do not wish for an autopsy to be performed, consent for a skin or liver biopsy as well as full radiographs and photographs should be made. The placenta should be sent fresh and not fixed in formalin, to be evaluated by a perinatal pathologist.

Substance Use in Pregnancy

Substance use during pregnancy presents a complex issue of challenges for the mother and her fetus and is a growing international concern. Illicit drug use is the ninth leading cause of death in the United States. The number of pregnant women reported using illicit drugs during pregnancy in the United States has increased from 2.8% during 1996–1998 to 4% in 2006. The prevalence was highest among women aged 18–30 years, unmarried and with less than a high school education. The Annual report of the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), estimates that there are as many as 30,000 pregnant women using opioids in Europe with a speculation that use of other drugs is equally high. Since 1996, the nonmedical use of analgesics has increased for pregnant women, with self-reported use increasing from 51,900 in 1993, to an average of 109,000 in 2002 to 2004. As these data are generated from self-report, they likely represent substantial underestimates. In addition to illicit drugs and nonmedically used analgesics, 35% of pregnant women are now using psychotropic medications to treat disorders such as anxiety and depression. These medications, although felt to be safe when used during pregnancy, have the potential of affecting the fetus and newborn.

Drug use during pregnancy is a public health concern not only because of the direct effect of the drug on the mother, but because of the associated morbidities encountered for the pregnant patient with respect to infectious diseases, social and personal stressors, comorbid mental illness either with or without concomitant illicit drug use, and risk to the fetus and neonate who require prolonged hospitalizations. Issues that deserve particular attention when considering a substance using pregnant woman and her fetus are discussed below. The effects of particular substances on the fetus and neonate are discussed under each particular drug.

Infectious Diseases

Infectious diseases including HIV, hepatitis B (HBV), and C (HCV), and other sexually transmitted diseases such as syphilis, chlamydia, and gonorrhea are more prevalent in the drug using pregnant population. Early identification of these illnesses can ensure a reduction in the risk of vertical transmission. As of September 2006, the US Centers for Disease Control (CDC) recommended universal screening for HIV in all pregnant women regardless of risk. Current practice in the United States reflects state law. Given the reduction of the risk of vertical transmission to under 2% with treatment, practitioners are strongly encouraged to offer testing. Without treatment, HIV perinatal transmission rates range from 25% to 30%.

Ten to 20% of women seropositive for HBsAg transmit the virus to their neonates in the absence of immunoprophylaxis. In women who are both positive for HBsAg and HBeAg, vertical transmission is approximately 90%. In patients with acute hepatitis B, the likelihood of transmission is greater if infection develops in the third trimester. Hepatitis B testing in pregnancy is recommended by the CDC and the World Health Organization (WHO). With appropriate hepatitis B immunoprophylaxis, breastfeeding poses no increased risk for transmission to the neonate.

The prevalence of hepatitis C in a healthy pregnant woman is 3.44%. Injecting drug use accounts for 60% of HCV transmission in the United States, and is the leading cause of transmission in the UK. The risk of vertical transmission is related to the level of viremia in the mother and not her mode of delivery. Neither the CDC, the American Academy of Pediatrics (AAP), or the American College of Obstetrics and Gynecology (ACOG) recommend operative birth for mothers with hepatitis C. Approximately 7–8% of hepatitis C-positive women can transmit hepatitis C to their offspring, with a higher rate of transmission seen in women co-infected with HIV. While routine screening is not recommended in the general pregnant population, women who have ever injected illegal drugs, including those who injected once or a few times many years ago and do not consider themselves drug users should be screened. Breastfeeding does not increase the risk of transmission to the neonate.

Societal Stressors

Compounding the expected stress of pregnancy and substance use are issues of homelessness, unemployment, legal complications, fractured relationships, and physical and emotional abuse. Infant neurodevelopmental outcome has as much to do with fetal exposures as it does with the environment. Determining developmental risk for fetal drug exposure is often complicated by the confounding environment in which many of these

children reside. Prenatal clinics and drug treatment centers should offer multidisciplinary coordinated services to address the many needs of this population and ensure adequate intervention.

Psychiatric Comorbidity

Up to 70% of pregnant women experience depressive symptoms and 9–14% of all pregnant women will display signs of depression or fulfill criteria for the diagnosis of depression. For bipolar disease and severe chronic depression, pregnancy and the postpartum period present an especially greater risk period. Untreated depression is associated with significant morbidities including inadequate self-care, hypertension, spontaneous abortion, preeclampsia, fetal growth restriction, and substance abuse. Furthermore, patients should understand that stopping antidepressant medications during pregnancy because of a concern about exposing the fetus, can led to a maternal discontinuation syndrome, as well as a significantly greater risk of relapse when compared to the treated patient.

The selective serotonin uptake inhibitors (SSRI), first introduced in 1988, are the treatment of choice for mood disorders during pregnancy. These medications, which readily cross the placenta, expose the fetus to increased serotonin levels. Epidemiologic studies have demonstrated that first trimester exposure to Paroxetine (Paxil) has been associated with an increased risk of cardiac malformations. As a result, in 2005, the US Food and Drug Administration (FDA) issued an advisory reclassifying Paroxetine as category D and warned against its use in pregnancy.

There is evidence to support the notion that infants exposed to SSRI medications, particularly in the last trimester can exhibit either a discontinuation syndrome or serotonin toxicity, manifest by irritability, crying, tremulousness, hypertonia, feeding and sleeping difficulties, and rarely seizures. The symptoms can develop in a few hours up to a few days, and are typically short-lived, but can last for up to a month. Most infants are managed with supportive care, and rarely require medication intervention. Phenobarbital is generally the drug of choice in those situations where environmental intervention is not sufficient. Additional complications for the neonate born to a mother using an SSRI include prematurity, admission to a special care nursery, poor neonatal adaptation, and in rare cases pulmonary hypertension. As SSRIs are relatively new, inquiries regarding the long-term neurobehavioral effects of these drugs on the newborn and developing child are ongoing.

The decision to treat a pregnant woman with psychotropic medications during pregnancy should be made with the following considerations. Each patient should be treated individually using the lowest possible medication dose and avoiding multiple medications. The practitioner should be aware of the particular side effects when these medications are used, and the patient should be educated as to the risks/benefits and uncertainties of pharmacotherapy as well as the risk of not treating significant mental illness. These conversations should be documented in the medical record. Collaboration with mental health professionals regarding alternative therapies including cognitive, behavioral, interpersonal, and electroshock therapy should be considered.

Drugs Used During Pregnancy

Licit Drugs

Nicotine Pregnant women who use drugs also frequently drink alcohol and smoke cigarettes. While neither substance is illegal, both have known adverse effects for the mother, her fetus, and her neonate. Cigarette smoke is a complex mixture of chemicals with approximately 4,000 compounds including those that cross the placenta and may affect the fetus. Prenatal nicotine exposure, described as the most widespread prenatal drug insult in the world, is also one of the known preventable causes of low birth weight, prematurity, placental abruption, and miscarriage. Neonates born to mothers who smoke weigh an average of 150–250 g less than infants born to unexposed women. Neurotoxic effects of prenatal tobacco exposure on newborn neurobehavior have been noted 48 h after birth, with poorer self-regulation, and an increased need for external intervention as late as 27 days of age. Smoking in pregnancy is decreasing in high-income countries, increasing in low- to middle-income countries and is strongly associated with poverty, low educational attainment, poor social support, and psychological illness.

Those women who start smoking by 15 years of age are less likely to stop and report higher levels of nicotine dependence when compared to women who initiate smoking later in life. Furthermore, offspring of mothers who smoked a pack or more of cigarettes during pregnancy are at increased risk of developing nicotine dependence as an adult. Smoking cessation programs during pregnancy can reduce the proportion of women who continue to smoke in late pregnancy and reduce the incidence of low birth weight and preterm birth, stressing the value of early education on minimizing these untoward outcomes.

Alcohol Fetal alcohol spectrum disorder (FASD) is used as an umbrella term to describe the range of outcomes associated with all levels of prenatal alcohol exposure. Risk drinking during pregnancy (enough to potentially damage the fetus) has been defined as an average of more than one drink (0.5 oz) daily, or less if massed (binges of >5 drinks per episode). Adverse childhood behavioral outcomes have been noted after these exposures, leading the AAP and ACOG to recommend abstaining from alcohol during preconception and pregnancy. Testing for alcohol exposure is imprecise, and most clinicians rely on maternal history where underreporting is common. While there is no standard neonatal screen for alcohol exposure, identifying stable biologic markers of ethanol, such as fatty acid ethyl esters is being explored as a potential screening tool.

Infants with FASD have a characteristic facial dysmorphology (midface hypoplasia, long smooth philtrum, thin upper lip, small hyperteloric eyes, and inner epicanthal folds). They can be growth restricted and have relative microcephaly, ophthalmologic involvement, and over time neurodevelopmental, cognitive, and behavioral abnormalities. Making a diagnosis in the newborn period can be difficult, as features can be subtle, and often an accurate history is not obtained. Exposure to alcohol during pregnancy has been implicated as the most common cause of mental retardation and the leading preventable cause of birth defects in the United States, accounting for significant educational and public health expenditures. Substantially higher rates of FASD have been demonstrated among low socioeconomic and minority groups, with African American children more than five times as likely and American Indian/Alaskan Native children 16 times more likely than white children to exhibit FAS. Additionally, up to 50% of women of childbearing age consume alcohol and 15–20% acknowledge continuing to drink during pregnancy. Up to 1% of pregnant women drink at levels considered heavy, with such consumption more common among women 30 years or older, unmarried, and with low incomes. Routine use of a screening tool for alcohol consumption during pregnancy should be a part of every prenatal assessment.

Illicit Drugs

Toxicology Screening

Screening for illicit substance use begins with assessing the maternal history. The Committee on Substance Abuse of the AAP recommends obtaining a comprehensive medical and psychological history that includes specific information regarding maternal drug use. As this information is not always reliable, providers should develop a nonjudgmental set of criteria for when screening should be performed. Establishing substance exposure risk might include inadequate prenatal care, clinical concerns such as inappropriate behavior, disorientation, somnolence, or physical signs of substance use or withdrawal. If there is a known history within the past year of substance use, substance screening should be considered. Urine screening for the mother and urine and meconium screening for the infant are the typical specimens provided. While urine testing demonstrates recent exposure to drugs, meconium testing can ascertain remote exposure, as early as 12–13 weeks of gestation, when fetal swallowing begins. Because drugs can accumulate in the meconium from the second trimester until delivery, meconium testing affords a greater window of detection. Maternal and neonatal hair testing can detect prenatal drug exposure, as drugs of abuse are incorporated into the hair shaft at the time of formation of the follicle and can be subject to analysis. Hair sampling can be problematic given inadequate hair to sample in some infants, the fact that coarse black hair incorporates more of the drug than brown or blonde hair, requiring a differential scaling for hair color, and that parents may object to shaving the infant's hair. Testing of umbilical cord tissue with ELISA-based screening has been shown to detect fetal exposure to methamphetamine, opiates, cocaine, and cannabinoids. Unlike meconium sampling which can take days to collect, umbilical cord tissue is available immediately after delivery. It is important to know which substances are tested in the substance screen ordered, as this can vary from one screen to another. Furthermore some substances, such as buprenorphine, are not routinely identified in the standard screen, and require a separate order. Relying solely on the results of a toxicology screen to dictate care may underserve the neonate, as false negative results can occur if the exposure was early in pregnancy, or the urine sample was not obtained right after birth, or laboratory variability is not sensitive enough to pick up small amounts of drug. Each physician should also be familiar with local laws regarding screening, consenting, and reporting of prenatal substance exposure.

Opiates

In 2008, the United Nations Office of Drugs and Crime (UNODC) estimated that between 12.8 and 21.9 million people worldwide abused opioids, with the prevalence ranging between 0.3% and 0.5% of the global population aged 15–64. In a US prevalence survey of prenatal drug

exposure, 53,400 used heroin or nonprescribed opioid medications annually. There are two approaches to the opioid-dependent pregnant woman, namely, detoxification and maintenance therapy. While detoxification has been reported to be safe in select populations, the dropout rate can be as high as 50% with a relapse rate approaching 70%. Furthermore, the stabilization of the pattern of use of one drug may be associated with the misuse of other drugs. Because opioid withdrawal has been associated with morbidities including preterm labor, poor fetal growth, and fetal death, and because decades of research has demonstrated methadone's safety and effect on improving the outcome for both the mother and her fetus, many countries including the United States and Australia currently recommend methadone maintenance as the treatment of choice throughout pregnancy. To date, however, neither methadone nor buprenorphine are approved for use in pregnancy by the FDA, and remain listed as category C medications.

Methadone

Methadone, a full mu opioid receptor agonist, has been the most frequently studied medication during pregnancy, and has been available in the United States as an opioid maintenance medication since the 1970s. Interestingly, methadone treatment in Russia is illegal, as health officials are not convinced of the treatment's efficacy. Instead, doctors encourage immediate abstinence from drug use, rather than the gradual process of substitution therapy.

Methadone maintenance during pregnancy has both direct and indirect effects on the fetus. Pregnant women stabilized on methadone are more likely to seek prenatal care, and less likely to engage in injection related risk-taking and illicit behaviors. As the metabolism of methadone is increased with pregnancy resulting in a shortened half-life, particularly during the third trimester, women will frequently require an increase in maintenance dosing. This information should be made known to the pregnant women, as often, there is great resistance to dose adjustment.

Buprenorphine

Buprenorphine, a partial opioid agonist has been available in France since 1996, and approved for use in the United States in the nonpregnant adult population since 2002, and in the European Union since 2006. Unlike methadone, buprenorphine has a high affinity at the mu receptor, but a low activity. As such, when taken, it displaces the full opioid agonist from the receptor, but has limited activity, leading to a "ceiling effect" where if more drug is taken, no more opioid effect is realized. Given this difference in maximal opioid effect between full and partial opioid agonists, buprenorphine is not a replacement for all methadone clients, as, with higher methadone dosing requirements, replacing with buprenorphine could precipitate withdrawal. Buprenorphine is available as Subutex (buprenorphine alone) and Suboxone (buprenorphine + naloxone). Suboxone was developed in an effort to limit its appeal as a substance of abuse, as, if it is crushed and injected (normal route of administration is sublingual), the buprenorphine component will remain inactive and the naloxone activated, precipitating acute withdrawal. Subutex is the form of buprenorphine preferred in pregnancy so as to limit the fetus to naloxone exposure.

Abrupt cessation of buprenorphine has resulted in a milder withdrawal in the adult population when compared to methadone. Until recently comparative effects of methadone vs. buprenorphine during pregnancy and effects on the neonate were limited to case series and short studies, most of which had methodological flaws such as lack of blinding, small sample size, and concomitant additional drug use.

Neonatal Withdrawal

Between 55% and 94% of neonates born to women on maintenance, opioid therapy will experience neonatal abstinence syndrome (NAS). There are conflicting data regarding the effect of maternal dosing on the degree of neonatal withdrawal. Most studies do not support a clear relationship, and if the mother is taking other prescribed medications or using other illicit drugs, estimations about degree of neonatal withdrawal become speculative at best. While maternal dose of opioid may not clearly parallel degree of neonatal withdrawal, the type of opioid used during pregnancy may affect the neonatal course. Results from the MOTHER (Maternal Opioid Treatment: Human Experimental Research) trial, a double blind double dummy prospective randomized clinical trial, demonstrated that while the number of infants who required neonatal morphine did not differ between the methadone- and buprenorphine-exposed infants, the buprenorphine cohort required significantly less morphine to treat NAS and had a significantly shorter duration of hospitalization. These results suggest that for select patients, buprenorphine might be the optimal medication given its amelioration of NAS in the newborn when compared to the methadone exposed neonate.

NAS is characterized by central and autonomic nervous system irritability, gastrointestinal dysfunction, and some component of respiratory distress. Management often requires prolonged hospitalization due to pharmacologic intervention. Assessment of NAS is performed using a standardized scoring tool to allow for objective

data to guide care. The most frequently used scoring tool, developed by Finnegan, is a 31 item scale administered every 4 h. Alternative tools used include the Lipsitz Score, the Ostrea tool, the Neonatal Withdrawal Inventory, and the Neonatal Narcotic Index. Most centers utilize the Finnegan score or its variations, given its comprehensive nature and recommended treatment schedule. A limitation of the tool is that it was developed for the full-term infant during the neonatal period, and as such does not fully address the needs of the preterm neonate, nor the infant who requires hospitalization beyond the neonatal period.

Multiple medications have been described to treat neonatal withdrawal including morphine, diluted tincture of opium (DTO), methadone, phenobarbital, clonidine, diazepam, clorpromazine, and buprenorphine. Paregoric, a camphorated tincture of opium that contains many potentially toxic substances, such as anise oil, benzoic acid, camphor, and alcohol is no longer recommended. Opioid medications are felt to be the most effective agents in the treatment of neonatal opioid withdrawal, although a recent Cochrane review failed to find one opioid superior to another. Phenobarbital and clonidine have both been studied as adjuncts to DTO in the treatment of NAS, and found to be superior when compared to treatment with DTO alone. Infants who require medication should remain hospitalized given the fact that opioid medications are prescribed in very small doses and inadvertent administration of a larger dose could lead to serious respiratory depression. Furthermore, allowing a mother who has opioid dependency to take home a prescribed opiate medication could be a trigger for relapse which could place the infant at risk. Finally, infants undergoing withdrawal exhibit a spectrum of symptoms the management of which can change frequently and require repeated intervention, which cannot easily be provided in the home setting.

Medications to treat withdrawal are generally begun when environmental intervention alone is insufficient to relieve symptoms. The dose of the opiate is increased until scores are stabilized (less than 8 for the Finnegan scale) at which point the dose is maintained for 48 h before weaning is begun. Opiate weaning is usually offered once daily, or up to twice daily if the scores demonstrate minimal withdrawal (i.e., <4 on the Finnegan scale). The nature of withdrawal is such that some infants will require a reescalation of opiate medication once weaning has begun. Generally, reescalation doses are less than the initial escalating dose. Once the opioid medication is discontinued, an observation period for 24–48 h occurs to ensure that the infant remains comfortable without medication, at which point discharge can occur. If an additional medication has been used, such as phenobarbital, it is continued at the time of discharge, and weaned as an outpatient.

In addition to medication intervention, following adequate growth and nutrition is vital, as some infants will continue to lose weight despite adequate caloric intake, or fail to gain weight because of poor feeding. Intervention strategies include higher calorie formula or nasogastric feedings. Breast-feeding is compatible with opiate exposure, although care should be taken if breast-feeding is erratic or acutely stopped as withdrawal signs can worsen.

Long-term outcome for infants exposed to opiates in utero is compounded by the environmental stressors frequently encountered in this population. In addition, some studies compare the opiate-exposed newborn to a healthy control without similar environmental stressors. When controlling for confounding factors, Messinger et al. found no significant differences between opiate-exposed and non-drug-exposed infants at 1, 2 and 3 years of age.

Cocaine

According to the National Survey of Drug Use and Health (NSDUH), of the 3.3% of women who used illicit drugs during pregnancy, 10% used cocaine. From the mid-1980s into the early 1990s, observations were made describing fetal teratogenic and toxic effects of cocaine. The maternal lifestyle study (MLS), a large multisite, prospective, randomized investigation was conducted to confirm or negate the hypothesis that fetal cocaine exposure during pregnancy has no impact on maternal and infant outcomes. Unlike previous studies that noted an increased risk of congenital anomalies, this was not supported by the MLS. While human studies conflict in terms of an association between cocaine exposure and cardiovascular changes, animal studies demonstrate that fetal cocaine exposure results in changes on the cellular and genetic level that may not manifest as neonatal gross cardiac problems, but result in an increase risk of heart disease over time. The possibility that fetal cocaine exposure could affect cardiac programming warrants continued investigation as this exposed population ages.

Growth restriction, prematurity, and increased central and autonomic nervous system dysfunction have been noted with cocaine exposure. In the MLS study, the cocaine-exposed infants were more tremulous, had a higher pitched cry, irritability, excessive suck, and hyperalertness during the first days of life. Because the neurobehavioral symptoms can occur before the half-life of the drug, there is reason to believe that these symptoms

are a reflection of cocaine toxicity rather than withdrawal. While these symptoms warrant close observation, rarely do they require pharmacologic management. At 1 month of age, subtle effects of cocaine persist and may be dependent on degree of exposure. Higher excitability has been seen in heavy cocaine exposure, while lower arousal scores are noted in neonates exposed to lesser amounts of cocaine, suggesting that there may be a dichotomous presentation based on degree of exposure. Similarly, long-term developmental outcomes, often confounded by multiple exposures and environmental risk, appear to be related to degree of cocaine exposure. When controlling for confounding factors, it appears that deficits in language, cognition, and motor skills parallel the degree of cocaine exposure, namely, the greater the exposure, the greater the deficit.

Methamphetamines

Methamphetamine is a highly addictive central nervous system stimulant, and the most potent member of the amphetamine group of synthetic drugs. Since 1992, methamphetamine use in pregnant US teenagers has more than quadrupled. While it was the primary substance of abuse in 4.3% of treated pregnant teens in 1992, by 2007 that number had risen to 18.8%. In New Zealand, referrals for methamphetamine use to the Alcohol Drug and Pregnancy Team (ADAPT) program increased from 10% of total referrals in 2001 to 59% in 2003.

While the pharmacologic properties of methamphetamines are similar to cocaine, methamphetamine has a longer half-life and greater sympathomimetic effects, which can result in vasoconstriction. The few human studies published concerning methamphetamine use in pregnancy have demonstrated an increased risk of preterm delivery, placental abruption, fetal growth restriction, and heart and brain abnormalities. However, these investigations have methodological flaws including small sample size, lack of a comparison group, and the confounding effect of multiple drug exposures. In the IDEAL (The Infant Development, Environment, and Lifestyle) study, a prospective longitudinal investigation that evaluated the effects of prenatal methamphetamine exposure on the newborn, there was an increased incidence of small for gestational age (SGA) and lower birth weight infants suggesting a direct methamphetamine-induced growth restrictive effect on the developing fetus. Neurobehavioral testing with the NNNS (NICU Network Neurobehavioral Scale) demonstrated decreased arousal, increased stress, and poor quality of movement. These results were affected by time of exposure as well as degree of use.

Like with many drugs, the environment of methamphetamine users is often characterized by chaos, neglect, abuse, and criminal activity, all of which can affect the outcome for the exposed child. In addition, these children face acute health and safety hazards from fires, explosions or toxic chemicals if exposed to a home methamphetamine lab. What little research is available regarding long-term effects of prenatal amphetamine exposure suggests that at birth, 1 and 4 years of age, mean weight, height, and head circumference are below the mean for their peers. In addition, there is a suggestion of a link between exposure and aggressive behavior, peer problems, and hyperactivity. These results are limited due to a lack of a matched comparison group, and the effect of other drug exposures. Additional work has suggested that prenatal methamphetamine exposure influences the development of the verbal memory system, long-term spatial memory, and visual motor integration. Confirmatory investigations in a prospective, controlled manner are vital so as to avoid drawing conclusions based on limited data as was the case with the early cocaine literature.

Marijuana

Marijuana is the most frequently used illicit drug among women of childbearing age in the US. Of the 3.3% of women who used illicit drugs noted in the 2002 SAMHSA report, 80% used marijuana. Marijuana abuse among pregnant teenagers has more than doubled from 1992 to 2007, accounting for 45.9% of the primary substance of abuse. The principal psychoactive component of marijuana is delta-9-tetrahydrocannabinol (THC), which rapidly crosses the placenta and can remain in the body for 30 days. Depending on frequency of use, cannabis can be detected in the urine between 2 and 4 days for infrequent users and up to 1 month for heavy chronic users. THC is secreted into the breast milk.

While infrequent marijuana use (less than once/weekly) is not associated with decreased birth weight, in a meta-analysis, a 131-g decrease in birth weight was noted in infants born to mothers who used marijuana >4 times weekly. Regular exposure to marijuana (six or more times weekly) has been associated with withdrawal-like symptoms, namely, excessive crying and tremors, as well as difficulty with state regulation. At school age, children exposed prenatally to marijuana have decreased impulse control and attention especially regarding problem solving, hypothesis testing, and planning, as well as poorer visual-spatial ability. Marijuana should not be considered a benign drug. Prevention programs aimed at adolescent pregnancy to address parenting skills, at risk behaviors, and comorbidities that lead to drug use should be incorporated into the reproductive health visit for the young adolescent teen.

35 Common Procedures in Neonatology

Jayashree Ramasethu

The medical care of increasingly smaller and sicker newborn infants in the past century has been made possible by innovations in technology, but has not obviated the need for invasive procedures in the neonatal intensive care unit (NICU). In order to reduce iatrogenic morbidity, healthcare providers performing the procedures must be familiar with the indications, contraindications, and potential complications, and use appropriate equipment and precautions. The procedures should be performed or closely supervised by personnel with the necessary expertise. Documentation of the procedure in the records is important for patient care and is a medicolegal requirement in most institutions. The length of insertion of catheters and endotracheal tubes should be recorded for monitoring purposes, and details of problems encountered during the performance of a procedure may help if the procedure has to be repeated for any reason.

Informed Consent

Routine medical care is covered by the "general informed consent" obtained on admission of a patient, but the definition of "routine" varies from institution to institution and between NICUs. Consent is implied for certain procedures, such as intubation for respiratory support, obtaining blood samples, and venous access, when an infant is admitted to a NICU. It is judicious to obtain specific informed consent for invasive procedures from the parents or legal guardians whenever possible, unless a life-threatening emergency dictates immediate action. Consent should be obtained after a discussion of indications, important risks and benefits, and alternatives, if any, to the procedure and documented in the patient's records. While it is important to provide adequate information, too much information on every potential and rare complication may overwhelm and paralyze parents into being unable to make a decision and ultimately be detrimental to the patient.

Analgesia and Homeostasis

Adequate lighting and access to the infant are essential to allow procedures to be completed expeditiously. Nevertheless, every effort should be made to maintain homeostasis in infants undergoing procedures. Continuous cardiorespiratory monitoring is prudent to ensure stability, particularly if narcotic analgesics or sedatives are administered. Appropriate temperature and light control, calming touch and swaddling, kangaroo mother care and breast feeding all play a part in reducing stress. Sterile sucrose solution (12–50% concentration) on a pacifier is an effective analgesic for some procedures. Topical anesthetics such as lidocaine-prilocaine cream or tetracaine gel require application to the skin for 30–60 min under an occlusive dressing. They are appropriate for circumcisions but have not been shown to be effective in reducing the physiological responses associated with procedures such as peripheral IV cannulation or lumbar punctures in neonates. Local injection of 1% lidocaine is also effective for circumcisions, and has been shown to reduce traumatic lumbar punctures in children. Intravenous narcotic analgesics such as fentanyl or morphine are recommended for intubation or chest tube insertion.

Aseptic Preparation

Invasive procedures breach intact skin, a vital barrier to infection in neonates. Aseptic preparation for procedures includes the preparation of the personnel for the procedure, preparation of the patient's skin, and use of clean or sterile equipment as appropriate. Hand hygiene is the single most important intervention to prevent nosocomial infection. Hands should be decontaminated before and after any direct patient contact and before wearing sterile gowns or gloves to perform procedures. Current evidence indicates that alcohol-based rubs used for hand antisepsis in preparation for surgery are equally or more effective than aqueous scrubs. Chlorhexidine-based aqueous scrubs are more effective than povidone iodine-based aqueous scrubs in terms of the number of colony forming units on the hands. In neonates, the use of antiseptics is limited by the thinness of the stratum corneum and the possibility of absorption and toxicity. Hexachlorophene is not used in neonates because of its potential for transcutaneous absorption and central nervous system toxicity in

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_35,

infants. Alcohol (70–90%) is adequate for minor procedures such as peripheral IV catheter placement, since it is bactericidal, dries rapidly, and acts quickly. Iodophors and chlorhexidine have a longer duration of action. Iodine containing antiseptics may be absorbed through the skin and have the potential to suppress thyroid gland function in preterm infants. Although chlorhexidine gluconate in isopropyl alcohol has been found to provide persistent antimicrobial activity and reduces the rate of catheter-related bacteremia, it has the potential to cause burns in very immature infants. It is best to remove excess antiseptic from the procedure site by wiping with sterile water as soon as the procedure is completed. Masks, drapes, and gowns are important barriers to microorganisms shed into the air from skin and mucous membranes.

Preparation for procedures such as central venous or umbilical catheterization or chest tube insertion should be as rigorous as preparation for a major surgical procedure, with appropriate hand hygiene, wearing of sterile gowns and gloves, skin preparation, and draping of the "surgical" site. In extreme emergencies, such as pericardial tamponade or tension pneumothorax with severe hemodynamic compromise, the operator may be forced to omit certain steps in the interest of time. The aseptic preparation in these circumstances may simply be hurriedly swabbing the area with antiseptic or pouring antiseptic solution on the skin before using a needle and syringe to evacuate the air or fluid.

Capillary Heelstick Blood Sampling

Capillary blood sampling is the most common procedure performed on newborn infants. It is a simple technique to collect small volumes of blood. The advantage of capillary sampling is that repeated testing may be carried out, and peripheral veins may be saved for intravenous access. The preferred areas for sampling are the outer aspects of the heel (*Fig. 35.1*), avoiding the posterior aspect of the heel, which is close to the calcaneum. The skin to calcaneal perichondrium is at least 3 mm in most term babies and in 91% of babies at 33–37 weeks gestation; so the plantar surface of the heel may be used if the lateral aspects of the heel are compromised by previous repeated tests.

Equipment

Automated heel lancing devices, which have encased, sharp, spring-loaded, retractable blades provide a controlled and consistent width and depth of incision for blood testing. The incision depth/width ranges from 0.65/1.4 mm for babies weighing less than 1,000 g, to 1.0/2.5 mm for term infants. Manual stylets are not recommended for use in babies since the depth of incision cannot be controlled. Additional supplies required are a warm towel or heel warmer, heparinized capillary tubes for blood gas measurements, blood collection microtubes, antiseptic solution or wipes, and a small adhesive bandage.

Figure 35.1
Recommended sites for capillary heelstick blood sampling in neonates

Procedure

Warm the heel by wrapping it in a warm towel or heel warmer for a few minutes just before the procedure. Swaddle the baby and provide non-pharmacologic pain control measures. Wash hands, wear gloves, and cleanse the site with antiseptic solution, followed by alcohol or sterile saline, and allow to air dry. Place automated heel lancing device on selected site and activate. Wipe away the first drop of blood with gauze and then collect samples required into capillary tube or blood collection microtubes. The calf may be squeezed gently intermittently to increase blood flow until all samples are obtained. Apply pressure to the puncture site to stop further bleeding and apply small adhesive bandage.

Complications

Hyperalgesia, cellulitis, abscess formation, perichondritis, osteomyelitis, and calcified nodules have all been described following heel stick sampling.

Peripheral Intravenous Cannulation

Intravenous cannulation of peripheral veins is most often performed for administration of fluids, medications, and for transfusion of blood products. The larger antecubital veins are preferred for venous blood sampling, particularly if volumes of 1 ml or more are required, since the smaller veins tend to collapse with the negative pressure exerted by the syringe when aspirating blood. A butterfly needle with most of the extension tubing cut off, leaving a 3–4 cm remnant, is useful to collect small samples of blood from the dorsum of the hand by the drip method. The veins useful for fluid administration are the dorsal venous plexus on the back of the hand, median antecubital vein or accessory cephalic vein on the forearm, basilic or cephalic vein in the antecubital fossa, or saphenous veins of the foot. The veins of the scalp may be used if none other is available. In critically ill neonates, it is judicious to reserve the veins in the antecubital fossa or the greater saphenous vein for potential percutaneous central venous catheterization.

Equipment

A variety of IV catheters made of polyethylene, polyvinylchloride, polyurethane, or Teflon ranging in size from 20 to 24 gauge and in length from 2 to 3 cm is available for use in neonates. In addition, a T-connector attached to a 3-ml syringe with sterile normal saline, transparent dressing, or adhesive tape for securing the cannula, additional adhesive tape for securing the arm or foot, and appropriate-sized arm board for restraint are required. A tourniquet and transilluminator are optional.

Procedure

Wash hands and wear gloves. Select an appropriate vein for cannulation. Apply a tourniquet proximal to the insertion site (optional). Prepare the selected area with antiseptic and allow drying for 30 s. Hold the limb with the nondominant hand, stretching the skin to immobilize the vein, and using the index finger and thumb as a tourniquet to distend the vein if a tourniquet is not used. Holding the catheter in the dominant hand, insert the needle into the skin a few millimeters distal to the point of entry into the vessel, at about a 30° angle (as in *Fig. 35.2*) and then maneuver it into the vessel in the same direction as the blood flow. When blood is visible in the cannula, withdraw the stylet and advance the cannula further into the vein, at a lower angle of 10–15°. Remove the tourniquet. Connect the T-connector to the hub of the cannula and flush 0.5–1 ml of normal saline to ensure that the cannula is within the vessel. Secure the cannula hub to the skin with adhesive tape or transparent dressing. Secure the limb to a board in an anatomically comfortable position, ensuring that all fingers and toes are visible and not constricted before taping. Attach the IV tubing to begin fluid administration.

Complications

Bruising and small hematomas are common if the procedure is unsuccessful. Extravasation or inadvertent infiltration of fluids into subcutaneous tissue from peripheral intravenous (IV) catheters is a frequent adverse event in neonates with complications ranging from minor transient swelling to loss of tissue and severe scarring, with resultant cosmetic or functional impairment. The recognition and management of extravasations has been addressed in several reviews.

Peripheral Artery Sampling or Cannulation

The radial, ulnar, posterior tibial, and dorsalis pedis arteries may be used for blood sampling or cannulated with

Figure 35.2
Introducer cannula with stylet for venipuncture prior to insertion of peripherally inserted central catheter (PICC)

indwelling venous cannulas for continuous blood pressure monitoring and for repeated blood sampling. Peripheral arterial catheters should be used only for blood sampling and continuous arterial blood pressure monitoring. No fluids other than heparinized saline should be administered through them and the rate of infusion should not exceed 2 ml/h.

Although the brachial and axillary arteries are easily accessible, catheterization of these vessels is not recommended because of the risk of vascular compromise to the arm. Catheterization of the temporal artery may be associated with neurological sequelae. The radial artery is preferred since the predominant blood supply to the hand is usually from the ulnar artery, but there are multiple variations in arterial vasculature. The modified Allen test has long been advocated to assess adequacy of the collateral circulation of the hand prior to radial artery catheterization, but the test is inaccurate and suffers from poor interobserver reliability. The radial artery is located at the proximal wrist crease by palpation or transillumination with the wrist supine and slightly extended. In extremely preterm infants, the vessel is superficial and often visible to the naked eye. In some infants, the ulnar artery is more easily located at the wrist than the radial artery. The posterior tibial artery is posterior to the medial malleolus with the foot in dorsiflexion. The dorsalis pedis is located in the dorsal midfoot between the first and second toes, but this artery is generally the last choice, since it may be very small or absent in some patients or may provide the main blood supply to the toes in others.

Equipment

Equipment for peripheral arterial blood sampling consists of sterile gloves, antiseptic solution, 23 or 25 gauge venipuncture (butterfly) needle with extension tubing, appropriate syringes, and blood collection tubes. Equipment for peripheral artery cannulation consists of sterile gloves, antiseptic solution, 22 or 24 gauge cannulas with stylets, T-connector with stopcock attached to 3-ml syringe flushed through with heparinized saline, sterile adhesive strips, materials for restraint of the arm or foot (arm board, adhesive tape, gauze pads, or cotton balls) arterial pressure transducer with extension tubing prepared with 0.5 N or Normal saline with 1 unit of heparin/ml, and continuous infusion pump capable of delivering 0.5–1 ml of fluid per hour. The importance of having the arterial pressure transducer and the continuous infusion pump ready before starting the cannulation cannot be overemphasized. The arteries are of very small caliber and need a continuous infusion of heparinized saline as soon as they are cannulated to remain patent.

Procedure

Arterial catheterization should be performed with sterile technique, preparing the area with antiseptic and using sterile gloves and equipment. For radial arterial sampling, puncture the skin just distal to the proximal skin crease with a butterfly needle and penetrate the artery at a 30–45° angle with the bevel of the needle facing upward (*Fig. 35.3*). Apply gentle suction on the syringe as soon as blood flow is observed. Maintain the needle in the same position until all blood samples have been collected. If no blood flow is obtained, or the blood flow ceases, the depth of penetration or the angle of the needle may have to be adjusted. After the needle is removed, apply direct pressure on the site for at least 2 min to secure hemostasis and inspect the fingers for circulatory compromise.

The procedure for peripheral arterial cannulation is similar. The artery is cannulated with an appropriate-sized cannula with stylet, instead of the butterfly needle. As soon as blood return is noted, decrease the angle to about 15° and advance the cannula forward up to the hub while withdrawing the needle (stylet), ensuring that the blood is continuing to flow. Inability to advance the catheter or the development of a hematoma at the insertion site usually means that the cannula/stylet has penetrated the dorsal or lateral wall of the vessel. The situation may be salvaged at times by withdrawing the cannula slightly and redirecting it. Attach a T-connector flushed with

Figure 35.3
Radial arterial blood sampling using butterfly needle

heparinized saline to the hub of the cannula, aspirate to check for blood return, and then flush 0.5–1 ml of saline through gently. Use transparent semipermeable dressing or adhesive tape to secure the cannula in place, and restrain the hand and wrist on an arm board with adhesive tape, in a physiological position, making sure that *all* fingers are visible at *all* times for visual inspection. The T-connector must be attached immediately to extension tubing and pump with a constant infusion of 0.5–1 ml/h of heparinized saline to maintain patency of the catheter. The arterial pressure transducer may be connected for constant pressure monitoring.

Complications

Although there are multiple case reports of ischemic injury, and there are very limited data in extremely low birth weight infants, the overall risk of ischemic injury secondary to radial or ulnar artery catheterization appears to be approximately 5%. Peripheral ischemia may be immediately recognized as cyanosis or pallor of the fingers and the cannula removed to avoid gangrene and permanent loss of the digits. Topical nitroglycerine has been found to be effective in restoring perfusion in a few cases where radial artery catheterization has resulted in cold, cyanotic, and stiff hands with absent radial pulses.

Nonischemic complications of arterial catheterization or even repeated attempts at catheterization include bleeding, pseudo aneurysms, arteriovenous fistulae, median nerve palsy, carpal tunnel syndrome, and injury to the tendon sheaths.

Umbilical Arterial and Venous Catheterization

Catheterization of the umbilical vessels soon after birth provides immediate vascular access in critically ill infants. Umbilical arterial catheterization is vital for continuous blood pressure monitoring, and for blood sampling for arterial blood gases, biochemical and hematological testing. Umbilical venous catheterization provides stable intravenous access for infusion of parenteral nutrition, medications, and for exchange transfusions.

The umbilical arterial catheter (UAC) passes from the umbilical artery into the internal iliac and then the common iliac artery, into the descending aorta. The recommended placement of an UAC is such that the tip is located between vertebral bodies T6 and T9 or T10

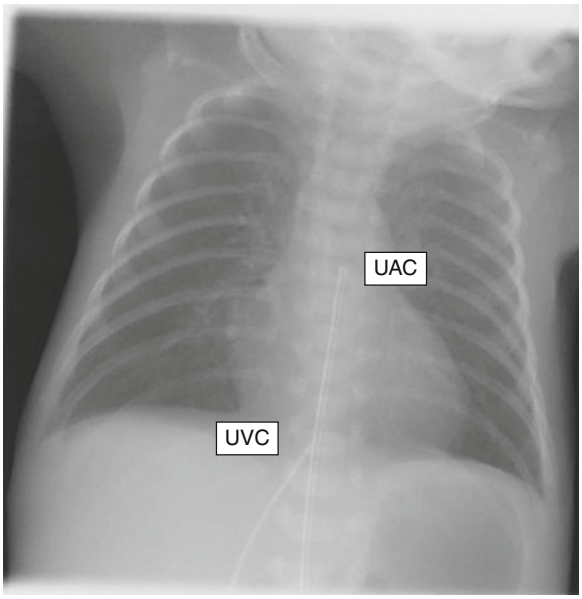

Figure 35.4
CXR showing appropriate location of tip of umbilical arterial catheter (UAC) and umbilical venous catheter (UVC)

(*Fig. 35.4*). The alternate location, "low aortic placement," below the level of the renal arteries and above the aortic bifurcation (vertebral bodies L3–4 on the X-ray) has been associated with increased risk of vascular complications. The UVC passes through the umbilical vein into the left branch of the portal vein, through the ductus venosus into the inferior vena cava (IVC). The tip is generally located at the junction of the IVC and the right atrium (*Fig. 35.4*). In an emergency situation, such as during resuscitation at birth, when immediate venous access is required, the UVC may be advanced to only a few centimeters into the umbilical vein, aspirated to ensure blood return and then used for administration of saline, dextrose, or epinephrine, without radiological confirmation of placement.

Prior to placement of the UAC or UVC, the length to which the catheter should be inserted to obtain proper placement should be estimated using standard formulae or published nomograms. The Shukla–Ferrara calculation (UAC length in cm = 3 × birth weight in kg+9; UVC length in cm = ½ × UA length calculation+1) is appropriate for most large babies, but has been found to overestimate catheter insertion length in very low birth weight (VLBW) infants. The modified formula of 4 × birth weight in kg +7 has been found to be more appropriate for UAC placement in VLBW infants.

Equipment

Sterile equipment for umbilical catheterization consists of gown and gloves, surgical drapes, cup with antiseptic solution, 4 × 4 in. gauze sponges, forceps to hold sponges, narrow umbilical tape tie, No.11 scalpel blade with holder, two curved mosquito hemostats, non-toothed iris forceps, small needle holder, 4–0 silk suture on small curved needle, suture scissors, 10-ml syringes, three-way stopcocks with Luer-Locks, 0.5 N or Normal saline flush solution (with 1 unit of heparin/ml of fluid), and the appropriate-sized catheters. Umbilical catheters may be made of polyvinyl chloride, polyurethane, or silicone. All have smooth non-thrombogenic ends, end holes, measurement markings, and are radiopaque. The use of feeding tubes as umbilical catheters is not recommended because they have side holes and are more thrombogenic. Single lumen catheters of 2.8 or 3.5 French (Fr) are used for UACs in babies weighing less than 1,200 g, and 5 Fr size catheters for larger infants. Single- or double-lumen catheters ranging in size from 2.8 to 8 Fr, depending upon the size of the infant may be used for UVCs. Single lumen catheters are recommended for exchange transfusions.

Procedure

The baby's limbs should be restrained to prevent contamination of the sterile area, but sedation or analgesia is not required. Standard aseptic precautions should be observed for placement of catheters, and sterile gowns and gloves are required. Hyperoxia causes potent constriction of the umbilical artery; therefore, weaning FiO_2 as appropriate to achieve saturation in the low normal range may facilitate UAC insertion.

Prepare the umbilical catheters by attaching a three-way stopcock to each catheter and flushing it with sterile-heparinized saline, making sure all air bubbles are removed. Clean the umbilical stump and the area around it with povidone iodine. Place a 10–15-cm piece of sterile umbilical tie tape around the umbilical stump loosely with a single knot. The knot may be quickly tightened to prevent blood loss if there is excessive bleeding when the umbilical cord is cut. Cut the umbilical cord horizontally with a scalpel blade approximately 1 cm from the skin surface. The umbilical arteries will be visible as two thick-walled, slightly protuberant vessels, while the umbilical vein appears larger, thin walled, and more patulous. Apply the two curved mosquito hemostats to the Wharton's jelly, on opposite sides of the cord, to stabilize the area (optional). Using the toothed forceps to grasp the stump, gently insert the tips of the curved iris forceps into the lumen of one of the umbilical arteries, initially keeping the points of the forceps together. Then allow the points to spring apart and maintain the forceps in this position for 15–30 s to dilate the artery. Grasp the saline-filled UAC about 1 cm from the tip, using non-toothed forceps, and insert the tip into the lumen of the artery between the prongs of the iris forceps, and advance it into the vessel with steady, firm pressure. The iris forceps may be removed once the catheter is inserted to a depth of 2–3 cm. It may be possible to pass the UAC into the artery without dilation in larger infants. Continue to advance the catheter into the vessel, 2–4 mm at a time, using non-toothed forceps, until the predetermined length has been reached. Mild traction of the cord toward the head of the infant will allow the UAC to navigate the slight angle between the cord and the abdominal wall. It should be possible to aspirate blood from the catheter after insertion of about 5–10 cm, to check its intraluminal position, but the blood should be cleared from the catheter by gently flushing 0.5–1 ml of heparinized saline intermittently, while the catheter is being advanced further to its final site. The UAC may be secured by a purse string suture through the Wharton's jelly, around the base of the cord, avoiding the vessels or the skin, after which the catheter itself is looped and taped to the abdomen with transparent semipermeable dressing. Other methods of securing the UAC are to enclose it within a tape bridge, or to suture a piece of tape attached to the catheter to the purse string suture. It is important to monitor the perfusion of the lower extremities immediately after the procedure and regularly thereafter while the UAC is in place (see "Complications").

Insertion of the UVC is often easier than inserting the UAC. The vessel walls are flaccid and dilation with iris forceps is not required. The iris forceps may be required to remove clots within the lumen. The saline-filled catheter is advanced gently into the vessel to the predetermined length and then sutured into position after ensuring that good blood return is obtained on aspirating the syringe attached to the catheter. Obstruction to easy passage of the catheter often implies that the catheter has wedged itself into an intrahepatic branch of the portal vein. The catheter may be withdrawn by 2–3 cm and reinsertion attempted. Occasionally a catheter in the portal circulation may be bypassed by the placement of another catheter in the same vessel with a 50% success rate.

Final placement of the UAC and UVC should be confirmed radiographically (*Fig. 35.4*) or by ultrasound scans.

Complications

The most serious complications of UACs are malposition, vascular spasm, and thromboembolic disease. Malpositions of the UAC into the femoral, gluteal, renal arteries, and into the celiac plexus have been noted, with severe complications in some cases. Numerous cases of gluteoperineal necrosis associated with sciatic nerve palsy secondary to thrombosis of the inferior gluteal artery have been recorded, some even when the catheter has been in an appropriate position and infused only with heparinized saline. Similarly, cases of acute and irreversible paraplegia following umbilical arterial catheterization have been attributed to infarction of the spinal cord following vasospasm or thromboembolic phenomena involving the artery of Adamkievicz, which supplies the anterior spinal artery. UACs may be associated with thromboembolic complications involving the aorta, iliac, renal, and mesenteric or other vessels. Symptoms of arterial TE include pallor or coldness of the lower extremities with diminished or absent pulses, and systemic hypertension, with or without renal failure if the renal arteries are affected. In a large systematic study of UAC-associated thrombosis, abdominal aortic thrombi have been detected by 2-D abdominal sonography in 32% of 99 patients in one study, which estimated that the risk of an aortic thrombus secondary to a UAC increased progressively from 16% after 1 day to 78% at 21 days. When vascular complications are noted, the catheter should be removed immediately.

Complications of umbilical venous catheterization are similar to that of peripheral central venous catheterization (described below). Portal vein thrombosis secondary to umbilical venous catheterization is a common cause of portal hypertension in childhood, and is more common in those with inappropriately placed umbilical venous catheters or with severe grades of thrombosis.

Percutaneous Central Venous Catheterization

Peripherally inserted central catheters (PICCs) are long, soft, flexible catheters made of silicone, polyurethane, polyethylene, or polyvinylchloride, inserted into a peripheral vein through a special breakaway or peel-away introducer needle and threaded into larger central veins. The advent of PICCs has significantly reduced the need for surgical placement of venous catheters in neonates. The peripheral veins usually used for placement of PICCs are the cephalic, basilic, median cubital, or axillary veins in the upper extremity, the saphenous vein in the lower extremity, and a scalp vein or external jugular vein in the head and neck. The tip of the PICC is typically positioned in the inferior vena cava (IVC) or superior vena cava (SVC), close to the heart (*Fig. 35.5*), to facilitate rapid hemodilution of the infusate. There is general consensus that the catheter tip should not be within the heart, because of the risk of pericardial effusions.

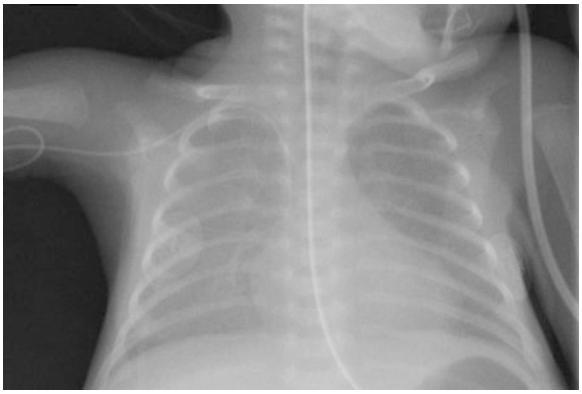

Figure 35.5
CXR showing tip of peripherally inserted central catheter (PICC) at junction of superior vena cava and right atrium

PICCs are placed in neonates primarily to provide stable intravenous access for parenteral alimentation, or for administration of medications or hyperosmolar fluids and medications that cannot be administered through peripheral IV cannulas. PICCs are not usually used for routine blood sampling or for blood transfusions in neonates because of their smaller caliber and propensity to clot.

Equipment

Commercially available PICC catheters used in neonates range in size from 1.2 to 3 Fr, and are usually single lumen, although a double-lumen version is now available. PICC introducer needles are available in 19, 20, 22, and 24 gauge with the size of the baby dictating the size of the introducer needle and the catheter. All equipment used, except for the head cover, mask, and tape measure, must be sterile. Many commercial kits contain the necessary equipment: catheter, introducer needle, 5–10-ml syringe with heparinized saline, forceps, gauze pads, antiseptic solution for skin preparation, transparent dressing, sterile tape strips, sterile surgical gown, gloves, and drapes.

Procedure

Restrain the infant by appropriate swaddling and provide non-pharmacologic comfort measures such as sucrose solution on a pacifier or a small dose of sedative or narcotic analgesic. Position the baby to facilitate a sterile field for insertion of the catheter, and using surface landmarks and tracing the approximate course of the vein, measure the distance from the insertion site to the point where the catheter tip will be placed. For catheters placed in the upper extremities or head and neck, the surface landmark for the SVC close to the heart is approximately at the second right intercostal space close to the sternum. For catheters placed in the lower extremity, the surface landmark for tip placement in the IVC would be at the infrasternal notch.

Wear the mask and cap, and then scrub hands thoroughly with antibacterial soap or alcohol-based scrub solution, and wear the sterile gown and gloves. Prepare the catheter by flushing it with sterile-heparinized saline using a 3- or 5-ml syringe. Smaller (1 ml) syringes may generate too much pressure, and are not recommended. Prepare the selected insertion site and the surrounding area with antiseptic solution. In small infants, it may be easier to swab the whole limb with sterile antiseptic than to prepare a small area. Drape the baby with sterile drapes leaving the insertion site exposed. A tourniquet may be applied on the limb proximal to the vein, if required.

Insert the introducer needle with the bevel up, about a centimeter distal to the insertion site at an angle of 15–30° and advance it into the vein (*Fig. 35.2*). As soon as a flashback of blood is obtained, decrease the angle, and advance the needle a few millimeters further to ensure that the entire bevel of the needle is within the vein. If an introducer cannula with a stylet is used, the same technique is used, but the stylet is removed as soon as the introducer cannula is well within the vein. Do not reintroduce the stylet into the introducer sheath if the venipuncture is unsuccessful. This could result in a severed sheath, which would be difficult to extract. If a tourniquet is used, it should be removed at this stage. Successful venipuncture is indicated by the steady flow of blood from the end of the needle or cannula. Gentle pressure over the insertion site can help to control bleeding.

Using fine non-toothed forceps, grasp the PICC about a centimeter from its end and insert it into the hub of the introducer needle/cannula, and then continue to nudge it along, a few millimeters at a time (*Fig. 35.6*). Do not advance the introducer needle or pull back to retract the catheter while it is in the introducer needle – it could result in shearing of the PICC, leaving a portion within the vein. When the PICC has advanced to a distance of 6 or 7 cm (or well beyond the length of the introducer), stabilize the catheter in the vein by applying digital pressure to the vein 2–3 cm distal to the introducer, withdraw the introducer needle or sheath carefully, and remove it by splitting or peeling the wings apart and away from the catheter. Complete catheter advancement to the premeasured length by nudging it further, a few millimeters at a time. Aspirate to check for easy blood return and flush with heparinized saline to clear the catheter. Verify the length of the catheter inserted and adjust if necessary. Apply gentle pressure with a sterile gauze pad at the insertion site to control any bleeding. Secure the catheter at the insertion site with a sterile tape strip. It is ideal to obtain radiographic confirmation of the position of the PICC tip before dressing the site so that adjustments may be made while the sterile field of operation is maintained. If the catheter has not been trimmed, the excess length may be coiled close to the insertion site and secured to the skin with sterile tape, ensuring that there is no kinking or stretching of the catheter under the tape (*Fig. 35.7*). Remove antimicrobial prep solution from the skin with sterile water or saline and dry before dressing the site with a semipermeable transparent dressing. Start fluid infusion through the catheter immediately after confirming appropriate placement.

Figure 35.6
Threading PICC through the introducer sheath after removal of the needle

The care and maintenance of PICCs requires significant commitment for continued use and prevention of serious complications. Quality indicators such as infection rates, dwell times, and complications should be closely monitored. Dedicated PICC teams of doctors and nurses to insert PICCs and monitor adherence to policies and procedures help to reduce complication rates.

Figure 35.7
Excess PICC coiled and secured with sterile transparent dressing

The insertion site and dressing should be inspected daily and the dressing changed as needed. Transparent dressings should be changed every 7 days except in those patients where the risk of dislodging the catheter outweighs the benefit of changing the dressing. Sterile technique must be used for each dressing change. Aseptic technique is used for line changes, connecting medications, IV fluids. A continuous infusion of intravenous fluids of at least 1 ml/h is required to maintain patency for neonatal PICCs, with maximal flows dependent on catheter size and the manufacturer's recommendations. The addition of heparin (0.5–1 unit of heparin/ml of IV fluids) does appear to prevent occlusion of the catheter, but has not been shown to prevent thrombosis.

PICCs should be removed as soon as they are no longer medically necessary by gentle traction on the catheter at the insertion site after cleaning the area with antiseptic solution. There may be difficulty in removal of the catheter if a fibrin sheath has formed around it. The length of catheter removed must be crosschecked with the length that was originally inserted to ensure that no segment of the catheter has been left behind.

Complications

The major complications from PICCs (and from UVCs) are catheter migration or malposition, extravasation, infection, thromboembolism, catheter breakage, and dysfunction.

The tip of the catheter may inadvertently reach deep inside the cardiac chambers or fall short of the caval veins and end in the brachiocephalic or subclavian vein, or migrate through venous tributaries to entirely unexpected locations. Appropriate initial placement does not always ensure that the catheter will stay in place, since secondary catheter migration has also been described, possibly as a consequence of poor catheter fixation at the skin surface, or movements at joints. Sites of misplacement of PICCs include the cardiac chambers, internal jugular veins, contralateral subclavian vein, ascending lumbar, and superficial abdominal and renal veins. Extravasation of fluid from the catheters in each of these positions has led to serious, and occasionally, lethal complications. When the tip of the catheter is in the internal jugular vein or the contralateral brachiocephalic vein, spontaneous correction toward the superior vena cava can sometimes occur within 24 h, probably due to the direction of venous blood flow and may be facilitated by the movement of the arm.

Pericardial effusion with pericardial tamponade is a rare (estimated incidence ranges from 0.76–1.8%) but occasionally lethal complication, due to extravasation of the PICC fluid into the pericardial cavity. The tip of the catheter has been noted to be in the right atrium in most reports, with only rare reports of pericardial effusions occurring with the umbilical venous catheter tips in the "correct" location at the junction of the IVC and right atrium. Pericardial effusions have been described with all types of catheters including the very pliant silicone or Silastic catheters. The most common clinical presentation is sudden cardiovascular collapse. Unexplained or subacute cardiorespiratory instability and a sudden requirement for inotropic or respiratory support are present in about a third of patients. Urgent echocardiography is the mainstay of diagnosis and immediate pericardiocentesis the only lifesaving therapy. In a large series of 61 central venous catheter-related pericardial effusions in infants, mortality was reported to be 8% in patients who had pericardiocentesis, and 75% in patients who did not. The physical and biochemical characteristics of the pericardial fluid obtained by pericardiocentesis or noted at autopsy has been consistent with the infusate. Perforation with or without myocardial necrosis/thrombosis has been noted on autopsy, but in some cases no perforation has been detected. In view of this finding and the fact that the pericardial effusion is not bloody, it is postulated that constant abrasion of the endocardial wall by the tip of the catheter in the thin-walled right atrium leads to inflammation, and then necrosis or thrombosis with perforation that may self-seal or that there is transmural diffusion of hyperosmolar fluid across the injured endocardium and myocardium.

Pleural effusions due to extravasation of parenteral alimentation fluid are not an uncommon complication

of PICCs in the newborn, although the actual incidence is not known. Respiratory distress due to pleural effusions may arise within a few hours or several days after placement of the catheter. Although some effusions may be due to actual erosion or perforation of the intrathoracic veins, in other cases, migration of the catheter into the pulmonary artery or pulmonary vein has been described.

Inadvertent malposition of a PICC in the ascending lumbar vein after placement of the catheter in a vein in the lower extremity may lead to neurological complications, including seizures and flaccid paraplegia. The ascending lumbar vein drains the vertebral venous plexus into the common iliac vein, and is easily accessed by femoral or saphenous vein catheterization. On standard anteroposterior abdominal radiographs, the catheter may appear to be in the iliac vein or IVC, but cross-table lateral radiographs will reveal that the catheter is superimposed on the spinal canal or deviating posteriorly at the level of L4–L5, rather than anterior to the spinal column if the catheter is truly in the IVC. Symptoms in neonates may be nonspecific, prompting a "sepsis workup," but lumbar puncture reveals "milky" spinal fluid, with very elevated glucose or triglyceride levels, consistent with the composition of parenteral alimentation fluid.

Catheter-related sepsis is the most common complication of central venous catheters with rates ranging from 0% to 29% of catheters placed, and from 2 to 49 per 1,000 catheter days, with the smallest and most immature infants being at the greatest risk. The rate of infections also varies significantly among different neonatal units, secondary to differences in patient population, practice styles, and reporting variances. Removal of the catheter is often necessary for eradication of the infection but is not always possible in small and sick infants. The outcome for infants in whom the catheter is not removed within 24 h of identification of the organism is significantly worse than it is for those whose catheters are removed promptly, with increases in risks of end-organ damage or death. Prompt removal of the catheter is recommended for catheter-related sepsis due to *Staphylococcus aureus*, non-enteric gram negative bacteria, and candida. Treatment with appropriate antibiotics without removal of the catheter may be attempted for coagulase negative staphylococcal bacteremia, but removal of the line is essential if the blood cultures are repeatedly positive.

Catheter-related infection may be minimized with simple interventions, including the use of maximal barrier precautions (long sleeved gown, sterile gloves, mask, cap and large sterile sheet drape) during insertion of the catheter, use of chlorhexidine-containing antiseptics for preparing the catheter insertion site rather than povidone iodine, decreased manipulations of the catheter and the use of closed medication systems, and early feeding to reduce duration of catheter use. Strict protocols for central line care and education of physicians and nurses, with a methodology of surveillance and data feedback have been shown to reduce infection rates.

With the exception of renal vein thrombosis, almost all (approximately 90%) of venous thromboembolism (TE) in neonates is associated with central venous catheters. Catheter-related venous TE may be asymptomatic or result in severe complications such as deep vein thrombosis, portal vein thrombosis, superior vena cava syndrome, intracardiac thrombosis, or pulmonary embolism. Clinical manifestations of symptomatic catheter-related thrombosis in neonates depend on the site of the thrombosis. Catheter dysfunction, thrombocytopenia, or persistent bacteremia may be associated with vascular thrombosis at any site. Apart from the loss of venous access from catheter-related thrombosis, there is potential danger of injury to vital organs secondary to thrombus propagation, embolization, or infection. The management of catheter-related venous TE in neonates is controversial, and must be individualized. A full discussion of anticoagulants and thrombolytics in neonates is beyond the scope of this chapter; existing guidelines are updated as new data becomes available. A free consultative service, maintained 24 h a day for physicians caring for children with thrombosis, provides current management protocols and links to the network and its services. The toll-free number in the United States is 1-800-NO-CLOTS (Web site www.1800noclots.ca).

Endotracheal Intubation

Endotracheal intubation may be required for neonatal resuscitation, for endotracheal suctioning of meconium, surfactant administration, or for providing prolonged assisted ventilation.

Equipment

Supplies for endotracheal intubation should always be readily available in the delivery room, and the NICU, preferably in the form of a ready kit or tray. The supplies required are laryngoscope with extra batteries and bulbs; laryngoscope blades, preferably straight rather than curved blades (No. 1 for term infants, No. 0 for preterm infants, No. 00 for extremely preterm infants); endotracheal tubes with inside diameters of 2.5, 3.0, 3.5, and

4 mm; and stylets for the endotracheal tubes. Endotracheal tubes used in neonates are usually non-cuffed, have a uniform diameter through the length of the tube, and have centimeter markings. Tapered (shouldered) tubes are rarely used in the United States, but are popular in some parts of the world. Cuffed tubes are not recommended. A stylet provides additional stiffness and maintains the tube curvature during intubation, but its use is optional. The stylet should be secured so that the tip does not protrude from the end or side hole of the endotracheal tube; it should not slip further into the tube during intubation and yet should be easy to remove quickly as soon as intubation is accomplished. Additional equipment required is adhesive tape, scissors, stethoscope, suction equipment with 10 Fr suction catheter and size 5 or 6 Fr catheter for endotracheal tube suctioning, meconium aspirator, and a self-inflating or flow-inflating bag with mask or T-piece resuscitator and gas source.

Procedure

Premedication with a rapidly acting analgesic agent should be given intravenously just prior to the procedure for all endotracheal intubations in neonates, except for those in the delivery room or in acute emergencies in infants without venous access. Fentanyl at 1–4 μg/kg has almost immediate onset of action and lasts 30–60 min. Muscle relaxants and vagolytic agents may also be used in addition to the analgesic agents to facilitate intubation and prevent bradycardia.

Select the appropriate-sized laryngoscope blade and endotracheal tube (*Table 35.1*). Position the infant on a flat surface with the head in the midline and neck slightly extended. A small roll under the baby's shoulders may help, but it is important to avoid overextending the neck. Hold the laryngoscope in your left hand with the blade inferior and pointing away from you. If the laryngoscope is held in the right hand, the closed part of the blade will obscure your view of the glottis making intubation impossible. Insert the laryngoscope blade into the mouth, over the right side of the tongue, pushing the tongue to the left side of the mouth until the tip of the blade is in the vallecula or on the epiglottis. Lift the blade slightly, by pulling in the direction the handle is pointing, lifting the tongue out of the way to expose the pharyngeal area. Oral and pharyngeal secretions may need to be suctioned for better visibility of the glottis. If the tip of the blade is correctly positioned, the vocal cords should be visible on either side of the glottis as an inverted letter "V." Slight external pressure on the cricoid cartilage on the neck may help to bring the glottis into view. Holding the endotracheal tube in your right hand, introduce it into the right side of the baby's mouth, with the curve of the tube in the horizontal plane to prevent it from blocking your view of the glottis. *Keeping the glottis in view*, insert the tip of the tube between the vocal cords until the vocal cord guide markings on the tube are at the level of the cords. Do not force the tube through closed vocal cords, but wait for them to open. It is also important to actually visualize the tube passing between the vocal cords and not attempt to do it "blindly." Quickly verify the length of tube insertion of the tube at the level of the baby's lips, stabilize the tube by holding it between thumb and forefinger at the lips, and remove the laryngoscope blade from the mouth. The tube may now be stabilized by using a forefinger to hold it against the hard palate while the stylet is quickly but carefully removed. The tube is now ready for use. The meconium aspirator may be attached and meconium suctioned from the tube or positive pressure ventilation may be commenced. If the endotracheal tube is being used to provide respiratory support, it is important to ensure it is in correct position. Adequate chest movement with positive pressure ventilation, visible vapor condensing on the inside of the tube during exhalation, audible and equal breath sounds on auscultation high on the lateral sides of the chest bilaterally (in the axillae), and improving heart rate are reassuring signs. Colorimetric CO_2 detectors connected to the endotracheal tube change color in the presence of CO_2, indicating successful intubation, but do not indicate if the tube is correctly positioned. They are also unreliable in babies with very poor or no cardiac output as in cardiac arrest.

The endotracheal tube is probably not in the trachea if the baby remains cyanotic and bradycardic despite positive pressure ventilation or if the abdomen becomes

Table 35.1
Endotracheal tube size and depth of insertion in newborn infants

Weight (g)	Endotracheal tube size (inside diameter)	Depth of insertion (from upper lip)
<750 g	2.5 mm	5.5–6 cm
1,000 g	2.5–3.0 mm	7 cm
2,000 g	3.0–3.5 mm	8 cm
3,000 g	3.5 mm	9 cm
4,000 g	4.0 mm	10 cm

Source: Adapted from American Academy of Pediatrics and the American Heart Association (2006) Textbook of neonatal resuscitation, 5th edn. Chicago

distended or there are "sounds" over the abdomen but poor breath sounds over the chest, and no misting of the tube. In this situation, stabilize the tube with your right hand and reinsert the laryngoscope blade with your left hand to visualize the larynx and see if the tube is in the glottis or in the esophagus. Pull the tube back, visualize the glottis and reinsert the tube. It may be better to remove the tube, stabilize the baby's heart rate and oxygen saturation by bag and mask ventilation for a few minutes before the next attempt at endotracheal intubation.

If the endotracheal tube is required for positive pressure ventilation for more than a few minutes, it should be shortened to reduce the dead space and secured to the face as soon as it is judged to be in an appropriate position. The tube may be secured with a small piece of adhesive tape cut in an H shape with one limb of the H attached like a moustache to the upper lip and the other limb encircling the tube. Several proprietary devices are also available for securing endotracheal tubes. Radiographic confirmation of tube placement with the head in the midline is recommended to verify that the tube is in an appropriate position, preferably midway between the clavicle and carina.

Complications

Complications of endotracheal intubation include trauma to the lips, alveolar margins, and oropharynx from the laryngoscope. The stylet or endotracheal tube may cause trauma to the vocal cords, perforation of the trachea or esophagus, with pneumothorax, pneumomediastinum, or tracheoesophageal fistula as potential complications. The tube may be malpositioned in the right main-stem bronchus or the esophagus may be erroneously intubated. Prolonged fixation of the endotracheal tube may cause oral commissure defects or palatal deformity. The incidence of acquired subglottic stenosis has decreased in the past decade, and is estimated to range from 0% to 2%.

Lumbar Puncture

The primary indication for a lumbar puncture (LP) or spinal tap in a newborn infant is to obtain a sample of cerebrospinal fluid (CSF) for the diagnosis of meningitis or meningoencephalitis of bacterial, viral, or fungal origin. In neonates, specific signs of meningitis such as neck stiffness and bulging anterior fontanelle are often absent, and CSF cultures may be positive even when blood cultures are negative so an LP is generally included as part of the "complete sepsis workup." LPs are also performed to monitor efficacy of therapy in patients with meningitis, by monitoring changes in culture results, cell counts, and viral loads. In infants with posthemorrhagic hydrocephalus, drainage of CSF has been shown to improve cerebral hemodynamics. Although serial LPs have not been shown to reduce the need for shunt placement, drainage of 10–15 ml/kg of CSF two or three times a week in infants with posthemorrhagic communicating hydrocephalus permits deferment of ventriculo-peritoneal shunt placement until the baby is larger, more stable, and high CSF protein content has decreased to near normal levels.

Lumbar puncture is contraindicated if there is significant cardiorespiratory instability, which could be exacerbated during the procedure. Infection of the skin or tissues at or near the site is also a definite contraindication to the procedure. Thrombocytopenia (platelet count $< 100{,}000/mm^3$) or bleeding disorders should be corrected before an LP is attempted. The risk of transtentorial herniation following an LP due to increased intracranial tension is low since the sutures are open.

The spinal cord terminates at the L1/L2 spine in the majority of adults. Early in fetal life, the spinal cord stretches through the whole vertebral canal with the nerve roots traversing the intervertebral foramina horizontally. At 6 months of fetal life, the lowest limit of the spinal cord is at S1 level. Between 25 and 33 weeks gestation, the cord terminates at the level of L3 or above, but significant variation is present before 25 weeks. A line joining the most superior part of both iliac crests will intersect the midline at the L4 spine or the L4/L5 interspace, the recommended insertion site for lumbar punctures in infants.

Equipment

All equipment other than the cap and facemask is sterile. Spinal needles for neonatal use are available in 22 and 25 gauges, and have a short bevel and stylet. Other supplies required are sterile towels or drapes, iodophor antiseptic solution, gauze swabs, holder for the swabs, 3 or 4 specimen tubes with caps, adhesive bandage, 0.5 ml of 1% lidocaine in a 1-ml syringe with a 25 or 26 gauge small needle.

Procedure

The procedure may be done with the baby in the lateral decubitus position or in the sitting position. Continuous

cardiorespiratory monitoring during the procedure is recommended. Local anesthetic cream may be applied to the insertion site about 60 min before the procedure to reduce pain. An assistant should restrain the infant in the lateral decubitus position, keeping the back perpendicular to the surface on which the baby is lying, the hips perfectly symmetrical, flexing the spine by holding the shoulders and the legs. The neck should be in neutral position. The baby does not need to be held in tight flexion until the actual insertion of the spinal needle. Alternatively, the assistant may position the infant in a sitting position, with the back and neck flexed.

After putting on a cap and mask, wash hands thoroughly as for a major procedure and wear sterile gloves. Clean the lumbosacral area three times with antiseptic, using a fresh sterile gauze swab each time, starting at the L4–L5 interspace in the midline and cleaning in concentric circles toward the periphery. Allow antiseptic to dry for at least 30 s. Drape the baby's back and iliac region, leaving the puncture site exposed. Lidocaine (0.3–0.5 ml of 1% lidocaine) may be infiltrated into the subcutaneous space, if local anesthetic cream is not used. Increased volume or injection into deeper structures may make the procedure more difficult by making it more difficult to feel the spinous processes. Insert the spinal needle with the stylet in place in the midline, into the L4–L5 interspace, with the bevel of the needle in the sagittal plane, directing the needle slightly cephalad toward the umbilicus. The needle will pass through the supraspinous and interspinous ligaments, through the ligamentum flavum and dura mater into the subarachnoid space. In older children or adults, a change in resistance or "pop" is felt as the needle pierces the dura mater, but this is harder to appreciate in neonates. After the needle is inserted to 1 or 1.5 cm, continue to advance the needle by 1–2 mm at a time, removing the stylet intermittently to check for CSF flow, replacing the stylet each time before advancing the needle further. One may also have to wait for the CSF flow for a few seconds since it may be less brisk in neonates than in older children. If no fluid is obtained, rotate the needle about 90° to reorient the bevel. Allow the CSF to flow passively into the sterile collection tubes; never aspirate CSF with a syringe. Generally 0.5–1 ml per tube is adequate for most diagnostic studies; 10–15 ml/kg may be drained over 5–10 min for treatment of communicating hydrocephalus. If the spinal tap is traumatic and the fluid bloody, due to puncture of the epidural venous plexus on the posterior surface of the vertebral body, withdraw the needle by a few millimeters and allow the fluid to clear. Replace the stylet before removing the needle to prevent entrapment of spinal nerve roots. Place an adhesive bandage over the puncture site after removing the needle. Clean off the remnants of the antiseptic from the skin with sterile water.

Complications

The most common complication in neonates is transient hypoxemia during the procedure; this may be circumvented by careful attention to positioning and adjustments to the respiratory support. The other common complication is a traumatic or bloody tap, which is usually of no immediate consequence to the infant, but may lead to difficulty in interpretation of cerebrospinal fluid cell counts. Infections, bleeding into the spine, and spinal cord injury with nerve damage are very rare complications. Failure to use a stylet can lead to implantation of epithelial cells in the spinal canal with development of an intraspinal epidermoid tumor.

Thoracocentesis or Needle Aspiration of the Pleural Space

Needle aspiration of the pleural space is performed to evacuate air or fluid from the pleural space, sometimes as an emergency temporizing measure to recover cardiorespiratory stability while preparations are being made to insert a chest tube. The recommended site for aspiration of a pneumothorax is the third or fourth intercostal space at the anterior axillary line, while pleural fluid is more easily aspirated from the fourth intercostal space in the midaxillary line. The fourth intercostal space is located at the level of the nipples. The needle should be inserted over the upper border of the rib to avoid the intercostal vessels.

Equipment

Sterile gloves, antiseptic solution, 20, 22, or 23 gauge intravenous cannula or butterfly needle (based on the size of the baby), three-way stopcock, and 20-ml syringe.

Procedure

If possible, turn baby to the side, with the side of the pneumothorax superior, to allow the air to rise. Scrub hands, wear sterile gloves, and clean the insertion area with antiseptic solution. Insert the intravenous cannula perpendicular to the chest wall, just over the top of the rib in the fourth intercostal space. Remove the stylet and

attach the three-way stopcock and syringe to the hub of the catheter. Aspirate the air or fluid into the syringe. Turn the stopcock to close entry into the chest, while emptying the syringe, and then turn it again to allow further aspiration from the chest if required. If using the butterfly needle, attach a three-way stopcock and syringe to the needle. Insert the needle over the upper border of the rib, aspirating continuously with the attached syringe once the needle has punctured the skin. Stop advancing the needle when air or fluid flows back into the syringe. Remove the needle or cannula as soon as air/fluid aspiration is complete or a chest tube has been inserted. Apply a small adhesive dressing to the site.

Thoracostomy

Chest tube drainage of a pneumothorax is an emergency in infants with respiratory distress due to surfactant deficiency, meconium aspiration, or pulmonary hypoplasia. Chest tubes may also be required for drainage of large persistent pleural fluid collections.

Equipment

There are different types of chest tubes, with slightly different insertion techniques for each. The most commonly used chest tubes are polyvinyl chloride tubes, in sizes 8 (smallest), 10, and 12 Fr, which are available with or without trocars. Trocars are not recommended for use in neonates. An evacuation device consisting of extension tubing, connectors, and a bottle filled with sterile water for underwater seal is also necessary. Several proprietary evacuation devices are available. A general all-purpose surgical tray with curved hemostats, No. 15 surgical blade, nonabsorbable sutures on a small cutting needle are required, together with sterile drapes, petrolatum gauze, semipermeable transparent dressing, antiseptic skin solution, 1% lidocaine for local anesthesia or appropriate intravenous narcotic analgesic.

Procedure

Position the infant so that the side of the chest is accessible and restrain the arm over the head, away from the chest. Prepare as for a sterile procedure. Administer narcotic analgesic intravenously while preparing the skin over the lateral portion of the chest from the midclavicular line to the posterior axillary line with antiseptic solution. Cover the other areas with sterile drapes. Locate the nipple to ensure that the tube will be well away from the breast tissue. A vertical line at the level of the nipple will help to identify the fourth intercostal space. Locate the skin incision site at the fifth or sixth intercostal space between the anterior and midaxillary lines. Infiltrate the skin and subcutaneous tissue at the site with 0.5–1 ml of 1% lidocaine. Using the scalpel blade, make a small incision (0.5–1 cm) in the skin at the site, at the upper border of and parallel to the rib. Insert the curved hemostat through the incision and direct it superiorly in the subcutaneous plane to the fourth intercostal space. At the intersection of the nipple line with the anterior axillary line, apply pressure with the tip of the finger on the closed hemostat so the tip pushes through the intercostal muscles and parietal pleura to enter the pleural space in the fourth intercostal space. A slight "pop" or a rush of air may be felt at this point. Open the hemostat slightly and leave it in place. Remove the trocar from the chest tube and direct the tube into skin incision and through the opened tips of the hemostat into the pleural space. The curved points of the hemostat may then be rotated to direct the tube anteriorly and cephalad, the best position for evacuation of a pneumothorax in an infant who is lying in the supine position. A posteriorly placed chest tube would be appropriate for drainage of fluid. Remove the hemostat and advance the tube further to the predetermined length. Ensure that the side holes are within the pleural space. "Misting" of the chest tube indicates intrapleural position, which is further confirmed by bubbling when the tube is connected to the underwater drainage system. Apply 10–20 cm negative pressure to the underwater system to facilitate evacuation of the pneumothorax. Apply one or two interrupted sutures to close the skin incision and secure the tube by wrapping and tying the ends of the sutures to the tube. Purse string sutures are not recommended because the resultant scar may be puckered. Clean the remnants of antiseptic from the skin, and apply a small piece of petrolatum gauze at the incision site. Secure the chest tube to the skin with an adhesive tape bridge or with semitransparent dressing. Avoid a large dressing that could obscure chest examination or tube displacement. Obtain anteroposterior and lateral radiographic confirmation of appropriate positioning of the chest tube.

The chest tube may be removed when there has been no air or fluid draining for 24–48 h. The suction may be discontinued and the tube left to underwater drainage for a further 12–24 h, and transillumination or radiography used to document that there has been no re-accumulation of air or fluid. Administer analgesic medication intravenously just prior to removal of the tube. Remove the tape

bridge or dressing. Wearing sterile gloves, clean the incision site, the part of the tube entering the chest, and the surrounding area with antiseptic. Cut the sutures holding the tube to the skin. Hold a piece of sterile petrolatum gauze close to the insertion site and cover the site quickly with it as soon as the tube is withdrawn, to prevent air from entering the pleural space. If possible, remove the chest tube during the expiratory phase of respiration in spontaneously breathing infants and during inspiration in mechanically ventilated infants. Keep the skin sutures in place unless the skin is inflamed. The sutures may be removed later when healing is complete. If the skin is inflamed, remove the sutures and approximate the edges of the incision with sterile adhesive strips. Remove residual antiseptic and cover petrolatum gauze with dry gauze and small transparent dressing.

Complications

Chest tubes can cause perforation of the lung, bronchopleural fistulas, and hemorrhage from perforation of a major vessel such as the internal mammary or intercostal vessels, and diaphragmatic paralysis due to phrenic nerve injury.

Pericardiocentesis

Although pericardiocentesis is not a common procedure, it is described here since it could be lifesaving when performed for acute tamponade, a clinical condition with reduced cardiac output due to impaired ventricular filling, secondary to fluid or air in the pericardial space. Pericardial effusion can occur in the NICU secondary to perforation or transudate from an umbilical or percutaneous central venous catheter (see above). Ideally, pericardiocentesis should be performed with real-time ultrasound or guidance to determine the depth of penetration of the needle, but in an emergency, the procedure may be performed without sonographic imaging.

Equipment

The equipment for pericardiocentesis is readily available in any NICU, and consists of a standard 18–24 gauge intravenous cannula over a 1–2 in. needle, a three-way stopcock, extension tubing (optional), 10–20-ml syringes, local anesthetic, antiseptic solution, and sterile drapes and gloves. Two-D echocardiography equipment would be invaluable if available. A transilluminator may be useful to diagnose pneumopericardium and assess the efficacy of drainage, but does not reliably distinguish between air in the pericardial space or in the mediastinum.

Procedure

Wear a mask, wash hands, and wear sterile gloves. Clean the skin over the xiphoid, precordium, and epigastric area with sterile antiseptic, and cover the area with sterile drapes, leaving the subxiphoid area exposed. Inject local anesthetic (0.5–1 ml of lidocaine) subcutaneously near the xiphoid process, if time allows. Connect a 10-ml syringe to a three-way stopcock and an 18–24 gauge intravenous cannula over a 1–2 in. needle (depending upon the size of the baby), with the stopcock open to the needle and syringe. Insert the needle/cannula in the subxiphoid space, about 0.5–1 cm below the tip of the xiphoid process, in the midline or 0.5 cm to the left of the midline, directing the needle toward the left shoulder, at an angle of 30–40° to the skin. If 2-D echocardiography is used, finding the fluid-filled pericardial sac at the point closest to the body surface localizes the ideal entry site. While advancing the needle, apply gentle negative pressure with the syringe. Stop advancing the needle as soon as fluid or air is obtained, advance the cannula further and withdraw the steel needle. The position of the cannula in the pericardial space may be confirmed by echocardiography by the injection of a small amount of agitated saline. Aspirate as much fluid or air as possible from the pericardial space. The fluid may be bloody, serosanguineous, milky, or resemble the parenteral fluid infusing through the central venous catheter. A rhythmic tugging sensation, corresponding to the heart rate may be felt when the cannula is in the pericardial space, and does not necessarily mean that the cannula has entered the heart. Withdrawal of 5–10 ml of fluid from the pericardial space leads to improvement in the hemodynamic condition within seconds. Remove the cannula as soon as the aspiration is completed, and apply an adhesive bandage, after removing with antiseptic solution with sterile water.

Complications of pericardiocentesis include pneumopericardium, pneumomediastinum, pneumothorax, cardiac arrhythmia, cardiac perforation, and perforation of the liver. Complications are rare if echocardiography is used. Hypotension may occur when a large amount of effusion is drained rapidly, and may require fluid boluses.

Suprapubic Bladder Aspiration

Needle aspiration of the distended bladder is the recommended method of obtaining a specimen of urine for culture in infants. The risk of contamination and false positives is low, but success rates range from 25% to 100%. The use of portable ultrasound scan or transillumination to check if the bladder is full prior to the procedure can increase the likelihood of success. The procedure is contraindicated if the baby is dehydrated or if the abdomen is distended due to bowel dilatation or enlargement of other organs, or if there is evidence of a bleeding disorder or severe thrombocytopenia.

Equipment

Gloves, 3- or 5-ml syringe, 22 or 23 gauge straight or butterfly needle, antiseptic swabs, local anesthetic cream, and container for urine collection. All equipment is sterile.

Procedure

Ensure that the baby is well hydrated and has not voided in the last hour. Apply local anesthetic cream to the needle insertion site (1 cm above the symphysis pubis in the midline) at least 60 min before the procedure. Wash hands thoroughly and put on sterile gloves. Clean the suprapubic area in the midline including the symphysis pubis with antiseptic solution three times with antiseptic and wait for 30 s. Attach the needle to the syringe. Insert the needle 1 cm above the symphysis pubis in the midline, aiming the needle slightly cephalad. Aiming too far caudad will cause the needle to enter the bladder neck. Apply gentle negative pressure on the syringe once the needle has been inserted about a centimeter. Stop advancing the needle once urine is obtained or if the needle has been inserted up to approximately 2.5 cm in a term infant, less in a smaller baby. Do not manipulate the needle or redirect it in different directions if no urine is obtained. Remove the needle after the specimen is collected and apply gentle pressure over the puncture site with sterile gauze. Clean off any remaining antiseptic with water.

Complications

The most common complication is transient hematuria. Hematomas, abscesses, and symptomatic perforation of a viscus are rare complications. However, ultrasound observation indicates that the needle might easily enter the uterus or bowel when the bladder is not full and the needle inserted beyond 2 cm in preterm infants.

Bladder Catheterization

Catheterization of the bladder is an acceptable alternative method to obtain urine for culture. The procedure has a higher success rate, but is associated with higher contamination rates. Bladder catheterization may also be required for monitoring urinary output, relieving urinary retention, quantifying residual urine in the bladder, or to instill contrast agent in the bladder for cystourethrography. There are no definite contraindications to the procedure. Sterile precautions must be used for the procedure, regardless of the indication, since introduction of bacteria into the urinary tract during catheterization could lead to urinary infection and sepsis.

Equipment

All equipment must be sterile. Silicone urinary catheters in sizes 3.5, 5, or 6.5 Fr are suitable for neonates. A 5-Fr feeding tube or 3.5- or 5-Fr umbilical catheter may be used if urinary catheters are not available. The smaller 3.5-Fr catheters are more suitable for babies weighing less than 1,000 g. Catheters will need to be connected to a closed drainage system for monitoring urinary output; this may be accomplished with commercial prepackaged urinary drainage kits or by connecting the catheter with IV extension tubing to a collection burette. In addition, gloves, drapes, nonalcohol-based antiseptic solution, gauze sponges, and surgical lubricant are required.

Procedure

Restrain the infant in a supine frog-leg position. Wash hands thoroughly and put on sterile gloves. For a male infant, stabilize the shaft of the penis with the nondominant hand. This hand is now considered contaminated. Gently retract the foreskin to just enough to expose the meatus. Neonates have physiological phimosis and the foreskin cannot be fully retracted. Using the free hand, clean the glans three times with antiseptic solution, beginning at the meatus and cleaning down over the shaft of the penis. Use the "contaminated" hand to apply gentle pressure over the base of the penis to prevent reflex urination. Drape sterile towels over the lower abdomen and over the

infants' legs. Lubricate the tip of the catheter with sterile lubricant and gently insert it into the meatus. Gentle upward traction on the penis will prevent kinking of the urethra and aid in passage of the catheter. Slight resistance is sometimes met at the external sphincter, but the sphincter spasm generally relaxes in a brief period. Do not force the catheter if obstruction is encountered at any stage. The catheter should be advanced only to the length at which urine flow is obtained and no further, since additional length of catheter in the bladder could increase the risk of trauma and knotting of the catheter. Collect the urine specimen in a sterile container and remove the catheter, or, if continuous urinary drainage is required, connect the catheter to a closed system. For continuous drainage, the catheter should be taped securely to the inner thigh. If the foreskin has been retracted, ease it back over the glans following the procedure to prevent paraphimosis.

In a female infant, an assistant may be required to retract the labia with cotton-tipped applicators or gauze sponges. The area between the labia minora should be cleaned with antiseptic solution, swabbing from the anterior to the posterior direction to prevent fecal contamination of the sterile field. The urethral meatus lies anterior to the vaginal opening and may be difficult to see in extremely low birth weight infants. Advance the catheter a short distance until urine is obtained. The female urethra is very short; do not advance beyond 1–2 cm if no urine is obtained.

Complications

Urinary tract infection is the most common complication of bladder catheterization. Using a strict aseptic technique, maintaining a closed sterile collection system, and removing the catheter as quickly as possible decrease the risk of infection. Other complications such as perforation of the bladder or urethra and knotting of the catheter are rare.

Exchange Transfusion

An exchange transfusion (ET) involves replacing a major proportion of a patient's blood with donor blood, by repeatedly removing and replacing small aliquots of blood over a short time period, generally 1–2 h.

In newborn infants, the most common indication for an ET is severe unconjugated hyperbilirubinemia due to any cause, when intensive phototherapy has failed or there is a risk of kernicterus. ET may mitigate neurological abnormality even when there are signs of early or intermediate stages of acute bilirubin encephalopathy. The serum bilirubin level at which ET is recommended for smaller and more immature infants is variable and often individualized based on the risk benefit assessment, since ET in very immature infants is technically more difficult and can be associated with significant morbidity and mortality. In infants with severe alloimmune hemolytic disease of the newborn, ET may be performed early before the development of severe jaundice, both for the correction of severe anemia and also to replace antibody-coated neonatal red cells with antigen negative donor cells that are not susceptible to hemolysis. Partial ET has been used to correct anemia in neonates with severe anemia and congestive heart failure or hypervolemia. ET is also used in infants with polycythemia to reduce the hematocrit and therefore hyperviscosity, but there is no definitive evidence of clinically significant short- or long-term benefit of ET for this indication, particularly when the baby is asymptomatic. Other rare indications for ET in neonates include use in drug toxicity or overdose, the removal of metabolic toxins, such as in hyperammonemia, organic acidemia, and lead poisoning, removal of antibodies or abnormal proteins as in neonatal myasthenia, and in neonatal sepsis or malaria.

Communication with the blood bank is essential to determine and obtain the most appropriate blood product for the ET. The blood should be as fresh as possible (<7 days), and subjected to standard blood bank screening for HIV, Hepatitis B, etc. Donor blood should be screened for G6PD deficiency and sickle cells in populations endemic for these conditions. Plasma-reduced whole blood or packed red cells reconstituted with plasma with a packed cell volume adjusted to 0.50–0.60 is suitable for correction of anemia or hyperbilirubinemia. Blood may be anticoagulated with citrate phosphate dextrose (CPD or CPDA1) or with heparin. Red blood cells with additive anticoagulant solutions are generally avoided, but if this is the only blood product available, the additive solutions may be removed by washing or by centrifugation, prior to reconstitution of the red cells with plasma. Special attention has to be paid to compatibility testing in the presence of alloimmunization. If delivery of an infant with severe alloimmune hemolytic disease or any severe anemia is anticipated, O Rh-negative blood cross-matched against the mother may be prepared before the baby is born. Donor blood prepared after the baby's birth must be negative for the antigen responsible for the hemolytic disease, and the blood must be cross-matched against the infant. In Rh HDN, the blood should be Rh negative, and may be O group or the same group as the infant. In ABO HDN, the blood must be type O and either Rh negative or Rh compatible with the mother and

infant. The packed cells must be washed free of plasma or have low titer of anti-A or anti-B antibodies. Type O cells with AB plasma are suitable, but this results in two donor exposures per ET. Irradiated blood is recommended for all exchange transfusions, to prevent graft versus host disease, particularly if blood is obtained from first- or second-degree family members, or if postnatal ET follows an intrauterine fetal transfusion. There is a significant increase in potassium concentration in stored irradiated units, so irradiation should be performed as close to transfusion as possible (<24 h). In infants with polycythemia, the optimal dilutional fluid for a partial ET is isotonic saline rather than plasma or albumin.

A double volume ET, calculated as twice the infant's blood volume (2×80 ml/kg in term infants, 2×100–120 ml/kg in preterm infants), in fact exchanges only 85% of the infant's blood volume. Double volume ETs are performed for removal of bilirubin, antibodies, toxins, etc. A single volume ET results in approximately 60% of the infant's blood volume being replaced by donor blood, and may be adequate for correction of anemia or polycythemia. The volume of blood necessary for a partial ET for anemia may be calculated by the following formula:

$$\text{Volume(ml)} = \frac{\text{infant's blood volume} \times (\text{Hgb desired} - \text{Hgb initial})}{\text{Hgb of packed red cell unit} - \text{Hgb initial}}$$

The volume of saline for a partial ET for polycythemia is calculated as:

$$\text{Volume(ml)} = (\text{infant's blood volume} \times \text{desired hematocrit change}) / \text{initial HCT}.$$

Equipment

The equipment for neonatal ET consists of a suitable surface (infant warmer or incubator) with appropriate heat source, temperature and cardiorespiratory monitor, equipment for central and peripheral vascular access, and an exchange transfusion set. Sterile preassembled disposable sets with a special stopcock are available for ETs, but the procedure may be performed just as easily with sterile equipment assembled in the NICU, consisting of two three-way stopcocks with locking connections, IV connecting tubing, 5-, 10-, or 20-ml syringes, and a sterile waste receptacle like an empty IV bottle or bag. A thermostatically controlled blood warmer with appropriate coils is essential when an ET is performed on a small preterm infant, and is recommended even for larger infants. Resuscitation equipment and medications should be readily accessible.

Procedure

Two people are required to perform the ET. The person performing the ET should prepare as for a major surgical procedure with hand antisepsis, and wear a mask, head cover, sterile gown, and gloves. An assistant is required to monitor the infant closely, record vital signs and the volume of blood exchanged during the procedure.

Venous and arterial access should be obtained prior to the exchange transfusion based on the type of ET planned and may necessitate umbilical venous and arterial catheterization or peripheral venous and radial artery catheterization. The ET may be performed by a "push–pull" technique, generally through an umbilical venous catheter, or by an "isovolumeteric" technique with infusion of donor blood through a central or peripheral venous catheter and simultaneous removal of the patient's blood from an umbilical or radial arterial catheter. The isovolumetric technique is preferred for sick or unstable neonates since there is less fluctuation of blood pressure and alteration of cerebral hemodynamics. If an umbilical venous catheter is inserted for an ET, a single lumen catheter is recommended; double- or triple-lumen catheters have very small internal diameters and make withdrawal and infusion of blood extremely difficult. The position of the umbilical venous catheter should be verified to be in the IVC radiographically prior to the procedure. If the UVC cannot be positioned in the IVC, it may still be used for an ET in an emergency, when placed in the umbilical vein, if adequate blood return is obtained.

ET by the "push–pull" technique may be performed using an umbilical venous catheter and a special four-way stopcock or by using two three-way stopcocks in tandem. It is important to familiarize oneself with the setup and stopcock connections prior to the procedure. The special four-way stopcock has three ports to which a syringe and IV tubing are attached and a handle that points to the port that is open (*Fig. 35.8*). The handle and syringe may be rotated in a clockwise direction allowing the following sequence during the ET: (a) withdraw blood from the patient into the syringe, (b) eject the patient's blood into the waste bag or bottle, (c) draw donor blood into the syringe, and (d) inject donor blood into the baby. The sequence is repeated multiple times until the ET is completed. If the special four-way stopcock is not available, two standard three-way stopcocks may be used in tandem. The proximal stopcock is attached to the umbilical catheter and the IV extension tubing to the sterile waste blood container. The distal stopcock is attached to the tubing from the blood administration set/blood warmer and to the 10- or 20-ml syringe.

Restrain the baby suitably so that the sterile barrier is not compromised. Sedation or pain relief is not usually

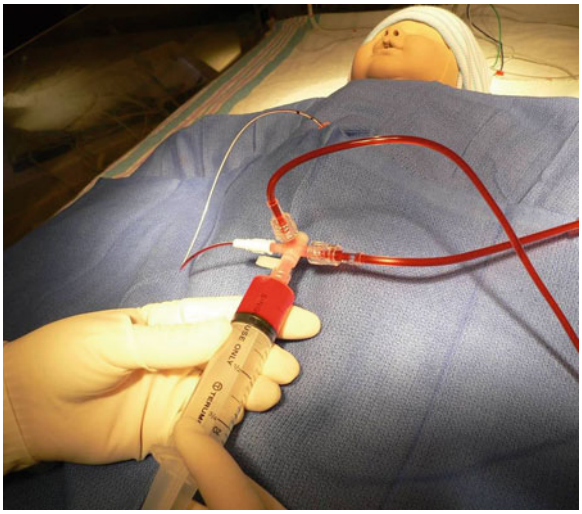

Figure 35.8
Demonstration of exchange transfusion using umbilical venous catheter (UVC) with special four-way stopcock and push–pull technique. Note that the direction in which the handle is pointing indicates the port that is open to the syringe, while other ports are closed. The handle and syringe ensemble are rotated clockwise to complete an exchange of one aliquot of blood

required. Conscious infants may suck on a pacifier during the procedure. The infant should not be fed for about 4 h prior to the procedure, if possible. Place an orogastric tube and empty the stomach prior to the procedure. Attach cardiorespiratory monitors and obtain baseline vital signs prior to the procedure. A peripheral intravenous line should be placed to provide IV infusions or medications as required.

Diagnostic laboratory tests in the infant such as antibody studies to evaluate hemolysis, antiviral antibody titers, metabolic screening, or genetic tests should be drawn prior to the ET. Pre-exchange blood tests include hematocrit, platelet counts, serum electrolyte, calcium, glucose and bilirubin levels, blood gases, and blood coagulation tests.

The principles and techniques for using the special stopcock or the three-way stopcocks are the same. It is important to ensure that all junctions are tight to produce a closed sterile system. Attach the blood administration set to the blood warmer tubing and the blood bag. Open the equipment tray using aseptic technique. Once all the connections are made, open the stopcock to the blood source and clear all air into the syringe and then into the waste bag. Consider measurement of central venous pressure using a pressure transducer in an unstable baby. Draw a sample of blood for pre-exchange laboratory tests. If the infant is hypovolemic, start the ET by transfusing an aliquot of 5-ml/kg into the catheter. If the infant has a high CVP or signs of congestive failure, start by withdrawing the pre-calculated aliquot. The usual rate of removal and replacement of blood during the ET is aliquots of 5 ml/kg over 2–4 min cycles. For example, in a baby weighing 3 kg, 15 ml of blood may be withdrawn from the UVC slowly taking about a minute and then flushed rapidly into the waste bag; 15 ml is drawn quickly from the blood administration set, and then given slowly over a minute to the baby through the UVC. Continue the sequence as described above with every withdrawal of an aliquot of infant's blood ("pull") being followed by ejection into the waste container, followed by a transfusion ("push") of an aliquot of fresh donor blood from the blood bag, with the assistant ensuring that the cumulative volumes are balanced throughout the exchange. The assistant should agitate the blood bag every 10–15 min to prevent red cell sedimentation, which may lead to exchange with relatively anemic blood toward the end of the exchange. Ensure that the stages of withdrawing and infusing blood from and into the infant are done slowly, taking at least a minute each to avoid fluctuations in systemic blood pressure, which may be accompanied by changes in intracranial pressure. Rapid withdrawal of blood from the umbilical vein may also induce a negative pressure that is transmitted to the mesenteric veins and may contribute to ischemic bowel complications. Continue exchanging aliquots of blood until the calculated volume is reached. Ensure that there is an adequate volume of donor blood left in the bag to infuse after the last withdrawal, so that the baby is not left with a net negative balance. Draw a post-exchange blood sample from the baby to check hematocrit, bilirubin levels, and necessary laboratory tests. The total duration of a double volume ET is usually 60–120 min.

If an isovolumetric technique is used for the ET, attach a three-way stopcock to the umbilical arterial catheter or a three-way stopcock with an extension tube to the peripheral arterial catheter. Attach an empty 5- or 10-ml syringe to one port and an IV extension tube connected to an empty sterile bag or bottle to another port. Attach a three-way stopcock and syringe to the umbilical or peripheral venous catheter and to the blood warming coil or blood administration set. Withdraw small aliquots of blood from the arterial line at the rate of 2–3 ml/kg/min and infuse the same volume drawn from the donor blood into the venous catheter simultaneously, keeping the flow as steady as possible and maintaining equal cumulative volumes on the arterial and venous sides. The arterial catheter may need to be flushed with small volumes of heparinized saline intermittently. The total duration of an isovolumetric ET is

usually about 60 min, but may take longer for sicker and smaller unstable infants.

Hypocalcemia may occur during the ET secondary to the use of citrated blood, and may be asymptomatic or manifested by changes in the Q-Tc interval or by agitation and tachycardia. If hypocalcemia is documented, 1 ml of 10% calcium gluconate may be administered slowly with careful observation of the heart rate and rhythm, after the line is cleared of blood with normal saline. Calcium will reverse the effect of the anticoagulant in the donor blood and may cause clotting of the umbilical venous catheter, so the UVC must be flushed clear with heparinized saline before resuming the ET.

Following the ET, continue to monitor vital signs closely for the next 6–12 h. Intravenous fluids should be continued to ensure normoglycemia. Infants are generally not fed for at least 4 h, and then feeds are restarted cautiously if the clinical condition is stable, with close monitoring of the abdominal girth, bowel sounds, and feeding tolerance if the umbilical vessels have been used for the ET. Serum ionized calcium and platelet counts should be rechecked immediately after the ET in sick infants and then as indicated. Hemoglobin and bilirubin levels should be checked immediately post exchange and further as clinically indicated. A double volume ET replaces 85% of the baby's blood volume, but eliminates only about 50% of the intravascular bilirubin. Bilirubin levels may rebound significantly within a few hours of the ET because of equilibration of intra- and extravascular bilirubin and continued breakdown of red cells by maternal antibody in alloimmune hemolytic disease of the newborn.

The risk of mortality or serious sequelae secondary to ET is estimated to be less than 1% in term otherwise healthy infants, but as high as 12% in sick infants. The most common complications of ET, noted during or soon after the ET in infants who are preterm and/or sick are apnea and bradycardia, hypocalcemia and thrombocytopenia. Other complications include derangements in acid–base balance and glucose concentrations, hematological problems such as neutropenia and coagulopathy, and vascular catheter-related complications such as vascular spasm and thromboembolism, and potential transfusion-related infection. Feeding intolerance and necrotizing enterocolitis have been described following ET, but the risk of omphalitis and septicemia should be low if strict aseptic technique is followed.

36 Neurodevelopmental Follow-up and Outcomes

Betty R. Vohr · Bonnie E. Stephens

Prematurity continues to be a major public health problem, and despite advances in antenatal care, prematurity rates continue to rise in the United States. Advances in antenatal medicine, more aggressive delivery room resuscitation, and improved neonatal interventions and management have resulted in improved survival of preterm infants. The most dramatic improvements have been for infants born extremely low birth weight (ELBW, $\leq$1,000 g) and at the limits of viability (22–25 weeks). These improvements in survival have not been accompanied by proportional reductions in the incidence of neurologic, developmental, and behavioral disabilities in this population.

It has been almost universally accepted that neurodevelopmental outcome after preterm birth is the most important quality indicator for a neonatal intensive care unit. In addition, it is now accepted that there may be a disconnect between a neonatal intervention with positive short term results and an infant's subsequent long term outcome. Examples are the association of oxygen treatment for respiratory distress with blindness from retinopathy of prematurity, and the use of postnatal steroids to wean infants from a ventilator with subsequent cerebral palsy. These observations resulted in the current standard for the majority of large clinical trials in the field of neonatology to include a measure of post-discharge neurodevelopmental status as a component of the primary outcome.

Ideally there are three objectives for a Neonatal Follow-up Program that include the following:

1. Surveillance: The implementation of a database for the systematic monitoring of care and interventions for high risk infants during the neonatal hospitalization, and post-discharge, with assessments of general health, growth, vision, hearing, neurologic, developmental, and behavioral status, are an important component. The data gathered are used as feedback for staff, counseling of families, and system development.
2. Family Support: A fully developed follow-up program provides specialized, therapeutic, family-centered transition support, including education, evaluation, feedback, and referrals for families of high risk neonates, with the goal of preventing rehospitalization and maintaining close communication with primary care providers. When a formal program is not available, it is the obligation of the primary care provider to more closely follow, support, and refer, as needed, the high risk infant and family.
3. Research: Individual hospitals or networked follow-up programs that develop standardized protocols, assessments, and age of assessment can systematically investigate and report on the safety, efficacy, and impact of antenatal, perinatal, and neonatal interventions on both short term neonatal and long term post-discharge outcomes.

Eligibility for Follow-up

Most follow-up programs determine eligibility for follow-up by a birth weight or gestational age cutoff. The majority of published reports on outcomes of premature infants have focused on very low birth weight (VLBW) infants $\leq$1,500 g or extremely low birth weight (ELBW) infants $\leq$1,000 g. Recent interest in examining outcomes by gestational age has led to focus on the extremely low gestational age newborns (ELGAN; $\leq$27 weeks). In addition, study eligibility may be determined by the intervention studied (type of ventilation, phototherapy, steroids) or a specific morbidity (i.e., bronchopulmonary dysplasia or intra ventricular hemorrhage).

Age of Follow-up Assessment

While no single optimal age of assessment has been agreed upon, the current consensus among most investigators is the use of corrected age until 30 months of age. Corrected age is age from due date, rather than birth date, thus it takes prematurity into account. Subsequent assessments are completed at the chronologic age. Although follow-up

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_36,

to school age is optimal for determining ultimate function, this is usually not practical. Because of the administrative challenges and high cost of tracking, most clinical and research studies report outcomes between 18 months and 2 years corrected age.

What Are the Assessments?

Standard assessments for a follow-up program should include at a minimum health status, growth parameters, neurodevelopmental status, hearing, and vision. *Table 36.1* shows

Table 36.1
Categories of assessment at 18–24 months, 2–5 years, and school age

Assessment category	18–24 Months	3–5 Years	School age
Growth and Nutrition	Weight, length, head circumference, growth, velocity	Weight, length, head circumference, growth velocity	Weight, length, head circumference, growth velocity
	Skin folds, circumference, calorie and protein intake	Skin folds, circumference, calorie and protein intake	Skin folds, circumference, calorie and protein intake
	Body mass index, *z* scores	Body mass index, *z* scores	Body mass index, *z* scores
Neurologic assessment and neuroimaging	Standard for age	Standard for age	Standard for age
	Amiel Tison	Amiel Tison	
	MRI, DTI, DWI, CT	MRI, DTI, DWI, CT	MRI, DTI, DWI, CT
Vision	Eye exam and ophthalmologist reports	Eye exam	Eye exam
		Picture tests	Snellen letters or numbers, "E" test
		Ophthalmologist reports	Ophthalmologist reports
Hearing	Tympanometry, acoustic reflex	Tympanometry, acoustic reflex	Tympanometry, acoustic reflex
	Vision reinforcement audiometry	Behavioral audiometry	Standard audiometry
	Auditory brainstem response	Auditory brainstem response	
Gross Motor	Bayley III Motor Composite	GMFCS	GMFCS
	Bayley III gross motor scale score		
	GMFCS		
Fine Motor	Bayley III Motor Composite	Beery vision motor integration	Beery vision motor integration
	Bayley III fine motor scale score		
Cognition	Bayley III Cognitive Composite	Intelligence testing, executive function, vision motor skills	Intelligence testing, executive function, memory
Language	Bayley III Language Composite	Peabody Picture Vocabulary Test (PPVT)	PPVT, Reynell
	Bayley III receptive language scale score	Parent Checklists	
	Bayley III expressive language scale score		
	Parent checklists		
Functional	WeeFIM, Vineland, PEDI	WeeFIM, Vineland, PEDI	WeeFIM, Vineland, PEDI

		Connor parent report	
Education	Early intervention	Preschool placement	Regular class, resource assistance, self-contained special education
		Special education preschool	

categories for assessment and the assessment tools used at three ages: 18–24 months, 3–5 years, and school age.

Growth parameters including weight, length/height, and head circumference should be obtained using standard techniques at each visit. If there are serial visits, longitudinal growth and growth velocities can be evaluated. Assessment of nutritional status including protein and calorie intake is most easily achieved during infancy. Subsequent collection of this information for clinical management can be achieved for research purposes but is costly and requires 3–5 day records. However, body mass index and *z* scores can be calculated and skin fold measurements obtained using calipers.

It is important to complete a neurologic assessment at each visit. The NICHD Neonatal Network uses the Amiel Tison examination for their 18–22 month and 30 month examinations. Important classifications of neurologic status need to be determined a priori; classifications which include normal, suspect, and abnormal, or moderate to severe cerebral palsy, mild cerebral palsy, and no cerebral palsy. Radiographic follow-up is currently being done for clinical management. Research studies have used this methodology for children age 7 and older when sedation is generally not needed.

Since blindness, myopia, amblyopia, and strabismus are common among preterms, an eye exam is recommended for each visit. By age 3 a standard picture test can be administered and children older than 5 can cooperate for a Snellen letters or numbers chart test.

Rates of congenital hearing loss and late onset loss are higher in the NICU population. In addition, VLBW infants are at increased risk of chronic middle ear effusions, thus tympanometry with acoustic reflex testing is recommended during the first 3 years. Follow-up with an audiologist for standardized audiology testing is recommended for all infants who passed the newborn hearing screen but have a risk factor for hearing loss (i.e., VLBW) by 24–30 months, or sooner if there is a suspicion of hearing loss.

Developmental outcome is a component of most follow-up studies. The new Bayley Scales of Infant and Toddler Development III was developed for infants 1–42 months. It contains separate composite scores for cognitive, motor, and language skills. In addition, it has scale cores for receptive language, expressive language, fine motor and gross motor skills.

The Gross Motor Function Classification System (GMFCS) is a reliable and validated system to describe severity of motor dysfunction in children with cerebral palsy and has been shown to be stable between 2 and 12 years of age. It is easy to administer and describes levels of function ranging from 1 (walks without restrictions) to 5. (Self-mobility is severely limited even with the use of assistive technology). The Bayley III gross motor scale can also be used between 1 and 42 months of age.

Fine motor skills can currently be assessed up to 42 months with the Bayley III fine motor scale. In older children the Beery Visual Motor Integration (VMI) test can be used in conjunction with fine motor skill assessment during the neurologic examination.

Cognitive abilities are assessed using the Bayley III cognitive composite score up to 42 months. In older children an intelligence test can be administered which may provide a verbal IQ, performance IQ, and full scale IQ in addition to a spectrum of subscores assessing discrete neuropsychological abilities. Mean normed scores on most of these assessments are 100 ± 15.

Preterm infants are at high risk of language delays and careful assessment of these skills is recommended. The previously used Bayley II had an MDI that contained both language-based and non-language-based tasks. The benefit of the new Bayley III is that cognition and language can be evaluated separately. Because of the influence of culture and primary language on test scores it is expected that the new cognitive composite score will be both more reliable and possibly higher than the Bayley II MDI. Prior to the development of the Bayley III language composite score, the primary mode of assessment was vocabulary checklists completed by parents. By 3 years, the Peabody Picture Vocabulary Test (receptive skills) can be administered in conjunction with a verbal IQ. The MacArthur Communicative Development Inventories (CDI) (parent report) was developed to serve as a valid and efficient measure of parental perception of a child's communicative development. The CDI Words and Gestures Inventory is designed to be completed by a caregiver of an 8–16 month old infant, and the CDI Words and Sentences Inventory is designed to be used with children between 16 and 30 months. A Spanish normed version is available. The Reynell is a standardized, individualized language assessment that utilizes toys and objects as manipulatives to assess verbal comprehension and expressive language skills. It is appropriate for children aged 12 months through 6 years 11 months.

Functional skills are essential skills of self-care, mobility, communication, and learning. Functional assessments can be administered to a reliable observer and by telephone interview. Examples include the Functional Independence Measure for Children (WeeFIM), the Vineland Adaptive Behavior Scales, the Battelle Developmental Inventory, and the Pediatric Evaluation of Disability Inventory (PEDI).

Assessment of behavior problems among former preterm infants continues to gain importance. The Child Behavior Checklist is a comprehensive measure of children's behaviors designed to assess in a standardized format the social competencies and behavioral problems of children 1 ½ to 5 years of age, as reported by their parents. Internalizing/externalizing and total problem scores are computed. The Conners Rating Scales-Revised (CRS-R) have three versions – parent, teacher, and adolescent self-report – all of which also have a short and long form available for assessing inattention, oppositionality, and hyperactivity.

Service utilization post-discharge for the former preterm population, many of whom are children with special health care needs, is also an important outcome. Education support services, physical therapy, occupational therapy, speech therapy, deaf educator services, and services for the blind should be recorded at each visit.

Current Status of Outcomes for Very Low Birth Weight Infants

Short Term Outcomes

Survival rates in the early 2000s are approximately 85% for very low birth weight (VLBW, $\leq$1,500 g) and 70% for ELBW infants. Survival has continued to improve for even the most preterm infants born at the limits of viability (23–25 weeks, $<$800 g) but few infants born $<$23 weeks or $<$500 g survive to discharge.

VLBW and ELBW infants who do survive remain at high risk for medical, neurodevelopmental, and behavioral morbidities which, like mortality, are inversely proportional to gestational age and birth weight. Due to these high rates of morbidities, many infants born extremely preterm are discharged home with special health care needs, including home oxygen and monitoring, multiple medications, growth failure, feeding difficulties, and need for gastrostomy tube feeds. Preterm infants are also at increased risk of rehospitalization within the first year of life.

Short term morbidities such as chronic lung disease, intraventricular hemorrhages, and periventricular leukomalacia also increase the risk of long term neurodevelopmental morbidities. Numerous authors have reported on the developmental outcomes of ELBW infants in infancy and early childhood and there is now increasing evidence of sustained adverse outcomes into school age and adolescence (*Table 36.2*).

Neurodevelopmental Outcomes

The primary focus of most published reports of neurodevelopmental outcome in infancy is the incidence of moderate to severe disability, often defined as mental retardation, cerebral palsy, blindness, and/or moderate to severe hearing impairment. This has been the outcome of interest due to the severity of the developmental impact of these severe and often combined morbidities. Unlike mortality rates which have dramatically improved, the incidence of moderate to severe disabilities has not changed significantly over the past 20 years. Rates of disability generally increase with decreasing gestational age and birth weight. In the NICHD Neonatal Network, rates of neurodevelopmental impairment (NDI) defined as the presence of any of the following: moderate to severe cerebral palsy, cognitive or motor scores more than two standard deviations below the population mean on standardized testing, bilateral hearing impairment requiring amplification, or bilateral blindness range from 28% to 40% in infants born 27–32 weeks and 45–50% in infants born 22–26 weeks. In two recent reports, only 21–27% of all ELBW infant survivors were unimpaired at 18 months.

Cerebral palsy (CP) is typically defined as a disorder of movement and posture that involves abnormalities in tone, reflexes, coordination and movement, delay in motor milestone achievement, and aberration in primitive reflexes. Rates of CP among ELBW survivors vary from 5% to 30% but are most recently sited at 5–12%. The most common form of CP in this population is spastic diplegia, accounting for 40–50% of all cases, followed by spastic quadriplegia and hemiplegia.

Arguably more important than the type or location of impairment is the functional level of the affected infant. A diagnosis of CP includes a wide spectrum of motor performance. In the Neonatal Network, 27% of ELBW infants diagnosed with CP at 18–22 months have moderate to severe gross motor function (Level 3–5), but 28% have gross motor function consistent with level 0 or 1 and are ambulatory when classified with the GMFCS.

Functional delays are observed in VLBW infants with and without severe impairments such as CP. While 93% of ELBW infants achieve sitting balance, 83% walk, and 86% feed themselves independently by 18–22 months corrected age, more subtle functional deficits become apparent later in life. At 10–14 years of age, 27% of children who were VLBW and 32% of those who were ELBW report restricted physical activity; 24% of VLBW and 29% of ELBW report they are unable to participate in sports.

Table 36.2
Outcomes for ELBW infants

Assessment category	18–24 Months	3–5 Years	School age
Growth and nutrition	Growth restriction: 30–33%	Shorter and weigh less than term controls	4–6 cm shorter and 4–6 kg less in weight
	Shorter and weigh less than term controls		
Neurologic assessment	NDI: 45–50% of 22–26 week infants 28–40% of 27–32 week infants	Decrease in NDI rates noted	History of brain injury: 50% NDI
			No History of brain injury: 7% NDI
Vision	Blind: 1–5%	Increasing diagnosis of myopia	Blind services:
	Myopia, strabismus, no stereopsis: 9–25%		History of brain injury 16%
			No History of brain injury 1.6%
			Glasses: 33–46%
Hearing	Require amplification: 1–9%	Gradual increase in rates of permanent HL seen	Hearing Aids:
	Mild hearing loss: 28%		History of brain injury: 12%
			No history of brain injury 2.5%
Gross motor	CP: 5–12%%	CP: 5–12%	CP: 5–12%
	Of those with CP: 28% GMFCS 0–1 45% GMFCS 2 27% GMFCS 3–5		DCD: 31–34% of VLBW 50% of ELBW
Fine motor	Bayley PDI $<$ 70: 20–30%	Increasing rates of fine motor impairments identified	Impairments in 70%
Cognition	Mean Developmental Quotient 70–89	Improving IQ with increasing rates of learning disability	Mean IQ 82–105
	Impairment: 37–47% of 22–26 week infants 23–30% of 27–32 week infants 34–37% of $<$1,000 g infants		Impairment: 16%
			Learning disability: 25–40%
			More subtle impairment: 50–70%
Language	Delayed receptive and expressive language scores	Improving language scores	Mean scores 85–90
			Impairment: 13–24%
Functional	93% sitting	Gross motor function improves but emerging fine motor dysfunction	27% restricted physical activity
	83% walking		24–29% unable to participate in sports
	86% independent feeding		
Behavior	Increased rates of behavior problems Autism: 21–25% screen positive True incidence unknown	Increased evidence of inattention and hyperactivity	Inattention/Hyperactivity: 23–27% VLBW 33–37% ELBW
			Anxiety/Social Withdrawal: 25–50%
			Generalized Anxiety Disorder: 8–14%
			Psychiatric Disorder: 25–28%
Education	Early intervention: 74–85%	Increased rates of preschool special education	Special education: 25–62%
	Increased needs for community supports		Grade repetition: 15–34%
			Graduation rate: 56–74%

While CP is the most well known and potentially most disabling motor abnormality associated with prematurity, infants born preterm often demonstrate less severe differences in their neurologic development. During the first year of life transient dystonia is a common deviation in the motor development of VLBW infants. Transient dystonia occurs in 21–36% of preterm infants with a peak incidence at 7 months corrected age. It involves increased extensor

tone of the trunk and lower extremities and increased adductor tone in the lower extremities, leading to shoulder retraction and hip rotation, persistent primitive reflexes, head lag on pull to sit, and delayed supportive responses. The presence of these findings increases the risk of later cognitive and motor problems including CP. Twenty percent of infants with transient dystonia go on to be diagnosed with CP. But the specificity of these findings is low, as they are truly transient in 80% of the infants in which they occur, disappearing gradually between 8 and 12 months of age.

Children born preterm are also more likely to have difficulty with motor coordination. In the past these children were often labeled as "clumsy" but in recent years the diagnosis of developmental coordination disorder (DCD) has been used. DCD is defined as impairment in motor performance sufficient to produce functional impairment that cannot be otherwise explained by the child's age, cognitive ability, or neurologic or psychiatric diagnosis. DCD is found in 31–34% of VLBW and 50% of ELBW infants at school age.

Difficulties with fine motor skills, visual perception, visual-motor control, hand–eye coordination, or visual-motor integration, are seen in as many as 70% of children born VLBW or ELBW. These difficulties can impact on academic performance and in functional abilities in 23% at 5 years of age.

While much less common than motor disabilities, rates of neurosensory disabilities are higher in ELBW infants than the general population. Unilateral or bilateral blindness occurs in up to 1–5% of ELBW infants. Milder visual impairments including myopia, strabismus, and lack of stereopsis (depth perception) occur at rates of 9–25%. Hearing impairment requiring amplification is reported in 1–9% of ELBW infants. Milder hearing impairment has been reported in up to an additional 28%.

The most common severe impairment seen in preterm infants at 18 and 30 months is cognitive impairment, defined as scores that are more than two standard deviations below the mean on standardized cognitive testing. Average scores on cognitive testing at 18 and 30 months range from 70 to 89 for ELBW infants, compared to 85–115 for the general population. Like rates of motor impairments, rates of cognitive impairment are inversely proportional to gestational age and birth weight. Rates of cognitive impairment at 18–22 months corrected age are reported at 37–47% in 22–26 week infants 23–30% in 27–32 week infants, and 34–37% in all infants $<$1,000 g in the NICHD Neonatal Network.

While cognitive functioning can be measured in infancy, it is not predictive of cognitive functioning later in life. The assessment of an infant's cognitive function is highly dependent on their motor, language, and social-emotional development. In one cohort of 330 ELBW infants, mean MDI at 20 months was 76 compared to a mean cognitive score of 88 at 8 years, and rate of cognitive impairment dropped from 39% at 20 months to 16% at 8 years. The positive predictive value of having a low cognitive score at 8 years ($<$70) given a low cognitive score at 20 months ($<$70) was only 0.37.

The mean intelligence quotient (IQ) for VLBW and ELBW infants during school age, adolescence, and adulthood is higher than at 18 and 30 months, ranging from 82 to 105. Although these mean IQs are within the average or low average range, they are 0.5–1.0 SD lower than those of normal birth weight peers and reflect significantly higher rates of cognitive impairment. Cognitive scores at school age and beyond remain reflect significantly correlated with gestational age and birth weight.

More subtle cognitive impairments are detected in 50–70% of children born VLBW at school age. These include relative impairments of executive functioning, visual-motor skills, and memory, especially verbal memory. These children score lower on tests of academic achievement, have poor perceptual-organizational skills, difficulty with visual processing tasks, and delays in adaptive functioning compared to their normal birth weight peers. Rates of learning disabilities are high, especially in mathematics, ranging from 25% to 40%.

Speech and language also develops atypically during early childhood in previously ELBW infants, with delays in the acquisition of expressive language, receptive language, and articulation. Children born at or before 25 weeks gestation have significantly lower scores on standardized language tests (90 vs 104) and higher rates of language impairment (16% vs 2%) than the general population at 6 years of age. Former ELBW infants continue to have significantly lower scores (92 vs 105) and higher rates of impairment (13% vs 4%) on the PPVT, as well as lower expressive, receptive, and total scores (85–87 vs 100–103) and higher rates of impairment (22–24% vs 3–4%) on the CELF at age 12.

While language development in infancy and early childhood is often an early proxy for overall cognitive development, specific language deficits have been described including phonological short term memory, and prosodic processing. At 12 years of age, children born $<$1,250 g have less pronounced differences on tests of lower level language skills (phonological processing, phonemic decoding, and sight word reading) compared to term controls, but exhibit significantly more difficulty with higher level skills (syntax, semantics, verbal language memory, and reading

comprehension). In addition, when given a semantic processing task, preterm children have abnormal patterns of brain activity on functional MRI, resembling the brain activity of term controls during phonologic processing.

Behavioral and Psychological Outcomes

Very low birth weight has been associated with a wide variety of behavioral and psychological diagnoses and disabilities. Recent concern has arisen that rates of Autism Spectrum Disorder (ASD) may be higher in ELBW infants than previously thought. Though low birth weight (<2,500 g) may result in a 2–3 fold increase in the risk of ASD, true risk of ASD in very preterm infants is unknown. Recent studies report that 21–25% of VLBW infants screen positive on the M-CHAT at 18 months. However VLBW infants with other severe impairments often have a false positive screen. The rate of positive screens in those without severe impairment was 10%. Neither of these studies performed diagnostic confirmation. Thus, further studies are needed to determine the true risk of autism in this population.

Parents and teachers of VLBW/ELBW infants report higher rates of inattention and hyperactivity at school age (8–12 years old), with rates of 23–27% in VLBW and 33–37% in ELBW infants. One quarter to one half of children born VLBW/ELBW have symptoms of anxiety and/or social withdrawal, 8–14% meet criteria for generalized anxiety disorder (compared to 1–4% of peers), and 25–28% meet criteria for a psychiatric disorder (compared to 7–10% of peers). These children continue to score higher on measures of inattention, anxiety/depression, withdrawn behavior, and social problems at 17 years of age.

Possibly as a result of higher rates of developmental and psychological sequelae, VLBW teens and adults score significantly lower on measures of self-esteem, and report less confidence in their athletic, school, romantic, and job related abilities. However they report lower rates of alcohol and drug use, sexual activity, and pregnancy than adults born normal birth weight.

Educational Outcomes

Due to high rates of impairments, ELBW infants have high rates of academic underachievement and increased needs for special education services. Teachers of VLBW infants report rates of below average school performance in all academic areas, ranging from 24% to 41%. Approximately 25% of VLBW infants and up to 62% of ELBW infants receive special education services. Between 15% and 34% require grade repetition. Only 56–74% of preterm children, significantly fewer than term birth weight teens, graduate from high school. Significant gender differences exist in graduation rates: 66% of VLBW males compared to 75% for term males and 81% for VLBW females compared to 90% for term females.

Late Preterm

The majority of neonatal outcomes research has focused on the ELBW infant. But during the 1990s the rates of delivery at 40 or more weeks gestation decreased while rates of deliveries between 34 and 36 weeks increased steadily, causing the rate of late preterm births to increase from 7.3% to 9.1% of all births between 1990 to 2005. These "late preterm infants" have higher mortality rates and higher rates of neonatal morbidities, with the potential to increase the risk of long term neurodevelopmental sequelae. Infants born 34–36 weeks are 3.39 times as likely as term infants to develop CP and 1.25 times more likely to have cognitive impairment than infants born at term. They are more likely to qualify for special needs preschool and are more likely to have problems with school readiness. In kindergarten and first grade they have lower reading scores, teachers report math skills below those of their full term peers, and they are more likely to qualify for special education services.

37 Ethics and Decision Making in Neonatology

Annie Janvier · Keith J. Barrington · John D. Lantos

Introduction

The history of neonatology parallels that of bioethics. Improvements in the care of neonates that led to major decreases in mortality are rather recent. Before the 1970s, babies born even mildly prematurely would usually die. Patrick Bouvier Kennedy, the son of the late US president John F Kennedy, provides a useful historical landmark. He was born in 1963, at a gestational age (GA) of 35 weeks and weighing 2 kg. He died in a hyperbaric oxygen chamber at Boston Children's Hospital on the second day of life. Even for the most powerful family in the world, doctors could do nothing.

Today, many more treatments are available and survival rates for premature babies are much better. Advances in treatment have led to new ethical dilemmas. The most common ethical dilemma involves a decision about withholding or withdrawing life-sustaining treatment in a situation where such treatment could save or prolong the life of a baby but might leave the baby with profound physical or neurologic deficits. In such cases, the traditional medical obligation to save life conflicts with the obligation to reduce pain and suffering.

These dilemmas are not unique to neonatal care. They also occur in other areas of pediatrics. Dialysis, heart surgery, extracorporeal membrane oxygenation (ECMO), or bone marrow transplant, for example, may save lives but may also leave survivors severely impaired. Neonatal issues are unique, however, for two reasons. First, decisions about newborns often take place at the moment when the fetus becomes a baby. At that moment, their legal status changes dramatically. The fetus does not have independent legal status. The newborn does. This legal change becomes the basis for a profound shift in moral obligations. Prior to birth, the doctors caring for a pregnant woman and her fetus must balance the risks and benefits of interventions that might help the fetus but harm the pregnant woman. After birth, the treatment decisions for the baby no longer need to consider the effects of those treatments on the woman's body. Second, decisions at the borderline of viability are associated with greater prognostic uncertainty than decisions in many other areas of pediatrics. Outcomes for tiny premature babies or asphyxiated infants cover the spectrum from completely unscathed to neurologically devastated. Much of the work of modern neonatal bioethics has been an attempt to develop coherent and consistent philosophical responses to such dilemmas.

The Evolution of Neonatology and Bioethics

The 1960–1990s brought a rapid evolution in neonatal care. Innovations such as amniocentesis and prenatal ultrasound allowed identification of high-risk pregnancies and earlier diagnosis of fetal anomalies. The regionalization of perinatal care allowed the concentration of expertise in regionalized referral centers. Antenatal corticosteroids and screening of pregnant women for group B streptococcal infections prevented or ameliorated the severity of newborn respiratory distress syndrome and neonatal sepsis. Better techniques for mechanical ventilation and parenteral nutrition supported fragile premature babies through the first perilous weeks of life. As a result, babies who would have died 20 years ago now routinely survive. Babies who would have been impaired as a result of sepsis or hypoxia now survive unimpaired. In the past 20 years, the disability rate has gone down at each gestational age, and for most neonatal problems. However, because more babies survive, the overall rate of disability as a result of perinatal complications has remained about the same. But the moral implications are different. In the past, babies used to survive or die in spite of our best efforts to save them. Now, often, a choice can be made about whether to allow them to die or to intervene.

Bioethics initially emerged as a response to dubious research protocols involving human subjects. After the birth of research ethics, clinical ethics has developed to answer questions often raised by the developing technologies and medical progress. For example, in vitro fertilization, organ transplants, ECMO, and open heart surgery have changed the way relationships, the human body, and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_37,

life are looked at. They have also raised many ethical questions and dilemmas. One widely discussed approach to these dilemmas is the reliance on the four principles of Beauchamp and Childress. These principles are sometimes referred to as if they are "the" principles of bio-ethics: autonomy, beneficence, non-maleficence, and justice. Although these principles are valuable for framing the debate, they are no more objective than any other approach to ethical reasoning. Beneficence is in the eye of the beholder, an approach which is considered beneficent by one person, may seem excessively onerous and maleficent to another. Moreover, these four principles often contradict each other. The physician may think intervention is beneficent to an infant, but the baby's parents may disagree (autonomy), and they might also think that this disabled neonate is too much of a risk for their other children and their family life (distributive justice). Societies differ in the importance given to individual autonomy, as compared with community values. Other approaches (consequentialism, communitarism, feminist ethics, compassionate ethics, and others) are also valid and bring other insights to help address these dilemmas.

From Fetus to Person

Debates about neonatal bioethics have been inseparable from debates about abortion and the moral status of the fetus. This is because the bright legal dividing line between fetus and baby does not reflect the biological reality that is continuous rather than dichotomous. Intrauterine events influence neonatal outcomes. Antenatal decisions are as prognostically important as postnatal decisions. The instantaneous transition from intrauterine to extrauterine life has enormous moral and legal implications. Where abortion is legal, the fetus has no legal right to life, although most countries' abortion laws recognize a growing state interest in the life of the viable fetus.

This split between biological realities and legal realities is part of what makes neonatal bioethics unique. Neonatologists are physicians who can consult for patients who are not yet legal persons. They see mothers in consultation regarding problems which affect their fetuses. They create estimates regarding outcomes for patients who are not yet born. Sometimes, they never even meet their ex-fetus patients, either because the fetus dies in utero and never becomes a person, the pregnancy is terminated, or because the high-risk pregnancy is carried to term and the baby never needs to be admitted to the NICU.

The uniquely ambiguous moral status of the in utero patient shapes the ethical responses of the neonatologist. He or she must make decisions about what should or should not be done for the baby at the moments following birth, but those decisions are often somewhat tentative, being based on information that usually gives a wide range of possible outcomes, leaving enormous uncertainty.

NICU Patients and Ethical Questioning

The majority of babies in the NICU are there because they were born premature. Other babies are there because of infection (or suspicion of), congenital anomalies, asphyxia, metabolic disturbances, and other conditions that require them to be closely observed. About 12% of births in the United States and 8% in Canada are born preterm, before 37 weeks of gestational age. Of these, two thirds are born between 34 and 36 weeks and one third are before 34 weeks. Approximately half of late preterm babies, and virtually all babies born before 34 weeks are admitted to the NICU. About 3% of babies are born with a moderate to severe congenital anomaly, and approximately half are admitted to the NICU. Thus, roughly two third of NICU admissions are accounted for by prematurity. Although most articles in neonatal ethics have focused on extremely preterm infants, babies who are born severely asphyxiated, who have a grave metabolic disease, who have a serious neuromuscular disease, or congenital anomalies often raise many, if not more, ethical questions than extremely preterm infants.

Late preterm babies are at higher risk for long-term disabilities than full-term babies. Many late preterm births follow obstetrical decisions to medically induce delivery. These obstetric decisions require a complex trade-off between the risks of *in utero* insult (and liability) in a high-risk pregnancy and the risks of preterm delivery. The rate of medically induced preterm birth has been steadily rising in most industrialized countries and accounts for a big proportion of the rise in preterm births. More babies with disabilities originate each year from late preterms than from extremely preterm or full-term infants. Half the patients in cerebral palsy registries were not sick nor admitted to an NICU at birth. For the remaining half, most were of a gestation greater than 28 weeks at birth. In general, there would be no ethical question about whether to admit these babies to the NICU and offer active treatment. It is worth remembering, then, that policies to limit treatment for babies at the borderline of viability will not have much effect on the overall rate of cerebral palsy and disabilities in society.

Extremely premature babies, with a gestation of less than 28 weeks (Extremely Low Gestational Age Neonates,

ELGANs) or a weight of less than 1,000 g (also called Extremely Low Birth Weight babies, ELBW), comprise 0.8% of all deliveries and about 10% of NICU admissions. For these babies, birth weight and gestational age correlate with survival rates, although other factors are also very important. Infants weighing 1,000 g or born at 27 weeks gestation have an approximately 90% chance of survival. Infants who weigh 500 g at birth and are 23 or 24 weeks of gestational age have 30–60% chance of survival, but a high risk of severe neurodevelopmental disability.

For some babies in the NICU, multiple follow-up studies exist that can help parents and physicians predict outcomes. For example, for extreme prematurity and birth asphyxia probabilistic predictions of survival and disability can be made based on specific clinical features; one can question the utility of a prediction of a specific percentage risk of disability or survival, but some parents seem to appreciate this sort of information. The ethical dilemma here is dealing with the remaining considerable uncertainty. For a particular baby and family, statistics about cohorts of ELBWs might not be that helpful. An unborn ELBW baby with a 10% predicted risk of cerebral palsy will either have 0% or 100% cerebral palsy (albeit the severity of the affliction is highly variable, increasing the complexity of the decision-making). Other babies are born with multiple congenital anomalies, a specific syndrome, or serious metabolic diseases where research may be much scantier, but where babies are unambiguously impaired from birth. These diseases may have a narrower range of outcomes, but for some, there remains considerable uncertainty. For such babies, the ethical dilemma has less to do with weighing the probabilities and dealing with uncertainty; rather it is deciding what degree of impairment should be considered too severe and thus justifies limitation of life-sustaining therapy.

When medical technology develops quickly, many ethical and moral questions arise at the same time as a new development is made or, all too often, afterward. For what survival and long-term outcomes should very sick patients receive intervention? Do parents always have a choice when their newborn is at risk of disability, or is disabled? Should they be entirely responsible for the decisions, or should others also be involved? How are the neonate's best interest evaluated?

Prognostication and the Borderline of Viability

Prognostication in the NICU is difficult. There is no way to completely eliminate uncertainty. Babies who are doing well and who are predicted to survive may have an unexpected complication that leads to an unpredicted death. Babies who are not doing well may be predicted to die, but such predictions are often wrong. Both illness severity scores and our clinical intuitions are imperfect in predicting death or disability with high accuracy.

There are two possible responses to this uncertainty. One is to develop guidelines for treatment based upon probabilities. Given this uncertainty, many professional societies have developed policies about babies in the NICU. Unfortunately, these policies have described decision-making for babies born at the borderline of viability and ignored other equally important issues such as the baby with anomalies.

Such policies consider gestational age, birthweight, and other factors in order to classify babies as fitting into one of three "zones." One zone is that in which good outcomes are likely and thus in which treatment is considered morally obligatory. A second zone is often called "the gray zone." In the gray zone, outcomes are considered sufficiently ambiguous or uncertain as to allow non-treatment as an ethically defensible option. Finally, there is a zone in which newborns are not considered viable or, to put it another way, in which treatment is considered "futile." Today, in the policies of most developed countries, the "gray zone" is defined as between 22 and 26 weeks of gestation. It should be noted that in some countries, a baby in the gray zone could be in the futile zone in another country, or in the "good outcome" zone in yet another! Such policy statements are user friendly and simple. They are, however, both scientifically and morally problematic.

There are a number of problems with such algorithmic policies. First, these policies are often based on gestational age and prenatal determination of gestational age is imprecise. It can be off by a week or two in either direction. Thus, in the "gray zone," pre-birth decisions about resuscitation based on gestational age should be either tentative or avoided altogether. Second, birth weight, gender, place of birth, multiple birth, infection, and use of antenatal steroids are all independent predictors of outcome; adjusting for these factors improves the prognostic estimates. For example, a female infant born at 24 weeks weighing 700 g whose mother received steroids has a 74% chance of survival. A male infant born at the same gestational age but who weighs only 500 g and whose mother did not receive steroids has only a 26% chance of survival. Clearly, gestational age alone is not a very precise predictor of outcome.

A second approach to prognostic uncertainty would be to individualize treatment. By this approach, treatment could be initiated whenever there was a reasonable possibility of success, and decisions would be made about

whether to continue or to discontinue treatment based upon the baby's response to therapy. This approach also has disadvantages. Estimating "a reasonable possibility of success" is subjective. The problem with individualized treatment decisions is that prognosis does not necessarily improve with time. Some babies "declare themselves" by doing either better or worse than expected. This is particularly true for the tiniest babies. For many babies, however, there are no reliable predictors of outcome that can be assessed over time. For extremely preterm infants, resuscitation based upon an assessment of the newborn in the delivery room is also commonly offered. While this approach is appealing, epidemiologic studies suggest that there are no reliable predictors of outcome that can be obtained in the first minutes or hours of life.

Framing Issues and Informed Consent

Most professional guidelines suggest that doctors should share decision-making authority with parents for babies in the gray zone. Most doctors agree, in theory, with these guidelines. In practice, however, they often do not share decisions with parents. By their own self-report, they make unilateral decisions about resuscitation. Sometimes, they decide to resuscitate, sometimes not.

It is not clear whether physician paternalism with regard to extremely premature babies is more likely to lead to overtreatment of babies in situations when their parents would have wanted comfort care, or undertreatment of babies who had a reasonable chance for a good outcome. In all studies, parents are more likely than doctors or nurses to think that every effort should be made to save babies, regardless of their birthweight or chances for survival; parents also generally rate quality of life higher for babies with severe disabilities than do doctors or nurses. Interestingly, such differences are greater among parents who have had a premature baby than among parents of term babies.

In order for parents to give truly informed consent for treatment or for non-treatment, doctors need to be able to explain to them the complicated probabilities about survival and impairment. This task is complicated for a number of reasons. First, survival statistics differ at different units. Sometimes, these differences reflect policies about treatment in those units. Policies often turn into statistics. Thus, units that do not routinely resuscitate babies under 25 weeks will have much fewer survivors under 25 weeks. The policy becomes a self-fulfilling prophecy. It would be technically true to tell parents in such a unit that survival is extremely rare, in that unit, at 23 weeks. It would also be misleading, since other units, and even entire countries, report survival rates above 50% at 23 weeks.

A second reason why informed consent is complicated is that the information to be explained is inherently complex. For prenatal consults when there is a high risk of delivery of an extreme preterm in the "gray zone," the American Academy of Pediatrics (AAP) recommends physicians to inform parents of survival, and of all the relevant risks of short-term complications and long-term impairment. This risks swamping the parents with a potentially enormous quantity of information and percentage estimates. Parents in this extremely stressful situation need to be treated with compassion, and with realistic expectations of their abilities to recall information provided. Some parents want a lot of information, and knowing everything that can happen gives them some control. Other parents have difficulty dealing with everything the AAP recommends us to tell them. When families are counseled about these critical decisions their attention is often focused on a very different issue: they just want to continue the pregnancy.

A third complexity relates to framing issues. Psychometric studies show that people respond differently when told the same information in different ways. This has been directly confirmed in a study examining treatment decisions at extremely low gestations, volunteers were far more likely to decide for intensive care if the information was framed in a positive manner (for example, 25% survival), than if exactly the same information was framed negatively (75% will die).

One helpful way to break down the issues is to make sure that parents understand five possible scenarios for babies in the "gray zone": (1) Comfort care in the delivery room and death. (2) Admission to the NICU for a trial of therapy with possibility of withdrawal of intensive care if the infant develops severe illness or is predicted to survive with severe disabilities. (3) Admission to the NICU and death despite continued maximal medical therapy. (4) Admission to the NICU and survival with disability. (5) Admission to the NICU and survival without disability. Estimating the probability of options 2–5 might help parents decide whether or not to opt for option 1. All these options will directly affect parents and families for all their lives, including option 5. Interestingly, there are studies about how families cope with options 2, 5, but not option 1.

Disabilities and Quality of Life

Survival is not the only factor to consider. Other important considerations are the burden of prolonged intensive

care, and the risks of long-term disability, or of later death. Twelve to twenty-five percent of babies born before 27 weeks gestational age will have major neurological or developmental disabilities. These include cerebral palsy (8–10%), deafness (3%), blindness (3%), and developmental retardation (10–20%); up to 50% will have behavioral or educational problems: hyperactivity, learning difficulties, dyslexia, or behavioral problems. Rates of disability are higher in near-term babies than in term babies, and higher in ELGANs than in near-term babies, but, among ELGANs, gestational age does not correlate with the rate of long-term disability. Furthermore, the rate of severe disability is similar for babies at each gestational age between 22 and 25 weeks. In other words, for babies less than 26 weeks, the frequency of most disabilities, among survivors, changes very little and therefore, the chance of survival can be used as a proxy for all these outcomes. Mild cognitive deficits and learning problems are common. Severe deficits are rare. The mean IQ of ELBW infants is approximately 79, one standard deviation below that of control infants. It is interesting to note that for the past 10 years, surgeries and interventions for babies with Down syndrome are rarely questioned, and that their IQ is on average 42.

Motor dysfunction (cerebral palsy) may occur in up to 8–10% of very premature babies. Like the cognitive deficits, cerebral palsy is generally not catastrophic, compared for example, to babies born asphyxiated. The vast majority of babies with cerebral palsy are ambulatory without assistance. Importantly, some disabilities classified by physicians as being "minor," for example, hyperactivity or learning disability, can have far more devastating consequences to some families than some that are classified as "major" disabilities such as cerebral palsy and deafness. The way physicians place survivors in a "normal," "major disability," or "minor" disability category is necessary to scientifically quantify exactly adverse outcomes in this population, but it should be remembered that few studies look at functionality of these families. Multiple major disabilities that leave a child unable to ever live independently arise in less than 5–10% of babies born at less than 28 weeks.

The degree of disability is not correlated with either self-reported quality of life and parental reports of their child's quality of life. Parents of preterm infants, and the infants themselves when they are older, judge their quality of life to be much better than judgments made by health care providers. Not surprisingly, then, parents of both full term infants and of very premature babies are more likely than health professionals to favor the treatment of extremely premature infants. For example, 64% of parents were in agreement with the statement, "we should try to save all newborn infants independently of their birth weight," in comparison with 6% of healthcare providers.

Given these parental preferences, pediatricians often face a conflict between their negative assessment of an infant's long-term prognosis and the parents' desire for continued life-sustaining treatment. In such a situation, the burden of proof is on the physician who must be convinced that continued treatment is not in the interest of the baby. In the past, pediatricians have been criticized by advocates for the disabled for making decisions that undervalue the lives of people with disabilities. Moreover, it has been shown that non-treatment decisions are considered more often for extremely premature babies than for other patients with the same or even worse prognosis. When physicians are fairly certain that treatment will only lead to survival that is associated with intractable suffering for the infant, doctors should recommend non-intervention. Otherwise, they should defer to parents' wishes after they have informed parents of likely outcomes. Obviously, this standard requires careful judgments to be made under conditions of uncertainty: what life is worth being lived? When is death better than a life with disabilities? Are these decisions being taken for babies only, or also for their families, for ourselves, for society? Making a judgment of the value of the future for a small baby is never easy.

Practice Variation and Informed Consent

In all areas of medicine variations in practice occur. However when such decisions occur in life-or-death situations patients should be offered the same opportunities. In fact, decisions regarding whether or not to institute intensive care rather than palliation are much more variable in neonatology than in other domains: Although the initial therapy offered to women with advanced breast cancer varies across the USA, the number of women offered palliation as initial therapy does not (practically zero, everywhere). There are obvious differences in decision-making between resource-limited parts of the world with limited availability of intensive care facilities, equipment, and trained personnel and industrialized countries. However, enormous variations in survival of extremely preterm infants occur between countries with otherwise similar medical systems. In industrialized countries, most of this variation is due to differences in attitudes, infants being much more likely to die without an attempt at active intervention in some countries than in others. Some physician groups are prepared to institute palliative care for infants with an 83% chance of survival, an attitude which would be frankly unacceptable for older children, adults or

the elderly. Others are prepared to institute active care even when they feel that it is "futile." These variations in philosophy and approach lead both to avoidable deaths on the one hand, and avoidable intensive care with little or no hope of success on the other.

Consistency and consensus in these decisions is not by itself a worthwhile goal; it is possible to be consistently wrong! It seems, however, morally problematic that a mother presenting with the same high-risk pregnancy to two hospitals with the same capacity to intervene will have two discussions which are diametrically opposed, and will have her decisions influenced in opposite directions. The challenge is to find the right balance between consistency and local ethos.

Are Neonates Valued Differently from Older Individuals?

The Neonatal Resuscitation Program (NRP) textbook, which is the standard neonatal resuscitation text used in North America and many other parts of the world, states: "The ethical principles regarding resuscitation of newborns should be no different from those followed in resuscitating an older child or adult." On the other hand, current practice suggests that the principles are, in reality, very different. There is clear evidence of categorical separation of the ethical assessments associated with treatment or non-treatment decisions for newborns from similar decisions for older children or adults, assessments of whether resuscitation is in the best interests of a patient are not closely related to survival rates, nor to disability.

Setting an upper age limit for resuscitation is not a new concept, but is very controversial. While there appear to be no official policies or professional association guidelines which suggest an upper age limit for resuscitation, a lower age limit for the premature infant is almost universally promoted. At 24-weeks gestation, many national associations (for example, the Canadian Pediatric Society) deem prognosis to be so poor that life-saving interventions are considered to be futile, or optional. The current chances of an infant delivered at 24-weeks GA are a 50–70% survival rate and 50% "normal outcome" among survivors or better. There is no other group of incompetent patients for whom such results are thought to be too dismal to intervene, or to defer life and death decision entirely to the family. Policy statements for preterm infants often state survival and handicap as justification for optional intervention, the fact that such outcome statistics would not justify such approaches in other populations suggests that some other powerful factors are at work. These might include a sense that a premature baby is not yet a full-fledged person, that he does not have a "real" disease, a sense that neonatal care is disproportionately expensive, or an unduly pessimistic understanding of the likely outcomes.

Cost-Effectiveness of NICU Care

One concern often raised concerning neonatal intensive care is of its cost-effectiveness. Official guidelines have even invoked the expense of NICU care as a reason for denying intensive care to high risk infants. However, objective analyses of NICU care demonstrate that the large majority of NICU costs are expended on infants who will survive and have good outcomes. Because most infants who die do so within a few days, only 10% of NICU costs are expended on infants who do not survive. By this measure, NICUs are far more cost-effective than medical ICUs for adults, where 30–50% of expenditures go toward patients who do not survive until hospital discharge.

Another way to analyze cost-effectiveness is to calculate the dollars spent per quality adjusted life year (QALY) that results. By this measure, too, NICUs are highly cost-effective. For even the tiniest babies, NICUs achieve cost-effectiveness of <$10,000/QALY. This compares favorably to the $40,000–50,000/QALY benchmark that is used to evaluate many other medical therapies. NICU care is one of the most cost-effective tertiary care interventions in all of medicine. It is far more cost-effective than adult intensive care, coronary bypass surgery, solid organ transplantation, renal dialysis, or many other well-accepted interventions. If the provision of intensive care services were to be made on the basis of cost-effectiveness, NICUs would always be given the first priority in funding.

Preventing Prematurity

The rate of preterm birth in the United States has gone up by more than 50% over the last 25 years, from a little over 8–12.5%. The USA has the highest rate of preterm birth of any industrialized country, but preterm birth rates are rising in most industrialized countries. A critical (and maybe the most important) ethical issue in neonatology is how to prevent preterm birth.

Many approaches have been tried to decrease preterm birth. One approach is to provide better prenatal care. This was once thought to be the panacea, since preterm birth rates were much higher among women with inadequate or no prenatal care than with women who received

comprehensive prenatal care. Unfortunately, better access to prenatal care has not resulted in fewer preterm deliveries. More than half of preterm births are near term babies and many of those preterm deliveries are medically induced. Practice guidelines for Cesarean sections or inductions may lower the rate of unnecessary preterm delivery.

Another factor associated with the rise in preterm birth is the rise in treatments for infertility and delaying child birth. Both pharmacologic stimulation of ovulation and in vitro fertilization are associated with multiple pregnancies and multiple pregnancies are associate with preterm birth. Many countries have addressed the large increase in multiple births and the attendant complications by reimbursing costs of assisted reproduction technologies and adopting policies that mandate signle embryo transfer in IVF clinics. This has led to a progressive decrease in multiple gestations. In Sweden, only 5% of babies created through IVF are multiples; in the USA, it is 32%. In a North-American NICU study, iatrogenic avoidable multiple pregnancies from IVF were responsible for 16% of NICU admissions, and for significant avoidable mortality and morbidity, which produce unacceptable financial and emotional costs. If responsible fertility treatments were used in the USA and Canada, it would avoid many unnecessary NICU admissions and many complications to mothers and their children.

Global ethical issues include the world wide infant mortality. While ethical debate in developed countries focus on babies who are admitted to the NICU and are at elevated risk of later disabilities, many babies born in the world still die of benign infections, mild prematurity, and even malnutrition. This ongoing tragedy is beyond the scope of this chapter, but merits considerable reflection and thought.

Conclusions

Most babies who now survive intensive care would have died 40 years ago. Nature would have decided the outcomes. Ethical discussions about initiating or withholding resuscitation would have been unnecessary and irrelevant. Today, policy makers, administrators, families, and physicians often decide if a baby should be offered life-sustaining treatment. These decisions directly affect our society and our population health. A moral framework for making such decisions needs to consider the baby's interests, the family's interest, the cost of care, and availability of resources. While neonatal intensive care is often uncontroversial and beneficial, it can also lead to tragic outcomes that increase pain and suffering at enormous expense. Also, neonatal intensive care should not be seen as the only solution to preterm birth, prevention of prematurity is feasible and should be a public health proirity. Careful consideration of the medical facts, the issues of resource allocation, and the psychological implications of decisions will maximize benefit and minimize harm. While there are no easy formulae to "solve" these dilemmas, open discussion of these issues among clinicians, between clinicians and families will maximize the likelihood that the best decisions are made in each individual case.

Inborn Errors of Metabolism

Pinar T. Ozand

38 Disorders of Organic Acid and Amino Acid Metabolism

Pinar T. Ozand · Mohammed Al-Essa

A large number of pediatric disorders occur as a result of inborn errors occurring in the metabolic pathways of amino acids or organic acids. These diseases are common pediatric problems with dramatic clinical presentations. Their initial clinical presentations differ according to age. A convenient manner of classification is as follows:

1. *Diseases of neonatal onset.* The first clinical symptoms appear soon after birth or within the first few weeks of life. Such diseases are always associated with central nervous system (CNS) symptoms. Occasionally an infant will be born with an encephalopathic picture and stupor, with profoundly disturbed neurologic function at birth. More often, an infant normal at birth will soon develop lethargy, progressing rapidly into coma in association with other severe neurologic signs. The disease will cause neurologic handicaps and death if intervention is not prompt. These diseases are therefore called "devastating metabolic diseases of the newborn." In this age group other systems, particularly the hematopoietic system and the liver, may also be involved.
2. *Diseases of later infancy or childhood.* In this age group amino acid and organic acid disorders will also lead to profound derangement of CNS functions. However, other systems, particularly the liver, might be involved. An important category of diseases is "silent," "neurologic," or "cerebral" organic acidemias. As the name implies, these are diseases that manifest only with progressive neurologic findings, without any disturbance in acidbase, ammonia, or glucose metabolism. As was the case for diseases of neonatal onset, if these disorders are not recognized early, they can lead to neurologic handicaps and death.

Devastating Metabolic Diseases of the Newborn

Clinical Presentations

The main diseases in this category are shown in *Table 38.1*, which does not include some of the rarer entities, but lists only common diseases.

Most of these patients will be normal at birth, except those with nonketotic hyperglycinemia and peroxisomal disorders who have severe stupor and encephalopathy. In the remainder, a prodrome with refusal to feed, vomiting, and lethargy that starts a few hours to days after birth rapidly evolves into profound coma in association with seizures and change of muscle tone. Vomiting may be so severe that occasionally the infant will be diagnosed as having intestinal obstruction or pyloric stenosis, and will undergo unnecessary laparotomy. The dramatic clinical picture is often interpreted as sepsis or meningitis without due consideration for an underlying metabolic disease. Since, at times, the metabolic disease leads to sepsis, proper diagnosis will be missed for many days and the underlying metabolic disease, since it is not treated appropriately, will lead to tragic consequences with irreversible neurologic damage. This is particularly true for maple syrup urine disease (MSUD or branched-chain aminoacidemia); such a patient, for example, is prone to a gram-negative or gram-positive sepsis, and will have no readily detectable clinical biochemical disturbance, leading to diagnosis only when the infant experiences a second devastating episode during the first month of life, by which time the patient will have suffered extensive CNS damage and will not have any hope of treatment.

Despite a great deal of similarity in their clinical presentation, several clinical symptoms give clues to the diagnosis. These clues are described in the following sections.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_38,

Table 38.1
Devastating metabolic diseases of the newborn

Organic acidemias
Propionic academia
Methylmalonic academia
Isovaleric acidemia
3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) lyase deficiency
Multiple carboxylase deficiency
3-Methylglutaconic aciduria
Multiple acyl coenzyme A dehydrogenase deficiency (glutaric aciduria type 2)
Primary lactic acidosis:
Pyruvate carboxylase deficiency
Pyruvate dehydrogenase deficiency
Cytochrome *c* oxidase (COX) deficiency
5-Oxoprolinuria (pyroglutamic aciduria)
Amino acidemias
Urea cycle disorders:
Carbamylphosphate synthetase deficiency
Ornithine transcarbamylase deficiency
Citrullinemia
Argininosuccinic aciduria
Maple syrup urine disease, classic form (classic MSUD)
Diseases associated with encephalopathy and stupor
Nonketotic hyperglycinemia
Zellweger syndrome and neonatal adrenoleukodystrophy
Menkes disease
Miscellaneous disorders
Nesidioblastosis

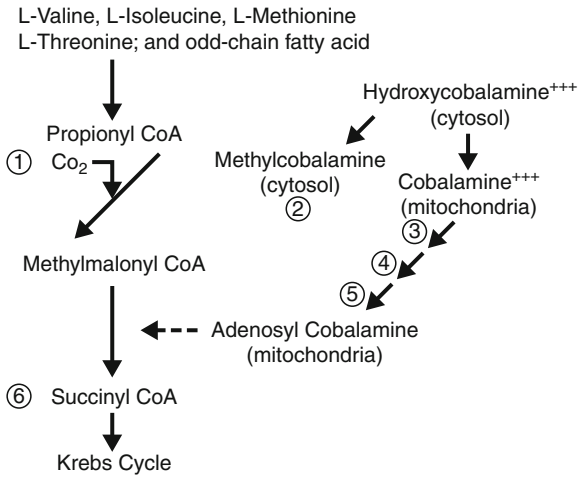

Figure 38.1
Metabolism of propionic and methylmalonic acid. Enzymes involved: (1) propionyl-CoA carboxylase, (2) methylcobalamin, which is involved in the methylation of homocysteine to methionine through the tetrahydrofolic acid methyltransferase, (3–5) two reductases and adenosyltransferase, and (6) methylmalonyl-CoA mutase, the cofactor of which is adenosylcobalamin. Diseases related to deficiency of the aforementioned enzymes: (1) propionic acidemia, (2) homocystinuria with methylmalonic acidemia, and (3–6) methylmalonic acidemia

Organic Acidemias

Propionic Acidemia

This is a disorder caused by the deficiency of propionyl coenzyme A (CoA) carboxylase (*Fig. 38.1*). Approximately half of the patients with propionic acidemia will present with devastating metabolic disease in the newborn period. The biochemical symptoms include metabolic acidosis, hyperammonemia, hypoglycemia, and hyperglycinemia, features shared by other organic acidemias such as methylmalonic acidemia. The pathogenesis is not clear. However, elevated propionic acid in the blood is implicated in the immune deficiency and thrombocytopenia. The central hypotonia is attributed to the neurotoxic effect of tiglyl-CoA that accumulates in the CNS. The hyperammonemia of propionic acidemia is usually severe (>400 μM). The reasons for these findings are shown in *Fig. 38.2*. These babies typically have a face with a depressed nasal bridge (organic acidemic face), except that they usually have a long philtrum of the upper lip (*Fig. 38.3*). A patient with propionic acidemia will almost always show profound central hypotonia. Approximately 25% of the patients will show nipple abnormalities, such as inverted, hypoplastic, or supernumerary nipples. Newborns with the severe form of propionic acidemia will quickly develop sepsis with *Candida* species or unusual bacteria, since the disease causes immune deficiency and hypoplasia of the thymus.

Propionic acidemia in the newborn may be a very confusing disease. It might have a prodrome of vomiting, leading to a misdiagnosis of intestinal obstruction or pyloric stenosis, and unnecessary surgery might be performed. In rare instances, the disease might manifest only with hyperammonemia and lead to an incorrect diagnosis of a urea cycle disorder. The acidosis of

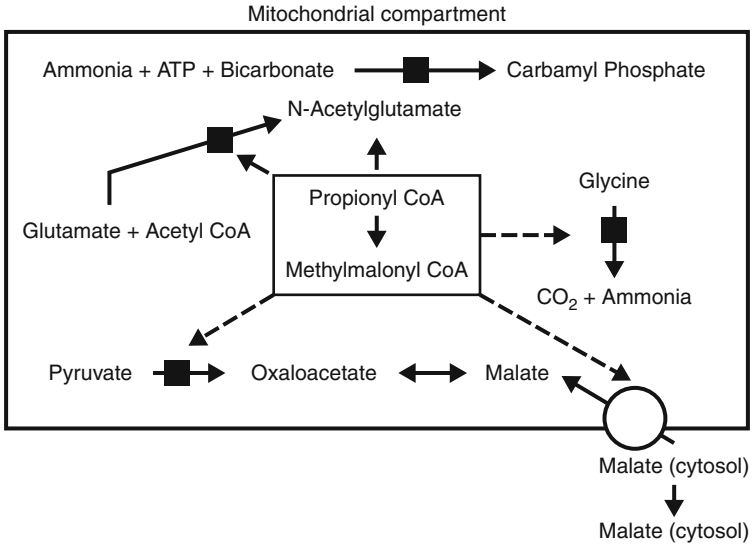

Figure 38.2

Mechanisms of hyperammonemia, hyperglycinemia, and hypoglycemia in patients with propionic acidemia and methylmalonic acidemia; the disturbed mitochondrial functions are indicated by *solid blocks*. Enzymes inhibited by propionyl-CoA or methylmalonyl-CoA and the resultant disturbed biochemical function: (1) pyruvate carboxylase (gluconeogenesis), (2) the transmitochondrial malate shuttle (gluconeogenesis), (3) glycinecleaving enzyme (hyperglycinemia), (4) carbamylphosphate synthetase (hyperammonemia), and (5) *N*-acetylglutamate synthetase (hyperammonemia). *Dashed arrows* indicate the site of inhibition

propionic acidemia is easier to correct than that of methylmalonic acidemia; a newborn with the metabolic crisis of propionic acidemia might have received enough alkalinizing treatment before referral, and only hyperammonemia may remain. A patient with propionic acidemia must be given large amounts of glucose, with insulin if necessary, to establish an anabolic state as quickly as possible. Patients with blood ammonia levels greater than 400 μM should receive peritoneal dialysis despite the danger of *Candida* peritonitis and sepsis, as well as sodium phenylbutyrate. Adequate management of coma can be measured by the disappearance of urine ketones. The disease causes neutropenia and an unusually severe and precipitous thrombocytopenia. Therefore, such a newborn should be monitored daily for platelet counts and must be given platelet transfusions when the count drops to 50,000/mm^3.

This is a disease that can fortunately be diagnosed within less than an hour when a tandem mass spectrometry (MS) system is available. Profound hypotonia in an acidotic baby with the aforementioned dysmorphic features should prompt a workup for propionic acidemia. Any child with hyperammonemia with or without acidosis, with or without treatment for urea cycle disorder, must be given large amounts of glucose and intravenous (IV) L-carnitine, until a definite diagnosis is reached.

Case History. Sultan was the product of a normal pregnancy and term delivery. On the second day of life he started to vomit bile and became lethargic. The parents were first cousins. The family history indicated the deaths of three previous newborns following a similar clinical history. On the third day of life Sultan developed labored respiration and became comatose, soon showing myoclonic seizures. The physical examination indicated a male infant who had no systemic findings, with normal abdominal sounds and a barely palpable liver. He could not be aroused and did not have sucking, rooting, or Moro reflexes. He was extremely floppy and the deep tendon reflexes could not be elicited. A catastrophic metabolic disease was suspected, and a preliminary workup indicated a blood glucose of 3 mM, bicarbonate of 10 mM, blood lactate of 5.6 mM (normal: $\leq$2 mM), blood ammonia of 235 μM (normal: $\leq$92 μM), blood pH of 7.32, base excess (BE) of −12 mEq/L, and 2+ ketonuria. This biochemical profile suggested either propionic acidemia, methylmalonic acidemia, or isovaleric acidemia. Considering that the infant had no foul smell in the diaper area, isovaleric acidemia was considered as remote. Since he was

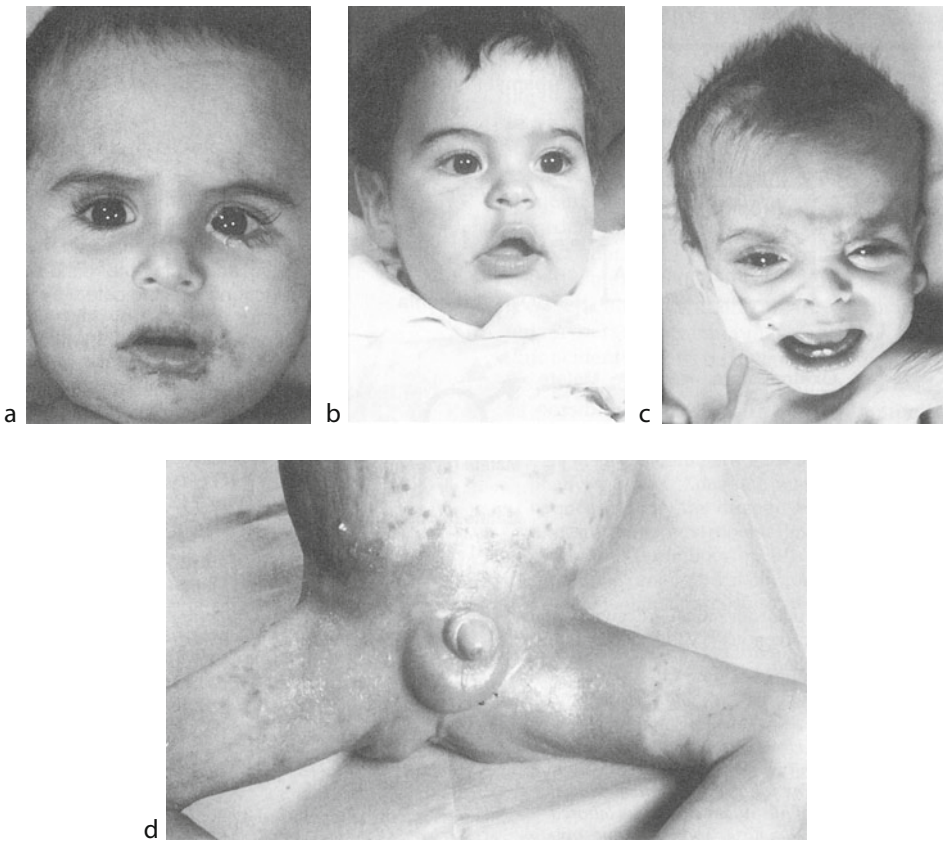

Figure 38.3
(a) An 8-month-old boy with propionic acidemia; note the depressed nasal bridge, partial epicanthic folds, and long philtrum of the upper lip, with *Candida* infection at the corner of lip (culture proven). (b) A 1-year-old girl with propionic acidemia successfully treated, showing the same type of face. (c) A 2-year-old patient with severe propionic acidemia; note the marasmus. He had severe anorexia and had to be fed by NG tube, and he had continuous diarrhea due to poliomyelitis infection. (d) Same patient with the severe *Candida* infection of the skin at the perineum

extremely floppy, a presumptive diagnosis of propionic acidemia was made. He was placed on propionic acidemia formula (a milk formula restricted in isoleucine, valine, threonine, and methionine), L-carnitine (IV 200 mg/kg/day), and biotin (10 mg/kg/day), and the acidosis was corrected by administration of sodium bicarbonate. He promptly responded and there remained no need for peritoneal dialysis or total parenteral nutrition (TPN) with insulin. A few days later the results of the plasma amino acids became available; glycine was 1,860 μM (normal: ≤500 μM; results indicated ketotic hyperglycinemia). A urine gas chromatography/mass spectrometry (GC/MS) revealed greatly increased excretion of 3-hydroxypropionic and methylcitric acids; a blood tandem MS revealed increased propionylcarnitine. All these results confirmed the clinical suspicion of propionic acidemia. Three months later, fibroblasts cultured from a skin biopsy indicated a profound deficiency of propionyl-CoA carboxylase (<5% of normal activity).

Methylmalonic Acidemia

This is a disorder caused by deficient activity of methylmalonyl-CoA mutase (*Fig. 38.1*). The cofactor of the enzyme is activated cobalamin (vitamin B_{12}), and methylmalonic acidemia can be caused by either deficiency of the mutase (mutant 0 or –) or deficiencies of cobalamin-activating enzymes (cobalamin a and b mutants). The pathogenesis of the disease is similar to that of propionic acidemia. Elevated methylmalonic acid is considered to be responsible for the bone marrow depression noted with the disease. The CNS toxicity has been attributed to the inhibition of succinyl-CoA

dehydrogenase, a key component of the tricarboxylic acid cycle, by methylmalonic acid. Patients with methylmalonic acidemia also show the same "organic acid face" (Fig. 38.4), but their muscle tone is usually increased. The ketolactic acidosis of the disease is protracted and will require a prolonged duration of treatment. The hyperammonemia in methylmalonic acidemia is not as pronounced as that of propionic acidemia. The thrombocytopenia and neutropenia during this period are either absent or mild. Such a patient must be administered large amounts of fluid in order to wash out the methylmalonic acid. Injections of 1 mg hydroxycobalamin should be given to any newborn with severe ketolactic acidosis, until the results of tandem MS or GC/MS become available. The tandem MS-based determinations will show elevated propionyl-carnitine in both propionic and methylmalonic acidemia. Therefore, the definitive diagnosis of methylmalonic acidemia is through detection of methylmalonic and methylcitric acids in urine by GC/MS. The response to treatment is easily followed by frequent measurement of urine ketones, which will become negative when the metabolic coma is under control.

Case History. Abdullah was born following an uneventful pregnancy. He was noted to have a heart murmur. The echocardiogram revealed a cribriform atrial septal defect. He refused feeding on the fifth day of life, with frequent vomiting and lethargy. The next day he had difficulty breathing and became comatose. The parents were closely related. The family history indicated the death of a previous infant with acidosis in the neonatal period. The physical examination indicated a 3-cm hepatomegaly, and neurologic examination indicated increased muscle tone and deep tendon reflexes. A metabolic disease was suspected, and biochemical workup indicated a blood pH of 7.20, plasma bicarbonate of 6 mM, blood glucose of 3.1 mM, lactate of 6 mM, and 3+ ketonuria. A presumptive diagnosis of methylmalonic acidemia was reached, and the patient was started on IV L-carnitine and daily intramuscular injection of 1 mg hydroxycobalamin, and his acidosis was corrected by IV administration of sodium bicarbonate. Within days, his clinical condition and acidosis improved. A urine sample obtained during the acute phase revealed a large peak of methylmalonic, methylcitric, and 3-hydroxypropionic acids. The blood acylcarnitine profile as analyzed by tandem MS showed a greatly increased peak of propionyl-carnitine. Therefore, the clinically presumed diagnosis was confirmed. He was placed on the propionic acidemia formula, since both diseases share a common pathway. He was kept on oral carnitine (200 mg/kg/day), daily intramuscular injections of 1 mg hydroxycobalamin, and oral tricitrates (Polycitra, 5 mEq/kg/day), and was discharged home in good condition. At present, Abdullah is 6 years old and has done well on the same regimen, experiencing only two or three acidotic crises in the interval. His intramuscular injections were substituted by intranasal vitamin B_{12} (Nascobal), 0.5 mg b.i.d.

Isovaleric Acidemia

This disorder is caused by the deficiency of isovaleryl-CoA dehydrogenase in the catabolic pathway of L-leucine (Fig. 38.5). The severe form of the disease will manifest

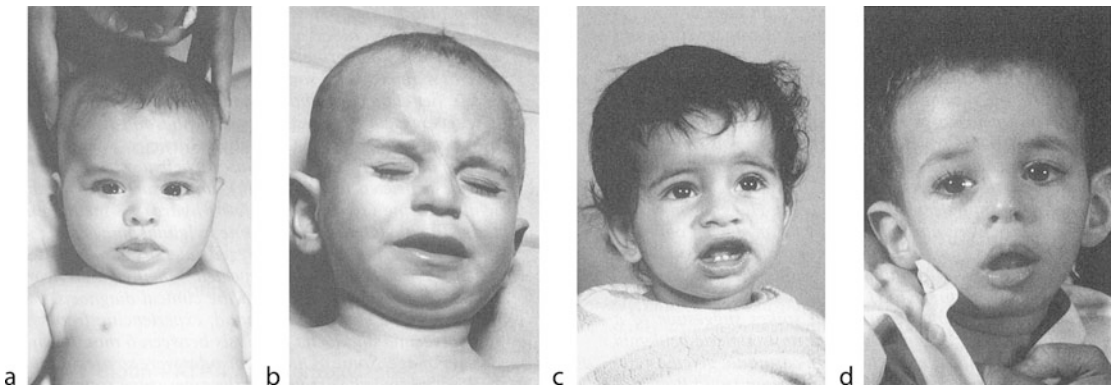

Figure 38.4

(a) A newborn with methylmalonic acidemia; note the wide nasal bridge with pseudoepicanthic folds, and upturned upper lip with short philtrum. (b) A 1-year-old boy with methylmalonic acidemia, with depressed nasal bridge, pseudoepicanthic folds, and upturned upper lip with short philtrum. (c) A 2-year-old boy with methylmalonic acidemia with similar facial features. (d) A 30-month-old girl with methylmalonic acidemia and similar face

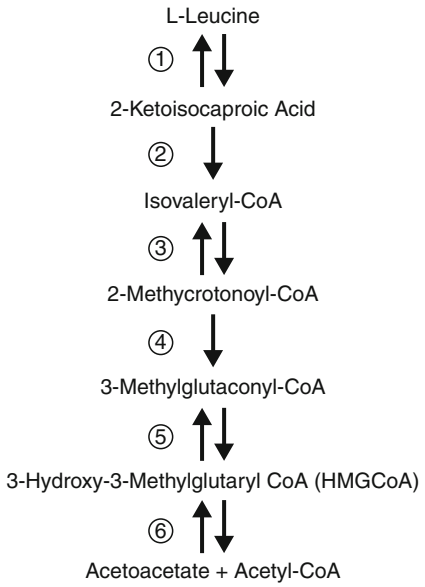

Figure 38.5
Breakdown of L-leucine and the enzymes lacking in various inborn errors of metabolism. Enzymes involved: (1) branched-chain amino acid transaminase, (2) branched-chain α-keto acid dehydrogenase, (3) isovaleryl-CoA dehydrogenase, (4) 3-methylcrotonyl-CoA carboxylase, (5) 3-methylglutaconyl-CoA hydratase, and (6) HMG-CoA lyase. Diseases related to deficiency of the aforementioned enzymes: (2) maple syrup urine disease (MSUD), (3) isovaleric acidemia, (4a) multiple carboxylase deficiency due to biotinidase deficiency, (4b) multiple carboxylase deficiency due to holocarboxylase synthetase deficiency, (4c) 3-methylcrotonyl-CoA carboxylase deficiency, (5) 3-methylglutaconic aciduria due to hydratase deficiency, and (6) HMG-CoA lyase deficiency

by devastating metabolic disease of the newborn. Isovaleric acid has a foul smell, like that of "unwashed feet" or "smelly cheese," and the disease can immediately be suspected by this unusual smell permeating the intensive care unit. The baby usually shows the typical face (i.e., depressed nasal bridge and upturned philtrum) of patients with organic acidemia. The muscle tone is usually increased. A severe form of the disease will cause profound thrombocytopenia and intracranial bleeding. The metabolic crisis will usually occur with sepsis, usually due to a gram-negative organism. This can lead to an erroneous diagnosis of disseminated intravascular coagulopathy (DIC). The DIC can also superimpose as a terminal event. Milder forms of the neonatal disease can have a prodrome of severe continuous vomiting, which can lead to the diagnosis of intestinal obstruction or pyloric stenosis and unnecessary laparotomy. Attacks later in life may be associated with acute pancreatitis. Any newborn with metabolic acidosis or sepsis with thrombocytopenia should receive a workup to rule out propionic acidemia (hypotonic baby), or isovaleric acidemia (baby with increased muscle tone), in order to prevent neurologic damage and death.

Case History. Hoda was 1 month old when she was first seen. The past history indicated that 3 days after birth she had vaginal bleeding that was attributed to maternally transmitted hormones. At 1 week of age severe bleeding from the mouth was observed, and she developed profound acidosis with severe thrombocytopenia and prolonged prothrombin time (PT) and partial thromboplastin time (PTT). The parents were first cousins. Despite the family history of death in the newborn period of an infant with acidosis, this child's condition was attributed to sepsis and DIC. She was treated with platelet transfusion and antibiotics. Her thrombocytopenia persisted and no bacteria could be isolated from the blood or from the cerebrospinal fluid (CSF). A few days after clinical stabilization, she developed a repeated episode of ketoacidosis and a urine sample revealed urine organic acids characteristic of isovaleric acidemia. She was transferred for management. At the time of admission she was jittery, had poor visual tracking, and had severely increased muscle tone and deep tendon reflexes. Her clinical chemistry values were normal, except for a platelet count of 50,000/mm^3. Computerized tomography (CT) studies of the brain revealed frontal white matter disease. The electroencephalogram (EEG) showed disorganized background activity and generalized spikes suggestive of a seizure disorder. She was placed on isovaleric acidemia formula (L-leucine restriction), L-carnitine, glycine (500 mg/kg/day), phenobarbital (5 mg/kg/day), and Polycitra (5 mEq/kg/day). She quickly stabilized. At present she is 5 years old and has no neurologic sequelae. CT of the brain and an EEG were normalized within 1 year. She never experienced a second metabolic attack on the treatment regimen given.

3-Hydroxy-3-Methylglutaryl Coenzyme A Lyase Deficiency

The disease is caused by the deficiency of 3-hydroxy-3-methylglutaryl (HMG)-CoA lyase, which is the final enzyme in the catabolic pathway of L-leucine (*Fig. 38.5*). The ethnic origin of most patients (more than 50%) is the Middle East. Approximately 70% of the cases will manifest before 24 h of life. A typical history is a devastating hypoglycemic lactic acidotic crisis after the first breast feeding. Despite profound acidosis,

there will be no ketones in the urine. The HMG-CoA inhibits gluconeogenesis. Synthesis of ketone bodies in the liver starts from the products of HMG-CoA lyase; therefore, when the enzyme is absent no ketogenesis occurs. This accounts for absent ketonemia in the presence of severe hypoglycemia and lactic acidosis. Upon appropriate treatment, the baby will recover quickly with no neurologic sequelae. A rapid clinical response to glucose and alkalinizing treatment in a newborn, and absent ketosis, strongly suggest the presence of HMG-CoA lyase deficiency. The presence of the deficiency must be quickly established in order to place the baby on appropriate formulas (low fat and leucine restricted) and L-carnitine, and to prevent further devastating attacks, which will recur when the patient fasts or is shifted to solid foods with high-fat and high-protein content.

Case History. Salha was delivered after a normal pregnancy and delivery. Six hours after birth, after first breast feeding, she experienced a devastating metabolic acidosis with severe hypoglycemia. The parents were second cousins. She came from a village where death due to the same disease was known to have occurred in at least six other infants. She was the second child in the family, and the previous sibling was normal. Her liver was 3 cm below the costal margin. The Moro, rooting, sucking, and tonic neck reflexes could not be elicited and she was in a deep coma. The blood pH was 7; CO_2 was 1 mM, blood glucose 0.5 mM, blood lactate 20 mM, and blood ammonia 235 μM, and urine ketones were negative. She was given IV glucose and sodium bicarbonate and, by 1 day of life, her clinical condition and chemistries normalized. The severe lactic acidosis, hypoglycemia, and absent ketonuria suggested HMG-CoA lyase deficiency. She was placed on an HMG-CoA lyase deficiency formula (L-leucine-restricted low-fat milk), and L-carnitine. Meanwhile, a urine GC/MS revealed 3-hydroxy-3-methylglutaric, 3-methylglutaric, and 3-methylglutaconic acids; the blood acylcarnitines as analyzed later by tandem MS, when she was 8 years old, revealed 3-methylglutarylcarnitine, all of which confirmed the clinical diagnosis.

Salha had a stormy childhood, experiencing frequent hypoglycemia and lactic acidosis between 6 months and 3 years of age. Some of these episodes were so precipitous and severe that she arrived at the emergency room (ER) and coded three times during this period, each time being successfully resuscitated. She developed a seizure disorder requiring anticonvulsant treatment. Meanwhile, fibroblasts grown from a skin biopsy revealed the absence of HMG-CoA lyase activity. After 5 years of age her disease became milder, with only infrequent mild acidotic comas. Despite a totally normal clinical appearance, she excretes the urine organic acids and has the acylcarnitine characteristic of HMG-CoA lyase deficiency. At present she is 14 years old, and is an excellent student with no neurologic sequelae or any evidence of seizure activity.

Multiple Carboxylase Deficiency

Multiple carboxylase deficiency (MCD) in the neonatal period is caused by the deficiency of holocarboxylase synthetase (HCS), an enzyme that activates and binds biotin to four apocarboxylases (propionyl-CoA carboxylase, pyruvate carboxylase, acetyl-CoA carboxylase, and 3-methylcrotonyl-CoA carboxylase) (*Fig. 38.6*). The neonatal form of the disease is very severe and will appear with severe ketolactic acidosis resistant to treatment. The symptoms may be attributed to the combination of severe propionic acidemia and pyruvate carboxylase deficiency. Such a newborn will usually show severe hypotonia, hepatomegaly, profound coma, and an irreversible acidosis, which will lead to death in a few days. Since some forms of the disease are responsive to biotin, large doses of this

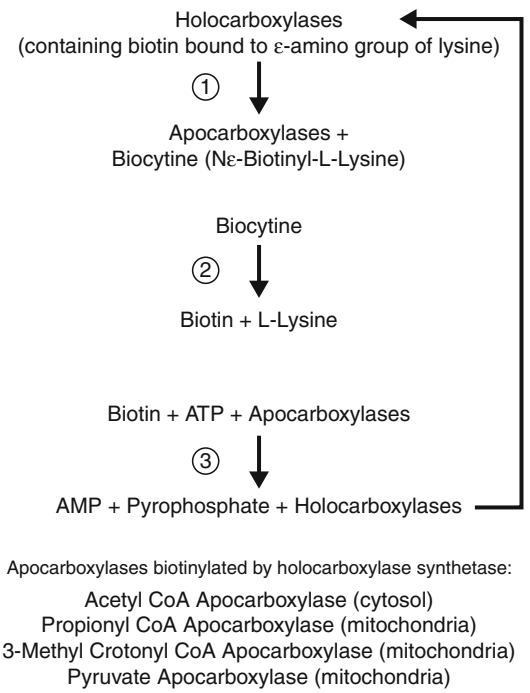

Figure 38.6

Endogenous biotin circle and biotin metabolism. Enzymes involved in biotin addition to apocarboxylases and biotin turnover: (1) normal proteolysis of holocarboxylases (biotin bound to active center), (2) biotinidase, and (3) holocarboxylase synthetase, which adds biotin to all four apocarboxylases indicated

vitamin must be provided in any newborn with ketolactic acidosis. The control of lactic acidosis within a few days in such a newborn will indicate biotin responsiveness, although neurologic damage due to severe acidosis may not be reversed. In families in which a previous sibling died of biotin-responsive HCS deficiency, the mother should be given 100–200 mg/day biotin during the last 1–2 months of pregnancy. If the disease is biotin responsive, the baby will be saved from neurologic crippling and certain death.

3-Methylglutaconic Aciduria

The cause of this disease is unknown, but possibly involves defective utilization of mevalonate (i.e., the mevalonate shunt), which is linked to oxidative phosphorylation. The mevalonate pathway is involved in the syntheses of cholesterol, ubiquinone, and dolichol, important key molecules of cell membranes and oxidative phosphorylation. Therefore, dysmorphic features are common, such as epicanthic folds and undescended testicles. Although a less severe form of 3-methylglutaconic aciduria occurs later during childhood, as a result of 3-methylglutaconyl-CoA hydratase deficiency (◉ *Fig. 38.5*), during the neonatal period it is the more severe form of the disease that will be encountered. Approximately half of the patients with the neonatal form of 3-methylglutaconic aciduria will have severe hypoglycemia (<1 mM) and lactic acidosis (in the range of 6–12 mM). Another variant with no neonatal acidosis and hypoglycemia will also show these biochemical findings periodically, later during infancy. Both variants lead to a rapidly progressive encephalopathy, characterized by severe spastic quadriplegia and death by 1–2 years of age. In both variants of 3-methylglutaconic aciduria, the newborn should be given ubiquinone, phytanedione, and ascorbic acid, since in some instances the disease might be responsive to this treatment. An example of the former variant, with neonatal hypoglycemia and lactic acidosis, is the following patient.

Case History. A male infant was born to first-cousin parents, with two previous children with 3-methylglutaconic aciduria, diagnosed after extensive neurologic damage had occurred. Both of his siblings had devastating metabolic disease with hypoglycemia and lactic acidosis at birth. Due to high risk, this patient was delivered under close observation. When examined at 2 h of age, he was a normal newborn with appropriate reflexes. The blood pH was 7.3, BE −7.5 mEq/L, glucose 3.1 mM, and lactate 3.5 mM at the age of 4 h. At the age of 10 h the baby became obtunded, with labored breathing and cortical fisting, and the blood pH was 7.20, BE −15 mEq/L, glucose 2 mM, and lactate 10.6 mM. He was immediately placed on IV glucose, sodium bicarbonate, phytanedione (0.2 mg/kg/day), ascorbic acid (20 mg/kg/day), coenzyme Q (10 mg/kg/day), L-carnitine, and riboflavin (100 mg/kg/day). His acidosis and hypoglycemia improved over the next week. His neurologic status also improved, and CT of the brain and an EEG were normal. The urine, during both the acute phase and recovery, showed 3-methylglutaconic acid and 3-hydroxyisovaleric acid, confirming the diagnosis. He was discharged home in stable condition without neurologic deficits. When seen next at the age of 3 months, he remained stable.

Multiple Acyl-CoA Dehydrogenase Deficiency

Multiple acyl-CoA dehydrogenase deficiency (MADD) is caused by defective riboflavin-dependent proteins (electron-transfer flavoproteins, or ETFs). The ETFs are essential parts of fatty acids and other dehydrogenases involved in the breakdown of fats: L-leucine, L-isoleucine, and L-lysine. In the absence of ETFs, a complex biochemical picture evolves with predominant formation of glutaric acid (◉ *Fig. 38.7*). This is the reason that the disease is also called glutaric aciduria type 2, implying the formation of glutaric acid from the breakdown of L-lysine. The disease is basically similar to profound riboflavin deficiency, and reflects the teratogenic effect of riboflavin absence on the developing fetus. Such patients show many dysmorphic features, increased muscle tone, and hepatomegaly (◉ *Fig. 38.8*). Eventually, they will develop severe cardiomyopathy and the infant will expire due to either heart or liver failure. The presence of hypoglycemia in a newborn with dysmorphic features should prompt a workup for this disease. The neonatal variant of MADD is usually not responsive to treatment with riboflavin and L-carnitine.

Primary Lactic Acidosis-Pyruvate Carboxylase Deficiency

Pyruvate carboxylase (PyC) is involved in the first step in gluconeogenesis (◉ *Fig. 38.9*). Besides gluconeogenesis, its activity is required for the transport of reducing equivalents from cytosol into mitochondria through the malate/aspartate shuttle. Malate can only enter into, and aspartate can only exit from, mitochondria (◉ *Fig. 38.10*). Therefore, when PyC is deficient, cytosol is in a more-than-normal reduced state and mitochondria are in a less-than-normal reduced state. This leads to a high ratio of blood lactate to blood pyruvate in the presence of low blood 3-hydroxybutyrate/acetoacetate ratios, which is diagnostic for this deficiency; these ratios are normal in pyruvate dehydrogenase (PDH) deficiency and are elevated in other oxidative phosphorylation disorders.

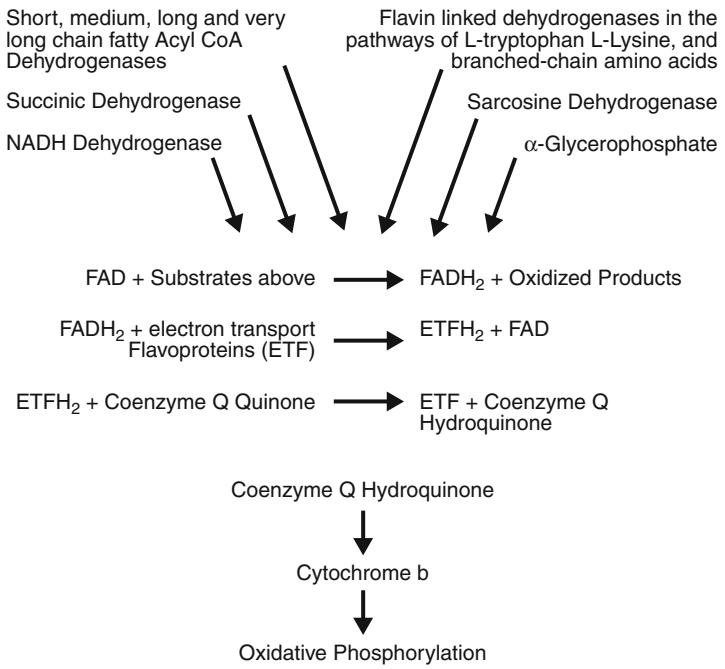

Figure 38.7
Flavin-linked oxidations in mitochondria

Approximately one third of cases with PyC deficiency will manifest at birth with severe refractory ketolactic acidosis, mild hypoglycemia in association with hepatomegaly, and increased muscle tone. The baby will not show intrauterine growth retardation (IUGR), which readily differentiates this acidosis from the primary lactic acidosis caused by PDH deficiency. Despite hepatomegaly, the liver functions are not unduly perturbed. The absence

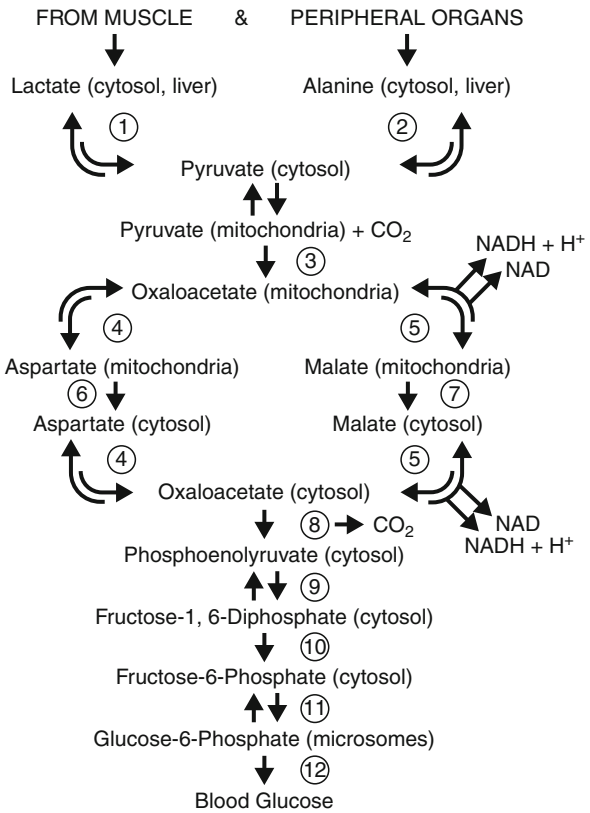

Figure 38.9
Gluconeogenesis in liver. Enzymes involved: (1) lactate dehydrogenase, (2) alanine transaminases, (3) pyruvate carboxylase, (4) oxaloacetate aspartate transaminase, (5) malic dehydrogenase, (6) aspartate port, (7) malate port, (8) phosphoenolpyruvate carboxykinase, (9) triosephosphate enzymes of glycolysis, (10) fructose-1,6-diphosphatase (FDPase), (11) phosphoglucose isomerase, and (12) glucose-6-phosphatase. Steps 3, 6, 7, 8, 10, and 12 are irreversible steps assuring the gluconeogenic flow

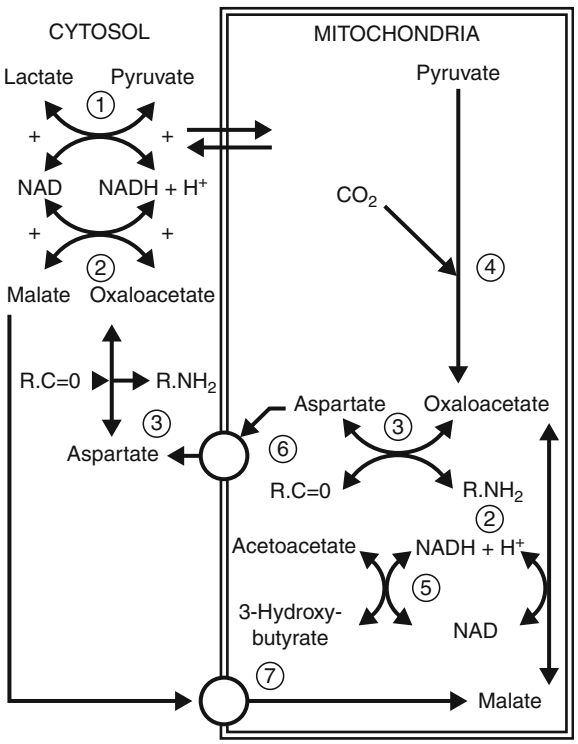

Figure 38.10
Malate-aspartate shuttle. Enzymes and transport systems involved: (1) lactate dehydrogenase, (2) malate dehydrogenase, (3) oxaloacetate aspartate transaminase, (4) pyruvate carboxylase (unidirectional reaction), (5) 3-hydroxybutyrate dehydrogenase, (6) aspartate port (unidirectional, transports aspartate only from mitochondria to cytosol), and (7) malate port (unidirectional, transports malate only from cytosol into mitochondria)

of severe liver and heart involvement differentiates PyC from cytochrome *c* oxidase deficiency. The blood lactate/pyruvate ratio will be greater than 25 (normal: $\leq$25), with elevated alanine. The absence of singly elevated glycine differentiates the disease from propionic, methylmalonic, and isovaleric acidemias of this age group. The blood tandem MS studies in PyC deficiency will indicate significantly elevated acetylearnitine, which is reduced in patients with PDH deficiency.

Case History. Maha was a 1-day-old who was referred for workup of severe neonatal lactic acidosis. She was born to first-cousin parents who lost two babies to a similar disease during the first week of life. She had no dysmorphic features; she showed hyperpnea and tachypnea and was mildly jaundiced. She stayed in the hospital for 6 days, during which time her blood pH ranged from 6.92 on admission to 7.30 at best, despite the administration of large amounts of bicarbonate and tromethamine (THAM). Her BE varied between −28 and −16.5 mEq/L, blood lactate between 12 and 30 mM, and plasma pyruvate between 200 and 400 μM (normal upper limit: 80 μM). The 3-hydroxybutyrate was 200 μM and acetoacetate 400 μM. The lactate/pyruvate rations ranged between 45 and 60 (normal: $\leq$25) and the 3-hydroxybutyrate/acetoacetate ratio was 0.5 (normal: >2). The plasma showed greatly increased alanine, threonine, citrulline, lysine, and phenylalanine. She had continuous

ketonuria, ranging from 2+ to 4+. An ultrasound of the head revealed marked cavitation in the region of the caudate nuclei with surrounding areas of increased echogenicity. CT of the brain further revealed extensive encephalomalacia within the bilateral temporal areas and severe periventricular white matter disease with scattered hypodense lesions throughout the brain. On the sixth day she developed a clinical picture of DIC, shock, hypotension, and bradycardia and died despite intensive support. Postmortem blood culture was sterile. Postmortem muscle biopsy did not show abnormal mitochondria. The muscle stain for cytochrome *c* oxidase was normal. Fibroblasts grown from a skin biopsy revealed profound deficiency of pyruvate carboxylase (3% of normal).

Primary Lactic Acidosis–Pyruvate Dehydrogenase Deficiency

Pyruvate dehydrogenase is active in the first step in the tricarboxylic acid cycle, converting pyruvic acid into acetyl-CoA. In its absence, pyruvate will be reduced into lactate.

The concept of anaerobic versus aerobic glycolysis is shown in Fig. 38.11. Anaerobic glycolysis provides scant ATP; therefore, when aerobic glycolysis is impaired, the newborn will suffer severe energy depletion. As the pathogenic considerations indicate, partial or total PDH deficiency also leads to stunted embryonic growth starting in the third trimester of pregnancy, and these babies will be born as IUGR infants. For the same reasons, the disease causes dysmorphia involving the face, brain, nipples, and viscera. The typical face of an infant with partial PDH deficiency is shown in Fig. 38.12.

The effect of energy deprivation will primarily manifest in the CNS. Therefore, PDH deficiency is incompatible with life if the enzyme is totally absent, or causes severe brain damage if the deficiency is partial. The phenotype is a Leigh encephalomyelopathy with severe lactic acidosis. Respiratory irregularities, such as apnea and "sighing," are common, and provide the most important clue for a diagnosis of PDH deficiency in an IUGR newborn. There will be early optic atrophy. Reflexes will be diminished, with early hypotonia. Magnetic resonance imaging (MRI) of the brain will reveal diffuse or patchy demyelination. The EEG will show a "burst suppression pattern" and profound background changes. The neonatal form of the disease is usually not responsive to treatment with thiamine, lipoic acid, dichloroacetate, or L-carnitine.

Primary Lactic Acidosis–Cytochrome *c* Oxidase Deficiency

The most common disease involving oxidative phosphorylation in the neonate is the deficiency of cytochrome *c* oxidase (COX; complex 4). The disease presents with severe ketolactic acidosis and multisystem involvement, with severe encephalopathy, liver failure, and cardiomyopathy. There is usually early optic atrophy. The presence of liver and cardiac involvement in a neonate should prompt a workup for COX deficiency, which can be achieved by immune histochemical studies for COX in a muscle or liver biospy or by measuring the COX activity in cultured cells. Milder forms of the disease due to partial

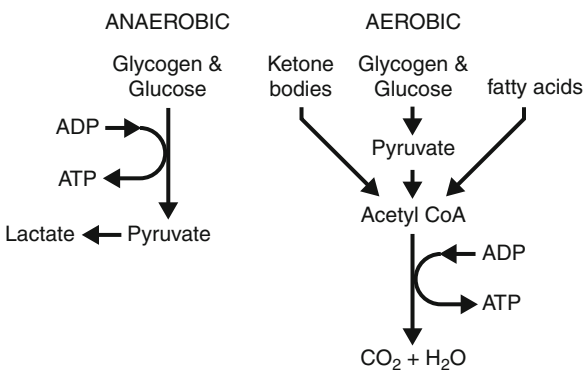

Figure 38.11
Two modes of cellular energy metabolism

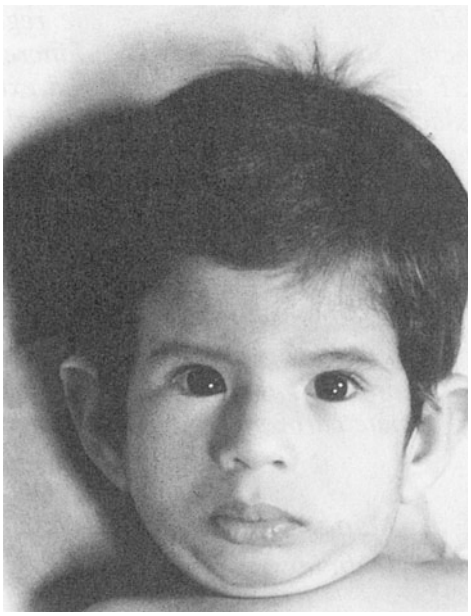

Figure 38.12
Facial photo of a 6-month-old girl with partial pyruvate dehydrogenase deficiency. Note the epicanthic folds, depressed nasal bridge, and the long philtrum of the upper lip

COX deficiency will appear with a similar clinical presentation later during infancy or in childhood. There is no treatment, and the neonatal form of the disease is incompatible with life.

Case History. A female infant developed respiratory distress, cyanosis, severe metabolic acidosis, and hypoglycemia at the age of 8 h in the referral hospital and was referred at the age of 7 days for diagnosis. The parents were first cousins, and three female siblings had died of a similar disease before 2 months of age. The patient's birth weight was 3.5 kg and she was appropriate for gestational age. Her admission weight, height, and head circumference were at the 50th percentile. She had a depressed nasal bridge and a long philtrum of the upper lip. The liver edge was 4 cm below the costal margin. She had mild central hypotonia and diminished deep tendon reflexes. She showed continuous myoclonic seizure activity. Chest x-ray indicated an enlarged heart. CT of the brain indicated cavum septum pellucidum, with bilateral frontal and bitemporoparietal white matter disease, The EEG showed poor background activity and spikes and polyspikes at the parieto-occipital and temporo-occipital areas. During admission her blood glucose values ranged from 3.3 to 5.4 mM; her blood lactate varied between 4.6 and 9.6 mM, and her pyruvate between 82 and 215 μM (normal: ≤80 μM). The lactate/pyruvate ratio varied between 36 and 53 (normal: <25). The muscle biopsy stained for COX revealed a deficiency of the enzyme. Her seizures responded to clonazepam, and she was discharged home. She died at home at the age of 4 months.

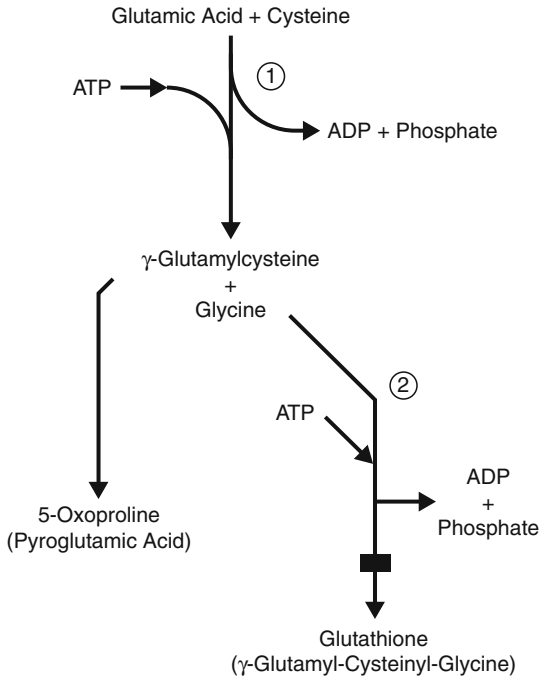

Figure 38.13
Metabolic pathway of glutathione synthesis. Enzymes involved in the pathway and deficiency responsible for pyroglutamic aciduria: (1) γ-glutamylcysteine synthetase, and (2) glutathione synthetase, deficiency of which results in deficiency of glutathione and increased excretion of 5-oxoproline (pyroglutamic acid)

Pyroglutamic Aciduria

This disease is caused by a deficiency of glutathione synthetase. The glutathione synthetic pathway is interrupted, and 5-oxoproline (pyroglutamic acid) is excreted in the urine in large quantities (*Fig. 38.13*). The disease appears as compensated/severe metabolic acidosis in association with mild to severe episodes of hemolytic anemia. Therefore, it combines the clinical features of glucose-6-phosphate dehydrogenase deficiency with those of an organic acidemia. The disease causes a slowly progressive encephalopathy and leads to mental retardation.

Case History. Hameed was referred at the age of 43 days for the evaluation of metabolic acidosis and hemolytic anemia. He developed severe metabolic acidosis at the age of 12 days, and a hemolysis diagnosed as ABO incompatibility. The parents were first cousins, and two of their offspring had expired with a similar disease within their first month of life. Despite the negative Coombs test in the referring hospital, Hameed received exchange transfusions twice. In between exchange transfusions he developed severe metabolic acidosis and increasing indirect hyperbilirubinemia. He also developed heart failure due to severe anemia and had to be digitalized. The urine ketones remained negative, there was no hyperammonemia, and blood lactic acid remained normal during acidotic attacks. At the time of transfer his weight was 2.1 kg, height 49 cm, and head circumference 35 cm. He had hepatosplenomegaly, with both organs measuring 4 cm below costal margins. He had Kussmaul breathing. The blood pH was 7.10, with an anion gap of 22; however, the lactic acid was normal (1 mM) and he had only trace ketonuria. He had glucosuria, phosphaturia, and proteinuria, indicating a renal Fanconi syndrome. Septic workup was negative, CSF analysis was normal, and there was no laboratory evidence of DIC. His hemoglobin was 70 g/L, and reticulocyte count 8%. His indirect bilirubin was markedly elevated (17.8 mg/dL), and liver enzymes were only mildly perturbed. The erythrocyte glucose-6-phosphate dehydrogenase was normal repeatedly, and no abnormal hemoglobin was found by repeated

electrophoresis. He was given continuous alkalinizing treatment by IV and oral bicarbonate solutions and repeated blood transfusions to combat the acidosis and anemia. His clinical condition eventually stabilized, and urine GC/MS revealed large amounts of 5-oxoproline. Further clinical follow-up revealed a child with mild mental retardation, with no renal sequelae of the disease. He had two further attacks between 6 months and 5 years of age, each time with hemolytic anemia and metabolic acidosis.

Amino Acid Disorders

Certain amino acid disorders will appear primarily during the neonatal period. These are the urea cycle disorders (UCDs) and MSUD.

Urea Cycle Disorders

Ammonia is converted into urea through a series of reactions known as the urea cycle (*Fig. 38.14*). The deficiencies of four of these enzymes are important causes of hyperammonemic devastating metabolic disease with normal or elevated blood pH during the neonatal period. The deficiencies of carbamyl phosphate synthetase (CPS) and ornithine transcarbamylase (OTC) are common diseases in the West. All four deficiencies present in a similar manner. The newborn is difficult to arouse to feed early on, and this evolves into a deep coma, which may be associated with myoclonic seizures. There are no associated dysmorphic features or other systemic findings. A normal or elevated blood pH and normal BE (which excludes organic acidemias), with profound coma and absence of alternating hypotonia with hypertonia (a hallmark of MSUD), should alert the pediatrician to a UCD. Such an infant found to have hyperammonemia (>200 μM) should receive either exchange transfusion, peritoneal dialysis, or preferably hemodialysis immediately. Treatment through a nasogastric (NG) tube with sodium phenylbutyrate (500 mg/kg/day) with L-arginine (500 mg/kg/day) should be initiated. L-Carnitine should be given until the absence of propionic acidemia can be established. The administration of L-arginine is essential to prevent CNS damage. The symptoms of UCD are caused by

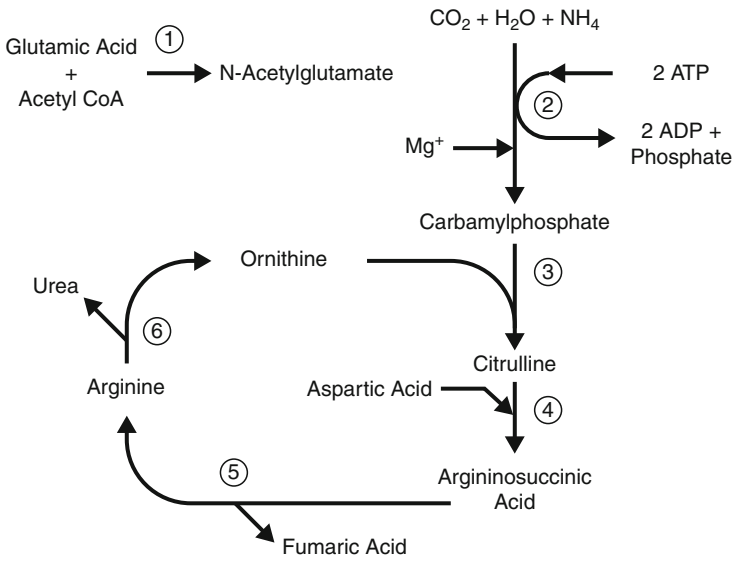

Figure 38.14

Urea cycle. Enzymes involved and related deficiencies: (1) *N*-acetylglutamate synthetase, deficiency of which causes hyperammonemia, (2) carbamylphosphate synthetase (CPS), deficiency of which causes severe hyperammonemia (the enzyme requires *N*-acetylglutamate as an activator), (3) ornithine transcarbamylase (OTC), deficiency of which is an X-linked disease (causes orotic aciduria in addition to hyperammonemia), (4) argininosuccinic acid synthetase, deficiency of which causes hyperammonemia and citrullinemia, (5) argininosuccinic acid lyase, deficiency of which causes hyperammonemia and argininosuccinic aciduria, and (6) arginase, deficiency of which causes periodic hyperammonemia and hyperargininemia

increased glutamine synthesis in glial cells in the CNS due to a high concentration of ammonia, which causes severe brain edema.

Among the four listed disorders, citrullinemia (due to the deficiency of argininosuccinic acid [ASA] synthetase) and argininosuccinic aciduria (due to deficiency of ASA lyase) may have more benign courses compatible with normal life. The hyperammonemia may also develop more slowly than in CPS or OTC deficiencies. There will be lactic acidosis and mild elevation of urinary orotic acid. In these latter diseases the same treatment modalities are used. Sodium phenylbutyrate is given with enough L-arginine to prevent hyperammonemia and the catastrophic elevation of citrulline in the blood. The photo of the patient with citrullinemia described in the following case history (◉ *Fig. 38.15*) shows the typical facial features of the disease. One form of argininosuccinic aciduria is mild and will manifest in later infancy or childhood.

Case History. Rakan developed lethargy progressing into deep coma, myoclonic seizures, difficulty feeding, hypothermia (33.5°C), and peripheral shock at the age of 5 days, for which he was admitted to another hospital. His chemistries at the time of that admission revealed a pH of 7.45, normal blood glucose and CO_2, but ammonia of 330 μM (normal: <129 μM). The symptoms and chemistries supported the diagnosis of a UCD; a Tenckoff catheter was placed and peritoneal dialysis was given. A blood amino acid study indicated L-citrulline to be extremely elevated, at 999 μM (normal: <40 μM), and showed absent argininosuccinic acid. A diagnosis of citrullinemia was reached and he was referred for detailed workup.

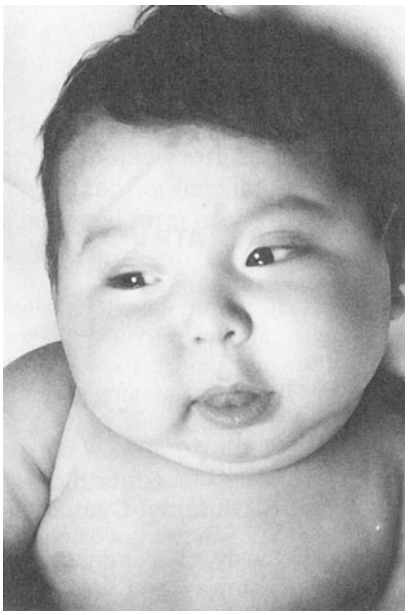

Figure 38.15
The facial appearance of a patient with citrullinemia; note the blepharophimosis, wide nasal bridge, epicanthic folds, and long philtrum of the upper lip

At the time of admission he was 12 days old, obtunded, and pale looking. He had an asymmetric tonic neck reflex and weak Moro, sucking, and rooting reflexes. He had spastic quadriparesis and 3+ increased deep tendon reflexes. The laboratory studies indicated low red blood cell count and hemoglobin (70 g/L). A bone marrow biopsy showed hypoplastic anemia. The ammonia was 168 μM, and citrulline 1,268 μM. He was placed on L-arginine (500 mg/kg), to which he responded promptly, and the ammonia decreased to 30 μM within 24 h. Although an EEG was normal, there was diffuse dysmyelination both infra- and supratentorially. He was discharged home on L-arginine, sodium benzoate (250 mg/kg/day), sodium phenylacetate (250 mg/kg/day), folic acid (5 mg/day), and pyridoxine (25 mg/day). Following a minor respiratory infection, he refused to eat and developed a second hyperammonemic episode at the age of 7 months and had to receive the same treatment. At present he is a very chubby boy and still has mild hypoplastic anemia. Neurologically he could sit independently at the age of 7 months, with good traction response, and he showed normal bipedal reflexes at the age of 8 months. Despite normal ammonia, his last citrulline level at the age of 9 months was 1,845 μM. Later, he had a sister who also had citrullinemia, but her disease was diagnosed at birth. She is growing as a totally normal child on the same therapy as her brother.

Maple Syrup Urine Disease (Branched-Chain Aminoacidemia): Classic Form

This disease is not common in the West, but it is the most common cause of devastating metabolic disease of the newborn in Middle Eastern countries. The disease is caused by a deficiency of branched-chain α-keto acid dehydrogenase (◉ *Fig. 38.16*). Since MSUD does not create biochemical disturbances readily detectable by the routinely available clinical biochemical analyses, it will be missed frequently. It has a typical prodrome. It remains asymptomatic for 5–7 days of neonatal life. The mother notices that the infant refuses to take the nipple and will spit out the milk as soon as it is given, but will tolerate water. The disease then rapidly progresses into a coma with myoclonic or grand mal seizures, and sepsis might be superimposed. Clinically the baby will show alternating

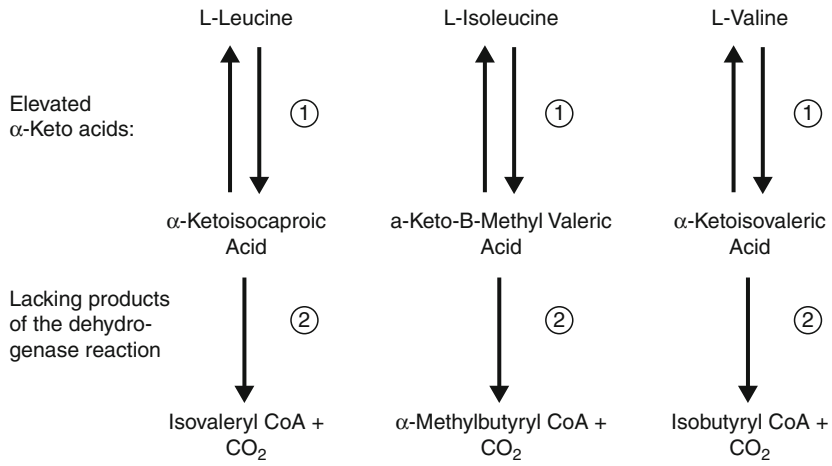

Figure 38.16
The branched-chain amino and α-keto acids elevated in maple syrup urine disease. (1) Branched-chain transaminase. (2) Branched-chain α-keto acid dehydrogenase that is missing in patients with MSUD

hypotonia and increased muscle tone and will show opisthotonus (*Fig. 38.17*). The reason for these symptoms is brain swelling or edema caused by elevated L-leucine, particularly in the brain stem. CT or MRI of the brain is so characteristic that an experienced radiologist can recognize MSUD and alert the pediatrician before laboratory results become available (*Fig. 38.17*). The keen clinician or parent will easily pick up the sweet smell of maple syrup coming from the diaper area, under the armpits, or the hair. A urine dinitrophenylhydrazine test will be strongly positive and can be secured within an hour in most settings. These two simple observations will raise suspicion in all cases. The diagnosis can then be confirmed by special analyses. Classic MSUD has poor prognosis if it is diagnosed after 2–3 weeks of life. Such a baby will incur such severe CNS damage, suffering frequent septic episodes and progression of the CNS damage, that the infant will not recover even after vigorous treatment. In the long run, even the best-controlled patients with MSUD may have some degree of neurologic damage. The disease is frequently associated with dermatitis due to disturbed L-leucine/L-isoleucine/L-valine ratios (*Fig. 38.17*). Poorly controlled patients will have abnormally long eyelashes and prominent fat pads in the cheeks due to malnutrition (*Fig. 38.17*).

MSUD is a true pediatric emergency and should be immediately and vigorously treated. The aim of the treatment is to reduce the blood level of branched-chain amino acids (BCAAs), particularly L-leucine, which are responsible for the brain edema. The primary source of L-leucine in a fasting infant is muscle, released through catabolism. In a newborn of 3 kg, 48 h of fasting will raise the blood leucine level to near 3,000 μM (normal upper limit: 120 μM). Therefore, the treatment includes administration of high levels of calories in the form of dextrose and lipids given together with regular insulin administration (1–1.5 U/kg) every 6–8 h, or given as a continuous drip. The blood glucose should be monitored to prevent hypoglycemia; when present, it should be corrected by extra glucose administration or by withholding the next injection of insulin. In a newborn with profound MSUD coma, peritoneal dialysis or exchange transfusion should be performed. If the newborn tolerates it, the MSUD formula should be slowly administered through the NG tube. The case histories of a poorly controlled and a well-managed MSUD patient are presented below.

Case History. Mohammed was the first child of a first-cousin marriage; he had poor Apgar scores, 3 at 1 min and 5 at 3 min, with meconium aspiration. He had continuous lethargy and was hospitalized in the neonatal intensive care unit for 10 days. At home he started to refuse breast feeding and developed generalized myoclonic seizures and opisthotonus with apneic spells at the age of 14 days. He was hospitalized at a peripheral hospital and suffered cardiorespiratory arrest at the age of 16 days. His blood gases, pH, glucose, CO_2, lactate, and ammonia were all within normal limits. The physician suspected MSUD, since the patient's urine and diaper area smelled of maple syrup. A blood sample revealed very elevated L-leucine, L-isoleucine, and L-valine levels of 2,030, 1,732, and 780 μM, respectively (normal upper limits: 175, 80, and 300 μM, respectively). He was referred for admission

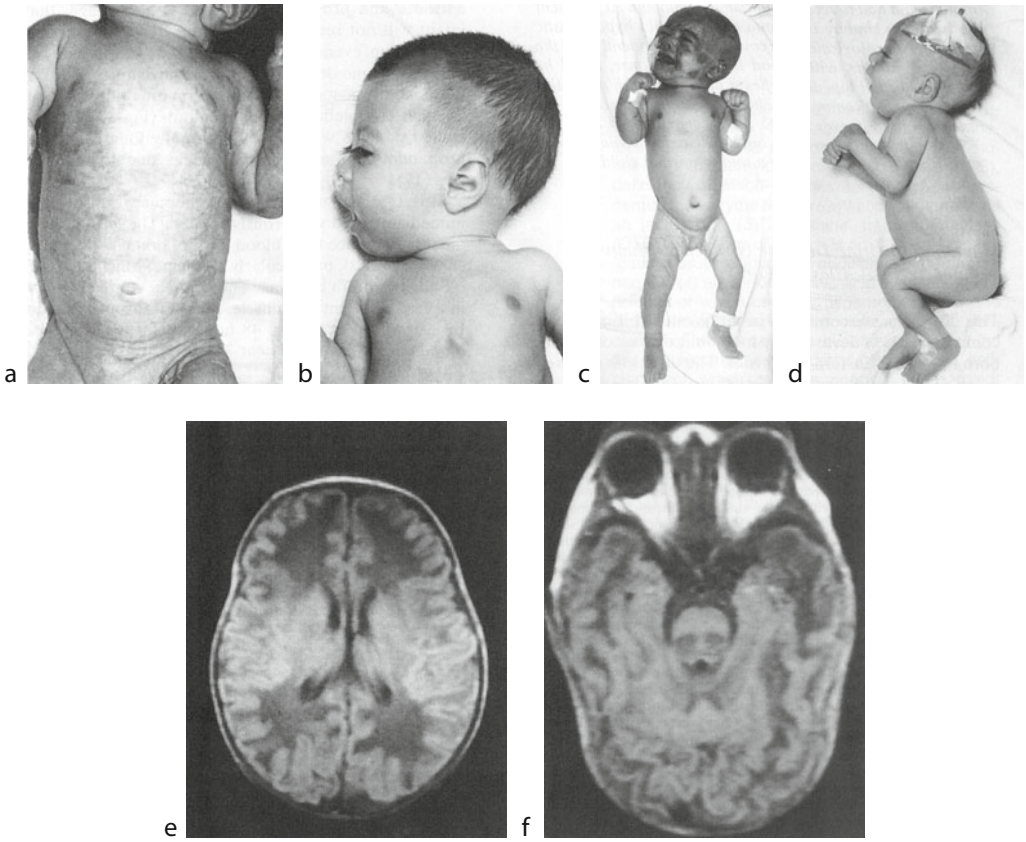

Figure 38.17

MSUD. (a) The body rash due to imbalance of branched-chain amino acids in blood. (b) Evidence of malnutrition on the face; very long eyelashes and fat accumulation in cheeks. (c) Skin lesions on cheek, severe pyramidal tract signs as evidenced by cortical fisting. (d) Opisthotonic posture is evidence of brain stem lesion. (e) MRI of the brain showing the severe central white matter disease in a neonate with MSUD. (f) MRI of the mesencephalon in the same infant showing the characteristic lesions of MSUD in the pons and brain stem

and management at the age of 3 weeks. Physical examination indicated optic atrophy, severe dermatitis in the diaper area, liver edge 2 cm below the costal margin, opisthotonus, and quadriplegia with increased deep tendon reflexes. CT of the brain indicated severe white matter disease. He was managed by an MSUD diet (L-leucine-, L-isoleucine, and L-valine-restricted milk), thiamine (100 mg/kg/day), and a pediatric trace element mixture (1 mL/day). He was discharged home in good clinical condition. The parents were extremely conscientious and followed the diet strictly. Over the subsequent 15 months, he never had another metabolic crisis and his blood levels of BCAAs returned to within normal limits. However, at the age of 15 months he still had mild optic atrophy, he could not sit independently, and he had central hypotonia. His verbal and social skills were approximately at the age level of 12 months. CT of the brain indicated generalized atrophy and a thin corpus callosum. The EEG was normal at the age of 15 months.

Case History. Lulwa was 8 days old at the time of admission. She was normal at birth. At the age of 5 days she started to refuse feeding, cried frequently, and showed myoclonic seizures and opisthotonus. The parents were first cousins and had 11 children, 6 of whom died of a presumed "hyperammonemic" disease. At the time of admission she was in deep coma, showing frequent myoclonic jerks, with alternating hypo- and hypertonia. She had opisthotonus, cortical fisting, and 4+ increased deep tendon reflexes. She had bilateral optic atrophy. An initial workup revealed normal blood gases, pH, glucose, CO_2, lactate, and ammonia. MSUD was suspected. A urine dinitrophenylhydrazine test was strongly positive. Plasma amino acids revealed the L-leucine level to be 3,127 μM (normal: $\leq$175 μM); L-isoleucine and L-valine were also

elevated, at 966 and 839 μM, respectively (normal: ≤80 and 300 μM, respectively). A Tenckoff catheter was placed and she was given peritoneal dialysis for the next 6 days. She developed coagulase-positive Staphylococcus aureus sepsis and peritonitis on day 15, but responded well to vancomycin treatment. She was placed on MSUD formula. CT of the brain at the age of 18 days showed severe demyelination. The EEG revealed no state transition and was disorganized. The brain stem auditory evoked response (BAER) showed severe brain stem dysfunction. The levels of BCAAs became normal by the tenth day of admission, and she was discharged for clinical follow-up.

Her subsequent clinical course has been very benign. The parents were most conscientious, and Lulwa never had a second metabolic crisis. At the age of 12 months the patient was so normal that the mother discontinued the diet, believing she was cured. Her blood BCAAs rapidly increased and she started to show cerebellar ataxia, irritability, and somnolence. She was placed on the diet again and improved quickly. At the age of 22 months she was age-appropriate neurologically. She did not have optic atrophy, and her BAER and EEG were normal. MRI of the brain was within normal limits except for mild periventricular demyelination. Her plasma BCAAs could be maintained near normal limits. At present she is 9 years old, and for all purposes she is a normal child with no neurologic sequelae, except for moderate attention-deficit disorder.

Diseases Associated with Neonatal Stupor and Encephalopathic Presentation

This category contains nonketotic hyperglycinemia, peroxisomal diseases, and Menkes disease. These three disorders do not show an evolving clinical picture, but are usually associated with severe encephalopathy in a newborn. Therefore, they are easily confused with the devastating metabolic diseases of the newborn since an accurate history might not always be available. They should always be included in the differential diagnosis.

Nonketotic Hyperglycinemia

This disease is caused by a defect in the glycine catabolic pathway, leading to accumulation of glycine in blood, CSF, and urine. Such babies are born with severe encephalopathy, showing myoclonic seizures, and the disease is usually confused with either 3-methylglutaconic aciduria or Zellweger syndrome. All three diseases show hypotonia, but the hypotonia in nonketotic hyperglycinemia is so severe that the patient has stridor. Glycine is the neurotransmitter for anterior horn cells in the spinal cord, and, when hyperglycinemia is present, hypotonia is observed. Patients with nonketotic hyperglycinemia do not have many facial dysmorphic features but may have partial or total agenesis of the corpus callosum. They will not have other systemic findings. Some cases of nonketotic hyperglycinemia can be managed with dextrometorphan (25–35 mg/kg/day) and sodium benzoate (500 mg/kg/day).

Case History. Hamad was 3 months old at the time of referral. His mother noted decreased fetal movements during pregnancy. At birth he was extremely hypotonic and required ventilatory support for 2 weeks. After discharge the parents noticed that he never vocalized and had very poor sucking. At home they also noticed him to have jerky movements of the neck and limbs. The parents were first cousins, and another baby had died soon after birth with a similar complaint. Hamad was referred with a presumed diagnosis of Menkes disease. At the time of admission he had a dolicocephalic head. His height, weight, and head circumference were all less than 3%. He showed polyfocal myoclonic jerks. He did not respond to visual threat, loud sound, or cueing. Eyegrounds examination showed pale optic discs and possible retinitis pigmentosa. The microscopy of the hair was normal. He never showed ketosis. Urine GC/MS for propionic acidemia was negative. Serum copper and ceruloplasmin were normal. Blood chemistries, including lactate, were normal. Plasma amino acids showed greatly increased glycine, at 1,123 μM (normal upper limit: 500 μM), and the glycine concentration in the CSF was 235 μM (normal upper limit: 10 μM), with a CSF glycine/blood glycine ratio of 20 (normal: 0.02), confirming the diagnosis of nonketotic hyperglycinemia. The knee x-ray did not indicate abnormal stippling seen in peroxisomal disorders. CT of the brain showed partial agenesis of the corpus callosum and severe diffuse dysmyelination or demyelination in the centrum ovale. The EEG was abnormal, with slow background, very frequent discharges, spikes, and polyspikes. He was placed on sodium benzoate (500 mg/kg/day) and dextromethorphan (35 mg/kg/day). He was lost to follow-up.

Zellweger Syndrome and Neonatal Adrenoleukodystrophy

The absence of peroxisomes due to a failure of peroxisomal assembly (Zellweger syndrome), or absence of oxidizing enzymes for very-long-chain fatty acids (neonatal adrenoleukodystrophy), is highly teratogenic to the developing fetus. Both diseases appear with severe myoclonic seizures. Patients with Zellweger syndrome have typical dysmorphic features, which may not be as

apparent in a patient with neonatal adrenoleukodystrophy. Zellweger syndrome is associated with systemic findings that include facial and cranial dysmorphia, earlobe creases, eye involvement in the form of cataracts and retinitis pigmentosa, hepatomegaly, skeletal findings indicating abnormal bone maturation in the form of stippling of the patella or femur heads, and severe central hypotonia. The appearance of a typical patient with Zellweger syndrome is shown in ❯ *Fig. 38.18*. These findings are missing in nonketotic hyperglycinemia. Most dysmorphic features characteristic of Zellweger syndrome might also be observed in another teratogenic disease, such as MADD; however, the latter will show intermittent severe hypoglycemia, while this is not a feature of peroxisomal diseases.

Case History. Hasna was a 2-month-old infant at the time of admission. She was the product of a 37-week gestation with assisted breech delivery. Her birth weight was 2.3 kg and she was extremely floppy at birth, unable to support respiration and requiring intubation and assisted ventilation for 3 weeks. The mother had a previous baby girl similar to Hasna who had numerous dysmorphic features, including a high forehead, depressed nasal bridge, cloudy cornea, cataracts, bilateral talipes, and elevated aspartate transaminase (AST) and alanine transaminase (ALT), who died at 7 months of age. On admission, Hasna's height and weight were 48.5 cm and 2.7 kg, respectively, significantly below the fifth percentile. She was jaundiced, with various dysmorphic features that included a broad forehead, shallow orbits, proptosis, depressed nasal bridge, wide anterior fontanel measuring 5 × 6 cm, highly arched palate, low-set ears, and micrognathia. She had an ejection systolic murmur. A firm and sharp liver edge was felt 3 cm below the costal margin. The spleen tip was palpable. She had normal external genitalia with a normal-size clitoris. She had severe central hypotonia and diminished reflexes. Pertinent laboratory findings were ALT of 402 U/L (normal upper limit: 43 U/L), AST of 578 U/L (normal upper limit: 40 U/L), and total bilirubin of 63 μM (normal upper limit: 21 μM). Plasma amino acids, blood gases, glucose, pH, urine ketones, and urine GC/MS were not remarkable. A skeletal survey indicated coronal clefts in the vertebrae and focal calcifications in the patella and in the posterior ends of the lower ribs. No cysts were observed in the liver, kidney, or spleen. EEG showed absent sleep spindles. The very-long-chain fatty acids in plasma were elevated: C26 was 3.33 μg/mL (normal upper limit: 0.24 μg/mL), with normal phytanic acid of 1.71 μg/mL (normal upper limit: 5.6 μg/mL), which confirmed the clinical diagnosis of Zellweger syndrome.

Menkes Disease

Menkes disease is caused by defective transport of copper into and out of cells, particularly neurons. The deprivation of copper in cells will impair oxidative phosphorylation

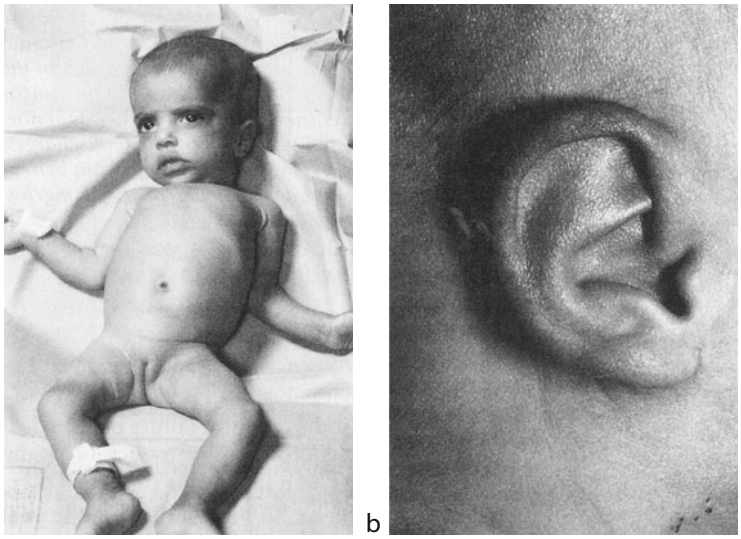

Figure 38.18
(a) A 1-month-old girl with Zellweger syndrome; note the head structure, severe hypotonia, and distended abdomen due to hepatomegaly. (b) The earlobe creases typical of Zellweger syndrome

and development of elastic tissue and hair. The consequences of the disease therefore are early dementia with typical facial structure due to sagging cheeks, abnormal hair structure or pili torti (Fig. 38.19), tortuous vessels in the brain and viscera leading to early subdural hematoma, diverticula in the bladder leading to rupture and acute abdomen, and copper-deficiency anemia. The disease is usually suspected in an infant with encephalopathy and stupor after one of the aforementioned complications occur. Early or prenatal administration of histidine-copper chelate (1 mg copper/day) has been found to be effective in the treatment of this disorder.

Case History. Nasser was 9 months old at the time of admission. The mother noted that he would not follow her visually at the age of 1 month, at which time he was severely floppy. He had myoclonic seizures at the age of 2 months following a febrile disease. He was admitted to another hospital at the age of 7 months, since the seizures could not be controlled. The family history indicated the death of another male sibling at 18 months and the presence of a normal boy at age 13 months. On examination the patient was found to have sagging cheeks, no visual tracking, no response to sounds, and severe central hypotonia. Microscopy of the hair indicated pili torti. MRI of the brain revealed a large bilateral subdural hematoma and diffuse white matter disease. A cystogram revealed no diverticula but right-sided reflux. Cerebral and abdominal angiograms did not reveal arterial tortuosity. Serum copper was 3 μM (normal: 11–22 μM), and ceruloplasmin was 50 mg/L (normal: 120–350 mg/L). Peripheral blood showed hypochromic, microcytic anemia with many target cells. He was not given chelated copper treatment, considering the advanced stage of disease. He was followed in the clinic until 3 years of age, at which time he died at home.

Miscellaneous Disorders

In the neonate with nesidioblastosis or in infants of diabetic mothers (IDMs), the severe hypoglycemia and seizures might be confused with the encephalopathies created by the deficiencies of fatty acid-oxidizing enzymes, and particularly by MADD.

Nesidioblastosis

At times a newborn with nesidioblastosis might be referred for the workup of an inborn error of metabolism. The hypoglycemia in an infant with nesidioblastosis is unremitting, but such a neonate is otherwise normal. Discordance between glycemia and blood insulin and elevated C-peptide levels easily reveals the disease. In borderline instances, a leucine provocation test by means of the administration of 100 mg/kg L-leucine will invariably cause hypoglycemia and an increase in blood insulin and C-peptide.

Diagnosis

Clinical Differential Diagnosis

The devastating metabolic diseases of the newborn are serious pediatric emergencies in most instances. The neonatologist must reach a quick presumptive diagnosis and initiate the treatment promptly. There are several clinical

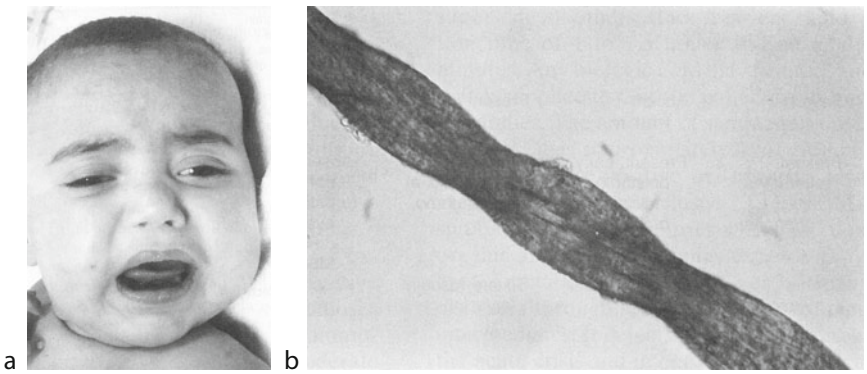

Figure 38.19
(a) Facial photo of an 8-month-old boy with Menkes disease; note the chubby cheeks. (b) Microscopic appearance of his hair, which shows ''pili torti''

and biochemical clues that will guide the pediatrician to a reasonably correct presumptive diagnosis. The helpful clinical signs are summarized in *Table 38.2*.

Certainly the tone of the infant is most helpful. For example, central hypotonia is suggestive of propionic acidemia and Zellweger syndrome. Alternating tone and opisthotonus are pathognomonic of MSUD. Hypertonia suggests methylmalonic acidemia or isovaleric acidemia. Seizures indicate primary gray matter involvement; they are very severe and invariably present in nonketotic hyperglycinemia, MSUD, and Zellweger syndrome. Unless hypoglycemia or anoxia and profound acidosis are present, seizures occur rarely in other devastating metabolic diseases. Subtle dysmorphic features are certainly most helpful indicators. In a case of primary lactic acidosis, for example, the presence of dysmorphia in an IUGR patient is very suggestive of PDH deficiency. In a baby with hypoglycemia, dysmorphic features support the diagnosis of MADD. Severe and persistent hypoglycemia in an otherwise normal infant suggests the presence of

Table 38.2
Devastating metabolic diseases of the newborn: clinical signs and symptoms

Category of diseases	Hypotonia	Hypertonia	Seizures	Dysmorphia	Liver disease	Associated infections
Organic acidemias	Present (e.g., propionic academia)	Present (e.g., methylmalocni academia, isovaleric academia)	Usually present (can be myoclonic or grand mal seizures)	Involving brain, midfacial structures, philtrum of the lip; different dysmorphia in different organic acidemias	Present in fatty acid oxidation disorders and diseases of oxidative phosphorylation	Almost always present, confusing the diagnosis; *Candida* species, gram-negative and -positive microorganisms
Urea cycle diseases	Severe	Absent	Present (usually myoclonic)	Absent	Preserved normal liver enzymes in plasma	May be present
Maple syrup urine disease (MSUD) (brached-chain) amino academia)	Present, alternates with hypertonia	Present, early opisthotonus indicating brain stem disease	Present (usually myoclonic, at times grand mal)	Absent at birth but all patients eventually develop the MSUD face	Absent	Almost always present, mainly gram-negative and unusual microorganisms
Nonketotic hyperglycinemia	Severe hypotonia, stridor, encephalopathy with stupor	Absent	Severe (usually myoclonic)	Absent	Absent	Usually absent
Zellweger syndrome and other peroxisome diseases	Severe encephalopathy with stupor	Absent	Severe (usually myoclonic)	Typical face, earlobe, abnormalities; dysgenesis of brain, retina, bones, liver, and kidney	Early liver disease with elevated bilirubin and liver enzymes in blood	Usually absent
Nesidiobastosis	Absent	Absent	Present (usually grand mal seizures)	Absent	Absent (inappropriately elevated insulin or C-peptide in the presence of hypoglycemia)	Absent

nesidioblastosis. Hepatomegaly and liver disease are associated with COX deficiency and MADD and Zellweger syndromes. Intercurrent infections with unusual organisms, and in terminal patients DIC, are almost always observed in cases of propionic acidemia and MSUD. Neonates with propionic acidemia are prone to infections with *Candida*.

Biochemical Differential Diagnosis

The presumed clinical diagnosis must be supported rapidly by chemical tests that are available in most clinical care settings. These are blood gases and pH, blood glucose, ammonia, lactic acid, and simple urine ketone testing. A combination of results of these tests will allow the clinical diagnosis to be refined. A summary of findings of these clinical chemistry tests is shown in ❯ *Table 38.3*.

The presence of overt or compensated acidosis, for example, in the presence of hyperammonemia is indicative of an organic acid disorder, while the absence of acidosis, with or without alkalosis, in a patient with hyperammonemia indicates a UCD. The absence of mild/moderate acidosis, hypoglycemia, and ketone bodies in a profoundly comatose newborn strongly suggests MSUD. The presence of severe hypoglycemia in an otherwise normal newborn is suggestive of nesidioblastosis, unless the baby is an IDM. The presence of severe persistent lactic acidosis suggests a primary lactic acidosis due to an oxidative phosphorylation defect, although urine ketones will test positive. In HMG-CoA lyase deficiency, on the other hand, urine ketones are absent despite severe lactic acidosis and hypoglycemia. The presence of severe ketolactic acidosis is suggestive of propionic acidemia, methylmalonic acidemia, and isovaleric acidemia. In patients with 5-oxoprolinuria despite severe acidosis, no lactic acid or ketones are detected, and the patient has hemolytic anemia.

Conclusive Diagnosis

Treatment must be initiated with the aforementioned clinical and biochemical clues. However, the diagnosis

Table 38.3
Devastating metabolic diseases of the newborn: associated biochemical findings

Category of disease	Blood pH	Blood glucose	Blood ammonia	Blood lactic acid	Urine ketone bodies
Organic acidemias	$<$7.35 or BE $>$ $-$5.0 mEq/L	Normal or mild/severe hypoglycemia	Usually mild/severe elevation	Usually mild/severe elevation	Normal or mild/severe positive
Urea cycle diseases	Normal or alkalotic with no appreciable BE	Normal	Rapidly rising within days or hours of birth, raising $>$400 μM	Normal; may be elevated in citrullinemia	Normal
Maple syrup urine disease (MSUD)	Normal	Normal in newborn; moderate hypoglycemia later during MSUD crisis in infancy	Normal	Normal	Normal in newborn but mildly/strongly positive later during MSUD crisis in infancy
Nonketotic hyperglycinemia	Normal	Normal	Normal	Normal	Normal
Zellweger syndrome and other peroxisome diseases	Normal	Normal	Normal	Normal	Normal
Nesidioblastosis	Normal	Severe hypoglycemia, either continuous or episodic	Normal	Normal	Normal

must then be confirmed at a tertiary care center where sophisticated specialized biochemical tests are available. These tests include GC/MS study of organic acids in the urine and CSF; amino acid quantification by high-performance liquid chromatography (HPLC) in blood; tandem MS studies in blood, urine, and CSF; and enzyme measurements in leukocytes, cultured fibroblasts, or lymphoblasts. The use of these tests and the findings in each disease are summarized in *Table 38.4*.

These tests, particularly GC/MS, require technical expertise, and they are usually time consuming. For example, GC/MS is an excellent method for the diagnosis of organic acidemias. However, it will require transport of the urine sample to the laboratory in a cold state, and the results will not usually be available in fewer than 2–3 days. Only a limited number of samples may be run per week (e.g., 40), which delays the reports further, unless several technicians and machines are present. In certain organic acidemias, such as fatty acid oxidation defects, the results of GC/MS will usually be equivocal. GC/MS is useful only for the analysis of organic acids during the metabolic crisis; the results might be equivocal in between attacks. The HPLC technique is excellent for quantification of amino acids, but it also has the same drawbacks listed for GC/MS. Unless a special request is made, argininosuccinic acid will not be measured.

Tandem MS is a new technique and will undoubtedly supersede all others, since it is very rapid, with a preparation time of 1–1.5 h and an analytical time of 2 min. Any biologic fluid may be used, and these samples may be applied to Gutherie paper, dried, and sent or mailed for studies. The amount of sample required is minimal; for example, it is approximately 7 μL for blood. There are few or no false-positive or false-negative results; the results are almost always conclusive. Tandem MS is particularly suitable for use in countries where the number of diverse organic and aminoacidemias exceeds all other inborn errors of metabolism. It detects over 30 organic or amino acid disorders through semiquantitative estimation of relevant intermediates. It detects most of these diseases both during the acute crisis and in between metabolic attacks. It is the gold standard for fatty acid oxidation disorders. The cost of reagents required is minimal. Since it detects only propionylcarnitine, it does not differentiate between propionic and methylmalonic acidemias. However, this does not pose a particular difficulty, since the treatments of both disorders are alike, and the newborn can be placed on treatment covering both possibilities until the results of GC/MS become available. Its only drawbacks are the substantial cost of the machine and the sophisticated technical expertise required.

Special enzyme tests, except in a few instances where red blood cells may be used, usually will not provide results before a couple of months, since cultured cells, and not leukocytes, are the preferred source. Only a few laboratories have the required expertise, and the maintenance of a cell culture laboratory and repository are very costly.

Genetics and Incidence

In the absence of a comprehensive neonatal screening for these disorders, it is impossible to state the incidence of devastating metabolic diseases of the newborn. In descending order, primary lactic acidosis, methylmalonic acidemia, propionic acidemia, and MSUD are the most frequently observed causes for devastating metabolic diseases of the newborn. These four account for approximately 60–80% of cases of these disorders. Isovaleric acidemia, HMG-CoA lyase deficiency, and 3-methylglutaconic aciduria occur less frequently.

With recent advances in molecular genetics, the gene locations for most of these disorders are increasingly established. The genes involved in causing devastating metabolic diseases of the newborn are listed in *Table 38.5*. An increasingly available diagnostic approach is to establish the diagnosis through genotyping, using the cDNAs available for the gene. Such a molecular genetic approach is particularly useful in screening the population for the prevalence of carriers once the mutation(s) involved are identified.

Prevention or Neonatal Screening

The diseases of organic and amino acids should be identified as early as possible, preferably before a metabolic crisis occurs. The period between birth and identification before damage occurs is called the "safety window." The safety window for some diseases is established. For example, in the case of classic phenylketonuria (PKU) it is 6 weeks, while in most of the organic acid disorders and MSUD it is probably only a few days after birth. In some other disorders, such as glutaric aciduria type 1 or homocystinuria, this period has not yet been established.

Most of the neonatal screening programs include only PKU, MSUD, and biotinidase deficiency. A broad-based neonatal screening program is highly desirable and should be mandatory in countries where these diseases prevail. The recent availability of tandem MS systems should

enable the implementation of such broad-based screening programs.

Previous screening procedures were based on the Guthrie test, that is, stimulation of bacterial growth in the presence of inhibitors (MSUD, PKU) or chemical reactions (biotinidase, galactosemia), based on a single mutation in the gene (cystic fibrosis, galactosemia). Besides the cumbersome technical nature of these tests, false-positives and false-negatives have always been a major problem. The principle of tandem MS technique is essentially different. It relies on identification and estimation based on molecular weight and a pathognomonic fragmentation pattern. Therefore, false-negative and false-positive results are not usually a problem. Despite the initial cost of the machine, it requires minimal chemical and technician costs, can be run automated, and is user friendly. The medium of choice is dried blood spots, but tandem MS can easily be applied to dried urine samples. The diseases listed in *Table 38.6* are detectable by this technique.

Treatment

Management of Acute Crisis

Fluid Therapy

Acidosis must be promptly corrected. For this purpose, $NaHCO_3$ should be administered at 1–2 mEq/kg over a period of 20 min to 1 h, and repeated every 1–4 h, depending on the severity of acidosis. The acidosis of methylmalonic acidemia can be very persistent, and soon hypernatremia may appear. In methylmalonic acidemia with severe acidosis, 1–2 days of adjunct treatment with 6 mL/kg THAM (a pharmaceutical preparation containing Tris buffer), administered slowly and repeated every 4 h, will usually normalize the pH within 24–36 h. Primary lactic acidosis is very resistant to alkaline administration, and a certain degree of acidosis (pH 7.20–7.30) is unavoidable. The acidosis in such patients might be treated by peritoneal dialysis using long-term indwelling peritoneal catheters. In patients with E_1 subunit abnormality of PDH, 50–100 mg/kg/day sodium dichloroacetate solution (pH = 7) might be tried orally, and might reduce the lactic acidosis without much benefit to the evolving encephalopathy. However, the pediatrician must use his or her judgment, since, except for those variants that are cofactor responsive, there is no long-term treatment for primary lactic acidosis. Depending on the severity and duration of acidosis, hypokalemia might be present, and should be treated cautiously, if the patient is passing urine, by adding potassium to the fluid, not to exceed 40 mEq/L.

A general rule is to overhydrate babies with methylmalonic acidemia and overfeed them with propionic acidemia or MSUD.

Treatment of Hyperammonemia

Hyperammonemia is a medical emergency and must be treated if it exceeds 300–400 μM. This is best achieved either by an exchange transfusion, by peritoneal dialysis using short-term indwelling catheters, or by hemodialysis.

Table 38.5

Location of genes of organic and amino acid disorders primarily related to devastating metabolic diseases of the newborn

Disease/enzyme	Chromosome location
Propionic acidemia/propionyl-CoA carboxylase	α Subunit: 13q32
	β Subunit: 3q21-q22
Methylmalonic acidemia/methylmalonyl-CoA mutase, hydroxycobalamin reductases, and adenosyltransferase (A, B, C, D, F complementation groups)	Multase: 6p21
	Cobalamin A, B, C, D, F: unknown
Isovaleric acidemia/isovaleryl-CoA dehydrogenase	15q14-q15
HMG-CoA lyase deficiency/HMG-CoA lyase	1pter-p33
HCS deficiency/holocarboxylase synthetase	21q22.1
3-Methylglutaconic aciduria/variety with unknown enzyme involvement	Unknown
Glutaric aciduria type 2/α-ETF, β-ETF, ETF-QO	α-eTF: 15q23-q25; β—*ETF*: 19; *ETF-QO*:? 4
Oxidative phosphorylation disease; pyruvate carboxylase	*PyC*: 11q13.4-q13.5
(PyC) deficiency; pyruvate dehydrogenase (PDH) deficiency; cytochrome *c* oxidase (COX) deficiency	*PDH*: $E_{1\alpha}$, Xp22.1-22.2; $E_{2\beta}$, 3p13-q23; E_3, 7q31-q32 Locations of its kinase and phosphatase are?
	COX: Contains 13 polypeptides; peptide, I, II, and III are coded on mitochondrial (mt) DNA gene locations of nuclear coded polypeptides are unknown
UCD/carbamylphosphate synthetase	2q35
UCD/ornithine transcarbamylase	Xp21.1
UCD/citrullinemia (argininosuccinic acid synthetase)	9q34
UCD/argininosuccinic aciduria (argininosuccinic acid lyase)	7cen-p21
Maple syrup urine disease/branched-chain a-keto acid dehydrogenase (E_1, E_2, E_3 subunits)	$E_{1\alpha}$: 19q13.1-q13.2; $E_{1\beta}$: 6p21-p22; E_2: 1p31 E_3:7q31-q32
5-Oxoprolinuria (pyroglutamic aciduria)/glutathione synthetase	20q11.2
Nonketotic hyperglycinemia/contains P, H, and T proteins	*P Protein*: 9p22; *T protein*: 3p21.2-p21.1; *H protein*: the cDNA is available
Neonatal peroxisomal disorders: Zellweger syndrome, neonatal adrenoleukodystrophy, infantile Refsum disease, and hyperpipecolic acidemia (contains 10 complementation groups)	*Peroxisomal assembly factor 1*: 8q21.1
	A peroxisomal marker is known on 7q11.23-q22.1
	PXPMP-1 marker: 1p21-p22
Menkes disease	Xq13

In patients with organic acidemia, particularly during the newborn period, the L-carnitine deficiency leads to the accumulation of organic acyl-CoA in liver mitochondria and causes hyperammonemia through inhibition of UCDs (see *Fig. 38.2*). In these diseases, administration of L-carnitine IV at a dose of 200–400 mg/kg/day, divided into four equal doses 6 h apart, given diluted in 5% dextrose in water and injected over 30 min, will control the hyperammonemia in 24–48 h. In UCDs, acute severe hyperammonemia is best treated by sodium phenylbutyrate (500 mg/kg/day given in four equal doses). All patients with UCDs must receive L-arginine (500 mg/kg/day divided into four equal doses) either orally or, in cases with acute hyperammonemia, IV at the same dose and intervals. In patients with argininosuccinic aciduria or citrullinemia, the administration of L-arginine will promptly reduce hyperammonemia, since the initial steps of the urea cycle are intact.

Treatment of Hypoglycemia

Hypoglycemia must be treated immediately by administering 10% dextrose (2–3 mL/kg), repeated as frequently as required. The blood glucose level at the bedside might be monitored by Dextrostix.

Table 38.6
Diseases that are screened in a neonate by tandem mass spectrometry

Isovaleric acidemia

Argininemia
Primary lactic acidemias
Pyruvate carboxylase deficiency
Nonketotic hyperglycinemia
Primary carnitine deficiency
Malonic aciduria

Total Parenteral Nutrition and Central Line Insertion

It is advisable that a central line be inserted in all newborns with devastating metabolic disease, since the clinical course will be labile, with the recurrence of metabolic attack or superimposed sepsis. A secure line should be present, usually for a period of 10–20 days, through which medications, fluids, and antibiotics can be immediately administered as required, until the patient can be stabilized.

Newborns with a severe crisis of propionic acidemia and MSUD must be treated with TPN. Both diseases require the administration of large amounts of calories to reinstate the anabolic state. Such TPN fluids usually contain 12.5–25% dextrose, and lipids are gradually increased depending on the liver enzymes, and per the discretion of the TPN pharmacists. Regular amino acid mixtures should not be used since they contain large amounts of BCAAs. The best option is to use specially prepared amino acid mixtures in TPN. These amino acid solutions lack BCAAs when used in patients with MSUD and lack L-isoleucine, L-valine, and methionine when used in case of propionic acidemia. If such special amino acid mixtures are not available, routinely available amino acid mixtures might be added at 0.5–1 g/kg/day. The special formulas available for propionic acid or MSUD should be given at half-strength by slow infusion through a NG feeding tube. The gastric residue must be checked every 4–6 h. After the first day of TPN, regular insulin injections (1 U/kg/dose) may be given every 6 h or insulin may be given through a continuous drip. The blood glucose must be monitored frequently, and extra glucose should be given if the infant becomes hypoglycemic. The efficacy of the treatment is best monitored by the daily weight gain in a nonedematous baby, by the decrease in phosphate and potassium, and by the increase in rate of glucose utilization per minute. When the daily weight gain plateaus, the baby can be gradually shifted to full oral administration of the special milk and gradual discontinuance of TPN.

Albumin and Blood Transfusion

Even the best-controlled newborn will develop hypoalbuminemia due to disturbed liver functions, hypercatabolism, and difficulties of providing adequate amounts of amino acids and protein. Albumin should be monitored biweekly in a nonedematous, and daily in an edematous, newborn. Albumin solution (1–2 g/kg) should be given to assure a normal blood albumin level and to prevent edema. Since the management of devastating metabolic disease will require very frequent and voluminous blood drawing, such babies will quickly develop anemia, and the hemoglobin should be maintained at greater than 100 g/L by blood transfusions.

Treatment of Thrombocytopenia

Infants with propionic acidemia will develop severe and precipitous thrombocytopenia, every time and at every age when they experience a metabolic crisis. Such a patient will die due to intracranial bleeding if the intercurrent thrombocytopenia is not suspected. A patient with propionic acidemia who develops a metabolic attack should receive daily platelet counts. Although less severely

and less commonly, patients with methylmalonic acidemia and isovaleric acidemia, particularly in the newborn period, might experience significant thrombocytopenia, and the same precautions should be observed.

Calcium and Other Supplements

During the management of the crisis, a patient with organic acidemia may develop hypocalcemia, which should be corrected by the administration of an appropriate dose of the available IV or oral calcium preparations. The TPN formula usually contains mixtures of trace elements. These babies, when shifted to oral formulas, should be given added trace element mixtures, and multivitamins in appropriate doses. Patients with UCDs should be given folic acid (5 mg) and pyridoxine (25 mg) daily. When large doses of hydroxycobalamin are used in the management of methylmalonic acidemia, folic acid (5 mg/day) must also be given.

Management of Chronic Disease

Patients with devastating metabolic diseases will require special care for their lifetimes. The parents must therefore be taught how to provide such care, and the pediatrician involved should frequently monitor the efficacy of the treatment. Noncompliance by parents and neglect by the pediatrician will only provoke frequent metabolic crises, each requiring costly hospitalization or intensive care. Therefore, a team consisting of a physician, nutritionist, and social worker is essential for successful management of these patients.

The principles of long-term management are to provide (a) chronic detoxification, (b) special foods restricted in certain amino acids, and (c) certain cofactors with the hope of activating a defective enzyme or stabilizing the small amounts of the existing enzyme.

Detoxification

L-Carnitine is the most important and most frequently used drug in the management of organic acid disorders. Under normal conditions, it is synthesized from L-lysine. It is responsible for the back-and-forth transport of acyl-CoA moieties from mitochondria and cytosol, since acyl-CoA cannot be transposed between these two compartments otherwise. Carnitine and acylcarnitines are water soluble and will be freely excreted into the urine. When an organic acidemia is present, L-carnitine soon will be depleted, since the rate of synthesis will not be able to cope with its rate of transacylation and eventual excessive loss of acylcarnitines through the urine. The transport role of L-carnitine is shown in *Fig. 38.20*. L-Carnitine is also considered to stabilize the dehydrogenase complexes and so is used, in addition to thiamine, in the management of patients with dehydrogenase deficiencies such as PDH and MSUD.

During acute attacks, L-carnitine should be used IV, at 200–300 mg/kg/day divided into four equal doses. When the patient is stable, it can be given at the same dose orally. No toxicity of the drug is known if the L-form is used. The DL-form shows CNS toxicity and must never be used. Oral absorption is usually less effective since only 10–20% of the drug is absorbed. Oral L-carnitine may

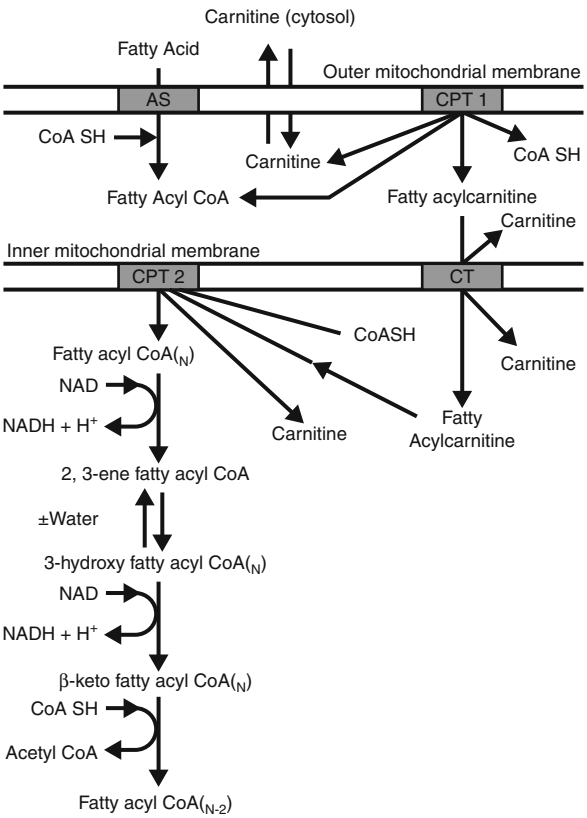

Figure 38.20
Fatty acid oxidation and role of carnitine. Enzymes involved: (AS) fatty acyl-CoA synthetase, (CPT 1) carnitine palmitoyl transferase 1, of outer mitochondrial membrane, (CPT 2) carnitine palmitoyl transferase 2, of inner membrane, (CT) carnitine/acylcarnitine translocase, (1) acyl-CoA dehydrogenase (short-, medium-, and very-long-chain specific (SCAD, MCAD, and VLCAD) types, (2) enoyl hydratase, (3) 3-hydroxyacyl-CoA dehydrogenase (LCHAD; trifunctional enzyme with broad specificity for chain length), and (4) β-keto-thiolase

cause some loose stools due to its high sorbitol content, and at times a fishy smell due to its breakdown by intestinal bacteria. None of these side effects should hinder its chronic use, since it truly is a life-saving drug.

In isovaleric acidemia and MADD, glycine is given at 500 mg/kg/day, divided into four equal doses, since isovaleryl-CoA and acyl-CoA intermediates of MADD can be detoxified by a liver enzyme that uses glycine (*N*-acylglycine conjugase).

In UCDs, L-arginine must be provided at 500 mg/kg/day divided into four equal doses. L-Arginine is an essential amino acid in the newborn period, cannot be synthesized in a patient with a UCD, and is absolutely essential for the normal development of the CNS.

Citric acid displaces methylcitric acid, which is produced from the condensation of propionyl-CoA with oxaloacetate, from mitochondria. Methylcitric acid inhibits numerous mitochondrial functions. Therefore, in diseases in which propionyl-CoA accumulates, such as propionic acidemia, methylmalonic acidemia, and MCD, citric acidcontaining preparations such as Polycitra or Shohl solution should be preferred over oral sodium bicarbonate therapy.

Special Formulas

The selectively amino acid–restricted formulas play a pivotal role in the long-term management of these disorders. These formulas are shown in *Table 38.7*. There are numerous commercial preparations, all equally effective. Some preparations contain L-carnitine already added to the formula, and are easier to use. Such formulas are for long-term usage; when the infant grows into a child, there are also special food substances that are deprived of selective amino acids. These are specially prepared flours and rice and pasta preparations that can be used in addition to formulas, together with other permissible food substances. The reader is referred to publications dedicated to this subject for detailed discussion of the use of available preparations.

Cofactors, Vitamins, and Medications Used in Long-Term Management

The medications used to treat devastating metabolic diseases of the newborn over the long term are shown in *Table 38.7*. Since L-carnitine is more or less universally used for most organic acidemias, it is not included in this table. In most of the disorders listed, fasting, or a fasting state created by vomiting, will prompt the crisis. In all such instances, the infant should be given IV dextrose solutions to prevent the breakdown of fats and proteins. Polycose, four to five scoops according to the age of the infant given ad lib in flavored electrolyte solution (Pedialyte), should be utilized upon minor vomiting, diarrhea, or anorexia since it prevents major hypoglycemia.

An important source of propionic acid is bacterial production in the intestines; therefore, metronidazole should be used during the acute crisis of propionic acidemia. The infant better tolerates Polycitra or Shohl solution, if sweetened. The treatment that may be effective in certain variants of 3-methylglutaconic aciduria should be tried in all patients with a mitochondrial disease.

Nonketotic hyperglycinemia is a very severe disease. Its outlined treatment will only make it less severe, and complete cure should not be anticipated.

There are several procedures to prepare copper-histidinate chelate, and either one may be used in the treatment of Menkes disease. A patient with Menkes disease should be delivered around 32 weeks of gestation, before the blood–brain barrier matures, in order to assure the entry of copper into the CNS.

A patient with 5-oxoprolinuria is severely deficient in reduced glutathione and should be carefully protected from exposure to oxidizing drugs and foods.

Outcome

The prognosis of these disorders depends on the genotype/phenotype and on the early or late detection of the disease. These considerations are summarized in *Table 38.8*. The prognoses cited are for patients in whom the disease is identified either early (i.e., within the period of the safety window) or before the first metabolic breakdown. Certain genotypes lead to very severe phenotypic presentations, while the reverse is also true. For example, methylmalonic acidemia due to cobalamin a mutation is a disease that allows rewarding treatment, while cobalamin c mutation or mutant 0 lead to very severe disease. The same disease in different children of the same family might also manifest either in severe or milder forms. All patients should receive vigorous treatment since it is next to impossible to assign a prognosis at the initial encounter. For example, MSUD causes such severe and early cerebral edema that mild to severe optic atrophy is invariably present at the time of initial encounter. Most MSUD patients will gain full visual function despite this finding if treated appropriately. In most instances, a primary lactic acidemia patient is abandoned because, despite vigorous therapy, including prolonged peritoneal dialysis, the physician will never be able to maintain a normal acid–base balance. Such an infant will develop severe pyramidal tract signs and loss of vision and

Table 38.7

Formulas and medications used for long-term management of infants who had devastating metabolic diseases of the newborn

Disease	Formulas[a]	Cofactors and medications[b]
Propionic acidemia	L-Isoleucine, L-valine, and L-methionine–restricted formulas	+LC. (Biotin, 5–10 mg/kg/day)[c]; metronidazole, 30 mg/kg/ ÷ t.i.d.; citrate, 4–6 mEq/kg/day
Methylmalonic acidemia	Same formula as described for propionic acidemia	+LC. *Acute crisis*: 1 or 2 × 1 mg IM daily hydroxycobalamin
		Chronic management: 1 or 2 × daily intranasal 0.5 mg B_{12}; citrate, 4–6 mEq/kg/day
Isovaleric acidemia	L-Leucine-restricted diet (not more than 83 mg/kg/day)	+LC. Glycine, 500 mg/kg/d; bicarbonate or citrate, 4–6 mEq/kg/d
HMG-CoA lyase deficiency	L-Leucine–restricted diet (as above); low-fat diet	+LC. Bicarbonate or citrate, 4–6 mEq/kg/day; Polycose for vomiting and diarrhea
Multiple carboxylase deficiency	N.R.	+LC. Biotin, 5–10 mg/kg/day; citrate, 4–6 mEq/kg/day
3-Methylgluaconic aciduria	N.R.	–LC. Ubiquinone, 25–50 mg/day; vitamin K_1, 5–10 mg/day; ascorbic acid, 250–500 mg/day; bicarbonate or citrate, 4–6 mEq/kg/day
Glutaric aciduria type 2	N.R.	+LC. (Riboflavin, 50–100 mg/kg/day); glycine, 200 mg/kg/day
Oxidative phosphorylation disease	N.R.	–LC. *PyC deficiency*: biotin, 5–10 mg/kg/day)
		±LC. *PDH deficiency*: thiamine, 50–100 mg/kg/d; (dichloroacetate, 50–100 mg/kg/day
		In all: bicarbonate or citrate, 4–6 mEq/kg/day
5-Oxoprolinuria	Same dietary precautions as for glucose-6-phosphate dehydrogenase deficiency	–LC. Same pharmacologic restrictions as for glucose-6-phosphate dehydrogenase deficiency; sodium bicarbonate or Polycitra 4–6 mEq/kg/day
Urea cycle disorders	UCD formula (mixture of essential amino acids and Polycose)	–LC. Sodium benzoate, sodium phenylacetate, or sodium phenylbutyrate, singly or in combination not to exceed 500 mg/kg/day[d]
		L-arginine, 250–500 mg/kg/day; folic acid 5, mg/day; pyridoxine, 25 mg/day
Maple syrup urine disease (MSUD)	MSUD (restricted in BCAA) formula	±LC. (Thiamine, 50–100 mg/kg/day); trace mineral mixture; zinc sulfate orally, 25 mg/kg/day; niacin, 50 mg/day; mixture of polyunsaturated fats, 1–2 g/day
Nonketotic Hyperglycinemia	N.R.	–LC. Sodium benzoate, 500 mg/kg/day; dextromethorphan, up to 35 mg/kg/day; folinic acid, 15 mg/day
Neonatal peroxisomal disorders	N.R.	(Oral bile acids)
Menkes disease	N.R.	–LC. Baby is delivered as early as compatible with life; copper-histidine chelate, 1 mg/M 2–3 × week

[a]N.R., not effective

[b]+LC, L-carnitine is used in these disorders at a dose of 200–400 mg/kg/day (it is administered IV during acute crisis); ±LC, L-carnitine may be of use in PDH deficiency and MSUD; −LC, L-carnitine not a part of the treatment. Treatments within parentheses are experimental, and might be effective in cofactor-responsive variants

[c]They may be beneficial

[d]Usually not used or used in reduced doses in patients with argininosuccinic aciduria, unless it is a severe case

Table 38.8
Outcome of devastating metabolic diseases of the newborn when diagnosed and treated early and appropriately

Disease	Outcome
Propionic acidemia	*Mild phenotype:* 20–30% compatible with a normal lifestyle; death is usually due to unsuspected thrombocytopenia during a crisis
	Severe phenotype: incompatible with life
Methylmalonic acidemia	*Most phenotypes:* easy to manage, leading to a normal lifestyle, except these children are prone to fulminant viral diseases
Isovaleric acidemia	*Most phenotypes:* easy to manage and are compatible with life, leading to normal lifestyle
HMG-CoA lyase deficiency	Excellent, except close supervision is required for the precipitous lactic acidotic hypoglycemia that will occur when the child has an infection and refuses to eat. Can be prevented by using Polycose
Holocarboxylase synthetase deficiency	Incompatible with life, except on rare occasion when the disease is biotin responsive and diagnosed early, receiving early and intensive treatment
3-Methylglutaconic aciduria: neonatal variants	Usually severe progressive encephalopathy leading to crippling and early death; except on rare occasions might be responsive to coenzyme Q and phytanedione
Multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type 2)	Usually incompatible with life; rarely good response to cofactors in this age group
Oxidative phosphorylation diseases	*Pyruvate carboxylase deficiency:* usually fatal, except on rare occasions may be biotin responsive
	Pyruvate dehydrogenase and cytochrome c oxidase deficiencies: usually fatal
5-Oxoprolinuria (pyroglutamic aciduria)	Chronic and slowly progressive neurodegenerative disease with mental retardation
Urea cycle disorders	Compatible with near-normal lifestyle if diagnosed early and treated vigorously. Better prognosis for citrullinemia. Argininosuccinic aciduria, which might appear late, will have good prognosis if diagnosed and treated early
Maple syrup urine disease (MSUD)	*Classic MSUD:* if diagnosed early and treated vigorously, is compatible with normal lifestyle. Severe phenotypes and patients who are diagnosed late will develop severe neurologic sequel and will die
	Intermediate and intermittent phenotypes: excellent prognosis
Nonketotic hyperglycinemia	Moderate to severe neurologic crippling even in early-diagnosed and aggressively managed patients. Incompatible with life if diagnosed late and if not treated appropriately
Neonatal peroxisomal diseases	Incompatible with life
Menkes disease	Early delivery and treatment with copper-histidine chelate will be beneficial. Prenatally diagnosed and treated patients provide better results. Severe neurologic crippling and death in untreated cases

will eventually expire. The E_1 abnormal phenotype of PDH deficiency might respond to the administration of dichloroacetate, and the acid–base balance in such a neonate might be managed with more ease, delaying the eventual CNS manifestations. Some forms of pyruvate carboxylase, or holocarboxylase synthetase deficiency, are biotin responsive, and such a baby might be eventually managed without progression of the CNS disease. It is therefore recommended that, in each instance, the baby should be given at least 1 month of intensive cofactor treatment before any decision is made.

Diseases of Later Infancy and Childhood Involving Organic Acid, Amino Acid, and Carbohydrate Metabolism

Clinical Presentation

The list of diseases that will manifest periodically with metabolic crisis (e.g., acidosis, hypoglycemia, liver failure) in the period of later infancy and childhood includes organic and amino acid disorders as well as carbohydrate disorders. Among the latter, galactosemia is of special

importance since it may occur in the neonate but may also manifest at a few weeks to a few months of age. Since the acute or chronic manifestation of carbohydrate disorders is readily confused with organic acidemias, their manifestations are included in this chapter.

Organic Acidemias of Newborns that Also Occur in Later Infancy

The main diseases in this category are shown in *Table 38.9*. Some of these diseases have already been discussed in the section "Devastating Metabolic Diseases of the Newborn" and will not be presented again, with two exceptions.

Propionic Acidemia

A significant percentage of propionic acidemia will present in a different manner later during infancy, that is, it does not appear with devastating metabolic acidosis. Two significant presentations of the disease are one phenotype that presents primarily as a case of immune deficiency, and another that presents primarily with seizures or other neurologic manifestations. If these presentations are not recognized, the disease eventually will cause significant neurologic damage or death.

3-Methylglutaconic Aciduria with Extrapyramidal Tract Signs

The etiology of this organic acidemia is not known; circumstantial evidence suggests a block in the pathway of mevalonic acid that leads to the interruption of either cholesterol or ubiquinone (coenzyme Q) synthesis. Therefore, the clinical symptoms are those of either disturbed membrane function or an oxidative phosphorylation defect. A distinct subtype of the disease leads to the degeneration of basal ganglia and manifests with extrapyramidal tract signs. The presence of 3-methylglutaconic aciduria should be ruled out in any child who presents with rigidity, dystonia, or choreoathetiform movements. The dystonic posturing of a patient with this disease is shown in *Fig. 38.21*.

Table 38.9
Organic and amino acidemias of later childhood

Organic Acidemias
Neonatal disorders that also occur in later infancy
Propionic acidemia
Methylmalonic acidemia
Isovaleric acidemia
3-Hydroxy-3-methylglutaryl-CoA (HMG-CoA) lyase deficiency
Mild phenotypes of oxidative phosphorylation disease
3-Methylglutaconic aciduria with extrapyramidal symptoms
Diseases of primarily of infantile/childhood period
3-Ketothiolase deficiency
Glutaric aciduria type 1
Medium-chain acyl-CoA dehydrogenase deficiency (MCAD)
Very-long-chain acyl-CoA dehydrogenase deficiency (VLCAD)
Biotinidase deficiency
Biotin-responsive holocarboxylase synthetase deficiency
4-Hydroxybutyric aciduria
Disorders of Carbohydrate Metabolism
Associated with either lactic acidosis, hypoglycemia, or both
Fructose sensitivity (fructose-1, 6-bisphosphatase [FDPase] deficiency)
Glycogen storage disease type 1
Galactosemia
Amino Acidemias
Hyperphenylalaninemia (classic PKU)
Biopterin-dependent hyperphenylalaninemia (malignant PKU)
Dihydrolipoyl dehydrogenase (E_3) deficiency
Homocystinuria (cystathionine β-synthetase deficiency)
Tyrosinemia type 1 (fumarylacetoacetate hydrolase deficiency)

Case History. A 4-year-old boy was the product of a first-cousin marriage with four normal siblings. He was normal at birth but experienced cyanosis within 2 h, requiring intensive care hospitalization. His further development was normal; he was sitting and crawling at 8 months and saying a few words. He started to lose milestones at 1 year and developed severe dystonic posturing. He had several tonic seizures after 2 years. He was small for stature, with his height, weight, and head circumference corresponding to median values of 12, 24, and 9 months, respectively, at the chronologic age of 48 months. He showed pseudobulbar affect, severe rigidity, and dystonic posture. Eyegrounds revealed optic atrophy; deep tendon reflexes were increased, with Babinski sign. Blood chemistries, lactic acid, pyruvate, pH, gases, ammonia, and blood count were normal. A urine GC/MS study revealed increased 3-methylglutaconic aciduria. The EEG showed diffuse background slowing. MRI of the

Figure 38.21
A 3-year-old boy with 3-methylglutaconic aciduria with putaminal necrosis; note the dystonic posturing

brain revealed atrophic changes in the posterior fossa, a small vermis, and delayed myelination with isointense subcortical white matter in the posterior parietal region. Lentiform nuclei bilaterally showed slit-like, low T1- and high T2-intensity lesions with involvement of the heads of the caudate nuclei.

Organic Acidemias Occurring Primarily in the Infantile/Childhood Period

Organic acidemias that occur primarily during this period are numerous; however, six of these are important, since they can be managed successfully and, if missed, cause severe neurologic handicap and death.

3-Ketothiolase Deficiency

This is a disease caused by the deficiency of the ketothiolase responsible for the breakdown of 2-methylacetoacetyl-CoA, the metabolite of the final step of degradation of L-isoleucine (*Fig. 38.22*). It causes periodic severe ketoacidosis and will require intensive measures to correct the acidosis. When the diagnosis is missed, the repeated acidosis causes CNS damage in approximately a third of the patients, while treatment with L-carnitine and a low-protein diet prevents the acidotic attacks as well as the neurologic sequelae.

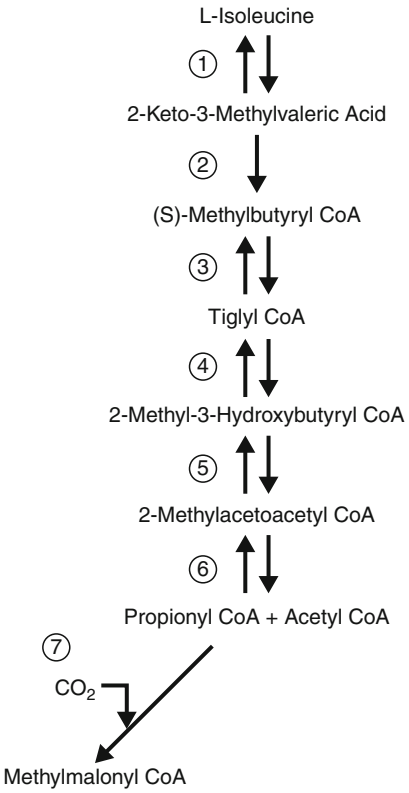

Figure 38.22
Breakdown of L-isoleucine and the enzymes lacking in various inborn errors of metabolism. Enzymes involved: (1) branched-chain amino acid transaminase, (2) branched-chain α-keto acid dehydrogenase, (3) 2-methyl branchedchain acyl-CoA dehydrogenase, (4) tiglyl-CoA hydratase, (5) 2-methyl-3-hydroxybutyryl-CoA dehydrogenase, (6) mitochondrial β-ketothiolase (2-methylacetoacetyl-CoA 3-ketothiolase), and (7) propionyl-CoA carboxylase. Diseases related to deficiency of the aforementioned enzymes: (2) MSUD, (6) mitochondrial β-ketothiolase deficiency, and (7) propionic acidemia

Case History. An 8-month-old boy was slow in achieving the appropriate developmental milestones, sitting only with support at 8 months. He had acute otitis media and developed fever, seizures, and vomiting with Kussmaul breathing. Examination revealed profound lethargy, a palpable liver edge, and central hypotonia. He had massive ketonuria; blood pH was 7.05, BE −26 mEq/L, pCO_2 1.45, and bicarbonate 2.5 mEq/L, with normal blood glucose. His EEG showed slow-wave discharges over the right anterior areas. MRI of the brain showed highintensity T2 lesions within the posterior lateral part

of the putamina, continuing toward the lower part of the corona radiata. The urine study showed massive amounts of acetoacetate, 3-hydroxybutyrate, and intermediates characteristic of the disease (i.e., 2-methylacetoacetate, 2-methyl-3-hydroxybutyrate, and tiglylglycine). His fibroblasts, grown from a skin biopsy, revealed a deficiency of mitochondrial 3-ketothiolase activity. He was placed on an L-isoleucine restricted diet, L-carnitine, and Polycitra. He did not have any further attacks. When last seen at the age of 2.5 years, he was normal and had no neurologic sequelae.

Glutaric Aciduria Type 1

This is a disease caused by the deficiency of glutaryl-CoA dehydrogenase, an enzyme on the breakdown pathway of L-lysine (*Fig. 38.23*). It leads to severe degenerative loss of basal ganglia and underdevelopment of anterior portions of the frontal and temporal lobes, causing a pathognomonic neuroradiologic sign known as "wide operculum" or very widened sylvian fissure. In addition, central white matter disease is observed. The pathogenesis remains unknown. Glutamate excitotoxicity due to glutamate accumulation in the basal ganglia as caused by the inhibitory action of glutaryl-CoA on glutamate decarboxylase has been implicated. Another hypothesis is the stimulation of alternate catabolic pathways of tryptophan and accumulation of quinolinic acid, which is highly toxic to the neurons in basal ganglia. Clinical signs reflect the neuropathology; such cases show macrocephaly and increased deep tendon reflexes in addition to basal ganglia symptoms such as severe dystonic posturing, rigidity, and choreoathetosis. The disease usually appears following either metabolic stress or an infection. The severe CNS signs that suddenly appear often lead to an erroneous diagnosis of meningitis or encephalitis while the underlying disease is missed. The disease then progresses, causing severe choreoathetotic cerebral palsy, and the patient will require placement in a handicapped-children's facility. If the disease is discovered before the first metabolic breakdown, during neonatal screening, it can be managed to prevent the appearance of neurologic signs. Such children will then lead a nearnormal life. The disease does not cause chemical disturbances detectable by routine laboratory chemistries, such as acidosis, hypoglycemia, or hyperammonemia; therefore, it is a "silent," "neurologic," or "cerebral" organic aciduria. Since the disease is panethnic, its detection should be part of neonatal screening programs universally. Its treatment or prevention includes the use of a lysine-restricted diet, riboflavin, carnitine, valproate, or baclofen, and rigorous management of even minor infections or metabolic stress. The characteristic dystonic posturing and the wide operculum sign are shown in *Fig. 38.24*.

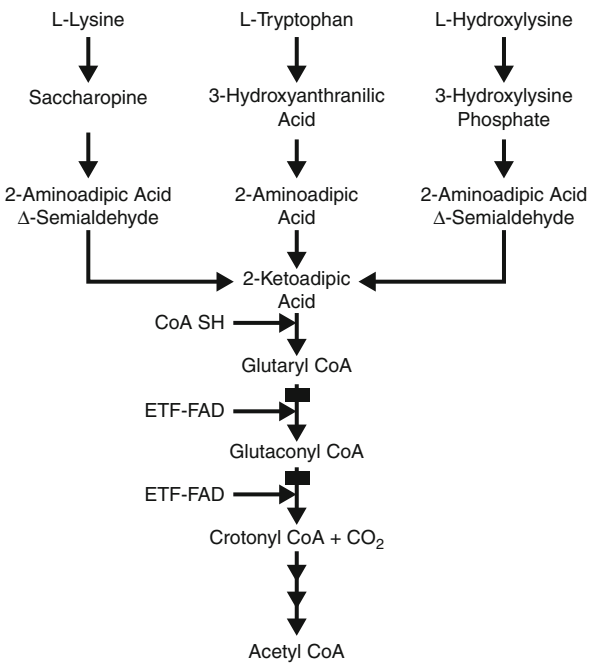

Figure 38.23
L-Lysine, L-hydroxylysine, and L-tryptophan metabolism and glutaric aciduria type 1. Defective enzyme in glutaric aciduria type 1: glutaryl CoA dehydrogenase; probably the same enzyme catalyzes the dehydrogenation of both glutaryl-CoA and glutaconyl-CoA. Defective enzyme in glutaric aciduria type 2 (multiple acyl-CoA dehydrogenase deficiency): flavin-adenine dinucleotide containing electron-transport flavoprotein (ETF-FAD)

Case History. A boy who was first seen at the age of 1 year had developed normally until 7 months, at which time he suffered a head trauma. The next day he developed fever, vomiting, and diarrhea; this was followed by focal seizures involving the left side of the body and the face, and oculogyric crisis. He was diagnosed to have encephalitis, and the CSF revealed elevated protein (500 mg/L). CT of the brain was obtained at the referring hospital; although the "wide operculum" sign, central white matter disease, and diffuse brain atrophy were observed, the significance of these neuroradiologic findings was not appreciated. He lost his acquired milestones and showed dystonic posturing of the hands and opisthotonus. On examination he had macrocephaly, rigid quadriplegia, increased deep tendon reflexes, and Babinski reflex. The routine laboratory examination was unremarkable, with

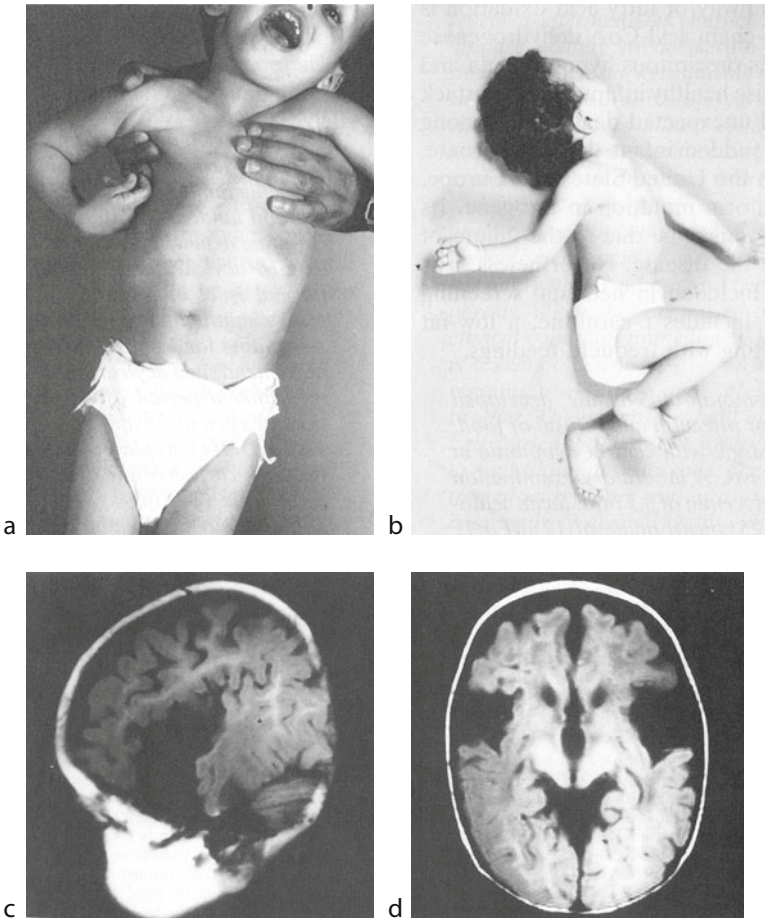

Figure 38.24
(a) A 2-year-old boy with glutaric aciduria type 1; note the choreic grimacing, dystonic posturing, and rigidity. (b) A 2-year-old girl with glutaric aciduria type 1; note severe dystonic posturing, rigidity, and macrocephaly. (c) MRI of the brain in glutaric aciduria type 1; note the widened arachnoid space at the sylvian fissure and the frontal and temporal lobe atrophy. (d) The wide operculum sign with frontotemporal lobe atrophy, generalized brain atrophy, some central white matter disease, and total degeneration of the basal ganglia, including the caudate nucleus

borderline elevated lactate (3 mM) and compensated metabolic acidosis, with BE −6.8 and −7.5 mEq/L on two occasions. MRI of the brain confirmed the findings of the previous CT of the brain. The EEG, visual-, and auditory-evoked potentials were normal. A urine GC/MS study revealed the characteristic intermediates of type 1 glutaric aciduria (i.e., glutaric, 3-hydroxy-glutaric, and glutaconic acid). He was placed on riboflavin (100 mg/kg/day), L-carnitine (200 mg/kg/day), valproic acid, niacin, and the lysine- and tryptophan-restricted diet used for type 1 glutaric aciduria. His disease did not progress over the next 3 years, but he did not regain the lost neurologic functions. The diagnosis was later reconfirmed by the detection of glutarylcarnitine in the blood by tandem MS, as well as the absent activity of glutaryl-CoA dehydrogenase in fibroblasts, at a referral laboratory.

Acyl-CoA Dehydrogenase Deficiencies

Medium-Chain Acyl-CoA Dehydrogenase Deficiency This is a disease caused by the deficiency of the initial dehydrogenase involved in the oxidation of medium-chain-length fatty acids. The pathway of fatty acid oxidation is shown in *Fig. 38.20*. Medium-chain acyl-CoA dehydrogenase deficiency (MCAD) causes precipitous hypoglycemia and lactic acidosis in an otherwise healthy infant. Such an attack might lead to sudden and unexpected death. It is among the recognized causes of sudden infant death syndrome. It is a common disorder in the United States and

Europe, and is due to a single uniform mutation in the gene. Its rare occurrence elsewhere might be due to the failure of pediatricians to recognize the disease. Nevertheless, it is treatable and it must be included in neonatal screening programs. The treatment includes L-carnitine, a low-fat diet, and avoidance of fasting with frequent feedings.

Case History. An 18-month-old female developed lethargy following a minor infection and refusal of food. She was profoundly lethargic with central hypotonia at the time of arrival at the ER. A laboratory examination revealed profound hypoglycemia of 0.5 mM, lactic acidosis of 8 mM, pH of 7.25, bicarbonate of 12 mEq/L, and BE of −10 mEq/L. The history failed to reveal any sensitivity to sweets and sucrose, and she had no hepatomegaly, which clinically ruled out a fructose sensitivity and glycogen storage disease type 1. She was revived with the administration of glucose, bicarbonate, and fluids. A urine examination revealed C6 and C8 dicarboxylic aciduria, and a study of the blood by tandem MS revealed elevated concentrations of C6 through C10 acylated carnitines, confirming the diagnosis. She had no further metabolic crisis; at present she is an entirely healthy 8-year-old girl.

Very-Long-Chain Acyl-CoA Dehydrogenase Deficiency This is a disease caused by deficiency of the initial dehydrogenase involved in the oxidation of long-chain fatty acids (*Fig. 38.20*). It appears that there are two enzymes involved with overlapping substrate specificity, a long-chain and a very-long-chain acyl-CoA dehydrogenase. The latter is more active with longer chain fatty acids, and its deficiency is known as very-long-chain acyl-CoA dehydrogenase deficiency (VLCAD). Only the deficiency of VLCAD is known in humans. The clinical presentation of VLCAD can be mild to very severe. Mild forms will present with myopathy, cardiomyopathy, and periodic hypoglycemia with mild lactic acidosis. The severe disease manifests with severe hypertrophic cardiomyopathy, hepatomegaly, intractable hypoglycemia, and lactic acidosis. The mild form of the disease will respond to treatment with L-carnitine, medium-chain triglyceride (MCT) oil (1 g/kg/day), and a low-fat diet. The severe form of the disease is invariably lethal. VLCAD also may present with acute hepatic failure leading to precipitous death. This form is highly responsive to the aforementioned treatment.

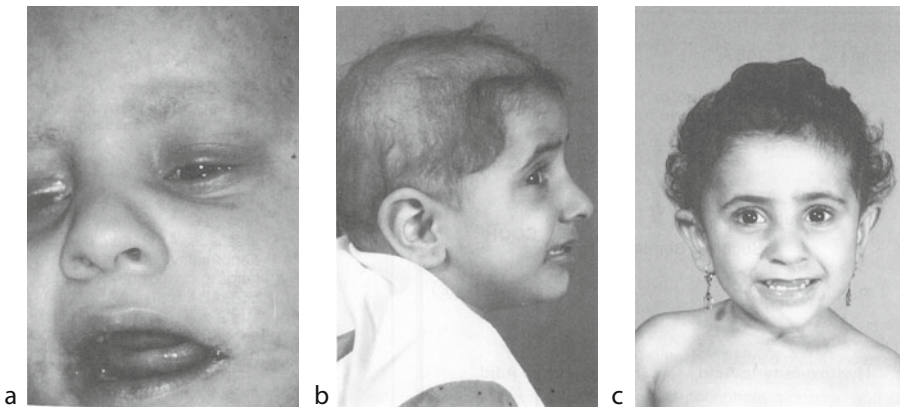
Case History. A 7-month-old boy was referred for the evaluation of his hepatomegaly, which was noticed soon after birth. The family history was interesting. The parents were first cousins; they had three normal children but had lost five infants to fulminant hepatic failure. According to the parents, these children, two girls and three boys, were normal and grew normally until the age of 4–8 months. They abruptly developed severe jaundice and died within 1–3 days with acute liver failure. The patient was a normal child whose growth parameters were at borderline normal percentile. His liver was enlarged 4–5 cm below the right costal margin and had a soft, blunt edge. He had no splenomegaly and neurologic examination was normal. The blood chemistries revealed lactate of 3.6 mM, glucose of 3.5 mM, ALT of 96 U/L (normal range: 10–40 U/L), and AST of 85 U/L (normal range: 10–40 U/L). Serum ammonia and amino acids were normal. Since the family history suggested death due to VLCAD, a blood tandem MS study was obtained, which showed carnitine deficiency and increased concentrations of C12–C18 acylcarnitines, including one to two times the normal level of unsaturated fatty acylcarnitines in the same chain-length range. When the patient was given an L-carnitine load of 200 mg/kg, the concentration of the aforementioned acylcarnitines increased. While on carnitine, after a period of 8 h of fasting, this increase became even more apparent, confirming the diagnosis of VLCAD. He was placed on frequent feedings with a low-fat, high-carbohydrate diet, MCT oil (1 g/kg/day), and L-carnitine (200 mg/kg/day). Over the next 2 years he grew without any metabolic crisis. At present he is 7 years old and his growth parameters are at the 95th percentile without any evidence of a liver disease.

Biotin Deficiency

Biotin deficiency does not occur in normal individuals, since a very effective physiologic mechanism exists that permits the preservation of biotin stores in the body. Biotin is a cofactor for various carboxylases, and the enzyme HCS binds biotin to the ε-amino group of lysine in the active center of carboxylases (*Fig. 38.6*). When carboxylases are biologically degraded, biotin is liberated bound to lysine, as biocytin (biotinyl-ε-aminolysine). This peptide is further broken down into free biotin and L-lysine through the action of a liver enzyme, biotinidase (*Fig. 38.6*). The small amount of biotin lost daily through urinary excretion is compensated by intestinal bacterial synthesis and through diet. When either biotinidase or HCS is deficient, biotin deficiency occurs. Both conditions are encountered during infancy. The symptoms of biotinidase deficiency are more severe in infants who are fed by breast milk, since it contains less biotin than commercial formulas. Although biochemically both of these diseases share a common pathology, their clinical presentations are significantly different.

Biotinidase Deficiency Two different phenotypes, one associated with absence and another one associated with deficiency, exist. The absence of biotinidase manifests during early infancy, initially with seizures and/or with loss of hair, eyebrows, and eyelashes and *Candida* dermatitis, particularly of the perineum. This is associated with early central deafness, and later in some instances by visual loss, pyramidal tract signs, and metabolic acidosis. The appearance of a patient with biotinidase deficiency before and after treatment is shown in ◉ *Fig. 38.25*. Any infant who has any one of the aforementioned symptoms should be tested for biotinidase absence, particularly when an etiologically obscure seizure disorder or loss of hair is encountered. The reason for the inclusion of biotinidase in the battery of neonatal screening is this multitude of nonspecific symptoms and early deafness associated with the disease. Upon appropriate treatment, most symptoms, including visual loss and pyramidal tract signs, disappear, but the deafness will remain. Biotinidase absence has one of the most rewarding outcomes of the inborn errors of metabolism in its treatment using biotin 1–5 mg/kg/day. Partial deficiency of biotinidase leads to a progressive encephalopathy with extrapyramidal tract signs and seizures. Finally, biotinidase will be detected to be transiently low in the presence of an ongoing liver disease. Therefore, when biotinidase is detected at a low level, it must be measured several times, months apart, while the patient is kept on biotin treatment, before a final verdict is reached.

Case History. A 3-year-old girl lost all her hair and eyelashes at the age of 20 days; however, both grew again a few weeks later, to be lost entirely again at 4 months. Since her primary dentition was also poor and she had extensive dermatitis, the primary physician diagnosed her tentatively as having ectodermal dysplasia. Her further development was delayed; she sat independently at 1 year, and never developed verbalization. Her hearing was tested at 18 months and she was found to be profoundly deaf. The parents noticed her to have poor vision at 20 months of age, and she developed spastic quadriparesis. She had several attacks of grand mal seizure at the age of 30 months and experienced a metabolic crisis with hypoglycemia, ketolactic acidosis, and hyperammonemia at 3 years, when she was referred for detailed investigations. At that time she had no hair, eyelashes, or eyebrows and had extensive Candida dermatitis under the armpits, neck, and arm folds, with severe inflammation of the perineum. She had bilateral optic atrophy, spastic quadriparesis, Babinski sign, and brisk deep tendon reflexes. The blood chemistries revealed lactic acid of 3.9 mmol/L (normal upper limit: 2 mmol/L); pyruvate of 219 μmol/L (normal upper limit: 80 μmol/L), ammonia of 71 μmol/L (normal upper limit: 55 μmol/L), zero to + ketonuria. The urine collected during the metabolic crisis revealed intermediates characteristic of MCD. The biotinidase activity in the serum was absent. The EEG showed diffuse background slowing, and CT of the brain showed diffuse brain atrophy with scattered foci of demyelination. She was placed on biotin 50 mg twice daily, with additional L-carnitine and Polycitra. Her response to treatment was dramatic, with hair growth after 3 weeks and improved spasticity and gain of visual acuity. The parents were not convinced of the value of treatment and discontinued biotin after 6 months of treatment. She lost her hair within 1 month and became spastic with quadriparesis. When she was placed on biotin



◘ Figure 38.25
(a) A 30-month-old girl with profound biotinidase deficiency, severe facial rash, and lack of eyebrows and eyelashes. (b) The alopecia of biotinidase deficiency. (c) Same girl after 1 month of biotin treatment

once again, her clinical condition immediately improved. At present she is 6 years old with nearly normal mentality, except she remains profoundly deaf. Meanwhile, she had a new brother. The parents brought him in for testing since his hair started to fall out at 3 weeks, and he was also found to have biotinidase absence. The brother was immediately treated with biotin, and at present he is 3 years old and is an entirely normal child with no hearing deficit.

Holocarboxylase Synthetase Deficiency The deficiency of this enzyme will lead to deficiencies of propionyl-CoA carboxylase, pyruvate carboxylase, 3-methylcrotonyl-CoA carboxylase, and acetyl-CoA carboxylase activities (*Fig. 38.6*). This form of multiple carboxylase deficiency often results in an early devastating metabolic disease of the newborn (see previous section) associated with hypoglycemia, hyperammonemia, and ketolactic acidosis. If the enzyme activity is totally deficient, the disease is not compatible with life; however, in some instances pharmacologic doses of biotin will restore enough activity of a deficient enzyme to secure near-normal biochemical function, and the child will survive.

Case History. A 10-day-old girl, the product of a normal pregnancy and delivery, suddenly developed coma and acidosis. At the time of initial encounter, she was comatose with acidotic breathing, and had severe hypotonia with diminished neonatal reflexes. The blood pH was 7.15, BE −21 mEq/L, blood glucose 1.5 mM, ammonia 176 μM, pyruvate 125 μM, and lactic acid 5 mM. The urine GC/MS revealed high amounts of lactic acid, 3-hydroxybutyric acid, 3-hydroxypropionic acid, 3-hydroxyvaleric acid, 3-hydroxyisovaleric acid, methylcitrate, 3-methylcrotonylglycine, propionylglycine, and propionylcarnitine, namely, the organic characteristic of MCD. The serum biotinidase was 5.6 U (normal: 4–8 U). She was given glucose, sodium bicarbonate, and large dose of biotin and L-carnitine. She recovered from this episode in 1 week and was maintained on the same medications. A fibroblast culture grown from a skin biopsy indicated low propionyl-CoA carboxylase, pyruvate carboxylase, and 3-methylcrotonyl-CoA carboxylase activities. The baby is now 2 years old, with only one further metabolic attack following a chest infection. She is neurologically intact with normal milestones. Undoubtedly she has a biotin-responsive holocarboxylase deficiency.

4-Hydroxybutyric Aciduria

This is a disease characterized by excessive formation of 4-hydroxybutyric acid. The enzyme responsible for the normal breakdown of succinic semialdehyde, succinic semialdehyde dehydrogenase, is deficient and, in place of the normal process of further oxidation, succinic semialdehyde is reduced to its alcohol, 4-hydroxybutyric acid (*Fig. 38.26*). The source of succinic semialdehyde is 4-aminobutyric acid or γ-aminobutyric acid (GABA), and it is formed by the transamination of the latter compound. 4-Hydroxybutyric acid is a very powerful neuropharmacologic agent with many actions in the CNS; at low concentrations it is excitatory, while at high concentrations it is inhibitory. Reflective of the diverse pharmacologic actions of 4-hydroxybutyric acid, the clinical presentation of succinic semialdehyde deficiency is nonspecific and is different at different age groups. In the neonate, it causes severe central hypotonia, to a degree compromising respiration, and myoclonic seizures probably due to the inhibition of oxidative phosphorylation by succinic semialdehyde. It is not unusual for such neonates to have retinitis pigmentosa or cataracts similar to the presentation of a mitochondrial disease. Later in life, ataxia, reflective of cerebellar involvement, and severe mental retardation complicate the clinical picture. The diagnosis of the disease depends upon the detection of 4-hydroxybutyric acid in the urine by GC/MS. This compound forms an inner ester (a lactone) easily, which is highly volatile and might be lost totally during the preparation of the sample. Since succinic semialdehyde inhibits various enzymes of oxidative phosphorylation, the urine of such a patient contains the intermediates characteristic of glutaric aciduria type 2, and the disease might easily be misdiagnosed as such. Approximately 60% of the reported patients are of Middle Eastern origin. The presence of 4-hydroxybutyric aciduria must be searched for in any profoundly hypotonic infant or in any mentally retarded child with ataxia. Vigabatrin (γ-vinyl GABA), a noncompetitive inhibitor of GABA transaminase, as well as dextromethorphan, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, have been used to manage the disease, but the results have not always been rewarding.

Case History. A 2.5-year-old girl was found to have profound hypotonia at birth, resulting in difficulty sucking and swallowing. She developed slowly and always showed severe central hypotonia, supporting the head only at 18 months and rolling over at 20 months. She could sit only with support at 26 months. She recognized her mother at 2 years. She never vocalized. The parents were first cousins, and she had a similarly affected brother and two profoundly mentally retarded aunts and an uncle. Despite central hypotonia, a myopathy was suspected and a muscle biopsy was obtained that showed few lipid droplets; urine GC/MS showed intermediates of type 2 glutaric

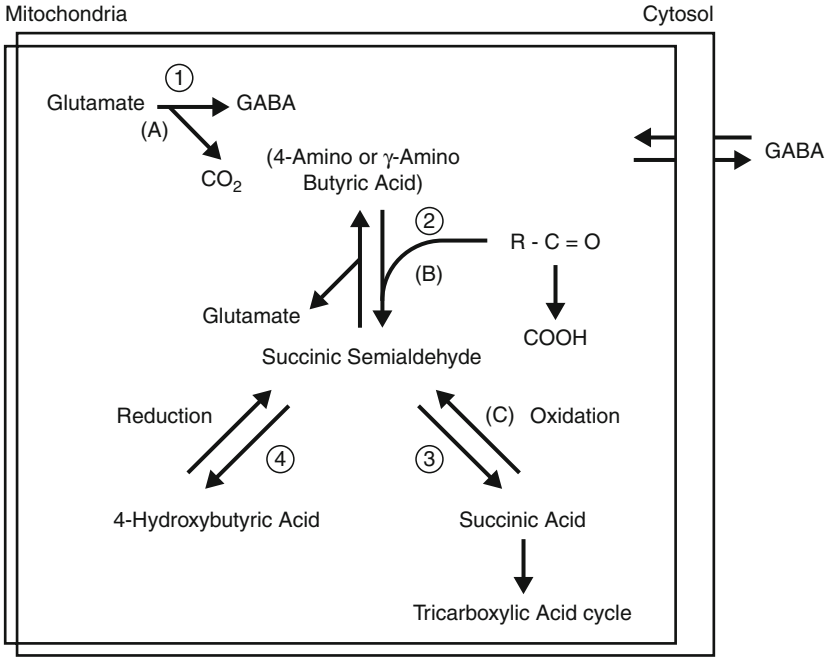


Figure 38.26

Metabolism of 4- (or γ)-aminobutyric acid and 4-hydroxybutyric aciduria. Enzymes involved and diseases caused by the deficiency of enzymes: (1) glutamate decarboxylase, (2) GABA transaminase, (3) succinic semialdehyde dehydrogenase, and (4) the reductase auxiliary pathway for succinic semialdehyde. (a) Glutamate decarboxylase abnormality or pyridoxine deficiency; leads to pyridoxine-dependent seizures. (b) GABA transaminase, the other substrate of which is α-ketoglutaric acid. Vigabatrine inhibits this enzyme noncompetitively. (c) The deficiency of this enzyme leads to 4-hydroxybutyric aciduria, since the indicated auxiliary pathway leads to the production of 4-hydroxybutyric acid, a powerful neuropharmacologic agent responsible for the symptoms of the disease

aciduria. She was considered to have a variant of this disease, or a mitochondropathy. She was referred to our center for further evaluation. At the time of admission she lay in the pithed-frog position; she had relative macrocephaly, poor eye contact, and mild temporal pallor of the optic discs, showing frequent choreoathetiform movements, severe central hypotonia, and diminished deep tendon reflexes. Her psychometric assessment was 8 months at 30 months of age. Her blood chemistries were normal and a repeat muscle biopsy was found to be normal. The EEG showed polyspike wave abnormalities. MRI of the brain indicated bilateral scattered high T2-intensity focal lesions. The urine GC/MS indicated large amounts of 4-hydroxybutyric acid, and, in addition, organic acids encountered in MADD (glutaric aciduria type 2). She was placed on vigabatrin (500 mg q.i.d.), dextromethorphan (30 mg/day), and clonazepam (6 mg/day) (weight 10 kg). Her seizures improved and her central hypotonia became less pronounced, but she has not gained speech or any new milestones. When assessed at 4 years of age, her intellectual development was found to remain at 8 months.

Disorders of Carbohydrate Metabolism

Three disorders listed in ❯ *Table 38.9* are of importance, since they manifest with dramatic metabolic disturbances.

Fructose-1, 6-Bisphosphatase Deficiency (Fructose Sensitivity)
This is a frequently encountered, but not frequently diagnosed, disorder. The presentation is usually after the infant has been exposed to food substances that are sweet, such as orange juice, honey, cereals, or milk with added sugar, or fasts for a prolonged period. The disease may be due either to a deficient or abnormal fructose-1-phosphate aldolase (aldolase B), or to the deficiency of fructose-1,6-bisphosphatase (FDPase) (❯ *Fig. 38.27*). The presentation of the former deficiency is early infantile, with a clinical picture more like that of galactosemia,

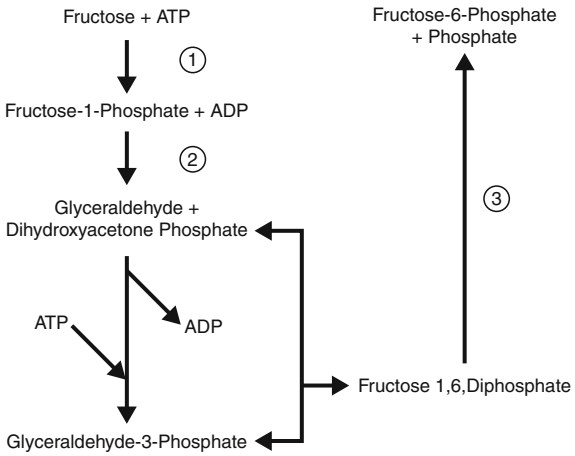

Figure 38.27
Fructose metabolism and enzyme deficiencies related to fructose metabolism. Enzymes involved in fructose metabolism: (1) fructokinase, (2) fructose-1-phosphate aldolase, and (3) fructose-1,6-diphosphatase (FDPASE). Diseases associated with enzyme deficiencies: (1) essential fructosuria, (2) aldolase deficiency, and (3) fructose-1,6-diphosphatase deficiency

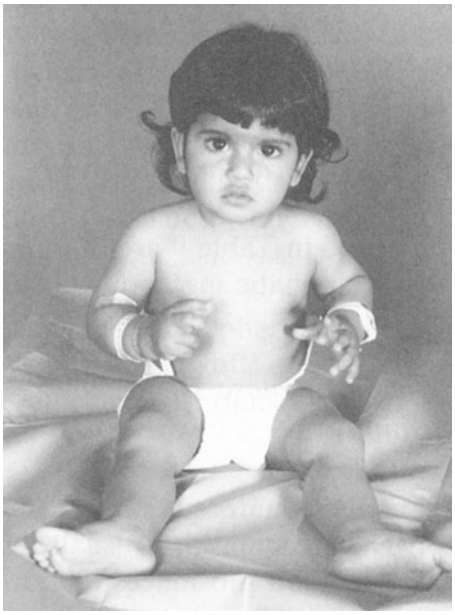

Figure 38.28
An 8-month-old girl with fructose-1, 6-diphosphatase deficiency. Her growth parameters were in the 90th percentile. There were no neurologic findings

while FDPase deficiency usually presents at 6–9 months, when the child first consumes fructose-containing food or fasts. The child may rapidly develop severe hypoglycemia, hypophosphatemia, and hyperlactic acidemia with coma and peripheral shock, which poses serious problems to the ER physician who has to manage the infant.

One suspects the presence of chronic subclinical hypoglycemia and chronic hyperinsulinism, since these infants are both bigger and heavier than their normal siblings (*Fig. 38.28*). The presence of ketone bodies in the urine at the time of crisis helps to differentiate the metabolic attack from that of HMG-CoA lyase deficiency, which never shows significant ketonuria. The hepatomegaly is not as pronounced as that of glycogen storage disease type 1. In a clinically suspect case, a liver biopsy may be obtained and measurement of the aforementioned enzymes may be attempted. A cautious fructose provocation with a small dose such as 200–250 mg/kg IV load, or short-term fasting, will lead to increased lactic acidemia, hypophosphatemia, and mild hypoglycemia, and will establish the diagnosis. If necessary, a glucagon provocation test (0.05–0.1 mg/kg glucagon injection followed by the measurement of blood glucose and lactic acid) will readily differentiate the disease from glycogen storage disease (GSD) type 1. A patient with FDPase deficiency is prone to develop precipitous metabolic crisis when fasting, or when given sugar containing antipyretic or antibiotic preparations for an infection. Fructose-containing food substances should be eliminated from the diet. Artificial sweeteners may be used. Such a patient will in time develop an aversion to sweet foods and, in an older child, the excellent condition of the teeth indicates avoidance of consumption of sweets.
