Negative pressure rooms (with antechambers) are usually reserved for respiratory isolation for the protection of staff and other patients. Positive pressure rooms are for protective isolation of the patient who is immunocompromised. Negative pressure isolation and strict barrier isolation is reserved for highly infectious pathogens. SARS and Ebola Virus are examples where this may be necessary.

All intensive care staff should strictly adhere to hand washing practices (with a Chlorhexidine based product). Unfortunately this is not the case and medical staff are often the worst offenders in this regard. Active and repeated awareness campaigns should be carried out to reinforce this basic but very important healthcare related activity.

Summary

Severe infectious processes are common reasons for admission to the pediatric intensive care unit. Children in the PICU are at risk for developing severe infections.

Increasingly children with a dysfunctional immune system survive their primary illnesses and are admitted to the PICU with severe infections. Secondary immune deficiency is common in the course of prolonged critical illness.

Rapid sampling of body fluids and commencement of broad-spectrum antibiotic cover is of the utmost importance. It is shown that even 5 min of delay in starting appropriate antibiotics has been associated with increased mortality. If there are reasons to believe there is an anatomical source of infection (collection of pus, infected central venous line, infected prosthesis etc.) often the antibiotics would not achieve their effects until the source of infection is dealt with effectively (surgical evacuation/removal, drainage).

Optimizing the hemodynamic status of the patient (oxygen delivery, addressing preload, after load, and contractility) should start from the moment one considers the diagnosis of sepsis or severe life threatening infection. Diagnostic and therapeutic interventions all go hand in hand and start in parallel from the initial encounter with the patient.

It is vital that every unit has an updated knowledge of the prevalence and sensitivity of the micro organisms prevalent in their community and in the hospital. Colleagues in clinical microbiology or infectious disease departments are invaluable members of any PICU team in dealing with these issues.

Prophylactic measures such as effective hand washing, observing strict sterility while placing central venous lines, measures to reduce incidence of the VAP, discontinuing the invasive lines and catheters when not indicated anymore, and adherence to universal exposure precautions should be implemented and monitored and audited regularly. They save more lives and money than much more expensive interventions.

Effective antibiotic stewardship, tailoring the antibiotic coverage when sensitivities of the causative organisms are known, and discontinuing broad-spectrum antibiotics as soon as clinically prudent will decrease the burden of antimicrobial resistance in the intensive care unit.

269 Diabetic Ketoacidosis

Omar M. Hijazi

Diabetic ketoacidosis (DKA), a life-threatening complication of diabetes mellitus (DM), is the most common pediatric endocrine emergency. Furthermore, DKA is the leading cause of hospitalization, morbidity, and mortality in children with type 1 diabetes mellitus. The basic pathology in DKA is absolute or relative insulin deficiency. In Pediatrics, insulin deficiency is usually absolute as in type I diabetes mellitus (DM) and can be relative as in Type II DM. Guidelines and experience in DKA management in children, is based on patients with type I DM. Experience with type II DM–related DKA is limited. In up to 67% of the cases of new onset diabetes mellitus (DM), DKA is the initial presenting clinical picture.

Definition and Classification

There is a consensus on the definition of diabetic ketoacidosis (DKA). This consensus is adopted by American and European diabetic societies. As per this consensus, DKA is diagnosed when the patient is having hyperglycemia, serum glucose more than 200 mg/dL, and metabolic acidosis (venous pH less 7.3 and/or bicarbonate less than 15 mmol/L). DKA can be mild (pH 7.2–7.3, HCO3 10–15), moderate (pH 7.1–7.2, HCO3 5–10), and/or severe (pH $<$ 7.1, HCO3 $<$ 5). Furthermore, DKA is also associated with ketonmia, ketonuria, hyperosmolality, dehydration, and electrolyte disturbances.

Etiology

DKA is caused by insulin deficiency and excess of glucagon and counter-regulatory hormones. Insulin deficiency in DKA can be absolute or relative. In pediatric age group, DKA was thought to be associated only with absolute (type I DM), insulin-dependent DM. Now it is known that DKA can occur in and can be the first presenting clinical picture for children with type II DM especially in stressed obese Afro-American children.

Epidemiology

DKA can be the first clinical presentation of type I and II DM. The likelihood of having DKA as the first presentation for type I DM is related to the patient's age (increases with young age less than 5 years), sex (females more than males), and socioeconomic status (more with poor and medically uninsured). In 15–67% of newly diagnosed type I DM, DKA can be the first presenting clinical picture. In type II DM, DKA can be the first presentation especially in obese Afro-American patients who are having significant stress like severe infection. In pediatric patients known to have type I DM, the incidence of DKA is around 8 per 100 person-years. The incidence increases with increasing age in girls (4 per 100 person-years for girls $<$7 years vs. 12 per 100 person-years for girls $>$13 years), increasing HbA1C, increasing insulin dose, lack of medical insurance, and in the presence of psychiatric disorders.

Pathogenesis

DKA usually follows poor hyperglycemic control. Patients with hyperglycemia $>$240 mg/dL need frequent glucose and ketones checks. Poor glycemic control increases the risk of DKA. DKA is also triggered with poor compliance with treatment, stress, and medications. Stress can be due to infection, trauma, and psychological stress. Stress increases glucagon, catecholamines, cortisol, and growth hormone leading to hyperglycemia, acidosis, and ketosis. Medications like corticosteroids, thiazides, and diazoxide can also trigger DKA.

Presentation

As mentioned above, DKA can be the first clinical presentation for new onset type 1 DM. Fifteen to sixty-seven percent of new onset Type I DM in children present with DKA as the first presentation. Children who are young (less than 5 years) and those of low socioeconomic status

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_269,

are at increased risk for this presentation. Patients with DKA usually present with signs that are related to insulin deficiency and glucagon excess. Hyperglycemia in excess of the renal threshold leads to osmodiuresis, dehydration, and electrolyte disturbances. Hyperglycemia increases intravascular osmolality. Hyperosmolality stimulates thirst center leading to polydypsia. Insulin deficiency and glucagons excess leads to ketoacidosis. To compensate for the metabolic acidosis, the patient breathes faster and deeper to wash out carbon dioxide. Patients with DKA may have fever and other signs of infection that precipitated the DKA. Infections that precipitate DKA are usually viral. Antibiotics are usually not indicated. Patient's appetite can increase in the beginning but decreases when the patient gets sicker. In severe DKA, the patient may have signs of altered mental status secondary to brain edema.

DIAGNOSTIC EVALUATION — Diagnosis of DKA is based on clinical and laboratory findings. Deep labored breathing in a patient known to have DM will raise suspension of DKA. However, in a patient who is not known to have DM, diagnosis of DKA can be delayed. Some patients with undiagnosed DKA were treated as bronchial asthma with no improvement to be discovered to have DKA only after laboratory results are out. Clinical signs and symptoms of DKA are a reflection of hyperosmolality, dehydration, and acidosis.

Signs and symptoms — Patients present with polyuria secondary to osmotic diuresis, polydypsia secondary to hyperosmolality-stimulating thirst. Polyuria may be associated with nocturia, diurnal enuresis, dehydration, and weight loss.

In very young children, polyuria can be missed; polydypsia cannot be expressed delaying DKA diagnosis. Young children can present with decreased activity, weight loss, dehydration, and irritability. Severe candidal diaper rash, unexplained metabolic acidosis and hypovolemia should raise the suspicion for DKA. DKA Patients may present with nausea, vomiting, and abdominal pain: a picture that can mimic appendicitis. To compensate for the DKA-induced metabolic acidosis, patients breath faster and deeper (Kussmaul), mimicking attack of bronchial asthma. Exhaled acetone can give fruity smell to the patient's breath. Patients with DKA usually have significant volume loss. However, hyperosmolality and water shift from the intra- to the extracellular compartment ameliorate signs of intravascular volume depletion. The level of consciousness in a patient with DKA can range from fully conscious patient to a patient who is in deep coma. Change in blood pH, osmolality, and glucose can be responsible for the depressed level of consciousness. Clinical brain edema occurs in 0.5–1% of children with DKA. Brain edema is the most common cause of morbidity and mortality in DKA This life-threatening complication needs early recognition and intervention.

Fluid and electrolyte deficits — Patients with DKA present with dehydration and electrolyte disturbances. Hyperosmolality helps maintain the intravascular volume. So, clinical examination may underestimate the degree of volume loss. Hyperosmolar renal water loss will lead to sodium, potassium, calcium, and phosphorus loss. Initial serum level of these electrolytes may not reflect this loss. The average losses per kilogram body weight in patients with DKA are as follows: Na 5–13 meq, K 6–7 meq, and water 30–100 ml. DKA patients usually present with 5–10% dehydration. Patients with moderate DKA are managed as 5–7% dehydration. Patients with severe DKA are managed as 10% dehydration. To help decrease the risk of brain edema, initial fluid bolus is limited to 10 ml/kg of glucose free isotonic fluid as 0.9 normal saline. A second bolus will be given only if the patient's intravascular volume is severely compromised.

Laboratory findings: After initial assessment, blood should be collected for serum glucose, bedside glucose testing, blood gases, serum sodium, potassium, phosphorous, creatinine, blood urea nitrogen, hemoglobin, glycoslated hemoglobin, and, if available, blood level of β-hydroxybutyrate. The diagnosis of DKA is confirmed by the findings of hyperglycemia serum glucose >200 mg/dL, a wide anion gap acidosis pH < 7.3 and HCO3 < 15 meq/L, and ketonemia.

Hyperglycemia: Hyperglycemia, serum glucose more than 200 mg/dL and acidosis are the two main biochemical criteria for the diagnosis of DKA. However, hyperglycemia is not a must for the diagnosis of DKA. Patients with DKA may present with normal or low serum glucose as with decreased oral intake or after starting treatment with insulin. Hyperglycemia exceeding the renal threshold will lead to osmodiuresis, dehydration, and increased risk of candidal infection in the genital area.

Metabolic acidosis: Metabolic acidosis with venous pH less than 7.3 and/or serum bicarbonate less than 15 mea/L is the second biochemical criteria for the diagnosis of DKA. The hyperglycemia and the metabolic acidosis are the result of insulin deficiency, and excess of glucagon and other counter-regulatory hormones. The cells need the glucose to produce energy. The glucose needs the insulin to enter the cells. In DKA, with shortage of insulin, the glucose stays in the blood, the cells fast, and the body releases stress hormones leading to hyperglycemia, gluconeogenesis, and lipolysis. Lipolysis will lead to increase free fatty acids and triglyceride in the blood. Glucagon helps the entry and metabolism of free fatty

acids to the mitochondria forming ketone bodies. Acetoacetate, the first ketone body formed can be reduced to β-hydroxybutyrate acid or decarboxylated into acetone. Acetone is an inert compound that does not contribute to the acidosis, but can help in the diagnosis of DKA by giving a fruity smell to the patient's breath and reacting to the nitropruside test. β-hydroxybutyrate is the major ketone body in DKA forming up 75% of the total DKA ketone bodies. β-hydroxybutyrate the major contributor to the acidosis, with DKA treatment it converts back to acetoacetate. B-hydroxybutyrate does not react with nitropruside test. Nitropruside test, by detecting acetone and acetoacetate and missing the major ketone body β-hydroxybutyrate underestimate the ketone level in DKA. On the other hand, during recovery β-hydroxybutyrate is converted to acetoacetate and acetone, which persist for a longer period. As a result, urine testing may give a false impression of worsening ketoacidosis while total ketone bodies and the patient's clinical condition are actually improving. Therefore, direct measurement of serum β-hydroxybutyrate at the laboratory or at bedside should be used whenever possible.

The degree of ketoacidosis in DKA is related to the balance between rate of ketone formation averaged 51 meq/hr, urinary excretion of ketones averaged 15 meq/hr, and conversion of acetoactate to the inert acetone ranging 15–25%. Treatment of DKA with insulin decreases ketone production and enhances its metabolism clearing the ketoacidosis.

Metabolic acidosis in DKA can be multifacorial; insulin deficiency leading ketoacidosis, severe dehydration and poor perfusion leading to lactic acidosis, and late in the course the iatrogenic hyperchloremic acidosis secondary to excess treatment with sodium chloride–containing solutions.

The anion gap in DKA is mainly a reflection of the ketone bodies. The narrowing of the anion gap during the process of DKA treatment is an indication of improvement in ketosis and acidosis. Anion gap can be used to help follow-up for ketosis if blood testing for β-hydroxybutyrate is unavailable. However, the anion gap may also underestimate the degree of acidosis. The loss of ketoacid anions in the urine (as the sodium and potassium salts of β-hydroxybutyrate and to a lesser degree acetoacetate) lowers the anion gap without affecting the plasma bicarbonate concentration or therefore the degree of acidosis.

Ketone bodies are potential HCO3. With insulin treatment, metabolis of ketone bodies will result in the generation of NaHCO3. So, ketone bodies are potential HCO3 donor. Urinary loss of ketone bodies represent loss of potential HCO3.

The serum anion gap is calculated by checking the difference between serum sodium and the sum of chloride and bicarbonate. The normal value in children is 12 ± 2 mmol/L.

Serum sodium — In DKA, patients usually present with hyponatremia. This hyponatreia is due to true and/or factious hyponatremia. True hayponatremia results from intravascular hyperosmolality shifting water from intra- to extracellular compartment leading to dilutional hyponatremia. As per standard correction, serum sodium is estimated to be lowered by 1.6 meq/l per 100 mg/dl increase in serum glucose above 100 mg/dl. However, the physiological decrease is more than that. It was found to be 2.4 meq/L per 100 mg/dL increase in serum glucose above 100 mg/dL. This dilutional hyponatremia is opposed by water depletion resulting from hyperglycemic osmodiuresis, increase insensible loss due hyperventilation and decrease oral intake later in the course of DKA. However, increased water intake stimulated by hyperosmolarity can exaggerate hyponateremia. Hyperlipedemia in patients with DKA, by decreasing the plasma volume in which sodium is present, leads to factious hyponatremia.

Serum potassium: Patients with DKA may be present with normal, low, or high serum potassium. However, total body potassium is depleted. Potassium is lost through kidney hyperglycemic osmodiuresis. Furthermore, vomiting and diarrhea if present will exacerbate potassium loss. In average, a child with DKA potassium losses is 6 meq/kg. This loss of potassium is ameliorated by decrease in intracellular potassium entry due insulin deficiency and intravascular hyperosmolarity induced water and potassium shift to the extracellular compartment. With treatment of DKA, the hydration increasing renal potassium loss, and insulin increasing potassium shift to the intracellular compartment, serum potassium level will be lowered.

Serum phosphate: Patients with DKA usually have depleted body phosphate. Serum phosphate can be normal or high. Insulin deficiency, hyperglycemia, and metabolic acidosis shift phosphate from intra- to extracellular compartment. This helps maintain normal serum phosphate level balancing phosphate loss. Total body phosphate is depleted due to increased renal loss and decreased intake. With treatment, hydration and insulin, shift phosphate to the intracellular compartment uncovering phosphate deficit.

Blood urea nitrogen: High blood urea nitrogen in a patient with severe DKA is an indicator of significant volume loss, and a predictor of increased risk of brain edema.

Differential diagnosis: Polydypsia and polyuria can be seen in uncontrolled diabetes mellitus, diabetes

insipidus, hypokalemic nephropathy, and psychogenic polydupsia. Dehydration and labored breathing can be seen with ketoacidosis and bronchial asthma in a patient who is having increased insensible loss and decreased intake.

Treatment

General Care: Early recognition and proper intervention help improve the outcome of patients presenting with DKA. DKA diagnosis can be straightforward as in a patient who is known to have DM who is presenting with tachypnea and dehydration. However, in a patient who is not known to have DM the same presentation can be initially misdiagnosed as bronchial asthma. Most of the experience in DKA treatment comes from treatment of children with type I DM. The data on the management and outcome of DKA in children with type II DM is limited. Regardless of the severity of DKA, the basics of management are the same. In addition to close clinical bedside monitoring, patients with DKA need appropriate fluid, insulin, electrolyte, and blood gasses monitoring and treatment. However, the setting in which the child with DKA should be placed in is based on the DKA severity that is determined based on clinical and laboratory findings.

Where to treat the patient: Neurological status, degree of dehydration, anion gap, severity of acidosis, and duration of symptoms are used to assess the acuity of DKA presentation. The more depressed the mental status, the more severe the dehydration, the wider the anion gap, the lower the venous pH and HCO3 and the longer the duration of symptoms the more severe is the DKA. Severity determination helps the doctors place the patient in the right setup of care. A patient with depressed mental status and severe dehydration needs critical care setup. While a child with mild DKA, normal neurological examination, and good oral intake, may be managed on outpatient basis with the help of cooperative family.

Once diagnosis is made on clinical and lab findings (hyperglycemia, metabolic acidosis, and ketonemia), treatment should be started. The following points are important in the approach for a patient with DKA.

Laboratory: Before staring the treatment, blood and urine should be collected for appropriate laboratory test mentioned above.

Monitoring: Sick patients with DKA need close monitoring in a critical care area. They should be connected to a monitor for continuous monitoring of heart rate and rhythm, respiratory rate, and oxygen saturation. Blood pressure and temperature should be monitored as the patient's condition mandates. In a patient with DKA, heart rate can be high due dehydration, anxiety, pain, and fever. Bradycardia may indicate increased intracranial pressure. Electrocardiogram may show changes of electrolytes disturbances. Breathing can be fast and labored as a compensation for the metabolic acidosis, it can be normal or it can be slow due to increased intracranial pressure. The patient can be hypotensive due to dehydration and can be hypertensive due to increased intracranial pressure. The patient can be febrile due to precipitating infection. Fever increases insensible loss. In general, fever in DKA is not related to bacterial infections and does not justify starting antibiotics. In any sick patient, oxygen saturation should be monitored. Patients with DKA present with dehydration. Assessing the degree of dehydration in DKA can be difficult. Hyperosmolality of the intravascular compartment helps maintain the intravascular volume on the expense of intracellular compartment. In general, monitoring of the urine output is important to assess the status of hydration and tissue perfusion. However, urine output in a patient with DKA can be misleading; the patient can have increased urine output while dehydrated secondary to hyperglycemic osmodiuresis and can have decreased urine output while well hydrated secondary to syndrome of inappropriate antidiuretic hormone secretion (SIADH). Elevated urine specific gravity is usually an indication of dehydration. In patients with DKA, glucosuria and ketonuria will increase the urine specific gravity. This makes urine specific gravity undependable in assessing the degree of hydration in a patient with DKA. Hematocrit and blood urea nitrogen are good predictors of intravascular volume and degree of dehydration in DKA. Hourly intake output charting should be done. The fluid balance should be monitored. If the patient is having depressed mental status, a urinary catheter should be inserted. Optimizing oxygen delivery is the target of the intensivist. Oxygen supply should be given to the patient as needed to maintain saturation in the mid-90s. In addition neuro-vital should be monitored closely in a sick patient with DKA. The patient can have gradual or sudden deterioration in the level of consciousness. This can be due to many causes as hypoglycemia, brain edema, and hyperosmolar coma. Early recognition and proper intervention for the cause of drop in the level consciousness will help improve the outcome. In addition to vital signs monitoring, DKA patients need close monitoring of serum glucose, electrolytes (Na, K), venous blood gases, blood β-hydroxybutyrate if available, and anion gap. This monitoring is done initially hourly for the first 3–4 h then every 2 h as the patient's condition

stabilizes. If bedside capillary glucocheck is used, readings should be compared to the laboratory results. Patients with DKA usually present with low Na. This hyponatremia can be true (dilutional) or factious (due hyperlipedemia). Serum sodium is monitored closely during DKA treatment. During the course of DKA treatment, glucose should go down while sodium should go up. Should the sodium fail to increase while the glucose is decreasing, the patient needs close monitoring. Such a patient is at higher risk for brain edema. This could be due to excess free water administration or syndrome of inappropriate antidiuretic hormone release (SIADH). In such a case, sodium concentration in the infusate should be increased and/or the volume of infusate should be decreased.

Fluids: DKA patients are dehydrated and have increased intravascular osmolality. This usually happens over time allowing the formation of intracellular osmolar molecules to maintain a balance between intracellular and extracellular osmolality. Fluid boluses will be given only if there are signs of severe intravascular volume depletion. In general, isotonic fluid as 0.9 normal saline 10 ml/kg is given slowly over 60 min. Repeat fluid boluses will be avoided unless the patient is still showing signs of severe intravascular volume depletion. Patients with DKA have fluid deficit that is between 5% and 10%. This deficit is replaced over next 48–72 h. After fluid bolus, plain isotonic fluid (isotonic saline or lactated Ringers) will be started to cover for the maintenance and the deficit. Potassium will be added after assuring urine output and normal or low serum potassium. As an example a 5-year-old, 20 kg, male known diabetic patient presenting with severe DKA tachycardia, hypotension, venous pH 7.0, serum glucose of 700 mg/dL, and ketonemia will be given 200 ml of 0.9 normal saline over 60 min. Based on the diagnosis of severe DKA with10% dehydration will be given 2,000 ml for fluid deficit to be given evenly over the next 48–72 h. For maintenance he will need 1,500 ml. So he will be given 1,000 (half deficit) and 1,500 ml as maintenance evenly over first 24 h. Infusate will be started as 0.9 normal saline. To prevent hypoglycemia, glucose 5% will be added to the infusate once the blood glucose reaches 300 mg/dL. Should the glucose continue to drop before the resolution of DKA, higher concentration of glucose will be added to the infusate.

Insulin: For patients with mild DKA and no vomiting, insulin can be given as subcutaneous (sc). For sick patients with DKA, insulin will be given as continuous IV infusion. The infusion will start after the initial fluid bolus and checking the serum glucose. In general, insulin bolus before starting the insulin infusion is not needed if adequate dose is given. The usual staring dose is 0.1 unit/kg/h. The infusion will start after completion of the fluid bolus. Delaying the initiation of insulin infusion for hour or more, may help decrease the risk of brain edema. At the above infusion dose, an insulin blood level of 100–200 microunit/ml will be reached in an hour. This level is enough to facilitate glucose and ketone metabolism, and suppress gluconeogenesis and ketogenesis. In general in sick patients with DKA, insulin is given as intravenous infusion. Subcutaneous (SC) and intramuscular (IM) routes are to be avoided in such cases. Absorption of SC and IM can be unpredictable especially in a patient with poor perfusion. However, there are reports about treating DKA with SC insulin infusion. Blood glucose will be monitored hourly and whenever there is a change in the level of consciousness. With hydration and insulin blood glucose will decrease. The target is to achieve a gradual drop in glucose at a rate of 50–100 mg/dL/h. If the drop is faster than that, glucose will be added to the infusate. If the glucose continues to drop fast, insulin dose will be decreased and more glucose will be added to the infusate. The aim of using insulin infusion is resolution of the acidosis and ketosis. The target is not to treat hyperglycemia only. The target is to treat ketosis, acidosis, and hyperglycemia. Hyperglycemia usually resolves before the resolution of ketosis and acidosis. Insulin infusion should continue until the resolution of ketoacidosis. Ketoacidosis is resolved when the patient's ph $>$ 7.3 and/or serum bicarbonate $>$15 meq/L, serum ketones negative or trace and plasma glucose $<$200 mg/dL.

Potassium: Patients with DKA, usually present with normal or high serum potassium. Hypokalemia at presentation is uncommon. However, total body K is depleted. In DKA, there is increase in potassium loss by the renal and gastrointestinal systems, while, insulin deficiency and hyperosmolality increase intravascular potassium. With treatment, hydration improving the kidney perfusion and insulin improving the entry of glucose and K to the cells, and resolution of metabolic acidosis serum K will decrease. So, K should be added to the infusate with the start of insulin therapy if the patient is having good urine output and the serum K level is normal or low. If the patient is hypokalemic, potassium should be added immediately to the infusate. Insulin should be delayed or started at low dose until achieving normokalemia. Potassium can be added to the infusate as potassium chloride or a mixture of potassium chloride and potassium phosphate.

Sodium Bicarbonate: With DKA treatment, ketone bodies are metabolized producing bicarbonate. Hydration improves tissue perfusion and control lactic acidosis. Although patients with severe DKA can be very acidotic, NaHCO3 should be avoided. In general, HCO3 should not

be given in the venous pH $\geq$ 7.0. There is no proven benefit from treating DKA acidosis with bicarbonate. Furthermore, treating DKA acidosis with bicarbonate can lead to cerebrospinal fluid (CSF) paradoxical acidosis, delay resolution of ketosis, and hypokalemia. However, in certain conditions as severe DKA with pH $<$ 6.9 and poor myocardial function, and hyperkalemia, bicarbonate may be given.

Phosphate: As with potassium, total body phosphate is depleted in patients with DKA. With DKA treatment, hypophsphatemia becomes more apparent. Studies showed that hypophphatemia did not affect tissue oxygenation and treatment of hypophosphatemia is not essential part in the treatment of DKA. Furthermore, treatment of hypophsphatemia can lead to hypocalcemia and hypomagnesemia. However, if phosphate level is less than 1 mg/dL, it should be treated.

In a febrile patient with DKA it was found that fever, white blood cell (WBC) count, and WBC differential are not significant predictors of bacterial infection. However, it was found that there is correlation between WBC count and pH and serum HCO3. WBC count reflected the severity of DKA, patients with high count had lower venous pH and HCO3. Majority of febrile patients with leukocytosis and DKA are not having bacterial infection and antibiotics are not needed.

When to switch from iv insulin infusion to sc insulin: Once the DKA resolves (pH $>$ 7.3 and HCO3 $>$ 15, glucose $<$ 200 mg/dL and absent or trace ketone bodies or normal anion gap), subcutaneous insulin will be given and 30 min later insulin infusion will be discontinued and the patient will be allowed to eat.

What can go wrong: While taking care of patient with DKA, the patient can have deterioration in the level of consciousness, electrolyte imbalance like hypokalemia, hyperkalemia, hypoglycemia, failure of the Na to increase while the serum glucose is decreasing, hemodynamic instability due to inadequate fluid intake arrhythmia, and brain edema. Reported mortality risk in DKA ranges 0.15–0.5%. The most common cause of death in DKA is brain edema. DKA patients are at increased risk of deep venous thrombosis. DKA patients who had central venous femoral catheters are at higher risk. In two recent studies, 50% of DKA patients who had central venous femoral line inserted had clinical evidence of deep venous thrombosis. DKA patients with altered mental status are at increased risk of aspiration if they vomit. They should be kept NPO (nothing per orem or orally) and have nasogastric tube connected to low grade intermittent suction. Electrolytes imbalance as hyperkalemia and hypokalemia increases the risk of arrhythmia in patients with DKA; these patients need close monitoring of their potassium and heart rhythm. Elevated pancreatic enzymes occur in around 40% of children with DKA. This elevation does not reflect pancreatitis. Pancreatitis diagnosis is based on clinical, radiological, and laboratory basis. Clinical pancreatitis occurs in 2% of DKA cases.

Brain edema complicating DKA: Clinical brain edema complicates 0.3–1% of DKA. The risk is higher in children, and in newly diagnosed DKA. Laboratory risk factors include elevated blood urea nitrogen, low serum bicarbonate, high serum glucose, and failure of the sodium to increase as the glucose decreases during the treatment of DKA. There was no clear association between treatment factors and DKA-related brain edema. Clinical brain edema carries high morbidity and mortality. One third of the patients die or survive in vegetative state. The majority of brain edema in DKA takes place hours after the initiation of treatment. However, in average 20% of DKA-related brain edema declare itself before initiation of DKA treatment. In a recent Canadian study, brain edema was present at presentation in 19% of the DKA-related brain edema cases. It continues to occur even in the optimally managed patients. Once the patient develops signs of increased intracranial pressure and pending herniation, there is limited time to treat. Continuous monitoring of the patient's clinical and laboratory data is essential for early recognition and intervention. High index of suspicion should be applied. Headache, vomiting, irritability, and lethargy may be signs of brain edema. Brain imaging may be normal initially while the patient is having clinical signs. Normal brain imaging, should not delay brain edema treatment.

Prevention: DKA is a serious life-threatening complication of DM. The best way to decrease DKA morbidity and mortality is prevention. Early diagnosis and proper intervention of DM by screening and follow-up of high-risk group can decrease the incidence of DKA. In known diabetic patients, DKA usually follows poor glucose control. If a diabetic demonstrates serum glucose $>$240 mg/dL, frequent testing for glucose level and close follow-up should be done. Patient and family education to help increase awareness about the short- and long-term DM complications is vital. Studies done in the United States and Europe showed up to 60% of the cases of recurrent DKA occur in only 5% of patients with DM. Having multidisciplinary team that include pediatrician, endocrinologist, social worker, diabetic educator that will study the causes of recurrence in these cases, educate, support these high-risk patients will help direct the resources to the needy patients.

The targets of this team are to improve the quality of life, decrease morbidity, mortality, hospitalization, and increase productivity for this high-risk group.

Pediatric Burns

Fuad Hashem

270 Burns

Fuad Hashem · M. M. Al Qattan

Pediatric burns are recognized as a challenging problem. There is a significant contrast between the adult and the child in terms of the anatomy, metabolism, hormonal changes, immune responses, pathophysiology, and therapy of burns. Continuous physical, reconstructive, and psychosocial problems will occur as the child is developing. The goals of treatment are survival of the patient, preservation of function, and restoration of normal appearance.

Epidemiology and Prevention

Burns in children can be caused by heat or cold, chemicals, electricity, or radiation. The average age of occurrence of a pediatric burn is 32 months. The incidence of burns in children varies with age, sex, and socioeconomic status. In the United Sates, 100,000 children per year require hospitalization due to burn injuries. Scald burns are common in children less than 5 years of age, while flame burns occur more between the ages 5 and 10 years. Boys have a higher incidence of burns than girls. Before the age of 2 years, the male-to-female ratio is 1.5:1. This ratio increases to 3.5:1 in the 13–18 year age range. The risk of burns in children increases in low socioeconomic conditions where there is inferior education and reduced supervision of children.

Recently, Sharma et al. studied the epidemiology pediatric burn in a gulf country (Kuwait) and reported an overall incidence of 17/100,000 children aged 0–14 years. In that study, scald was the main cause of burns (67%) followed by flame (23%).

In an interesting review of epidemiology of burns, Al-Qattan and Al Zahrani stressed on several specific etiologies of pediatric burns in various countries in relation to nation-specific traditions, social habits, or religious activities, and these are summarized in *Table 270.1*. Note should be given that most of these burns are preventable.

Education about environment and socioeconomic risks play an important role in reducing the incidence of burns in children. The prevention of accidents requires the continuous supervision of the child and removal of hazards from their environment. Better design of home equipment and more widespread use of flame-proof textiles are the most effective strategies in the prevention of pediatric burns.

An important cause of pediatric burns is child abuse. Recognition of non-accidental injury requires the admission of any child who is suspected of being abused for management and investigation. Child abuse is diagnosed when there is a history inconsistent with physical findings, such as history of delay in seeking medical attention, fearfulness, unexplained injuries, dehydration, malnutrition, and systemic injuries. The pattern of the burn is usually linear and deep. Immersions burns often show sparing of the intertriginous zone by the protective fetal positioning (*Fig. 270.1*), while contact burns are uniform. Evaluation consists of a blood count to rule out anemia, a complete radiologic skeletal survey to rule out fractures, and photographic documentation of injuries.

Emergency Management

An adequate airway and ventilation must be established first. All burned and smoldering clothing should be removed. Intravenous access with large-bore venous cannula for fluid resuscitation should be established and tetanus prophylactics given. A nasogastric tube and bladder catheter should then be inserted. The criteria for the admission of burned child are as follows:

Second- and third-degree burns more than 10% of total body surface area (TBSA)
Second- and third-degree burns involving the face, hands feet, genitalia, perineum, or a major joint
Third-degree burns more than 5% TBSA
Electrical burns
Chemical burns
Inhalation injury
A preexisting medical condition
Associated trauma
Suspected child abuse

Young reviewed the emergency management of burns in children and noted several important and unresolved issues: (1) the care of burned children in hospitals are frequently provided without burns teams, (2) inadequate

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_270,

Table 270.1
Pediatric burns related to traditions, social habits, religious activities, and festivals

Country	Mechanism of pediatric burns
Korea	Steel chopsticks are common in Korea. Young children insert the chopsticks into the wall socket
United Kingdom	"Low-lying" disposable barbeques are common. The barbeques are easily reached by young children
Middle Asia	"Sandal" burns in toddlers: "Sandal" is a hole made in the floor of the room for specially prepared line coals (used for heating). Toddlers crawl and fall into the coal
Spain	"Ember" burns: The family burns olive trees to produce incandescent residues. Infants may crawl into it
Developed countries with cold weather	Contact burns to gas fireplaces
Saudi Arabia	"Street soccer" friction burn to the foot: Children play barefoot on the street. As the car tire impacts on the child's foot, the driver stops the car resulting in a friction burn
Israel	"Shabbes" burns: Scald burn in Jewish orthodox children during "sabbath" bath with hot water
Turkey	"Flying toy balloon" burn: Instead of helium, acetylene gas is used to fill flying toy balloons. Acetylene gas is highly flammable
All Countries	Fireworks related burns are common in children all over the world and they can occur during national feast/festivals such as new year's eve, Halloween, the American Fourth of July holiday, and the Muslim Eid

numbers of critical care beds for children with burn, and (3) morbidity after small burns (e.g., toxic shock syndrome is still leading to death in burnt children). Potokar stressed that the situation may be a disaster in certain conditions and gave example of burnt children from the conflict in Iraq.

Inhalation injury occurs in enclosed spaces. Hypoxia caused by inhalation injury should be diagnosed early and treated. Mortality is more than 50% with acute asphyxia and carbon monoxide poisoning being the main causes of early death. Bronchoscopy is important in diagnosis, and changes in the upper airway range from mild erythema to complete desquamation of the epithelium. Humidified 100% oxygen is given by mask to clear the carbon monoxide. Intubation is indicated if there is deterioration of blood gases.

In acute burns, the child's cardiac and pulmonary condition should be evaluated, followed by an assessment of the associated blunt and penetrating trauma, prevention of burn wound contamination by covering burns with clean dressings, and relief of pain by intravenous narcotics (morphine 0.05–0.1 mg/kg every 2–3 h as needed). Cold soaks in the first 15 min reduce pain and tissue damage in partial-thickness burns, but hypothermia should be avoided to decrease the risk of arrhythmia. Circulation in circumferential burns of the extremities is monitored by distal pulses, Doppler, capillary refill, and assessment of the need for early escharotomies or fasciotomies (*Fig. 270.2*). The indications for escharotomy are impaired capillary filling, progressive neurologic changes, loss of palpable pulses, and compartment pressure of more than 30 mmHg.

Pudre et al. stressed upon several specific issues regarding pediatric emergency chemical and electrical burns. Except for hydrofluoric acid burns which require calcium glucorate management, almost all other chemical burns should begin with immediate irrigation with large quantities of tap water. Neutralization of acids or alkalis is not appropriate. Irrigation of eye burns is carried out at the same time. Chemical burns are generally uncommon in children, although domestic chemical burns are seen frequently in developing countries by Pikanen and Al-Qattan.

High voltage electrical burns are caused by current greater than 1,000 V. The hallmarks of electrical burns are the presence of contact points (the so-called entrance and exit wounds). Tissue damage is regions immediately adjacent to contact points is the most severe and is frequently associated with compartment syndrome or muscle necrosis. Therefore, fluid resuscitation in high voltage electrical burns cannot be calculated accurately from the amount of cutaneous burn. Instead adequate resuscitation is given to establish a urine flow of 1, 1.5, and 2 mL/kg/h in older children, younger children, and infants, respectively. Furthermore, initial cardiac monitoring and aggressive management of myoglobinuria (if present) are unique emergency issues in high voltage electrical burn.

In children, the most common low voltage electric burns involve the oral commissure and these will be discussed later in more details.

Definitive Management and Treatment

The treatment of burns includes fluid resuscitation, nutritional support, infection control, burn wound excision, skin grafting, and rehabilitation. The extent and depth of the burn injury determine the severity. In calculating the percentage of the burn, the estimate includes wounds of second- and third-degree depth only. ❯ *Fig. 270.3* shows the burn estimate diagram employed to calculate the extent of pediatric burn injury by body surface area in children of different age groups. First-degree burns are the most superficial and are similar to sunburn. The skin is light red in color, without blisters, and painful, usually healing in 3–6 days. Second-degree burns (❯ *Fig. 270.4*) are divided into superficial and deep dermal injuries. Superficial second-degree burns are bright red in color with a moist surface, are severely sensitive to stimuli, and usually heal within 10–21 days. Deep dermal burns are dark red to yellow-white in color, with a slightly moist surface. They heal in 3 weeks or more and often cause hypertrophic scar formation. Third-degree (❯ *Fig. 270.5*) or full-thickness burns are white and charred, with thrombosed superficial burns that require grafting for the wounds to heal.

The presence of inhalation injury significantly increases mortality in patients with burns. Singed nostril hair is not a reliable indicator of inhalation burn. The presence of inflammation of the mucosa in the oropharynx confirms edema in the upper airway. Other signs are turbulent air flow in the upper airway, wheezing, brochorrhea, a brassy cough, and hoarseness. A partial pressure of O_2 of less than 70 mmHg is an indication for intubation and ventilation. Fiberoptic bronchoscopy assists in the diagnosis and management of inhalation injury. An endotracheal tube can be passed over the fiberoptic scope. Mucosal edema, erythema blebs, and slough can be diagnosed. Carbonaceous debris and brochorrhea are extramucosal findings. Mild edema is seen in mild injuries; the severity depends on the involvement of the supraglottic (false cords) area. In severe cases the true vocal cords are not visualized. Because of the prolapsed of the arytenoids into the airway lumen, there is marked erythema, and the mucosa may slough entirely. False cords bulge together in the midline, causing complete obstruction of the airway. No antibiotics or steroids should be given in the treatment of inhalation burns.

Fluid Resuscitation

The goals of fluid resuscitation are to restore the fluid volume and electrolyte homeostasis, maintain perfusion pressure, and minimize edema. Fluid resuscitation in children differs from that in adults because children have a larger TBSA relative to body weight. Children with second- and third-degree burns of more than 10% TBSA require fluid resuscitation. A central line is inserted if the burn is more than 40% TBSA. The fluid requirement may increase if the burn is associated with trauma or inhalation injury. An indwelling urethral catheter is used to monitor urine output for adequate resuscitation (urine output at 1 mL/kg/h). Severe hypoglycemia may develop in 24 h because of decrease glycogen stores in children. Therefore, glucose-containing fluid should be added to the resuscitation fluid initially.

Many formulas have been used to calculate fluid requirements based on the weight of the child, the size of the burn, and the surface area. Use of the Parkland formula (4 mL/kg/% burn) as the total 24-h fluid replacement underestimates in infants and small children. In young children, estimation of burn-related fluid losses and the maintenance fluid requirement, known as the "two-figure formula," indicate the safe amount of resuscitation fluid required.

In the first 24 h, children weighing less than 30 kg should receive lactated Ringer's solution (4 mL/kg/% burn) plus maintenance fluid; half of the calculated fluid is given in the first 8 h, and half in the next 16 h. In the second 24 h, dextrose in 5% saline and colloid (5% albumin) 0.5 mL/kg/%burn) are required to maintain a urinary output of 1 mL/kg/h. In infants, 5% dextrose in lactated Ringer's solution is given to decrease the risk of hypoglycemia. Children weighing over 30 kg should receive lactated Ringer's solution (4 mL/kg/h) in the first 24 h and colloid fluid (0.5 mL/kg% burn) and 5% dextrose in the second 24 h to maintain urine output at 1 mL/kg/h. In the second 24 h, the volume delivered is an estimate of free water loss plus allowance for urinary output. Colloid is given in the second 24 h (0.5 mL/kg/% burn) because capillary leaks that develop in the first 24 h seal.

The surfaces area formula results in 5,000 mL/m^2 as burn-related fluid losses plus 2,000 mL/m^2 as fluid maintenance in the first 24 h. Half of the calculated fluid is given in the first 8 h and half in the subsequent 16 h.

In the first 24 h after the burn, vascular permeability is increased. Controversy still exists regarding colloid administration in the first 24 h. Brouhard demonstrated extravasation of albumin into the interstitium in burn models. Resuscitation with a formula containing colloids maintains the colloid osmotic pressure and corrects the hemodynamics with smaller amounts of fluids. Adequate resuscitation is monitored by hourly urine output (1 mL/kg/h), vital signs, hematocrit, and electrolyte levels.

Invasive methods, including central pressure measurements, cardiac output, and mean arterial pressure, are used for monitoring large burns.

Metabolic Changes and Nutritional Support

Burn injuries induce hypermetabolic responses and increase energy expenditure, as characterized by protein and fat catabolism. In large burn injuries, the basal metabolic rate may increase up to twice the resting level. The signs of catabolism are persistent tachycardia, tachypnea, hyperpyrexia, and marked body wasting.

In the shock phase, fluid loss causes hypovolemia, and hypoperfusion stimulates the secretion of aldosterone and antidiuretic hormone, causing sodium and water retention. After resuscitation, there is an increase in cardiac output, urinary nitrogen losses, tissue catabolism, and basal metabolic rate. Thermal injury causes the production of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. ACTH stimulates the adrenal cortex to produce cortisol. Cortisol levels remain high for many weeks and cause mobilization of amino acids from skeletal muscle. The adrenal medulla secrets epinephrine, which stimulates hepatic glycogenolysis and gluconeogenesis, together with the release of glucagon and glucocorticoids. There is a decrease in insulin and further glucose production.

Gluconeogenesis depletes body protein. To improve the nitrogen balance, glucose and nitrogen should be added to the diet of a burned child, via the enteral route whenever possible. A nasogastric tube should be inserted for burns more than 20% TBSA. If the patient is stable and there are bowel sounds, enteral feeding should be started within 6–8 h after injury. The hypermetabolic response decreases with early implementation of enteral feeding. The goal of nutritional support is to maintain the body weight at preadmission levels. Many formulas have been proposed to estimate nutritional requirements. As children have a greater body surface area than adults, caloric demands can be accurately calculated using a formula based on surface area. Infants should receive 1,000 kcal/m^2 body surface area burned plus 2,100 kcal/m^2 body surface areas for maintenance per day, and children should receive 1,300 kcal/m^2 body surface burned plus 1,800 kcal/m^2 body surface areas for maintenance. Children should receive supplements of vits C and A, zinc, potassium, and calcium.

Indirect calometry is considered relatively accurate to estimate energy expenditure in pediatric burns and Liusuwan et al. concluded that the WHO formula is more accurate than Harris Benedict and Mayes formula in a pediatric burn population.

Burn Wound Management

The burn wounds are first cleaned and dressed with a topical agent (e.g. 0.5% silver sulfadiazine, 0.5% silver nitrate, and mafenide acetate). Silver sulfadiazine is the most commonly used topical agent. Side effects include thrombocytopenia, leucopenia, and skin rash. Silver nitrate can cause hyponatremia, hypokalemia, hypochloremia, and hypocalcemia, because of the leeching effects of the silver salt. These agents penetrate the burn eschar poorly. Mafenide acetate penetrates the burn eschar well and controls bacteria, but it is painful and can cause allergic reactions. It contains a carbonic anhydrase inhibitor that causes bicarbonate wasting.

If the patient's condition is stable, once- or twice-daily hydrotherapy is started on the second day to remove nonviable tissue and accumulated bacteria. Burn wound infections occur when bacteria multiply in viable tissue beneath the burn eschar. Daily assessment of burn wounds in children is important for detecting early signs of invasive infection. Signs of invasion infection are focal areas of red-brown discoloration of the eschar, accelerated separation of the eschar, and a moth-eaten appearance. Burn biopsy and histologic examination confirm the presence of invasive burn wound infection, which is most commonly caused by gram-negative organisms and Candida. Surgical excision and systemic antibiotics are also considered in the treatment of burn wound infection. After excision of the burn eschar, the wound can be covered with an autograft or temporarily covered with a biologic dressing.

Perhaps the most outstanding and remarkable change in pediatric burn wound management is the use of silver dressing for partial-thickness burns. Cuttle et al. studied burn wound management is an Australian pediatric burn center. Up to 2002, the authors used silver sulfadiazine and then switched to silver dressing. The latter was cost effective and resulted in less admissions, reduced frequency of dressing changes, and quicker healing.

Surgical (Wound Excision) Management of Burn Wounds

Early burn excision has reduced morbidity and mortality in children with large burns. Early excisions improve immunologic, hematologic, metabolic, and functional

status, and decreases both blood loss and the need for later reconstruction. Burns should be excised 3–5 days after the child has been resuscitated and edema has subsided.

Superficial burns heal in 2–3 weeks without hypertrophic scarring. Full-thickness burns require excision and skin grafting, while intermediate-thickness burns may require more than 3 weeks to heal. The healing process may produce hypertrophic scars and contractures. If a burn wound fails to have adequate epithelialization after 3–4 weeks, then it should be excised and grafted. Early excision and grafting of intermediate- and full-thickness burns will reduce the risk of developing hypertrophic scars and burn contractures. Children with large full-thickness burns should have early excision of eschar after completion of resuscitation to reduce complications. Tangenital excision is performed under general anesthesia. Adequate excision is determined by the punctate bleeding pattern. The amount of blood loss during excision should not exceed 50–60% of the total blood volume. Up to 15% of the TBSA can be excised and grafted during the same anesthesia session. To decrease the amount of blood loss, excision is divided into separate areas to control bleeding. Skin grafts are harvested and meshed, homeostasis is established by application of topical thrombin and electrocautery, and adequate blood and crystalloid are given to maintain the normal hematocrit. Intraoperative monitoring should include urinary output, vascular filling pressure, and body temperature. Occasionally, the wound may need to be excised more deeply, to the subcutaneous fat or even to the deep fascia which will lead to significant cosmetic and functional deformity. Skin grafts are then applied to the debrided areas and secured with staples. Meshed grafts should not be used on exposed areas such as the face, neck, and hands. Donor sites are covered with bulky, absorbent dressings for 7–9 days. Allografts provide a temporary covering when there is a shortage of skin grafts and act as a biologic dressing in unhealthy recipient sites. They also prevent wound infection, desiccation, and loss of heat, water, proteins, and red blood cells from the wound.

Postoperatively, splitting is required for grated extremities and joints in neutral positions to increase grafts takes. The dressing is removed on the fifth postoperative day and the grafts are examined. Physiotherapy should be started as early as possible to improve function and decrease the risk of contracture.

Rehabilitation

The burn team includes the physician, burn nurse, physical and occupational therapist, social worker, and nutritionist. Teamwork must be maintained to gain the trust, confidence, and compliance of the child. A long-term relationship develops between the burn team, the child, and the family. The burn outlines comprehensive short-term and long-term plans for the burned child. The goals of rehabilitation are to maintain function and reduce the risk of contracture. The rehabilitation program begins as early as 2–3 days after admission and continues on a daily basis. It includes hydrotherapy, occupational and physical therapy, the upper and lower extremities range of movement, and play therapy.

The range of movement and ambulation are assessed, and any limitations in function are identified. The patient is positioned so as to avoid contracture, with the neck maintained in slight extension, the shoulders abducted, and the upper extremities elevated. Joints are maintained in a functional position (e.g., extension of the wrist, elbow, and knee joints and flexion of the ankle joint) by proper positioning and splitting. Family supports, with involvement of the burn team, increase the compliance of the child.

Rehabilitation after burn wound healing is a continuation of the acute stage. Hypertrophic scars, caused by damage to the reticular dermis, are common after partial-thickness or full-thickness burns. These scars are hard, raised, and red within the boundary of the wound. Initially they are red and itchy, but they fade and soften as they mature (12–18 months). Inadequate treatment of hypertrophic scars causes severe contracture and functional impairment.

Pressure therapy reduces the risk of contracture and accelerates the maturation of hypertrophic scars. Use of pressure garments designed to cause linear organization of collagen is usually started at 6–8 weeks. They are worn continuously except during exercise, bathing, and meals. Splinting continues after burn wound healing and is gradually discontinued.

Growth hormone supplementation as part of the post-burn rehabilitation program in children was recently proposed by Mlcak et al. Children who recovered from major burns received growth hormone (0.05 mg/kg/day) for 12 months. The authors noted that these children had less muscle wasting, more weight gain, and better catch up with their growth curved. Furthermore, these children had better cardiac ejection fraction than controls.

Burn Reconstruction

Scalp

There is very little soft tissue covering the skull, the scalp is often damaged, and excision may expose the underlying

skull. If there is concern over deep involvement of the meninges and brain, especially electrical burns, a computerized tomography scan or magnetic resonance imaging should be obtained to rule out brain involvement and abscess formation. Scalp alopecia, which is found in 25% of children with deep burns, results from burns to hair follicles. Conservative tangential excision and skin grafting are used for wound care. If the bone is exposed, a local scalp flap is used for coverage; if the defect is too large, a free tissue transfer should be used. Small areas of alopecia can be treated with staged excision. Tissue expansion is very effective technique in the treatment of large areas of alopecia of the scalp; there is no donor site defect and lost tissue is replaced with adjacent tissue of the same color and texture. The vascular anatomy of the scalp allows the use of long and narrow flaps. Orticochea used a local flap to cover a large scalp defect. In extensive and deep burns to the scalp, free flaps are indicated for coverage.

Eyelids

Early correction and reconstruction of the burned eyelid is indicated to prevent corneal exposure, which can lead to ulceration and loss of vision. In acute facial burns, careful examination of the eye, including the use of fluorescein dye, should be performed to rule out corneal injuries. If there is a corneal injury, the eye should be irrigated thoroughly and an ophthalmologist consulted. Atrophine (1%) should be applied to prevent ciliary spasm. Topical antibiotics and 1% methylcellulose should be applied. Tarsorrhaphy can cause destruction of the eyelid margin and is not effective in closing the eyelids. There is no risk of corneal exposure in the early days after a burn, owing to eyelid edema. After the edema subsides, early excision and skin grafting can be performed. If the depth of the burn cannot be assessed, the eye can be protected with a sclera lens.

Cicatricial ectropion deformity of the eyelid is released using an incision at the ciliary margin. The release should overcorrect the deformity and extend beyond the medial and lateral canthi; then the defect in the upper eyelid is lined with a medium-thickness skin graft while the lower eyelid defect is lined with a full-thickness skin graft. The upper and the lower eyelids should not be grafted in one sitting as this makes it difficult to produce an adequate correction.

Face

Facial burns and scarring can cause significant disfigurement (❯ *Fig. 270.6*), associated with psychological and social problems to both the child and the family. Treatment in the acute phase involves early excision and skin grafting with a nonmeshed skin graft. Attention should be paid to the donor sites for the skin graft and to the regional esthetic units of the face. Skin grafts harvested from donor sites above the clavicle produce a good color match to the face. Scalp skin is also an excellent donor site. Once all facial burns have been covered, facial elastic pressure garments and molded masks should be used to improve the quality of the scar, speed maturation, and reduce the risk of developing hypertropic scars.

Nose

The nose is commonly affected in facial burns because of its projection in the center of the face. The nasal lining and skeleton are usually spared, except in very severe facial burns, whereas the skin covering the nose is frequently involved. In the early phase, conservative debridement and skin grafting are conducted. After wound healing, an elastic pressure garment and an orthoplastic mask are applied to improve wound maturation. In planning nasal reconstruction, the esthetic units of the nose should be considered. Skin grafts from the supraclavicular area provide an adequate size and good color match for nasal coverage. Local forehead flap and distant flaps are used for nasal reconstruction in patients with extensive burns.

Ears

Burns to the ears are common because of its exposed position. In the early phase it is important to prevent and treat chondritis. Chondritis can be prevented by avoiding pressure and applying topical mafenide acetate. Suppurative chondritis is a serious complication that may lead to contracture and loss of the external ear. It is treated by the early drainage of abscesses and the removal of necrotic cartilage. Reconstruction of the ear may require many stages, and skin coverage is a significant problem. In total ear reconstruction, a partial temporofascial flap is used to cover a cartilage frame or Medpor implant. This flap is then covered with a skin graft.

Neck

Early excision, grafting, and splinting have helped significantly in reducing the development of neck contracture. After complete release of the neck contracture, skin grafts

are used to cover the defect. Linear bands are best treated with Z-plasties. Local transposition flaps are used in mild contracture, while in moderate defects tissue expanders can provide enough skin coverage. Tissue expanders in the neck should be used carefully as they may exert pressure on important structures such as the trachea, internal jugular vein, and carotid arteries.

Mouth

One of the most difficult and common burn injuries in children is electrical burns to the mouth (◉ *Fig. 270.7*), which usually affect children under the age of 5 years. The burn is often caused by the child chewing on an electrical cord, which then becomes defective. The saliva in the mouth helps to produce an electrical short circuit and an arc. Extensive heat is produced (3,000°C), causing destruction of the commissure with its vermilion and the underlying orbicularis oris muscle. Secondary hemorrhage from the labial artery 1–2 weeks after the injury occurs in 25% of cases and it is treated by applying pressure. The wound is conservatively treated with the application of topical antibiotics and splinting. Al-Qattan et al. showed that early splinting of these burns may obviate the need for commissuro platy in the future. Oral commissure reconstruction should be delayed for approximately 1 year, until scar maturation has occurred. Many procedures are available for commissure reconstruction, including mucosal, vermilion, and tongue flaps and Z-plasty.

Breast

Breast thermal burns to the anterior chest in girls may damage the breast buds beneath the nipple and areola. Careful conservative debridement should be performed in the acute phase to preserve the breast buds. Al-Qattan and Zuker recommended debridement of acute deep burns of the female pediatric chest area leaning the breast bud area for spontaneous eschar separation. This is thought to preserve the maximum amount of viable tissue in this important area. As the breasts start developing underneath the burned skin, the skin should be released early and resurfaced with a thick, split-thickness skin graft. Additional release and skin grafting may be required as the breast develops. If the breast buds are damaged, the breast can be reconstructed, either with tissue expanders or by using a latissimus dorsi or rectus abdominis musculocutaneous flap.

Axilla

Axillary contractures are a common problem in children. The shoulder has a great range of motion. Flexion contracture and hypertrophic scars are effectively reduced by the early application of elastic compression and splinting. Multiple Z-plasties are used if the scar contracture involves either the anterior or the posterior axillary fold. Severe contracture is treated by a releasing incision and split-thickness skin grafting. Contractures may develop as the child grows, and can be treated with release and skin grafting. Flap reconstruction is delayed to the final definitive stage of reconstruction.

Hands

Hand burns are common in children. Deep thermal burns to the hand may require escharotomy. Early tangential excision and skin grafting reduce the healing time and improve function. Early physical therapy, elevation, elastic pressure, and splinting reduce edema and increase the range of movement. In children, a claw deformity can develop secondary to hyperextension contracture of the metacarpophalangeal joint. Splinting the hand in the "anticlaw" position is important to reduce the risk of permanent contracture. Other deformities include palmar contracture, burn syndactyly, and, in severe cases, amputation deformity (◉ *Fig. 270.8*). Severe palmar contractures occur in crawling infants around camp fires. Al-Qattan compared the results of release of contractures and coverage using either thick split-thickness skin grafts or full-thickness skin grafts. On long-term following group had less recurrence of contracture indicating that full-thickness grafts may be able to "grow" better than split grafts.

Pediatric Poisoning

Khaled M. Al-Haidari and Nada S. Al-Qadheeb

271 General Management of Poisoned Patients

Khaled M. Al-Haidari

Introduction and Epidemiology

Children are commonly seen sick in emergency departments (ED) after unintentional ingestion of drugs. Due to their nature to explore the surrounding environments using their sense of examining things by their taste, they are led some times to serious toxic exposure to dangerous substances including drugs.

The 2008 Annual Report of the American Association of Poison Control Centers reported that 83.8% of poison exposures were unintentional and 92.9% cases of exposures occurred at the patient's residence.

Children younger than 3 years were involved in 38.7% of exposures and 51.9% occurred in children younger than 6 years. Ingestion was the route of exposure in 79.3% of cases.

Cosmetics/personal cares products, cleaning substances (household), foreign bodies, pesticides, and plants were the most commonly ingested non-pharmaceutical products in the pediatric population in this 2008 report.

Topical preparations, cold and cough preparations, vitamins, antihistamines, gastrointestinal preparations, antimicrobials, hormones and hormone antagonists, cardiovascular drugs, electrolytes, and minerals were the most commonly ingested pharmaceutical products in the pediatric population.

In general, items that are easily accessible and posse attractive colors are most likely to be ingested.

The World Health Organization (WHO) also reported that the common poisoning agents in low-income and middle-income countries are fuels such as paraffin oil (also known is some countries as kerosene), organophosphates, pharmaceuticals, and cleaning agents. Fatal poisoning rates in low-income and middle-income countries are four times that of high-income countries.

Many household cleaners contain caustic substances such as sodium or potassium hydroxide or sulfuric acid. Severity of the injury from ingesting such substances depends on their strength, acidity, dose/quantity, and contact time. Some manifestations of caustic ingestion include local irritation and swelling of the lip or tongue, burning pain, drooling, dysphasia, and red or white plaques on the tongue. Treatment requires that the poisoned child received nothing by mouth and esophageal endoscopic evaluation is performed to determine the severity of injury once the vital functions have been stabilized.

Death after unintentional ingestion of poisons in children is uncommon; this may be due to the improvement in the packaging "child-proof containers," increase in public awareness and education, and improvement in the medical management.

Poison prevention education of parents and caregivers should be provided before children become mobile as it is highly recommended and believed to reduce the risk of mortality and morbidity. Appropriate storage and proper disposal of medications and toxic substances should be part of the routine education.

This chapter focuses on the general management of poisoning in children, and discusses in detail some selected but commonly ingested substances.

General Approach and Management of Poisoned Patients

Initial Management of Poisoned Patients

The primary goal in treating a suspected or poisoned child is to carefully assess and support the vital functions, as the patient's life may be in an immediate danger. The general approach to treat a patient with acute poisoning is listed below:

- **Assessment and treatment**:
  Checking and stabilizing:
  - ABC:
    - **A**irway
    - **B**reathing
    - **C**irculation
  - Central nervous system (CNS): mental status and seizure control
  - BG: correct hypoglycemia
  - Temperature: correct hypothermia
  - Resuscitation antidotes

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_271,

- **Physical examination:**
  - Thorough physical examination
  - Reassess the patient's vital signs frequently and monitor the need for supportive care
- **Laboratory (individualize):**
  - Arterial blood gas (ABG) and electrolytes
  - Electrocardiogram (ECG)/cardiac monitor
  - Toxicological screening of suspected medication
- **Patient history once stabilized:**
  - Age, sex, time and type of possible exposure (including any mediation present at home; recent illness medications, visiting family members medications)

The child needs to be reassessed often as the status can change frequently until stabilized.

Only after these functions are stabilized can the poisoning be evaluated. Symptomatic and supportive care to ensure vital organ function shall include:

1. Establishing airway
2. Providing ventilation (O_2 therapy if necessary)
3. Establishing intravenous (IV) access for cardiovascular support and the administration of medications (fluid, electrolytes, pressors)
4. Maintaining adequate body temperature

Pertinent laboratory data such as serum electrolytes, glucose, and arterial blood gases should be obtained on admission and monitored frequently. Once the vital functions have stabilized, the patient should be evaluated carefully by obtaining detailed history and complete physical examination. Asymptomatic or mildly symptomatic patients should be closely observed for at least 4–6 h or longer for patients who ingested slow release preparations. The patient may be discharged if he continues to be asymptomatic after the observation time.

Empirical drug treatment may be indicated in comatose or altered mental status pediatric patients as in adults. Blood glucose level should be checked immediately. If the level is below normal range or not obtainable and any patients who swallowed oral hypoglycemic agents, an initial dose (IV push) of 0.25–1 g dextrose per kilogram of glucose as a 10–20% solution should be administered except in patients with documented hyperglycemia. Empirical Naloxone therapy is important in pediatrics. In the past, dosing recommendations were 0.01–0.1 mg/kg based on body weight. Recently, many clinicians favor a standard dose of 1–2 mg for the acute overdosed patient of all ages (beyond the neonatal period). Administered intravenously, intramuscularly, or endotracheally, Naloxone may be repeated every 2–5 min until a therapeutic response is achieved or a total dose of 10 mg is given (narcotic – induced toxicity should be questioned if there is no response after 10 mg is given). Thiamine 100 mg IV dose should be considered in adolescent patients who may be thiamine deficient (e.g., patients with eating disorders, chronic inflammatory bowel diseases), although routine administration to pediatric patients should be avoided.

History

Once vital functions are stabilized, a brief history should be obtained in an attempt to identify the substance and type of exposure. In a child with known or suspected exposure, questions should include what agent(s) was ingested, quantity, and when. General medical condition and history of allergies should be obtained. Family, medical, and social history may be important and any family member currently ill or taking any medications should be noted (e.g., visiting relative, pregnant or postpartum mother on iron supplement) and retrieval of the container must be attempted. However, in a poisoned child a distinct history of toxic exposure is usually unclear and the following symptoms highly suggest the possibility of poisoning: acute onset of illness, past medical history of accidental ingestion (for children aged 5 years and below), environmental stresses, multiple organ system dysfunctions, altered consciousness, and a puzzling clinical presentation.

Physical Examination (PE)

Complete and careful PE should be performed, since this is often helpful in the diagnosis and guidance for a specific intervention. A complete reassessment of the vital functions and body temperature should also be done. The clinician should focus on the central, autonomic nervous systems, pupil size and reactivity, skin or mucous membrane changes, and presence of any odor on the breath or patient's clothing (See *Table 271.1*). These findings form a collection of signs and symptoms, referred to as toxic dorms (See *Table 271.2*) that will determine possible toxicological agents and guidance for early therapeutic intervention.

Laboratory Findings

This may be helpful in confirming a diagnostic impression or in determining metabolic abnormalities caused by

Table 271.1
Clinical manifestations of selected drugs overdose

Signs	Symptom or sign	Agents
Temperature	Hypothermia	Opiates, sedatives hypnotics, hypoglycemic agents, alcohol, lithium
	Hyperthermia	Amphetamines, anticholinergics, antihistamines, B-blocker, cocaine, cyclic antidepressants, isoniazid, monamine oxidase inhibitors, phencyclidine salicylates, phenothiazines
Respiratory system	Bradypnea	Acetone, barbiturates (late), clonidine, ethanol, ibuprofen, narcotics, nicotine, sedative hypnotics
	Tachypenia	Organophosphates, opiates, barbiturates (early), B-blockers, benzodiazepines, alcohol, clonidine
Respiratory rate	Tachycardia	Anticholinergics, antihistamines, amphetamines, caffeine, cyanide, cyclic antidepressants, propoxyphene, sympathomimetics, theophylline
	Bradycardia	Sedative hypnotics, calcium channel blockers, clonidine, B-blockers, opiates, digitalis, nicotine, alcohols
Blood pressure	Hypotension	Ace inhibitors, calcium channel blockers, digoxin, nitrites, B-blockers, imidazolines, cyclic antidepressants, theophylline, propoxyphene, qunidine sedative hypnotics, heroin, methadone
	Hypertension	Amphetamines, phencyclidine, anticholinergics, nicotine, cocaine, sympathomimetics, thyroid supplements
Neuromuscular	Seizures	Ammonium fluoride, amphetamines, anticholinergics, antihistamine, B-blocker, caffeine, camphor, carbamates, carbon monoxide, cocaine, cyclic antidepressants, diethyltoluamide, dilantin, ergotrate, ethanol, hydrocarbons, hypoglycemics, ibuprofen, imidazolines, isoniazid, lead, lidocaine, lithium, nicotine, opioids, phencyclidine, phenothiazines, phenylpropanolamine, physostigmine, propoxyphene, salicylates, theophylline
Pupil size	Miosis	Barbiturates, carbamates, clonidine, clonidine, ethanol, isopropyl alcohol, organophosphates, opioids, (mepiridine may cause mydriasis) phencyclidine, phenothiazines, physostigmine, pilocarpine
	Mydriasis	Amphetamines, anticholinergics, antihistamine, cocaine, cyclic antidepressants, dopamine, drug withdrawal, glutethimide, lysergic acid diethylamide, monamine oxidase inhibitors, phencyclidine

known ingested toxic substance. Commonly ordered laboratory investigations include: routine chemistries, arterial blood gases (ABGs), osmolar gap, and anion gap (*Table 271.3*). Interpretation of these measurements may be helpful in a patient's management. Detection of toxins in the blood and/or urine may be helpful for seriously ill patients with occult ingestion or for adolescent patients with intentional overdose, when clinical appearance does not fit with the stated history. Drugs such as acetaminophen, anticonvulsant, carboxyhemoglobin, digoxin, ethanol, ethylene glycol, iron, lithium, methanol, salicylate, and theophylline require an immediate quantitative determination of their levels in the management of the poisoned patient.

Initial Treatment

The general treatments of a poisoned child include gastric *evacuation*, as well as blocking the absorption and enhancing elimination.

The traditional treatment practice for poisoned patients which includes gastric decontamination "use of emetics, activated charcoal usage and or gastric lavage" is no longer routinely recommended. Activated charcoal and gastric lavage should be considered for severe cases such as symptomatic patients presented within 1 h of ingestion of a toxic substance, symptomatic patients who ingested substances that decrease the gastrointestinal motility, ingestion of a sustained resale medication, and for patients

Table 271.2
Common toxidromes

Type of poisoning	Agents	Toxic symptoms
Anticholinergic	Antihistamines, atropine, belladonna alkaloids, mushrooms (some), psychoactive drugs	Blurred vision, fever, tachycardia, mydriasis, warm and dry skin, urinary retention, ileus, delirium, seizures
Acetaminophen	Acetaminophen	Abdominal pain, nausea/vomiting, elevated aspartate transaminase level (greater than 1,000 IU/l after 24 h), jaundice, confusion, somnolence, coma, disorientation
Anticoagulant	Warfarin (coumadin), rodenticides	Bleeding ecchymosis, prolonged prothrombin, and bleeding times
Cholinergic	Carbamates, physostigmine, pilocarpine pyridostigmine	(SLUDGE) salivation, lacrimation, urination, diarrhea, GI cramps, emesis, wheezing, diaphoresis, bronchorrhea, bradycardia, miosis
Cyanide	Cyanide	Cyanosis, hypotension, syncope, psychosis
Hallucinogenic	Amphotamines, cannabioniods, cocaine, lysergic acid diethylamide, phencyclidine	Hallucinations, psychosis, panic, fever, mydriasis, hyperthermia
Iron-containing products	Iron-containing products	Dyspepsia, nausea, vomiting, diarrhea, dark stools
Opioid	Opioids (e.g., morphine, hydrocodone methadone)	Hypoventilation, hypotension, miosis, sedation, hyperthermia, ileus
Salicylates	Aspirin-containing products	Disorinatation, fever, lethargy, nausea, vomiting, tachpnea, tinnitus

Table 271.3
Anion gap and osmolar gap use in toxicology

Calculated osmolarity = $2Na^{+}(mEq/L) + \frac{BUN(mg/dl)}{2.8} + \frac{glucose(mg/dl)}{18}$
Osmolar gap = Measured osmolarity − calculated osmolarity (*Normal measured osmolarity is 280–295 mmol/kg*)
If osmolar gap is >10, common drugs and poisons that should be considered: Acetone, ethanol, methanol, ethylene glycol, isopropanol, mannitol-diuretics, glycerol-diuretics, sorbitol-diuretics
Anion gap (AG): AG = $Na^{+} - (Cl^{-} + HCO3^{-})$ (*Normal 8–16 mmol*)
Drugs that may *increase* AG: Magnesium, lithium, bromide Drugs and medical conditions that may *decrease* AG: methanol, uremia, DKA (diabetic ketoacidois), paraldehyde phenformin, iron, isoniazid, lactic acidosis, salicylates, carbon monoxide

that ingested a large quantity of life-threatening substances.

The American Academy of Clinical Toxicology and the European Association of Poisons Centers and Clinical Toxicologists is no longer recommending ipecac for home use. There is not enough evidence that syrup of ipecac improves the outcome of the poisoned patients.

Initial Decontamination

The choice of the GI decontamination method depends on the toxin and the circumstances of the ingestion.

Activated Charcoal

It is an extremely effective adsorbent for most toxins and drugs especially when given during the first several hours after ingestion. It prevents the absorption in the gastrointestinal tract leading to decreasing systemic absorption of the toxin. Initial dose is usually 1 g per kilogram body weight with a minimum dose of 20 g in a child and 50–100 g in an adolescent. A dose of 0.25–1 g per kilogram body weight may be repeated every 1–6 h until the patient is clinically stable (including ingested drug serum concentrations, if indicated). Airway reflexes must be preserved or airway protected.

Procedure: Dilute activated charcoal with water in a 4:1 or 8:1 ratio to increase palatability and then 70% sorbitol (premixed preparations as charcoal with sorbitol are also available) may be added to enhance toxin elimination from the gastrointestinal tract. Shake the mixture until it becomes like a thickened soup or heavy cream. Repeat the dose if patient vomits. Smaller and more frequent doses may be better tolerated and antiemetics may be indicated. Multiple doses of charcoal in water are indicated for select patients (e.g., ingestion of phenobarbital, carbamazepine, digoxin, and theophylline).

Contraindication: Do not administer when bowel sounds are absent or hypoactive or following ingestion of caustic agents or drugs known to be poorly adsorbed (e.g., iron, mineral acids or base, alcohol, lithium, cyanide, and heavy metals).

Toxicity: Constipation, obstruction, poor palatability, and aspiration are the main adverse effects.

Cathartics

These eliminate toxins from the gastrointestinal tract by causing diarrhea and they are also useful in preventing charcoal-induced constipation. Magnesium (sulfate and citrate) and sorbitol are the most commonly used agents and have the advantage of not being adsorbed by the activated charcoal. However, lately it was observed that there is no evidence shown their value. There is no need to administer cathartics with each dose of activated charcoal but should be administered as needed only. Sorbitol is considered the drug of choice due to fewer interactions with serum electrolytes. The usual dosages are 20% magnesium sulfate solution 250 mg/kg (maximum dose), magnesium citrate 4 mL/kg up to 300 mL (10 oz), or 70% sorbitol 0.5 g/kg (10–20 mL in children, and 50–100 mL in adolescents).

Cautious use of cathartics in children is recommended to avoid risk of dehydration and electrolytes imbalance especially in young children.

Contraindications are absent bowel sounds or gastric obstruction, diarrhea, abdominal trauma, and renal failure because magnesium intoxication risk limits the use of cathartics. Oil-based cathartics should be avoided because of the risk of aspiration and the possibility of enhanced toxic absorption.

Whole Bowel Irrigation (WBI)

The entire gastrointestinal tract is flushed of toxins and their absorption is prevented. Preferred solutions are polyethylene glycol such as Colyte or Golytely. The solutions are not absorbed from the gastrointestinal tract and do not lead to fluid and electrolyte abnormalities. WBI has been used in children successfully, and found to be particularly useful in pediatric iron overdose, sustained slow release preparations, and other substances that do not bind to charcoal (e.g., lithium, slow release potassium chloride and theophylline, mercury). The initial dose is 0.5 L per hour for small children and 2 L per hour for adolescents given orally or via a nasogastric tube until the rectal effluent is clear. WBI is not indicated in the presence of bowel obstruction, perforation, ileus, or hemorrhage of the gastrointestinal tract.

WBI should be used with caution in children to avoid risk of dehydration and electrolytes imbalance especially in young children.

Gastric Evacuation ''Emesis''

Ipecac syrup was the drug of choice for emesis induction and can be expected to induce emesis in almost all children at home within 20–60 min after administration for many years. The dose for a child of 6–12 months of age is 10 mL, 15 mL for 1–5 years of age, while 30 mL is recommended for children >5 years old. Ipecac syrup should be taken with one or two glasses of water or any other liquid.

Contraindications to emesis: Children less than 6 months of age; comatose patients or patients with impaired or absent gag reflex due to the risk of aspiration. To avoid the risk of injuries, emesis is not indicated when sharp or solid objects, caustic or corrosive substances, and hydrocarbons have been ingested.

Toxicity to ipecac is uncommon but observes for central nervous system effects such as lethargy, tremors, and convulsions. Gastrointestinal effects include protracted vomiting, diarrhea, and significant bleeding (Mallory–Weiss), and electrocardiographic irregularities and tachycardia are the main cardiovascular adverse effects associated with the administration of ipecac.

However, the routine use of Ipeaca at home is no longer recommended because of its limited outcome or no improvement as well as the toxicity seen above. And the fact that it may prolong vomiting and the patients may not be able to receive additional medications such as activated charcoal or acetylcysteine.

Gastric Lavage

This is used to be an alternative mechanical technique to ipecac-induced emesis for gastric decontamination *and it*

is also not recommended as a routine management of poisoned pediatric patients.

Lavage should only be considered when life-threatening toxins were ingested, mainly when life-threatening singes and symptoms are seen or there is a high risk of toxicity that is suspected. Lavage may be necessary in poisoned pediatric patients after ingestion of certain toxins such as calcium channel blockers, iron, tricyclic antidepressants, lithium, and substances that cannot be absorbed by activated charcoal such as alcohols, heavy metals, and glycols.

Contraindication to gastric lavage is ingestion of caustic or nontoxic substances, and sharp objects.

Procedure: Intubation (endotracheal or nasotracheal) should precede gastric lavage for the unconscious or convulsing patient with or without gag reflex. Patient should be placed on the left side with the head slightly lower than the feet and a tube of appropriate length should be inserted in the stomach through the mouth or the nose (e.g., 16–28-Fr. orogastric tube). Confirmation of the presence of tube in the stomach is essential before lavaging. Aspirate gastric contents initially before lavage fluid is introduced; follow it by a saline lavage solution (0.45% or NS – to prevent hyponatremia) with 50–100 mL aliquot and continue lavage until the return is clear. This usually requires a total volume of 500–1,000 mL in a child. After getting a clear return, the tube may be left in place for the administration of activated charcoal and cathartics.

Complications to gastric lavage may include aspiration, mechanical injury, ventilation, fluid and electrolyte abnormalities, bradycardia, and cardiac arrest (vasovagal effect).

These complications are commonly seen and for this the gastric lavage is not routinely recommended.

Antidotes

A list of commonly used antidotes is included in *Table 271.4*. However, indiscriminate use of antidotes is discouraged. *Other methods of enhanced elimination* are given below.

Table 271.4
Common antidotes

Type of drug/poisoning	Agents	Antidotes
Acetaminophen	Acetaminophen	*N*-acetylcysteine
Anticholinergics	Antihistamines, atropine, belladonna alkaloids, mushrooms (some), psychoactive drugs	Physostigmine
Anticholinesterases		Atropine
Anticoagulant	Warfarin (coumadin), rodenticides	Vitamin K
Benzodiazepines		Flumazenil
Calcium channel blockers		Calcium chloride10% solution
Carbon monoxide		Oxygen
Cholinergic, muscarinic	Carbamates, some mushrooms, organophosphates, physostigmine, pilocarpine pyridostigmine	Atropine/pralidoxime
Cholinergic, nicotinic	Black widow spider bites, carbamates, insecticides, nicotine	Atropine/pralidoxime
Digoxin		Digoxin -specific antibodies
Cyanide	Cyanide	Sodium nitrite 3%, sodium thiosulfate 25%
Ethylene glycol, methanol	Antifreeze, rubbing alcohol	Ethanol 10% or fomepizole, thiamine, and pyridoxine
Iron-containing products	Deferoxamine (desferal)	Iron-containing products
Opioid	Opioids (e.g., morphine, hydrocodone, methadone)	Naloxone
Salicylate	Aspirin products	–
Sulfonylureas	Sulfonylurea	Octreotide

Urinary pH modification may enhance systemic elimination and prevent renal tubular reabsorption of some agents. Hemodialysis and hemoperfusion are also effective for the elimination of dialyzable agents. Binding resins (sodium polystyrene sulfonate) and toxin specific antidotes (e.g., Digibind) are also used.

272 Acetaminophen

Rania Slika

Acetaminophen is the most commonly used analgesic and antipyretic in pediatrics with few side effects if used in the proper therapeutic doses. The 2007 Annual Report of the American Association of Poison Control Centers' National Poison Data System (AAPCC-NPDS) documented 140 deaths from acetaminophen only. Acute acetaminophen overdose can lead to hepatotoxicity and is the leading cause of acute liver failure in the United States and United Kingdom. Acetaminophen is available alone or in combination with opioids, antihistamines, and cough and cold preparations.

Acetaminophen is primarily metabolized in the liver by glucuronidation or sulfation to nontoxic metabolites. Approximately 5% of the therapeutic dose is metabolized by cytochrome P450, mainly CYP2E1, to the reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI). This metabolite is toxic to the liver due to covalent binding to proteins and nucleic acids. However, it is detoxified through conjugation with glutathione and excreted in the urine as a mercapturate conjugate. In acute acetaminophen overdose, hepatic glutathione stores are depleted resulting in the accumulation of NAPQI. This accumulation can lead to hepatic necrosis and cell death.

The acute ingestion of more than 150 mg/kg acetaminophen can lead to hepatotoxicity. Several factors can increase the risk for acetaminophen hepatotoxicity including coingestions and nutritional status. Chronic use of certain medications or herbs that induce CYP2E1, which is responsible for the formation of NAPQI, can increase the risk of acetaminophen hepatotoxicity. Fasting as the result of a febrile illness or gastroenteritis can lead to the depletion of the glutathione stores and the accumulation of the toxic metabolite, thus representing another risk factor for acetaminophen hepatotoxicity.

Clinical and Laboratory Manifestations

The signs and symptoms of acetaminophen overdose depend on several factors including the time since ingestion, presence of risk factors, and the use of other medications. The clinical findings are stratified into different stages as shown in *Table 272.1*. In the first stage, the first 24 h post ingestion, patients will develop gastrointestinal disturbances such as anorexia, abdominal pain, nausea, vomiting, lethargy, and diaphoresis. If measured, the laboratory finding will appear normal. In the second stage, the latent phase, 24–72 h following ingestion, patients usually appear well, but biochemical markers of hepatotoxicity begin to rise. Some patients may experience right upper quadrant pain and appear jaundice. Elevations in the serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin, and prothrombin time occur. Some patients will develop nephrotoxicity and oliguria in this stage.

Stage three, 72–96 h after ingestion, is the stage where the maximal hepatic injury occurs. Gastrointestinal symptoms will reappear including anorexia, nausea, vomiting, abdominal pain accompanied with malaise, jaundice and central nervous system symptoms like confusion, somnolence, and coma. The liver function tests peak where AST levels exceed 10,000 IU/L. Renal insufficiency occurs in 50% of the patients due to acetaminophen-induced acute tubular necrosis. Metabolic disorders including hypophosphatemia, hypoglycemia, and metabolic acidosis can accompany this stage. Hypoglycemia reflects impaired gluconeogenesis and elevated levels of insulin. Lactic acidosis is due to tissue hypoxia and decreased hepatic clearance of lactate. Coagulation disturbances with elevations in prothrombin time (PT) and International normalized ratio (INR) can be associated with high mortality rate. There are several indicators for poor outcome including: prothrombin time greater than 100 s, grade 3 or 4 encephalopathy, renal failure, development of acute liver failure, cerebral edema, and metabolic acidosis ($pH < 7.3$). In stage four, the recovery phase, 70% of patients will survive acute liver failure by 4 days to 2 weeks after ingestion. If patients are left untreated with toxic acetaminophen levels, death will result within 4–18 days.

Management

Management of acetaminophen overdose depends on the amount ingested, time after ingestion, and serum concentration of acetaminophen. When there is an excessive

Table 272.1
Stages of acetaminophen toxicity

Stages	Time post ingestion	Clinical manifestations
Stage 1	1–24 h	Anorexia, abdominal pain, nausea, vomiting, lethargy, diaphoresis
Stage 2	24–72 h	Right upper quadrant pain, jaundice; elevated AST, ALT, prothrombin time, total bilirubin; oliguria, flank pain, hematuria, proteinuria
Stage 3	72–96 h	Gastrointestinal symptoms will reappear as anorexia, nausea, vomiting; confusion, somnolence; peak elevation in liver enzymes; hypophosphatemia, hypoglycemia, metabolic acidosis
Stage 4	4 day–2 weeks	Resolution of hepatic injury or deterioration, coma, and death

amount of drug ingested, more than 150 mg/kg or the history is unclear, the patient should be referred to the emergency department and acetaminophen serum levels obtained. The use of ipecac to induce emesis is typically not recommended. If the patient presents within 4 h of ingestion, gastric decontamination with activated charcoal can be useful. Activated charcoal is best effective when given within 1 h of ingestion. Optimum dose is not established; usual dose is 25–50 g in children aged 1–12 years and 10–25 g in infants up to 1 year old. Baseline liver function tests, bilirubin, prothrombin time, serum creatinine, and urinalysis should be obtained upon admission in addition to the acetaminophen serum level.

N-Acetylcysteine (NAC) is the treatment of choice for acetaminophen overdose. It works by binding directly to acetaminophen toxic metabolite and thus replenishing the glutathione stores and enhances nontoxic sulfate conjugation in liver cells. The overall mortality rate decreased

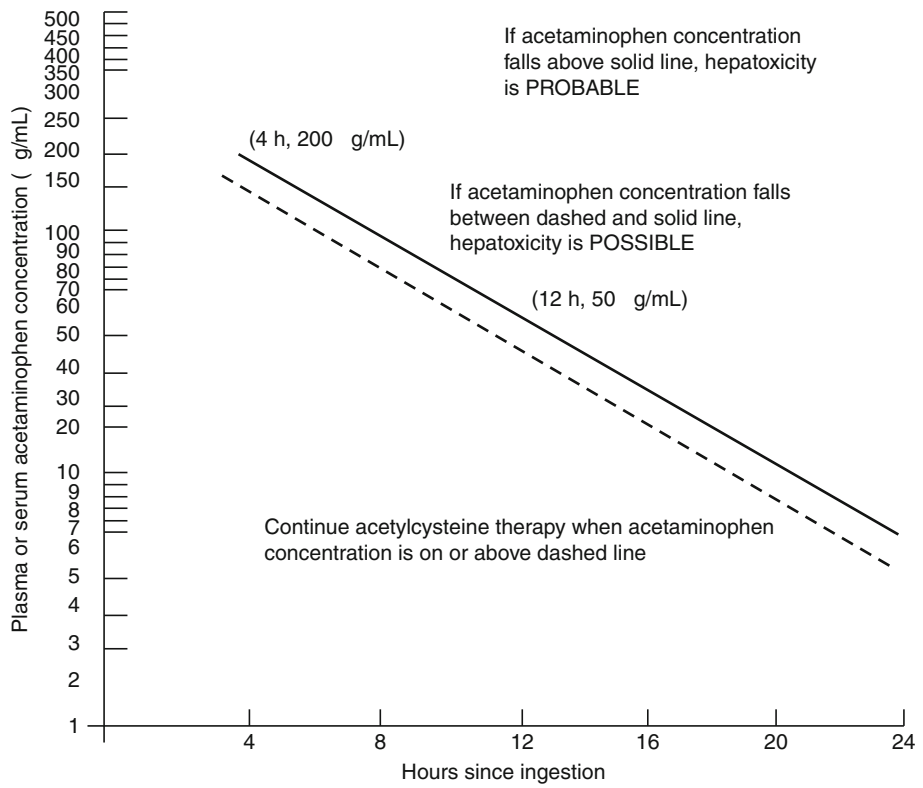

Figure 272.1
Nomogram relating plasma or serum acetaminophen concentration and probability of hepatotoxicity at varying intervals following ingestion of a single toxic dose of acetaminophen. (Modified from Rumack BH, Matthew H. Acetaminophen poisoning and toxicity. *Pediatrics* 1975; 55:871–876; and Rumack BH, Peterson RG, Koch GG, et al. Acetaminophen overdose: 662 cases with evaluation of oral N-acetylcysteine treatment. *Arch Intern Med* 1981; 141:380–385)

Table 272.2
Comparison of intravenous and oral regimens for acetylcysteine in the treatment of acute acetaminophen overdose

	Oral route	Intravenous route
Regimen	140 mg/kg loading dose followed 4 h later by 70 mg/kg every 4 h for 17 doses diluted to 5% with juice or soft drinks	Loading dose: 150 mg/kg IV over 60 min
		50 mg/kg IV over 4 h
		100 mg/kg IV over 16 h
Total Dose (mg/kg)	1330	300
Duration (h)	72	21
Adverse events	Anaphylactoid reactions (rash, angioedema, hypotension, bronchospasm), flushing	Nausea and vomiting

from 5% to 0.7% with the use of N-acetylcysteine. Plasma acetaminophen level should be obtained 4 h after ingestion or as soon as possible thereafter.

The Rumack–Matthew nomogram was established to predict patients who would develop hepatotoxicity from acetaminophen overdose (*Fig. 272.1*). According to the nomogram, when the serum acetaminophen concentration is above the treatment line or the possible hepatotoxicity line (150 μg/ml at 4 h), a full course of treatment with acetylcysteine is indicated. For patients having risk factors for increased hepatotoxicity, treatment with acetylcysteine is started if the serum acetaminophen level is above 100 μg/ml at 4 h. The best effective time of administration is within 8–10 h post ingestion, but it can be still indicated for as late as 24 h or more especially in patients with apparent liver toxicity. Patients should receive a full course of acetylcysteine in the absence of any serum acetaminophen level when it is suspected that more than 150 mg/kg have been taken over 24 h.

N-Acetylcysteine is available in both oral and intravenous formulation. No studies have shown better efficacy of the oral or the intravenous mode of administration when N-acetylcysteine is used within 10 h of acetaminophen overdose. *Table 272.2* outlines a comparison between the two regimens. There are certain differences in terms of the total dose administered, the duration of therapy, and adverse reactions. Patients, who vomit after oral acetylcysteine, should take another dose. Patients with coagulopathy or elevated creatinine clearance should be admitted for further monitoring and should receive acetylcysteine at a dose of 150 mg/kg every 24 h until INR falls below 2.

Patients experiencing angioedema, hypotension, and bronchospasm should be treated with diphenhydramine, corticosteroids, and bronchodilators. Acetylcysteine infusion should be stopped and then restarted later at a lower rate. Antiemetics can be used for patients having vomiting like ondansetron, Metoclopramide, or droperidol. Therapy is monitored by obtaining regular acetaminophen blood levels. Liver function tests, prothrombin time, and bilirubin monitoring are important to detect improvement in liver function. Other monitoring parameters during the detoxification process include: creatinine, blood urea nitrogen, glucose, and electrolytes.

273 Alcohol

Sakra S. Balhareth

Epidemiology

Alcohol is one of the most commonly abused substances globally. Alcohol-related injuries accounted for 10–18% of the total emergency visits in some studies. In 2009 alcohol represented 3.20% of the total poisoning cases in the USA.

Ethanol (Ethyl Alcohol, Absolute Alcohol, and Dehydrated Alcohol)

Ethanol is found mainly in alcoholic beverages, some over-the-counter medications such as mouthwashes, cold and cough preparations, and cleaning products. Ethanol is rapidly absorbed orally (80–90%) with peak onset of 30 min. Inhalation and skin absorption is widely reported. It is readily distributed (volume of distribution of 0.6 mL/kg) and extensively metabolized by the liver. The elimination rate ranges from 10 to 34 mg/dL/h.

Ethanol exerts its action by enhancing the inhibitory effect of gamma-aminobutyric acid (GABA) through binding to GABA receptors in the central nervous system (CNS). Moreover, it antagonizes the excitatory effect of *N*-methyl-D-aspartate (NMDA) glutamate resulting in its sedative effect.

The signs and symptoms of ethanol intoxication range from vomiting, euphoria, and ataxia in mild to moderate toxicity. In severe toxicity, respiratory depression, hypothermia, severe hypoglycemia, coma, and death can occur. Usually, signs and symptoms of intoxication in children >10 years resemble those of adults. In younger children, hypoglycemia is the hallmark. The mechanism of ethanol-induced hypoglycemia involves the inhibition of gluconeogenesis.

Ethanol toxicity is very difficult to diagnose in children; hence, clear and accurate history is extremely important. The general approach to diagnose known or suspected intoxication should be followed. Blood glucose level, electrolytes, and ethanol blood level (EBL) should be obtained. Change in level of consciousness is directly proportional to the ethanol blood level (EBL). However, specific correlation between EBL and symptoms is not well established in children as it is in adults. In young children, dose of 0.5 mL/kg of absolute ethanol (95–99%) resulting in an estimated EBL of 50–75 mg/dL may cause significant intoxication. Ingestion of 3 g/kg of absolute ethanol has been reported to cause death in children.

Isopropyl Alcohol (Isopropanol)

Isopropyl alcohol is widely used in cosmetics, disinfectants, solvents, and mouthwashes. It is metabolized by alcohol dehydrogenase to acetone giving the characteristic fruity odor of the intoxicated patient's breath. Isopropyl alcohol can be toxic upon both topical and oral ingestion. Ingestion of 2–2.5 mL/kg may lead to the same features seen with the ethanol poisoning with the additional complication of severe gastritis. Isopropyl alcohol blood level is of a limited clinical value especially in presence of ketonemia or ketonuria which confirm the diagnosis.

Ethylene Glycol

Ethylene glycol is a sweet-tasting liquid known as antifreeze. It can be found in humectants, pesticides, and solvents. It is rapidly absorbed after oral ingestion and extensively distributed (volume of distribution of 0.5–0.8 L/kg). Toxicity appears rapidly due to the short elimination half-life of 3 h. Ethylene glycol is oxidized via alcohol dehydrogenase (ADH) to two toxic metabolites, glycolic acid and glyoxylic acid. The later is further metabolized to several products such as oxalic acid and glycine. In order for such conversions to take place, thiamine and pyridoxine as cofactors are required. The accumulation of these toxic metabolites can lead to metabolic acidosis, calcium oxalate crystal deposition in all vital organs, and encephalopathy. In children, ingestion of as much as 0.2 mL/kg of 100% solution can be fatal. The signs and symptoms of intoxication are directly proportional to the amount ingested and the period elapsed after ingestion. Intoxicated patient might present with nausea and vomiting in mild cases or renal failure and encephalopathy in severe toxicity.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_273,

Serum electrolytes, renal function tests, and ethylene glycol concentration should be monitored. Ethylene glycol is rapidly metabolized and so the blood level might not be reflective in patient with late presentation after ingestion. Ethylene glycol concentration of >20 mg/dL confirms the diagnosis.

Methanol

Methanol is widely used as an industrial solvent. It is found in windshield washer solution, paint remover, and cleaning solvents. It is rapidly absorbed orally achieving maximal concentration within almost 60 min. Inhalation and skin absorption have been reported. Methanol is hepatically metabolized via alcohol dehydrogenase (ADH) to formaldehyde, which is then converted to formic acid. These toxic metabolites are responsible for methanol toxicity. Onset of methanol toxicity is delayed due to slow metabolism, which allows time for treatment. Signs and symptoms of toxicity can be manifested after the ingestion of 0.1 mL/kg of 100% solution.

High anion gap metabolic acidosis and vision disturbances that might progress to blindness are the main features of methanol toxicity. Methanol level of >20 mg/dL confirms the diagnosis.

Table 273.1
Dosing and administration information of commonly used medications in treatment of alcohol poisoning

	Dose and administration	Comments
Dextrose	IV:	Administer thiamine prior to the administration of dextrose in chronic ethanol abusers. Maximum concentration of dextrose solution that can be administered through peripheral vein is 12.5%
	Infants ≤ 6 months:	
	10% solution: 2.5–5 mL/kg	
	25% solution: 1–2 mL/kg/dose	
	50% solution: 0.5–1 mL/kg	
	Maximum: 25 g/dose	
	Infants >6 months and children:	
	10% solution: 5–10 mL/kg	
	25% solution: 4 mL/kg/dose	
	50% solution: 1–2 mL/kg	
	Maximum: 25 g/dose	
	Adolescents and adults:	
	25% solution: 40–100 mL	
	50% solution: 20–50 mL	
Thiamine	Adults: initial: 100 mg IV, then 50–100 mg/day IM or IV	Administer thiamine prior to the administration of dextrose in chronic ethanol abusers
Folinic acid	1 mg/kg IV over 30–60 min every 4–6 h; maximum 50 mg	
Pyridoxine	50 mg IV every 6 h until the intoxication has resolved	
Fomepizole (Antizol®):	IV: initial: 15 mg/kg, followed by 10 mg/kg every 12 h for four doses, then 15 mg/kg every 12 h thereafter. Adjust in hemodialysis	Fomepizole is the treatment of choice for ethylene glycol and methanol toxicity
Ethanol (Absolute ethyl alcohol 10%)	IV: Initial: 600 mg/kg	Ethanol should only be used when fomepizole is not available or in patients with known hypersensitivity to fomepizole or other pyrazoles
	Maintenance:	*Goal of therapy:* maintain serum ethanol levels >100 mg/dL
	Nondrinker: 66 mg/kg/h	
	Chronic drinker: 154 mg/kg/h	
	Adjust in hemodialysis	

IV intravenous, IM intramuscular

Management of Alcohol Toxicity

Supportive measures should be employed whenever needed. In general, induction of emesis and activated charcoal are not effective and should not be tried. Gastric lavage (decontamination) is only effective if the patient presented within 1 h of ingestion.

Ethanol and isopropyl alcohol have no specific antidote. The mainstay treatment of ethanol poisoning in children is to quickly detect and correct hypoglycemia. In mild to moderate cases, the treatment is mainly supportive. Ethanol and isopropyl alcohol can be removed by hemodialysis. However, this modality should be reserved for patients with severe intoxication not responding to supportive care and patients with impaired hepatic function. Thiamine (vitamin B1), pyridoxine (vitamin B6), and folate are used in patients with suspected chronic ethanol abuse to prevent serious withdrawal symptoms (Wernicke syndrome).

Ethanol and fomepizole (Antizol®) are approved antidotes for ethylene glycol and methanol poisoning. Both are alcohol dehydrogenase blockers. Fomepizole has an affinity to ADH 8,000 times greater than ethanol and is considered the treatment of choice. Compared to ethanol, fomepizole has fewer side effects, can be administered peripherally, does not require intensive care for administration, requires less monitoring, and does not cause CNS depression or hypoglycemia. Available literature suggests that fomepizole might preclude the need for hemodialysis in severe ethylene glycol and methanol toxicity in patients with normal function. Though fomepizole is more expensive than ethanol, the indirect cost of ethanol (continuous administration, frequent monitoring, and possible side effects) may make the cost more comparable. Although fomepizole is not approved for children, it has been used in the literature.

In menthol poisoning, folate should be administered to increase clearance of formate. If ethylene glycol toxicity is suspected, thiamine and pyridoxine should be administered to enhance the formation of less toxic metabolites. Calcium should not be administered routinely due to the risk of increasing the formation of calcium oxalate. It should be reserved for patients with hypocalcemia. Dosing and administration information of commonly used medications in treatment of alcohol poisoning is outlined in *Table 273.1*.

274 Antidepressants

Rania Slika

According to the 2009 Annual Report of the American Association of Poison Control Centers National Poison Data System (NPDS), there were 1,02,792 human ingestions of antidepressants reported to poison centers in the USA. Children less than 5 years of age accounted for 14,310 of all reported antidepressant exposures.

There are three major classes of medications used for the management of depression including: cyclic antidepressants, selective serotonin reuptake inhibitors, and monoamine oxidase inhibitors (*Table 274.1*). Cyclic antidepressants are considered the second to analgesics as the most common drugs implicated in fatal drug overdose.

Since the use of monoamine oxidase inhibitors in children is uncommon as much safer medications are available, only cyclic antidepressants and selective serotonin reuptake inhibitors overdose management will be discussed.

Cyclic Antidepressants

Ingestion of 10–20 mg/kg of most antidepressants may lead to coma and cardiovascular symptoms and the ingestion of as little as 15 mg/kg may be fatal in a child. The toxic effects from cyclic antidepressants overdose result from exaggeration of their pharmacologic effects. They have four major pharmacologic effects: inhibition of the fast sodium channels leading to decreased myocardial contractility, inhibition of norepinephrine reuptake, direct α adrenergic block, and anticholinergic effects.

Clinical and Laboratory Manifestations

Patients presenting initially after cyclic antidepressant overdose may have no symptoms but deteriorate rapidly within 1 h. The clinical features of cyclic antidepressants overdose can be grouped according to their effects on the central nervous system, the peripheral autonomic system (anticholinergic effects), and the cardiovascular system (*Table 274.2*).

Prolongation of the QRS complex on ECG is the most important toxic effect of cyclic antidepressant overdose. It is due to the inhibition of the sodium channels that delays the propagation of depolarization through the myocardium and conducting tissue with a predisposition to cardiac arrhythmia. Sinus tachycardia, which is due to the inhibition of norepinephrine reuptake and the anticholinergic effects, is the most common cardiovascular effect. Another cardiovascular effect is hypotension that is due to vasodilation and impaired cardiac contractility. Cyclic antidepressant overdose–related mortality is mainly due to refractory hypotension. Delirium manifesting as disorientation and agitation occurs in the initial hours after ingestion and may develop in later stages into coma. Seizures often occur within 2 h and may result in acidosis and hyperthermia.

Electrocardiogram ECG is obtained upon presentation in patients with suspected or known cyclic antidepressant overdose. Serial ECGs should be obtained later. Prolongation of the QRS $>$ 100 ms, abnormal morphology of the QRS, and abnormal size and ratio of the R and S waves in lead AVR (R wave $>$ 23 mm) predict cardiotoxicity and are important tools in diagnosis and management. ECG changes are better predictors of seizures or ventricular arrhythmia than plasma drug levels. Plasma level of cyclic antidepressants has limited therapeutic or prognostic utility.

Management

Patients having cyclic antidepressants overdose should have a baseline electrocardiogram and be monitored for a minimum of 6 h. Patients with significant symptoms or with any ECG changes, or with mild persistent symptoms (sinus tachycardia or lethargy) should be admitted and monitored in the intensive care unit. If the patient remains symptom-free, then the patient may be referred for psychiatric clearance. Aggressive supportive care and alkalinization using sodium bicarbonate represent the mainstay of treatment (*Table 274.3*). Whenever a patient is suspected to have cyclic antidepressant overdose, the initial management would include: securing the patient's airway, breathing and circulation, obtaining baseline ECG with continuous monitoring, pulse oximetry, and have an IV line inserted. Many patients may require

Table 274.1
The different classes of antidepressants

Cyclic antidepressants	Amoxapine
	Desipramine
	Nortriptyline
	Protriptyline
	Maprotiline
	Imipramine
	Amiriptyline
	Doxepin
	Trimipramine
Selective serotonin reuptake inhibitors	Citalopram
	Escitalopram
	Fluoxetine
	Paroxetine
	Sertraline
	Fluvoxamine
Serotonin/norepinephrine reuptake inhibitor	Duloxetine
	Venlafaxine
Serotonin reuptake inhibitor/antagonist	Trazodone
	Nefazodone
Monoamine oxidase inhibitor	Phenelzine
	Selegiline
Dopamine reuptake inhibitor	Bupropion

Table 274.2
Clinical features of cyclic antidepressant overdose

Cardiovascular effects	Central nervous system effects	Anticholinergic effects
Sinus tachycardia	Drowsiness	Dry mouth
Prolonged PR/QRS/QT	Coma	Blurred vision
Heart block	Seizures	Constipation
Hypotension	Rigidity	Urinary retention
Ventricular fibrillation/ tachycardia	Respiratory depression	Dilated pupils
Asystole		Pyrexia

intubation. Supplemental oxygen should be available if needed. Laboratory tests required include serum electrolytes, blood urea nitrogen, serum creatinine, glucose, and arterial blood gases.

Gastric decontamination with gastric lavage and activated charcoal can be used even on late presentation because of delayed gastric emptying secondary to anticholinergic effects. Ipecac-induced emesis is not recommended because rapid neurologic and hemodynamic deterioration may occur. Gastric lavage can be used if it can be performed within 1 h of ingestion. Activated charcoal is used to enhance elimination by adsorption of the cyclic antidepressant and decreased enterohepatic recirculation. The recommended dose of activated charcoal is 1 g/kg. The use of multiple dose activated charcoals is generally not recommended in cyclic antidepressant overdose because of the potential of adverse effects such as impaction and intestinal infarction.

Intravenous sodium bicarbonate is a first-line treatment for QRS complex prolongation, ventricular tachycardia, and hypotension caused by cyclic antidepressant overdose. Sodium bicarbonate at a dose of 1–2 mEq/kg is administered as a bolus infusion and repeated as necessary to achieve an arterial blood pH of 7.5–7.55. Excessive use of sodium bicarbonate may lead to dangerous alkalemia and ventricular arrhythmia. Sodium bicarbonate is also used to treat ventricular dysrhythmias. For those unresponsive, consider magnesium, beta-sympathomimetics, overdrive pacing, or lidocaine. Class IA (Quinidine, disopyramide, and procainamide) and class IC antiarrhythmics are contraindicated as their effects on myocardial conduction are similar to that of the cyclic antidepressants. Treatment with beta-blockers for supraventricular tachydysrhythmias may be needed if the rate exceeds 160 beats per minute and the patient demonstrates signs and symptoms of hemodynamic instability. Benzodiazepines (diazepam or lorazepam) are used for the treatment of cyclic antidepressant-induced seizures. Phenobarbital is used for seizures refractory to benzodiazepines. Flumazenil is used to antagonize the effects of benzodiazepines, but its use in cyclic antidepressant overdose has been associated with seizures and is contraindicated. Vasopressors such as norepinephrine, phenylephrine, or dopamine are used in patients with hypotension refractory to fluid and sodium bicarbonate. Use of physostigmine, an anticholinesterase, is not recommended since it has been associated with the development of seizures and fatal dysrhythmias.

Selective Serotonin Reuptake Inhibitors

Pediatric ingestions of selective serotonin reuptake inhibitors (SSRIs) are generally well tolerated and much safer than cyclic antidepressants. SSRIs have a wide therapeutic range and thus fatalities are uncommon with pure SSRI overdoses but may occur in the presence of coingestants such as

Table 274.3
Drug therapy for antidepressants overdose

Indication	Drug	Dosage regimen
Gastric decontamination	Activated charcoal	1 g/kg
Wide QRS complex, ventricular arrhythmias, hypotension	Sodium bicarbonate	1–2 mEq/kg bolus infusion
		Repeated to reach arterial blood pH 7.5–7.55
Refractory ventricular arrhythmias	Lidocaine	1 mg/kg IV push initially; followed by 20–50 mcg/kg/min continuous IV infusion
Seizures	Lorazepam	0.05–0.1 mg/kg slow IV over 2–5 min (max 4 mg/dose) repeated every 10–15 min if seizures persist
	Diazepam	0.2–0.5 mg slow I.V every 2–5 min to a maximum of 5 mg ; repeat in 2–4 h if needed
		Children $\geq$ 5 years: 1 mg slow I.V. every 2–5 min to a maximum of 10 mg ; repeat in 2–4 h if needed
Torsade de pointes	Magnesium sulfate	25–50 mg/kg/dose IV ; not to exceed 2 g/dose

benzodiazepines or ethanol. They are unlikely to cause seizures, severe CNS depression, or significant cardiotoxicity. Citalopram is likely the most cardiotoxic SSRI; its use may be associated with prolongation of the QTc interval and can predispose a patient to torsade de pointes. Since SSRIs have little or no antagonist effect on muscarinic, histaminic, or adrenergic receptors, they do not cause anticholinergic symptoms, hypotension, or significant sedation.

Since most selective serotonin reuptake inhibitors overdoses develop no or minimal toxicity, supportive care would be the mainstay of therapy. Management includes: securing airway, breathing and circulation, gastric decontamination with one dose of activated charcoal (1 g/kg), treating seizures with benzodiazepines (diazepam or lorazepam), managing prolonged QRS interval with sodium bicarbonate, and treating torsade de pointes if present with magnesium sulfate. Most cases resolve without complications within 24–36 h with adequate supportive measures. The patient who remains asymptomatic for several hours following an SSRI overdose needs no further medical evaluation and treatment.

Serotonin Syndrome

Serotonin syndrome is a potentially life-threatening condition secondary to excessive serotonin activity in the central nervous system. It results from therapeutic medication use, drug overdose, or interactions between medications. The incidence of serotonin syndrome with selective serotonin reuptake inhibitors overdose is 10–14% and many of these cases have mild presentations. It is characterized by mental status changes, autonomic hyperactivity, and neuromuscular abnormalities. Mental status changes are manifested by confusion, agitation, and coma. Hyperthermia, mydriasis, tachycardia, and hypertension are characteristics of autonomic hyperactivity. Neuromuscular abnormalities are manifested by myoclonus, rigidity, tremors, hypereflexia, clonus, and ataxia. Management of the serotonin syndrome involves the removal of the precipitating drugs, supportive care, the control of agitation with benzodiazepines, the control of autonomic instability, and the administration of serotonin antagonist (cyproheptadine 0.25 mg/kg/day divided twice or three times per day, max: 12 mg) depending on the severity of the illness. Severe cases that develop muscular rigidity and hyperthermia must be treated with neuromuscular paralysis, followed by orotracheal intubation and ventilation.

275 Digoxin

Nicole Gebran

Digoxin was first introduced as a drug in the treatment of atrial fibrillation in the early twentieth century. Only subsequently was the value of digitalis for the treatment of congestive heart failure established. The syndrome of digoxin toxicity was originally described in 1785 by Withering.

The therapeutic properties of cardiac glycosides such as digoxin, a product of the foxglove plant, have been known since the days of the ancient Romans who used red squill, derived from the sea onion, as a diuretic in heart medicine. Cardiac glycosides are found in certain flowering plants such as oleander and lily-of-the-valley and are components of some herbal dietary supplements. Digitalis toxicity was also well known in previous centuries, and some have suggested that the toxic visual symptoms of digitalis may have played a role in Van Gogh's use of swirling greens and yellows.

The public health burden of digoxin toxicity declined dramatically from 1991 to 2004 in the United Kingdom and the United States. The decline may be attributed to reductions in the overall utilization and dose. However in hospitalized patients, international statistics indicates that approximately 2.1% of inpatients on digoxin and 0.3% of all admissions develop toxicity. In the United States, approximately 0.4% of all hospital admissions and 1.1% of outpatients on digoxin develop toxicity. Data from the 2007 Annual Report of the American Association of Poison Control Centers reported 2,565 adult and pediatric digitalis exposure toxicities with 10 deaths reported.

Toxicity from plants, such as oleander, foxglove, and lily-of-the-valley, is uncommon but potentially lethal. Case reports of toxicity from these sources implicate the preparation of extracts and teas as the usual culprit. The relationship between digoxin toxicity and the serum digoxin level is complex; clinical toxicity results from the interactions between digoxin, various electrolyte abnormalities, and their combined effect on the Na+/K+ ATPase pump.

The mechanism of action of digoxin is by inhibition of Na+K+ATPase. This inhibits the transport of Na+ and K+ across the myocyte membrane, causing a rise in intracellular Na+, thus decreasing efflux of Ca2+ from the myocyte and augmenting myocardial contractility. The elimination half-life of digoxin is 36–48 h in patients with normal renal function. Steady-state levels are reached approximately a week after the initiation of maintenance therapy. Digoxin is excreted by the kidneys but is not cleared by hemodialysis. Skeletal muscles, and not adipose tissue, are the main reservoir and thus dosing should ideally be based on lean body mass. It has a narrow therapeutic index, and daily maintenance doses range from 2.5 to 5 μg/kg in older children to 5–10 μg/kg in younger children and infants. Loading doses may be given orally or intravenously when indicated. Digoxin toxicity occurs more commonly in neonates and infants or in old age and in patients with renal dysfunction and those taking other drugs such as carvedilol or other β-blockers or diuretics.

Clinical and Laboratory Manifestations

Digoxin toxicity may be acute in presentation, as in a toddler who accidentally over-ingests a family member's stock of medicament or chronic, as in a child who is being treated with digoxin and whose serum level exceeds the therapeutic range. Mechanistically, grossly acute poisoning with digoxin differs significantly from chronic toxicity. In acute overdose, the sodium–potassium pump is disrupted, enabling a decrease in intracellular potassium and an increase in extracellular potassium. The normal membrane resting potential is reduced, and electrical conduction is slowed. Eventually, there is a loss of myocardial electrical function that presents clinically as high-grade block and asystole that may be refractory to electrical pacing.

The usual signs and symptoms in acute toxicity include anorexia, nausea, vomiting, lethargy, confusion, weakness, and hyperkalemia. Atrioventricular block and ventricular dysrhythmias are also seen. In the setting of chronic toxicity, signs and symptoms include abdominal pain, anorexia, confusion, delirium, disorientation, headache, hypokalemia and hypomagnesemia, nausea, vomiting, and ocular disturbances.

Management

Diagnosis of toxicity should be made clinically. An ECG should be done to evaluate for rhythm disturbances.

From Smith TW, Antman EM, Friedman PL, et al. Digitalis glycosides: mechanisms and manifestations of toxicity. Part III. Prog Cardiovasc Dis 1984; 27: 26, with permission.

Digoxin levels are used to corroborate the diagnosis but may not always correlate with the extent of toxicity, especially after acute ingestion. Children without cardiovascular disease may tolerate higher levels without clinical symptoms. In general, the smaller the infant, the higher the levels may be before toxic effects are observed. Levels drawn within 6–8 h after ingestion of a dose reflect the initial tissue distribution and are not necessarily indicative of toxicity. Normal levels, even in the setting of profound clinical toxicity, can occur with acute ingestion of nondigoxin glycosides such as foxglove and oleander, owing to nonreactivity with the digoxin radioimmunoassay. The clinical presentation of digoxin toxicity is unpredictable. The usual signs and symptoms may be noncardiac (*Table 275.1*), particularly gastrointestinal complaints, or cardiac such as rhythm disturbances. In nearly half the cases of digoxin toxicity, cardiac manifestations precede the noncardiac events. Atrioventricular block is the most common cardiac manifestation of severe digoxin toxicity in pediatrics. This population appears to be more resistant to the cardiotoxic effects of digoxin at a given serum level compared to adults with the same serum level. In more severe intoxication, lethargy, disorientation, and electrolyte disturbances may also occur.

Management of a patient with digoxin toxicity includes stopping administration of the drug and correction of rhythm disturbances. If the patient is asymptomatic, simple observation and monitoring may suffice. Symptomatic sinus bradycardia can be treated with atropine. Cardiac pacing may be required for higher degrees of block. Ventricular ectopics or ventricular tachyarrhythmias can be treated with lidocaine. Cardioversion is relatively contraindicated because it may cause asystole or ventricular fibrillation. In case of dysrhythmias, which are potentially life threatening or are associated with hemodynamic instability, the treatment of choice is intravenous administration of Digibind® or DigiFab™, which contain digoxin specific Fab antibody fragments, cleaved from immunoglobulin G extract from sheep immunized with digoxin. These fragments are not very immunogenic in humans and after binding with digoxin, are rapidly distributed and renally excreted. The Fab-digoxin complexes are inactive, causing rapid resolution of symptoms upon administration. Other indications for use of Digibind® in patients with digoxin toxicity include but are not limited to those with acute ingestion exceeding 0.3 mg/kg of digoxin, serum digoxin exceeding 5 ng/mL, hyperkalemia, or rapidly progressive toxicity. When the ingested amount of digoxin is known, the dosage of Digibind® is calculated: each 38-mg or 40-mg vial binds approximately 0.5 mg or 0.6 mg of digoxin, and 80% of the calculated dose is administered intravenously during a 30-min period to account for incomplete absorption.

Acute Ingestion of an Unknown Amount of Digoxin

If the amount of ingestion is unknown, general dosing guidelines should be used. In children weighing more than 20 kg, 20 vials are adequate to treat most life-threatening ingestions. May be given as a single dose or as 10 vials, then response is observed and a second 10-vial dose is given if indicated. The larger dose (20 vials) has a faster onset of action but may cause a febrile reaction. Digibind is given as an infusion over 30 min using an in-line 0.22 micron membrane filter. If cardiac arrest is imminent, it may be given as a bolus injection. It is important to monitor for volume overload in children.

Acute Ingestion of a Known Amount of Digoxin

To determine the dose of digoxin immune Fab, first determine the total body load of digoxin (TBL) or digitoxin using the following formulas (depending upon which factor is known the amount ingested or the postdistribution serum digoxin/digitoxin concentration (C)): (*Table 275.2* summarizes few examples)

Table 275.2

Infants and children dose estimates of digoxin immune Fab (in mg)[a] from serum digoxin concentration

Patient weight (kg)	Serum digoxin concentration (ng/mL)						
	1	2	4	8	12	16	20
1	0.4 mg[b]	1 mg[b]	1.5 mg[b]	3 mg	5 mg	6–6.5 mg	8 mg
3	1 mg[b]	2–2.5 mg[b]	5 mg	9–10 mg	14 mg	18–19 mg	23–24 mg
5	2 mg[b]	4 mg	8 mg	15–16 mg	23–24 mg	30–32 mg	38–40 mg
10	4 mg	8 mg	15–16 mg	30–32 mg	46–48 mg	61–64 mg	76–80 mg
20	8 mg	15–16 mg	30–32 mg	61–64 mg	91–96 mg	122–128 mg	152–160 mg

[a]When a range in dose is listed, the lower number represents the Digibind® dose and the higher number represents the Digifab™ dose. A single dose is the same for both products.

[b]Dilution of reconstituted vial to 1 mg/mL may be desirable.

$$\text{TBL of digoxin (mg)} = \text{C (in ng/mL)} \times 5.6 \times \text{body weight (in kg)}/1000 \text{ or}$$

$$\text{TBL of digoxin (mg)} = \text{mg of digoxin ingested (as tablets or elixir)} \times 0.8$$

$$\text{TBL of digitoxin (mg)} = \text{C (in ng/mL)} \times 0.56 \times \text{body weight (in kg)}/1000 \text{ or}$$

$$\text{TBL of digitoxin(mg)} = \text{mg digitoxin ingested}$$

$$\text{Dose of Digibind® (in mg) I.V.} = \text{TBL} \times 76$$

$$\text{Dose of DigiFab™ (in mg) I.V.} = \text{TBL} \times 80$$

$$\text{Dose of digioxin immune Fab (Digibind® or DigiFab™) (\# vials) I.V.} = \text{TBL}/0.5$$

Chronic Digoxin Ingestion Toxicity

In infants and small children weighing <20 kg with chronic digoxin toxicity, a single 40-mg vial may be adequate. The ECG disturbances usually disappear 30–40 min after use of Digibind. Electrolyte abnormalities, especially hypokalemia, should be corrected. Hyperkalemia should be corrected if the serum potassium level is greater than 5.5 mEq/L and should be treated with sodium bicarbonate or glucose insulin drip, or both. Intravenous calcium should be avoided in those cases because it may precipitate ventricular fibrillation or cardiac arrest. Kayexalate (Sanofi-Aventis, Bridgewater, NJ) may precipitate hypokalemia if administered to these patients because digoxin-induced hyperkalemia reflects an extracellular shift of potassium rather than an overall increase in body potassium. Hyperkalemia as a manifestation of digoxin toxicity is more common in the acute setting.

Physicians should have a high index of suspicion for digoxin toxicity in a patient who is taking the medication and presents with symptoms of vomiting, visual disturbances, or changes in the cardiac symptoms. Diagnosis of digoxin toxicity should be clinically made and levels should be used only for confirmation. Routine monitoring of levels is neither useful nor indicated. Early diagnosis and appropriate management can help reduce the associated morbidity and mortality.

Morbidity is usually 4.6–10%; however, morbidity is 50% if the digoxin level is greater than 6 ng/mL. Complications related to arrhythmias include hypoxic seizures, encephalopathies, loss of vasoregulation, and acute tubular necrosis. On the other hand, in pediatric patients, hyperkalemia is the major electrolyte complication in acute digoxin poisoning.

Individualizing the dosing of digoxin is the key to its optimal use. The desired plasma concentration endpoint is 2 ng/mL in patients younger than 2 years and 1.5 ng/mL in patients older than 2 years. Parents of patient should be educated about the good home childproofing and preventive measures. Medical, nursing, and pharmacy staff should carefully monitor the prescription, dispensing, and administration of digitalis.

276 Household Products

Vivian Brown

Introduction

The key to management of suspected or confirmed household product ingestion by children is obtaining as much information as possible. Many household products list emergency measures on the product label in case of accidental ingestion and that the original product container be provided to health care professionals treating the ingestion.

Substances most frequently ingested by children in the developed world include household chemicals, medication, and plants (1) and in more than 90% of cases, the exposure is to a single substance and the vast majority of exposures occur at home. The majority of caustic ingestions occur in children between 12 and 48 months of age. Unintentional poisoning in developing countries can be much more serious, following ingestion of kerosene, caustic agents, herbal remedies, insecticides, or herbicides.

Prevention measures have included community-based strategies (moving toxic cleaning products to higher shelves) and educating consumers (safe storage of household products, use of warning labels, availability of poison control or hospital phone numbers). Warning labels (such as Mr. Yuk and skull and cross bones) are no longer recommended since they tend to attract children rather than deter them.

Age of Patient

Intoxications in children younger than 1 year may reflect accidental administration of an incorrect drug or dose by the caretaker, administration of a pharmaceutical by an older sibling, or parental abuse. Very young children are also subject to toxicity from passive exposure to agents such as smoke from marijuana and "crack" cocaine.

For children younger than 5, especially those aged 2 years and younger, unintentional behavior on the part of the child and parent are typically blamed for intoxication. Exploratory behavior, rather than purposeful harm, generally brings teens and preteens to medical attention, although suicidal gesture or frank suicide attempt might be considered for anyone over 9 years of age.

Nontoxic Household Product Ingestion

Many household products are nontoxic unless taken in huge amounts (*Table 276.1*). Mofenson and Greensher have developed criteria that qualify an ingestion as "nontoxic." These include:

- Assurance exists that only one identifiable product has been ingested and in a well-approximated amount.
- The product label includes no cautionary signal word.
- The child is symptom free and under 5 years old.
- Appropriate telephone follow-up is possible.

Other household products and management worth special note are:

1. Toothpaste containing fluoride typically contains a maximum of 1 mg of fluoride/g of toothpaste. Packaging often has warnings stating that if more than the amount used for brushing is ingested, medical attention is warranted. However, exploratory ingestion of sodium fluoride typically does not produce symptoms if the amount of fluoride ingested is less than 5 mg/kg.
2. Furniture polishes that contain petroleum distillates are not system poisons. They are dangerous if aspirated. There is no treatment indicated for the asymptomatic child who ingests furniture polish.
3. Hand dishwashing detergents can act as emetics; however, automatic dishwasher detergents can be alkali.
4. Diaper rash products are the most common topical preparations involved in pediatric poisonings. These may contain zinc oxide, emollients, and/or small quantities of vitamins A and D. The risk for vitamin A or D toxicity in this setting is negligible. With large ingestions, gastrointestinal upset may result.
5. Hydrogen peroxide 3% for household use/general disinfectant may cause gastrointestinal irritation but is unlikely to result in serious toxicity. However, it also is available as chlorine-free bleach (6%), fabric stain removers (5–15%), contact lens disinfectants (3%), hair dyes (6%), and teeth-whitening agents (15%), as well as concentrated solutions of 35% sold in health food shops for the purpose of "hyper-oxygenation therapy." It can cause toxicity via three main

mechanisms: corrosive damage, oxygen gas formation, and lipid peroxidation. Exposure can be ingestion, inhalation, injection, wound irrigation, rectal administration, dermal exposure, or ocular exposure.

6. Hydrofluoric acid (cleaning solutions) and methacrylic acid (in nail care products) are two products that have been responsible for serious injury and death. Although most cosmetics are of a low-order toxicity, nail care products (artificial nail primer, artificial nail glue, and artificial nail glue removers) can be very toxic causing methemoglobinemia and/or cyanide poisoning.

Toxic Household Product Ingestion

Table 276.2 lists products that are considered toxic if consumed in adequate amounts and provides a quick reference for product categorization. *Table 276.3* lists common non-pharmaceutical products and their symptoms and treatment following ingestion. *Figure 276.1* provides a household cleaning product algorithm. Specific treatment information for ingestion of caustics/corrosives is presented in *Fig. 276.2*; antidotes are listed in *Table 276.4*.

Management of Ingestion

Caustics/Corrosives

The approach to management of ingestion of caustics and/or corrosives begins with rapid clinical assessment of cardio respiratory function, neurologic status, and evidence of gastrointestinal hemorrhage. Gastrointestinal decontamination is not indicated after the ingestion of corrosive agents. Treatment by dilution is indicated only when the toxin produces local irritation or corrosion, in which case water or milk is acceptable. If the eyes are involved, they should be irrigated copiously with water for at least 15 min and then pH testing of fluids should be performed in the ocular cul-de-sac after irrigation to confirm neutralization; the normal pH of tears is 7 (also see *Tables 276.2* and *276.3*).

Hydrocarbons

Although hydrocarbons are still a major cause of pediatric morbidity via aspiration, systemic toxicity is limited and, if they are swallowed, is usually only a few swallows that

Table 276.2
Classification of household poisons by product category

Caustics/corrosives (alkaline)[a]
Cleano granules (caustic soda)
Oven cleaners (easy off)
Destop gel express drain and pipe cleaner (sodium hydroxide 20%)
Drain cleaners (Drano, liquid plumber)
Other products containing sodium hydroxide include: Clinitest tablets, powdered laundry, and dishwasher detergents
Sodium hypochlorite[a]
Clorox (5.25%) (treat as possible corrosive)
Ammonia[a]
Windex
Parson's Ammonia (cleaner)
Alcohols
Isopropyl alcohol 70%
Ethylene glycol (antifreeze)
Methanol (stove fuel, Sterno, paint remover)

are vomited spontaneously. Hydrocarbons and other water-insoluble compounds are poorly adsorbed by charcoal. Therefore, gastrointestinal decontamination is not indicated and may predispose to hydrocarbon aspiration. The exception to this is significant ingestion of hydrocarbons containing toxic chemicals, which are the halogenated and aromatic compounds.

Organophosphates (Anticholinesterases)

Found in pesticides, symptoms of acute poisoning usually develop during the first 12 h of contact. These include CNS symptoms (dizziness, headache, ataxia, convulsions and coma), nicotinic signs (sweating, muscle twitching, tremors, weakness and paralysis), and muscarinic signs, characterized by the SLUDGE mnemonic (salivation, lacrimation, urination, defecation, gastrointestinal cramping, and emesis). Additionally, miosis, bradycardia, bronchorrhea, and wheezing may occur. In severe cases, pulmonary edema may occur. The best clues to diagnosis are a history of exposure and the above clinical manifestations. Plasma cholinesterase level depression of 25% or more is strong evidence of poisoning, but this laboratory test is rarely readily available.

Aggressive gastrointestinal and dermal decontamination are crucial, and hospital staff must protect themselves from contaminated clothes and body fluids. Decontamination of the skin for topical exposure includes thorough scrubbing with soap to prevent further absorption (and bagging of contaminated clothing to protect medical personnel). Activated charcoal should be administered for oral poisoning. After decontamination, antidotal therapy should begin. (See *Table 276.5* for toxidromes and *Table 276.4* for general guidelines on antidote administration.) Atropine (0.05 mg/kg/dose) is given until an atropine effect is observed (tachycardia, dry flushed skin, mydriasis, fever, and drying of secretions). Atropine doses may be repeated every 1–4 h to maintain the atropine effect. A constant infusion of pralidoxime (10–15 mg/kg/h in a 1–2% solution) may be considered for very severe poisonings.

Alcohols

Treatments for ethylene glycol, methanol, and isopropanolol ingestion are listed in *Table 276.3*. The cornerstone of management includes the correction of acidosis, competitive inhibition of ADH, and hemodialysis-assisted elimination. The introduction of fomepizole as an antidote for ethylene glycol and methanol poisoning in 1998 constitutes a recent success in medical toxicology.

It acts through the binding of ADH 500–1,000 times more effectively than methanol, essentially eliminating the formation of toxic metabolites. Historically, a 10% ethanol solution IV or PO has been used to elicit competitive inhibition of toxic metabolites, keeping the serum ethanol concentration between 100 and 150 mg/dl. Most authorities ascribe an overall cost savings with the use of fomepizole; however, ethanol still exists as a viable option.

Table 276.3

Common non-pharmaceutical products involved in unintentional household poisoning in children (adapted and used with permission)

Product	Characteristics	Symptoms	Treatment
Aftershave, alcohols, cologne, mouthwash, perfumes	Ethanol-containing agents; perfumes contain up to 75–95%	CNS and respiratory depression, hypoglycemia, acidosis	Clinical observation and hospital admission depending on the ingested amount; blood glucose measurement; administer oral or intravenous glucose in hypoglycemic children depending on severity; respiratory support as needed
Bleach	Household solutions contain approximately 3–10% sodium hypochlorite or less commonly 3% hydrogen peroxide; extremely unpalatable; unlikely to cause serious damage. Industrial bleach: up to 50% of sodium hypochlorite	Nausea, emesis, diarrhea; esophageal injury rarely occurs; hypernatremia, hyperchloremic acidsis. External contamination may result in eye or skin irritation	Administer fluids; hospital admission of children at risk of developing esophageal injury (see esophageal burns)
Button batteries	Toxicity occurs when button batteries remain in the esophagus, the nose, the ear, or if they are leaky before ingestion. If they rapidly reach the stomach, toxicity is unlikely	Difficulty swallowing, vomiting, hematemesis. In case of ingestion of leaky battery, hypersalivation, drooling	X-ray to confirm ingestion. Battery lodged in the esophagus should be quickly removed by endoscopy. Same applies to battery impacted in the nose or ear. Batteries in the stomach or the intestine should not be removed unless there are signs of perforation, obstruction, or if they were leaky
Detergents	Three chemical categories: nonionic, anionic, cationic	Nonionic, anionic (low toxicity): Respiratory symptoms secondary to foam aspiration rarely occur. Cationic: corrosive lesions if concentrated solution is involved	Administer oral fluids; further treatment depending on the presence of respiratory symptoms and corrosive lesions (see esophageal burns)
Dishwasher powders, liquids, tablets	Older or professional use products: strongly alkaline; possible severe corrosive injury	Hypersalivation, drooling, vomiting, hematemesis, pain. Esophageal injury may occur in the absence of oral burns	Remaining products must be washed off; administer oral fluids; supportive treatment (see esophageal burns)
Disinfectants and antiseptics	May contain a number of toxic constituents (chlorhexidine, hexylresorcinol, hydrogen peroxide, ichthammol, iodine, phenol, potassium permanganate); usually they are found in very low quantities in diluted solutions	Irritation of the oral mucosa, transient gastrointestinal upset, possibly corrosive effects, aspiration pneumonia. Systemic toxicity: acidosis, CNS depression, hepatic/renal damage depending on substances involved	Administer fluids; precise identification of involved substance is essential. In case of esophageal injury (see esophageal burns)

Table 276.3 (Continued)

Product	Characteristics	Symptoms	Treatment
Essential oils	Volatile mixture of esters, alcohols, and ketones; some substances, e.g., camphor, are very toxic	Initial effects: mucosal irritation, vomiting, epigastric pain; secondary hepatic and renal failure possible; sedation, seizures; respiratory compromise if aspirated	Clinical observation; supportive treatment if indicated
Ethylene glycol	Found in various types of antifreeze and windscreen wash. Rapid absorption from the stomach. Metabolic degradation by alcohol dehydrogenase (ADH) to a variety of toxic metabolites. Increased anion gap	After ingestion of $\geq$0.1 ml/kg: nausea, emesis, abdominal pain, CNS depression, convulsions; $\geq$0.2 ml/kg: metabolic/lactic acidosis, hypocalcaemia, rental failure, CNS depression, convulsions	Hospital admission: Assessment of plasma ethylene glycol as well as measurement of blood gases, serum electrolytes, and renal function. Antidotes in symptomatic children or those with a plasma ethylene glycol level $>$3.2 mmol/l (20 mg/dl): ethanol (initial dosage 0.6–0.8 g/kg, followed by 0.1 g/kg/h). Fomepizole: initial dosage: 15 mg/kg, followed by four-times 10 mg/kg every 12 h. In case of renal failure, hemodialysis is required. Consider hemodialysis if level $>$8 mmol/l (50 mg/dl). Or if resistant metabolic acidosis. Fomepizole and ethanol are dialyzed and the dosage needs to be adjusted when dialysis is performed. Supportive care: correction of acidosis with sodium bicarbonate, and glucose for hypoglycemia
Isopropanol	Alcohol found in various household products (e.g., nail polishes, hairsprays, antifreezes, car screen washes). Rapid absorption from the stomach and mucus membranes. Conversion to acetone by ADH. Excretion through the lungs and kidneys	Gastric irritation, CNS depression, and hypotension. Ketonemia and ketonuria	Asymptomatic children: short period of clinical observations and administration of fluids. Symptomatic patients require intensive support. Hypotension: treatment with intravenous fluids and inotropes. Hemodialysis is rarely useful, but could be considered in patients with failure of supportive measures
Methanol	Constituent of antifreezes, windscreen washes, and various household products. Rapidly absorbed from the gastrointestinal tract; metabolization by ADH. Increased anion gap	Irritation of mucus membranes; abdominal pain, nausea, emesis, retinal toxicity, neuritis of the optic nerve, metabolic acidosis, convulsions, and coma	Hospital admission: measurement of blood gases, electrolytes, renal function, and methanol level. Treatment is similar to ethylene glycol poisoning, both ethanol and fomepizole inhibiting its metabolism. Antidotes in symptomatic children or those with a plasma methanol level $<$8 mmol/l (20 mg/dl). In addition, consider folic acid 1–2 mg/kg every 4–6 h. Consider hemodialysis if level $>$15.6 mmol (50 mg/dl). Or if resistant metabolic acidosis. Fomepizole and ethanol are dialyzed and the dosage needs to be adjusted when dialysis is performed. Supportive care: correction of acidosis with sodium bicarbonate, and hypoglycemia with glucose

Table 276.3 (Continued)

Product	Characteristics	Symptoms	Treatment
Nail care/nail varnish removers	Typically contain acetone or ethyl acetate, but other solvents may be used including methanol; artificial nail products containing methacrylic acid may cause severe caustic injury; artificial nail removers containing nitroethane may cause methemoglobinemia, and acetonitrile may cause cyanide poisoning	Irritation of mucus membranes, vomiting, CNS depression; ketosis, acidosis, hyperglycemia possible	Clinical observation may be indicated; hospital admission needed in symptomatic children; Nitroethane and acetonitrile ingestions require referral to the ED; measurement of blood glucose; monitor respiratory and renal function; supportive care. In case of esophageal injury (see esophageal burns)
Nicotine	Toxic alkaloid found in a range of plants, most notably tobacco and smoking cessation products that contain nicotine (gums, transdermal patches, nasal sprays). Most frequently ingested in the form of cigarette or cigarette butt	Vomiting is the most common symptom. Confusion, convulsions, and dysrhythmias may occur only if large amounts are ingested	Usually no specific treatment is required; consider activated charcoal depending on ingested amount and age; supportive care in case of seizures and cardiovascular compromise
Petroleum distillate (paraffin, kerosene, petrol, diesel, lubricating, engine oils)	Low systemic toxicity	Aliphatic hydrocarbons: Main hazard: chemical pneumonitis. Many aromatic and halogenated hydrocarbons may cause CNS depression, seizures, and cardiac arrhythmias	Clinical observation; hospital admission in symptomatic children; administer fluids; chest X-ray and supportive treatment if indicated. Extracorporeal membrane oxygenation (ECMO) could be used in severe cases of chemical pneumonitis
Rat and mouse poisons (domestic rodenticides)	Accurate identification of the constituents may be difficult; most substances are based on warfarin or long-acting anticoagulant substances; alphachloralose is used rarely; carbamate pesticides are used in some regions	Bleeding, CNS depression with alphachloralose; cholingeric features with carbamates (organophosphate pesticides)	Determination of prothrombin time or INR at 12 and 36–48 h post ingestion if ingested substance exceeds 0.5 mg/kg of warfarin, or if 0.01 mg/kg or any other anticoagulant has been ingested. Consider administering oral charcoal. Administer vitamin K per os if prolongation of prothrombin time
Toilet cleaner blocks	Two types: cistern or rim blocks; acid or detergent based; low systemic toxicity, local corrosive damage may occur	Gastrointestinal irritation/upset	Administer fluids. In case of esophageal injury, see esophageal burns

Table 276.3 (Continued)

Product	Characteristics	Symptoms	Treatment
Turpentine	Essential oil	Irritation of gastrointestinal mucosa, metabolic acidosis, hepatic/renal failure, altered level of consciousness. Respiratory compromise if aspirated into the lungs	Admit to hospital if symptomatic; supportive treatment
Laundry powder	Contains mixture of enzymes, perfumes, softeners, and anionic and nonionic detergents; low toxicity	Vomiting	No specific treatment required; administer oral fluids
White spirit/ turpentine substitutes	Relative low toxicity when ingested	Gastrointestinal irritation, CNS depression if ingested in large quantities. Main toxicity due to aspiration; Symptoms may develop after an interval of 24 h	Assessment of respiratory system in all patients, children with signs of chemical pneumonitis: chest X-ray; supportive treatment. ECMO could be used in severe cases of chemical pneumonitis

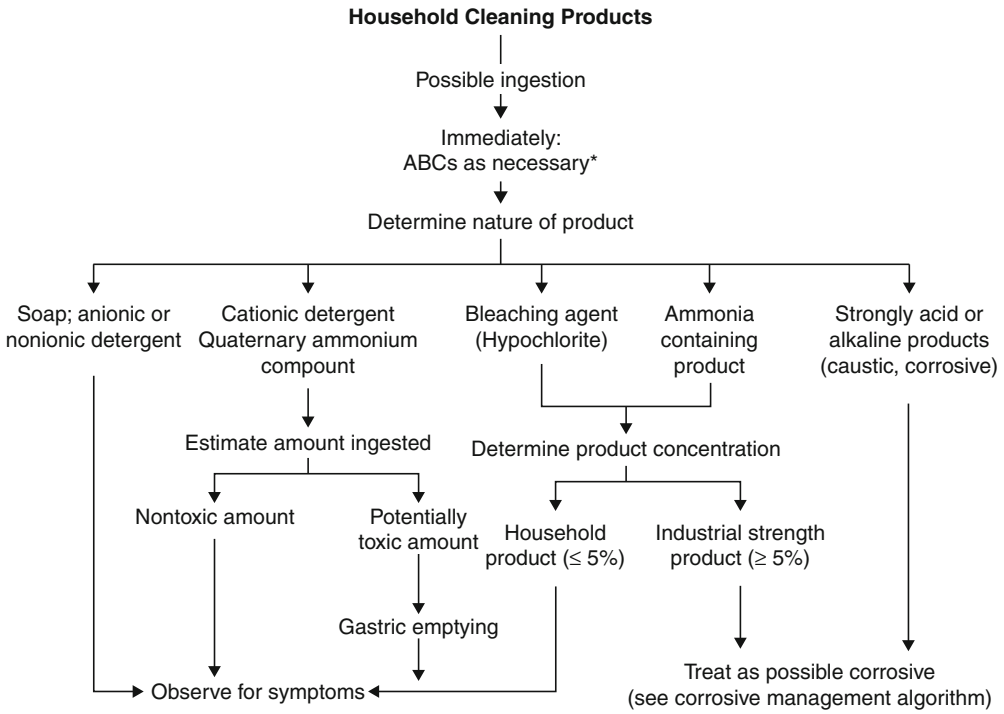

Figure 276.1

Algorithm for management of household cleaning product ingestion. *A, B, and C are airway, breathing, and circulation, the three basics of cardiopulmonary resuscitation (Adapted from Temple AR, Lovejoy FH Jr. (1980) Cleaning products and their accidental ingestion. Soap and Detergent Association, New York. With permission)

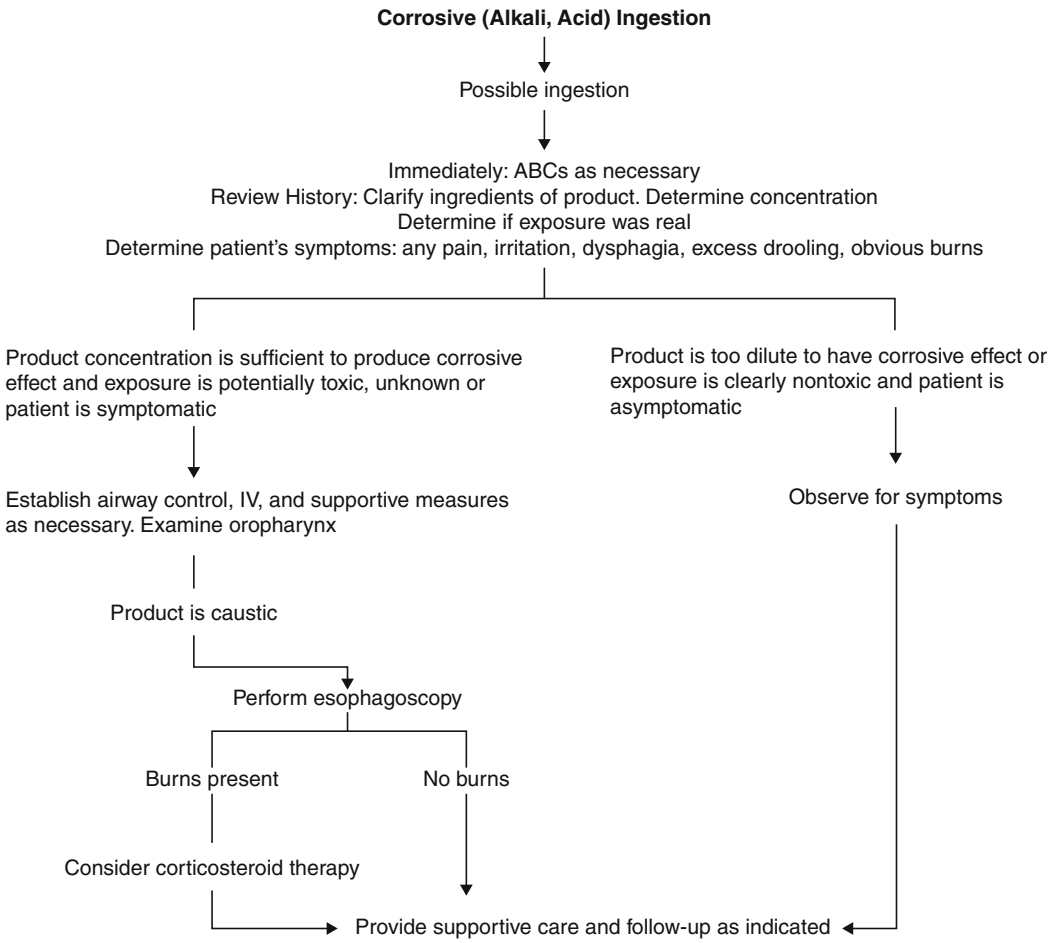

Figure 276.2
Management of ingestion of corrosives (Adapted from Temple AR, Lovejoy FH Jr. (1980) Cleaning products and their accidental ingestion. Soap and Detergent Association, New York. With permission)

For all ingestion assessments, the quantity of substance ingested is best known if the ingestion is witnessed, as well as accounting for original quantity and any amount that might have been spilled. The volume of a swallow is a function of body mass and is 0.27 ml/kg, or roughly 5 ml for a 2-year-old and 20 ml for an adolescent.

Foreign Bodies

1. Disc (button) batteries

   These contain several toxic elements, such as mercury, lithium, and potassium hydroxide, but their reported toxicity lies primarily in corrosive effects when they become dislodged in aural or nasal passages or in the esophagus. After ingestion, a radiograph should be obtained. Batteries lodged in the esophagus require immediate endoscopic removal. If the location is more distal, parental examination of stool until battery passage is required; the battery is usually expelled after 72 h. For any disintegrated battery (as evidenced by X-ray), collection of a 24-h urine for heavy metals (especially mercury) is recommended, with intestinal catharsis and chelation therapy as necessary. Surgical removal is almost never required.
2. Dessicants (such as silica gel) found in medicine bottles have warnings such as "do not eat" or a "skull and crossbones" symbol because they are a choking hazard. Most dessicants are benign, but some exist which contain a strong alkali.
3. Coins are a concern for esophageal lodging rather than systemic toxicity.

Table 276.4
Common pediatric antagonists and antidotes

Poison	Antidote		
Acetaminophen	*N-acetylcysteine (Mycomyst)*: initial dose of 140 mg/kg PO in water, fruit juice, or soda; then 70 mg/kg every 4 h for 68 h (17 doses)		
Anticholinergics	*Physostigmine*: 2 mg (adult), 0.5 mg (child) IV; may repeat in 15 min until desired effect is achieved; subsequent doses every 2–3 h prn		
	Caution: may cause seizures, asystole, cholinergic crisis		
Anticholinesterases	*Atropine*: 2–5 mg (adults), 0.05–0.1 mg/kg (children) IM or IV, repeated every 10–15 min until atropinization is evident		
Organophosphates	*Pralidoxime chloride*: 1–2 g (adults), 25–50 mg/kg (children) IV; repeat dose in 1 h prn, then every 6–8 h for 24–48 h (consider also constant infusion)		
Carbamates	Atropine as above; pralidoxime for severe cases		
Benzodiazepines	*Ftumazenil*: 0.01 mg/kg (not FDA approved for pediatric use as of March 1994)		
β-Adrenergic blockers	*Glucagon*: 50 μg/kg IV, followed by 50 μg/kg/h infusion as needed		
Calcium channel blockers	*Calcium chloride 10%*: 10 ml (adult), 0.2 ml/kg (pediatric) IV or		
	Calcium gluconate 10%: 30 ml (adult), 0.6 ml/kg (pediatric) IV		
	Glucagon: 50 μg/kg IV		
Carbon monoxide	Oxygen 100% by inhalation; consider hyperbaric for severe cases		
Cyanide	*Sodium (A/a) nitrite or thiosulfate*: dose based on body weight and hemoglobin:		
	Hemoglobin	Initial dose 3% IV Na nitrite	Initial dose 25% Na thiosulfate IV
	8 g	0.22 ml (6.6 mg)/kg	1.10 ml/kg
	10 g	0.27 ml (8.7 mg)/kg	1.35 ml/kg
	12 g	0.33 ml (10 mg)/kg	1.65 ml/kg
	14 g	0.39 ml (11.6 mg)/kg	1.95 ml/kg
	Na nitrite should not exceed recommended dose because fatal methemoglobinemia may result		
Digitalis	*Fab antibodies (Digibind)*: dose based on amount ingested and/or digoxin level (see package insert)		
Ethylene glycol	See methanol		
Fluoride	*Calcium gluconate 10%*: 0.6 ml/kg IV slowly until symptoms abate, serum calcium normalizes; repeat prn		
Heavy metals/usual chelators Arsenic/BAL Lead/BAL, EDTA, penicillamine, DMSA Mercury/BAL, DMSA	*BAL (dimercaprol)*: 3–5 mg/kg/dose deep IM every 4 h for 2 days, every 4–6 h for an additional 2 days, then every 4–12 h for up to 7 additional days		

Table 276.4 (Continued)

Poison	Antidote
	EDTA: 50–75 mg/kg/day deep IM or slow IV infusion given in three to six divided doses for up to 5 days; may be repeated for a second course after a minimum of 2 days; each course should not exceed a total of 500 mg/kg body weight
	Penicillamine: 100 mg/kg/day (maximum 1 g) PO in divided doses for up to 5 days; for long-term therapy, do not exceed 40 mg/kg/day
	DMSA (succimer): 350 mg/m^2 (10 mg/kg) PO every 8 h for 5 days, followed by 350 mg/m^2 (10 mg/kg) PO every 12 h for 14 days
Iron	*Deferoxamine*: 15 mg/kg/h IV for severe symptoms
Isoniazid	*Pyridoxine 5–10%*: 1 g per gram of INH ingested (70 mg/kg if dose unknown) IV slowly over 30–60 min
Methanol (and ethylene glycol)	*Ethanol*: loading dose to achieve blood level of 100 mg/dl
	Adult: 0.6 g/kg body weight + 7–10 g to be infused IV over 1 h
	Child: 0.6 g/kg body weight to be infused IV over 1 h
	Maintenance doses should approximate 10 g/kg/h in adults and 100 mg/kg/h in children, to be adjusted according to measured blood ethanol levels
	Folate: 50–100 mg IV every 6 h (methanol)
	Thiamine, 0.5 mg/kg, and *pyridoxine*, 2 mg/kg (ethylene glycol)
Methemoglobinemic agents	*Methylene blue 1%*: 1–2 mg/kg (0.1–0.2 ml/kg) IV slowly over 5–10 min if cyanosis is severe or methemoglobin level >40%
Opioids	*Naloxone*: 1–2 mg IV, IM, sublingual, or by ETT; may repeat up to total of 8–10 mg in adolescent/adult
Phenothiazines (dystonic reaction)	*Diphenhydramine*: 1–2 mg/kg IM or IV *or*
	Benztropine: 0.02 mg/kg, 1 mg max
Tricyclic antidepressants	*Sodium bicarbonate*: 1–2 mEq/kg IV
Warfarin (and "superwarfarin" rat poisons)	*Vitamin K*: 10 mg (adult), 1–5 mg (child) IV, IM, subcutaneous, PO
Animals	*Antivenin*
Snake: Crotalidae (all North American rattlers and moccasins)	Antivenin to Crotalidae, polyvalent (Wyeth)
Snake: coral	
Spider: black widow	Antivenin to *Micrurus fulvius*, monovalent (Wyeth)
	Antivenin to *Latrodectus mactans* (Merck, Sharp, and Dohme)

Adapted from Henretig FM, Shannon M (1996) Toxicologic emergencies. In: Fleisher G, Ludwig S (eds) Textbook of pediatric emergency medicine, 3rd edn. Williams & Wilkins, Baltimore, p 406. With permission.

PO orally, *IV* intravenously, *prn* as needed, *IM* intramuscularly, *FDA* Food and Drug Administration, *BAL* British anti-Lewisite, *EDTA* ethylenediaminetetra-acetic acid, *DMSA* dimercaptosuccinic acid, *INH* isoniazid, *ETT* endotracheal tube

Table 276.5
Common toxidromes in pediatrics

Toxin	Symptom or sign[a]	
Anticholinergics (atropine, antidepressants [tricyclics], antihistamines)	VS	Fever, tachycardia, hypertension/cardiac arrhythmias (TCA)
	CNS	Delirium/psychosis/convulsions/coma
	Eye	Mydriasis
	Skin	Flushed, hot dry skin
Amphetamines/cocaine	VS	Fever, tachycardia, hypertension
	CNS	Hyperactive to delirious and tremor, myoclonus, psychosis, convulsions
	Eye	Mydriasis
	Skin	Sweaty
Narcotics/clonidine	VS	Bradycardia, bradypnea, hypotension, hypothermia
	CNS	Euphoria to coma, hyporeflexia
	Eye	Pinpoint pupils
Organophosphates (and muscarinic mushroom poisoning)	VS	Bradycardia or tachycardia, tachypnea (secondary to pulmonary manifestations)
	CNS	Confusion to drowsiness to coma, convulsions; muscle fasciculations, weakness to paralysis
	Eye	Miosis, blurry vision, lacrimation
	Skin	Sweating
	Odor	Garlic
	Misc.	Salivation; bronchorrhea, bronchospasm, and pulmonary edema; urinary frequency and diarrhea
Barbiturates, sedative-hypnotics	VS	Hypothermia, hypotension, bradypnea
	CNS	Confusion to coma, ataxia
	Eye	Nystagmus, miosis or mydriasis
	Skin	Vesicles, bullae
Salicylates	VS	Fever, hyperpnea
	CNS	Lethargy to coma
	Odor	Oil of wintergreen (with methylsalicylate)
	Misc.	Vomiting
Phenothiazines	VS	Postural hypotension, hypothermia, tachycardia, tachypnea
	CNS	Lethargy to coma, tremor, convulsions
	EPS	Ataxia, torticollis, back arching, oculogyric crisis, trismus, tongue protrusion or heaviness
	Eye	Miosis (majority of cases)
Theophylline	VS	Tachycardia, hypotension, cardiac arrhythmias, tachypnea
	CNS	Agitation, convulsions
	Misc.	Vomiting

Adapted from Mofenson HC, Greensher J (1974) The unknown poison. Pediatrics 54:336–342. With permission.
[a] VS vital signs, CNS central nervous system, EPS extrapyramidal symptoms

Plants

The poinsettia (*Euphorbia pulcherrima*) has an undeserved reputation as being a toxic plant and infrequently causes symptoms after ingestion. Plants that contain calcium oxalates (such as dumbcane and philodendrons) can cause local irritation, edema, and pain. However, systemic symptoms are unusual. Treatment for oxalate-plant ingestions involves symptomatic are, usually cool liquids or an ice pop.

Plants that are considered toxic include: aconite, cantharidin, castor bean, clove oil, comfrey, fox glove, Na Hwang, certain mushrooms, nutmeg, oleander, and pennyroyal oil.

As a follow-up, health care providers should seek reasons for the ingestion to reduce the risk of recurrence. Attention should be given to family stressors, e.g., ill health, including psychiatric disturbances, marital discontent and separation, spousal abuse, unemployment, or other financial burdens since social determinants influence those at risk for exposure or poisoning.

277 Iron

Nicole Gebran

A common toxicological emergency in young children is iron poisoning. Signs of iron toxicity can be apparent in children with ingestions of 10–20 mg/kg of elemental iron. Serious toxicity is likely with ingestions of more than 60 mg/kg.

Accordingly, it is important to calculate the elemental content of iron supplements in order to estimate total exposure. Common forms of iron that can be ingested by children include the following percentages of elemental iron: ferrous sulfate (20%), ferrous fumarate (33%), and ferrous gluconate (12%). Children's multivitamins with iron preparations contain 8–18 mg of elemental iron per chewable tablet. A common iron-containing medication is a prenatal vitamin, which has 325-mg ferrous sulfate (65 mg elemental iron) per tablet.

Iron exerts both local and systemic effects and is corrosive to the GI mucosa and can affect the heart, lungs, and liver. The potential severity of iron poisoning is based on the amount of elemental iron ingested. Excess free iron is a mitochondrial toxin that leads to derangements in energy metabolism.

Contributing factors to iron poisoning include the availability of iron tablets and the candy-like appearance of multivitamin tablets. Because perinatal iron therapy is common, the presence of these tablets at home may pose a hazard to a mother's other young children.

Most iron toxicity exposures involve children younger than 6 years who have ingested pediatric multivitamin preparations. Many of the serious acute ingestions occur in children younger than 3 years. A report from the American Association of Poison Control Centers indicates that iron supplements were the single most frequent cause of pediatric unintentional ingestion fatalities, accounting for 30.2% of reported pediatric pharmaceutical unintentional ingestion fatalities over an 8-year period (1984–1992). Antidepressants, cardiovascular medications, and methyl salicylate follow in frequency of pediatric pharmaceutical deaths.

Much of the pathophysiology of iron poisoning is a result of metabolic acidosis and its effect on multiple organ systems. Toxicity manifests as local and systemic effects. Typically, iron poisoning is described in five sequential phases as discussed under clinical manifestations below. Patients may not always demonstrate all of the phases making it difficult for researchers to reach a consensus regarding the number of phases and the time of onset and duration assigned to those phases.

The absorption of iron is normally very tightly controlled by the GI system. However, in overdose, local damage to the GI mucosa allows unregulated absorption, which leads to potentially toxic serum levels.

Clinical and Laboratory Manifestations

Minor findings of iron toxicity include vomiting, diarrhea, and mild lethargy. Major clinical findings include stupor, shock, acidosis, hematemesis, bloody diarrhea, or coma. Leukocytosis and hyperglycemia may be observed but are not typical of acute iron poisoning. The clinical course includes the following phases relative to time post iron ingestion:

Phase I (0.5–6 h): Vomiting, hematemesis, abdominal pain, diarrhea, hematochezia, lethargy, shock, acidosis, and coagulopathy. Necrosis to the gastrointestinal (GI) tract occurs from the direct effect of iron on GI mucosa. Large losses of fluid and blood contribute to shock. Free iron and ferritin produce vasodilation that may also contribute to shock.

Phase II (6–12 h): Apparent recovery that may contribute to a false sense of security. At this stage, the child should be observed very closely.

Phase III (12–24 h): Profound shock, severe acidosis, cyanosis, and fever.

Phase IV (2–3 days): Possible hepatotoxicity and lung injury due to direct action of iron on the mitochondria. Liver function tests and bilirubin should be monitored.

Phase V (2–6 weeks): GI scarring and strictures leading to gastrointestinal obstruction. This should be evaluated with barium studies.

Sustained-release preparations have resulted in small intestinal necrosis with resultant scarring and obstruction. The phases of iron poisoning may not occur in all patients. After massive overdose, patients may present in shock. With less serious overdoses, the initial gastrointestinal symptoms may be the only findings to develop even without treatment.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_277,

Management

Iron toxicity is a clinical diagnosis and any studies are simply adjuncts. Toxic effects of iron may occur at doses of 10–20 mg/kg of elemental iron. Little is known about the absorption rate of iron in an overdose, the timing of peak serum iron levels, or the rate at which serum levels fall from their peak levels. Serum iron levels generally correlate with clinical severity: mild toxicity (level <300 μg/dL), moderate toxicity (level=300–500 μg/dL), and severe toxicity (level> 500 μg/dL).

There are several difficulties involved with the interpretation of serum iron levels. Serum iron levels may not be available in a timely fashion. The ideal serum iron level is a peak level at 2–6 h postingestion, and the time from ingestion is often unknown. Moreover, deferoxamine interferes with standard assays and leads to falsely decreased iron levels. Serum levels obtained more than 8–12 h postingestion may not be useful because iron redistributes into the tissues and the serum level does not reflect the total body burden of iron.

Total iron-binding capacity (TIBC) has traditionally been used to determine toxicity. Previously, a patient with a serum iron level greater than the TIBC was thought to be at risk for developing systemic toxicity. However, determining the TIBC in the presence of large amounts of iron or deferoxamine may yield a falsely elevated number. Hence, a TIBC above the iron level does not indicate sufficient binding capacity, and this test is not useful in determining the likelihood of toxicity.

Because iron levels are not always readily available, the predictive value of other laboratory test results has been explored. Previously, a WBC count greater than 15,000/μL and a serum glucose level greater than 150 mg/dL were said to correlate with iron levels greater than 300 μg/dL. However, more recent studies do not support the predictive value of these ancillary tests, and they are not useful in the setting of iron poisoning.

Abdominal radiography may offer information on the iron ingestion, both initially and subsequent to GI decontamination. However, treatment should not be delayed for radiography. A positive radiographic finding is one that shows radiopaque tablets or particles. This indicates that the ingested iron has not been completely absorbed.

An initial negative radiographic finding may mean that no iron was ingested or that the ingested iron tablets or solution have dissolved. In addition, liquid preparation and chewable vitamins are not visible on radiographs.

Obtaining a radiograph before GI decontamination and after GI decontamination may yield information as to the success of therapy. If the radiographic findings remain positive after decontamination, additional decontamination is required or endoscopy/surgery is needed for iron tablet removal to avoid gastric perforation and severe hemorrhage. If the radiographic findings were initially positive and are negative after GI decontamination, this indicates that GI decontamination was successful, although iron levels should still be monitored because of iron absorption prior to initiation of therapy.

The deferoxamine challenge test consists of administering a single dose of deferoxamine that binds available free iron and is excreted in the urine as the ferrioxamine complex (deferoxamine and iron) which changes the urine color to reddish (vin rosé), indicating the need for chelation. However, this test is not reliable because the urine does not change color reliably even when elevated serum iron levels are present. It does not alleviate the need for monitoring serum iron levels. Therefore, one should not rely on the deferoxamine challenge test.

In treatment of iron poisoning, consider both bowel decontamination with whole bowel irrigation and chelation using intravenous administration of deferoxamine. Although iron poisoning is a clinical diagnosis, serum iron levels are useful in predicting the clinical course of the patient.

The first step in treating a case of acute iron toxicity is to provide appropriate supportive care, with particular attention paid to fluid balance and cardiovascular stabilization. Initial treatment should also address the issue of preventing further absorption of iron by the GI tract.

Ipecac-induced emesis is not recommended especially with iron ingestion. As GI distress is an early finding in iron poisoning and is present in all potentially serious ingestions, Ipecac-induced vomiting may cloud the clinical picture.

Gastric lavage is of unlikely benefit and is not recommended because iron tablets are relatively large and become sticky in gastric fluid.

Whole bowel irrigation has been used to speed the passage of undissolved iron tablets through the GI tract. It is most effective if the ingestion occurred more than 1–2 h previously and in patients with radiographic evidence of multiple pills beyond the pylorus. A polyethylene glycol electrolyte solution (e.g., GoLYTELY) may be administered orally or nasogastrically at a rate of 250–500 mL/h for children 9 months to 6 years of age, 1 L/h for children 6–12 years of age, and 2 L/h for adolescents. Continue irrigation until the repeat radiographic findings are negative or rectal effluent is clear.

Deferoxamine is the chelating agent of choice which binds absorbed iron, forming an iron–deferoxamine

complex that is excreted in the urine. It does not bind iron in hemoglobin, myoglobin, or other iron-carrying proteins. Indications for using deferoxamine should be based on both clinical and laboratory parameters. These include shock, altered mental status, persistent GI symptoms, metabolic acidosis, pills visible on radiographs, serum iron level greater than 500 μg/dL, or estimated dose greater than 60 mg/kg of elemental iron. Chelation should be initiated if a serum iron level is not available and symptoms are present. The administration of deferoxamine may be intramuscular or intravenous. The intramuscular route is not recommended because it is painful and less iron is excreted compared with the intravenous route. The intravenous route is administered as a continuous infusion. The standard dose is 15 mg/kg/h, with an initial dose administered for 6 h. No clear end point of therapy is noted; however, indications for cessation include significant resolution of shock and acidosis. Deferoxamine, administered 6–12 h, has been suggested for moderate toxicity. For severe toxicity, 24 h of administration have been suggested. Because these end points are arbitrary, the patient should be observed for the recurrence of toxicity 2–3 h after the deferoxamine has been stopped. Adverse effects from deferoxamine include pulmonary symptoms (i.e., acute respiratory distress syndrome, tachypnea), especially in patients treated for more than 24 h. Rate-related hypotension may also occur. Therefore, patient monitoring is needed while titrating the infusion rate upward to a final rate of 15 mg/kg/h. *Experimentally*, deferoxamine and activated charcoal given as an oral slurry have reduced the GI absorption of ferrous sulfate in a small number of healthy volunteers. Animal data did not support this finding, but oral deferoxamine was found to increase the rate of iron excretion from the body, which could be enhanced by the coadministration of sodium bicarbonate. Oral deferoxamine has not been studied for the treatment of acute iron poisoning, and its routine clinical use is not recommended at this time.

Supportive treatment may include intravenous crystalloid fluids to treat shock, as well as dopamine and norepinephrine if the hypotension persists. Blood component therapy may be needed for those patients with blood loss. Exchange transfusion is sometimes considered in young patients who worsen despite deferoxamine therapy although its effectiveness is questionable.

Patients may be discharged home from the emergency department after 4–6 h of observation if they are asymptomatic, have serum iron levels less than 300–500 mcg/dl, and have a negative abdominal X-ray. Mortality is low in iron poisoning patients if they do not have shock or coma. With supportive treatment of patients with shock or coma, the mortality rate is about 50%. If deferoxamine treatment is added, the mortality rate drops to 10%. For cases of intentional ingestion, a psychiatric evaluation may be warranted.

Pregnancy is a major risk factor for iron poisoning in young children, and the period immediately after delivery is associated with the greatest risk. Almost half of all hospital admissions for iron poisoning in young children could be prevented by keeping iron supplements safely out of reach in the year before and after the birth of a sibling.

278 Salicylates

Nada S. Al-Qadheeb

Salicylates are common ingredients in a variety of prescription and nonprescription preparations. The most common is aspirin (acetylsalicylic acid) which is available as an over-the-counter medication in almost all households. Despite major reductions in recent years in acute childhood salicylate poisonings due to the reliance on alternative analgesics and the use of child-resistant containers, salicylates are still an important cause of accidental childhood and intentional adolescent poisoning.

Salicylate toxicity has multiple cellular and systemic effects that define its clinical presentations during intoxication. Initially, it stimulates the respiratory center and causes hyperventilation leading to respiratory alkalosis. As a compensatory mechanism, renal excretion of bicarbonate, sodium, and potassium is increased resulting in metabolic acidosis. In addition, salicylates directly interfere with aerobic metabolism via uncoupling of oxidative phosphorylation; consequently, anaerobic metabolism is increased and lactic acid accumulates. Salicylates also inhibit key dehydrogenase enzymes within the Krebs cycle, resulting in increased levels of pyruvate and lactate. Glycolysis, gluconeogensis, and protein and lipid catabolism occur eventually leading to the accumulation of ketone bodies and amino acids and an increased anion gap.

Other clinical features that may occur include hyperpyrexia and CNS toxicity (e.g., agitation, confusion, restlessness, and coma).

Clinical and Laboratory Manifestations

Children may be at greater risk of toxicity due to decreased hepatic metabolism and/or renal elimination with enhanced distribution to organs including brain, kidney, and liver. Children are also more likely to lose their natural respiratory drive (hyperventilation and respiratory alkalosis may be minimal); therefore, they are more likely to present with metabolic acidosis and are more susceptible to CNS toxicity. The type of salicylate intoxication may be acute, chronic, or acute-on-chronic. Chronic and acute-on-chronic toxicity are uncommon in children, since aspirin is rarely used on a daily basis in children.

The clinical manifestations of salicylate ingestion are dependent, to some extent, upon the ingested dose. Acute ingestion of less than 300 mg/kg (serum concentration $<$50 mg/dL) is associated with mild symptoms manifested by gastrointestinal upset, tinnitus, and mild tachypnea; ingestions of 300–500 mg/kg (serum concentration 50–100 mg/dL) are associated with moderate toxicity with fever, diaphoresis, and agitation; and ingestions of $>$500 mg (serum concentration $>$100 mg/dL) are associated with consistent coma and death. Death typically results from severe CNS toxicity with complete loss of function of the cardiorespiratory centers.

Management

Optimal management of salicylate poisoning depends on whether the exposure is acute or chronic. Gastric lavage and activated charcoal (1 g/kg) are useful for acute ingestion but not in cases of chronic salicylism. The use of multidose activated charcoal to enhance elimination is controversial. Specific therapeutic goals should include fluid and electrolyte correction plus enhancement of salicylate excretion. Generally a large volume of fluid must be given, such as 10–15 mL/kg/h for the first 1–2 h. Subsequent hydration with 4–8 mL/kg/h should be maintained until the salicylate level is therapeutic. For patients with serum salicylate concentrations greater than 50 mg/dL and severe metabolic acidosis, IV bicarbonate may be needed. The rationale for alkalinization is to increase urinary pH, ionize filtered aspirin, and inhibit its tubular reabsorption. Raising urinary pH from 6.1 to 8.1 results in 18-folds increase in renal excretion by preventing nonionic tubular back-diffusion. This decreases the half-life from 20 to 8 h. The initial fluid should contain 5% dextrose with 50–100 mEq/L of sodium bicarbonate.

Care must be taken to avoid hypokalemia, which prevents excretion of alkaline urine by promoting distal tubular potassium reabsorption in exchange for hydrogen ion. Urinary alkalinization must be used with caution in the presence of alkalemia due to salicylate-induced hyperventilation. Forced diuresis does not appear to increase the efficacy of urinary alkalinization. Repetitive determination of

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_278,

plasma salicylate levels should be obtained to confirm a declining level. Hemodialysis should be reserved for serious salicylate intoxication where the plasma level is >120 mg/dL acutely, or >100 mg/dL 6 h postingestion, refractory acidosis, coma or seizures, noncardiogenic pulmonary edema, volume overload, and renal failure.

279 Self-Poisoning

James Krebs

Suicide is the second most common cause of death, worldwide, in the 15–24 year-old age group. In the USA, the overall suicide rate for the 5–14 year-old age group is approximately 0.7 per 100,000 population, while the 5–14 year-old age group is approximately 10 per 100,000 population accounting for over 4,450 deaths per year. In European countries, the rate is similar or slightly higher. Suicide rates and suicide attempts have increased by 60% worldwide in the last 45 years. Rates among young people have been increasing to such an extent that they are now the group at the highest risk in a third of the countries, in both the developed and developing countries. Attempts are up to 20 times more frequent than completed suicide. While young women have higher rates of suicide attempts, young men complete suicide approximately four times greater than young women. The most common means of suicide are firearms, poisoning, and hanging.

Management of the patient who had attempted suicide by poisoning involves treating the acute manifestations of the ingestion, as well as an assessment of risk factors for suicide and a psychiatric evaluation. Follow-up to prevent future attempts is also very important.

Assessment of Risk Factors

Suicide is complex with psychological, social, biological, cultural, and environmental factors involved. Mental disorders (particularly depression and alcohol use disorders) are a major risk factor for suicide in Europe and North America; however in Asian countries impulsiveness plays an important role.

The following lists a variety of risk factors associated with suicide attempts. The presence of more than one risk factor in a child increases the overall risk for suicide. The strongest predictor is a psychiatric disorder. Approximately 80% of adolescent suicide attempters have a diagnosable psychiatric illness, with depression being the most common. Substance abuse plays a significant role in suicide and suicide attempts in adolescence. The increase in substance abuse among adolescents may be associated with the increase in adolescent suicide rates. Risk factors unique to the adolescent population include a history of child abuse and exposure to the suicidal behavior of others.

Risk factors for attempted suicide

- Presence of psychiatric illness (e.g., depression, personality disorder)
- History of suicide attempt
- Substance and alcohol abuse
- Interpersonal loss (e.g., breakup of a romantic relationship, death of someone close)
- History of parent-child conflict
- History of physical or sexual abuse
- Exposure to suicidal behavior of others
- Social isolation (e.g., period of absence from school, frequent moves)
- Presence of chronic illness (e.g., acquired immunodeficiency disorder, anorexia nervosa, seizure disorder)
- Family history of suicide
- Impulsive behavior

When a patient presents to the ED after an intentional self-poisoning ingestion, the actual risk of suicide must be assessed. Several direct questions must be asked, with the most important information to determine being intent and method. Questions include:

Have you thought about death or killing yourself?
Have you thought about how you would kill yourself?
Do you have the means available (e.g., gun, pills)?
How close have you come to carrying out this plan?
Do you tend to be impulsive?
What stops you from killing yourself?

From the patient who presents to the ED after an intentional ingestion, some of these questions will already have been answered.

Press and Khan proposed a model to obtain this information from a psychiatric examination based on the four basic components of a physical examination: observation (of the patients body language and level of distress), auscultation (listening), palpation (basic questions), and percussion (deeper understanding/questioning). To facilitate information gathering, they recommend the use of the mnemonic MALPRACTICE (*Table 279.1*). The risk

Table 279.1
MALPRACTICE mnemonic for psychiatric examination of suicidal patients

*M*ental health	Does the patient have a psychiatric disorder? A family history of mental illness?
*A*ttempts	Has the patient attempted suicide before? When?
*L*ethality	Does the patient have access to lethal means of self-harm? Did the patient want to die?
*P*lans	Is the patient able to make plans for the future (e.g., school, marriage, job)?
*R*isk-taking behavior	Is the patient engaged in risk-taking behavior?
*A*lcohol and drugs	What substances are being used?
Conflict	Was there an interpersonal conflict in the family?
*T*rauma	Is there a history of physical or sexual abuse?
*I*mpulsivity	How much planning went into the suicide attempt? Did the patient tell anybody about the attempt?
Community resources	Is there a social support system for the patient (family, friends)?
*E*xposure	Is there a history of attempted or completed suicide by family of friends? Has the patient recently been exposed to suicide on television or in the news?

level of the patient – high risk, with a genuine intent to die, a definite plan, and access to lethal means, versus low risk, with no definite plan and limited access to lethal means – will play an important part in further management and disposition of the patient. Since children as young as 5–14 years of age may attempt suicide, the ED physician should not hesitate to raise the topic of suicide and discuss it with a child of any age who may be at risk.

Management

The emergency department treatment of the suicidal patient consists of five main objectives: (1) protect the patient from further self-harm until the suicidal feelings have passed, (2) treat any medical complications of the ingestion, (3) identify the acute problem that precipitated the suicide attempt, (4) diagnose and treat any underlying psychiatric disorder predisposing the patient to suicidal behavior, and (5) deal with the acute reactions of family members to the suicide attempt.

Patient Protection and Medical Treatment

While in the ED, suicidal patients should be under some form of constant observation. All potentially lethal objects (e.g., scissors, needles, medications, and weapons) should be removed from the patient's immediate area. Physical and/or chemical restraints should be used only for patients who cannot be relied on not to hurt themselves further.

The treatment of any medical complications of an intentional ingestion is best done in the ED before deciding on the disposition of the patient.

Diagnosis and Treatment of Underlying Psychiatric Disorder

All suicidal patients should be considered to have an underlying psychiatric illness until proven otherwise. After a thorough assessment, the ED physician should be able to make a preliminary psychiatric diagnosis. The issue of whether, and when, to have a psychiatrist involved in the ED management of suicidal patients is controversial. Some studies have found that assessments made by ED physicians are not as complete or as well documented as assessments made by a psychiatrist. However, other studies have shown that the outcomes of patients evaluated by ED physicians or a general medical team are the same as those of patients referred to a psychiatrist. The rates of repeated self-poisoning or suicide were the same whether patients were referred to a psychiatrist or not.

In most patients, drug therapy for any psychiatric disorder should not be started in the ED. The acutely psychotic patient is an exception. Most psychotropic drugs used for chronic treatment require close follow-up by a physician when initiating therapy and also have a delayed onset of action (weeks, not hours or days). If the ED physician must prescribe medication for a patient being discharged, a drug that is nonlethal in an overdose should be selected and the smallest possible quantity prescribed (no more than 1 week's worth of medication).

For patients with depression, traditional therapy consisted of a tricyclic antidepressant (e.g., amitriptyline, imipramine) or a monoamine oxidase inhibitor (e.g., phenelzine). However, these drugs have many side effects and can be lethal in overdose. The new antidepressants, such as SSRIs (e.g., fluoxetine, paroxetine, sertraline),

nefazodone, and venalfaxine, are much safer when taken in overdose. These agents have been recommended as the treatment of choice in depressed, suicidal adolescent patients. Caution must still be used with these newer drugs due to the risk of converting the depression into a manic episode. Also, conflicting data exists about the effects of SSRIs on suicidal ideation. Case reports have described patients on fluoxetine who developed intense suicidal thoughts. On the other hand, some studies suggested that SSRIs might produce a more rapid improvement in suicidal ideation compared to other antidepressants.

A final factor to consider when initiating antidepressant therapy is the risk of suicide once the patient begins to come out of the depression. When a patient is severely depressed, he or she may not have the energy to carry out suicidal thoughts. However, when the patient starts to improve, he or she may gain the energy and drive to act on these ideations. This will often include taking an overdose of the medication that was prescribed to treat the depression.

Patient Disposition

Once the patient has been stabilized in the ED and an initial psychiatric evaluation has been completed, the disposition of the patient must be determined. Does the patient need to be admitted to the hospital, or can he or she be discharged with follow-up as an outpatient? If the patient needs further management of complications of the acute ingestion, then admission to the appropriate hospital service (e.g., general medicine or intensive care unit) is required.

Criteria that must be met before a patient can be discharged home from the ED include:

1. The patient must be medically stable and no longer suicidal.
2. The patient and caregivers must agree to the discharge plan, and to return to the ED if the suicidal feelings return.
3. The patient must not be intoxicated, delirious, or psychotic.
4. Potentially lethal means of self-harm must be removed from the patient's home.
5. The problem that precipitated the suicide attempt must have been identified and addressed.
6. Treatment for any psychiatric illness must be arranged.

If these criteria are not met, the patient must remain in the ED until all issues are resolved, or he or she must be admitted to a hospital (specialized psychiatric facility, if available). Patients discharged from the ED should have a relatively early follow-up (within days) with either their primary care physician or a psychiatrist.

Injury Prevention Education

Recent research concluded that the majority of the caregivers of adolescent suicide attempters (86%) did not receive injury prevention education in the ED. The caregivers who did receive injury prevention education were more likely to take action to limit access to means of suicide (e.g., locking up or disposing of medications). Another study reviewing all cases of pediatric injuries presenting to the ED found that the most common type of injury where injury prevention education was indicated was poisoning.

Suicide can be prevented by ensuring that young people have access to life skills training, promoting positive parental involvement in the lives of the young people, reducing the use of alcohol by young people, and reducing their access to lethal means (including firearms, knives, pesticides, medications). ED staff are in a good position to provide injury prevention education. At the time of a self-poisoning ingestion, the child and caregivers may be most receptive to this information and most likely to comply with the recommendations. This type of information may help to reduce the risk of future suicide attempts.

Conclusion

Self-poisoning is one of the most common means of attempted and completed suicide among children and adolescents. The management of those patients would include a thorough assessment of suicide risk factors and psychiatric evaluation to define any underlying mental illness. Whether the patient needs to be admitted to a hospital or referred for outpatient follow-up must also be determined. Providing injury prevention education in the ED may decrease the risk of future suicide attempts.

280 Snakebites and Spider Bites

Roaa Al Gain

Snakebites

Venomous animal bites cause considerable rate of morbidity and mortality among pediatrics. Those caused by reptiles as snakes could be the commonest. It was estimated that at least 421,000 envenomations and 20,000 deaths occur worldwide from snakebite annually. These figures may be as high as 1,841,000 enovenomations and 94,000 deaths annually with incidence of 6.28–27.5/100,000 person per year. India reported highest snakebites envenomation and death rate. Epidemiologic study conducted in 2007 estimated an average of two million snakebites per year in India, resulting in 35,000–50,000 deaths. In 2009, the American National Drug and Poison Center (NDPC) reported 3,361 snakebites in USA; 40% caused by copperhead snake and about 37% due to rattlesnake envenomation. Children 12 years or younger represents 12% of the total snakebites. According to the NDPC report, snakebites were associated with the highest death rate among other animal bites and envenomation; three out of five cases were due to rattlesnake. The report includes 789 envenomations in children who were younger than 19 years. Generally, children have been estimated to represent more than 20% of rattlesnake envenomation, but poison centers data suggests over 50% of all reported cases may involve pediatric patients in USA. In contrast, European countries has lower incidence of venomous bites compared to tropical parts of the world. In 2001, the annual incidence of snakebites estimated to be around 15,000–20,000 cases, resulting in about 50 deaths per year. In the Middle East, snakes are responsible for most bites and tend to be more venomous than European species, but deaths are rare with some estimating 100 fatal bites annually. In Australia, the majority of snake species are venomous. Death from snakebite is rare in Australia. This is because of wide availability and access to antivenoms.

Overall, snakebites peak in summer season. Agricultural and tropical regions report more snakebites than other regions. Male children are more likely than female children to be bitten by snake. Snakebite envenomation can be "dry" nonvenomous or "wet" venomous. Severity of snakebite envenomation varies among taxonomic species, which differ by the geographical region (see *Table 280.1*). The harm of venomous snake depends on the venom amount, venom type, bitten site, species and size of the snake, victim bodyweight, and individual sensitivity to the venom. Several studies showed that systemic envenomation in children are more apparent due to their smaller body mass. Consequently, children are at higher risk of death or permanent disability from snakebite envenoming.

Snake venom is a mixture of enzymes (e.g., hyaluronidase), metallic ions, lipids, carbohydrates, amino acids, active proteins, and peptides. The mechanism venom exerts its effect varies based on its components. Venom can result in direct injury of vascular endothelial cells, which increases permeability to plasma and erythrocytes into the extravascular space. Increased intracellular calcium in skeletal muscle may occur and result in prolonged contraction and necrosis. Hemolysis may occur as a result of increased permeability of erythrocyte membranes. Histamine is released if mast cell membrane is damaged. Fibrinolysis and thrombin-like peptide actions result in coagulopathy. Thrombocytopenia can result from platelet aggregation at sites of tissue injury or by direct venom effect on platelets.

Accordingly, each venom produces its clinical effect which can help in snake identification. Snake venoms are classified as either hemotoxin, that is, venom causes coagulopathy; neurotoxin, that is, venom causes weakness and muscle paralysis; or/and cardiotoxin, that is, venom causes circulatory failure and shock.

Clinical manifestations range from local reactions as pain, edema, erythema, to systemic manifestation of various degree of severity. Systemic symptoms may occur immediately after bite or delayed for a few hours. Petechia or ecchymosis may occur as early sign of coagulopathy. The venom may distribute through the lymphatic system and cause lymphangitis. Gastrointestinal signs and symptoms as vomiting, abdominal pain, and diarrhea are commonly encountered. Hypotension and tachycardia are other manifestations that occur especially after direct intravenous envenomations. Neurologic signs as ptosis, oculomotor paralyses, and dysphagia may occur especially with Mogave rattlesnake. Although fatality is very rare,

Table 280.1
Examples of common snakes

Snake family (common names)	Region	Comments
Acrochordidae (File snakes, wart snakes) *3 species*	South Pacific islands, Northern Australia, and Southern Asia	
Aniliidae (The Pipe Snake) *1 specie*	South America	
Atractaspididae (burrowing asps, stiletto snakes) *55 species*	Middle East, Africa	Venomous
Boidae (Boids) *70 species (include boa species and the python)*	*Subtropical and tropical regions*	*Non-venomous*
Colubridae (Colubrids) *1,800 species*	*Worldwide*	*Venomous and harmless species make up about two-thirds of the species of snakes in the world*
Elapidae (Elapids) *Over 250 species (*e.g., *Australian black snake, death adder, taipan, tiger snake cobras, mambas, and sea snakes)*	*Australia, Middle East*	*Venomous*
Loxocemidae (The Mexican Burrowing Snake) *1 specie*	*Central America and Mexico*	
Pythonidae (Pythons)	*Asia, Africa, and Australia*	
Typhlopidae (Blind Snakes)		
Uropeltidae (Shield-tailed snakes) *45 species*	*Southern India and Sri Lanka*	
Viperidae (Vipers) Pit vipers: 100 species and true vipers: ~50 species Pit vipers: North American rattlesnakes, copperheads, water moccasins True vipers: Gaboon viper, European viper	Pit vipers: North American True vipers: Asia, Middle East, Europe, and Africa	
Xenopeltidae (Sunbeam Snakes) *1 specie*	*Southeastern Asia*	
Hydrophiidae (Sea snakes) multiple species	Australia	

children have higher risk of death due to cardiovascular collapse, respiratory failure, sepsis or bleeding. Pit viper venoms produce acute local tissue damage and edema. However, subcutaneous and dermal tissue injury might occur and can reach the muscle in rare cases. Local tissue damage can lead to fluid loss and ischemia. In a multicenter study carried out in pediatric patients bitten by *Bothrops* spp, majority of them developed acute-phase reaction, characterized by increase of several serum cytokine concentrations (e.g., interleukin-6 and 8, TNF). Fasciotomy was required more often in patients with high cytokine levels. In contrast, local tissue injury is uncommon following coral snakebites. Their venom tends to inhibit acetylcholine receptors at the neuronal synapse and causes paresthesias and paralysis.

If the venom is sprayed into the eye, painful conjunctivitis and corneal ulceration may occur and in rare cases vision loss happen.

Renal failure and rhabdomyolysis may occur. Acute renal failure complicated about 30% of 100 cases followed in Brazil bitten by rattlesnake. Age less than 12 years was an independent risk factor for acute renal failure. Overall, delaying antivenom administration increased the risk of acute renal failure 10 times. Renal failure is commonly reported in victims of Russell's viper, hump-nosed viper, and sea snakebites. Severity of snakebite symptoms can be

graded into mild, moderate, and severe. The Snakebite Severity Score (SSS) is a validated and objective scale to assess severity of envenomation including six body categories: local wound, pulmonary, cardiovascular, gastrointestinal, hematologic, and nervous system effects. Severity can be categorized according to clinical manifestations. See *Table 280.2*.

Diagnosis can be made by physical assessment of bite site if fang marks are visible or local pain and edema. In very rare cases, fangless snakes may produce envenoming through skin or eye contact with venomous saliva.

Table 280.2
Snakebites severity grades

Grade	Severity	Signs and symptoms
0	*Absent*	Nonenvenomation, i.e., dry bite puncture wounds only; no systemic effect; no laboratory evidence of coagulation abnormalities; and no clinical evidence of abnormal bleeding
1–2	*Mild*	Swelling, pain, and ecchymosis limited to the immediate bite site; no systemic effect; coagulation parameters normal with no clinical evidence of bleeding
2	*Moderate*	Swelling, pain, and ecchymosis involving less than a full extremity or, if bite was sustained on the trunk, head, or neck, extending <50 cm; systemic signs and symptoms may be present but not life threatening, including but not limited to nausea, vomiting, oral paresthesia, or unusual tastes, mild hypotension (systolic blood pressure <90 mmHg), mild tachycardia (heart rate <150), and tachypnea; coagulation parameters may be abnormal, but no clinical evidence of bleeding present. Minor hematuria, gum bleeding, and nosebleeds are allowed if they are not considered severe in the clinical judgment
3	*Severe*	Swelling, pain, and ecchymosis involving more than an entire extremity or threatening the airway; systemic signs and symptoms are markedly abnormal, including severe alteration of mental status, severe hypotension, severe tachycardia, tachypnea, or respiratory insufficiency; coagulation parameters are abnormal, with serious bleeding or severe threat of bleeding

Source: Protherics Inc. 2008 (Modified)

Diagnosis can be confirmed if the snake is known or caught. In children, this might be challenging as most bites occur when children are left unattended. The venom identification (detection) kit can be used if available as in Australia.

First Aid Management

The ultimate goal is transporting the victim to nearest medical facility to initiate appropriate management. The national/private poison control centers, hospital drug information centers, herpetologists, and zoo personnel are vital source of information for identification, first aid management following snakebite envenomation.

Using traditional treatment, electrical shock, oral suction of venom, mechanical extractors, wound excision or incisions are strongly discouraged due to lack of evidence. Generally, victim shall remain still, immobilize the bitten area, keep affected limb at or below the heart level until transferred.

Pressure Immobilization

Pressure immobilization is recommended for neurotoxic snakebites (e.g., Australian elapids) or if delay in transportation is expected; however, it should not be employed in case of local necrotic snakebite (e.g., cobra, viper). Tight tourniquets might be harmful and can potentiate the local effect of necrotic venom and should be avoided. Applying appropriate pressure is crucial; if suitable, affected limb should be immobilized using splint with an average pressure of 50–70 mmHg or pressure pad applied on the bitten site. The efficacy of pressure immobilization has not been well established.

Wound Care

The need for cleansing snakebite wounds is not recommended outside medical facility with the exception of eye injuries. If the venom is sprayed on the eyes (e.g., spitting cobra), the eyes should be irrigated thoroughly with water. Unskilled cleansing at the bite site may worsen the tissue damage and introduce risk of secondary infection. Cleansing bite site should be carried with strict aseptic techniques. No evidence supports immersion of the bitten limb to slow envenomation or the use of cold water versus hot water. The venom presents on the bitten site can be used to identify the snake type if venom detection kit is available.

Snake Identification

Although identification of the offending snake is crucial, most of the reported children snakebite envenomations failed to identify the snake type. Snakebite in children occurs usually in unattended children, or during sleeping. Another way to identify the snake is through the characteristic envenomation features of the different snake type. In 2009, the WHO developed a database (http://apps.who.int/bloodproducts/snakeantivenoms/database/) to assess in identifying snakes among the different geographical regions, appropriate antivenom, access to antivenom, and poison control centers. The database is a great tool for all emergency personnel; it can be searched using the snake common name, family, or specie; region or location; or antivenom products.

Medical Management

At initial presentations all victims should be stabilized; maintaining airway, breathing, and circulation. Initial hospitalization should be considered for all children. For cases which require no medical management, observation shall be continued for minimum of 8 h and up to 24 h before discharge. This is important if Mojave rattlesnake bite is expected as it might be associated with delayed onset of significant neurotoxicity. Symptomatic management is indicated for the correction of hypovolemia and shock, allergic or anaphylactoid reactions, pulmonary edema, renal insufficiency, and hematologic/coagulation disorders. In cases of severe neurotoxic envenoming (e.g., respiratory paralysis), mechanical ventilation is warranted. Dialysis may be required if complications such as acute renal failure and rhabdomyolysis occur. Analgesics such as narcotics are indicated to control pain. Masking the venom neurotoxic effect should be considered when opioids are used for pain control. All pediatrics should be considered for tetanus prophylaxis if immunization history is unclear or incomplete. Doses and regimen shall follow the local or international guidelines (e.g., CDC).

Snake Antivenom

Antivenom binds and neutralizes the toxic venom and systemic effect will be ameliorated. The antivenom–venom complex will be eliminated thereafter in the urine. In children, there is limited clinical data describing the use of different snake antivenoms including FabAV approved by United States Food and Drug Administration (US-FDA). The majority of data stem from case reports and retrospective reviews of hospital data. The data showing efficacy of antivenom in pediatrics reported is available for all age groups including neonates. The first case of neonate treated successfully with polyvalent snake antivenom was reported in India, 2009. General limitations to antivenoms are the following: Hypersensitivity to papain or papayas is a contraindication; high cost; ineffective for fasciculations; potential for immediate or delayed hypersensitivity reactions; recurrence of local tissue swelling or hematologic abnormalities after treatment; coagulopathy may be refractory to antivenom treatment. Historically, the utility of antivenoms was limited by the frequency of significant reactions. In the literature, hypersensitivity reactions were reported in about 25–50% of patients given the unpurified products (mainly equine) and more than 50% developed serum sickness. This incidence reduced to 5% with the highly purified antivenom preparations development. Despite this, care should be taken especially with pediatric patients.

Antivenom is recommended to be used in the presence of signs of systemic and/or severe local envenoming and only in patients in whom the benefits of treatment are considered to exceed the risks of antivenom reactions (see *Table 280.2*). Generally, plasma venom concentration reaches a peak between 30 min and 4 h after the bite (half-life is $\sim$ 8 h). Antivenom administration within 4–6 h is preferable to control local symptoms and coagulation abnormalities.

Antivenom Regimen

Snakes inject the same dose of venom into children and adults; therefore, children must receive the same dose of antivenom as adults. It is recommended to use the molar dose of venom protein not based on the weight or age of the victim. Some might argue with this because the delivered venom amount to the body size is higher in infants and children than in adults. Although randomized clinical trials are not available to support this recommendation, majority of the retrospective studies and case reports used adult doses for pediatric patients regardless of their bodyweight. Another important factor is the similarity between the pharmacokinetics of venom–antivenom complex in both children and adults. The amount of antivenom administered corresponds on the severity of the envenomation. For specific dosing, the product information of each antivenom or local guideline shall be consulted.

Generally, antivenom shall be prepared and diluted in appropriate fluid (usually sodium chloride) and administered intravenously at slow rate to minimize risk of

infusion reactions. Infusion rate should be gradually increased. Close monitoring for acute reaction shall continue even after the end of infusion up to 1 h. Fluid adjustment must be considered for children weighing less than 10 kg or in case of fluid restrictions. If initial antivenom dose was ineffective in controlling the symptoms, second dose must be given. Maintenance doses every 6 h for up to 18 h post envenomation are advocated especially with the new formulation which has shorter half-life than the unpurified products.

Due to recirculation of the venom or its components recurrence may happen and repeated doses may be required. Recurrence of envenomation is defined as the reoccurrence of venom effect after that abnormality had previously resolved. Recurrence may happen early after discharge. Patient should be assessed after 2–3 days. Late recurrence after 1 week of envenomation has been reported. This would be return of progression of swelling or coagulopathy or increase in pain intensity. Coagulopathy recurrence may present as return of thrombocytopenia, hypofibrinogenemia, prolongation of prothrombin time (PT), or elevation of fibrinogen. Recurrence of coagulation abnormalities has been reported in more than 50% of patients treated with CroFab™ (US-FDA approved antivenom). This is probably related to its smaller Fab molecule that has shorter half-life than IgG molecules and may allow recurrence of venom effects. In one case report, coagulopathy recurrence was accompanied with significant bleeding (IV puncture site and ginigival) in a 3-year-old patient. Bleeding was significant and resulted in profound anemia. In such cases, blood product transfusion must be considered along with repeated administration of antivenom.

Allergy Testing and Premedication

Skin/conjunctival hypersensitivity testing is not recommended as negative result does not exclude hypersensitivity antivenom reactions. Currently, no intervention has proved effective for preventing antivenom reactions, including administration of prophylactic epinephrine. In order to minimize reactions, the antivenom should be administered by intravenous infusion at slow rate. Acute allergy treatment shall be always available at bedside. Premedication with corticosteroids, epinephrine, and antihistamines has been described in several pediatric reports. Efficacy results were inconsistent and final recommendation cannot be withdrawn.

Safety concerns exist with the prophylactic use of epinephrine because of the increased rate of fatality, due to intracranial bleeding, hypertension, and arrhythmias, especially if used routinely in children, pregnant, or cardiac patients.

Antivenom Side Effects

Patient may develop serum sickness which is more common with traditional antivenoms than the purified preparations (e.g., CroFab™). Flu-like symptoms with fever, malaise, arthralgias, lymphadenopathy, rash, pruritus, and urticarial can occur 10–20 days after antivenom administration. The higher dose administered of antivenom the higher risk of side effects. Side effects are self-limited. Administration of antihistamine and corticosteroids can control the symptoms effectively.

Antivenom Availability

In March 2007, snake antivenom immunoglobulins were included in the WHO Model List of Essential Medicines, acknowledging their role in the primary health care system. Antivenoms were discovered more than 100 years ago; however, they are produced by limited number of manufacturers worldwide and their availability is scarce in some regions. Snake antivenom immunoglobulins are either monospecific (monovalent) or polyspecific (polyvalent) antivenom. Antivenom neutralizes specific snake venom; however, certain polyvalent antivenoms have cross-activity against other snake species venom. The earlier antivenom preparations developed using equine origin. More purified preparations, such as the F(ab)2 equine antivenom and ovine Fab fragments were developed thereafter. The use of the traditional antivenoms (e.g., Polyvalent Crotalidae Antivenin, made by Wyeth) was limited by the possibility of hypersensitivity reactions to the equine component. The newer F(ab)2 preparations are less immunogenic and resulted in lower incidences of hypersensitivity reactions. In 2000, the US-FDA approved Crotalidae Polyvalent Immune Fab Ovine (CroFab™) and replaced the older Antivenom Crotalidae Polyvalent (ACP) available since 1954. See *Table 280.3*.

Antibiotics Use

Prophylactic antibiotic therapy is not well supported for all snake bitten victims. Initiation of antibiotic may be considered only if clinical signs and symptoms of infection

Table 280.3
Examples of available snake antivenom

Region	Snake type	Antivenom
Costa Rica	Coral snakes	Anticoral monovalent, Anti-mipartitus antivenom
Argentina	Coral snakes	Antimicrurus
Mexico	Coral snakes	Coralmyn
Colombia	Coral snakes	Anti micruricoscorales
Brazil	Coral snakes	Soro anti-elapidico, Antielapidico
South Africa	Boomslang	SAIMR Boomslang antivenom
South Africa	Saw-scaled vipers	SAIMR echis antivenom
South Africa	Mambas, Cobras, Rinkhalses, Puff adders (small adders: *B. worthingtoni*, *B. atropos*, *B. caudalis*, *B. cornuta*, *B. heraldica*, *B. inornata*, *B. peringueyi*, *B. schneideri*, *B. xeropaga*)	SAIMR polyvalent antivenom
Brazil	Pit vipers and rattlesnakes	Soro antibotropicocrotalico
USA	North American pit vipers (all rattlesnakes, copperheads, and cottonmouths)	Polyvalent crotalid antivenin (CroFab TM)
USA	Vipera spp.	Vipera tab
India	Saw-scaled viper (*Echis carinatus)*, Russell's viper (*Daboia russelli)*, spectacled cobra (*Naja naja)*, common krait (*Bungarus caeruleus)*	Polyvalent snake antivenom
Australia	Sea snakes	Sea snake antivenom
Australia	Many Australian snakes	Polyvalent snake antivenom
Australia	Brown snakes	Brown snake antivenom
Australia	Australian copperheads, Tiger snakes, Pseudechis spp., rough-scaled snake	Tiger snake antivenom
Australia	Pseudechis spp	Black snake antivenom
Australia	Taipan	Taipan antivenom
Australia	Death adder	Death adder antivenom
Saudi Arabia (Gulf Region)	Saudi snakes: *bitis arietans, cerastes cerastes, echis carinatus, echis coloratus, naja haje, walterinnesia aegyptia* venoms	Polyvalent snake antivenom
Saudi Arabia (Gulf Region)	Arabian cobra (*naja haje arabicus*) and the black desert cobra (*walterinnesia aegyptia*).	Bivalent snake antivenom

are apparent. The most frequently isolated organisms from venomous snake oral cavity were *Staphylococcus aureus and Enterobacteriaceae.* Anaerobes also were isolated including *Clostridium* spp. Secondary infection was quite common in children after snakebite envenomation; however, early initiation of antibiotics was not effective for prevention of local infection, reduce hospitalization or morbidity.

Surgical Intervention

Another controversy is soft-tissue debridement and fasciotomy after snakebite. Data showed that early and appropriate antivenom therapy would limit the need for surgical intervention in children. Only sparse data found that infectious complications were less frequent in patients who underwent early fasciotomy in comparison with those who did not have or delayed surgical intervention. Therefore, surgical consultation is recommended. The development of clinical signs and symptoms of compartment syndrome despite limb elevation (if applicable) and administration of adequate antivenom doses should be the only rational for fasciotomy. Before fasciotomy is performed, high intra-compartmental pressure shall be confirmed by direct measurement and haemostatics are secured. Limb amputation is rarely needed in children.

Laboratory Monitoring

Laboratory tests as complete blood cell count (CBC), prothrombin time (PT), activated partial thromboplastin

time (aPTT), international normalized ration (INR), and fibrinogen shall be obtained at baseline and then repeated to assess for improvement/worsening in thrombocytopenia and coagulopathy. If initial results are normal and minimal pain and edema present, repeat the test in 2–6 h. Creatinine phosphokinase (CPK), blood urea nitrogen (BUN), creatinine, and urinalysis should be monitored if signs of rhabdomyolysis, myoglobinuria, or renal insufficiency are present. Coagulation test should be repeated 2–3 days after initiation of antivenom therapy.

Blood cultures are not indicated for all patients and may reveal negative in most cases. Tissue swapping may be needed if clinical manifestations of infection occur.

Spider Bites

Spiders belong to the phylum Arthropoda in the animal kingdom, which consists of animals with segmented bodies and jointed appendages. They are different from insects. Spiders are found commonly worldwide. There are more than 100,000 different types of spiders in the world. Most spiders are harmless. Because spiders are very small, their venom is usually too little to cause significant clinical envenomation. Only few are venomous (e.g., Tegenaria, Dysdera, Cheiracanthium, Lampona, Missulena (mouse), Loxosceles, redback (black widow), Atrax robustus (Sydney funnel web) and Hadrychone). Spider bites are frequent but morbidity and mortality is of low incidence. Human contact with spiders is usually accidental. In children, spider bites occur at night while sleeping, indoor or outdoor.

In USA, around 2,700 spider bites reported in children less than 19 years old. Majority of bites were due to black widow spider. Fatality was not reported neither in adults nor in children in 2009 NDPC report. In Europe only black widow spider reported to cause envenomations. Australian funnel back spiders are common in Australia and cause at least two envenomations annually.

Spider venom is complex mixture of protein toxins. Toxins vary between species. For example, robustoxin is the main protein toxin responsible for envenoming caused by funnel web spider. In Redback spider venom, latrotoxins is the prominent protein.

Clinical Manifestations

Most spider bites are unnoticed by victims until late manifestations occur. Some could present 2–3 days after the injury which complicate the diagnosis. Spider bites are often diagnosed by the sign and symptoms of venom toxicity or if spider bite was witnessed or caught. Spider bites are usually single lesion on limited part of the body. Spider bites are either necrotic or neurotoxic based on the involved species. Common local reactions are wheals, pustules, redness, swelling, itching, and pain. However, spider bites are not always painful. Spider bite may cause systemic effects as well. Infection may result from spider bites and it implicates the development of tissue necrosis in many cases. Certain spider bites require antivenom administration for managing systemic symptoms (e.g., bites by widow spiders (worldwide), funnel web spiders (Australia), and banana spiders (Brazil)). Rarely allergic reaction to a spider (contact rather than bite) may be developed by both venomous and nonvenomous spiders (*Table 280.5*).

First Aids

Victims should stay still with limited movement to minimize venom spread. Elevate the affected limb to minimize swelling. Bite site should be washed with soap and water. Apply cold compresses or ice to alleviate pain and minimize swelling. Transfer to medical facility is mandatory if severe envenomation present or if symptoms persist for more than 24 h or worsen.

Regular doses around the clock of antihistamine and analgesics can be given orally. Avoid aspirin, nonsteroidal anti-inflammatory analgesics. Opioids may be given in severe pain at hospital setting. Topical antihistamine can be used to minimize local reactions (i.e., itching). Corticosteroid topical preparations should be avoided; may impair wound healing. In most cases, local reactions resolve spontaneously or with the aid of home management within 10 days. Generally, spider bites heal quickly unless tissue ulcer or necrosis happens.

Traditional home remedies as applying meat tenderizer (papain) is not supported by evidence and can be harmful. Avoid tourniquets, suctions, incision of wound. Do not apply any heat to the bite site.

Medical Management

All pediatrics victims bitten with black widow spider or hobo spider (with rapidly expanding lesion or necrotic area and evidence of hemolysis) shall be admitted for observation and pain control. Transfer to intensive care unit if cardiac or respiratory complications or convulsions

occur. Supportive therapy shall be carried out based on the clinical presentation of the victim. Black widow envenomation may cause hypocalcemia which precipitate muscle spasms. It can be treated by oral or parenteral benzodiazepines. Administration of calcium gluconate did not show to be effective and is not recommended.

Use of prophylactic antibiotics has not proven to be effective for spider bites unless clear evidence of infection present. Tetanus prophylaxis should be considered for all pediatrics if immunization history is unclear or incomplete.

Spider Antivenom

Antivenom shall be considered for severe symptoms (e.g., excessive salivation, lacrimation, twitching of the tongue, respiratory distress, or persistent hypertension) that are not controlled by supportive therapy and pain control including opioids and benzodiazepines. However, antivenom may be considered earlier in young children with severe toxicity.

Wound Care

Antivenoms are usually available in areas with frequent bites (see *Table 280.4*). It is administered intravenously or intramuscularly. Treatment for acute allergic reactions shall be readily available. For dosing regimen, the product information or local guidelines shall be consulted. Generally, if only mild symptoms present start with the usual doses. Double the dose if severe symptoms are apparent.

Recirculation of venom may cause the systemic toxicity to occur again after initial response to antivenom (e.g., salivation, respiratory depression). Repeated doses of antivenom are needed. In children symptoms of fluid overload may be confused with venom-related pulmonary edema and respiratory depression. The exact cause should be ruled out before administration of additional antivenom. Diuretics may be needed in such situation.

Serum sickness (e.g., rash, fever, joint pain, malaise) may happen 4–14 days later although it is uncommon. Treatment with antihistamines and/or corticosteroid is effective. Patients discharged after severe envenomation shall be followed for possible reaction. Most spider antivenoms are associated with low rate of side effects because of the small administered volume. Routine prophylactic epinephrine use is not well established. In Canadian systematic review for funnel spider bite, all infants and children tolerated the antivenom without side effects.

Dapsone is polymorphonuclear leukocyte inhibitor, historically used to minimize wound scarring. However, dapson is not recommended due to lack of beneficial evidence and safety concerns (i.e., methemoglobinemia and hemolytic anemia in patients with G6PD). Hyperbaric oxygen showed some benefit in treating necrotic wounds following brown recluse spider bites. Its routine use is not advised. Debridement may be needed for necrotic tissues. Discharged victims are followed up with wound care for 24–48 h.

Table 280.4
Available spider antivenom

Spider antivenom	Species	Country
Funnel web spider antivenom	Sydney funnel-web spider	Australia
Soro antiaracnidico	Brazilian wandering spider	Brazil
Soro antiloxoscelico	Recluse spider	Brazil
Suero antiloxoscelico	Chilean recluse	Peru
Aracmyn	All species of Loxosceles and Latrodectus	Mexico
Redback spider antivenom	Redback spider	Australia
Black widow antivenin	Black widow spider	USA
SAIMR Spider antivenom	Button spider	South Africa
Anti Latrodectus antivenom	Black widow spider	Argentina

Laboratory Monitoring

No commercial identification test or detection kit for identifying spider venom is available. Baseline coagulation profile, renal profile, and CBC shall be obtained upon admission. Common laboratory findings include leukocytosis, albuminuria, and elevated creatine-phosphokinases (CPK). Usually progress for about 24 h and then resolve gradually during the following days, even in the absence of treatment.

Table 280.5
Medically important spider bites

Spider	Region	Features	Envenomation manifestations	Treatment
Funnel web spider (Atrax robustus)	Australia	Large fangs and acidic venom	• Intense local pain • Systemic envenomations occur early after bite: tingling around the lips, twitching of the tongue, profuse salivation, lacrimation, sweating, piloerection, and muscle twitching/spasms • Hypertension and tachycardia occur, and respiratory distress due to rapid development of pulmonary edema; may be fatal • Early symptoms resemble those of organophosphate poisoning. Convulsions may occur. Few cases of death are reported due to funnel web spider bite	Antivenom and supportive
Widow Spiders (Latrodectus spp)	North America *(Black widow spider)*, South Africa (shoe-button spiders), New Zealand (Katipo), Australia (Redback spiders), Europe (Malmignatte or Karakurt), Middle East	• Female black widow is poisonous but males are not • Most dangerous spiders in the world • 15% of bites to humans are non-envenomating • Venom releases neurotransmitters (i.e., norepinephrine, gamma-aminobutyric acid, acetylcholine) • Venom toxin causes nerve cell dysfunction, hypocalcemia, and muscle cell twitching • Venom is neurotoxic	• Victim will feel pinprick sensation and sharp pain but goes unnoticed • Forms faint red halo mark and swelling of the skin symptoms may last 3–5 days if left untreated • Within 1–3 h, up to 24 h, victim may experience stiffness and intense pain • Generalized pain in lymph nodes, chest, and abdomen • Others: numbness, tingling, rashes, sweating, nausea, vomiting, dizziness, cramps, abdominal pain, chest tightness, weakness, and difficulty breathing, hypertension • Infants and young children present with irritability, refusal of feeds, crying, nonspecific erythematous rash, eyelid swelling, salivation, lacrimation, tremors especially in the legs • Compartment syndrome of the upper extremity and priapism may occur but uncommon • Rarely fatal, if happened due to respiratory or cardiac failure, with an overall mortality of $<5\%$	Antivenom and supportive

Table 280.5 (Continued)

Spider	Region	Features	Envenomation manifestations	Treatment
Recluse Spider (known as Violin or Fiddleback spider) (*Loxosceles spp)*	Warm dry climate Worldwide: North and South America, Australia, and tropical regions, Middle East	• Venom is necrotic • Venom cause direct cell wall destruction and immediate cell death. • It contains calcium-dependent enzyme and cause RBC hemolysis • Clotting abnormalities, local polymorphonuclear leukocyte infiltration	• Mild sting and pain at bite site (90%). • May progress to blister and profound swelling in 4–8 h • Tissue necrosis and ulceration may occur over 3–4 days (10%) • Skin grafting may be needed in 10% of the cases • Mild fever, nausea, vomiting (24–72 h) • *Rare:* renal impairment, bleeding, coagulopathies, respiratory depression, hypotension, jaundice, disseminated intravascular coagulation (DIC), convulsions, hemolytic anemia • Death is rare but children are at higher risk	Most resolve spontaneously No antivenom available in the USA Controversial: dapsone
Hobo Spider (known as Northwester Brown Spider) *(Tegenaria spp)*	Europe and central Asia, USA and Canada	• Venom is necrotic	• Once bitten the skin becomes red within a few minutes • Numbness and tingling around the bite • Blister will form within 36 h, tissue necrosis may occur later • Wound is less severe than that caused by recluse spider bite • Headaches, weakness, drowsiness, and hallucinations can last up to 1 week	Due to similarity of symptoms, brown recluse spider may be confused with Hobo spider bites
Wolf Spider (Lycosa spp)	Australia, USA	• Venom is mildly cytotoxic • Has large fangs	• Pain at bite site, redness, and swelling last for up to 10 days • Tearing of the skin may occurs	Most resolve spontaneously
Sac Spider (Chiracanthium spp) (100 species)	Worldwide Yellow Sac Spider in USA	• Nontoxic to humans • Venom is necrotic • Bites can cause damage to tissue and leave large open wound	• Pain at bite site, redness, swelling, and itchiness • Slight necrotic wound or ulcer may develop • Necrosis often heals without scarring or minimal scarring • Less necrotic than recluse spider	Local wound care and tetanus prophylaxis
Tarantula Spider (*Rheostica* or *Aphonopelma* spp)	USA (deserts)	Largest of all spiders Rarely bite, handling a tarantula can irritate the skin	• Minimal pain, surrounding edema, urticaria and pruritis that may persist for several weeks • Little or no tissue necrosis • No serious systemic effect • Hairs may cause keratoconjunctivitis or ophthalmia nodosa, a nodular, eye granulomatous lesion	Local wound care and tetanus prophylaxis Ophthalmology consultation

Table 280.5 (Continued)

Spider	Region	Features	Envenomation manifestations	Treatment
Jumping Spider (Phidippus spp)	*USA*		• *Painful, itchy, redness, significant swelling* • Serious: muscles, joints pain, headache, fever, chills, nausea and vomiting; last from 1 to 4 days	Supportive
King Baboon Spider (Harpactirinae spp)	Middle East, Africa		• Local pain, swelling, bruising • Lymph nodes swelling	Supportive
Banana Spider (known as Brazilian Wandering Spider) (Phoneutria spp)	Brazil (mainly), South and Central America	• Aggressive and highly venomous • Venom is potent neurotoxic • Has high concentration of serotonin • Inhibit calcium channel blocker	• Pinprick sensation, high and intense severe pain • Cause priapism • Muscle twitching, tachycardia, hypotension, parasthesia • Respiratory depression may result in death	Antivenom, supportive

281 Theophylline

Nada S. Al-Qadheeb

Theophylline is a dimethylxanthine bronchodilator used in the management of patients with obstructive lung disease. Despite declining use, it remains an important cause of intoxication with significant morbidity and mortality. It is available in a variety of dosage forms, including regular release tablets, sustained-release tablets and capsules, oral solutions, IV solution, and suppositories. The reasons for toxicity include the following: narrow therapeutic index, patient and physician dosing errors, and conditions or drugs that may decrease drug clearance (*Table 281.1*). Mild toxicity can occur within the therapeutic range (5–20 mg/L), but significant toxicity occurs with plasma levels >25 mg/L.

The metabolism of theophylline changes with a child's age. Neonates metabolize a portion of theophylline (less than 10%) to caffeine. As a child ages, the metabolic enzyme system matures and theophylline metabolism more closely resembles that of adults. However, children maintain a more rapid rate of metabolism. In the overdose setting, metabolic pathway saturation may occur, resulting in prolonged high serum theophylline concentrations.

The exact mechanism of action of theophylline is unknown. However, several potential mechanisms have been identified that may contribute to both its therapeutic and toxic effects. These include stimulating the release of catecholamines, increasing cyclic AMP concentrations through inhibition of phosphodiesterase, adenosine receptor blockade, stimulating the respiratory center, and enhancing diaphragmatic contractility.

Clinical and Laboratory Manifestations

Clinical features of theophylline overdose are classified into neurologic, cardiovascular, and metabolic manifestations. The occurrence of these manifestations depends on the type of overdose. Three forms of overdose exist: (1) acute – the result of a single, large, intentional ingestion; (2) chronic – the result of unintentional overmedication in a patient maintained on theophylline; and (3) acute-on-chronic – the result of a patient chronically on theophylline taking a large additional ingestion. *Table 281.2* lists the manifestations of theophylline overdose according to the type of overdose.

The onset of toxicity after acute ingestion of theophylline usually occurs within 1–2 h. However, onset maybe delayed more than 6–8 h after ingestion of sustained-release preparations. In acute ingestions, cardiovascular and CNS effects occur at a much higher serum concentrations than in chronic toxicity. In general, serum concentrations greater than 500 μmol/L (90 mg/L) in acute overdose are predictive of life-threatening events. In the chronic overdose setting, serum concentrations have little or no correlation with the clinical manifestations.

Management

Initially, evaluate and correct immediate life-threatening complications (e.g., airway, breathing, and circulation). The most serious complications of acute theophylline toxicity include seizures and tachyarrhythmia. Mortality is caused by intractable cardiac arrhythmias.

Gastric decontamination and extracorporeal removal of theophylline form the cornerstones of management of theophylline toxicity. The preferred mode of gastric decontamination is gastric lavage followed by activated charcoal for ingestions of >50 mg/kg. Gastric lavage may be useful for several hours after ingestion of sustained-release preparations. Because of high risk of seizure, emesis is contraindicated.

Since theophylline undergoes significant enterohepatic circulation, multidose activated charcoal (1 g/kg without sorbitol every 2–4 h) can enhance elimination. Serum theophylline levels may be repeated as often as hourly to help guide the management of patients.

Emesis associated with activated charcoal can be managed with antiemetic therapy; administration of smaller, more frequent doses; or continuous nasogastric administration of charcoal (0.25–0.5 g/kg/h). Activated charcoal should be administered even after extracorporeal removal is instituted.

Indications for extracorporeal removal of theophylline include intractable seizures, persistent hypotension

Table 281.1
Factors affecting theophylline clearance

Increase clearance	Decrease clearance
Drugs	
Carbamazepine Tobacco Ethanol (acute) Phenobarbital Phenytoin Rifampin	Allopurinol Cimetidine Ciprofloxacin Clarithromycin Erythromycin Oral contraceptives Propranolol Verapamil
Diseases	
Hyperthyroidism Cystic fibrosis	Congestive heart failure Liver cirrhosis Viral illnesses (acute) Chronic obstructive pulmonary disease Hypothyroidism
Food	
High-protein diet	High-carbohydrate diet

Table 281.2
Manifestations of theophylline overdose

Manifestations	Acute overdose	Chronic overdose
Nausea, vomiting, tremors, agitation	Common	Less common
Seizures	Observed when serum levels approach 80 mcg/mL	May occur without warning and at lower serum concentrations than acute ingestions
Sinus tachycardia, arrhythmias (atrial fibrillation, multifocal atrial tachycardia, ventricular tachyarrhythmias), and hypotension	Observed when serum levels approach 80 mcg/mL	May occur without warning and at lower serum concentrations than acute ingestions
Metabolic effects (hypokalemia, hypophosphatemia, hyperglycemia, metabolic acidosis)	More pronounced	Less pronounced

unresponsive to fluids and vasopressors, life-threatening arrhythmias, and serum theophylline concentrations greater than 500 μmol/L (90 mg/L) following acute ingestion or 333 μmol/L (60 mg/L) with chronic overmedication. Charcoal hemoperfusion is considered the removal method of choice due to the high affinity of activated charcoal. Hemodialysis also increases theophylline clearance and may be used when hemoperfusion is not available. Due to the technical difficulties with hemoperfusion in neonates and very small children, whole-blood exchange transfusions are another option to increase theophylline clearance.

Hypotension and tachycardia should initially be managed with IV fluids. Sinus tachycardia rarely requires further intervention. Vasopressors with alpha-adrenergic activity (e.g., norepinephrine) may be used for refractory hypotension. Since the hypotension is due to stimulation of β receptors, theoretically, a β-blocker (e.g., propranolol) would be useful. However, β-blockers must be used with caution since they may worsen the bronchoconstriction in patients with underlying pulmonary disease. Lidocaine and calcium channel blocking agents (e.g., diltiazem, verapamil) may be used to treat life-threatening cardiac arrhythmias.

Patients who develop seizures are at high risk for further morbidity and mortality. Benzodiazepines (e.g., diazepam) are the first-line therapy for seizures. For intractable seizures, phenobarbital and general anesthesia may be necessary. In animal models, phenytoin has been shown to be less effective or even harmful. Thus, its use is not recommended.

Theophylline has a narrow therapeutic index and a resultant high risk for serious morbidity and mortality. The clinical manifestations of overdose differ between large, acute ingestion and chronic overmedication. Aggressive supportive care, gastric decontamination, and extracorporeal removal are necessary in the management of theophylline overdose. Finally, the molecular adsorbent recirculating system (MARS) has been cited in case reports as being efficacious in the removal of protein-bound drugs such as theophylline. However, the literature is quite limited in the use of MARS in the pediatric population, especially for the treatment of drug toxicity.

282 Maintenance Fluid Therapy

Jordan M. Symons

Introduction

Multiple physiologic processes work in concert to maintain appropriate fluid and electrolyte balance. In health, interactions between the kidney, hormonal secretion, and neuronal signals preserve effective circulating volume and osmolar homeostasis. An important participant in this carefully calibrated scenario is the individual's perception of thirst and ability to consume water. In certain clinical situations, a child may not be able to take in the appropriate amount of water necessary to keep up with ongoing losses. Nausea, emesis, sedation, mechanical ventilation, and numerous other conditions encountered with a hospitalized child may limit enteral intake of fluids and jeopardize the ability to preserve physiologic balance. In these settings, one may provide intravenous fluids to deliver the daily requirement of water and electrolyte. Such fluids, designed to maintain homeostatic balance and compensate for normal daily losses, are often referred to as maintenance intravenous fluids.

Maintenance fluids replace the usual insensible losses and anticipated urinary output when a child cannot do so on their own by autoregulation, kidney function, thirst, and oral intake. Maintenance fluids are designed to prevent dehydration or volume depletion from occurring. They are not designed to correct fluid depleted states or to compensate for abnormal shifts of fluids between body compartments, nor are they intended to expand vascular volume prophylactically. In addition to providing the daily requirement of water, maintenance prescriptions usually also provide a daily amount of sodium, chloride, and potassium, the basic electrolytes lost in normal urinary excretion.

Systems to determine maintenance prescriptions rely on a series of assumptions, including normal volume status, normal renal function and urinary output, normal insensible losses, and a lack of additional ongoing losses. Situations where these assumptions do not hold will require review and adjustment to the maintenance fluid prescription.

Recently there has been controversy about the appropriate method for prescribing maintenance fluids, noting the potential for complications and calling into question the traditional system. The counterargument to this thesis has been that the original concepts underlying the maintenance theory have been forgotten and the traditional methods of maintenance therapy have been misused. Review of the history of maintenance intravenous therapy and the theory behind the maintenance prescription, coupled with a clear understanding of the potential for complications, can assist the practitioner in providing safe and appropriate therapy for the hospitalized child.

History

In a seminal paper published in 1957, Holliday and Segar described the maintenance need for daily water in children receiving parenteral therapy. Their method was based on older data that related energy expenditure to water requirements. They estimated the energy expenditure of a typical hospitalized patient and determined the average physiologic losses through urinary and insensible (respiratory and evaporative) routes. They proposed a system to calculate these losses and thus the appropriate amount of water to be given in daily parenteral therapy. They further extended their approach to include recommendations for daily needs for sodium, chloride, and potassium. The Holliday–Segar method for maintenance intravenous fluids has been adopted throughout the world.

Review of Holliday and Segar's original paper reveals that they included several caveats regarding the use of the maintenance fluid system. They made it clear that the prescription would need to be reevaluated and adjusted in situations where either insensible losses or urinary losses differed from the norm. In addition, they made it clear that there was no intention for their system to be used for replacement of a volume deficit or any other need beyond daily fluid requirements: "Finally, it should be emphasized that these figures provide only maintenance needs for water. It is beyond the scope of this paper to consider repair of deficits or replacement of continuing abnormal losses of water. These must be considered separately and must be added to the needs for maintenance."

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_282,

Theory and Concepts

As noted above, maintenance fluid therapy is based on assumptions about water need as related to metabolism and energy expenditure. Basal metabolism generates heat which is dissipated through insensible water loss via the skin and the respiratory tract. Metabolism also generates waste solutes which are excreted by the kidney, leading to an obligate daily water loss in the urine. Thus the ability to predict energy expenditure would guide the need for the amount of water required to balance these daily losses.

Of several methods to predict energy expenditure, the Holliday–Segar method is among the simplest and has become the most widely used. Their equation computed the expected energy expenditure for the average hospitalized patient, making the assumption that this level of expenditure would fall in between basal metabolic rate and previously described estimates of total expenditure with normal activity. They derived a simple construct based on the patient's weight:

- For patients who weigh up to 10 kg, anticipate expenditure of 100 kcal/kg/day
- For patients who weigh 10–20 kg, anticipate expenditure of 1,000 kcal/day (i.e., 100 kcal/kg/day for the first 10 kg) plus an additional 50 kcal/kg/day for each kg over 10 kg
- For patients who weigh 20 kg and over, anticipate expenditure of 1,500 kcal/day (i.e., 100 kcal/kg/day for the first 10 kg plus 50 kcal/kg/day for the second 10 kg) plus an additional 20 kcal/kg/day for each kg over 20 kg

See *Table 282.1* for a summary of this system.

Holliday and Segar further described the relationship between energy expenditure and physiologic water loss through insensible and urinary routes. Based on data from other investigators, they estimated that the average insensible water loss was 50 mL for every 100 kcal of energy expended per day. For urinary loss of water, Holliday and Segar recognized that variable solute loads to the patient and differing ability of the kidney to concentrate or dilute the urine would lead to variation in daily urinary output. Based on a presumed average solute load, they chose to target a mid-range urinary concentration of 375 mOsm/kg (i.e., a urinary specific gravity near 1.010) to avoid providing too little or too much water to a patient who may not have fully competent urinary concentrating or diluting capacity. This calculated to 66.7 mL of water for every 100 kcal of energy per day, making the total need to balance physiologic losses (insensible and urinary) 116.7 mL/100 kcal/day. Holliday and Segar then assumed that oxidative metabolism would likely generate 16.7 mL of water/100 kcal of energy expended, rounding their water–energy equation to 100 mL water/100 kcal of energy expended per day, noting, "Fortuitously then, average needs for water expressed in milliliters equals estimated energy expenditure in calories."

For maintenance electrolyte needs, Holliday and Segar noted that "less precise data are available." Recognizing the kidney's ability to regulate and adjust for errors in estimation, they chose to target daily needs for sodium, chloride, and potassium based on values between those provided by human milk and those provided by cow milk; these levels proved to be in agreement with values that had already been recommended for adults. Relating their recommendations for daily electrolyte needs to energy expenditure much as they had for daily water, they suggested providing sodium at 3 mEq/100 kcal/day, chloride at 2 mEq/100 kcal/day, and potassium at 2 mEq/100 kcal/day. These requirements are summarized in *Table 282.2*.

Prescribing Maintenance Water

Using the method as outlined by Holliday and Segar, one may easily develop a prescription for maintenance intravenous fluids. For example, consider a 25 kg child for whom maintenance intravenous fluids are indicated. The Holliday–Segar method allows one to calculate average

Table 282.1
Holliday–Segar method to calculate energy expenditure or maintenance water need, based on body weight

Weight (kg)	Energy expenditure (kcal) or maintenance water need (mL)
0–10	100/kg/day
10–20	1,000/day + 50/kg/day (for each kg > 10 kg)
>20	1,500/day + 20/kg/day (for each kg > 20 kg)

Table 282.2
Holliday–Segar estimates for daily maintenance electrolyte requirements, based on energy expenditure

Electrolyte	Maintenance need
Sodium	3 mEq/100 kcal/day
Chloride	2 mEq/100 kcal/day
Potassium	2 mEq/100 kcal/day

energy expenditure and, working on the assumption that 100 mL of water is required for every 100 kcal expended, we may substitute milliliters of water for kcal in the equations as follows:

1,000 mL/day for the first 10 kg (10 kg × 100 mL/kg/day)
PLUS
500 mL/day for the second 10 kg (10 kg × 50 mL/kg/day)
PLUS
100 mL/day for the 5 kg over 20 kg (5 kg × 20 mL/kg/day)
EQUALS
1,600 mL/day TOTAL WATER for 25 kg child

If given as a continuous intravenous infusion, this would call for a rate of about 67 mL/h (i.e., 1,600 mL/day divided by 24 h/day).

An adaptation of these equations has been developed to approximate this result in terms of milliliters of fluid to deliver per hour. Sometimes referred to colloquially as the "4-2-1 rule," it is constructed as follows:

- For the first 10 kg of body weight, deliver 4 mL/kg/h of intravenous fluid.
- For every kg of body weight between 10 and 20 kg, deliver an additional 2 mL/kg/h.
- For every kg of body weight over 20 kg, deliver an additional 1 mL/kg/h.

See *Table 282.3* for a summary of this method for calculating maintenance fluids.

Taking the example previously derived for the 25 kg child, the calculations would be:

40 mL/h for the first 10 kg (10 kg × 4 mL/kg/h)
PLUS
20 mL/h for the second 10 kg (10 kg × 2 mL/kg/h)
PLUS
5 mL/h for the 5 kg over 20 kg (5 kg × 1 mL/kg/h)
EQUALS
65 mL/h TOTAL WATER for 25 kg child

Table 282.3
Simplified "4-2-1 rule" for calculating hourly maintenance fluid rate

Weight (kg)	Hourly fluid rate for maintenance water
0–10	4 mL/kg/h
10–20	40 mL/h + 2 mL/kg/h (for each kg > 10 kg)
>20	60 mL/h + 1 mL/kg/h (for each kg > 20 kg)

Note: that this method is based on the standard Holliday–Segar method for calculating energy expenditure and daily maintenance needs

Prescribing Maintenance Electrolytes

Insensible losses are considered to be water; therefore, daily losses of electrolytes, which need to be replaced in a maintenance prescription, come entirely from urinary output. The Holliday–Segar method addresses electrolyte losses but, as noted above, the recommendations are based on less robust data than that available for determining water requirements. If following the Holliday–Segar plan for the 25 kg child previously described, and again assuming that 100 mL of water is required for every 100 kcal of energy expended, electrolyte requirements would be calculated as follows:

- Total daily water intake 1,600 mL/day
- Sodium requirement: 48 mEq/day (3 mEq/100 mL water/day)
- Chloride requirement: 32 mEq/day (2 mEq/100 mL water/day)
- Potassium requirement: 32 mEq/day (2 mEq/100 mL water/day)

This sodium content (48 mEq in 1,600 mL, or 30 mEq/L) is roughly equivalent to that found in standard hypotonic saline available for infusion (0.18–0.3% sodium chloride solution). Potassium content calculates to 20 mEq/L, a concentration also found frequently in standardized solutions. Chloride content in standardized solutions may deliver quantities in excess of those recommended by the Holliday–Segar calculation due to the necessity of maintaining electroneutrality in the intravenous fluid. However, as noted by Holliday and Segar with respect to electrolyte maintenance, "figures considerably in excess of the minimum requirements are readily handled."

Controversy

Recently, controversy has developed regarding the use of the Holliday–Segar method. Several authors have suggested that the use of hypotonic intravenous solutions, as suggested by Holliday and Segar, increases the risk for complications related to hyponatremia. While not challenging the fundamental basis of determining maintenance needs for water based on energy expenditure, it is proposed that isotonic intravenous solutions such as normal saline (0.9% sodium chloride solution) should be the intravenous maintenance fluid of choice. In support of this argument, authors note reported cases of hyponatremia, some with neurological sequelae, associated with the use of hypotonic intravenous solution. They

accurately note that hospitalized patients may have non-osmotic stimuli for the release of antidiuretic hormone (ADH), such as nausea, vomiting, pain, or volume depletion. Postoperative patients are also known to have secretion of ADH on a non-osmotic basis. ADH in these settings would promote the retention of free water and could lead to hyponatremia.

Inappropriate use of the maintenance fluid concept can easily lead to the complications cited above. Holliday and Segar clearly delineated that maintenance intravenous fluids were to be used for replacement of physiologic losses and should not be employed for correction of volume deficits, and that adjustments to the standard prescription would be required depending on the clinical situation.

Considerations

While the maintenance fluid method of Holliday and Segar remains a useful tool, it is clear that the system is based on a series of assumptions and generalizations that are not always true for every patient. This is especially true of the acutely ill child admitted to the hospital, or the child in the perioperative period. Urinary output may not achieve the levels predicted by Holliday and Segar, either due to volume depletion and activation of sodium-retaining mechanisms (renin/angiotensin II/aldosterone) or due to non-osmotic stimulation of ADH. Such patients could receive too much free water using the standard maintenance equations, putting them at risk for hyponatremia as described above. Holliday and Segar's estimates of energy expenditure may be overly generous for a given patient, such as a child who is immobilized following surgery or a child who is critically ill and sedated. Adhering to the maintenance theory, lower energy expenditure would obligate a smaller amount of water; thus, the standard equations for maintenance would again provide too much water for those with reduced caloric requirements. These examples demonstrate the importance of adjusting the intravenous fluid plan for a given patient, taking into consideration the clinical circumstances; rote application of the maintenance equations to all scenarios would be inappropriate.

Further, Holliday and Segar were very clear that the maintenance concept should not be applied to the child who requires deficit replacement; such clinical situations would be addressed better with the use of sufficient isotonic intravenous solution to correct the volume deficit while prescribing maintenance fluids (or an adaptation thereof) to balance anticipated routine daily losses from urinary and insensible routes. Consequently, provision of intravenous fluids using simple multiples of volumes calculated through maintenance equations (e.g., "one-and-a-half times maintenance," "twice maintenance") clearly goes outside of the construct developed by Holliday and Segar and may put the patient at risk for excessive free water delivery.

Recommendations

Review of the traditional method for calculating maintenance intravenous fluids demonstrates a relatively straightforward system that can be employed successfully in many hospitalized patients. Analysis of the potential risks, especially for hyponatremia and its complications, reveals the complexity of illness in childhood and serves as a reminder that careful thought and clinical judgment must be employed when caring for sick children. The majority of the time the standard approach for maintenance fluids will work, due in large part to the very effective autoregulatory ability of the functional kidney and associated neurohumoral systems. Recognizing the limitations of the method and those patients at risk for complications will help to avoid untoward outcomes. Whenever possible, discontinuation of intravenous fluids with return to normal oral intake of food and water is most appropriate.

283 Hyponatremia and Hypernatremia

Aaron Friedman

Abnormalities in water homeostasis, as manifested by low or high serum sodium, are a commonly encountered electrolyte disorder especially in hospitalized patients. *Hypo*natremia is far more common than *hyper*natremia. With either condition in the overwhelming majority of cases, the underlying etiology is water imbalance – not sodium imbalance. An understanding of how sodium and water homeostasis are maintained and why imbalances occur allow the clinician to appropriately diagnose, approach, and treat disorders of water imbalance.

Principles of Sodium and Water Balance

The plasma sodium concentration is normally 140 mmol/L with a normal range of 135–145 mmol/L. Sodium is the major extracellular cation and along with the anions, chloride and bicarbonate, accounts for nearly all of the milliosmoles (mOsm) in extracellular fluid. Intracellular cations that maintain electroneutrality and counterbalance the osmotic effects of extracellular ions are potassium (cation) and the anions, phosphate and proteins (*Table 283.1*). The normal extracellular (and intracellular) osmolality is 290 mOsm/kg H_2O. Since 1 mmol of sodium (potassium chloride or bicarbonate) contributes 1 mOsm to the osmolality, sodium is vital to maintaining extracellular volume, osmolality, and plasma volume. A handy quick equation for determining plasma osmolality is: plasma osmolality (mOsm/kg H_2O) = [2 × Na (mmol/L)] + glucose (mg/dL)/18 + BUN (mg/dL)/2.8. The division by 18 for glucose and 2.8 for BUN accounts for molecular weight and takes the concentration in mg/dL and converts it to mmol/L.

Water homeostasis is critical to all mammals. Thus careful regulation of water intake and excretion is necessary. The important physiologic components to water regulation include the hypothalamus and surrounding brain tissue, the circulating antidiuretic hormone or arginine vasopressin (AVP), and the kidney.

Since AVP plays such a central role in water homeostasis, the physiology of AVP production, release, and action on the kidney is important. In the late 1940s, Verney demonstrated that osmolality plays a role in the release of AVP from the hypothalamus. Under otherwise normal conditions, a small (1–2%) increase in serum osmolality sensed by paraventricular nuclei adjacent to the hypothalamus will result in the release of AVP from the hypothalamus. Conversely, a small (1–2%) decrease in serum osmolality will shutdown AVP release and decrease production.

Osmolality is not the only trigger to AVP release. Gauer and Henry demonstrated that "effective" circulating plasma volume is sensed by pressure or stretch receptors in the left atrium or large arteries in the chest. With a decrease in effective circulating volume, the pressure or stretch receptors sense a decrease and signal through the vagus and glossopharyngeal nerve resulting in the release and increased production of AVP. This type of AVP release is termed non-osmotic AVP release. Other stimuli for non-osmotic AVP release are listed in *Table 283.2*.

Once released into the circulation, AVP stimulates brain centers to increase thirst. The other important action in water homeostasis for AVP is water conservation by the kidney. AVP stimulates the active transport of urea by the thick ascending limb of the loop of Henle epithelial cells. This results in the creation and/or maintenance of a large osmotic gradient between the tubule lumen and the renal interstitium favorable to the movement of water from the tubule lumen into the interstitium and eventually into the extracellular space. AVP also results in the transtubular (transepithelial) transport of water in the collecting duct of the kidney. AVP acts primarily on the principle cells of the collecting duct by binding onto receptors on the basolateral (non-luminal) surface of principle cells leading to the opening of water channels – termed "aquaporins" – which serve as channels allowing solute-free water to traverse cells.

Following the release of AVP, action by the kidney is rapid. AVP circulates unbound and is metabolized by the liver or excreted by the kidney. Circulating half-life is approximately 20 min. The arrangement of water channels in the renal collecting duct under the influence of AVP does not require new protein synthesis. All of this means that the release of AVP under normal conditions results in water reabsorption by the kidney within minutes to hours.

Total body water is distributed within cells and in interstitial (between cells) fluid compartments. Except in

newborns total body water comprises 60% (or so) of total body weight. The distribution is essentially 2/3 within cells (intracellular fluid, ICF) and 1/3 outside of cells (extracellular fluid, ECF); 25% of ECF is in plasma. In the first 24–28 h after birth, total body water is 75–80% of total body weight with up to 70% in the ECF.

Sodium homeostasis is maintained by balancing intake, extracellular volume, and output. Intake of sodium in the industrialized world is ample, averaging 4–5 g/day in adults. The primary site of sodium excretion is the kidney. At the glomerulus, the filtered load of sodium is 140 mmol/L of filtrates. Approximately 60–70% of the sodium filtered per day is reabsorbed by the proximal tubule, 20–30% of the filtered sodium load is reabsorbed in the ascending limb of the loop of Henle and the remaining reabsorption occurs at the distal tubule and collecting duct under the influence of aldosterone.

Aldosterone secretion by the adrenal gland is mainly influenced through the renin-angiotensin aldosterone axis. In situations of extracellular volume contraction, stretch and volume sensors in the large vessels of the chest, and messages from renal efferent arterioles result in the release of renin from juxtaglomerular cells in the kidney. Renin then catalyzes the cleavage of circulating angiotensinogen to angiotensin I. Angiotensin-converting enzyme, also in the circulation, converts angiotensin I to angiotensin II. It is angiotensin II which stimulates the release of aldosterone from the adrenal cortex, increases the reabsorption of sodium by the proximal tubule, and feedbacks on the kidney to reduce renin release. Thus, in situations of extracellular volume contraction through the action of aldosterone, renal sodium reabsorption increases, and through the action of AVP, water reabsorption increases, which serves to help restore extracellular volume.

Hyponatremia

Hyponatremia is defined as plasma sodium under 135 mmol/L when the normal range is 135–145 mmol/L. Hyponatremia often occurs in situations of extracellular volume contraction, but can occur in situations of no perturbation of extracellular volume or extracellular volume expansion such as syndrome of inappropriate antidiuretic hormone (AVP) release termed "SIADH release." An elevated AVP *alone* does not result in hyponatremia. AVP elevated levels plus the intake of water or the provision of a hypotonic solution (intravenous fluids) leads to hyponatremia and hypoosmolality. *Tables 283.3–283.5* provide an algorithm for the approach to hyponatremia in children.

The clinical manifestations of a low serum sodium and hypoosmolality depend on the level of serum sodium or hypoosmolality and the rate of decline. Mild reductions in the osmolality usually do not result in significant symptoms. Symptoms typically become more apparent when

the sodium falls below 130 mmol/L and especially below 125 mmol/L. However, rapid changes, decreases that occur over a few hours, could result in symptoms. The symptoms are mainly neurologic and include agitation, anorexia, anxiety, malaise/lethargy, muscle weakness, hypothermia, which can then progress to disorientation, significant cognition defects, depressed deep tendon reflexes, seizures, coma, and death (usually due to brain herniation).

The approach to hyponatremia is to remember that hyponatremia usually, but not always, is representative of hypoosmolality. In order to appropriately manage a patient with a low serum sodium, knowing if the low sodium also means a low osmolality is crucial. *Tables 283.3–283.5* describe the approach to hyponatremia depending on whether it is associated with isoosmolality (*Table 283.3*), hyperosmolality (*Table 283.4*), or hypoosmolality (*Table 283.5*).

A common clinical situation in pediatrics is hyponatremic (hypoosmolality) dehydration often associated with gastroenteritis. The pathophysiology of this condition is loss of fluid and electrolyte from the gastrointestinal track leading to extracellular fluid volume contraction. As a result, both aldosterone and AVP are secreted. Aldosterone will increase renal sodium reabsorption and secretion, which can result in hypokalemia. AVP will increase renal water reabsorption. Hyponatremia (and hypoosmolality) can result when the patient consumes or receives hypotonic solution.

The signs and symptoms of dehydration are well described in *Table 283.6*.

The treatment of hyponatremic (hypoosmodal) dehydration is the restoration of extracellular volume. For mild to moderate dehydration, oral restoration fluid is often sufficient unless vomiting is persistent and even small amounts of fluid delivered frequently is not retained. For moderate dehydration, The World Health Organization recommends oral rehydration solutions. Such solutions contain at least 45 mmol/L of sodium with some solutions containing up to 90 mmol/L. The potassium content is usually 20–25 mmol/L. Many clinicians prefer to use intravenous fluids for moderate to severe dehydration. To restore extracellular volume, the intravenous solutions of choice are isotonic saline or lactated Ringers solution. An intravenous bolus of 20–40 mL/kg delivered over 1–2 h (especially in patients with tachycardia, hypotension and/or increased capillary refill time) will improve signs of dehydration and patient well-being. The improvement in extracellular volume will also improve gut perfusion, which will make oral rehydration better tolerated. This approach will also bring the serum sodium closer to normal.

An all too frequently used, but erroneous approach to treating children with dehydration, is to provide maintenance fluid to restore extracellular volume depletion. Maintenance fluid therapy is an estimate of the anticipated fluid and electrolyte needs of the euvolemic patient. It is based on caloric expenditure (*Table 283.7*). This solution is *not* a fluid that should be used to restore extracellular volume. The inappropriate use of

maintenance fluid solutions in situations of extracellular fluid volume contraction or other causes of nonosmotic release of antidiuretic hormone have resulted in serious injury or death due to cerebral edema. As a result, a modification of maintenance therapy was proposed that substitutes isotonic saline for the hypotonic solution published over 5 decades ago by Holliday and Segar. Studies, to date, across the full range of hospitalized children comparing isotonic and hypotonic maintenance solutions are still lacking.

Table 283.7
Caloric, water, and basic electrolyte requirements based on weight

Body weight (kg)	Calories	Water	Sodium mEq/ 100 mL H_2O	Chloride mEq/ 100 mL H_2O	Potassium mEq/ 100 mL H_2O
3–10 kg	100 mL/kg	100 mL/kg Or 4 mL/kg/h	3	2	2

>20 kg	20 mL/kg	1500 mL+20 mL/kg Or 60 mL/h+1 mL/kg/h	3	2	2

Example: Hyponatremic Dehydration

A 15 kg child has a 3-day history of fever, vomiting, and diarrhea. Your assessment is the patient is 7% dehydrated. The patient's serum electrolytes are sodium 127 mmol/L, potassium 3.7 mmol/L, chloride 95 mmol/L, bicarbonate 22 mmol/L, and glucose 100 mg/dL. You decide to use intravenous fluids to manage this patient.

Step 1. Treat extracellular volume depletion with 40 mL/kg or 600 mL of isotonic fluid over 1–2 h. 40 mL/kg is 4% of body weight.
Step 2. Reexamine patient for changes in signs and symptoms of dehydration.
Step 3. Attempt oral fluids or continue isotonic fluids 30 mL/kg over next 6–8 h. This should restore extracellular fluid unless vomiting and diarrheal losses remain high.
Step 4. Recheck serum sodium and other electrolytes.
Step 5. Consider oral fluids initiation or maintenance fluids only after extracellular volume is restored as demonstrated by increased urine output and decreasing urine osmolality.

In situations where the serum sodium is low, especially below 125 mmol/L, or the patient is exhibiting central nervous system symptoms noted above, then a more rapid increase in serum sodium and osmolality may be desired. Fortunately, central nervous system symptoms are rare. Hypertonic saline (3% NaCl) is the usual solution. 3% NaCl is 500 mmol/L or 0.5 mmol/mL. Changes in the serum sodium *should not* exceed 10 mmol/L/24 h or 20 mOsm/kg H_2O/24 h. To calculate the amount of sodium needed to raise the serum sodium concentration, the equation is:

$$(\text{Desired[Na]} - \text{Measure[Na]}) \times 0.6 \times \text{BW}$$

where [Na] is the serum sodium concentration in mmol/L; BW is the body weight in kg. Body weight multiplied by 0.6 is total body water (except in prematures and early newborns whose total body weight is closer to 0.7).

The entire body water space must be used in this calculation because the addition of sodium into the extracellular space will raise extracellular osmolality and draw water from the intracellular to extracellular space equalizing osmolality throughout the total body water space. In the 15 kg patient example above, if the serum sodium were 120 mmol/L and the patient was symptomatic using the equation above, the desire [Na] should be no higher than 130 mmol/L, the measure [Na] is 120 mmol/L, thus: (130–120) × 0.6 × 15 = 90 mmol. 3% NaCl has 0.5 mmol/mL, which will require 180 mL of 3% NaCl. A safe approach is to provide approximately 5 ml/kg/h of 3% NaCl (2.5 mmol/kg/h). In this patient, 75 mL of 3% NaCl per hour will deliver 37.5 mmol of sodium. Measuring the serum sodium after 1 h of infusion is prudent and recalculation may be necessary.

The Syndrome of Inappropriate Antidiuretic Hormone (SIADH) Release

Bartter and Schwartz described a syndrome of hyponatremia and hypoosmolality of serum, urine osmolality that is inappropriately high and higher than the serum osmolality, high urine sodium excretion, and normal renal, adrenal, and thyroid function. SIADH release is a condition of nonphysiologic AVP release. AVP release due to a high serum osmolality or extracellular volume depletion does not represent inappropriate AVP release. Thus, SIADH release is really due to (1) ectopic production, (2) abnormal release from the pituitary, or (3) exogenous administration. *Table 283.8* lists some of the causes of SIADH release.

With SIADH release, plasma sodium declines only if the patient continues to consume (or receive) water in excess of that which is lost in urine, sweat, and respiration.

Table 283.8
Comparison of syndrome of inappropriate ADH (SIADH) release and cerebral salt wasting (CSW)

	SIADH	CSW
Serum sodium	Low	Low
Extracellular fluid volume	Normal, high	Low
Blood pressure	Normal	Normal, low
Orthostatic hypotension	Absent	May be present
Serum AVP	High	Normal, high
Urine volume	Low	High
Urine osmolality	High	High
Urine osmolality with volume expansion	High	Decreased
Urine sodium excretion	>40 mmol/L	Very high
Serum uric acid	Low	Normal, low
Serum Albumin	Low	Normal, high
BUN, serum creatinine	Normal, low	Normal, high
Hematocrit	Normal, low	Normal, high
Brain natriuretic peptide	Normal	High

Because patients with SIADH release are *not* extracellular volume depleted (in fact, extracellular volume is usually expanded), urinary sodium excretion is not low.

The treatment of choice for SIADH release is to address the underlying condition, thus eliminating any exogenous source or shutting off endogenous production and release. This is often difficult, if not impossible. Fluid restriction is often effective. The goal is for total fluid intake/24 h to be less than the water lost in urine and through the insensible losses of breathing and sweating. This approach will slowly increase the serum sodium and serum osmolality. Other medical approaches include doxycycline, which interferes with the action of AVP but cannot be used in young children and is limited in its effectiveness and fludrocortisone, which increases sodium retention but also raises blood pressure and results in hypokalemia and AVP antagonists. AVP antagonists appear promising in short-term studies, but are untested in children.

Cerebral Salt Wasting (CSW)

Cerebral salt wasting is a less well-understood and probably infrequent cause of hypoosmolality/hyponatremia. Cerebral salt wasting is usually associated with central nervous system injury such as brain injury or brain surgery. The clinical manifestation includes hyponatremia and serum hypoosmolality, but urine volumes are high, urine sodiums are extremely high (concentrations can be greater than the plasma sodium concentration), and extracellular volume contraction. *Table 283.8* highlights the difference between SIADH release and CSW in both diagnosis and treatment. Making the distinction is important since fluid restriction is the primary approach to SIADH release, whereas, isotonic saline, sometimes in large volumes, is the recommended approach to CSW. Other therapies proposed in CSW include: AVP administration with concomitant sodium administration and the use of fludrocortisone to enhance sodium reabsorption. The use of fludrocortisone may necessitate the use of supplemental potassium.

Hypernatremia (Hyperosmolality)

Hypernatremia occurs less frequently than hyponatremia. The most important causes of hypernatremia are excessive water losses and/or inadequate water intake. Hypernatremia is always associated with hyperosmolality. In very rare instances, hypernatremia is due to the provision of too much salt. Normally the protection against hypernatremia includes activation of the thirst mechanism and increased water consumption as well as the excretion of concentrated urine initiated by the release of AVP. The major consequences of hypernatremia pertain to the loss of cell volume due to water shifting from the intracellular to extracellular, and the loss of interstitial and plasma volume as water is lost, and eventually from the body as a whole. The brain, especially in infants and young children, is particularly at risk.

The signs and symptoms of hypernatremia are: thirst, lethargy, and/or irritability, in infants a high-pitched cry, doughy feeling skin, nausea, vomiting, and eventually obtundation, coma, and death. The approach to the evaluation of hypernatremia is described in *Tables 283.9–283.11*. As noted above, with rare exception, hypernatremia is due to the loss of water or hypotonic fluid from the body and inadequate replacement. In children, gastrointestinal dehydration with stool and volume losses associated with inadequate fluid intake is the most common cause of hypernatremia. Patients with hypernatremic dehydration will demonstrate signs and symptoms of dehydration (*Table 283.2*). However, the percentage of dehydration will be greater than the signs and symptoms suggest. Thus, a hypotensive child with hypernatremia dehydration is critically ill. In newborns and young infants, inadequate fluid volume (inadequate

Table 283.9

Approach to hypernatremia

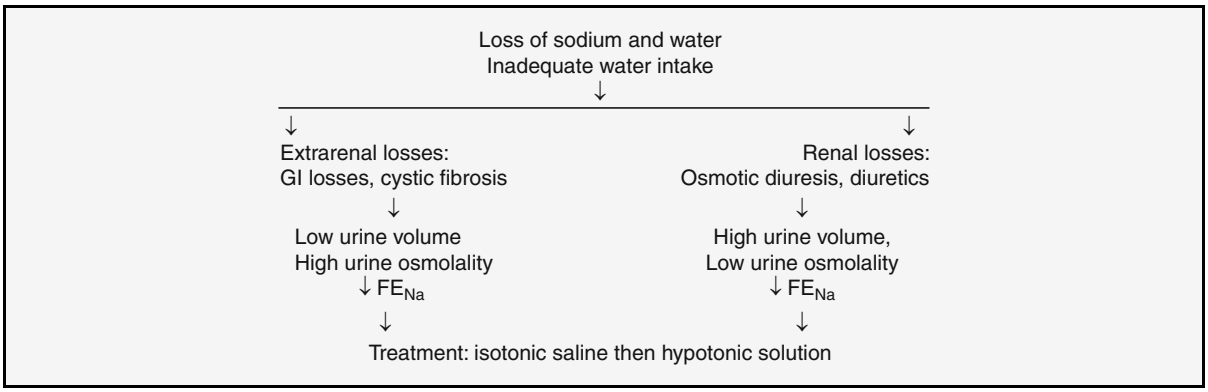

Table 283.10

Approach to hypernatremia

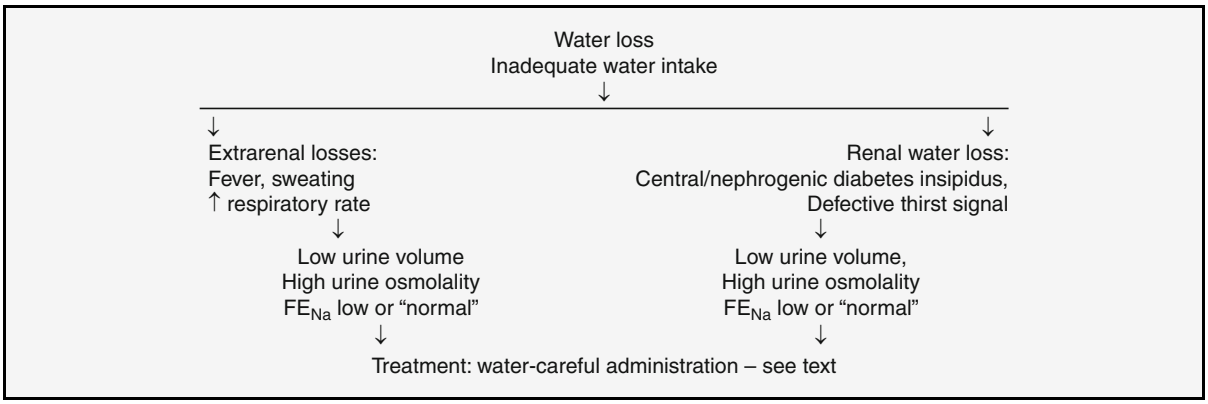

Table 283.11

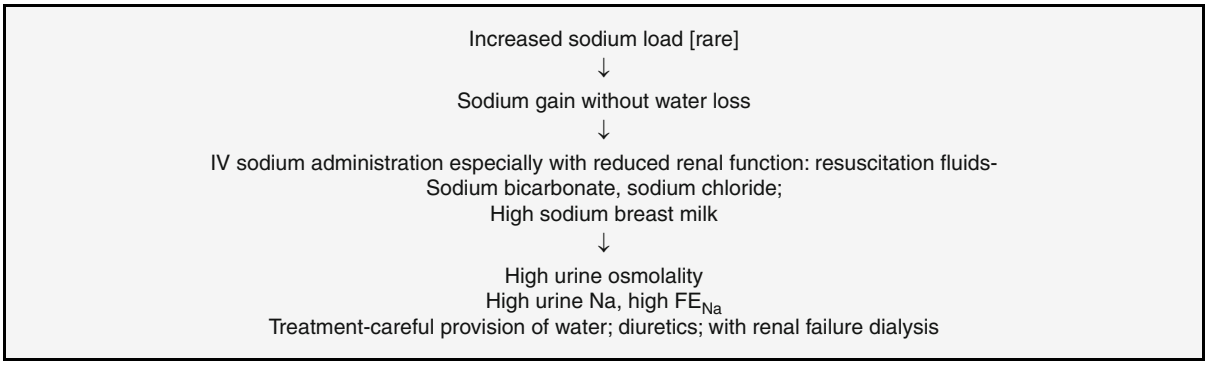
Approach to hypernatremia



breast milk volume, for example) is an important cause of hypernatremia. Another important etiology for hypernatremia is renal water loss associated with reduced (chronic kidney disease, obstructive uropathy) or nonexistent (central or nephrogenic diabetes insipidus) ability to reabsorb water. With extrarenal losses, but normal renal function, the extracellular volume depletion and hyperosmolality of the serum will lead to low urine volume, high urine osmolality, and low urine sodium, as well as low fractional excretion of sodium (FE_{Na}). With polyuria associated with loss of the ability of the kidney to reabsorb water, urine volumes are high and urine osmolality is low. The evaluation of polyuria is described in *Table 283.12*.

Diabetes insipidus (DI) leads to polyuria because of inability to excrete concentrated urine either due to absent or deficient AVP secretion (central DI) or renal resistance to the action of AVP (nephrogenic DI). *Table 283.13* lists causes of central or nephrogenic DI. Central DI may be idiopathic, but is more often the result of central nervous system trauma, infection, malignancy, or surgery. Patients will have polyuria, polydipsia, and dilute urine

Table 283.12
Approach to polyuria

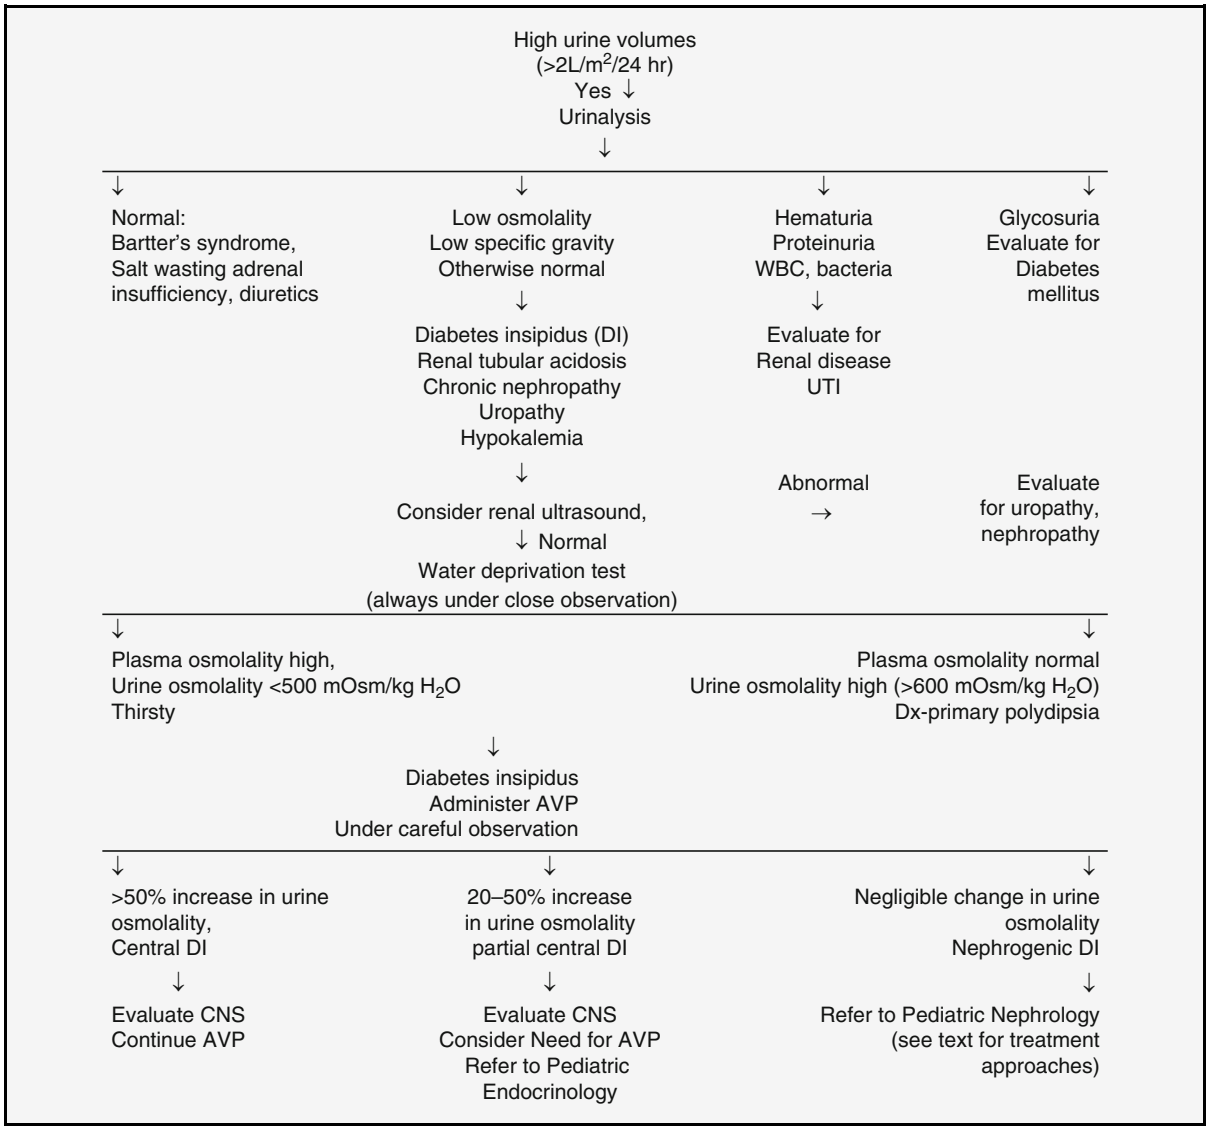


Table 283.13
Etiology: central vs. nephrogenic diabetes insipidus

Central diabetes Insipidus	Idiopathic
	Hereditary – autosomal recessive and autosomal dominant
	CNS condition – surgery, trauma, malignancy, especially near hypothalamus and pituitary
	Infection – tuberculosis, meningitis, encephalitis; granulomatous disease
	Histocytosis
Nephrogenic diabetes Insipidus	Congenital – ADH receptor defect (x linked), aquaporin defect (autosomal)
	Renal disease – obstructive uropathy, dysplasia, medullary cystic disease, polycystic disease, reflux nephropathy
	Systemic disease – sick cell, amyloid, sarcoid, multiple myeloma
	Hypokalemia
	Hypercalcemia
	Drugs – lithium, diuretics, aminoglycosides, phenytoin, vinblastine, amphotericin

with a decrease in urine volume and an increased urine osmolality associated with the provision of exogenous AVP. Nephrogenic DI results from the inability of the renal distal tubule and collecting duct to respond to AVP. Two receptors respond to AVP, V1 (AVPR1), and V2 (AVPR2). V2 is the receptor on the distal tubule and collecting duct. The gene is located on X chromosome (Xq-28). Familial nephrogenic diabetes insipidus accounts for 90% or more of the *heritable* forms of nephrogenic DI and demonstrates X-linked inheritance with mutations in the AVP-2 receptor. The condition usually presents in the neonatal period with polyuria, polydipsia, poor weight gain, unexplained fever, and hypernatremic dehydration. A far less common cause of nephrogenic DI is a defect in the AVP water channel, aquaporin-2, (AQP2) in distal tubule and collecting duct. The mutations in the AQP2 gene present with autosomal dominant or recessive mode of inheritance. In families with a known history of X-linked nephrogenic DI, prenatal diagnosis is possible and can help prevent early injury to baby from hypernatremic dehydration. Acquired nephrogenic DI is more common than heritable forms. Chronic kidney disease, the result of obstructive uropathy, cystic kidney disease, renal dysplasia, metabolic conditions such as hypokalemia, hypercalcemia, and diseases such as sickle cell disease result in nephrogenic DI.

With central DI, the treatment is the provision of AVP usually as desmopressin. *Table 283.12* describes the approach to both central and nephrogenic DI. The therapeutic approach to the child with nephrogenic DI is: first, assure access to water and second, decrease urinary volume by carefully restricting protein intake (1.6 g/kg/24 h) and restricting salt intake (0.7 mmol/kg/24 h). Additionally, the use of hydrochlorothiazide (1–2 mg/kg/24 h) will result in mild volume depletion and enhanced proximal tubule sodium and water reabsorption. The use of hydrochlorothiazide long term will result in hypokalemia prevented by the concomitant use of amiloside, indomethacin (a prostaglandin inhibitor), will further reduce urinary volume.

Excessive sodium intake is an unusual cause of hypernatremia. The intravenous administration of hypertonic sodium solutions such as sodium bicarbonate or sodium chloride or blood products high in sodium such as platelets can result in hypernatremia. Improper preparation of infant formula or boiling of skim milk may result in hypernatremia. In these situations (excluding acute renal failure), urine osmolality will be high and urine sodium will be elevated (FE_{Na} high as well).

Treatment of Hypernatremic Dehydration

The approach to treatment involves:

1. Identify the underlying cause.
2. If possible, treat underlying cause and minimize ongoing losses.
3. Treat extracellular volume contraction.
4. Replace water deficit.
5. Address ongoing losses.
6. Consider maintenance fluid therapy after extracellular volume contraction is treated. The treatment of extracellular volume contraction involves the use of isotonic saline or lactated Ringer's solution. Patients with hypernatremic dehydration are at least 10% dehydrated. Therefore, expect to provide at least 100 mL/kg of replacement fluid. The important caveat to the treatment of children with hypernatremic dehydration is that the serum sodium should *not* drop more than 10 mmol/24 h (approximately 0.5 mmol/h). With hypernatremic (hyperosmotic) dehydration, water leaves the intracellular space including the brain.

The response within the brain to this form of dehydration is the elaboration of intracellular osmoles, which reduces the volume loss by cells in the brain. Thus, too rapid a decline in extracellular osmolality will result in intracellular swelling and cerebral edema. Therefore, it is prudent when providing fluid therapy to a patient with hypernatremic dehydration to regularly follow the serum sodium.

Replacing the water deficit should begin after at least 50% of the extracellular volume deficit is treated (50 mL/kg of an isotonic solution) and rechecking the serum sodium. To calculate the water deficit and how much would be needed to restore normal osmolality, the equation is: water deficit = TBW × (Na measured – Na desired)/Na desired. TBW = total body water = 0.6 × weight in kg.

For example: a 10 kg infant with a serum sodium of 160 mmol/L. TBW is 0.6 × 10 or 6 L. 6 × (160–145/145) or 6 × 0.1 = 600 mL.

The desired final serum sodium should be 145 mmol/L – the upper limit of normal. In this example, the change from 160 to 145 in the serum sodium should be planned over 36 to 48 h to avoid a fall in serum sodium of greater than 10 mmol/L/24 h. Another approach would be to consider the water deficit to be provided in the next 24 h and set the Na measured – Na desired to 10 mmol. Thus, the same patient above a 10 kg infant with a serum sodium of 160 mmol/L:

1. The patient is at least 10% dehydrated. 10% is 1 L. Provide 50 mL/kg isotonic saline (sodium content 154 mmol/L) over 2–4 h. Reassess signs and symptoms, carefully monitor urine volume, and remeasure serum sodium.
2. Continue isotonic fluid therapy over the next 16–20 h to provide an additional 50 mL/kg to replace extracellular volume. Start water deficit replacement. Total body water is 6 L.

   Na measured = 160, Na desired in the next 24 h – 150 assuring the change in sodium is no greater than 10 mmol/24 h. 160−150 = 10.

   Water deficit = 6 L × (10/150) = 400 mL of free water. Slowly provide the free water over 24 h.
3. Continue monitoring serum sodium every 2 h to assure slow decline of serum sodium. Also continue careful measurement of urine volumes and monitoring of signs and symptoms of dehydration.
4. Provide additional free water the next 24 h (200 mL) and initiate maintenance fluids or oral intake.

284 Clinical Disorders Associated with Altered Potassium Metabolism

Farahnak Assadi

Pathophysiology

Ninety-eight percent of total body potassium (K^+) is confined to the intracellular compartment, primarily as a result of the activity of the cell membrane Na^+–K^+–ATPase. The intracellular fluid (ICF) K^+ concentration is approximately 120–150 mEq/L, while extracellular fluid (ECF) K^+ concentration is maintained at about 4 mEq/L. Clinically, a subject with an extracellular K^+ concentration of less than 3.5 mEq/L is referred to as *hypokalemia,* while a subject with an extracellular K^+ concentration of more than 5.5 mEq/L is referred to as *hyperkalemia.*

As a primary intracellular cation, K^+ plays an important role in cell growth and division, in the regulation of enzyme activity, and in volume regulation. The considerable concentration difference between intracellular and extracellular K^+ is also essential to the maintenance of the membrane potential. Changes in the intracellular K^+ concentration can therefore have particularly adverse effects on electrically excitable tissues such as the heart and nervous system. In general, both increases and decreases in plasma K^+ concentration can have adverse effects on neuromuscular activity, can suppress intestinal motility, and can cause ventricular arrhythmias. An increase in extracellular K^+ concentration reduces the resting membrane potential, while a decrease in extracellular K^+ concentration increases the resting membrane potential.

The ability to maintain a stable K^+ concentration is dependent on matching K^+ excretion to K^+ intake. For practical purposes, in a 60-kg person, the ECF volume is 12 L. Therefore, the total amount of K^+ contained within the ECF is 12×4 or 48 mEq. A typical daily diet may contain 100 mEq of K^+, 90% of which is reabsorbed into the body. Since this absorbed K^+ initially enters the ECF space, total K^+ content and therefore concentration could also triple ($48 + 90 = 138$ mEq $\div$ 12 L = 11.5 mEq/L. The marked increase in the plasma K^+ is faster than the kidneys to excrete it. However, this does not occur, since plasma K^+ of 11.5 mEq/L would be lethal. How is this avoided? The fact of the matter is that most of the K^+ absorbed from the gastrointestinal tract is initially rapidly taken up into the intracellular pool to prevent abrupt increases in plasma K^+ concentration. This excess K^+ is then excreted in the urine. To maintain overall body homeostasis, the balance concept dictates that if 90 mEq is taken in daily, then 90 mEq must be eliminated daily by the kidney.

This rapid cellular uptake of K^+ is stimulated by insulin and probably by aldosterone. These hormones increase the activity of the Na^+–K^+–ATPase, particularly in muscle, liver, and adipose tissue. The principal stimulus for increased aldosterone release is a rise in plasma K^+. There is also evidence to suggest that insulin release is K^+ sensitive and has an effect on cellular K^+ uptake through absorption of glucose and amino acids from the gastrointestinal tract.

Renal Handling of Potassium

Under normal condition, the filtered load of K^+ is extremely low (4 mEq/L $\times$ 180 L = 720 mEq/day). Approximately 65% of the filtered K^+ is reabsorbed in the proximal tubule. An additional 25% of the filtered K^+ is reabsorbed by the thick ascending limb of the Henle's loop. Thus, approximately 10% of the filtered load of K^+ (72 mEq/day) is delivered to the distal nephron. However, the kidney typically excretes an amount of K^+ that is equivalent to approximately 20% of the filtered load (144 mEq/day). Since only 10% of the filtered load (72 mEq/day) is delivered to the distal nephron, secretion into the tubular lumen must occur at the level of collecting tubule. This is possible because of the principal cells of the collecting tubule are capable of secreting K^+ into the tubular lumen. The rate of K^+ excretion is determined by rate of K^+ secretion into the collecting tubule.

Under conditions of K^+ deficit, tubular secretion effectively stops, and there is further net reabsorption of K^+ along the late segment of the collecting tubule, thereby reducing K^+ excretion to 1–2% of the filtered load (7–14 mEq/day). In contrast, under conditions of K^+ excess, K^+ excretion may reach levels that are equal to or greater than the filtered load. Suppose that plasma K^+

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_284,

concentration has increased to 6 mEq/L. Under this condition, the daily filtered load of K^+ would be 180 L/day × 6 mEq/L = 1,080 mEq/day. Approximately 10% of the filtered load, or 108 mEq, is delivered to the distal nephron. However, the amount of K^+ excreted would be greater than the filtered load. Since 108 mEq K^+ is delivered to the distal nephron, this suggests that 972 mEq/day of K^+ (1,080 − 108 mEq) must be secreted by the distal and collecting tubules. Obviously, this quantity of excreted K^+ is not delivered exclusively from the ECF compartment but rather from K^+ fluxes into the ECF from intracellular stores. Several factors can affect the rate of K^+ section including plasma K^+ concentration, tubular flow rate, and a change in ECF pH. Hypertonicity, cell lysis, exercise, and a fall in ECF pH (metabolic acidosis) can cause hyperkalemia as a result of enhanced flux of K^+ from ICF to ECF. In comparison, increased ECF pH (metabolic alkalosis) promotes an efflux of H^+ from the ICF. To maintain electrical balance across the membrane, there is a reciprocal flux of K^+ from the ECF to the ICF, thereby reducing ECF K^+ concentration.

The rate of K^+ secretion increases as ECF K^+ concentration increases. Increase in plasma K^+ directly stimulates aldosterone release which, in turn, increases NA^+–K^+–ATPase activity in the collecting tubule. Any reduction in reabsorptive capacity of proximal tubule and thick ascending tubule reduces K^+ reabsorption, and more K^+ is delivered to the collecting tubule under this condition. In addition, if more sodium is delivered to the distal nephron as a result of the upstream diuretic, sodium reabsorption at this site will be increased. The increased sodium entry into cell stimulates basolateral membrane Na^+–K^+–ATPase activity, and therefore increases intracellular K^+ concentration and also increases lumen-negative potential, thereby increasing the electrical gradient for K^+ efflux across this membrane.

Hypokalemia

Mild hypokalemia (>3.0 mEq/L) rarely causes symptoms and may be treated with oral K^+ supplements. Moderate-to-severe hypokalemia (<3.0 mEq/L) generally produces muscle weakness and may lead to cardiac and respiratory failure and require intravenous K^+ supplementation. Other symptoms may include nausea, vomiting, illus, tetany, and cardiac arrhythmias and ECG abnormalities (ST segment depression, short T wave with the appearance of U wave at the end of T wave.

Hypokalemia can result from poor intake, excessive loss from the body, or sudden shift of K^+ from extracellular fluid into cells. The most common causes are excess losses from the kidneys or gastrointestinal tract. The most common mechanisms leading to hypokalemia is increased urinary losses due to increased sodium delivery to distal nephron. Typically, this is often associated with mineralocorticoid excess, use of diuretics, or losses associated with increased urine flow, such as osmotic diuresis. Hypomagnesemia can also cause hypokalemia. Magnesium is required for adequate renal handling of K^+. This may become apparent when hypokalemia persists despite K^+ supplementation. A special case of K^+ loss occurs with diabetic ketoacidosis. In addition to urinary losses from polyuria and volume depletion, there is also obligate loss of K^+ from renal tubules as a cation partner to the negatively charged β-hydroxybutyrate. Familial hypokalemic periodic paralysis is a rare autosomal-dominant disease characterized by transient episodes of profound hypokalemia due to a sudden transcellular shift of K^+ into cells. Episodes are typically precipitated by a large carbohydrate meal or strenuous exercise, but variants have been described without these features.

Diagnostic Approach

It is helpful to proceed to the diagnosis of hypokalemia from the history, physical examination, and laboratory studies in a stepwise fashion. Potential processes that can be identified in the history include diet, vomiting, diarrhea, and the use of laxatives, insulin, diuretics, or bicarbonate supplements and muscle weakness and polyuria. First, check the urinary K^+ excretion in a random urine sample to differentiate between gastrointestinal and urinary losses as the major contributor. Next, evaluate acid–base and blood pressure status to help in the differential (Fig. 284.1).

A random urine K^+ value <15 mEq/L is evidence of appropriate urinary K^+ excretion and suggests poor intake, gastrointestinal losses, or a shift of potassium into cells. If hypokalemia is associated with episodic muscle weakness, then consider hyperthyroidism, familial or sporadic periodic paralysis. In the presence of metabolic alkalosis and a urine K^+ <15 consider surreptitious vomiting or congenital pyloric stenosis. A random urine K^+ value ≥ 15 mEq/L indicates renal K^+ wasting.

In a patient with a urine K^+ >15 who denies diarrhea, consider diabetic ketoacidosis or renal tubular acidosis (RTA-1 and RTA-2) in the presence of metabolic acidosis. The presence of hypertension, coexistent metabolic alkalosis, and urine K^+ >15 indicates that all causes of primary

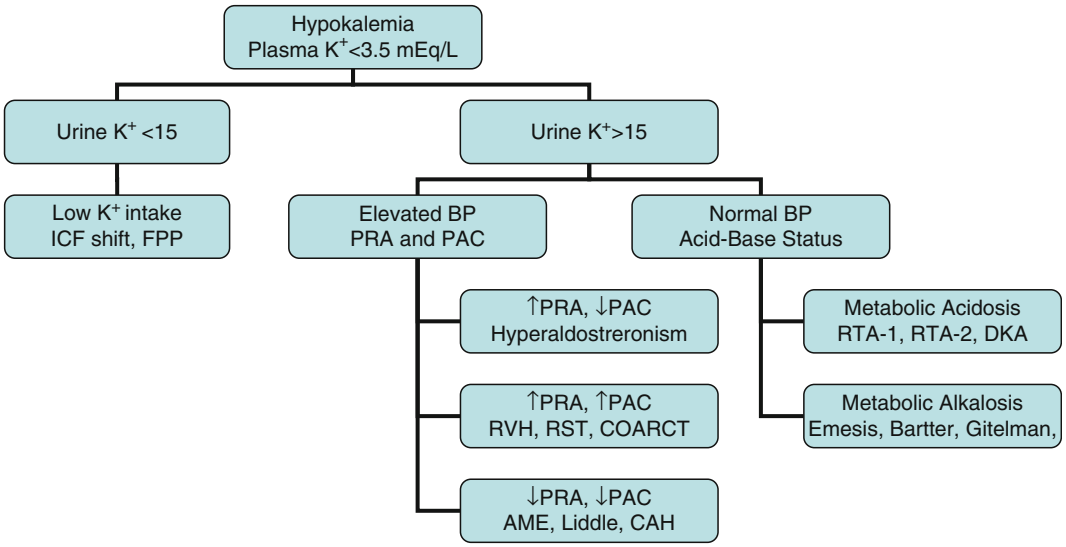

Figure 284.1

Diagnostic algorithm in hypokalemia. *Cr* creatinine, *ICF* intracellular fluid, *FPP* familial periodic paralysis, *BP* blood pressure, *PRA* plasma renin activity, *PAC* plasma aldosterone concentration, *RVH* renal vascular hypertension, *RST* renin-secreting tumor, *COARCT* coarctation of the aorta, *MAE* apparent mineralocorticoid excess, *CAH* congenital adrenal hyperplasia, *RTA* renal tubular acidosis, *DKA* diabetic ketoacidosis

and secondary hyperaldosteronism, Liddle syndrome, diuretic abuse in a patient with hypertension, as well as the various forms of apparent mineralocorticoid excess (AME). Measurements of plasma renin and aldosterone levels are necessary to differentiate these conditions.

Primary aldosteronism should be suspected when plasma renin activity (PRA) is suppressed and plasma aldosterone concentration (PAC) is increased. Secondary hyperaldosteronism (e.g., renal vascular hypertension, rennin-secreting tumor, and coarctation of the aorta) should be suspected when both plasma PRA and PAC are increased.

Liddle syndrome is a rare autosomal-dominant disorder characterized by severe hypertension, metabolic alkalosis, and hypokalemia. Liddle syndrome is caused by a genetic abnormality that increases the activity of the collecting tubule sodium channel in the absence of mineralocorticoid excess.

The presence of AME should be considered when both PRA and PAC are suppressed. The syndrome of AME is an autosomal-recessive form of hypertension in which 11-β hydroxysteroid dehydrogenase is defective. This enzyme converts cortisol to its inactive metabolite, cortisone. Because mineralocorticoid receptors themselves have similar affinitive for cortisol and aldosterone, decreased enzyme activity allows these receptors to be occupied by cortisol, which circulates at much higher plasma level than aldosterone. This can also occur in patients with congenital adrenal hyperplasia (17-α-hydroxylase deficiency) or familial cortisol resistance and in patients with severe Cushing syndrome. Licorice contains glycyrrhetinic acid and mimics the hereditary AME syndrome because it inhibits 11-βhydroxysteroid dehydrogenase. Diagnosis of AME syndrome is usually done by demonstration of an excess of free urinary cortisol over free urinary cortisone in a 24-h urine collection, although genetic testing can identify the congenital defect.

In the absence of hypertension, coexistent metabolic alkalosis associated with urine $K^+ > 15$, high levels of PRA and PAC are consistent with surreptitious vomiting, diuretic abuse, Bartter syndrome, or Gitelman syndrome. Bartter syndrome is caused by mutations in a furosemide-sensitive ion transport mechanism in the loop of Henle and is associated with hypercalciuria. Gitelman syndrome is caused by loss of function mutations in a thiazide-sensitive ion transport mechanism in the distal nephron and is associated with hypocalciuria. The differential rests upon measurement of urine calcium excretion, diuretic screen in urine, and genetic testing. A patient with Gitleman syndrome, unlike patients with Bartter syndrome, their calcium excretion is normal.

Treatment

Intravenous K^+ must be given to patients with severe hypokalemia (serum K^+ <2.5–3.0 mEq/L) or symptomatic (arrhythmias, marked muscle weakness) patients. Typically, 0.9% of saline is infused with 40 mEq KCl per liter at a rate of 10 mEq/h over 3–4 h. Giving intravenous K^+ at faster rate is not recommended as it may predispose to ventricular arrhythmia. Glucose solutions are avoided because elevation in the plasma insulin levels could result in transient worsening of hypokalemia. When giving K^+ intravenously, infusion via central line is encouraged to avoid the rare occurrence of phlebitis. Hypokalemia due to the renal losses of K^+ may be amenable to a K-sparing diuretic such as amiloride or spironolactone, as these diuretics reduce the renal excretion of K^+.

Hyperkalemia

In many patients, the cause of hyperkalemia is multifactorial and never clearly defined. The most common are renal disease, the ingestion of medications known to cause hyperkalemia or aldosterone deficiency. Other less common causes of hyperkalemia include massive crushing injury with resultant muscle damage, burns, high-volume blood transfusions, human immunodeficiency virus infection, tumor lysis syndrome, congenital adrenal hyperplasia, autosomal-dominant pseudohypoaldosteronism type 1, autosomal-dominant pseudohypoaldosteronism type 2 (Gordon syndrome), and hyperkalemic familial periodic paralysis.

The signs and symptoms induced by hyperkalemia are related to impaired neuromuscular transmission. Symptoms generally do not become manifest until the plasma K^+ concentration is >7.0 mEq/L or the rise in plasma K^+ concentration has been rapid. Muscle weakness, respiratory muscle weakness, cardiac conductive abnormalities (tall peaked T wave with shortened QT, prolonged PR interval, and wide QRS) are the most common manifestations. Other symptoms related to the underlying cause may be present, such as hypertension, renal failure, or diabetes mellitus.

Asymptomatic patients with a plasma K^+ concentration of <6.5 mEq/L whose electrocardiogram does not manifest signs of hyperkalemia can be treated with a cation exchange resin, a low potassium diet, and diuretics. In comparison, patients with plasma K^+ concentration of $\geq$ 7.0 mEq/L with severe muscle weakness or cardiac conduction abnormality require immediate treatment. The quickest, most efficient way to remove K^+ is through the use of hemodialysis. Hemodialysis should be instituted in patients with renal failure or if emergency treatment is ineffective.

Diagnostic Approach

The diagnosis of hyperkalemia must be considered in any patient with clinical risk factors that would predispose them to its development. Measurement of urinary K^+ excretion is of limited value in patients with persistent hyperkalemia, as most patients have underlying renal dysfunction, aldosterone deficiency, or are taking a medication known to impair urinary K^+ excretion. Patients should be questioned about the use of any drug that can impair K^+ excretion, such as angiotensin converting enzyme inhibitors, K^+-sparing diuretics, nonsteroidal anti-inflammatory drugs, heparin, cyclosporine, or the presence of a disease that can impair K^+ excretion such as diabetes mellitus, renal failure, Addison disease, and acquired immune deficiency syndrome. These conditions can be differentiated by measurement of serum electrolytes, BUN, creatinine, plasma renin activity, plasma aldosterone, and cortisol levels. Hyperkalemic patients with normal renal function, normal sodium handling, and aldosterone release who deny taking any medication probably have a selective impairment of K^+ secretion (*Fig. 284.2*).

Treatment

The initial treatment of severe hyperkalemia should be the infusion of calcium. Calcium antagonizes the effects of hyperkalemia at the cellular level to prevent the development of fatal cardiac arrhythmias. Calcium gluconate is the preferred preparation of intravenous calcium. The dose should be 10 mL of a 10% calcium gluconate solution infused over 2–3 min.

The effects of intravenous calcium occur within 1–3 min but last for only 30–60 min. Therefore, further, more definitive treatment is needed to lower serum potassium levels. Insulin, with glucose, and β_2-adrenergic agonists should then be quickly administered to decrease extracellular K levels. Intravenous insulin (10 units) is typically given, followed by close monitoring of serum blood sugar. Fifty milliliter of 50% dextrose is frequently coadministered with insulin in normoglycemic patients to prevent hypoglycemia. The effect of the insulin is seen within 10–20 min of administration and can be expected to decrease K^+ level by 0.6–1.0 mEq/L.

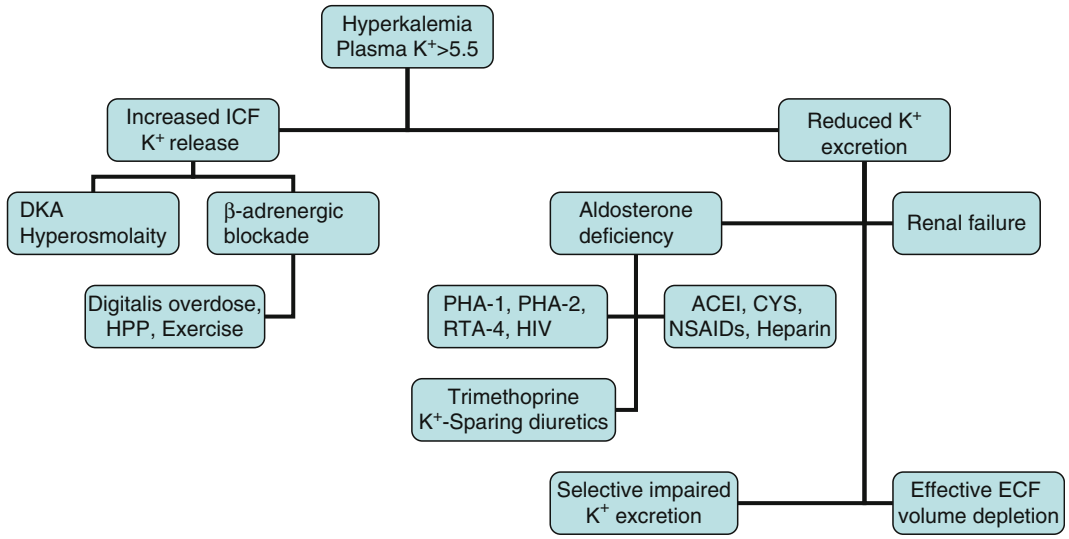

Figure 284.2

Nebulized albuterol, when given in very high doses (10–20 mg), can safely lower plasma K^+ level by 0.5–1.5 mEq/L. The onset of action for inhaled albuterol is immediate and lasts for 1–2 h. Sodium bicarbonate infusion can shift K^+ from the extracellular to intracellular space by increasing blood pH. However, sodium bicarbonate therapy has little use in the routine treatment of hyperkalemia unless severe metabolic acidosis is present or there is another indication for its administration. Ion exchange resins can be administered orally or rectally and work by exchanging gut cations, most importantly K^+, for sodium ions that are released from the resin. Most studies have found exchange resins to decrease serum K^+ levels by about 1 mEq/L over a 24-h period.

Exchange resins can cause significant constipation and are typically given in combination with a laxative such as sorbitol. Although generally safe, the combination of a resin and sorbitol has been reported to cause intestinal necrosis, and as such should be used cautiously and only when necessary.

Case Study

A 15-year-old girl was referred for evaluation of hypokalemia. She has no significant past medical history and denies the use of any medications. Recently, she began to experience occasional fatigue and muscle weakness during exercise. She also noted occasional abdominal pain for which she saw her regular physician. Laboratory studies in the office indicated hypokalemia and she was referred to you for evaluation. Repeat laboratory data show hemoglobin 13 g/dL, BUN 16 mg/dL, serum creatinine 1.0 mg/dL, sodium 140 mEq/L, K^+ 2.4 mEq/L, chloride 101 mEq/L, $HCO3^-$ 32 mEq/L, calcium 9.0 mg/dL, phosphate 3.9 mg/dL, magnesium 1.2 mg/dL, and albumin 4.6 g/dL.

If we proceed in a stepwise fashion to make the diagnosis, which study would be the best initial laboratory study for the diagnosis of the altered electrolytes disorders?

(a) Urine diuretic screen
(b) 24-h urine for calcium, magnesium, and creatinine
(c) Plasma renin and aldosterone levels
(d) Arterial blood gas
(e) 24-h urine for sodium, K^+, and creatinine

The answer is b. Measurement of the urinary magnesium excretion will help to distinguish between gastrointestinal loss of magnesium and renal magnesium wasting.

The urinary magnesium excretion was 120 mg/day, the urinary calcium 485 mg/day, and urinary creatinine 820 mg/dL.

Which diagnoses should receive further consideration (select all that apply)?

(a) Primary aldosteronism
(b) Bartter syndrome
(c) Laxative abuse
(d) Primary renal magnesium wasting
(e) Loop diuretic abuse
(f) Gitelman syndrome

The answers are b and e. Metabolic alkalosis, hypercalciuria (calcium to creatinine ratio 0.59), renal magnesium wasting, and hypomagnesemia all can occur in Bartter syndrome. Diuretic abuse is also a good choice because it causes the same type of transport defect.

Which study would you like now to differentiate between Bartter syndrome and diuretic abuse?

(a) Urine diuretic screen
(b) 24-h urine for calcium, magnesium, and creatinine
(c) 24-h urine for sodium, K^+, and creatinine
(d) Plasma renin and aldosterone levels

The answer is a. A diuretic screen is the only way to rule out diuretic abuse.

The urine diuretic screen was negative. However, the laboratory calls to tell you that the urinary calcium excretion in the 24-h collection was misreported – the correct value is 120 mg/24-h, not 485.

What is the likely diagnosis now? (select all that apply)

(a) Bartter syndrome
(b) Gitelman syndrome
(c) Primary aldosteronism
(d) Primary renal magnesium wasting

The answer is b. Gitelman syndrome is the only one of these conditions which is associated with hypercalciuria. Gitelman syndrome is a variant of Bartter syndrome, characterized by hypokalemia, hypomagnesemia, hypocalcemia, and hypovolemia.

Which ONE of the following statements is true?

(a) Hypokalemia can alter the renal handling of magnesium and cause hypomagnesemia
(b) Hypomagnesemia can alter the renal handling of K^+ and cause hypokalemia
(c) Both statements are true
(d) Neither statement is true?

The answer is b. Hypomagnesemia causes renal K^+ wasting likely by opening K^+ channels in the cortical thick ascending limb of the Henle's loop. For this reason, the diagnosis of combined hypokalemia and hypomagnesemia is best approached by considering causes of hypomagnesemia.

Case Study

A 19-year-old female who has had diabetes mellitus for more than 7 years was admitted to the emergency department because of a recent history of pneumonia. The diabetes has been in good control as a result of dietary measures and the use of oral hypoglycemic drug. She lost her appetite and noted more frequent voiding especially during the night. On examination, she was acutely ill, her mucous membranes were dry, temperature 38.5 C, blood pressure 127/75 mmHg, heart rate 130 beats/min, and respiratory rate 24 breaths/min. Urine was collected for 1 h, and the volume was 250 mL. Urinalysis revealed pH 6.0, specific gravity 1.012, glucose, 4+, ketones, trace, blood and protein negative. Urine osmolality was 305 mosm/kg, sodium 25 mEq/L, and K^+ 30 mEq/L. A venous blood sample revealed sodium 132 mEq/L, K 5.8 mEq/L, chloride 90 mEq/L, bicarbonate 24 mEq/L, glucose 750 mg/dL, creatinine 1.5 mg/dL, and BUN 40 mg/dL.

Which ONE of the following statements about this patient's potassium stores is MOST correct?

(a) The total body K^+ is increased due to volume contraction
(b) The total body K^+ is reduced due to osmotic diuresis
(c) Total body K^+ is increased due to metabolic acidosis
(d) The total body K^+ is normal

The correct answer is b. This patient was experiencing many of the symptoms of uncontrolled diabetes mellitus such as high blood glucose concentration and high glucose content of the urine. Plasma K^+ concentration is in the hyperkalemic range. High blood glucose concentration creates an osmotic driving force for efflux of water out of the intracellular space. As a result, intracellular K^+ concentration rises, which in turn increases the efflux of K into the ECF. The lack of insulin or reduced responsiveness to endogenous insulin also reduces the uptake of K^+ into intracellular stores. The urine volume was also very high. The 1-h collection of 250 mL translated to a daily urine output of 6 L. This increased urine output was caused by the high filtered load of glucose, which acts as an osmotic diuretic, and the increased urine flow rate contributed to the high rate of K^+ excretion of 180 mEq/day. Since this patient was not eating as a result of the pneumonia, this rate of K^+ excretion almost certainly exceeded intake. Therefore, despite an elevated

extracellular K^+ concentration, her total body K was probably reduced.

Which ONE of the following evaluation strategies would be MOST appropriate when ACE inhibitor is initiated in a patient with serum creatinine of 2.6 mg/dL and urinary protein excretion of 2.0 g/day?

(a) Evaluate serum K^+ and creatinine levels 2 weeks after initiating therapy, and stop therapy if hyperkalemia cannot be controlled by loop diuretics and dietary counseling, or if the serum creatinine increases >30% over baseline level.
(b) Evaluate serum K^+ and serum creatinine 2 months after initiating therapy
(c) Use of ACE inhibitor is contraindicated in such patient
(d) Such therapy should only be used in patients with type 1 diabetes mellitus

The correct answer is a. The risk of hyperkalemia in patients who would benefit from ACE inhibitor therapy can be minimized by the appropriate use of diuretics, a low potassium diet, and the use of low dose of potassium-binding resin. If metabolic acidosis is present, sodium bicarbonate should be given.

Case Study

A 17-year-old boy with type 1 diabetes mellitus and chronic renal disease develops muscle weakness. Laboratory data include serum sodium 128 mEq/L, K^+ 7.4 mEq/L, bicarbonate 15 mEq/L, Bun 63 mg/dL, creatinine 3.1 mg/dL, and glucose 276 mg/dL. When an electrocardiogram shows peaked T wave, he is given calcium gluconate.

In addition to this treatment, which ONE of the following would be the most consistently effective therapy for his hyperkalemia?

(a) Subcutaneous insulin and a slow intravenous infusion of glucose
(b) β2-adrenergic agonist
(c) Intravenous insulin
(d) Intravenous bicarbonate
(e) Oral cation exchange resin (Kayexalate)

The answer is c. Insulin directly activates Na^+–K^+–ATPase, augmenting cellular uptake of K^+. Concurrent administration of glucose is only necessary to prevent hypoglycemia Administration of 20 units of intravenous insulin causes a 1-mEq/L decrease in serum K^+ in less than 1 h. Intravenous insulin is preferable to subcutaneous insulin because the bolus infusion produces much higher plasma insulin level. β2-adrenergic agonist, like albuterol, also activates Na^+–K^+–ATPase, but approximately 20% of patients are resistant to this therapy and it is not possible to predict who will not respond. Serum bicarbonate and the cation exchange resin (Kayexalate) take several hours to lower the serum K^+ level.

285 A Practical Approach to Metabolic Acidosis

Farahnak Assadi

Pathophsiology

Hydrogen (H^+) concentration in the body is governed by a balance between intake and output. Most H^+ in the body is generated indirectly in the cells from formation of the ingested nutrients. It is the free H^+ concentration in the body (measured as pH) that is physiologically important. At a normal plasma pH of 7.40, the free H^+ concentration is 40 nmol/L. Metabolism of carbohydrates, proteins, and fats in the cells can generate a large amount of free H^+. However, the buffer system, the lungs, and the kidneys act in an integrated fashion to minimize any change in free H^+ concentration. Buffers are molecules that accept or donate free H^+. Phosphate, HCO_3^-, protein and hemoglobin are some of the most important buffers in the body.

The kidney regulates plasma HCO_3^- by secreting H^+ into the tubular lumen and returning HCO_3^- to the blood. The kidney forms titratable acids by combining H^+ with buffers in the tubular fluid. The H^+ generated from CO_2 and H_2O by carbonic anhydrase in the cell is secreted into the tubule lumen and combines with a titratable acid (HPO_4^{2-} to H_2PO_4). The titratable acids are then excreted in the urine. In the process of secreting H^+, the kidney simultaneously replenishes the plasma HCO_3^- used in the buffering. The net result is excretion of a bound H^+ and the formation of new HCO_3^-, which is added to the body. Although HPO_4^{2-} is the major titratable acid in the urine, any compound that can combine with the secreted H^+, including creatinine, sulfate, and the anion of fatty acids, may serve the function of a titratable acid and be excreted in the urine.

The kidney also forms NH_4^+ in the tubule fluid by combing secreted H^+ with lipid soluble NH_3 generated by the renal tubule cells ($NH_3 + H^+ \leftrightarrow NH_4^+$). The resulting NH_4^+ in the tubular fluid is lipid insoluble and is trapped. The NH_4^+ is then excreted in the urine, and the HCO_3^- is returned to the body as new HCO_3^-. Chronic increases in plasma H^+ concentration stimulates the production of NH_3 by the renal tubule cells.

The primary function of the kidney in the regulation of acid–base balance is to conserve the body store of HCO_3^- and maintain the plasma HCO_3^- concentration constant. Increased filtered HCO_3^-, increased plasma H^+ concentration, and increased arterial P_{CO2} increase renal tubular H^+ secretion and HCO_3^- generation. Aldosterone increases tubular H^+ secretion and HCO_3^- generation by stimulating H^+-ATPase in the distal nephron. Aldosterone also stimulates Na^+ reabsorption in distal nephron, resulting in increased H^+ secretion.

The simplest way to increase the body HCO_3^- stores is to increase its generation in the kidney. However, the major stimulus for HCO_3^- generation in the renal tubular cells is the arterial P_{CO2}, but because of the respiratory compensation, the P_{CO2} is decreased. Where then is the stimulus for increased HCO_3^- generation? The answer to this question lies in the quantitative relationship between the filtered load of HCO_3^- and H^+ secreted by the kidney. It has been shown that in both metabolic acidosis and metabolic alkalosis there is an advantageous physiologic mismatch between filtered HCO_3^- and the amount of H^+ secreted, so that the plasma HCO_3^- concentration eventually returns to normal levels. Therefore in the case of metabolic acidosis, the H^+ secretion is decreased, but it is still sufficient to reabsorb all the filtered HCO_3^- and increase the amount of new HCO_3^- (50–60 mEq) returned to the plasma as a result of the formation of titratable acids and NH_4^+. For every titrarable acid and NH_4^+ excreted in the urine, a new HCO_3^- is added to the plasma. The relationship between plasma HCO_3^- and P_{CO2} can be accurately estimated as determined by the Henderson–Hasselback equation:

$$[H^+] = 24(P_{CO2}) \div (HCO_3^-)$$

Diagnostic Approach

A metabolic acidosis can be characterized by decreased plasma HCO_3^- and a compensatory decrease in arterial P_{CO2}. The respiratory compensation for a metabolic

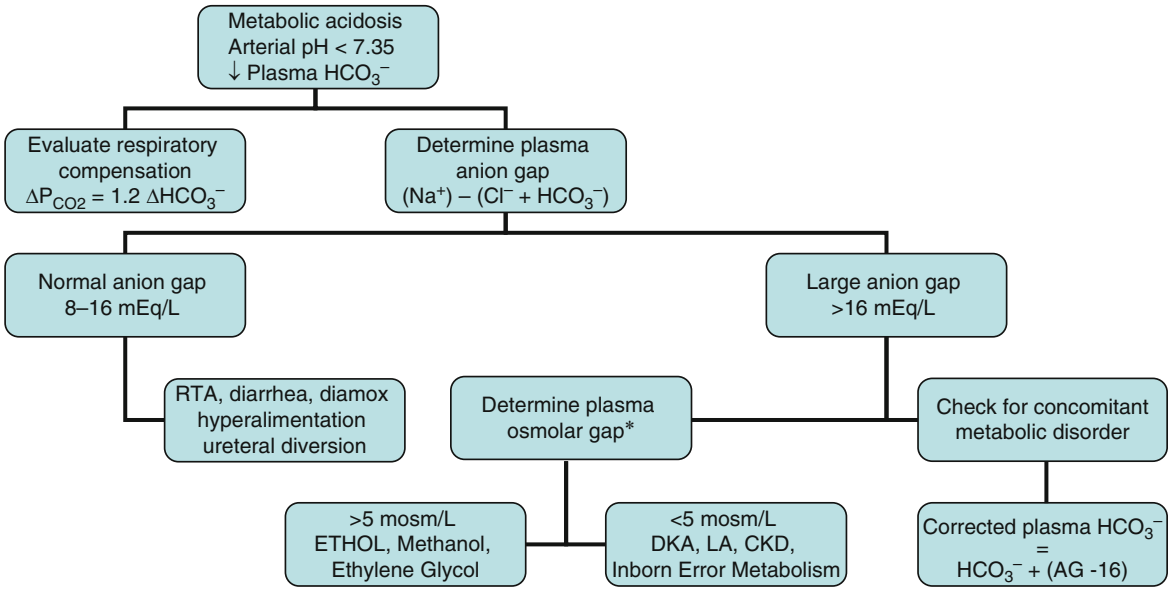

Figure 285.1

Diagnostic algorithm in patients with metabolic acidosis. DKA; diabetic ketoacidosis LA; lactic acidosis, CKD, chronic kidney disease. *osmolar gap is calculated as the differences between measured plasma osmolality and estimated plasma osmolality [2 (Na^+) + (BUN/mg/dL ÷ 2.8) + (glucose/mg/dL ÷ 18)]

acidosis is hyperventilation and an appropriate decrease in arterial P_{CO2} to minimize the acid–base disturbance. The diagnostic approach to metabolic acidosis utilizes information from the history and physical examination, and laboratory studies in a stepwise fashion (*Fig. 285.1*).

Step 1: Review history and physical examination – Identify potential processes in the history, and recognize the situations that often are associated with metabolic acidosis and review the physical examination for clue to diagnosis. Potential processes which can be identified in the history include diarrhea, diabetic ketoacidosis, renal failure, hypotension, hypoxia, sepsis, cardiopulmonary arrest, and inborn error of metabolism.

Step 2: Evaluate serum electrolytes and calculate serum anion gap – Diagnosis of the underlying causes of metabolic acidosis can be simplified by determining whether the disorder is associated with an increased or a normal anion gap. The anion gap is the concentration differences between the major cation, sodium, and the two major anions, chloride and HCO_3^-. In a normal individual, it typically ranges between 10 and 16 mEq/L with the sodium concentration greater than the sum of the chloride and HCO_3^- concentrations. This does not mean that the plasma is not electrically neutral. The anions are there, but they are simply not measured during a routine chemical analysis of the plasma.

$$\text{Anion gap} = (Na^+) - (Cl^- + HCO_3^-)$$

Metabolic acidosis occurring with a normal anion gap is usually caused by either gastrointestinal bicarbonate loss or renal tubular acidosis and the use of carbonic anhydrase inhibitors. Normal anion gap acidosis has also been reported in ureteral diversions, NH_4Cl infusions, and during hyperalimentation. The anion gap acidosis can be divided into five major categories: (1) renal failure; (2) ketoacidosis (diabetes, hypoglycemic ketoacidosis); (3) lactic acidosis (hepatic failure, circulatory failure, sepsis); (4) drugs and poisons (salicylate, paraldehyde, ethanol, ethylene glycol); and (5) inborn errors of metabolism. One important exception must be considered at this point. First, a patient may have an anion gap acidosis even with a normal anion gap. Because one of the most important unmeasured anions is albumin, a patient who is severely hypoalbuminemic may have a normal anion gap of only 4 or 5. In such a patient, an anion gap of 12 would represent a significant elevation and indicate the presence of an anion gap acidosis. Disorders associated with low serum albumin levels include cirrhosis, nephrotic syndrome, and severe malnutrition.

Step 3: Assess the degree of respiratory compensation – Is the respiratory system compensating adequately? The response of the respiratory system (i.e., the degree of

hyperventilation) is predictable because there is a linear relationship between P_{CO2} and serum HCO_3^- concentration in metabolic acidosis. In simple metabolic acidosis for each mEq decrease in HCO_3^- there is a 1.2 mEq decrease in the arterial P_{CO2}.

$$\text{Expected fall in } P_{CO2} = 1.2(25 - \text{patient's } HCO_3^-) \text{ or}$$
$$\Delta P_{CO2} = 1.2\ \Delta HCO_3^-$$

To illustrate, a patient with a measured serum HCO_3^- level of 10 mEq/L should have a P_{CO2} of 22 mmHg [(ΔP_{CO2} = 1.2 ΔHCO_3^- or 18; P_{CO2} (40–18)]. If this patient's P_{CO2} is outside the range of 22 mmHg, a primary respiratory disorder exists in addition to the metabolic acidosis. In this case, a $P_{CO2} < 22$ mmHg indicates a concomitant primary respiratory alkalosis. If the same patient had a $P_{CO2} > 22$ mmHg, a primary respiratory acidosis would be indicated even though the P_{CO2} is subnormal.

Step 4: **Identify concomitant metabolic disorder** – Is the anion gap increased above normal value (>16 mEq/L)? If yes, there should be concordance between the fall in the HCO_3^- concentration and the increase in anion gap. This relationship works because, for each mEq increase in the anion gap, there is a mEq decrease in the serum HCO_3^- concentration.

As an example, a patient who presents with diabetic ketoacidosis has serum HCO_3^- of 15 mEq/L and anion gap of 26 mEq/L. The anion gap has increased by 10 mEq/L from a normal value of 16 mEq/L. The HCO_3^- has fallen by 10 from a normal value of 25. Therefore, the concordance in the change in the HCO_3^- and the anion gap is consistent with a simple disturbance of metabolic acidosis.

$$\text{Corrected } HCO_3^- = \text{patient's } HCO_3^- + (\text{aniongap} - 16)$$

However, if the values were HCO_3^- 10 mEq/L and anion gap 22 mEq/L, concordance. would be lacking because the anion gap had increased by 6 from the normal value while the HCO_3^- had fallen by 15 from the normal value. Thus, some process in addition to increased metabolic acid production is contributing to the fall in HCO_3^- without affecting anion gap. This could be due to a concomitant respiratory acidosis or a mixed anion gap acidosis with a normal anion gap acidosis.

Case History

A 10-year old girl is brought to the emergency department because of increasing weakness. She has been having low grade fever and severe diarrhea for 4 days. Laboratory studies reveal sodium 140 mEq/L, potassium 2.4 mEq/L, chloride 115 mEq/L, HCO_3^- 15 mEq/L, BUN 18 mg/dL, creatinine 0.6 mg/dL, glucose 90 mg/dL, calcium 9.5 mg/dL, and plasma osmolality 284 mosm/L.

What Do You Estimate Her Arterial pH and p_{CO2} to be?

A. 7.20
B. 7.25
C. 7.30
D. 7.35
E. 7.40

The answer is C. The acid–base disturbance diagnosis is a simple metabolic acidosis due to severe diarrhea. This would allow estimating her P_{CO2} using the following equation:

$$\Delta P_{CO2} = 1.2(\Delta HCO_3^-) \text{ or } 12 \text{ mmHg}$$

$$\text{Predicted } P_{CO2} = 40 - 12 \text{ or } 28 \text{ mmHg}$$

The pH can then be calculated with the modified Henderson–Hasselback equation:

$$H^+ = 24(P_{CO2}) \div HCO_3^-$$

The value obtained is 45 nmol/L, which is equivalent to a pH of 7.35 (every 0.1 fall in pH is equivalent to a 10 nmol rise in blood H concentration).

Case History

A 19-year old male was found unconscious on the street and was brought into the emergency room. The patient was stuporous without focal neurological signs. Temperature was 37°C, blood pressure 120/80 mmHg, pulse 80 beats/min, and respiratory rate 20/min. Examination of the head, eyes, ears, nose, and throat was unremarkable. Chest was clear to auscultation and percussion. The remainder of the physical examination was unremarkable. Laboratory data showed a serum sodium concentration of 144 mEq/L, potassium 4.6 mEq/L, chloride 103 mEq/L, HCO_3^- 15 mEq/L, BUN 20 mg/dL, creatinine 0.7 mg/dL, and glucose 95 mg/dL. Serum ketones were trace positive and serum osmolality was 330 mosm/L. An arterial pH was 7.34 and P_{CO2} 28 mmHg.

What Is the Acid–Base Diagnosis?

A. Metabolic acidosis with respiratory acidosis
B. Metabolic acidosis with respiratory compensation
C. Metabolic compensation for respiratory alkalosis
D. Metabolic alkalosis with respiratory compensation

The answer is B. The blood gas data are compatible with anion gap metabolic acidosis and an appropriate respiratory compensation. The plasma HCO_3^- concentration decreased by 10 mEq/L and the P_{CO2} is depressed by 12 mmHg ($\Delta P_{CO2} = 1.2\ \Delta HCO_3^-$). Thus, the predicted P_{CO2} is 28 (40–12) mmHg. This level of respiratory compensation is appropriate for the steady state level of HCO_3^-.

What Is the Likely Cause of the Anion Gap Metabolic Acidosis in This Patient?

A. Alcohol intoxication
B. Primary lactic acidosis
C. Toxic ingestion (methanol, ethylene glycol)
D. Renal failure
E. Starvation ketoacidosis

The answer is A. The anion gap is 26 and it has increased by 10 from a normal value of 16 mEq/L. The HCO_3^- has also fallen by 10 from a normal value of 25 mEq/L. Thus, the concordance in the HCO_3^- and the anion gap is consistent with a simple metabolic disturbance. The potential causes of anion gap metabolic acidosis include starvation ketoacidosis, diabetic ketoacidosis, alcohol intoxication, methanol intoxication, ethylene glycol intoxication, lactic acidosis, inborn error of metabolism, and renal failure. In this patient, blood ketones are only trace positive, and the serum creatinine and blood glucose levels are normal. However, the measured serum osmolality is considerably higher than the estimated osmolality.

The difference between the measured and the estimated serum osmolality is often termed the osmolal gap. Methanol intoxication, ethylene glycol intoxication, and alcohol intoxication are disorders associated with anion gap metabolic acidosis and increased serum osmolality (osmolar gap). The measured serum osmolality in this patient was 330 mosm/L and the estimated serum osmolality 300 mosm/L ($2\ Na^+$ + BUN (mg/dL) ÷ 2.8 + glucose (mg/dL ÷18), giving an osmolal gap of 30 mosm/L. The patient had no oxalate crystals in the urine as found in the ethylene glycol intoxication and there was no evidence of optic papillitis on fundoscopic examination as might be anticipated in a patient with methanol intoxication. Thus, this patient's clinical and laboratory studies are consistent with acute alcohol intoxication. A very high blood alcohol level supported this diagnosis.

Case History

You are asked to see a 4-year old boy found to be stuporous at home. On examination, he appears well developed; stuporous; his temperature is 37°C; blood pressure, 114/65 mmHg; pulse, 88 beats/min; respiratory rate, 34/min; weight, 25 kg; and height, 88 cm. The heart rate is regular; there are no extra sounds or murmurs. The lungs are clear without rales or rhonchi. The abdomen is soft without palpable masses or organomegaly. Bowel sounds are present. There is no edema. Several ecchymoses are present over his trunk and limbs. Laboratory data reveals serum sodium 140 mEq/L, potassium 3.8 mEq/L, chloride 108 mEq/L, HCO_3^- 13 mEq/L, BUN 14 mg/dL, creatinine 0.6 mg/dL, glucose 89 mg/dL, calcium 9.3 mg/dL, albumin 4.0 g/dL, ketones 2+, plasma osmolality 284 mosm/L, arterial pH 7.36, and P_{CO2} 20 mmHg.

What Is the Acid–Base Diagnosis? (Select All that Apply)

A. Metabolic acidosis and respiratory acidosis
B. Metabolic alkalosis and respiratory acidosis
C. Metabolic acidosis and respiratory alkalosis
D. Metabolic alkalosis and respiratory alkalosis

The answer is C. This is a mixed disturbance of metabolic acidosis and chronic respiratory alkalosis. The P_{CO2} is decrease by 20 and the plasma HCO_3^- is decreased by 12. If this were a single metabolic acidosis, the fall in P_{CO2} should be 14 ($\Delta P_{CO2} = 1.2\ \Delta HCO_3^-$) and as a result the predicted P_{CO2} should be 26 (40 − 14) not 20. Therefore, there is a mixed disturbance with metabolic acidosis and respiratory alkalosis. Laboratory data also reveal that the anion gap is 19, and it has increased by 3 from a normal value of 16 mEq/L. The increased anion gap is consistent with the presence of large anion gap metabolic acidosis. However, the fall in bicarbonate concentration (−12 mEq/L) is greater than the increase in the anion gap (+9 mEq/L) suggesting the presence of another process which lowers the HCO_3^-; either chronic respiratory alkalosis or non-anion gap metabolic acidosis. The physical exam suggests that hyperventilation is present, which could indicate severe acidosis or primary alkalosis. The combination of anion gap metabolic acidosis and primary respiratory alkalosis occurs in several situations including

sepsis, salicylate intoxication, and the lactic acidosis in a patient with liver failure. Salicylate intoxication is the likely diagnosis in this patient in view of the presence of ecchymoses.

Case History

A 17-year old male was admitted to the emergency department in a semicomatose condition. Blood pressure was 110/70 mmHg; pulse, 87/min; and respiratory rate, 22/min. Laboratory data on admission revealed serum sodium of 135 mEq/L, potassium 2.1 mEq/L, chloride 111 mEq/L, and HCO_3^- 10 mEq/L. Arterial blood pH was 7.1 and P_{CO2} 33mmHg. Urinalysis showed a pH of 7.0. The urine sediment was normal. The patient was intubated, and potassium was given intravenously.

What Is the Most Likely Diagnosis? (Select All that Apply)

A. Proximal renal tubular acidosis (RTA-2)
B. Distal renal tubular acidosis (RTA-1)
C. Hyperkalemic distal renal tubular acidosis (TRA-4)
D. All of the above

The answer is B. The clinical diagnosis is distal renal tubular acidosis (RTA-1). This patient has normal anion gap metabolic acidosis and hypokalemia with an inappropriately high urine pH. The normal anion gap metabolic acidosis is complicated with respiratory acidosis. If this were a single metabolic acidosis, the fall in P_{CO2} should be 18 ($\Delta P_{CO2} = 1.2\ \Delta HCO_3^-$) and as a result the predicted P_{CO2} should be 22 (40–18) not 30. Therefore, there is a mixed disturbance with metabolic acidosis with respiratory acidosis. The respiratory acidosis is likely the result of weakness of the muscles of respiration secondary to profound hypokalemia.

The classic feature of distal RTA (RTA-1) is the presence of a normal anion gap metabolic acidosis with a urine pH that is persistently above 5.5 (*Fig. 285.2*). In addition to this defect in acid–base balance, K^+ is also frequently abnormal in this disorder. In most cases, hypokalemia is observed because, since H^+ excretion is impaired, more Na^+ must be reabsorbed in the cortical collecting tubule in exchange for K^+ to maintain electroneutrality. Type 1 RTA is frequently associated with renal calculi and nephrocalcinosis. Reduced excretion of citrate, a urinary inhibitor of calcium stone formation, is the principal cause for nephrolithiasis in distal RTA. In children, growth failure and bone disease are also observed. Autoimmune diseases like Sjogren syndrome, thyroiditis, and chronic active hepatitis are the major causes of this condition in adults, whereas hereditary RTA is most common in children. Amphotericin B is known to cause RTA-1.

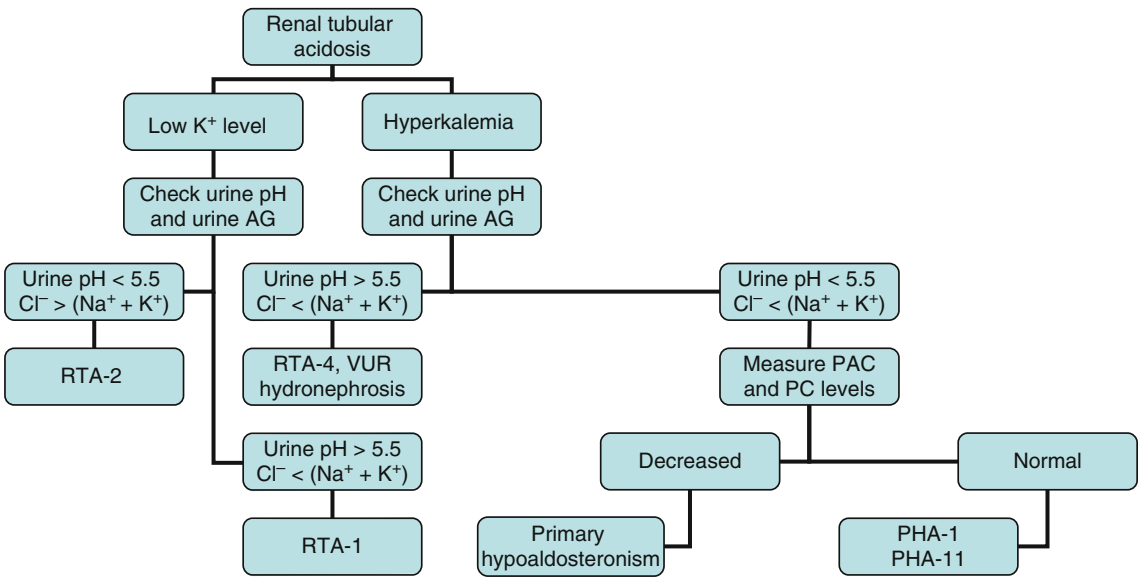

Figure 285.2
Diagnostic algorithm in renal tubular acidosis (RTA). AG; urine anion gap (Na^+, K^+, Cl^-), PAC; plasma aldosterone concentration, PC; plasma cortisol, PHA; psudohypoladosteronism

What Investigations Were Needed in the Emergency Department to Confirm the Diagnosis? (Select All that Apply)

A. Flat plate film of abdomen
B. Kidney ultrasound
C. Measurement of urine anion gap (Na^+, K^+, and Cl^-)
D. MRI of the brain

The answers are A, B, and C. A flat plate of the abdomen taken in the emergency department demonstrated bilateral nephrocalcinosis, a typical feature of this type of distal renal tubular acidosis, a finding never seen in proximal renal tubular acidosis. Measurement of the urinary anion gap is useful in the differentiation between proximal and distal renal tubular acidosis. A positive urine anion gap ($Na^+ + K^+ > Cl^-$) suggests distal renal tubular acidosis (RTA) type 1 or type 4. Measurement of serum potassium can be helpful in the differentiation between these disorders. In classic distal renal tubular acidosis (RTA-1), serum potassium level is markedly low. In comparison, an elevated serum potassium level suggests the presence of hyperkalemic distal RTA (RTA-4).

286 A Practical Approach to Metabolic Alkalosis

Farahnak Assadi

Pathophysiology

Metabolic alkalosis is the result of an increased plasma HCO_3^- concentration. The increased HCO_3^- results in a decreased H^+ concentration. The respiratory compensation for metabolic alkalosis is hypoventilation and the arterial P_{CO_2} increases. The appropriate renal response should be decreased HCO_3^- reabsorption and loss of HCO_3^- in the urine to lower the plasma HCO_3^- concentration. However, the respiratory compensation for metabolic alkalosis is not nearly as powerful as the respiratory compensation for metabolic acidosis. In severe cases of metabolic acidosis, the P_{CO_2} may fall to less than 20 mmHg, while in metabolic alkalosis the P_{CO_2} may increase by a few mmHg. This happens because increased arterial P_{CO_2} is a very potent stimulus to increase ventilation and thus P_{CO_2} slightly increases. Nevertheless, the relationship between plasma HCO_3^- and P_{CO_2} is predictable; that is, if the plasma HCO_3^- is known, the P_{CO_2} can be accurately estimated as determined by the Henderson–Hasselbalch equation

$$[H^+] = 24(P_{CO_2}) \div (HCO_3^-)$$

How then does the kidney decrease HCO_3^- reabsorption in the presence of increased arterial P_{CO_2}? The answer to this question lies in the quantitative relationship between the filtered load of HCO_3^- and H^+ secreted by the kidney. It has been shown that in both metabolic acidosis and metabolic alkalosis there is an advantageous physiologic mismatch between filtered HCO_3^- and the amount of H^+ secreted, so that the plasma HCO_3^- concentration eventually returns to normal levels. In the case of metabolic alkalosis, the plasma HCO_3^- concentration is increased. The appropriate respiratory compensation increases the arterial P_{CO_2} and the H^+ secretion will increase, but the increase in P_{CO_2} is inadequate to reabsorb all filtered HCO_3^-. As a result, the HCO_3^- will be lost in the urine, and plasma HCO_3^- concentration will decrease.

Diagnostic Approach

The first step in the diagnosis of metabolic alkalosis is to determine the acid–base condition of the blood. This can be determined by looking at the arterial pH. Any value greater than 7.40 is considered alkalosis. The second step is to identify the primary cause of alkalosis. There are only two possibilities for alkalosis. Either the arterial P_{CO_2} is decreased (respiratory alkalosis) or the plasma HCO_3^- is increased (metabolic alkalosis). Metabolic alkalosis is characterized by increased plasma HCO_3^- concentration and a compensatory increase in arterial P_{CO_2}. The next step is to determine the quantitative relationship between the change in the metabolic alkalosis and the change in the respiratory response. In an otherwise healthy individual with metabolic alkalosis, a 1 mEq/L increase in plasma HCO_3^- concentration should result in a 0.6 mmHg increase in arterial P_{CO_2} ($\Delta P_{CO_2} = 0.6\ \Delta\ HCO_3^-$). If the patient's blood gas agree with the predicated changes, a single disorder is most likely. If they do not, more than one disorder should be considered (mixed disorder). The next most important step is the determination of the cause of sustained metabolic alkalosis.

At least two mechanisms allow metabolic alkalosis to persist, and they are both related to the volume contraction and chloride depletion (Fig. 286.1). One mechanism by which the kidney reacts to volume depletion is to increase the proximal tubular reabsorption of filtered HCO_3^-. A second and probably the most important mechanism is related to the renin–angiotensin–aldosterone system. A decrease in the effective circulating volume leads to activation of the renin–angiotensin system and a subsequent increase in plasma aldosterone concentration. In addition to its Na^+ retaining effect, aldosterone also increases H^+ secretion in the distal nephron. For every H^+ secreted in the kidney, a HCO_3^- is added to the body.

The measurement of urinary chloride is useful in the differentiation between these disorders. The urinary

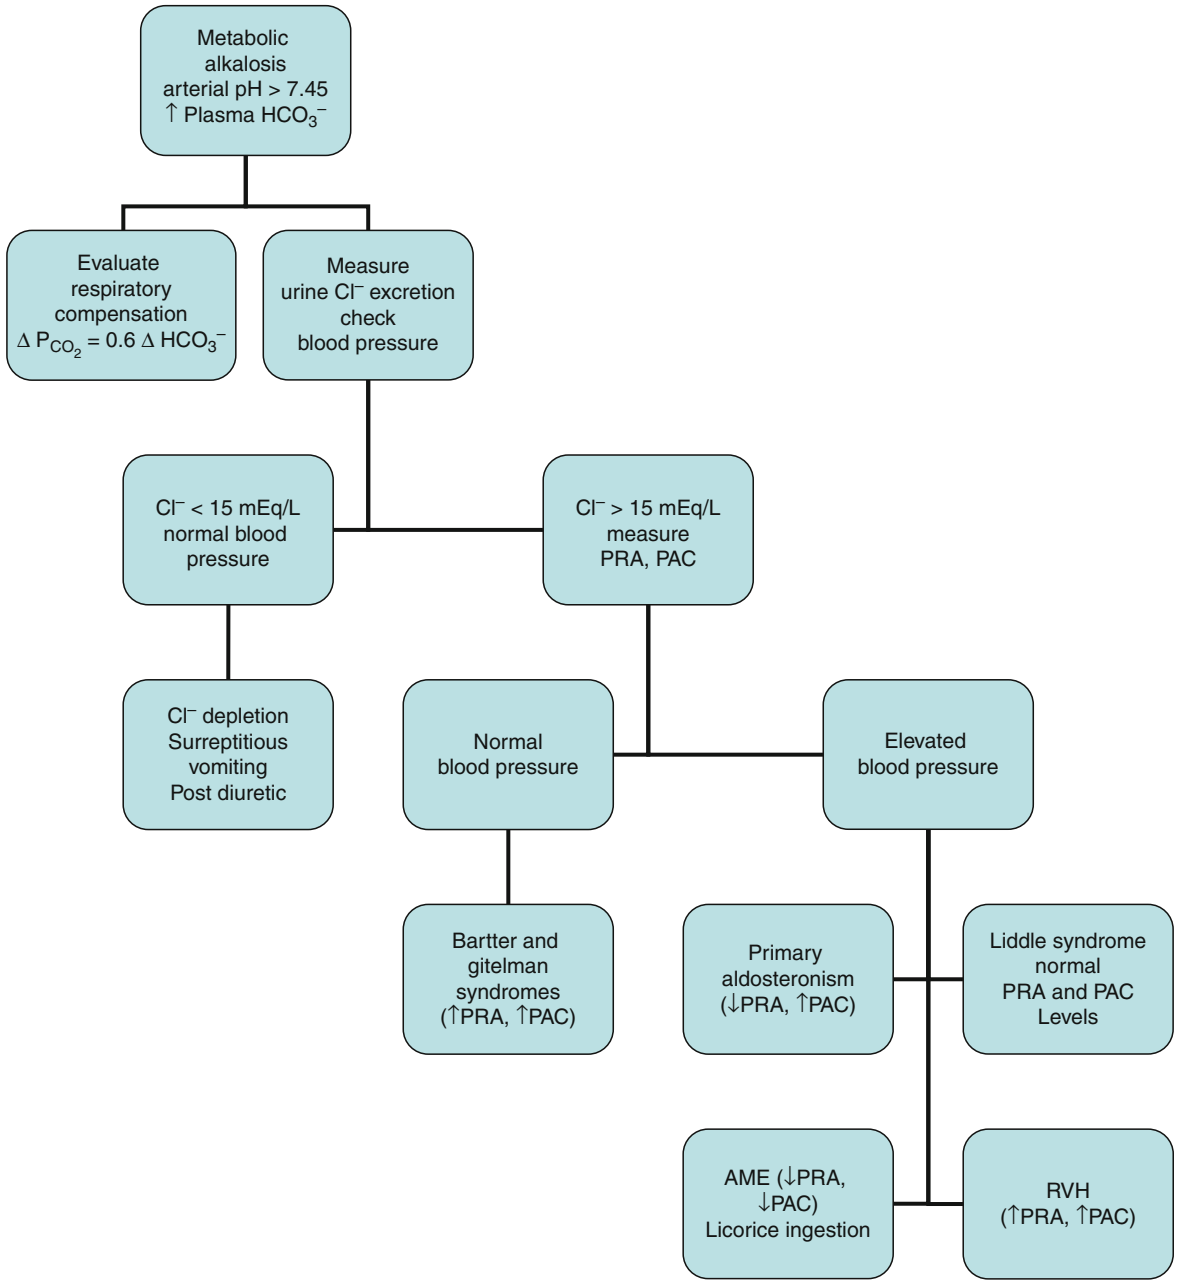

Figure 286.1

Diagnostic algorithm in metabolic alkalosis. *PRA* plasma rennin activity, *PAC* plasma aldosterone concentration, *AME* apparent mineralocorticoid excess, *RVH* renal vascular hypertension, ↑ increased, and ↓ decreased

chloride concentration is typically <15 mEq/L with hypovolemia and chloride depletion due to surreptitious vomiting or post diuretic therapy. In contrast, higher values are seen if the diuretic is still active, as in Bartter syndrome, severe hypokalemia, or primary aldosteronism. Screening the urine for diuretics is indicated if surreptitious ingestion is suspected.

The urine chloride is used in metabolic alkalosis because there may be a tendency to sodium wasting, particularly in the first few days. As the plasma HCO_3^-

concentration, and therefore, the filter HCO_3^- load increases during the generation of metabolic alkalosis, the capacity for tubular sodium HCO_3^- reabsorption decreases. The resulting loss of HCO_3^- in the urine is accompanied by a cation, predominantly, sodium, to maintain electroneutrality. In this setting, the urinary sodium concentration may be >20 mEq/L despite the presence of volume depletion; in contrast, the urinary chloride concentration is low due both to chloride and volume loss. HCO_3^- wasting can be detected by measurement of the urine pH, which will be above 7.5.

Metabolic alkalosis due to volume contraction and chloride depletion is usually correctable with administration of chloride (chloride-responsive metabolic alkalosis). Restoration of the extracellular volume will return the proximal tubule reabsorption to normal and also return plasma aldosterone concentration to normal, both of which will allow the filtered HCO_3^- to escape reabsorption. In comparison, giving chloride is ineffective when hyperaldosteronism, marked hypokalemia, or renal failure is responsible for the defect in bicarbonate excretion (chloride-resistant metabolic alkalosis).

Chloride-Sensitive Metabolic Alkalosis

The two most common causes of metabolic alkalosis are the loss of gastric secretions due to vomiting or nasogastric suction and diuretic therapy. The process of gastric acid secretion results in the retention of 1 mEq of HCO_3^- for each mEq of hydrogen ion that is secreted. This process does not lead to metabolic alkalosis in normal subjects, since 100–200 mEq of HCl secreted by the stomach each day enters the duodenum where it stimulates an equivalent of HCO_3^- secretion from the pancreas. When vomiting or nasogastric suctioning is present, the hydrogen ion secreted by the stomach cannot stimulate pancreatic HCO_3^- secretion, thereby leading to net retention of plasma HCO_3^-. Hypokalemia, which is often present due to concurrent renal or gastrointestinal losses, also can enhance HCO_3^- reabsorption and contribute to maintenance of the alkalosis. When potassium is lost from the extracellular fluid due to diuretics, or vomiting, potassium moves out of the cells to partially replete the extracellular stores. This process is accompanied by sodium and H^+ movement into the cells to maintain electroneutrality. The ensuing intracellular acidosis can, in renal tubular cells, stimulate H^+ secretion and, therefore, HCO_3^- reabsorption. Furthermore, the transcellular shift of H^+ out of the extracellular fluid can directly raise the plasma HCO_3^- concentration and exacerbate the alkalosis.

The treatment of metabolic alkalosis is more complex in edematous patients with congestive heart failure, hepatic cirrhosis, or the nephrotic syndrome. Renal perfusion is often reduced in these disorders, and the urine chloride concentration is typically below 15 mEq/L. However, saline administration will exacerbate the edema and will not sufficiently expand the effective circulating volume to permit excretion of the excess HCO_3^-. In this setting, the carbonic anhydrase inhibitor, acetazolamide, may be extremely effective. Potassium-sparing diuretics should be added if necessary.

If these combined modalities are ineffective, HCl should be given intravenously to lower the plasma HCO_3^- concentration. The desired bicarbonate concentration to lower the blood pH to 7.50 (equivalent to H^+ of 30 nmol/L) can be calculated as determined by the Henderson–Hasselbalch equation.

$$H^+ = 24(P_{CO_2}) \div \text{desired } HCO_3^-$$

As an example, a 30-kg patient presents with metabolic alkalosis and the following set of laboratory studies is obtained: arterial blood pH 7.60, P_{CO_2} 49, and serum HCO_3^- 40 mEq/L. Assume that the P_{CO_2} will remain at 40 mmHg, correct the pH from 7.60 to 7.50 (equivalent to H^+ of 30 nmol/L). The amount of the H^+ that will be needed can be calculated as follows:

$$30 = (24 \times 40) \div \text{desired } HCO_3^-$$
$$\text{Desired } HCO_3^- = 32 \text{ mEq/L}$$
$$\text{HCl(mEq)} = 0.4 \text{ weight}(\text{desired } HCO_3^-) - (\text{patient's } HCO_3^-)$$
$$\text{HCl(mEq)} = 12(32 - 40)$$

Patient's HCO_3^- is 40 and desired HCO_3 is 32, thus, patient's plasma HCO_3^- must be lowered by 8 mEq/L. The HCO_3^- space is 12 L (patient's weight × 0.4). Therefore, this patient needs 8 mEq of H^+ for each liter of the 12 L of HCO_3^- space or 96 mEq of H^+. The standard 0.1 M HCl solution contains 100 mEq of H^+/L. The amount of HCl needed to reduce the serum HCO_3^- concentration should be given slowly over 12–24 h using a large bore central vein needle to avoid corrosive damage to veins.

Chloride-Resistant Metabolic Alkalosis

Metabolic alkalosis with the urine chloride excretion greater than 15 mEq/L can be observed in patients with primary hyperaldosteronism, Liddle syndrome, apparent mineralocorticois excess (AME), Bartter syndrome, Gitelman syndrome, or severe hypokalemia. In these

disorders, hyperaldosteronism and hypokalemia are usually responsible for maintenance of the alkalosis by their ability to enhance renal H^+ excretion and, therefore HCO_3^- reabsorption. Volume depletion is generally absent, explaining the lack of dependence on chloride.

The presence of mineralocorticoid excess should be suspected in any patient with the triad of hypertension, hypokalemia, and metabolic alkalosis. Although there is initial sodium retention and volume expansion, a spontaneous natriuresis occurs within a few days, returning the extracellular volume to normal. It is possible that atrial natriuretic peptide, released in the response to volume expansion, contributes to this phenomenon. In addition to the direct effect of aldosterone on H^+ secretion, concurrent hypokalemia also is essential if a substantial rise in the plasma HCO_3^- concentration is to occur. As described above, this is largely due to intracellular acidosis induced by transcellular $K^+ - H^+$ exchange, a change that enhances H^+ secretion and HCO_3^- reabsorption. Primary aldosteronism should be suspected when plasma renin activity (PRA) is suppressed and plasma aldosterone concentration (PAC) is increased. Secondary hyperaldosteronism (e.g., renal artery stenosis, renin-secreting tumors, and coarctation of the aorta) should be considered when both PRA and PAC are increased.

Liddle syndrome is a rare autosomal dominant disorder characterized by severe hypertension, metabolic alkalosis, and hypokalemia associated with normal PRA and PAC. Liddle syndrome is caused by a genetic abnormality that increases the activity of the collecting tubule sodium channel in the absence of mineralocorticoid excess. Bartter syndrome or Gitelman syndrome cause hypokalemia, metabolic alkalosis, and associated with high levels of plasma PRA and PAC without hypertension, in a manner similar to that of diuretics. Gitelman syndrome is caused by loss of function mutations in a thiazide-sensitive ion transport mechanism in the distal nephron and is associated with hypocalciuria. Bartter syndrome is caused by mutations in a furosemide–sensitive ion transport mechanism in the loop of Henle and is associated with hypercalciuria. The diagnosis of Bartter syndrome is confirmed by demonstrating that, during 5% dextrose infusion, the fractional chloride excretion is greater than 15 mEq/100 mL glomerular filtration rate (GFR) or fractional distal chloride reabsorption ($C_{H_2O} \div C_{H_2O} + C_{Cl^-}$) is less than 85 mEq/100 mL GFR.

AME (deficiency of 11-β-hydroxysteroid dehydrogenase) should be suspected when both PRA and PAC are suppressed. Decreased enzyme activity allows glucocorticoids to act as mineralocorticoids and produce hypertension, hypokalemia, and metabolic alkalosis with low levels of renin and aldosterone. Diagnosis of AME is currently based on detection of an excess of free urinary cortisol over free urinary cortisone in 24-h urine samples.

Severe hypokalemia in addition to lowering the renal tubular cell pH can also impair distal chloride reabsorption. Thus, some of the sodium that is reabsorbed occurs in exchange for hydrogen rather than with chloride. In this setting, the urine chloride concentration is typically above 15 mEq/L even in the presence of volume depletion, a change that is reversible only after partial repletion of the potassium deficit.

Patients who have a urine chloride concentration greater than 15 mEq/L are unlikely to respond to sodium chloride and correction of metabolic alkalosis. The administered chloride in this setting is excreted in the urine since chloride deficiency is not a limiting factor in bicarbonate excretion. Furthermore, the high sodium intake will enhance urinary potassium losses and exacerbate the hypokalemia in patients with primary mineralocorticoid excess. Thus, treatment is aimed at decreasing the activity of the renin–angiotensin–aldosterone system as a means of decreasing urinary potassium and hydrogen losses. Nonsteroidal anti-inflammatory drugs, converting enzyme inhibitors, and mineralocorticoid antagonist (potassium-sparing diuretics) such as spironolactone and amyloride are usually effective in returning the plasma potassium and bicarbonate concentration to or near normal. Continued potassium administration is also required to return potassium deficit to normal.

Case Study

A 19-year-old girl on diuretic therapy for many months to control hypertension complains of weakness. She otherwise appears healthy. Laboratory data reveal sodium 132 mEq/L, potassium 2.5 mEq/L, chloride 93 mEq/L, and HCO_3^- 35 mEq/L.

What is the acid–base diagnosis?

A. A metabolic compensation for respiratory acidosis
B. Mixed metabolic alkalosis and respiratory acidosis
C. Mixed metabolic alkalosis and respiratory alkalosis
D. Metabolic alkaosis

The answer is D. The venous plasma HCO_3^- is elevated, which indicates a metabolic alkalosis or a compensated respiratory acidosis. If the condition were an acidosis, it may be anticipated that the plasma potassium concentration would be increased as the result of H^+ and potassium exchange in the cells. Since the plasma potassium is very low, the metabolic alkalosis is the most likely

diagnosis. The only way to make the diagnosis is to determine the acid–base status and all of the information necessary to calculate the H^+ is available. The appropriate respiratory compensation can be estimated by the following equation: ($\Delta P_{CO_2} = 0.6\ \Delta HCO_3^-$ or 6). Thus, the predicted P_{CO_2} is 46 mmHg. Using the Henderson–Hasselbalch equation ($H^+ = 24\ [P_{CO_2}] \div [HCO_3^-]$), the H^+ concentration is 30 nmol/L, which is equivalent to pH 7.50. Metabolic alkalosis results from long-term diuretic use. The decrease in total body sodium reduces the effective circulating volume and leads to activation of the renin–-angiotensin–aldosterone system. The increased aldosterone results in increased potassium secretion.

Case Study

A 15-year-old girl with a recent history of duodenal ulcer was admitted to the emergency department because of severe headache. She denies taking any medications. Physical examination revealed a thin female in no acute distress. Temperature is 37°C, blood pressure 122/70 mmHg, pulse 77 beats/min, respiratory rate 17/min, weight 51 kg, and height 165 cm. The heart is normal, lungs are clear, and abdomen is soft, non-tender without palpable masses or organomegaly. Neurological examination is intact. Laboratory data revealed sodium 136 mEq/L, chloride 95 mEq/L, potassium 3.0 mEq/L, HCO_3^- 32 mEq/L, BUN 15 mg/dL, phosphate 3.6 mg/dL, magnesium 1.7 mg/dL, and albumin 4.6 mg/dL. The arterial blood pH is 7.48 mmHg and P_{CO_2} 44 mmHg.

What further diagnostic tests should be done? (select all that apply)

A. Measurement of urinary aldosterone concentration
B. Measurement of urinary chloride excretion
C. Urinary diuretic screen
D. All of the above
E. None of the above

The answers are B and C. The findings of hypokalemia, metabolic alkalosis, and a normal blood pressure suggest the diagnosis of secondary hyperaldosteronism caused by surreptitious vomiting, diuretic abuse, Bartter syndrome, or Gitelman syndrome. Other forms of mineralocorticoid excess (primary hyperaldosteronism, Liddle syndrome, Cushing syndrome, renal artery stenosis, or apparent mineralocorticoid excess including licorice ingestion) are excluded by the normal blood pressure. Diet pills are often diuretics that may cause metabolic alkalosis. Urinary chloride excretion helps to distinguish between diuretics and vomiting or Bartter and Gitelman syndromes as causes of metabolic alkalosis. Vomiting is associated with extracellular fluid volume depletion, chloride depletion, and a urinary chloride excretion less than 15 mEq/L. In contrast, urinary chloride excretion is usually greater than 40 mEq/L in conditions associated with Bartter syndrome, Gitelman syndrome, or use of diuretics. Surreptitious diuretic abuse can be confirmed by obtaining a urinary diuretic screen. Therefore, the urine should be screened for the presence of diuretics and the plasma renin and aldosterone levels determined.

Case Study

A 17-year-old boy with a chronic history of obstructive pulmonary disease returns for follow-up examination. He has been complaining of shortness of breath on exertion as well as chronic cough with sputum production in the morning. He was placed on furosemide several weeks ago. On examination, his temperature is 37°C, blood pressure 136/88 mmHg, pulse 86 beats/min, respiratory rate 23/min, weight 61 kg, and height 165 cm. The heart rate is regular; there are no extra sounds or murmurs. Respiratory excursions are shallow and there is occasional wheezing. The abdomen is soft without palpable masses. Bowel sounds are present. There is 2+edema on lower extremities. Laboratory studies revealed a hemoglobin 12.0 mg/dL, WBC 6,600/mL, sodium 140 mEq/L, potassium 3.4 mEq/L, chloride 88 mEq/L, bicarbonate 42 mEq/L, calcium 9.3 mg/dL, magnesium 1.6 mg/dL, phosphate 3.5 mg/dL, glucose 95 mg/dL, and plasma osmolality 284 mOsm/L. The only available acid–base data is the P_{CO_2} 60.

What is the acid–base diagnosis? (Select all that apply)

A. Metabolic alkalosis
B. Respiratory acidosis
C. Respiratory alkalosis
D. Mixed metabolic alkalosis and metabolic acidosis

The answers are A and B. Since the P_{CO_2} and the HCO_3^- are both elevated, there could be either a respiratory acidosis with metabolic compensation or a metabolic alkalosis with respiratory compensation. The only way to make the diagnosis is to determine the acid–base status and all of the information necessary to calculate the H^+ and pH that is available. Using the Henderson–Hasselbalch equation [$H^+ = 24\ (P_{CO_2}) \div (HCO_3^-)$], the H^+ concentration is 33.5 nmol/L, which is equivalent to a pH of 7.56. Thus, this patient is alkalotic. The rise in P_{CO_2} represents an inappropriate respiratory compensation. If it were a single metabolic alkalosis, the P_{CO_2} should be increased by 10 ($\Delta P_{CO_2} = 0.6\ \Delta HCO_3^-$) and the predicted P_{CO_2} should be

50 mmHg not 60 mmHg. Therefore, the correct diagnosis is a mixed metabolic alkalosis and respiratory acidosis. The history and the physical examination indicate that the patient has chronic bronchitis and obstructive lung disease that can produce chronic respiratory acidosis.

287 Idiopathic Hypercalciuria

Fernando Santos

Definition and Epidemiology

Urinary elimination of calcium (1 mmol/L = 4 mg/dL = 2 mEq/L) is highly dependent on diet and child's age. Under identical dietary conditions, urine calcium has been shown to be lower in black than white children. Keeping this variability in mind, hypercalciuria is usually diagnosed in the clinical setting when urinary calcium excretion exceeds 4–5 mg/kg/day and suspected when urine calcium/creatinine ratio (UCa/Cr) is above 0.20–0.25 mg/mg. On the assumption that daily calcium elimination in urine follows a Gaussian distribution, approximately 5% of healthy children will be hypercalciuric. These limits cannot be used in infants in whom calciuria per unit of weight is physiologically much higher. UCa/Cr values as high as 0.80 or 0.40–0.50 mg/mg in spot urine samples are probably in the upper limit of normality during the first year of life and in early childhood, respectively. In fact, the diagnosis of hypercalciuria "per se" in an infant is rather questionable and variations in calcium elimination must be used to estimate the hypercalciuric effect of a disease or exogenous agent at this early age.

The diagnosis of idiopathic hypercalciuria requires the presence of normocalcemia and the absence of identifiable causes leading to intestinal hyperabsorption of calcium (vitamin D, high calcium intake), decreased tubular calcium reabsorption (furosemide, tubulopathies), or exacerbated bone resorption (immobilization, metabolic acidosis, corticosteroids).

Pathogenesis

Regarding the origin of the excess of urinary calcium in individuals with idiopathic hypercalciuria, attempts have been made to set different pathophysiological categories, that is, renal, absorptive, fasting, diet dependent, resorptive, etc. These classifications are of poor clinical benefit because the role played by bone, gastrointestinal tract, and kidney in the elevation of urinary calcium is difficult to differentiate in clinical practice. Nowadays, idiopathic hypercalciuria tends to be considered a single complex disorder determined to a great extent by a polygenic inheritance and the interaction with environmental factors. Approximately 50% of children with idiopathic hypercalciuria have at least one hypercalciuric first-degree relative.

Clinical Manifestations

Due to its frequent occurrence, idiopathic hypercalciuria can be diagnosed in association with a wide array of manifestations. However, the majority of hypercalciuric children are asymptomatic and few symptoms have a demonstrated cause–effect relationship with idiopathic hypercalciuria. Twenty-six to 36% of children have no identifiable basis for hematuria other than hypercalciuria; inversely, 31% of children with hypercalciuria have hematuria. The mechanism of hematuria caused by hypercalciuria is not known but it may be assumed that urinary calcium microcrystals produce a transient injury in the urothelial epithelium. This agrees with the typical presentation of idiopathic hypercalciuria in a child who, though otherwise asymptomatic, transiently voids 2–3 three urinations with macroscopic hematuria. The relationship between hypercalciuria and persistent microscopic hematuria is less convincing because of the likelihood of casual association between two prevalent disorders and the difficulty to find a common pathogenic mechanism. The passing of calcium crystals may explain the appearance of voiding symptoms such as dysuria, frequency, and urinary urgency found as presenting manifestations in some hypercalciuric children. Hypercalciuria is the most common metabolic abnormality detected in children with urolithiasis, found as a single risk factor in 19% of children with stones and in combination with other risk factors, such as hyperuricosuria, hypocitraturia, hyperoxaluria, cystinuria, etc., in up to 40–70% of cases. Urolithiasis is diagnosed in 5% of symptomatic children with idiopathic hypercalciuria. There is no way of predicting which children with idiopathic hypercalciuria will develop a urinary calculus during their childhood. The risk, although not well defined, is low but increases in the presence of very high levels of calciuria, positive family history of urolithiasis, and recurrent episodes of gross hematuria. To this respect, the prognostic significance of small hyperechogenic spots sometimes detected, as isolated and often transient findings, in the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_287,

renal ultrasounds of children with idiopathic hypercalciuria is unknown but probably do not indicate an increased risk of developing urolithiasis. The causal relation of idiopathic hypercalciuria with vesicoureteral reflux, recurrent urinary tract infections, enuresis, recurrent abdominal pain, proteinuria, etc. claimed in some studies remains to be demonstrated. Low bone mineral density, *z* score less than −1, has been reported to be up to 30–40% in some series of children with idiopathic hypercalciuria, the risk of reduced bone density being related with the presence of urolithiasis, hypocitraturia and family history of osteopenia. The pathogenesis of reduced bone density in these patients is probably not uniform and it is not clear if it results from decreased bone formation and/or increased bone resorption. It should be pointed out that the high percentage of low bone mineral density mentioned above does not likely correspond to the whole population of hypercalciuric children.

Diagnosis

Table 287.1 summarizes the studies recommended in the initial diagnostic approach of idiopathic hypercalciuria

Table 287.1
Diagnostic approach to idiopathic hypercalciuria

Medical history	Personal and family antecedents of urolithiasis, hematuria, and/or hypercalciuria
	Administration of vitamin D, furosemide, calcium salts, corticosteroids
	Characteristics of diet
Physical examination	Detailed physical examination including growth parameters: weight, height
Lab work-up – blood	Total calcium, phosphate, alkaline phosphatase, acid–base equilibrium, ionized calcium, magnesium, albumin, total proteins, creatinine, uric acid, sodium, potassium, osmolality, parathyroid hormone, 25 (OH) vitamin D
Lab work-up – random urine	Elemental uroanalysis, culture, calcium/creatinine ratio
Lab work-up – 24-h urine	Calcium, phosphate, magnesium, creatinine, urea, uric acid, sodium, potassium, osmolality, citrate
Image studies	Nephro-urological ultrasonography

in children. It is of note that hypercalciuria and hyperuricosuria are frequently associated and both disorders have been related with hematuria, calculi, and lower urinary tract symptoms. Measurement of bone density by DEXA should be restricted to patients with associated urolithiasis, family history of osteoporosis or very high levels of urinary calcium. Special functional tests to ascertain the pathophysiological type of idiopathic hypercalciuria are not routinely indicated. In special cases, an oral strontium load can be used to assess calcium absorption.

Treatment

Most children with idiopathic hypercalciuria do not need treatment. Families must be encouraged to dilute the child's urine by providing a high intake of fluids and to reducing calcium excretion, by limiting the excessive oral ingestion of animal proteins and sodium chloride, as happens very often in the case of children in Western societies. Families must be instructed against providing a low calcium diet because of the risk of adverse effects on body growth and bone health. In addition, some forms of hypercalciuria do not depend on diet and do not benefit from a dietary restriction of calcium which may, in turn, increase the urinary excretion of oxalate. Even if hypercalciuria persists, pharmacological treatment or more strict dietary limitations are not indicated in the vast majority of patients and should be reserved for those patients who have severe symptoms or develop progressive urolithiasis. A recent systematic review of the medical literature on the pharmacological interventions for preventing complications in idiopathic hypercalciuria concluded that thiazides and neutral potassium phosphate decreased calciuria in symptomatic patients and that administration of thiazides from 5 months to 3 years reduced the number of stone recurrence and the stone formation rate. Potassium supplementation and thiazides have also been shown to exert a beneficial effect on calculus formation in adults. In a small number of children and adolescents with idiopathic hypercalciuria and low bone mineral density, mean Z score in the lumbar spine of -2.0 ± 0.3, administration of bisphosphonates for 6–18 months normalized urine calcium excretion and improved bone density, up to a Z score value of -0.8 ± 0.8. Thus, selected patients with idiopathic hypercalciuria might benefit from pharmacological therapy although the duration of the treatment in these patients is an unsolved issue and the undesirable side effects of these drugs need to be closely monitored and counterbalanced with the potential benefits.

Kidney and Urinary Tract Disorders

F. Bruder Stapleton

288 Overview of Renal Function

Sami A. Sanjad

The main role of the kidney is to maintain the constancy of the extracellular volume (ECV) and composition. This is accomplished by fine tuning the rates at which water and solutes are excreted in the final urine. Thus, in spite of major daily variations in our food and water intake, extra renal losses of fluid and electrolytes, and the ongoing generation of metabolic waste products, the kidneys are able to maintain a remarkable constancy of the "internal milieu." The kidneys also play a major role in keeping the concentration of individual solutes such as sodium, potassium, calcium, hydrogen ion (pH), chloride, bicarbonate, and many others within a narrow range of normal variation.

The major aspects of kidney function may be summarized under five categories.

Glomerular Filtration

Compared to other organs, the kidneys are highly perfused with blood, receiving 20–25% of the cardiac output and a renal blood flow of about 700 mL/min/m^2. Glomerular filtration derives its force from the hydraulic pressure transmitted from left ventricular contraction. Other important factors that enhance filtration include the hydraulic pressure across the glomerular capillaries, the oncotic pressure (Starling's forces) of glomerular capillaries, the ultrafiltration coefficient, and the glomerular plasma flow. Plasma is filtered across the glomerular barrier with all its solutes, but with only a minimal amount of protein. Compared to the volume of the final urine excreted, the glomerular filtration rate (GFR) is very large. Thus, in a 10-year-old child (surface area 1 m^2), 100 L of plasma are filtered daily, compared to 1 L of urine excreted indicating that 99% of the glomerular filtrate is reabsorbed before final urine formation (*Fig. 288.1*, *Table 288.1*).

The GFR is usually calculated by standard clearance techniques. Inulin clearance is the gold standard used for GFR. Inulin is ideal because it is metabolically inert, is freely filtered by the glomerulus, and is neither reabsorbed nor secreted by the renal tubules. For practical purposes, however, the endogenous clearance of creatinine is a more convenient measurement of GFR in the usual clinical setting. Creatinine clearance, however, tends to overestimate GFR, particularly when GFR is low. The renal clearance of creatinine is calculated by the formula:

$$C_{Cr} = \frac{U_{\mathrm{Cr}} \times V}{P_{\mathrm{Cr}}}$$

where U_{Cr} and P_{Cr} represent the urinary and plasma concentration of creatinine in mg/dL or μmol/L, respectively, and V is the urine flow rate (usually in mL/min). Because creatinine clearance requires accurately timed urine collection, it may yield falsely high or low values, especially in an outpatient setting. The use of radioisotopes such as Cr-EDTA and I^{125} iothalamate have gained considerable popularity in estimating GFR which may be calculated from the rate of disappearance of the isotope from the plasma without the need for urine collection.

Several formulas have been derived for rapid estimation of the creatinine clearance. Of these, the Schwartz formula is the most widely used:

$$C_{Cr} = \frac{K \times L}{P_{\mathrm{Cr}}}$$

where L is length or height in centimeters, and K is a "constant" that varies with the child's size. $K = 0.33$ in pre-term infants; 0.45 in full-term infants; 0.55 in children and adolescent females; and 0.7 in adolescent males. P_{Cr} is plasma creatinine in mg/dL.

Alternative Markers of GFR

New markers of GFR have been introduced recently. Among these, Cystatin C, a cysteine protease produced by all nucleated cells, appears to be the most promising. Serum levels of Cystatin C may be superior to serum creatinine as a measurement of GFR. This is particularly true in the blind range of creatinine and in children with low muscle mass.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_288,

Tubular Reabsorption and Secretion: The Regulation of Extracellular Fluid Volume (ECV) and Composition

While a detailed account of the different reabsorptive and secretory processes taking place along the renal tubule is beyond the scope of this chapter, a brief description will contribute to a better understanding of the different pathological states that lead to renal tubular dysfunction. *Figure 288.1* illustrates the reabsorption of sodium along the various segments of the renal tubule. Note that two thirds of the filtered sodium is reabsorbed in the proximal tubule and that only 1% is excreted in the final urine.

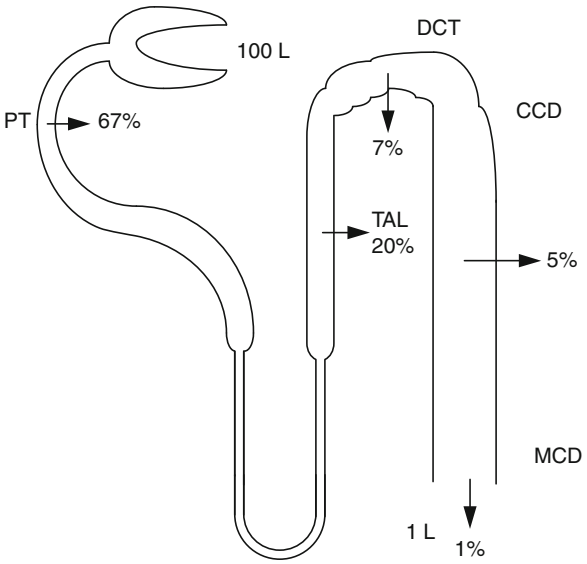

Figure 288.1
Sodium reabsorption along the different segments of the renal tubule. *PT* proximal tubule, *TAL* thick ascending limb of Henle, *DCT* distal convoluted tubule, *CCD* cortical collecting duct, *MCD* medullary collecting duct

The tonicity (osmolality) of the extracellular fluid is maintained fairly constant in spite of wide variations in water intake. This is accomplished by the kidneys' ability to concentrate or dilute the urine as needed. The ECV, on the other hand, is determined by the balance between sodium intake and sodium excretion by the kidneys. Thus, any event that threatens ECV integrity sets in motion several afferent and efferent pathways which result in sodium conservation by the proximal and distal tubules leading to reduced salt excretion. The reverse takes place when ECV is increased (except in edematous states). Under normal, physiologic states, urinary sodium excretion reflects dietary intake. By the age of 1 year, the renal tubules have matured and are capable, if the demand arises, of lowering the excretion of sodium to less than 5 mEq/24 h.

Proximal Tubular Function

Tubular reabsorption of the glomerular filtrate and its accompanying solutes constitutes one of the most important functions of the kidney. Because of the large number of invaginations, or microvilli, along their luminal (apical) membrane, the proximal tubular cells are particularly fit for that purpose due to the relatively large surface area for

Table 288.1
The magnitude of tubular function in a 10-year-old child (1.0 m^2 surface area)

	Plasma concentration	Glomerular filtrate	Urine excretion/24 h	% Reabsorption
Vol	1 L	100 L	0.3–1.0 L	98–99
Na	140 mEq	14,000 mEq	50–150 mEq	>99
Cl	100 mEq	10,000 mEq	30–90 mEq	>99
K	4 mEq	400 mEq	25–75 mEq	80–90

reabsorption. The microvilli are equipped with a brush border which contains specific carrier proteins that translocate solutes across the cell. Many of these carrier proteins have been determined by DNA sequencing and seem to exhibit a high degree of homology, but in many instances the molecular mechanism for a carrier protein to transport a specific substance has not been determined. Megalin, as the name implies, is a very large transmembrane protein that plays a crucial role in the endocytic reabsorption of a large number of low molecular weight proteins at the brush border of the proximal tubular cells. These include vitamin D binding protein, retinol binding protein, and alpha 1-microglobulin among others. The microvilli also contain the enzyme carbonic anhydrase IV which is crucial for bicarbonate reabsorption.

Reabsorption of the glomerular filtrate in the proximal tubule occurs isoosmotically, with no net change in filtrate tonicity. Both active and passive transport mechanisms are operative in solute reabsorption. Active transport implies the consumption of energy and takes place against an electrochemical gradient. The energy is provided by a Na–K-ATPase pump located in the basolateral cell membrane which maintains a low intracellular sodium concentration. It is worth emphasizing that sodium reabsorption along the whole length of the renal tubule takes place by a two-step process: (a) down an electrochemical gradient from tubular fluid across the luminal (apical) membrane to the tubular cell and (b) uphill, against an electrochemical gradient from the cell across the basolateral membrane to the peritubular capillary (Na–K-ATPase pump mediated). About two thirds of the sodium reabsorbed in the proximal tubule is by an active, transcellular mechanism; the remaining one third is by passive, paracellular reabsorption (*Fig. 288.1*).

Sodium Reabsorption and Hydrogen Secretion

Sodium is cotransported across the luminal membrane with several other solutes. These include D-glucose, D-galactose, L-amino acids, phosphate, lactate, sulfate, urate, and many other organic metabolites (*Fig. 288.2*).

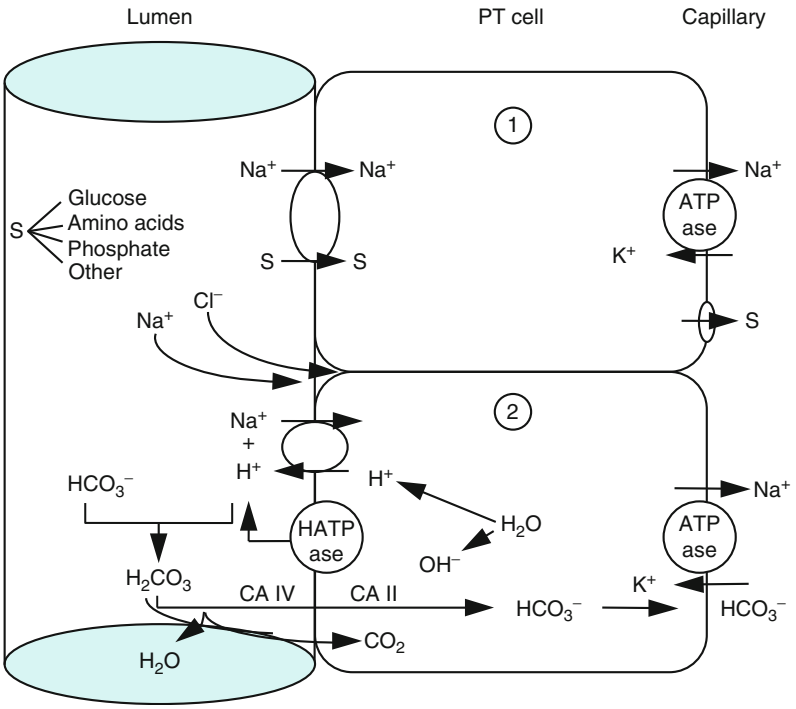

Fig. 288.2

Solute reabsorption by proximal tubular cells. The upper cell ① depicts a Na-solute cotransport mechanism facilitated by specific solute carrier proteins. The energy for this process is due to the low intracellular Na^+ concentration generated by the Na–K-ATPase pump on the basolateral cell membrane. The lower cell ② demonstrates the processes of proton secretion and bicarbonate reabsorption. About two thirds of H^+ secreted is by a countertransport with Na^+ (Na–H antiporter) and one third by a H-ATPase pump in the luminal membrane

Along with sodium, these solutes are reabsorbed with specific carrier proteins located in the brush border of the luminal membrane. Sodium is also counter transported or exchanged for hydrogen ion secreted from the cell to the tubular fluid. It is this phase of sodium reabsorption that is responsible for a significant regeneration of bicarbonate. Secreted hydrogen combines with filtered bicarbonate to form H_2CO_3, which, due to the presence of carbonic anhydrase IV in the luminal membrane, is rapidly dehydrated to form CO_2. The latter diffuses into the cell to combine with hydroxyl ion to generate bicarbonate, a reaction catalyzed by cellular carbonic anhydrase II. This "new" bicarbonate may now be returned, along with sodium via a Na^+-HCO_3 cotransporter (NBC1) at the basolateral membrane, to the peritubular capillaries (not shown). In addition to these electroneutral processes, the proximal tubular cell is equipped with an electrogenic H^+-ATPase pump located in the apical cell membrane, which contributes about one third of the proton secretion and bicarbonate reabsorption.

Normally, 85% of the filtered bicarbonate is reabsorbed in the proximal tubules by these mechanisms. Bicarbonate reabsorption in the proximal tubule represents a high capacity, low gradient process that bears an inverse proportion to changes in ECV. The remaining 15% of the filtered bicarbonate is reabsorbed in the more distal segments of the tubule. Proximal renal tubular acidosis (type 2 RTA) could occur if any of the forces involved in bicarbonate reabsorption, singly, or in combination became defective. These might be secondary to defects in the Na–H antiporter (NHE3), the Na–HCO_3 cotransporter (NBC1), carbonic anhydrase II or IV, or the H-ATPase pump. An abnormality in the Na–K-ATPase pump would result in impaired reabsorption of all solutes ordinarily cotransported with sodium and result in the Fanconi syndrome.

Potassium

Sixty-five percent of the filtered potassium is reabsorbed by the proximal tubules primarily by a process of diffusion and solvent drag through the intercellular (paracellular) pathways into the peritubular capillaries. Potassium transport in the proximal tubule has no specific role in the regulation of potassium balance.

Glucose

Glucose is freely filtered by the glomerulus and is actively reabsorbed in the proximal convoluted tubule by a sodium cotransport mechanism. Reabsorption has a tubular maximum (Tm) above which no further glucose is reabsorbed. The value for glucose Tm is 300 mg/min/1.73 m^2 and occurs at a plasma glucose concentration of 180 mg/dL. In the absence of hyperglycemia, urinary excretion of glucose is negligible. Euglycemic glucosuria is indicative of an isolated defect in proximal glucose transport, known as renal glucosuria, or due to multiple tubular defects in association with the Fanconi syndrome.

Phosphate

Eighty to ninety percent of the filtered phosphate is reabsorbed in the proximal tubule by an active sodium-coupled cotransport. Phosphate is an important urinary buffer that enhances excretion of hydrogen ion as titratable acid. Parathyroid hormone inhibits phosphate reabsorption leading to phosphaturia and hypophosphatemia. Tubular reabsorption of phosphate (TRP) is also impaired in vitamin D resistant rickets and in the Fanconi syndrome as part of a generalized proximal tubular dysfunction. The recently discovered phosphatonin, FGF23, seems to have an important phosphaturic property and may have an important role in phosphate homeostasis.

In addition to the reabsorptive processes described above, the proximal tubule has several secretory processes for organic anions and cations.

Distal Tubular Function

The major functions of the distal tubular cells are: (a) further reabsorption of sodium and chloride, (b) absorption and secretion of potassium, (c) hydrogen secretion into the lumen (urine acidification), and (d) concentration of the urine by the action of vasopressin on the collecting ducts.

Sodium Reabsorption

In the thick ascending limb of Henle, sodium is cotransported by an electroneutral process with one K and 2 Cl. The driving force for this transport is the downhill movement of sodium across the apical membrane. The intracellular sodium concentration is kept low by the Na–K-ATPase pump at the basolateral cell membrane. Loop diuretics such as furosemide, bumetanide, and ethacrynic acid are known inhibitors of this Na–K-2Cl cotransport. It is thought that they exert their effect by combining with the symporter (cotransporter) protein in the apical membrane and prevent its translocation

into the tubular cell. It has been shown recently that Bartter's syndrome is caused by mutations in this Na–K-2Cl cotransporter gene NKCC2. This is very much in keeping with the biochemical similarities seen between patients receiving loop diuretics and patients with Bartter's syndrome.

In the distal convoluted tubules (DCT), sodium and chloride are reabsorbed by a cotransport mechanism. The Na–K-ATPase pump is more active in this segment than any other part of the renal tubule. The Na–Cl cotransport in this part of the tubule is inhibited by the thiazide group of diuretics. Gitelman's variant of Bartter's syndrome is caused by mutations in this thiazide-sensitive Na–Cl cotransporter. Further down in the cortical collecting duct (CCD) sodium transport takes place across epithelial channels (ENaC) in the apical membrane by simple diffusion. As in other segments of the nephron, the driving force for this transport is the electrochemical generated by the basolateral Na–K-ATPase pump which keeps cell sodium concentration low. These sodium channels are inhibited by the diuretics amiloride and triamterene. Mutations in the sodium epithelial channel beta and gamma subunits causes Liddle's syndrome, an autosomal form of salt-sensitive hypertension associated with hypokalemic alkalosis. Inactivating mutations in the ENaC subunits causes pseudohypoaldosteronism type 1.

Potassium Reabsorption and Secretion

About two thirds of the filtered potassium is reabsorbed in the proximal convoluted tubule regardless of the final urinary excretion. Another 25% of the filtered potassium is reabsorbed along with sodium and chloride in the thick ascending limb of Henle (Na–K-2Cl cotransporter). In potassium depletion states, further reabsorption takes place by the intercalated cells of the DCT (3%) and CCD (9%). Potassium secretion occurs during normal rates of intake. As potassium intake increases, secretion by the principal cells of the DCT and CCD may be as much as 80% of the filtered potassium load. In addition to potassium intake, there are several factors that enhance potassium secretion. These include tubule fluid flow rate, sodium delivery to the distal tubule, mineralocorticoid activity, alkalosis, the presence of unreabsorbable anions, and vasopressin activity. Factors inhibiting potassium secretion include a high luminal potassium concentration, high chloride concentration, amiloride and triamterene, acidosis, and high urinary calcium.

A recently introduced value that has received considerable attention in clinical practice is the transtubular potassium gradient (TTKG). It is calculated from simultaneous measurements of plasma and urine potassium, and plasma and urine osmolality:

$$\mathrm{TTKG} = \frac{U_K \times P_{OSM}}{P_K \times U_{OSM}}$$

The TTKG is an approximation of the potassium concentration at the end of the CCD and is an indirect assessment of endogenous aldosterone activity in vivo. Under normal situations of dietary potassium intake, TTKG ranges between 4 and 10. A value below 4 in children and below 5 in infants is reflective of little or no mineralocorticoid activity. A high potassium intake or acute mineralocorticoid administration raises TTKG above 10–12.

Hydrogen Secretion: Urine Acidification

In the CCD and MCD, hydrogen secretion takes place by an electrogenic active transport with energy derived from an H^+-ATPase and an H–K-ATPase pump. Hydrogen secretion is accomplished by the alpha-intercalated cells which can establish much steeper hydrogen gradients than the Na–H antiporter mechanism that prevails in the proximal tubule. Thus, a 1,000-fold gradient (3 pH units) may be attained between plasma and urine at maximum urine acidity with a pH of 4.4.

Ammonium Secretion

Ammonium (NH_4^+) synthesis from the deamination of glutamine takes place primarily in the proximal tubular cells. The NH_4^+ is secreted into the luminal fluid by a Na–NH_4^+ exchange, but some NH_3 diffusion occurs as well. A significant portion of the secreted NH_4^+ is reabsorbed in the thick ascending limb of Henle and accumulates in the medullary interstitium as NH_4^+ and NH_3. The latter diffuses into the lumen of the distal tubule and collecting duct, where it combines with secreted hydrogen to form NH_4^+ which becomes trapped in the tubular lumen and excreted in the urine. Ammonium secretion by the renal tubules is stimulated by acidosis, potassium depletion, and glucocorticoids and inhibited by alkalosis, hyperkalemia, and adrenal insufficiency.

Titratable Acid

Hydrogen ion secreted in exchange for sodium can also combine with non-bicarbonate buffers. This fraction of secreted hydrogen can be measured in the urine by back

titration and is referred to as titratable acid. The most abundant of these non-bicarbonate buffers is phosphate. The rate of titratable acid excretion is influenced by the amount of buffer in the tubular fluid, the pH of the buffer and the pH of the tubular fluid. The hydrogen excreted with NH_3, as NH_4^+, and with phosphate, as titratable acid, accounts for the bulk of fixed acid excretion. This is also known as net acid excretion (NAE) which is equivalent to the amount of endogenous acid production (40–60 mEq/m^2/day) (*Fig. 288.3*).

Of note is that the distal tubular cells lack intraluminal carbonic anhydrase IV. Thus, the dissociation of H_2CO_3 in the luminal fluid into CO_2 and H_2O occurs very slowly. The CO_2 generated may be measured in the urine during bicarbonate infusion and is an indirect reflection of hydrogen secretion in the distal nephron.

Vasopressin and Other Hormonal Receptor Sites in the Distal Nephron

In the distal tubules and collecting ducts, further reabsorption of filtrate takes place. The DCT, CCD, as well as the medullary CD contain receptors for several hormone systems that participate in the modulation of electrolyte and water reabsorption: (a) vasopressin (ADH) increases water permeability in the CCD and MCD and results in the formation of concentrated urine. This occurs through passive reabsorption of water by means of an elaborate countercurrent mechanism generated by the hairpin configuration of the limbs of Henle. Because the ascending limb of Henle is impermeable to water, progressive hyperosmolality of the medullary interstitium takes place allowing for ADH-mediated water extraction from the distal tubules and collecting ducts, resulting in a hyperosmotic urine. Vasopressin binds to the V2R receptor on the basolateral membrane of the principal cell initiating adenyl cyclate activation and cAMP generation and protein kinase A stimulation. The latter enhances the redistribution of aquaporin2 (AQP2) water channels from intracellular vesicles to the apical basal membrane rendering the latter water permeable. (b) aldosterone enhances sodium reabsorption with concomitant hydrogen and potassium secretion, (c) parathyroid hormone increases calcium reabsorption, (d) other hormones having an effect on sodium reabsorption include glucagon, estrogens, thyroid, calcitonin, and the powerful atrial natriuretic peptides.

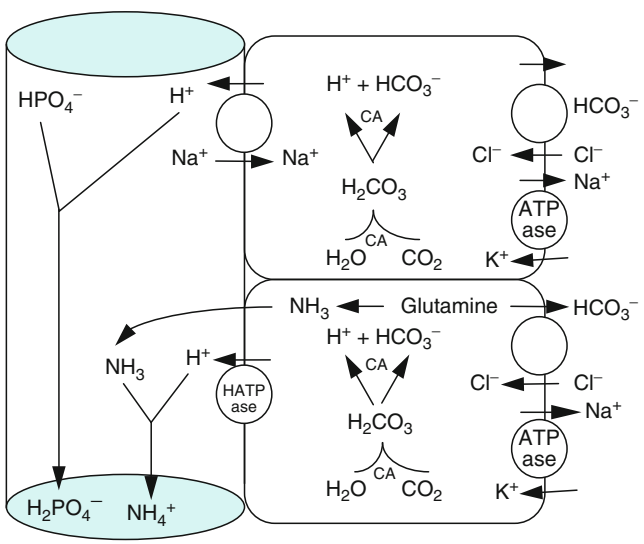

Fig. 288.3

Excretion of fixed acids of the distal nephron. Hydrogen secretion by the alpha-intercalated cells takes place via the H^+-ATPase pump in the luminal basement membrane. About 40% of the secreted hydrogen ions combine with filtered phosphate to form titratable acid. Most of remaining hydrogen secreted combines with NH_3 to form NH_4^+, but a small amount remains as full hydrogen ions and regulates urinary pH. Another small amount of secreted hydrogen combines with residual filtered bicarbonate that escaped absorption in the proximal tubule

Endocrine Function of the Kidney

The kidney is the site of production and release of many hormones affecting other target organs and tissues as well as autacoids which act locally. Renin acts on angiotensinogen leading to angiotensin I and angiotensin II production; kallikrein controls bradykinin formation resulting in local and systemic vasodilatation; erythropoietin stimulates the bone marrow for hemoglobin synthesis; 1-alpha hydroxylation of vitamin D in the proximal tubules yields the active metabolite 1,25 $(OH)_2D3$.

Prostaglandins and leukotrienes probably exert a local effect on sodium reabsorption and vasodilatation.

The Kidney as a Metabolic Organ

The kidney is an important organ in energy metabolism. It is second only to the liver as a source of gluconeogenesis during prolonged fasting. In addition, the kidney plays a significant role in lipid and amino acid metabolism. Respiratory fuels in the renal cortex include short and long chain fatty acids, ketone bodies, lactate, and amino acids. In the outer medulla, succinate and lactate and, in the inner medulla, glucose are the preferred substrates.

The Kidney as an Excretory Organ

In addition to secretory processes enhancing excretion of substances produced from normal metabolism, the kidney plays an important role in the excretion of many endogenous and exogenous toxins and drugs. Organic anions secreted by the proximal tubules include the thiazide diuretics, furosemide, salycilates, and penicillin. Organic cations include atropine, amiloride, cimetidine, and morphine.

289 Approach to Renal Disease in the Neonate

Robert L. Chevalier

The transition from fetal to postnatal life requires dramatic physiologic adaptation by many organ systems: the kidneys must suddenly completely assume the role provided by the placenta in maintaining neonatal homeostasis. The pediatrician must recognize that in the full term infant, the kidney is programmed for this transition with an initial diuresis and natriuresis followed in several days by avid sodium retention, which is necessary for normal growth. While these responses were formerly regarded as "limitations" of the immature kidney, they are physiologically appropriate. However, because the neonate has an attenuated renal response to acute volume expansion compared to the older child, the composition and rate of administration of fluids and electrolytes must be carefully monitored. In the preterm infant, renal function reflects a developmental stage adapted to fetal rather than extrauterine life and glomerular and tubular function are even more restricted. Identification of renal abnormalities or dysfunction in the neonate therefore requires familiarity with the normal range of parameters for preterm and term infants (*Table 289.1*). This chapter addresses the most frequently encountered renal disorders of the neonate.

Fetal kidney development. The development of the fetal kidney is a delicate process that involves differentiation of the metanephros in the first trimester. Abnormalities of embryogenesis in this period can result in ectopic kidney, duplex or horseshoe kidney, or in renal agenesis, dysplasia, or hypoplasia (*Table 289.2*).

Congenital anomalies of the kidneys or urinary tract (CAKUT) comprise over 50% of the causes of renal failure in infants and children. In addition to the structural anomalies comprising CAKUT, it is now recognized that the number of nephrons in each kidney varies by a factor of tenfold across the normal population: low nephron number represents a significant risk factor for long-term progression of renal insufficiency of any cause. Very low birth weight infants or those with intrauterine or extrauterine growth restriction are also subject to a permanent reduction in nephron number associated with an early deficit in protein-calorie intake.

Obstruction of the urinary tract at any point from the ureteropelvic junction to the urethra can impair renal growth and development in the fetus, and may even result in dysplastic changes. The ureteropelvic junction is the most common site for congenital obstructive nephropathy, and fortunately is generally unilateral (although the contralateral kidney or urinary tract is often also abnormal). An extreme example of the effects of ureteral atresia is the development of multicystic dysplasia, which is the most common cause of an abdominal mass in the neonate. In most cases, a multicystic dysplastic kidney undergoes involution and does not require surgical removal unless it is causing hypertension. Although posterior urethral valves are less common, this lesion involves both kidneys that generally exhibit dysplastic changes that are not completely reversible even after surgical relief of the obstruction. Such infants require the early involvement of the pediatric urologist. The indications for prenatal intervention are unclear at present, and in general should be considered in the realm of experimental therapy. Prenatal diagnosis, however, can alert the pediatrician to evaluation of the infant's renal status shortly after birth, in order to optimize growth and function of the kidney.

Renal anomalies. For reasons that remain poorly understood, the prevalence of CAKUT is significantly higher in males than females, approaching 2:1 in many reports. Renal anomalies are often associated with abnormalities of other organs. The phenotype of Potter syndrome includes large flat ears, infraorbital skin folds, and flat nasal bridge. These changes, in addition to pulmonary hypoplasia, result from oligohydramnios due to fetal oliguria or anuria. Thus, Potter syndrome can result from bilateral renal agenesis, or any other severe bilateral renal malformation, including hypoplasia, dysplasia, cystic kidney disease, or bilateral obstructive uropathy (*Table 289.2*). The placental corollary of Potter syndrome, amnion nodosum, consists of nodules of amorphous granular material on the surface of the amnion, fibrosis of chorionic villi, and placental edema.

A palpable abdominal mass in the neonate is generally due to an enlarged kidney. This may result from

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_289,

Table 289.1
Renal parameters in healthy neonates during the first 2 months

Parameter	Preterm infant	Term infant
Kidney length (ultrasound)	2–4 cm in fetus 22–32 weeks; EGA 3–5 cm in fetus >32 weeks EGA	4–5 cm in neonate
Renal pelvic diameter (ultrasound)	<5 mm in fetus >24 weeks EGA (not reliable for EGA < 24 weeks)	<7 mm 5 days of age; <10 mm 3 months old
Systolic blood pressure	<70 mmHg	<90 mmHg
Plasma creatinine concentration	<2.0 mg/dl (1–2 weeks); <0.8 mg/dl (>2 weeks)	<1.0 mg/dl (1–2 weeks); <0.6 mg/dl (>2 weeks)
Plasma potassium concentration	4–6 mEq/l	4–6 mEq/l
Plasma bicarbonate concentration	15–25 mEq/l	>20–25 mEq/l
Fractional excretion of sodium (FE_{Na})	<1% (EGA >32 weeks; not helpful for EGA < 32 weeks)	<1%
Urine calcium/creatinine ratio (mg/mg)	<0.8	<0.4

EGA estimated gestational age

Table 289.2
Congenital anomalies of the kidneys or urinary tract (CAKUT)

Ectopic kidney
Duplex/horseshoe kidney, duplicated collecting system
Renal agenesis
Renal dysplasia/hypoplasia (including multicystic dysplastic kidney)
Obstructive nephropathy (ureteropelvic junction obstruction, vesicoureteral junction obstruction, posterior urethral valves)
Vesicoureteral reflux
Exstrophy of the bladder
Myelodysplasia and neurospinal dysraphisms with neurogenic bladder
Polycystic kidney disease (autosomal recessive, autosomal dominant)

obstructive nephropathy, cystic kidney disease, renal vein thrombosis, or tumor. Infants with the prune belly syndrome have redundant and wrinkled abdominal skin, undescended testes, and bilateral hydronephrosis. These patients often have an element of renal dysplasia and renal insufficiency. It should be noted that cryptorchism may be associated with renal anomalies even in the absence of the prune belly syndrome. An additional constellation of abnormalities often associated with renal insufficiency in the neonate is the VATER association. This is an acronym for vertebral defects, imperforate anus, tracheoesophageal fistula, and radial dysplasia. Over half of these patients have abnormal renal development. The VACTERL association adds cardiac defects, most commonly ventricular septal defect. Myelomeningocele is associated with variable degrees of bladder dysfunction, which may lead to reflux nephropathy or hydroureteronephrosis and renal insufficiency. For all of these infants with lower urinary tract abnormalities, close monitoring of bladder function (including residual bladder capacity) is important, since intermittent bladder catheterization may prevent the progression of renal insufficiency. A number of chromosomal defects may include renal abnormalities. The most common are Down Syndrome (associated with hydroureteronephrosis), and Turner Syndrome (associated with horseshoe kidney or duplicated collecting system) (*Table 289.2*).

Signs of Renal Disease in the Neonate

Oliguria. The signs suggestive of renal disease in the neonate are nonspecific, and include pallor, poor feeding, vomiting, and convulsions. Fever and jaundice are compatible with urosepsis, which may accompany renal malformations. Of all the signs associated with neonatal

urinary disorders, oliguria is the most helpful. It should be noted that all normal newborns void within the first 24 h of life. Thus, an infant remaining anuric beyond the first day of age should be investigated. Abdominal examination may reveal a distended bladder consistent with bladder outlet obstruction (most commonly due to posterior urethral valves). Based on the ordinary dietary solute load and the maximal renal concentrating capacity of the newborn, the infant must produce 0.5–1.0 ml/kg/h of urine to remain in solute balance. Thus, by definition, neonatal oliguria is a urine output of less than 0.5–1.0 ml/kg/h.

Hypertension. Hypertension in the neonate is usually renovascular in origin (Table 289.3). This may be associated with microemboli from an indwelling umbilical artery catheter. Additional causes of hypertension include acute kidney injury, polycystic kidney disease, and obstructive nephropathy. However, non-renal causes of hypertension should also be considered, including bronchopulmonary dysplasia, congenital virilizing adrenal hyperplasia, intracranial hemorrhage, and neoplasms (Table 289.3).

Maternal drug and neonatal medication exposure should also be considered. Systolic blood pressure in term infants should be less than 90 mmHg during the first week of age, and less than 70 mmHg in the preterm infant (Table 289.1).

Edema. Neonatal edema may be associated with hydrops fetalis, which can result from Rh isoimmunization or fetal supraventricular tachycardia. The primary renal causes of neonatal edema are congenital nephrotic syndrome and lower urinary tract obstruction. Congenital nephrotic syndrome should be suspected in utero if the maternal serum alpha fetoprotein is elevated. In view of the loss of thyroid binding globulin in the urine of these infants, it is critical that thyroid function tests be monitored closely in infancy to allow appropriate thyroid replacement.

Table 289.3
Causes of hypertension in the neonate

Renovascular (aortic coarctation, renal artery stenosis or embolism, renal vein thrombosis)
Acute kidney injury, renal cortical necrosis, birth asphyxia
Polycystic kidney disease (autosomal recessive)
Renal hypoplasia/dysplasia, ureteropelvic junction obstruction
Bronchopulmonary dysplasia
Congenital adrenal hyperplasia, hyperthyroidism
Intracranial hemorrhage, increased intracranial pressure
Neoplasms (Wilms tumor, neuroblastoma)
Medications (dexamethasone, theophylline, caffeine, phenylephrine)
Maternal drugs (cocaine, heroin)

Hematuria. Gross hematuria in a newborn with a palpable abdominal mass, anemia, and thrombocytopenia strongly suggests renal vein thrombosis. Renal vein thrombosis should be suspected in the infant of a diabetic mother or in neonates with severe asphyxia. Cystic kidney disease and hydronephrosis can be associated with hematuria, and tumors such as mesoblastic nephroma or nephroblastomatosis may present with hematuria in the neonatal period. A number of drugs have been associated with hematuria in the neonate, including aminoglycosides, penicillins, anticonvulsants, aminophylline, and furosemide. Glomerulonephritis is a relatively rare cause of hematuria in the infant, although neonatal infections that can cause renal inflammation include syphilis, toxoplasmosis, and cytomegalovirus.

Proteinuria. Protein excretion is approximately 0.5 g/l on the first day of age, and falls rapidly to normal adult concentrations by the second week of age. Proteinuria may be seen with vascular disorders or inflammatory disorders described above. Heavy proteinuria in the neonate is most often associated with congenital nephrotic syndrome, which, unlike most nephrotic syndrome in young children, is not responsive to corticosteroids.

Bacteriuria. Less than 1% of neonates have asymptomatic bacteriuria, such that routine screening of neonates for bacteriuria is generally not indicated. Bacterial contamination of urine collected by plastic bag in neonates is over 6%. Febrile infants, however, are more likely to have bacteriuria as a manifestation of urosepsis, septicemia, vesicoureteral reflux, or obstructive nephropathy, and should have urine culture obtained by suprapubic aspiration or bladder catheterization.

Diagnostic Imaging of the Neonate with Prenatal Discovery of CAKUT

Ultrasound. Any neonate with a palpable abdominal mass or oliguria should have an abdominal sonogram. Normal values for length of neonatal kidneys measured by ultrasonography have been reported for term and preterm infants (Table 289.1), and it is important to relate measurements to gestational age. The position and echotexture of the kidneys can be determined, and Doppler ultrasound also permits the measurement of renal blood flow. Although polycystic kidney disease (including the autosomal

dominant form) can present in the neonatal period, the smallest cyst that can be resolved by sonography is approximately 5 mm so that not all cysts will be detected.

Postnatal evaluation of the neonate with prenatal hydronephrosis (renal pelvic diameter >5 mm) discovered by maternal ultrasonography should follow a sequence of steps to rule out correctible lesions, while minimizing invasive procedures or parental anxiety. An ultrasound examination of the kidneys and bladder should be performed at 5 days of age, and if normal, the ultrasound should be repeated at 1 month of age to rule out hydronephrosis that may only become apparent after this period of postnatal renal maturation. If the initial ultrasound is abnormal at either 5 days or 1 month, a voiding cystourethrogram (VCUG) should be obtained to rule out vesicoureteral reflux or bladder outlet obstruction (see below). If the VCUG is normal, a repeat ultrasound should be obtained at 3 months of age: infants with pelvic dilatation greater than 10 mm should undergo further evaluation (*Table 289.1*), including diuretic renography (see below). Preterm infants have a greater risk of adverse outcome, and should have prolonged follow-up.

Diuretic renography. The function of each kidney can be evaluated by renal scintigraphy using [^{99}Tc] tagged mercaptoacetyl triglycine (MAG3). This is preferable to intravenous pyelography in the neonate because radiation exposure is less, there is no significant osmotic load to the isotope, and renal visualization is superior. To evaluate functional ureteral obstruction, furosemide is administered, and the time required to clear half of the renal MAG3 ($T_{1/2}$) is determined for each kidney: $T_{1/2} < 10$ min is generally normal, while $T_{1/2} > 20$ min is indicative of obstruction ($T_{1/2}$ is indeterminate). While diuretic renography remains the best generally available technique to identify urinary tract obstruction in the neonate, there are many pitfalls in the procedure and its interpretation. For this reason, attempts have been made to standardize the protocol: one of the most widely used is the "well-tempered" renogram developed by the Society for Fetal Urology.

Voiding cystourethrogram. A VCUG should be performed in any infant found to have hydronephrosis or a significant renal anomaly by sonography. In addition to ruling out vesicoureteral reflux, VCUG also reveals details of bladder structural or functional abnormalities.

Measurement of Renal Function in the Neonate

Plasma creatinine concentration. Renal insufficiency in the hospitalized neonate is often detected first by an elevation in serum creatinine concentration. Unfortunately, serum creatinine concentration is notoriously unreliable in the neonatal period because of the lack of a steady state condition, and measurement at the lower limit of detection for the assay. Moreover, recent studies have shown that filtered creatinine undergoes tubular reabsorption in the neonate, which contributes to spuriously elevated values. The normal plasma creatinine concentration in 1–2-week-old term infants is 0.6–1.0 mg/dl (up to 2.0 mg/dl in the preterm infant) (*Table 289.1*). By 2 weeks of age, the concentration should fall to 0.2–0.6 mg/dl in the term infant, and 0.4–0.8 mg/dl in the preterm baby. Most useful is the determination of serial creatinine measurements in individual patients. An increase in plasma creatinine concentration over time is abnormal except for a transient increase in the first 2 weeks in very low birth weight infants. It should be recognized that renal maturation continues for at least the first 9 months of age, and that plasma creatinine concentration can plateau or decrease even in the face of a reduced number of nephrons (due to hyperfiltration by the remaining nephrons). In such patients, renal insufficiency may not be detected until later childhood or even adulthood.

Creatinine clearance. To track the glomerular filtration rate during growth of the infant (in whom body surface area is rapidly changing), it is useful to estimate the creatinine clearance using Schwartz's formula:

$$\text{Creatinine clearance}\left(\text{ml/min/1.73m}^2\right) = k \times L/P_{Cr},$$

where k equals an empiric constant (0.4), L equals body length in centimeters, and P_{Cr} equals plasma creatinine concentration in mg/dl. This measurement of renal function is adjusted for adult surface area: in very low birth weight neonates, creatinine clearance at birth is normally below 10 ml/min/1.73 m^2, a level that would be considered inadequate to support life in the older patient. However, glomerular filtration rate normally increases several fold during the first 2 months of age.

Renal concentrating and acidifying capacity in the neonate. While the neonate is able to produce dilute urine due to immaturity of the renal medulla, concentrating capacity is limited for the first 2 months of age to a maximum of 500–700 mOsm/kg (versus 1,200 mOsm/kg in the adult). For this reason, volume-contracted neonates are obligated to maintain a higher urine output than older children in order to stay in osmotic balance (to prevent a rise in BUN and creatinine). Neonates also have a reduced threshold for bicarbonate reabsorption, ranging from 15 to 25 mEq/l (*Table 289.1*): bicarbonate supplementation for neonates with plasma bicarbonate in this range do not exhibit

accelerated weight gain. The limited ability of neonates to excrete an acid load also improves by 6 weeks of age, and is more prolonged in the preterm infant.

Acute Kidney Injury

Most cases of acute kidney injury in the neonatal period are related to circulatory disorders (Table 289.4). Reduced renal perfusion due to hypovolemia may be a consequence of perinatal blood loss, asphyxia, septicemia, or vascular thrombosis with disseminated intravascular coagulation. Since a smaller proportion of the cardiac output supplies the kidneys of the neonate compared to the adult, heart failure may also profoundly reduce renal perfusion and glomerular filtration rate. Polycythemia (venous hematocrit greater than 65%) may cause hyperviscosity, and reduced renal plasma flow and glomerular filtration rate. In such cases, lowering the hematocrit by reduction exchange transfusion may restore glomerular filtration and urine output. Intravascular volume contraction may arise from severe hypoproteinemia due to congenital nephrotic syndrome. In each of these conditions of decreased effective circulating volume, fractional sodium excretion would be expected to be less than 1% for infants greater than 32 weeks gestational age (for lower gestational age infants, values are higher due to renal tubular immaturity).

Table 289.4
Causes of acute kidney injury in the neonate

Circulatory disorders
Hypovolemia (hemorrhage, dehydration)
Asphyxia
Septicemia
Vascular thrombosis, disseminated intravascular coagulation
Congenital heart disease (patent ductus arteriosus, aortic coarctation)
Polycythemia
Hypoproteinemia
Iatrogenic/toxic nephropathy (maternal or neonatal administration)
Angiotensin inhibitors
Prostaglandin synthase inhibitors (NSAIDs)
Aminoglycosides
Congenital anomalies of the kidneys and urinary tract (see Table 289.2)

The fractional sodium excretion can be calculated from urine obtained by in-and-out bladder catheterization, using the following formula:

$$FE_{Na} = 100\%(U_{Na} \times P_{Cr})/(P_{Na} \times U_{Cr}),$$

where P_{Cr} and P_{Na} represent plasma creatinine sodium concentration and U_{Cr} and U_{Na} are the urine creatinine and urine sodium concentrations, respectively. If an infant has a fractional sodium excretion less than 1% and evidence of hypovolemia without edema or congestive heart failure, intravascular volume expansion may restore urine output (Table 289.1). This must be done cautiously in the very low birth weight infant because rapid expansion may induce intraventricular hemorrhage or opening of the ductus arteriosus. With the development of established acute kidney injury, FE_{NA} exceeds 1% despite oliguria. Severe renal ischemia may lead to renal cortical necrosis. This is generally seen in the context of septicemia and disseminated intravascular coagulation.

Fetal exposure to maternal administration of angiotensin inhibitors (either angiotensin converting enzyme inhibitors or angiotensin receptor blockers) or nonsteroidal anti-inflammatory drugs can impair renal development and may result in severe perinatal renal insufficiency. As discussed below, neonates are exquisitely sensitive to angiotensin inhibitors administered postnatally, and may develop acute oliguria even with doses 10% of those used in older children. Prostaglandin synthase inhibitors, generally administered to infants with patent ductus arteriosus, can cause profound renal vasoconstriction and oliguria. It should be noted that acute kidney injury in a neonate resulting from administration of nephrotoxic antibiotics is often not oliguric, and may be detected only by following serial plasma creatinine concentration.

Management of acute kidney injury in the neonate. The initial priorities in a neonate with acute kidney injury include treatment of infection with broad spectrum antibiotics, maintenance of adequate tissue perfusion, and acid–base and electrolyte balance. One of the most useful parameters to follow is body weight. This should be determined accurately every 12 h. In the anuric infant, replacement of insensible losses may be estimated at 0.5–1.0 ml/kg/h for a term infant, but should be reassessed often with measurements of weight and serum electrolyte concentrations. Insensible losses are proportionately greater in the preterm infant (at least 1.5 ml/kg/h for a 1,000 g infant). Insensible losses should be replaced with 10–15% dextrose in water without added electrolytes. Additional losses in urine, gastrointestinal drainage, or other body fluid drainage, should be replaced with fluids of similar

composition or adjusted to compensate for electrolyte imbalances.

Arterial pH should be maintained above 7.2. Frequent administration of sodium bicarbonate solution to oliguric infants can result in significant hypernatremia, hypertension, congestive heart failure, patency of the ductus arteriosus, and intracranial hemorrhage. Peritoneal dialysis or hemofiltration should be considered in infants with uncontrolled fluid retention.

Although hyponatremia may be associated with overhydration, infants with hyponatremia and hyperkalemia may have congenital virilizing adrenal hyperplasia. Fractional sodium excretion is elevated (greater than 2.5%) in neonates with adrenal insufficiency regardless of glomerular filtration rate or state of hydration. Serum potassium concentration in the neonate is generally well tolerated up to 6 mEq/l (◉ *Table 289.1*). For higher potassium concentrations (or electrocardiographic evidence of hyperkalemia), infusion of calcium, glucose, and bicarbonate will reduce extracellular potassium concentration, but will not result in net removal of potassium from the body. Exchange transfusion with low potassium washed red blood cells reconstituted with fresh frozen plasma can reverse hyperkalemia in the neonate and may postpone the need for dialysis. Administration of ion exchange resin (Kayexalate) suspended in sorbitol can be given per rectum. This will also result in net removal of potassium from the infant but can lead to hypernatremia or bowel obstruction.

Careful attention must be paid to calcium and phosphorus balance. Infants should be given a formula with high calcium to phosphorus ratio and low potassium content. Calcium carbonate, administered orally in divided doses, should be used to control serum phosphorus in the normal range. Plasma calcium concentration should be monitored along with phosphorus, as infants with renal insufficiency may develop hypercalcemia. Aluminum containing compounds should be avoided due to the increased risks of aluminum encephalopathy and bone toxicity in infants.

Severe hypertension can be treated with intravenous hydralazine (0.15–0.6 mg/kg/dose), although a continuous intravenous infusion is preferable (0.75–5.0 μg/kg/min). To ensure adequate cerebral perfusion, hypotension should be avoided by continuous blood pressure monitoring via an indwelling arterial catheter or frequent cuff measurements (10–15 min intervals). Although angiotensin converting enzyme inhibitors can be administered at very low doses (0.1 mg/kg/day for captopril), these drugs are best avoided in very low birth weight infants because of an exaggerated hypotensive response.

Drugs in the infant with renal insufficiency. The optimal 1 h post-dose peak serum concentration for gentamicin is 4–8 mcg/ml, whereas the trough concentration should be 0.5–2 mcg/ml. The interval between doses of gentamicin in the sick, very low birth weight infant may be as long as 36 h if renal insufficiency is present. Careful monitoring of blood levels is therefore imperative.

Infants with cardiopulmonary or renal disease frequently receive furosemide. It should be remembered that the half-life of furosemide in the neonate is prolonged compared to adults, and doses should optimally be limited to no more than 2 mg/kg/day to avoid the development of ototoxicity. Prolonged use of furosemide (particularly when combined with glucocorticoids) predisposes infants to hypercalciuria, nephrocalcinosis, and urolithiasis. If chronic administration of furosemide is necessary, urine calcium/creatinine ratios should be checked weekly. In the term infant receiving breast milk, the ratio (mg/mg) should be less than 0.4 (up to 0.8 in the preterm infant) (◉ *Table 289.1*).

In addition to their effects on renal development, angiotensin converting enzyme inhibitors can severely lower glomerular filtration rate in neonates, and may even precipitate acute kidney injury. This is true also of cyclooxygenase inhibitors such as indomethacin, which is used to treat patent ductus arteriosus. It is best to avoid use of either angiotensin converting enzyme inhibitors or prostaglandin synthase inhibitors in infants with renal insufficiency or reduced functioning renal mass.

Long-Term Implications of Neonatal Renal Disorders

With increasing survival of very low birth weight and critically ill neonates, the long-term prognosis of these fragile patients is of growing importance. Acute kidney injury is independently associated with mortality in preterm infants weighing less than 1,500 g (a 1 mg/dl increase in serum creatinine concentration doubles the odds of death). As noted earlier, a perinatal reduction in nephron number increases the risk for cardiovascular and renal disease in older childhood or adulthood. Unfortunately, it appears that in very low birth weight infants, nephrogenesis does not progress normally (even if birth weight is appropriate for gestational age and regardless of additional perinatal renal insults). Given the growing epidemic of childhood obesity, even more disturbing is the discovery that obesity and preterm birth comprise additive risks for progression of kidney disease. Thus, every effort must be made by the pediatrician to avoid delay in

the detection of renal anomalies, renal injury, and renal dysfunction in the neonate. There is much justification for the continued follow-up (through adulthood) of renal function and blood pressure of every infant discharged from a neonatal intensive care unit.

290 Approach to the Child with Hematuria

Coral D. Hanevold · F. Bruder Stapleton

Hematuria is a common finding in children and adolescents, often causing significant anxiety and prompting an extensive evaluation. Hematuria may be the initial manifestation of significant genitourinary disease although in many cases a diagnosis is not established even after consultation with a specialist. When microscopic hematuria (without proteinuria) is found as an incidental finding, significant pathology is rarely identified. If significant pathology is suspected, a logical approach to this common pediatric issue should be pursued. A careful assessment is required to determine the need for further testing or referral to a specialist.

Definition and Classification of Hematuria

Microscopic hematuria is defined by the presence of more than five red blood cells per high power field (hpf). In reality, hematuria is often detected initially by a urine dipstick. While this testing method is convenient, it is critical that the urine be examined under the microscope to establish the diagnosis of hematuria. A positive finding for blood on the strip indicates the presence of red cells, free hemoglobin, or myoglobin. A peroxidase substrate impregnated in the strip is oxidized in the presence of hemoglobin or myoglobin, which leads to a color change. These strips are very sensitive and can detect as few as two to five red cells per hpf. False-positive results may occur due to contamination with detergents used to clean the perineum, urine ph >9, heavy bacteriuria, or menstrual blood. False negatives may occur with a high intake of ascorbic acid. Practitioners should note that red cells may lyse in old or very dilute urine, giving the impression of a false-positive result. Once confirmed, hematuria should be classified as gross (visibly discolored) or microscopic, asymptomatic or symptomatic, and isolated or accompanied by proteinuria. Gross or visible hematuria and symptomatic microscopic hematuria will require prompt evaluation. In asymptomatic patients, persistence of hematuria should be confirmed on three samples over 2–3 weeks prior to conducting further investigation.

Gross Hematuria

Visible discoloration of the urine is frightening to children and parents and usually results in an urgent visit to the emergency room or doctor's office. The incidence of gross hematuria is not well established, but it is certainly much less common than microscopic hematuria. Gross hematuria is reported to account for 1.3/1,000 pediatric emergency clinic visits. Although the etiology is often easily determined, the diagnosis remains elusive in many. Greenfield et al. recently reviewed their 10-year experience and found that no etiology could be established in 118 of 342 children (34%) seen in a pediatric urology clinic. Similarly, two studies from pediatric nephrology practices have reported a failure to rmake a diagnosis in 38–44% of children.

Initial evaluation must include a microscopic exam of the urine sediment to confirm the presence of red cells (see *Fig. 290.1*). Other substances that may cause red or brown urine include medications, food and dyes, and some disease states. Microscopic exam of the urine also allows for identification of casts, white blood cells, epithelial cells, crystals, and/or bacteria. The finding of few red cells on microscopic exam in the face of red or brown urine supports a diagnosis of hemoglobinuria or myoglobinuria. Examination of the serum will further aid in differentiating between these two entities as the urinary supernatant will be pink in both conditions but the serum will only be pink in hemoglobinuria.

Once hematuria has been confirmed, it is helpful to categorize the hematuria as glomerular or non-glomerular in origin so that the evaluation can be focused on a limited set of diagnoses. Determination of the location of the bleeding will be guided by the associated complaints, past medical history, family history, physical exam, and the characteristics of the urine.

Gross Hematuria: Non-glomerular Source

Red or pink urine is suggestive of non-glomerular bleeding. Under the microscope, the red cells will appear

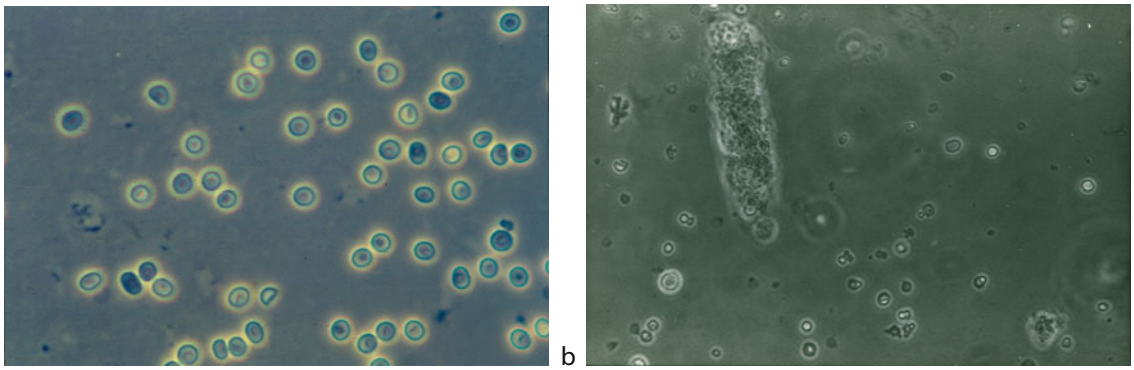

Figure 290.2
Red blood cells on microscopic examination of urinary sediment. Panel (a) shows eumorphic red cells with uniform size characteristic of non-glomerular hematuria. Panel (b) demonstrates dysmorphic red cells with variable sizes, shapes, and cytoplasmic blebs. A red cell cast is also demonstrated

uniform (see *Fig. 290.2a*). Proteinuria is typically minimal, but if urine is very bloody, proteinuria of +2 (or 100 mg/dL) may be seen in non-glomerular hematuria. The presence of clots or crystals would offer further support for a non-glomerular cause. It is helpful to determine if the urinary stream is discolored throughout the stream. Initial or terminal hematuria would indicate bleeding in the urethra or bladder trigone.

Common causes of non-glomerular gross hematuria include urinary tract infections, urethrorrhagia, trauma, hypercalciuria, nephrolithiasis, and exercise. Other causes include foreign bodies, autosomal-dominant polycystic kidney disease, coagulopathies, sickle-cell trait and anemia, and Wilms' tumor. Occurrence of hematuria after minor trauma raises concern about a preexisting anatomic abnormality such as hydronephrosis or a cystic kidney. Occasionally, non-glomerular hematuria may be factitious in nature. Associated symptoms such as abdominal or back pain, dysuria, frequency, urgency suggest a non-glomerular cause. A past history of urinary infections, hydronephrosis, renal cysts, sickle-cell trait or disease, and bleeding disorders would be pertinent. Relevant findings from the family history would include nephrolithiasis, vesicoureteral reflux, urinary infections, and sickle-cell trait or disease. On physical examination, the child should be assessed for an abdominal mass, costovertebral angle tenderness, abdominal or suprapubic tenderness, and evidence of trauma or abuse. Examination of the genitalia is always indicated to assess for evidence of abuse, trauma, or anatomic abnormalities.

Initial testing for non-glomerular hematuria may include urine culture, spot urine calcium/creatinine ratio, and imaging of the kidneys and bladder. A computed tomography (CT) scan with contrast is the best diagnostic study to investigate trauma, particularly in an unstable patient. A CT without contrast is the gold standard for identification of nephrolithiasis. However, if radiation exposure is a concern, an ultrasound is an acceptable alternative. Ultrasound will visualize most stones but may not reliably demonstrate small calculi and/or ureteral stones. Hypercalciuria has been reported to account for 16–43% of gross hematuria even if nephrolithiasis is not present. Abdominal pain, dysuria, and other urinary symptoms may also be associated with hypercalciuria. In a recent series, urethrorrhagia was identified as the etiology in 14–19% of the cases of gross hematuria. Urethrorrhagia occurs primarily in prepubertal boys and may be accompanied by dysuria and/or frequency. Spots of blood are often noted in the underwear. If the stream is observed the gross hematuria is usually terminal. The etiology of this process remains unclear, but the problem is usually self limited with resolution reported in 71% and 92% of the children within 1 and 2 years, respectively. Infrequently, painless gross hematuria occurs in patients with sickle-cell trait or sickle-cell anemia and typically originates from the left kidney. Although coagulation defects may result in hematuria, urinary bleeding is rarely the initial presentation for the defect.

Gross Hematuria: Glomerular Source

Brown- or tea-colored urine is characteristic of glomerular hematuria. In some cases, however, the urine will appear dark red, leading to some doubt as to the location of

bleeding. The concomitant finding of significant proteinuria (+2 or greater) and cellular casts would suggest a glomerular disease. Under the microscope, the red cells may show variability in size, and may have cytoplasmic blebs (see *Fig. 290.2b*).

Common causes of glomerular hematuria include post-infectious glomerulonephritis, Henoch–Schönlein purpura, IgA nephropathy, and, less often, Alport syndrome, systemic lupus erythematosus (SLE), and other types of acute or chronic glomerulonephritis. Symptoms of oliguria, unexplained weight gain, arthritis, arthralgias, recent pharyngitis or impetigo, rash, dyspnea, or fatigue would raise concern about glomerular disease. The family history should be reviewed for hematuria, hearing loss in adolescence or early adulthood, renal failure, and specific disorders such as SLE or Alport syndrome. On physical examination, findings of edema, hypertension, rash, purpura, arthritis, cough, or rales would be consistent with glomerulonephritis. Poor growth might suggest an underlying chronic kidney disease.

If glomerular hematuria is suspected, initial laboratory studies should include a serum creatinine, electrolytes, albumin, complete blood count, complement C_3 level (C_3), an antistreptolysin antibody titer (ASO titer), and a throat culture. The amount of proteinuria should be quantitated with a spot urine for protein and creatinine. A protein/creatinine ratio <0.2 mg/mg is normal. It should be noted that a negative ASO titer does not exclude post-infectious glomerulonephritis, which can follow a variety of bacterial, viral, and parasitic infections. However, the C_3 will be low with most post-infectious glomerulonephritis if the level is checked at the time of presentation. Hypertension and edema are frequently noted as well. Recurrent episodes of hematuria during upper respiratory illnesses would be suggestive of IgA nephropathy. In contrast to post-infectious glomerulonephritis, the C_3 is normal in IgA nephropathy, as is the blood pressure. Another differentiating point is the latent period, which is typically less than 5 days in IgA nephropathy versus 10–21 days following respiratory infections in post-infectious glomerulonephritis. Families should be educated on the need for follow-up after an initial diagnosis is made. Hematuria may persist on microscopic exam even after gross hematuria resolves. Exercise and illness can exacerbate an underlying chronic glomerulonephritis leading to episodes of gross hematuria superimposed on chronic microscopic hematuria. Significant proteinuria, hypertension, reduced renal function, oliguria, edema, or other systemic symptoms should prompt referral to a pediatric nephrologist for further evaluation and treatment.

Microscopic Hematuria

Microscopic hematuria is much more common than gross hematuria; screening of unselected populations in the past demonstrated a prevalence of 0.4–2% in children aged 6–15 years. While routine urine screening is no longer recommended by the American Academy of Pediatrics, microscopic hematuria may be detected when a urinalysis is performed in response to a symptom or a finding on physical exam. Not infrequently, the symptom or finding prompting the urinalysis resolves, leaving persistent, and often unexplained, hematuria.

When microscopic hematuria is detected, a complete history and physical exam should be performed addressing key points as mentioned in the discussion of gross hematuria. A genitourinary exam should be performed to exclude perineal irritation or anatomic abnormalities. The urine should be examined under the microscope at least once to confirm the presence of red cells and to assess for associated findings. In the absence of symptoms or signs, characteristics of the urine may offer the only clues as to the site of bleeding (as noted under gross hematuria). A very active urinary sediment with many red cells accompanied by white cells or cellular casts would raise concern for the possibility of significant glomerular disease. If there is no obvious cause for the hematuria, the child should be asked to avoid exercise for 24–48 h prior to subsequent checks to eliminate exercise as an etiology. If the child is symptomatic or if there are concerning findings from the history, the physical examination, or the urinalysis then a similar evaluation to that described for gross hematuria should be carried out.

Evaluation of Microscopic Hematuria

Common causes of microscopic hematuria include urinary tract infection, hypercalciuria, benign familial hematuria, IgA nephropathy, post-infectious glomerulonephritis, exercise, nephrolithiasis, and sickle-cell trait or anemia. In asymptomatic children, hypercalciuria, benign familial hematuria, and IgA nephropathy are the more frequently identified causes. In view of the favorable prognosis of microscopic hematuria, a limited evaluation is recommended. If the history and physical are not suggestive of an etiology, initial evaluation can be restricted to a spot urine calcium and creatinine, a check of urine samples from the parents for hematuria, and a hemoglobin electrophoresis in selected patients. Other studies are not necessary, but may be obtained in some cases to

alleviate parental anxiety. Parents may be reassured by checking a serum creatinine and renal ultrasound to demonstrate that renal function is normal and to exclude a renal or bladder mass. In fact, Wilms' tumor and other renal malignancies rarely present with isolated asymptomatic microscopic hematuria.

Common Causes of Microscopic Hematuria

Hypercalciuria has been implicated as a cause of microscopic hematuria in 11–16% of children. A higher prevalence of hypercalciuria is reported in children from the southern United States. While a 24-h urine is the ideal test, it is appropriate to screen for hypercalciuria with a random spot urine for calcium and creatinine. The urine calcium/creatinine ratio should be under 0.86 mg/mg for infants under 6 months, under 0.60 mg/mg for infants ages 6–18 months, under 0.42 mg/mg for children ages 19 months to 6 years, and under 0.2 mg/mg for children over 6 years. Hematuria may occur even in the absence of nephrolithiasis and has been attributed to mucosal irritation.

Benign familial hematuria is a frequent cause of microscopic hematuria. A large study of children with microscopic hematuria reported that a family history of hematuria may be present in up to 25% of children with microscopic hematuria. A urine sample should be obtained from the parents, if possible, to check for hematuria rather than relying on historical information. Recent studies have suggested that benign familial hematuria is inherited in an autosomal-dominant pattern. This entity is also referred to as thin membrane disease as the renal biopsy is characterized by exceeding thin glomerular basement membranes. While progressive disease has rarely been reported, most patients with this condition remain asymptomatic, maintain normal renal function, and have no extrarenal manifestations. Gross hematuria is not typical but may occur. Alport syndrome occurs less frequently and is usually inherited in a X-linked dominant pattern. Males without a positive family history could represent a new mutation or have autosomal-recessive disease. Males typically develop hearing loss, proteinuria, and progressive renal insufficiency in the second or third decade of life. Manifestations are generally less severe in females who generally maintain normal renal function and are less likely to develop hearing loss. Microscopic hematuria in a boy's father and a negative family history for males with hearing loss and renal failure in adolescence or young adulthood would support a diagnosis of benign familial hematuria. A hearing test to check for high frequency hearing loss may be helpful in older boys. While the diagnosis is usually made based on the clinical picture and family history, further diagnostic testing including genetic testing, or tissue biopsy may be indicated in some cases.

IgA nephropathy, the most common type of primary glomerulonephritis worldwide, may also present with isolated microscopic hematuria. Other presentations include intermittent gross hematuria with interim microscopic hematuria, a combination of hematuria and proteinuria, isolated proteinuria, or nephrotic syndrome. Although this entity may be suspected on clinical grounds, a kidney biopsy is required to definitively establish the diagnosis. Biopsy is usually deferred if manifestations are limited to microscopic hematuria as there is no recommended intervention in the absence of proteinuria. Follow-up of hematuria is crucial as up to 40% of patients with IgA nephropathy develop proteinuria and progressive disease over time. IgA nephropathy can be difficult to differentiate from post-infectious glomerulonephritis, which may present with microscopic hematuria as the sole manifestation. With post-infectious glomerulonephritis, the hematuria typically resolves within 4–6 months but will likely persist with IgA nephropathy.

Natural History of Microscopic Hematuria

If the child is asymptomatic and initial studies do not reveal a cause, observation is suggested. Follow-up should be performed every 4–6 months for the first year, and then yearly, to screen for the development of proteinuria, hypertension, or new related complaints. Many families need reassurance that observation is acceptable. Several studies support a limited evaluation for asymptomatic microscopic hematuria. In a retrospective review of 325 patients referred to two pediatric nephrology practices, the authors found that studies such as renal ultrasound, voiding cystourethrogram, C_3, and creatinine did not yield meaningful data in children with isolated asymptomatic microscopic hematuria. A large review of cases referred to a nephrology clinic reported that no cause was identified in 80% of children with microscopic hematuria. These investigators emphasized the need for follow-up. Over time, the prognosis of microscopic hematuria is excellent, with few children showing evolution to more significant disease. In many cases, the hematuria resolves over several months to years. Remission occurs at the rate of 25–30% per year. Children with more significant hematuria (more than 10–20 red cells per hpf) are more likely to show persistence of hematuria over time.

Criteria for Referral to Specialist

Gross and microscopic hematuria occur commonly in children and the pediatrician should follow a logical approach to the evaluation based on findings from the urinalysis, history, and physical examination. Consultation with a pediatric nephrologist should be considered in children with associated systemic complaints or disorders, edema, oliguria, significant proteinuria, an elevated creatinine, recurrent gross hematuria, and/or family history of renal failure, nephritis, or early onset hearing loss. In some cases, a referral may be indicated to offer reassurance to the family. Referral to a pediatric urologist is indicated in children with nephrolithiasis, anatomic defects, a history of trauma, or unexplained non-glomerular gross hematuria. The vast majority of children with hematuria can be managed by their primary care provider.

291 Approach to the Child with Proteinuria

Amanda W. Dale-Shall · Leonard G. Feld

Introduction

Protein in the urine, termed proteinuria, is a common urinary finding among pediatric and adolescent patients and can be indicative of a normal, benign process or of numerous types of pathologic renal diseases. This distinction can be determined through a stepwise evaluation process of the type and degree of proteinuria and associated systemic findings. In the 1800s, Dr. Richard Bright first described an association between proteinuria and renal disease. Since that time, many clinical diagnoses have been identified with the associated finding of proteinuria, which can be accompanied by edema, hypoalbuminemia, macroscopic or microscopic hematuria, hypertension, abnormal kidney function, or systemic findings. The general practitioner should begin initial urinary testing and then proceed to a pediatric nephrology referral depending upon the results of the initial evaluation.

Definition

Proteinuria is defined as urinary protein excretion at levels higher than 100–150 mg/m^2/24-h period. The main components of urinary protein include albumin, beta$_2$-microglobulin, immunoglobulins, and Tamm–Horsfall mucoproteins although many other plasma proteins may be present, depending upon the underlying disease process. High levels of protein excretion characterize nephrotic-range proteinuria and nephrotic syndrome. Abnormalities occurring at various locations of the nephron will lead to various types and degrees of proteinuria.

Proteinuria Measurement

Proteinuria can be evaluated in the following ways: urinary dipstick reagent testing, sulfosalicyclic acid (SSA) turbidity testing, random or first morning urine specimen evaluation for a urine protein-to-creatinine ratio (U_{Pr}/U_{Cr}), 24-h quantitative urine collection for urinary protein and creatinine content, urine protein electrophoresis, or urinary microalbumin level (*Table 291.1*). The most commonly used screening tool for urinary abnormalities and renal disease is the urinary dipstick test. This is a qualitative and semiquantitative method. Freshly voided specimens are preferred, but if this is not feasible, the urine should be refrigerated and then brought to room temperature before analysis. The reagent strip should be quickly removed from the bottle, immersed in the fresh urine specimen, blotted to remove any excess urine, and then analyzed within 30 s to 2 min. The reagent strip is impregnated with a chromatophore called tetrabromophenol blue, which is a pH indicator that changes color based upon the amount of amino acids in the urine. The color change begins with yellow at normal levels and changes to green and then bluish-green with higher levels of proteinuria.

The urinary dipstick method is most sensitive to the albumin content in the urine and is less sensitive to other types of proteins, such as low molecular weight proteins, globulins, and plasma proteins. A graded scale is then reported as follows: negative (less than 10 mg [mg] per deciliter [dL]), trace (10–20 mg/dL), 1+ (30 mg/dL), 2+ (100 mg/dL), 3+ (300 mg/dL), or 4+ ($\geq$2,000 mg/dL). False-positive results can occur when the reagent strip is immersed too long in the fresh urine specimen or with alkaline or highly concentrated specimens, pyuria, macroscopic hematuria, and certain detergents. False-negative results can occur in very dilute urine specimens or when the urinary protein content is not primarily albumin. A dipstick urine test is considered positive for proteinuria if at least three specimens collected one or more weeks apart are 1+ (30 mg/dL) or greater, depending upon the concentration and pH of the urine.

The qualitative SSA test is less commonly used but has the advantage of detecting a broader range of proteins in the urine, including albumin, immunoglobulins, and Bence-Jones proteins. This is a turbidometric method of urine testing. The SSA reagent is added to a freshly voided specimen, and the degree of turbidity is correlated to the amount of proteinuria based upon a predetermined scale. Acidification of the urine causes precipitation of urinary

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_291,

Table 291.1
Different types of urinary proteinuria measurements

Method	Technique	Normal range	Advantages	Disadvantages
Dipstick testing	Random or first morning specimen	Negative or trace (<20 mg/dL)	Ease of collection, screening tool, most sensitive to albumin	Qualitative, results sensitive to urine pH and specific gravity
SSA test[a]	Random or first morning specimen	Negative or trace (<10 mg/dL)	Broader range of urinary protein detection, including low molecular weight proteins	Subjectivity of results scale, sensitive to urine pH and specific gravity
(U_{Pr}/U_{Cr})[b]	Random or first morning specimen	<0.8; <6 months of age <0.5; 6–24 months of age <0.2; >2 years old	Semiquantitative, approximates 24-h collection	Unreliable if malnourished, low muscle mass, low GFR[c]
24-h urine collection	Total or recumbent versus upright collection	<150 mg/m^2/24 h	Most accurate quantitative method	Inadequate collection leads to inaccuracy, difficult to perform if incontinent and in children
Protein electrophoresis	Random specimen	N/A[d]	Detects percentage of albumin and low molecular weight proteins	Cost, test specificity may lead to result delays
Microalbumin level	First morning specimen	<20 mg albumin/g creatinine	Useful in diabetic patients	Ongoing research for appropriate interpretation

[a]Sulfosalicyclic acid (SSA) turbidity test

[d]Not applicable

proteins, which is graded in a fashion similar to urinary dipstick testing. A disadvantage to this type of testing is the subjectivity in the grading scale, and thus this technique is rarely used. False-positive results can occur with recent exposure to radiographic contrast material, high concentrations of penicillin or cephalosporin antibiotics, or with high uric acid concentration in the urine. False-negative results can occur in the setting of highly buffered alkaline or diluted urine specimens.

The urine protein-to-creatinine ratio is a highly useful tool for quantitative measurements of proteinuria in the pediatric population because 24-h urine collections are prone to inaccuracies in collection or are not possible in an infant or younger child who is not yet toilet trained. The correlation between (U_{Pr}/U_{Cr}) and 24-h urine collection results has been established in several studies and among many disease processes. The (U_{Pr}/U_{Cr}) can be calculated on a random, or untimed, specimen or on a first morning urine (FMU) specimen. Accuracy in the FMU collection is imperative in the diagnosis of certain types of proteinuria (*Fig. 291.1*). FMU analysis is preferred due to the large degree of variability in urinary protein levels throughout the day. A freshly voided urine specimen is sent for urine protein and urine creatinine levels in mg/dL units, and then the ratio is determined. The ratio result is then estimated to a 24-h urine collection. For example, a (U_{Pr}/U_{Cr}) of 0.2 is approximately equivalent to 150–200 mg of protein in a 24-h collection. The normal (U_{Pr}/U_{Cr}) range for infants less than 6 months of age is not clearly defined, but it has been shown that protein excretion rates in infants are higher than in older infants and children; ratio values higher than 0.8–1 in young infants are generally considered abnormal. The normal ratio for children 6–24 months of age is less than 0.5 and for children older than 2 years of age and adults is less than 0.2. Pathologic proteinuria occurs at ratio values greater than 1–2 in a pediatric population, but this value can also be considered normal in certain situations, as discussed below.

Although the (U_{Pr}/U_{Cr}) is utilized frequently for pediatric patients, there are some limitations to its use. The ratio is dependent upon the production and excretion of creatinine, which can be variable depending upon the child's body habitus. In children with severe malnutrition or low

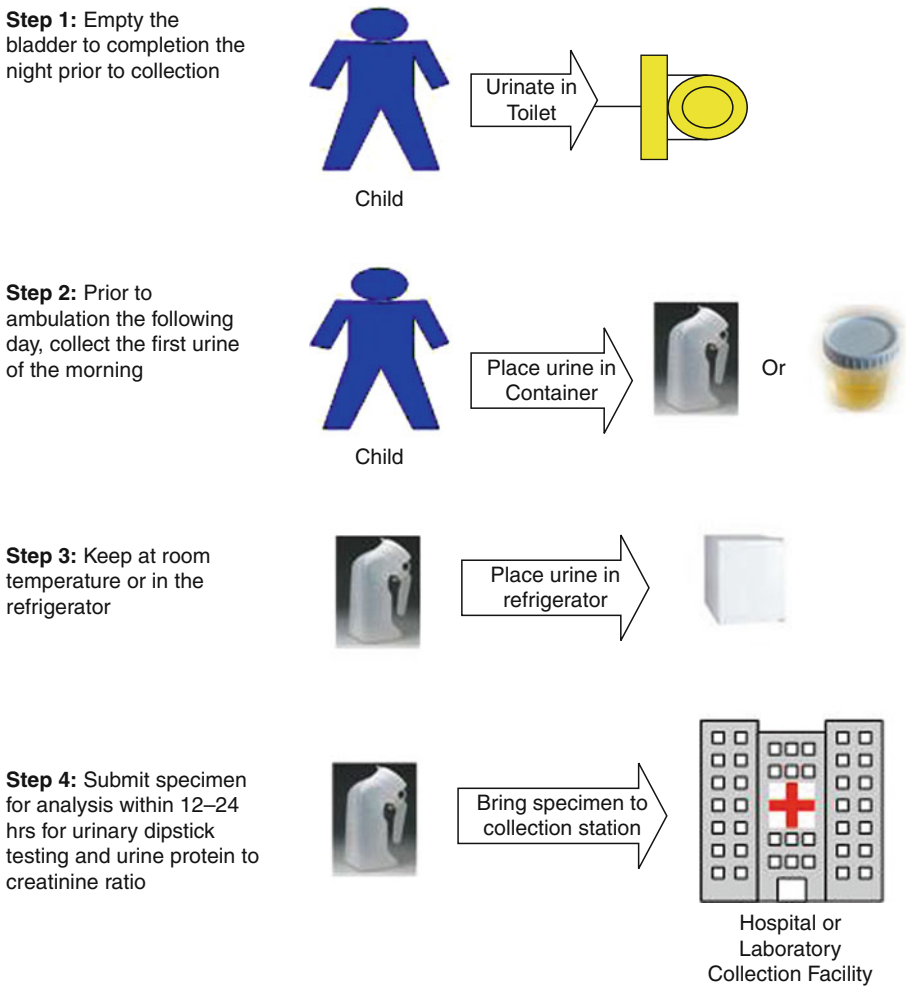

Figure 291.1
First morning urine (FMU) collection technique to assess for orthostatic proteinuria

muscle mass, creatinine excretion is expected to be low, which will result in an elevated (U_{Pr}/U_{Cr}). In patients with orthostatic, or postural, proteinuria, higher values are acceptable and expected for untimed urine specimens, and therefore first morning urine specimens should be utilized to more accurately assess protein excretion rates. Febrile patients or those who have exercised recently may demonstrate transient elevations in protein excretion, thus a (U_{Pr}/U_{Cr}) should be performed for afebrile patients at rest. Finally, the interpretation of (U_{Pr}/U_{Cr}) in patients with low glomerular filtration rates may be difficult and should be reserved for a pediatric nephrologist. If the results are potentially misleading, a 24-h urine collection should be attempted to confirm urinary protein quantification. Despite these potential limitations, the (U_{Pr}/U_{Cr}) is a highly useful assessment tool for proteinuria quantification in the pediatric population and can be utilized to track protein excretion over time in many clinical situations.

The gold standard for urinary protein quantitation among all populations is the 24-h urine collection. This can be performed as a total 24-h collection or as a split collection, with upright (ambulatory) versus supine specimens evaluated separately. The latter is primarily performed if orthostatic proteinuria is suspected. Most authors regard protein levels of 100–150 mg/m^2/24 h (mg/m^2/day) to be normal for infants, children, and adolescents; preterm infants and neonates have high levels of basal protein excretion and, therefore, higher amounts of proteinuria are acceptable. Proteinuria in pediatric patients greater than 1,000–2,000 mg in 24 h is generally

observed to be pathologic, except if orthostatic proteinuria is suspected. Variations in quantifying proteinuria can be diminished using body surface area with 24-h urine collection results as follows: normal $\leq$4 mg/m^2/h, abnormal 4–40 mg/m^2/h, and nephrotic-range proteinuria >40 mg/m^2/h. As noted previously, these collections can be cumbersome to perform, may have a high degree of under-collection leading to inadequate specimens (such as with incontinent patients), may delay the diagnostic work-up due to the length of time needed for collection and analysis, and cannot be performed in non-toilet-trained patients, limiting its utility in pediatric populations. Despite these limitations, this is the most accurate method to specifically quantitate the degree of proteinuria and can be quite useful in determining if further evaluation is warranted.

Two special situations may warrant additional evaluations for proteinuria. The first is in the setting of low molecular weight proteinuria, in contrast to albuminuria, which can be seen in tubular or interstitial renal diseases. Tubular proteinuria may be underestimated on urinary dipstick testing, due to the lower levels of albuminuria. In this circumstance, a urine protein electrophoresis should be evaluated on a urine bag specimen in infants or from a clean catch urine collection in older children and adolescents. This testing will elucidate the percent of proteinuria content, that is, albumin, beta$_2$-microglobulin, alpha globulins, monoclonal proteins, etc. If a malignancy involving the over-production of immunoglobulins is suspected, a urine immunofixation electrophoresis can also be assessed.

Second, in the setting of children with diabetes mellitus, more specific quantitation of lower levels of proteinuria than can be detected on urinary dipstick testing is required. The urine microalbumin level can be determined, and a urine microalbumin to creatinine ratio (MA:Cr) can be calculated, similar to a urine protein-to-creatinine ratio. The normal range is less than 20–30 mg of urine albumin per gram of creatinine on a first morning specimen. A consensus group defined microalbuminuria as a urine albumin excretion level of 20–200 μg/min/1.73 m^2 or 30–300 mg albumin per gram creatinine per 24 h and frank proteinuria as greater than 200 μg/min/1.73 m^2. This ratio should be assessed on a first morning urine specimen. In patients with type I and type II diabetes mellitus, microalbuminuria has been shown in numerous studies to be a predictor of progressive renal disease and potentially cardiovascular morbidity and mortality. One recent study, however, did not demonstrate a correlation between elevated urine microalbumin levels and progressive renal disease. Currently, the recommendation is to follow this ratio periodically in patients with diabetes mellitus and initiate therapy when the MA:Cr is above the normal range. Some have also proposed utilizing this ratio in hypertensive patients and in other clinical situations as an early indicator for end organ damage and deleterious long-term cardiovascular effects.

Epidemiology

The prevalence of protein in the urine will vary based upon the definition of proteinuria used and the number of urine specimens evaluated. Proteinuria is a common finding in urine specimens with an overall prevalence ranging between 5% and 15% in a single void specimen. One study of over 1,000 patients with abnormal urinary findings detected in a mass school urine screening process in Korea reported proteinuria in over 50% of the abnormal urine specimens; the majority of these patients had either transient or orthostatic proteinuria. Pathologic or persistent proteinuria occurs in a minority of patients, with rates ranging from 0.1% to 2%. About 1 in 1,000 school-aged children will have persistent proteinuria after testing of three or more specimens. The prevalence increases with increasing age and peaks in adolescence. One study reported that the peak prevalence in females is 13 years of age and in boys is 16 years of age. The incidence of idiopathic nephrotic syndrome (NS) has been reported to occur in a range of 2–7/100,000 children and a prevalence of about 16 cases per 100,000 children per year. Despite overall low rates of proteinuria among pediatric patients, early detection, evaluation, and treatment of pathologic proteinuria is critical due to the potential for significant long-term renal parenchymal disease and progression to end-stage renal disease.

Etiology of Proteinuria

Many renal diseases are associated with proteinuria, which may be asymptomatic or associated with other findings such as edema, hematuria, or diverse systemic symptoms. Various classification systems have been developed to distinguish different forms of proteinuria. There are important differences among the following classes of proteinuria: transient, orthostatic, isolated, and persistent (*Table 291.2*). Each of these categories will be discussed separately below and have different levels of concern for the primary care provider and pediatric nephrologists.

Transient proteinuria is not typically associated with significant renal parenchymal disease and will resolve when the inciting factor ceases. This type of proteinuria

Table 291.2
Categorization of proteinuria

Category	Testing method	Examples	Monitoring
Transient	Urinary dipstick	Fever, stress, dehydration, cold exposure, seizure activity, strenuous exercise	Repeat urine testing when inciting factor resolves to confirm negative result
Orthostatic	First morning urine dipstick test or (U_{Pr}/U_{Cr})[a] (rarely 24-h urine recumbent versus upright collection)	Common in older children and adolescents	Intermittent first morning urine and blood pressure assessments
Isolated	Urinary dipstick, (U_{Pr}/U_{Cr}), or 24-h urine collection	Asymptomatic patient with normal laboratory tests, physical exam and blood pressure	Periodic monitoring, consider pediatric nephrology referral
Persistent	Urinary dipstick, (U_{Pr}/U_{Cr}), or 24-h urine collection	Nephrotic syndrome, glomerular or systemic diseases	Detailed evaluation, long-term monitoring, pediatric nephrology referral warranted

[a]Urine protein-to-creatinine ratio

can be observed in the setting of fever, stress, dehydration, cold exposure, seizure activity, or strenuous exercise. Exercise-induced proteinuria usually remits within a few hours but may last as long as 48 h after completion of strenuous exercise. This proteinuria may be due to hemodynamic changes in glomerular blood flow resulting in increased protein diffusion into the urine. Urine dipstick test results are usually 2+ or lower and resolve on subsequent testing. Further evaluation is not necessary.

Orthostatic, or postural, proteinuria is a common finding in older children and adolescents, accounting for over 60% of all proteinuria and occurring in approximately 3–5% of adolescents. The hallmark of orthostatic proteinuria is elevated protein excretion in ambulatory, or untimed, urine specimens and normal or minimal protein excretion during recumbency. Precise first morning urine specimen collection by the patient is critical to accurately diagnose this type or proteinuria. Urinary dipstick testing via first morning urine collection, (U_{Pr}/U_{Cr}), and 24-h urine collections can all be used for diagnosis, but 24-h collections are rarely required if the FMU is collected appropriately. The total urinary protein excretion in orthostatic proteinuria rarely exceeds 1 g in a 24-h urine collection although some collections may exceed this value; a split 24-h urine collection with supine, or recumbent, versus upright specimens evaluated separately can easily yield the diagnosis, and affords more accurate distinction in proteinuria levels based on patient behavior. The precise etiology of this type of proteinuria is unclear, and some have proposed that renal hemodynamic changes, partial renal vein occlusion, increased permeability of the glomerular capillary wall, or circulating immune complexes may be factors. Follow-up studies of 20–50 years have observed that orthostatic proteinuria is a benign process with few to no long-term renal effects; however, rare cases of later onset glomerulosclerosis or other abnormalities have been reported. Therefore, periodic monitoring of first morning urine specimens and blood pressures is currently recommended and can be performed either by the primary care provider or by a pediatric nephrologist. Parents and patients can be counseled that the long-term prognosis is generally excellent.

Isolated proteinuria is characterized by asymptomatic proteinuria in an otherwise healthy patient with normal physical exam findings, blood pressure readings, urinary sediment, and laboratory findings at the time of diagnosis. Usually the degree of proteinuria is less than 2 g in 24 h; higher values indicate the need for a further investigation into the etiology of the proteinuria. The majority of these individuals do not have progressive renal disease, although in some studies, a minority of renal biopsy specimens revealed abnormal histology such as focal segmental glomerulosclerosis. Some studies predict a 20% risk for progressive renal damage over a 10-year period. Therefore, an initial thorough evaluation as well as close long-term monitoring is indicated, and a referral to a pediatric nephrologist is recommended.

Persistent proteinuria is defined as urinary dipstick results of 1+ (>30 mg/dL) or higher levels of proteinuria on three or more specimens separated by several weeks. A (U_{Pr}/U_{Cr}) and possibly a 24-h urine collection should be performed, assuming that orthostatic proteinuria has been excluded. A detailed patient history, physical exam, and family history should be followed by a more extensive

evaluation including laboratory and radiology studies. The list of potential etiologies is extensive and includes nephrotic syndrome, glomerulonephritis, and systemic renal diseases. A referral to pediatric nephrology should be initiated early in the evaluation process to help direct the evaluation and for counseling of patients and families. Depending upon the results of the aforementioned evaluations, a renal biopsy may also be warranted. Close long-term monitoring by a specialist in renal diseases will be required for this type of proteinuria.

Pathophysiology

In normal individuals, only low amounts of protein are excreted into the urine as a result of two processes that restrict passage of higher levels of protein. First, filtration of large serum proteins such as albumin is restricted at the level of the glomerulus. Second, low molecular weight proteins are filtered at the glomerulus but then are reabsorbed by the proximal tubule. These low levels of proteinuria are generally not detected on urinary dipstick testing. The approximate composition of normally excreted protein is 40% of high molecular weight albumin (approximately 65,000 Da), 40% of Tamm–Horsfall mucoproteins secreted by the ascending limb of the loop of Henle, and 20% of low molecular weight proteins such as $beta_2$-microglobulin (11,000 Da). Normal hemodynamic mechanisms in glomerular blood flow also prevent urinary protein loss.

In patients with renal disease, excessive urinary protein losses can occur as a result of increased permeability of the glomeruli, termed glomerular proteinuria, decreased reabsorption of low molecular weight proteins by the renal tubules, termed tubular proteinuria, or variations in glomerular blood flow. The size, charge, and concentration of a molecule determine the effectiveness of filtration and the subsequent amount in the urine. The normal glomerulus permits passage of fluid and small solutes with molecular weights less than 20,000 Da but restricts passage of larger molecules. Additionally, the glomerular basement membrane contains negatively charged heparin sulfate proteoglycans, which repel negatively charged molecules, such as albumin. In many renal diseases, one or both of these normal mechanisms is disrupted, thus allowing inappropriate passage of molecules into the urine at the glomerular level. Glomerular proteinuria is therefore mostly composed of albumin and generally leads to high levels of proteinuria. Some examples of diseases characterized by glomerular proteinuria include minimal change nephrotic syndrome, focal segmental glomerulosclerosis, membranous nephropathy, membranoproliferative glomerulonephritis, IgA nephropathy, and diabetic nephropathy.

Normally, small amounts of protein are filtered at the glomerulus, and then the majority of these filtered proteins are reabsorbed by the proximal tubule. In tubulointerstitial diseases, this reabsorption does not occur normally, leading to increased amounts of low molecular weight molecules in the urine such as $beta_2$-microglobulin. The degree of tubular proteinuria is generally less than that seen in glomerular proteinuria, with typical amounts less than 2 g/day. Some examples of diseases associated with tubular proteinuria include interstitial nephritis, Fanconi syndrome, and sickle cell disease nephropathy. Alternatively, overflow proteinuria can occur if low molecular weight proteins, such as immunoglobulins, cannot be efficiently reabsorbed by the proximal tubule. This is rarely seen in pediatric patients but is common in adult patients with multiple myeloma. An example of overflow proteinuria seen in pediatric patients is myoglobulinuria in the setting of rhabdomyolysis. Urine protein electrophoresis can effectively be used to diagnose both of these types of proteinuria.

There are also identifiable genetic abnormalities that lead to proteinuria, as seen in some forms of congenital nephrotic syndrome and focal segmental glomerulosclerosis. Expressed in the podocyte foot processes and slit diaphragm, abnormalities in the proteins termed nephrin and podocin lead to steroid-resistant forms of nephrotic syndrome. The *NPHS1* gene encodes the transmembrane protein called nephrin, which is located within the slit diaphragm and interacts with the epithelial cell, or podocyte foot processes, and the glomerular basement membrane. Several mutations in this gene have been shown to result in congenital nephrotic syndrome (CNS) of the Finnish type. Alternatively, the *NPHS2* gene encodes the podocyte protein called podocin, which can lead to steroid-resistant nephrotic syndrome such as focal segmental glomerulosclerosis. Other proteins that interact with the proteins nephrin and podocin include CD2AP, NEPH1, filtrin, alpha-actinin 4, and densin. A great deal of research is ongoing to further elucidate the role of genetic mutations that lead to abnormal protein products in the glomerulus for certain renal diseases and types of nephrotic syndromes.

Clinical Manifestations

The clinical manifestations of proteinuria occur along a broad spectrum, from entirely asymptomatic to systemic manifestations requiring hospitalization and an

expeditious evaluation. Asymptomatic proteinuria is the most common presentation and is detected with a screening urinalysis, typically performed by the primary care provider. Additionally, a child may present with nonspecific symptoms, and a screening urinalysis will reveal proteinuria with or without other abnormal findings. Alternatively, pediatric patients may present with classic nephrotic syndrome features including periorbital and lower extremity edema, ascites, and abdominal pain. Finally, some patients present with a myriad of systemic symptoms in addition to abnormal urinary results and require a prompt evaluation.

Nephrotic syndrome (NS) is defined by nephrotic-range proteinuria, hypoalbuminemia (<2.5 g/dL), edema, and hypercholesterolemia. Nephrotic-range proteinuria can be defined using different methods such as a (U_{Pr}/U_{Cr}) greater than 1–2, or a 24-h urine collection with greater than 50 mg/kg/day of proteinuria or greater than 40 mg/m^2/h of proteinuria.

Systemic renal diseases with proteinuria in addition to other renal findings such as hematuria or hypertension may manifest with classic physical exam findings, significantly aiding the diagnosis (Table 291.3). With post-infectious glomerulonephritis, patients will have a prodromal illness 2–4 weeks prior to the onset of the renal manifestations of macroscopic hematuria, proteinuria, and possible elevated creatinine levels. The preceding illness may include pharyngitis or skin lesions such as impetigo, especially in the setting of Streptococcal infections. Patients with IgA nephropathy will often present with abdominal or flank pain, fever, and macroscopic hematuria within 72 h of an upper or lower respiratory illness. The potential clinical manifestations of systemic lupus erythematosus are numerous and can include facial rash and other dermatologic findings, fatigue, fever, weight loss, mouth sores, shortness of breath, chest pain, joint pain or edema, and alopecia. Henoch–Schönlein purpura may present with lower extremity and buttock petechial and purpuric lesions, significant abdominal discomfort, migrating edema, and joint pain and edema. Patients with diarrhea-positive hemolytic uremic syndrome may have a history of bloody diarrhea, abdominal

Table 291.3
Clinical manifestations of systemic renal diseases associated with persistent proteinuria

Systemic disease	Renal findings	Physical findings	Laboratory tests
Post-infectious GN[a]	Macroscopic or microscopic hematuria, pyuria, urine cellular casts, elevated creatinine level	Streptococcal pharyngitis or skin lesions or other infectious symptoms 2 to 4 weeks prior to renal findings	Positive anti-streptolysin O or anti-DNase B titer, decreased complement C3 level
IgA nephropathy	Macroscopic or microscopic hematuria, rarely elevated creatinine level	Abdominal or flank pain, fever, URI symptoms[b] 2 to 3 days prior to renal findings	Normal complement – C3 and C4 levels
Henoch–Schönlein purpura	Macroscopic or microscopic hematuria	Abdominal pain, lower extremity and buttock purpura, arthralgia, arthritis, peripheral edema	Normal complement – C3 and C4 levels
Hemolytic uremic syndrome	Macroscopic hematuria, oliguria, elevated BUN and creatinine levels	Bloody diarrhea, abdominal pain, emesis, pallor, anorexia	Anemia, thrombocytopenia, elevated LDH level,[c] normal complement – C3 and C4 levels
Systemic lupus erythematosus	Microscopic hematuria, urine cellular casts, elevated creatinine	Fever, weight loss, alopecia, facial rash, chest pain, shortness of breath, arthralgia, arthritis	Positive ANA and anti-ds DNA titer, decreased complement C3 and C4 levels, elevated ESR[d]
Interstitial nephritis	Elevated urine eosinophil level, sterile pyuria, dysuria, microscopic hematuria, elevated creatinine level	Fever, rash, nausea, emesis, infectious symptoms, recent exposure to antibiotics or other medications, back pain	Elevated ESR level, eosinophilia, anemia

[a]Glomerulonephritis (GN)
[b]Upper respiratory infection (URI) symptoms
[c]Lactate dehydrogenase (LDH)
[d]Antinuclear antibody (ANA), anti-double-stranded DNA (anti-ds DNA), erythrocyte sedimentation rate (ESR)

pain, emesis, anorexia, pallor due to anemia, decreased urine output, and rarely petechiae. Interstitial nephritis may present with allergic symptoms such as rash or a history of recent exposure to antibiotics or other medications. Utilizing the history and physical exam features can assist in detecting systemic renal diseases associated with proteinuria.

Diagnosis

When proteinuria is discovered, a microscopic urinary evaluation should be performed to determine the presence or absence of hematuria with eumorphic or dysmorphic red blood cells, pyuria, bacteriuria, cellular or noncellular casts, urine eosinophils, oval fat bodies, or crystals (*Table 291.4*). Abnormal urinary microscopic sediment findings should prompt a pediatric nephrology evaluation, since many of these findings suggest an underlying renal disease. In the absence of an abnormal urinary microscopic analysis, an initial systematic evaluation process should be implemented when proteinuria is detected in a pediatric patient. Utilization of a stepwise approach affords an efficient and cost-effective approach to the work-up of proteinuria (*Fig. 291.2*). The initial steps can be performed by the primary care provider, while the more specific and extensive evaluation should be reserved for a pediatric nephrologist.

Table 291.4
Urine microscopy interpretation

Urine microscopy result	Suggested interpretation
Eumorphic RBC[a]	Upper or lower urinary tract process
Dysmorphic RBC	Upper urinary tract process such as glomerulonephritis
WBC[b]	Infection, exudative glomerulonephritis, interstitial nephritis
Hyaline casts	Volume depletion
Granular casts	Chronic renal disease
Fatty casts or oval fat bodies	Nephrotic syndrome, systemic lupus erythematosus nephritis
WBC casts	Pyelonephritis, exudative glomerulonephritis, interstitial nephritis
RBC casts	Glomerulonephritis, vasculitis
Urine eosinophils[c]	Interstitial nephritis

[a]Red blood cells (RBC)
[b]White blood cells (WBC)
[c]To detect the presence of urine eosinophils, request the laboratory to perform Wright, Giemsa, or Hansel staining of the urine

The first step in the evaluation process is to complete a detailed patient and family history and physical exam. Specific attention toward signs or symptoms suggesting an underlying renal disease should be the focus, including accurate blood pressure and growth assessments. Pertinent findings in the patient history include recent infections, changes in weight, appearance of edema, symptoms of hypertension, macroscopic hematuria, oliguria, polyuria, skin lesions, joint symptoms, pain, previous abnormal urinalyses, and a list of recent medications. A family history of renal disease, hypertension, autoimmune disease, deafness, or visual impairment is pertinent. Random and first morning urine specimens may be collected and analyzed; if orthostatic proteinuria is diagnosed, no further evaluation is needed except for periodic monitoring of FMU specimens on an every 6–12 month basis in addition to blood pressure monitoring. If three separate urine specimens that are separated by weeks continue to demonstrate proteinuria $\geq$1+ (30 mg/dL) on a dipstick test, the next step in the assessment process should be performed.

As part of the second step, laboratory studies including a complete blood count, electrolytes, renal function, serum albumin level, and a complement C3 level with or without a complement C4 level should be included. Consideration for additional tests including streptococcal markers such as the anti-streptolysin O titer or anti-DNase B titer, an antinuclear antibody (ANA) level, and a cholesterol level can be ordered in certain circumstances. More specific quantification of the degree of proteinuria is necessary at this stage and can be accomplished with either a (U_{Pr}/U_{Cr}) or a 24-h urine collection, if feasible. From a radiology perspective, a chest X-ray or a renal ultrasound may be beneficial to review, looking for evidence of volume overload or structural renal abnormalities, respectively. Other laboratory or radiology studies should be reserved for the next level of testing to be performed by a pediatric nephrologist.

A referral to a pediatric nephrologist can occur at any stage of the work-up depending upon the primary care provider's level of comfort with the evaluation, but certain findings should initiate an immediate evaluation by a specialist. These include persistent non-orthostatic proteinuria, the additional finding of hematuria or abnormal urine microscopy, associated systemic manifestations, hypertension, peripheral edema, elevated blood urea nitrogen or creatinine levels, electrolyte abnormalities, an

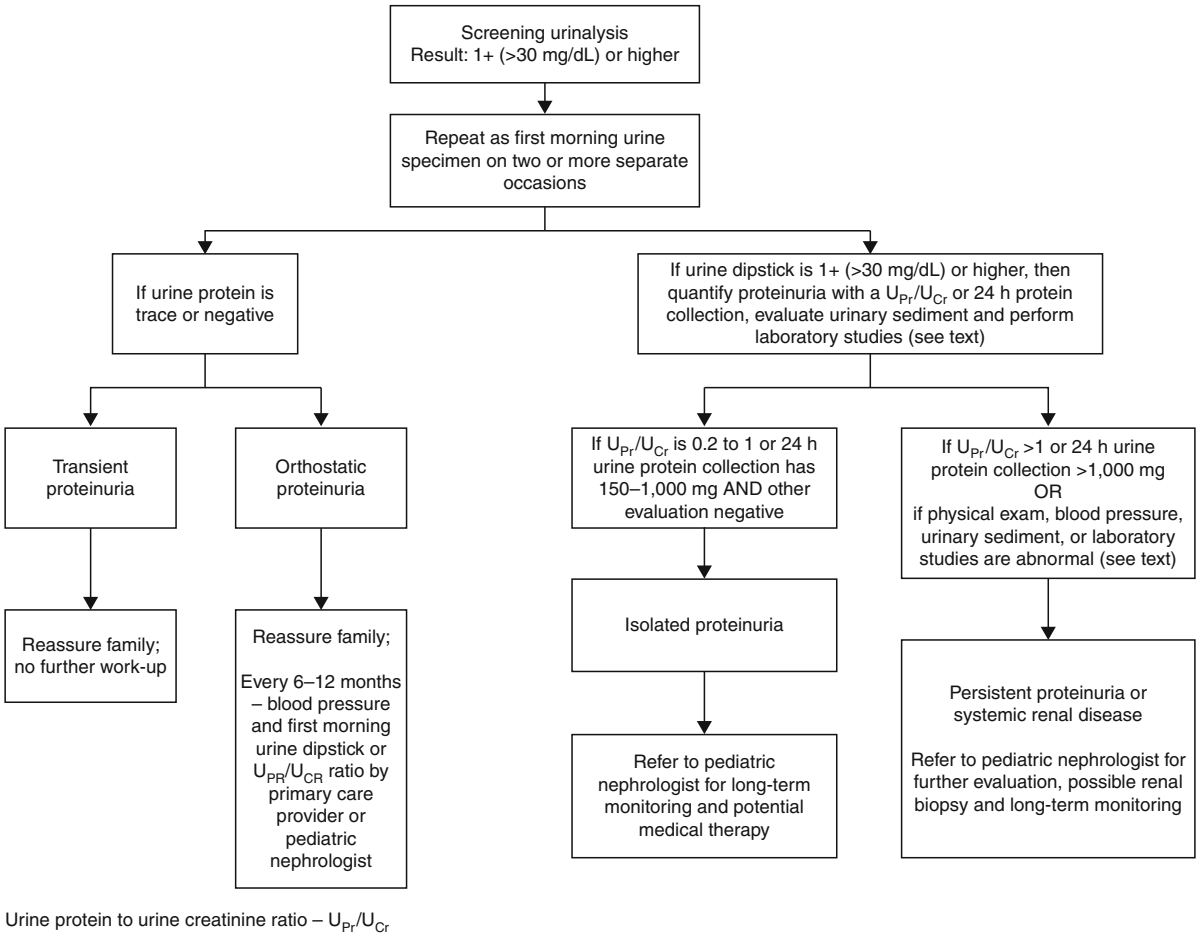

Figure 291.2
Algorithm of the stepwise diagnostic approach for the evaluation of proteinuria

abnormal renal ultrasound or other renal imaging study, or a family history of significant renal disease. Further testing may comprise of an HIV test, hepatitis B and C serologic testing, more specific autoimmune or vasculitis laboratory studies, further quantification of the degree and perhaps the type of proteinuria, and potentially a renal biopsy.

A percutaneous renal biopsy is reserved for special situations and concerning clinical findings in order to confirm a diagnosis (*Table 291.5*). Oftentimes, patients with presumed MCNS are initiated on corticosteroid therapy at presentation without histologic confirmation. If the patients do not respond predictably, a renal biopsy is frequently recommended. This is especially proposed if the patients demonstrate a frequently relapsing,

Table 291.5
Possible indications for percutaneous renal biopsy in patients with persistent proteinuria

Elevated creatinine concentration
Persistent macroscopic or microscopic hematuria
Hypertension
Persistent hypocomplementemia
Suspicion of ANCA vasculitis
Consider with frequently relapsing, steroid-dependent and steroid-resistant nephrotic syndrome
Family history of chronic renal disease or end-stage renal disease
Parental anxiety

steroid-dependent, or steroid-resistant pattern to their nephrotic syndrome, which suggests an alternative diagnosis to MCNS. Other indications for pursuing a renal biopsy in patients with significant proteinuria include concomitant persistent hematuria, either microscopic or macroscopic, hypertension, an elevated creatinine level, or persistent hypocomplementemia. Any suspicion of a systemic disease with persistent proteinuria warrants close monitoring and likely a renal biopsy to determine the diagnosis, treatment regimen, and long-term prognosis. Patients with a concerning family history of renal disease may also merit histologic evaluation via a renal biopsy. Finally, parental or patient anxiety about an underlying renal disorder may prompt a thorough discussion of the risks and benefits of pursuing a renal biopsy. A percutaneous renal biopsy is performed by either a nephrologist or a radiologist trained in renal biopsy procedures. Rarely, a renal biopsy may need to be performed by a general or transplant surgeon.

Differential Diagnosis

The differential diagnosis of proteinuria is broad, given the differing degree and types of proteinuria that may be observed in pediatric patients. Differentiation among transient, orthostatic, isolated and persistent proteinuria is the initial step in developing a list of potential etiologies for the proteinuria. If persistent proteinuria is identified, the potential etiologies for the underlying process are extensive.

In patients with nephrotic-range proteinuria or nephrotic syndrome, consideration should be given to the following diagnoses: minimal change nephrotic syndrome, focal segmental glomerulosclerosis, membranous nephropathy, membranoproliferative glomerulonephritis, and, rarely, IgA nephropathy. If the patient is less than 12 months of age, congenital and infantile NS need to be considered. Nephrotic syndrome can be confused with an allergic reaction, angioedema, protein-losing enteropathies, congestive heart failure, significant liver disease, or hepatic failure, and therefore these diagnoses should be excluded during the evaluation process. When both proteinuria and hematuria are present, the following diagnoses should be considered: post-infectious glomerulonephritis, IgA nephropathy, familial nephritis, membranoproliferative glomerulonephritis, and systemic lupus erythematosus. If both proteinuria and systemic findings are found, the list of potential etiologies include Henoch–Schönlein purpura, systemic lupus erythematosus, hemolytic uremic syndrome, Wegener's granulomatosis or other forms of Anti-neutrophil cytoplasmic antibodies (ANCA) vasculitis, and Goodpasture's disease.

Treatment

Depending upon the type and degree of proteinuria, numerous treatment recommendations have been established. For confirmed transient and orthostatic proteinuria, no therapy is needed. Intermittent long-term monitoring of first morning urine specimens and blood pressure readings should be performed by the primary care provider in the setting of orthostatic proteinuria. For isolated proteinuria, therapeutic recommendations vary from no treatment to consideration of proteinuria lowering agents such as angiotensin-converting-enzyme inhibitor (ACE I) or angiotensin receptor blocker (ARB) medications. Mostly, these medications are reserved for use in patients with persistent proteinuria and thus will be discussed below.

Patients with persistent proteinuria represent a heterogeneous group; therefore, both general and specific therapeutic recommendations are prudent. Among patients with higher grade or nephrotic-range proteinuria, ACE I medications can be useful as primary or adjunctive therapy. Among patients with type 1 and type 2 diabetes mellitus, ACE inhibitors are usually started at the onset of abnormal levels of microalbuminuria, although one recent study did not demonstrate a long-term advantage in this particular patient population. Other important treatments to address in patients with diabetes mellitus and microalbuminuria are strict blood glucose and blood pressure control. At low doses, ACE I medications have been shown to reduce proteinuria and have the additional benefit of lowering blood pressure in hypertensive patients. Advantages specific for pediatric patients include ease of dosing with suspension or tablet formulations and a one-time-per-day dosing schedule.

Most patients tolerate ACE I medications well, although there are side effects and monitoring parameters that need to be considered prior to initiation. First, laboratory studies to evaluate for bone marrow suppression, electrolyte abnormalities, and renal function changes need to be periodically monitored. In a minority of patients, development of a dry cough due to bradykinin effects may prohibit long-term usage and should prompt discontinuation of this group of medications. Due to the intrarenal glomerular mechanism of action of ACE I medications, patients with acute or chronic volume depletion should not continue ACE I treatment as this could lead to acute renal failure. Finally, women of child-bearing age should be thoroughly counseled about the potential teratogenic effects of ACE I use during pregnancy. If patients are considering pregnancy, discontinuation of ACE I medications should occur immediately, as the potential

teratogenic effects begin early in the first trimester. Many physicians will not prescribe ACE I therapy in this population unless consistent oral contraceptive use is employed. Rarely, angioedema can occur with this group of medications.

ARB medications have similar advantages and disadvantages as ACE I, except that they are primarily utilized in older adolescent and adult patients and currently do not have an available suspension formulation. Studies among pediatric patients with proteinuria, hypertension, or both in addition to ARB safety and efficacy informative studies are currently ongoing. Adult studies have observed significant advantages using combined ACE I and ARB therapy for proteinuria reduction and improved long-term cardiovascular health. These advantages may also be observed in the pediatric population and may be recommended in the future for younger age groups.

The treatment for nephrotic syndrome and other systemic diseases associated primarily with proteinuria are discussed elsewhere.

Prognosis

Transient and orthostatic proteinuria renders an excellent long-term prognosis, while isolated and persistent proteinuria often portends poorer long-term outcomes.

Prevention

Although there are no specific recommendations for proteinuria prevention, the initial evaluation and continued long-term monitoring of these patients can significantly alter potential progression of the underlying process. This monitoring should be done by the primary care provider in conjunction with a pediatric nephrologist in most situations. Prompt diagnosis and treatment is beneficial for long-term outcomes. In a pediatric population, protein restriction is rarely advised given the potential deleterious effects on growth and development. Therefore, children should receive the recommended daily intake of protein, based upon age. Other dietary or fluid restrictions are also generally not recommended, except in specific circumstances. Family and age-appropriate patient education and counseling should be performed at or soon after the diagnosis of significant proteinuria is confirmed and then continued over time by a multidisciplinary team. Specific parameters to call the primary care provider or pediatric nephrologist should also be provided to the parent or guardian and patient in order to avoid potential complications associated with persistent proteinuria.

292 Systemic Hypertension

Joseph T. Flynn

In this chapter, key features of childhood hypertension will be reviewed, with a focus on diagnosis and management.

Classification

Classification of Childhood Blood Pressure

The National Heart, Lung and Blood Institute (NHLBI) has issued consensus guidelines with recommendations for the identification and management of elevated blood pressure (BP) in childhood on four occasions since 1977. The most recent of these, "The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents" (National High Blood Pressure Education Program [NHBPEP] Working Group, 2004) adapted terminology and staging criteria utilized in consensus guidelines for adult hypertension to pediatric hypertension, and also emphasized the possibility of preventing adult cardiovascular disease by early intervention in children and adolescents with elevated BP.

The diagnostic criteria for elevated BP in childhood are based on the concept that BP in children increases with age and with body size, which makes it impossible to utilize a single BP level to define hypertension as is done in adults. Furthermore, the lack of cardiovascular end points in childhood necessitates that the definitions of normal and elevated BP be statistical criteria derived from large-scale, cross-sectional studies of BP in normal children. The NHLBI database of childhood blood pressure, upon which the current normative BP values are based, now contains BP information on over 83,000 healthy children aged 1–17 years.

Normal BP in children aged 1–17 years is defined in the Fourth Report as systolic AND diastolic BP $<$ the 90th percentile for age, gender, and height, and hypertension is defined as systolic AND/OR diastolic BP persistently $\geq$ the 95th percentile (*Tables 292.1* and *292.2*). Children with systolic or diastolic BP between the 90th and 95th percentiles, or adolescents with BP $\geq$120/80, are now classified as pre-hypertensive, as opposed to the "high-normal" classification that was used previously.

The Fourth Report additionally provides guidelines for staging the severity of hypertension in children and adolescents, which can then be used clinically to guide evaluation and management (*Fig. 292.1* and *Table 292.3*). As indicated in the table, children or adolescents with stage 2 hypertension should be evaluated and treated more quickly and/or aggressively than those with lower degrees of BP elevation.

Etiology

Causes of Hypertension in Children and Adolescents

Given the many influences on blood pressure (see below), it is not surprising that the differential diagnosis of pediatric hypertension can be extensive. This is reflected in the traditional teaching that most hypertension in children should be considered secondary to an underlying disorder. As can be seen in *Table 292.4*, this is certainly the case for infants and young children. In hypertensive children in these age groups, renal disease, renovascular disease, or cardiac disease will often be found after an appropriate diagnostic evaluation. Primary hypertension in young children is, therefore, usually considered a diagnosis of exclusion, making it necessary to undertake at least some advanced testing to arrive at the correct diagnosis.

In adolescents, however, hypertension is most likely to be primary in origin (*Table 292.4*). In many case series published since the mid-1990s, the vast majority of adolescents with persistent BP elevation have no identifiable underlying cause. Features that support the diagnosis of primary hypertension in teenagers include normal growth (and/or obesity), lack of symptoms of hypertension, unremarkable past medical history, and a family history of hypertension. Hypertensive adolescents who fit this profile may not need as extensive an evaluation as those who do not.

Neonates compromise a unique population with respect to the causes of hypertension. In this age group, coarctation of the aorta and renovascular disease constitute the most frequent causes of hypertension (*Table 292.4*), with other diagnoses such as congenital structural renal

disease and bronchopulmonary dysplasia also being relatively frequent. Most infants with renovascular hypertension have a history of umbilical catheter placement, which may lead to hypertension from intraparenchymal thromboembolism. Clearly, it is important to keep this unique differential in mind when approaching neonates with hypertension.

Epidemiology

Epidemiology of Hypertension and Impact of the Childhood Obesity Epidemic

Through the 1990s, the prevalence of hypertension in children and adolescents was felt to be low, approximately

Table 292.2

Blood pressure levels for girls by age and height percentile. To use the table, first plot the child's height on a standard growth curve (www.cdc.gov/growthcharts). The child's measured SBP and DBP are compared with the numbers provided in the table according to the child's age and height percentile. (Reproduced from "The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents, 2005.)

BP: blood pressure

2% or less. However, over the past decade, it has become apparent that the prevalence of hypertension has increased, with recent population surveys demonstrating that nearly 4% of children are hypertensive, and up to 10% pre-hypertensive. Most of this increase can be attributed to the childhood obesity epidemic, which has emerged as a significant issue affecting child health worldwide.

In the USA, the prevalence of childhood obesity has more than trebled over the past 30 years, and now approaches 20% in children aged 6–11 years. A similar picture is emerging among younger children as well: in New York City, among 16,000 children (mean age 3.5 years) enrolled in the Head Start Program in 2004, 27% were obese and 15% were overweight. Recent school

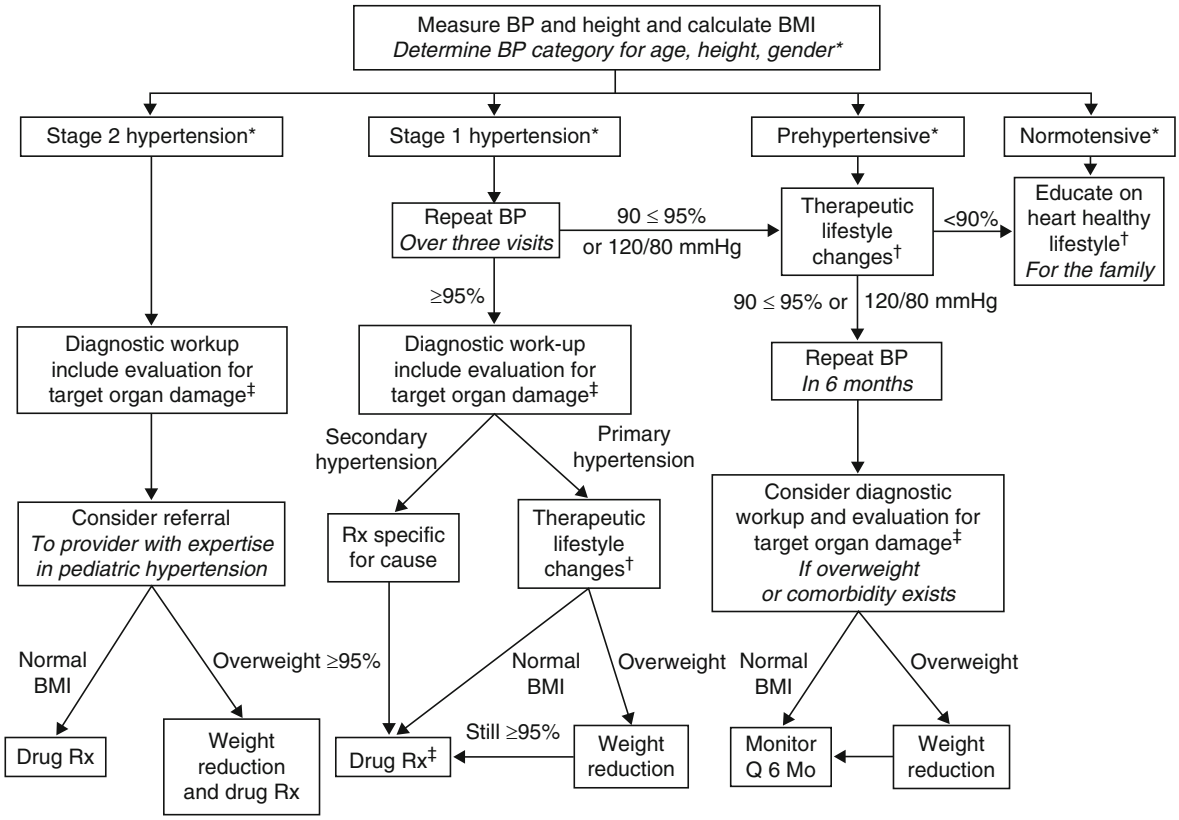

Figure 292.1

Summary of classification of BP and recommended management of children and adolescents with elevated blood pressure. BMI, body mass index; BP, blood pressure; Q, every; RX, treatment. *, See *Table 292.3*; †, diet modification and physical activity; ‡, especially if younger, very high BP, little or no family history, diabetic, or other risk factors. (Reproduced from "The Fourth Report on the Diagnosis, Evaluation and Treatment of High Blood Pressure in Children and Adolescents," 2005)

screening studies conducted in the USA over the past several years have provided ample evidence of the effect that obesity has had on the prevalence of hypertension. In Houston, Texas, for example, the prevalence of hypertension in adolescents has been shown to be as high as 10% among those with body mass index (BMI) ≥97th percentile. Strong associations between overweight and elevated BP have also recently been reported in sixth graders in Seminole County, Florida and in even younger children in Anadarko, Oklahoma.

Significant increases in childhood obesity have been documented in several European countries, including Poland and Italy. Among a randomly selected sample of children and adolescents in Catanzaro Italy, 18% of children were classified as being at risk for overweight (BMI percentile 85–94%) and another 11% were classified as obese (BMI percentile ≥95%). Lesser-developed countries are experiencing significant increases in childhood obesity as well. Anthropometric data obtained in 23,459 children in the Seychelles demonstrate an increase in the prevalence of obesity from 2.1% to 5.2% in boys and from 3.1% to 6.2% in girls between 1998 and 2004, with analogous increases in the percentage of children at risk of overweight.

Obese children in the Italian study mentioned above were more likely to have elevated systolic or diastolic BP than non-obese children, and BMI was a significant predictor of elevated BP. In another Italian study, the prevalence of pre-hypertension was nearly 12 times that in a control group of normal-weight children and pre-hypertension was associated with insulin resistance. Thus, the epidemic of childhood obesity appears to be having enormous effects on the prevalence and epidemiology of hypertension across the globe, and unless appropriate, population-based preventative measures are instituted, an epidemic of early adult cardiovascular disease is likely on the horizon.

Table 292.3
Classification of hypertension in children and adolescents, with measurement frequency and therapy recommendations (Reproduced from "The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents," 2005.)

	SBP or DBP percentile[a]	Frequency of BP measurement	Therapeutic lifestyle changes	Pharmacologic therapy
Normal	<90th	Recheck at next scheduled physical examination	Encourage healthy diet, sleep, and physical activity	—
Prehypertension	90th–<95th or if BP exceeds 120/80 even if below 90th percentile up to <95th percentile[b]	Recheck in 6 months	Weight management counseling if overweight, introduce physical activity and diet management	None unless compelling indications such as CKD, diabetes mellitus, heart failure, LVH
Stage 1 hypertension	95th percentile to the 99th percentile plus 5 mmHg	Recheck in 1–2 weeks or sooner if the patient is symptomatic; if persistently elevated on two additional occasions, evaluate or refer to source of care within 1 month	Weight management counseling if overweight, introduce physical activity and diet management	Initiate therapy based on indications in text or if compelling indications as above
Stage 2 hypertension	>99th percentile plus 5 mmHg	Evaluate or refer to source of care within 1 week (or immediately) if the patient is symptomatic	Weight management counseling if overweight, introduce exercise and diet management	Initiate therapy

BP, blood pressure; CKD, chronic kidney disease; DBP, diastolic blood pressure; LVH, left ventricular hypertrophy; SBP, systolic blood pressure
[a] For sex, age, and height measured on at least three separate occasions; if systolic and diastolic categories are different, categorize by the higher value
[b] This occurs typically at 12 years old for SBP and at 16 years old for DBP

Pathogenesis

Pathophysiology of Hypertension

Blood pressure can fundamentally be viewed as a function of cardiac output and systemic vascular resistance. Cardiac output depends on cardiac stroke volume and heart rate. Stroke volume in turn depends on myocontractility and preload. Systemic vascular resistance is dependent on vessel elasticity, myocontractility, and afterload. Numerous hormonal and neuronal factors, as well as relationships at the cellular and molecular levels, exert important effects on blood pressure, all in the context of the patient's genetic background. Derangements in any of these myriad processes can influence either cardiac output or systemic vascular resistance, thereby leading to the development of hypertension. Given the many potential mechanisms, a detailed discussion of pathophysiology is beyond the scope of this chapter; however, a few important mechanisms will be highlighted.

Abnormalities of renal sodium handling are central to the development of hypertension in many patients. Important insight into the role of renal sodium handling has been gained from the study of several Mendelian forms of hypertension, including Liddle's syndrome, apparent mineralocorticoid excess, Gordon's syndrome, and glucocorticoid-remediable aldosteronism. All of these disorders lead to increased sodium reabsorption in the distal nephron, producing volume overload hypertension. An important diagnostic clue in these patients is suppressed plasma renin activity.

The other major mechanism that leads to the development of hypertension in many patients is insulin resistance, which can be present in both obese and non-obese hypertensives. Insulin resistance has been associated with altered renal sodium handling, activation of the

Table 292.4
Differential diagnosis of childhood hypertension by age

Age Group	Causes[a]
Newborn infants	Umbilical catheter-related thromboembolism
	Bronchopulmonary dysplasia
	Congenital renal disease/ malformations

sympathetic nervous system, and alterations of vascular structure and function – all processes that have significant effects on blood pressure. Finally, new research on uric acid has suggested that hyperuricemia may also contribute to the development of hypertension in some patients, probably through altered endothelial function.

Pathology

Consequences of Childhood Hypertension

Hypertensive Target-Organ Damage

Left ventricular hypertrophy (LVH), increased carotid intima-media thickness (cIMT), and even impaired cognitive function stand as concrete evidence of the consequences of elevated BP in childhood and the potential for life-long morbidity. LVH was first demonstrated to occur in hypertensive youth by Laird and Fixler in the early 1980s, and has subsequently been shown to occur in a significant proportion of hypertensive children and adolescents, with reported prevalences ranging between 20% and 41% depending upon the diagnostic criteria utilized. It is especially interesting that the development of LVH in the young may not be related to the level of blood pressure elevation. While studies from a center in Houston have repeatedly demonstrated a correlation between the severity of blood pressure elevation and the likelihood of developing LVH, a larger multicenter study failed to demonstrate any relationship between LVH and specific parameters of blood pressure elevation. As will be discussed later, this underscores the need to perform echocardiography at the diagnosis of hypertension and periodically thereafter in children and adolescents, as recommended in the Fourth Report.

Vascular effects of elevated BP that can be seen in childhood include retinal changes and increased carotid intimal-medial thickness (cIMT). Hypertensive retinopathy has long been known to occur in childhood. The relationship between elevated childhood BP and retinal arteriolar narrowing was recently confirmed in a study of over 1,900 children in Australia and Singapore. Increased cIMT, well-documented as a cardiovascular consequence of elevated BP in large population studies has also been found in children and adolescents with primary hypertension in single-center reports. While early studies of cIMT in hypertensive youth were confounded by the effects of obesity, one carefully conducted study that controlled for BMI demonstrated a definitive relationship between elevated BP itself and increased cIMT in young patients.

An additional target-organ effect of elevated BP recently described in the young is impaired cognitive function. While long-standing hypertension has long been recognized as a risk factor for development of cognitive impairment and even dementia in the elderly, this study demonstrated that children and adolescents with BP >90th percentile had poorer performance on selected tests of cognition compared to normotensive children. This provocative finding, while requiring confirmation, adds impetus to consensus recommendations for instituting antihypertensive drug therapy in children and adolescents with persistently elevated BP.

Fewer pediatric data are available on the other major target-organ effect of hypertension, namely, renal damage. Although hypertension commonly accompanies chronic kidney disease in children, it is rarely its cause. Even

microalbuminuria, which is commonly seen in hypertensive adults, is infrequently seen in children with isolated hypertension, even when LVH is present. However, a more recent study demonstrated that approximately 58% of hypertensive adolescents had microalbuminuria, with an increased prevalence in Stage 2 hypertension compared to Stage 1. Reduction of BP in the latter study was accompanied by a reduction in both microalbuminuria and LVH. Given these conflicting data, additional studies are clearly needed to determine the renal effects of elevated BP in the young.

Diagnosis

Approach to the Child or Adolescent with Elevated Blood Pressure

Clinical Vignette

A 14 year-old soccer player presents to your office after an elevated BP was detected at a pre-sports participation screening at her school. Blood pressures obtained at the screening ranged from 139–149/71–77. She is at the 50th percentile for height and weight and has no other chronic health problems or abnormal physical exam findings. Her mother is obese, hypertensive and has type 2 diabetes; her paternal grandfather died at age 50 from a myocardial infarction.

Confirmation of Hypertension

As emphasized in the Fourth Report, one of the most important steps in the evaluation of children with suspected hypertension is to ensure that the blood pressure is being measured correctly. Whatever device is being used to measure blood pressure, the first step is to choose an appropriately sized cuff. The bladder of the cuff should encircle 80–100% of the circumference of the upper arm, and its width should be at 40% of the upper arm circumference. Since too narrow of a cuff will create a falsely elevated blood pressure reading, children with longer upper arms than others of the same age will require a wider cuff. A variety of cuff sizes should be kept on hand so that the proper size will be available. Not to be overlooked is a large adult or thigh cuff for use in obese children.

The patient should be seated quietly for at least 5 min prior to BP determination. The arm should be supported at heart level. Infants' blood pressures should be obtained in the supine position. When BP is measured by auscultation, the disappearance of the fifth Korotkoff sound should be used for the diastolic reading. If the initial elevated BP was obtained using an automated device, it should be repeated manually at the same visit. Given the current unavailability of mercury column sphygmomanometers, an aneroid device should be used for the repeat reading. The exception to this would be infants and young toddlers who cannot cooperate with manual blood pressure determination.

A single isolated elevated BP reading does not diagnose hypertension, but does indicate the need for repeated measurements over time. The Fourth Report recommends that in most cases, at least three abnormal readings, obtained at different times, should be obtained before the "diagnosis" of hypertension should be entertained and a work-up initiated (*Table 292.3*).

Role of Ambulatory BP Monitoring

Ambulatory BP monitoring (ABPM) has been endorsed as an appropriate technique for the evaluation of elevated BP in children and adolescents in recommendations from several consensus panels. Potential applications of ABPM in children include identification of white coat and masked hypertension (*Table 292.5*), assessment of BP control in those treated with antihypertensive medications, and investigation of hypotensive episodes. ABPM has also been demonstrated to reduce the cost of evaluation of elevated BP by identifying those with white-coat hypertension, who then could receive a less extensive work-up, and to identify those children more likely to have secondary causes of hypertension.

Table 292.5
Classification of BP and cardiovascular risk using office and ambulatory BP

	Ambulatory BP	Office BP	Cardiovascular risk
Normal BP	Normal	Normal	No additional effect
Sustained HTN	Elevated	Elevated	Increased
White Coat HTN	Normal	Elevated	Possibly increased
Masked HTN	Elevated	Normal	Increased

BP, blood pressure; HTN, hypertension

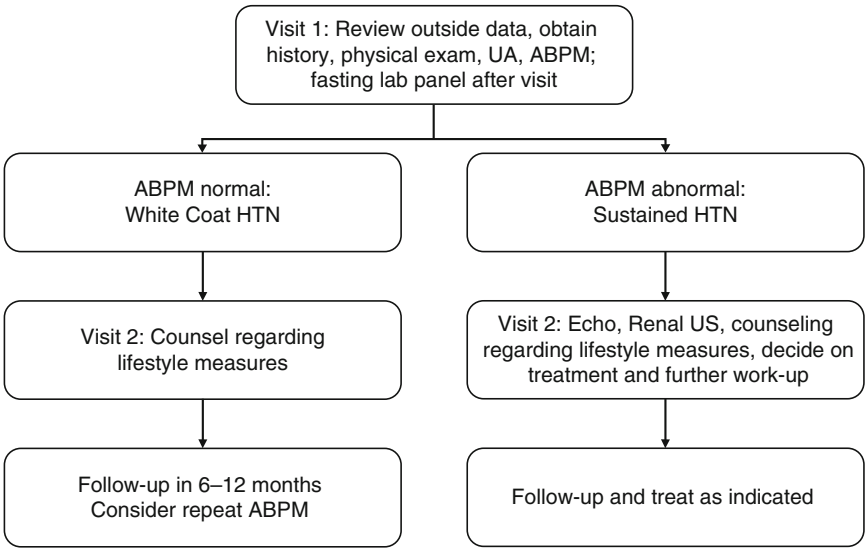

Figure 292.2
Proposed algorithm for incorporation of ambulatory blood pressure monitoring into evaluation of children and adolescents with elevated blood pressure. ABPM, ambulatory blood pressure monitoring; echo, echocardiogram; HTN, hypertension; UA, urinalysis; US, ultrasound

White coat hypertension, defined as elevated office BP but normal out-of-office BP, appears to be at least as common in children as it is in adults. In adults, white coat hypertension is not felt to be associated with significant cardiovascular morbidity or mortality, so pharmacologic treatment of such patients is not recommended. Although proving that a child has white coat hypertension could help avoid unnecessary exposure to medications and reduce unnecessary diagnostic testing, a few recent studies have indicated that children found to have white coat hypertension actually have early signs of target-organ damage such as increased left ventricular mass. These data, in combination with data from tracking studies that suggest that these children are likely at increased risk of development of hypertension in the future, imply that children found to have white coat hypertension should receive lifestyle modification and should be followed prospectively for the development of definite or sustained hypertension.

Masked hypertension, defined as elevated out-of-office BP in a patient with normal office BP, has also been recently described in pediatric populations, and is associated with hypertensive target-organ damage, specifically left ventricular hypertrophy. Such children probably merit further evaluation for underlying secondary causes of hypertension, and institution of pharmacologic treatment. In adults, masked hypertension is clearly associated with increased risk of cardiovascular disease (*Table 292.5*).

Given the above, and given the need to confirm the presence of hypertension before beginning an extensive diagnostic evaluation, wider use of ABPM has been advocated. A proposed algorithm for incorporation of ABPM into the evaluation of children with elevated BP is presented in *Fig. 292.2*. However, despite its potential utility, ABPM is still considered a specialized technique, necessitating referral to a dedicated pediatric hypertension clinic (*Fig. 292.3*).

Diagnostic Evaluation

The evaluation of a child with elevated BP can be divided into distinct phases, beginning with confirmation that the blood pressure is indeed elevated, then proceeding through a series of more specific and specialized studies until the correct diagnosis is made and treatment initiated (*Table 292.6*).

As in any patient, a thorough history and physical examination will often provide sufficient information to at least substantially narrow the differential diagnosis. Symptoms of hypertension may be caused by the hypertension itself, may be produced by the underlying cause of the hypertension, or may be completely absent. Given this,

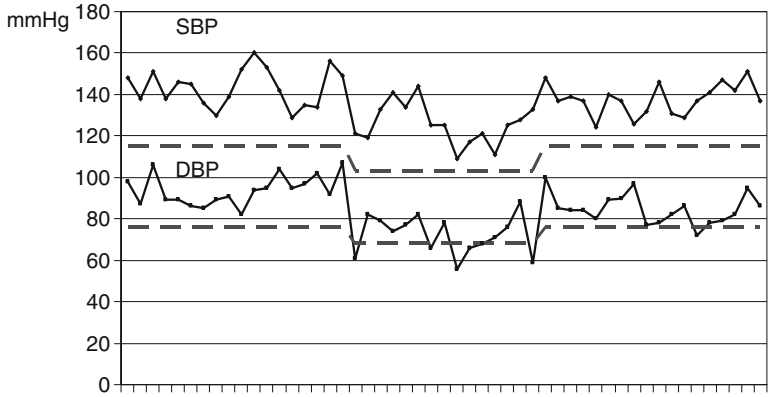

Figure 292.3

Ambulatory BP study in a child with sustained hypertension. The solid lines are the patient's systolic and diastolic BP's over the monitoring period, and the heavy dashed lines represent the 95th percentile ambulatory BP value. The patient was later found to have reflux nephropathy

and given the potentially wide differential diagnosis of hypertension, especially in an infant or younger child, a high index of suspicion should be maintained. It is especially important to try to elicit clues to underlying secondary causes (*Table 292.7*).

Other important aspects of the history include past medical history and family history. A history of recurrent urinary infections in early childhood may be a clue to underlying reflux nephropathy. Recent infections such as pharyngitis suggest acute glomerulonephritis. A family history of early-onset hypertension can be seen in patients with single-gene hypertensive disorders such as Liddle's syndrome. The family history should also include questions about other cardiovascular diseases such as hyperlipidemia and stroke. Since many substances can elevate BP (*Table 292.8*), a careful medication review should be included, and questions asked about illicit substance used, when appropriate.

The physical examination should begin with determining the child's height and weight percentiles, and calculation of BMI. Whether or not a child is normally grown is an enormously important clue to the presence of an underlying chronic illness. Following this, obtain seated blood pressures in each arm, and no matter what the child's age, supine blood pressures in one arm and one leg in order to rule out coarctation of the aorta. The remainder of the physical examination should focus on discovering specific findings that may provide clues to the etiology and/or degree of hypertension. Common examples of physical exam findings that are associated with specific secondary causes of hypertension are listed in *Table 292.7*.

Patients with confirmed hypertension should then undergo laboratory testing and diagnostic imaging to follow up on findings from the history and physical examination, and to assess for other coexisting cardiovascular risk factors. As outlined in *Table 292.6*, it is customary to begin with a basic set of screening studies in all patients, which should also serve to screen for other coexisting conditions such as impaired glucose tolerance or dyslipidemia. Plasma renin activity is sometimes also included in this initial set of studies, especially when the patient's hypertension is severe, or if both systolic and diastolic hypertension are present.

Of the more specific tests, only those indicated by the history, physical examination, and screening test results should be obtained. For example, chest radiographs need only be obtained in hypertensive children with heart murmurs, or those with a gradient of more than 30 mmHg between the upper and lower extremity blood pressures. Renin and aldosterone should be obtained if there is hypokalemia on the screening electrolytes, as a suppressed renin in conjunction with hypokalemia strongly suggests a single-gene disorder such as Liddle's syndrome. Renal ultrasounds (*Fig. 292.4*), which should be routinely obtained in all hypertensive pre-adolescent patients, may be omitted in adolescents and some older pre-adolescent children with stage 1 hypertension if the screening studies are normal, and if other features of primary hypertension are present, including obesity, a positive family history, and isolated systolic hypertension. Those with stage 2 hypertension, with abnormal screening studies, or with diastolic hypertension should get an ultrasound.

Table 292.6
Diagnostic testing for children with elevated blood pressure

Phase	Studies
Confirmation of BP elevation	Repeated office measurements
	Home/self-measured blood pressure
	Ambulatory BP monitoring
Screening tests	Urinalysis (+ culture if indicated)
	Electrolytes, BUN, creatinine, calcium, phosphorus
	Fasting glucose and lipid panel (cholesterol, triglycerides, etc.)
	Consider: CBC with differential, platelet count
	Plasma renin activity
Specific tests	24 h urine collection (protein excretion, creatinine clearance)
	Plasma normetanephrine to norepinephrine ratio
	Other hormone levels (thyroid, adrenal, etc.)
	Echocardiogram, retinal exam
	Renal ultrasound (± Doppler)
	Polysomnography
Specialized studies	Renin profile (plasma renin and 24 h urine sodium excretion)
	Captopril renal scan
	MR or CT angiography
	Renal angiography (± renal vein renin sampling)
	Renal biopsy

Table 292.7
History and physical exam findings suggestive of secondary hypertension

Present in history	Suggests
Known UTI/UTI symptoms	Reflux nephropathy
Joint pains, rash, fever	Vasculitis, SLE
Acute onset of gross hematuria	Glomerulonephritis, Renal venous thrombosis
Renal trauma	Renal infarct, RAS
Abdominal radiation	Radiation nephritis, RAS
Renal transplant	Transplant RAS
Precocious puberty	Adrenal disorder
Muscle cramping, constipation	Hyperaldosteronism
Excessive sweating, headache, pallor and/or flushing	Pheochromocytoma
Illicit drug use	Drug-induced hypertension
Present on examination	**Suggests**
BP > 140/100 at any age	Secondary hypertension
Nocturnal HTN on ABPM	Secondary hypertension
Leg BP < arm BP	Aortic coarctation
Poor growth, pallor	Chronic renal disease
Turner syndrome	Aortic coarctation
Cafe-au-lait spots	Renal artery stenosis
Delayed leg pulses	Aortic coarctation
Precocious puberty	Adrenal disorder
Bruits over upper abdomen	Renal artery stenosis
Edema	Renal disease
Excessive sweating	Pheochromocytoma
Excessive pigmentation	Adrenal disorder
Striae in a male	Drug-induced HTN

ABPM, ambulatory blood pressure monitoring; BP, blood pressure; HTN, hypertension; RAS, renal artery stenosis; SLE, systemic lupus erythematosus; UTI, urinary tract infection

As recommended in the Fourth Report, additional imaging studies, including renal angiography, nuclear renal scans, and voiding cystourethrograms should only be obtained as indicated based upon the results of the history, physical examination, and initial diagnostic studies. With respect to angiography, it is now common in many centers to begin with a noninvasive modality such as magnetic resonance (MR) or computed tomographic (CT) angiography (*Fig. 292.5*), before proceeding to traditional arteriography. A negative MR or CT angiogram in an adolescent can effectively rule out renal artery stenosis, but may still need to be followed by arteriography in a younger child given their smaller blood vessels and the propensity for intrarenal involvement in young children with fibromuscular dysplasia.

As discussed previously, left ventricular hypertrophy occurs commonly in hypertensive children, so echocardiograms should be obtained routinely in patients with confirmed hypertension. Ophthalmologic exams should be obtained, but should be performed by an experienced pediatric ophthalmologist as hypertensive retinal changes are likely to be subtle in the young. The presence of hypertensive target-organ damage indicates that the blood pressure elevation has been long-standing, and that pharmacologic therapy is warranted.

Table 292.8
Substances that can elevate blood pressure in children and adolescents

Prescription medications	Non-prescription medications	Others
Calcineurin inhibitors (cyclosporine, tacrolimus)	Caffeine	Cocaine
COX-2 inhibitors (celecoxib, others)	Ephedrine	DHEA (dehydroepiandosterone)
Erythropoietin, darbepoetin	Non-steroidal anti-inflammatory drugs[a]	Ethanol
Glucocorticoids	Pseudoephedrine	Heavy metals (lead, mercury)
Migraine mediacations (ergotamine, sumatriptan)		Herbal preparations (*Ephedra, Glycyrrhiza, Yohimbine*)
Oral contraceptives		MDMA ("Ecstasy")
Phenylpropanolamine		Tobacco
Pseudoephedrine		
Stimulant medications[a] (dexedrine, methylphenidate, amphetamine derivatives)		
Tricyclic antidepressants[a]		

[a]These cause elevated blood pressure relatively infrequently compared with the other agents in the table

Figure 292.4
Renal ultrasound demonstrating multiple large cortical cysts consistent with autosomal dominant polycystic kidney disease

Figure 292.5
Three-dimensional reconstruction of CT angiogram images demonstrating stenosis at origin of left renal artery

Treatment

Management of Hypertension

Non-pharmacologic Measures

Non-pharmacologic measures are currently recommended as the initial approach for children and adolescents with less severe hypertension, or those with primary hypertension and no hypertensive target-organ disease (*Fig. 292.1*). Although the magnitude of change in BP may be modest, dietary modification, weight loss, and exercise have all been shown to successfully reduce blood pressure in children and adolescents.

Once hypertension has been established, "salt sensitivity" becomes more common, and reduction in sodium intake is likely to be of benefit in lowering blood pressure. Other nutrients that have been examined in patients with

hypertension include potassium and calcium, both of which have been shown to have antihypertensive effects. Therefore, a diet that is low in sodium and enriched in potassium and calcium may be more effective in reducing blood pressure than a diet that restricts sodium only. An example of such a diet is the so-called DASH diet (Dietary Approaches to Stop Hypertension; http://www.dashdiet.org), which has been shown to have an antihypertensive effect even in patients receiving antihypertensive medication. Successful blood pressure reduction has recently been demonstrated in a study of the DASH eating plan in adolescents.

Numerous studies have demonstrated that weight loss in obese adolescents can lower blood pressure. In studies where a reduction in BMI of about 10% was achieved, short-term reductions in blood pressure were in the range of 8–12 mmHg. Unfortunately, weight loss is notoriously difficult and usually unsuccessful, especially in the primary care setting. However, identifying a medical complication of obesity such as hypertension can perhaps provide the necessary motivation for patients and families to institute appropriate lifestyle changes.

Increasing physical activity may also have beneficial effects on BP, particularly for children who are overweight and need to improve their BMI. Increased physical activity may have a number of other beneficial effects such as improvement in vascular function and should be recommended for children with hypertension. In addition to increasing physical activity, children should have limitations placed on their sedentary time, with no more than 2 h/day spent on television, computers, video games, and other sedentary pursuits. Recent studies have demonstrated that short-term dietary and exercise interventions can result in weight loss, reduced BP, and improvements in laboratory abnormalities associated with the metabolic syndrome in overweight children and adolescents. These studies support the recommendation made by the NHBPEP Working Group that therapeutic lifestyle changes should be considered primary therapy for obesity-related hypertension in children and adolescents. These measures should be incorporated into the treatment plan of all hypertensive children and adolescents, even those who require antihypertensive medications.

Pharmacologic Therapy

Given the intensive nature of non-pharmacologic approaches, and since some hypertensive children may have hypertensive target-organ damage that could be reversed with effective treatment, antihypertensive medications may be needed. As has already been noted, the long-term consequences of untreated hypertension in an asymptomatic, otherwise healthy child or adolescent remain unknown. Additionally, there are few data available on the long-term effects of antihypertensive medications on the growth and development of children. Therefore, use of pharmacologic therapy is usually limited to children and adolescents with one of the following indications:

- Symptomatic hypertension
- Secondary hypertension
- Hypertensive target-organ damage
- Diabetes (Types 1 & 2)
- Persistent hypertension despite non-pharmacologic measures

The historical lack of pediatric drug trials has been largely rectified by passage of the Food and Drug Administration Modernization Act (FDAMA) in the USA in 1997. This legislation contained a provision that granted six additional months of patent protection to drug manufacturers if they conducted pediatric trials. Subsequent legislation (Best Pharmaceuticals for Children Act, Pediatric Research Equity Act, FDA Amendments Act of 2007) has extended this provision and also has led to other initiatives, including posting of internal FDA pharmacology and efficacy reviews on the Internet, and mechanisms to promote studies of medications with lapsed patent protection. These initiatives have led to a significant number of pediatric clinical trials of antihypertensive medications and have also increased the number of such medications with specific pediatric labeling, thereby significantly increasing the amount of clinically useful information for practitioners. Similar legislation has recently been adopted in the European Union.

Unlike in adults, large-scale comparative trials of different classes of antihypertensive agents have not been conducted in children. Therefore, the choice of initial antihypertensive agent for use in children still remains up to the preference of the individual practitioner. Diuretics and beta-adrenergic blockers, which were recommended as initial therapy in the First and Second Task Force Reports, have a long track record of safety and efficacy in hypertensive children and are still appropriate for pediatric use, although they are now mostly used as second-line agents. Newer classes of agents, including angiotensin converting enzyme inhibitors (ACEIs), calcium channel blockers, and angiotensin receptor blockers (ARBs), have now been shown to be safe and well tolerated in hypertensive children in recent industry-sponsored trials, and may be prescribed if indicated. As a matter of fact, these newer agents, particularly calcium channel blockers and ACE inhibitors, have become the most widely utilized initial agents in the pediatric age group.

It is reasonable to try to base the choice of agent upon the assumed pathophysiology of the child's hypertension. Additionally, consideration should be given to using specific classes of antihypertensive medications in certain hypertensive children and adolescents with specific underlying or concurrent medical conditions. The best example of this would be the use of ACEIs or ARBs in children with diabetes or proteinuric renal diseases, in whom such agents may have a beneficial effect in slowing progression. An additional example would be children with hypertension who are receiving stimulant medications for attention deficit hyperactivity disorder – such children are commonly tachycardic and could benefit from treatment with a beta-blocker.

Antihypertensive drugs in children and adolescents are generally prescribed in a stepped-care manner (*Fig. 292.6*). The patient is started on the lowest recommended dose of the initial agent and the dose is increased until the highest recommended dose is reached, or until the child experiences adverse effects from the medication. At this point a second drug from a different class should be added, until the desired goal BP is reached. Since many antihypertensive drugs now have specific FDA-approved pediatric labeling, the generalist should restrict their choices to those agents. Recommended doses for selected antihypertensive agents for use in hypertensive children and adolescents are given in *Table 292.9*.

Many children and adolescents with "uncomplicated" primary hypertension may require two or more drugs to achieve target BP. Children with secondary hypertension, particularly those with renal disease, almost always require multidrug regimens to achieve adequate BP control. Combination antihypertensive preparations are widely available and offer advantages that may improve adherence to treatment. Although only one such preparation has been studied in children to date, they may be very useful in certain children, particularly those who require an ACE inhibitor or angiotensin receptor antagonist plus a diuretic; many preparations offering this combination are available.

BP treatment goals for children and adolescents were clarified in the Fourth Report. For children with uncomplicated primary hypertension and no hypertensive target-organ damage, the recommended target BP is <95th percentile for age, gender, and height, whereas for children with secondary hypertension, diabetes, or hypertensive target-organ damage, target BP should be <90th percentile

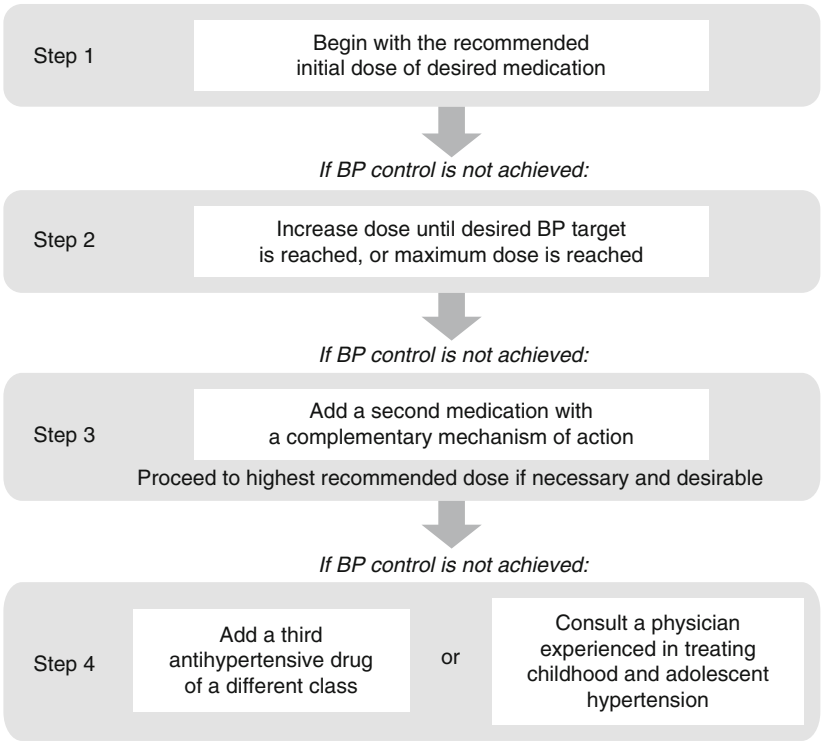

Figure 292.6
Stepped-care approach to pharmacologic management of hypertension in children and adolescents (BP, blood pressure)

Table 292.9

Recommended doses for selected antihypertensive agents for use in hypertensive children and adolescents

Class	Drug	Starting dose	Interval	Maximum dose[a]
Aldosterone receptor antagonists	Eplerenone	25 mg/day	QD-BID	100 mg/day
	Spironolactone[b]	1 mg/kg/day	QD-BID	3.3 mg/kg/day up to 100 mg/day
Angiotensin-converting enzyme (ACE) inhibitors	Benazepril[b]	0.2 mg/kg/day up to 10 mg/day	QD	0.6 mg/kg/day up to 40 mg/day
	Captopril[b]	0.3–0.5 mg/kg/dose	BID–TID	6 mg/kg/day up to 450 mg/day
	Enalapril[b]	0.08 mg/kg/day	QD	0.6 mg/kg/day up to 40 mg/day
	Fosinopril	0.1 mg/kg/day up to 10 mg/day	QD	0.6 mg/kg/day up to 40 mg/day
	Lisinopril[b]	0.07 mg/kg/day up to 5 mg/day	QD	0.6 mg/kg/day up to 40 mg/day
	Quinapril	5–10 mg/day	QD	80 mg/day
Angiotensin-receptor blockers	Candesartan	4 mg/day	QD	32 mg/day
	Losartan[b]	0.70 mg/kg/day up to 50 mg/day	QD	1.4 mg/kg/day up to 100 mg/day
	Olmesartan	2.5 mg/day	QD	40 mg/day
	Valsartan[b]	1.3 mg/kg/day up to 40 mg/day <6 years: 5–10 mg/day	QD	2.7 mg/kg/day up to 160 mg/day <6 years: 80 mg/day
α- and β-adrenergic antagonists	Labetalol[b]	2–3 mg/kg/day	BID	10–12 mg/kg/day up to 1.2 mg/day
	Carvedilol	0.1 mg/kg/dose up to 12.5 mg BID	BID	0.5 mg/kg/dose up to 25 mg BID
β-adrenergic antagonists	Atenolol[b]	0.5–1 mg/kg/day	QD–BID	2 mg/kg/day up to 100 mg/day
	Bisoprolol/ HCTZ	0.04 mg/kg/day up to 2.5/6.25 mg/day	QD	10/6.25 mg/day
	Metoprolol	1–2 mg/kg/day	BID	6 mg/kg/day up to 200 mg/day
	Propranolol	1 mg/kg/day	BID–TID	16 mg/kg/day up to 640 mg/day
Calcium channel blockers	Amlodipine[b]	0.06 mg/kg/day	QD	0.3 mg/kg/day up to 10 mg/day
	Felodipine	2.5 mg/day	QD	10 mg/day
	Isradipine[b]	0.05–0.15 mg/kg/dose	TID–QID	0.8 mg/kg/day up to 20 mg/day
	Extended-release nifedipine	0.25–0.5 mg/kg/day	QD–BID	3 mg/kg/day up to 120 mg/day
Centralα-agonist	Clonidine[b]	5–10 mcg/kg/day	BID-TID	25 mcg/kg/day up to 0.9 mg/day
Diuretics	Amiloride	5–10 mg/day	QD	20 mg/day
	Chlorthalidone	0.3 mg/kg/day	QD	2 mg/kg/day up to 50 mg/day
	Furosemide	0.5–2.0 mg/kg/dose	QD-BID	6 mg/kg/day
	HCTZ	0.5–1 mg/kg/day	QD	3 mg/kg/day up to 50 mg/day
Vasodilators	Hydralazine	0.25 mg/kg/dose	TID–QID	7.5 mg/kg/day up to 200 mg/day
	Minoxidil	0.1–0.2 mg/kg/day	BID–TID	1 mg/kg/day up to 50 mg/day

[a]The maximum recommended adult dose should never be exceeded

[b]Information on preparation of a stable extemporaneous suspension is available for these agents

BID, twice-daily; HCTZ, hydrochlorothiazide; QD, once-daily; QID, four times daily; TID, three times daily

for age, gender, and height. Recent studies have suggested that an even lower BP goal is needed in those with chronic kidney disease. Home blood pressure measurement can be helpful in ensuring that blood pressure control has been achieved. In some patients, repeat ambulatory BP monitoring may be necessary if office BP measurements appear to indicate "resistant hypertension."

In addition to ongoing monitoring of blood pressure, treatment of hypertension should include surveillance for medication side effects, periodic monitoring of electrolytes (in children treated with ACEIs, ARBs or diuretics), counseling regarding other cardiovascular risk factors, and continued emphasis on therapeutic lifestyle changes. Hypertensive target-organ damage such as left ventricular hypertrophy, if present, should be reassessed periodically. Children with uncomplicated primary hypertension, especially obese adolescents who successfully lose weight and maintain their weight loss, may be candidates for gradual withdrawal of drug therapy. These children should receive continued BP monitoring after drug therapy is withdrawn, and should continue non-pharmacologic treatment.

Prognosis

Childhood BP and Subsequent CV Disease

There are no data at present that clearly document a relationship between childhood BP and cardiovascular morbidity and mortality in adulthood. However, a number of studies have shown that BP and other traditional cardiovascular risk factors in childhood predict the subsequent presence of cIMT and arterial stiffness, two well-accepted surrogate markers for atherosclerosis and cardiovascular events.

Additionally, longitudinal studies have demonstrated that children with elevated BP are at increased risk of development of the metabolic syndrome as adults, and that, components of the metabolic syndrome, an important risk factor for cardiovascular morbidity, track over time from childhood to adulthood. Taken together, these data indicate that over time, adult morbidity and mortality will be more tightly connected with childhood precursors, and emphasize the need for early intervention.

Acute Severe Hypertension

Clinical Vignette

An 8 year-old boy is brought to the Emergency Department by ambulance after having a generalized tonic-clonic seizure at school. Lorazepam was administered in the field and there has been no further seizure activity. Blood pressures in the ambulance ranged from 150–162/97–110 and a repeat reading in the Emergency Department is 154/102. His mother arrives from work and mentions that his urine has been dark brown in color for the past 2 days.

Presentation and Differential Diagnosis

Acute severe hypertension has traditionally been divided into hypertensive emergencies and hypertensive urgencies. The clinician should understand that there is a spectrum of severity of acute hypertension, and that any classification scheme dividing the clinical presentation of acute severe hypertension into separate categories is by its nature arbitrary. That said, severe symptomatic elevation in BP *with* evidence of acute target-organ damage has classically been classified as a hypertensive emergency; while severe symptomatic elevation in BP *without* evidence of acute target-organ damage has classically been classified as a hypertensive urgency.

Hypertensive encephalopathy is the most frequent life-threatening symptom in children and adolescents with severe hypertension, emphasizing the need for slow, controlled reduction in BP to prevent complications arising through loss of normal autoregulatory processes. Other severe symptoms sometimes seen in pediatric patients with severe hypertension include cortical blindness and congestive heart failure. Less severe symptoms may include nausea, vomiting, or unusual irritability; since these may be somewhat nonspecific, especially in younger children, a high degree of clinical suspicion must be maintained.

Nearly every child or adolescent who presents with severe acute hypertension has secondary hypertension. Common underlying conditions that may produce acute severe hypertension in a child or adolescent include acute or chronic renal disease, solid organ transplantation, renal artery stenosis, or congenital renal disease such as autosomal recessive polycystic kidney disease. Medication non-adherence in patients with established primary hypertension, the most common cause of acute severe hypertension in adults, occurs rarely in pediatric patients (except perhaps in those with chronic kidney disease).

Evaluation and Management

The child with acute severe hypertension requires prompt evaluation and therapy in order to avoid further development of target-organ effects. In most such children, the

underlying diagnosis will be obvious from the medical history, and little additional information will be needed other than determining the severity of symptoms the patient is experiencing, as this will guide treatment. For patients newly presenting with severe hypertension who have no prior history, in addition to assessing symptom severity, questions will need to be asked regarding the onset of symptoms, as well as recent and past medical history, focusing on eliciting clues to whatever underlying condition is producing the severe hypertension.

Usually, only a brief physical examination is necessary in evaluating children with acute severe hypertension. Just as in the outpatient with elevated BP, it is important to confirm that the BP has been accurately measured. The examination should then focus on assessment of volume status, cardiac status, and neurologic status. Other parts of the examination will help narrow the differential diagnosis in those children without prior histories of hypertension. Extensive diagnostic studies will not be necessary in most patients, but laboratory assessment of renal function, urinalysis (if possible), electrolytes, and assessment of cardiopulmonary status by chest x-ray and/or echocardiography should be obtained. Renal or abdominal ultrasonography may be helpful in confirming findings on physical examination, but usually can be deferred until BP has been lowered to a safe level. Other

Table 292.10
Antihypertensive drugs for management of severe hypertension in children and adolescents

Useful for severely hypertensive patients with life-threatening symptoms				
Drug	**Class**	**Dose**	**Route**	**Comments**
Esmolol	β-adrenergic blocker	100–500 mcg/kg/min	IV Infusion	Very short-acting–constant infusion preferred. May cause profound bradycardia
Hydralazine	Direct vasodilator	0.2–0.6 mg/kg/dose	IV, IM	Should be given q 4 h when given IV bolus
Labetalol	α- and β-adrenergic blocker	Bolus: 0.20–1.0 mg/kg/dose, up to 40 mg/dose Infusion: 0.25–3.0 mg/kg/h	IV Bolus or infusion	Asthma and overt heart failure are relative contraindications
Nicardipine	Calcium channel blocker	Bolus: 30 mcg/kg up to 2 mg/dose Infusion: 0.5–4 mcg/kg/min	IV Bolus or infusion	May cause reflex tachycardia
Sodium Nitroprusside	Direct vasodilator	0.5–10 mcg/kg/min	IV Infusion	Monitor cyanide levels with prolonged (>72 h) use or in renal failure; or co-administer with sodium thiosulfate
Useful for severely hypertensive patients with less significant symptoms				
Drug	**Class**	**Dose**	**Route**	**Comments**
Clonidine	Central α-agonist	0.05–0.1 mg/dose, may be repeated up to 0.8 mg total dose	PO	Side effects include dry mouth and drowsiness
Enalaprilat	ACE inhibitor	0.05–0.10 mg/kg/dose up to 1.25 mg/dose	IV bolus	May cause prolonged hypotension and acute renal failure, especially in neonates
Fenoldopam	Dopamine receptor agonist	0.2–0.8 mcg/kg/min	IV infusion	Clinical trial demonstrated modest BP reductions in patients ≤12 years
Hydralazine	Direct vasodilator	0.25 mg/kg/dose up to 25 mg/dose	PO	Extemporaneous suspension stable for only 1 week
Isradipine	Calcium channel blocker	0.05–0.1 mg/kg/dose up to 5 mg/dose	PO	Stable suspension can be compounded
Minoxidil	Direct vasodilator	0.1–0.2 mg/kg/dose up to 10 mg/dose	PO	Most potent oral vasodilator; long-acting

ACE, angiotensin-converting enzyme; BP, blood pressure; IM, intramuscular; IV, intravenous; PO, oral

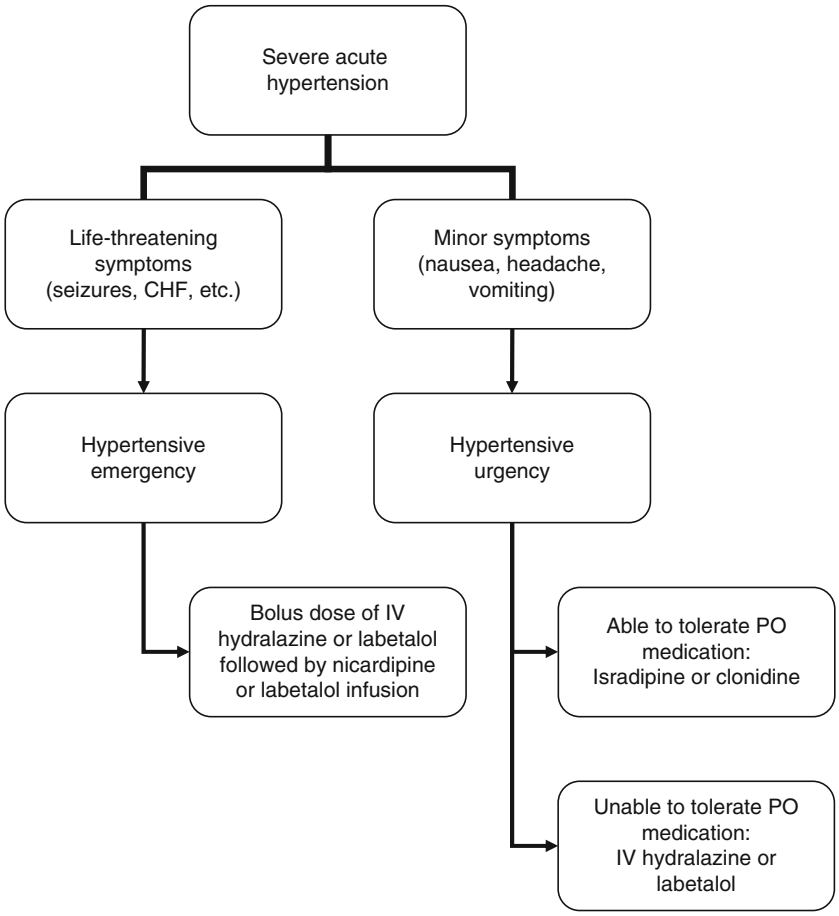

Figure 292.7
Proposed algorithm for management of severe acute hypertension in children and adolescents (CHF, congestive heart failure; IV, intravenous; PO, oral)

diagnostic studies suggested by the physical examination or initial lab tests can also be obtained at a later stage of management.

Although evidence-based recommendations are lacking, the usual goal in treatment of a hypertensive emergency is to reduce the BP by no more than 25% over the first 8 h, with a gradual return to normal/goal BP over 24–48 h. Treatment of hypertensive emergencies in children should be initiated with a continuous infusion of an intravenous antihypertensive, with nicardipine and labetalol being the agents most commonly used. Oral antihypertensive agents can be used in patients with acute severe hypertension who do not have life-threatening symptoms. The choice of oral antihypertensives for use in management of severe hypertension in pediatric patients is fairly limited. Short-acting nifedipine, which had remained in use in children until recently, is no longer recommended. For suggested doses of oral and intravenous drugs useful in treatment of acute severe hypertension in children and adolescents, see *Table 292.10*. An algorithm to the classification and suggested management of the child or adolescent with acute severe hypertension is presented in *Fig. 292.7*.

293 Poststreptococcal Acute Glomerulonephritis

Abdelaziz Y. Elzouki

Definition

Acute glomerulonephritis (AGN) is a clinical complex characterized by the presence of hematuria or red blood cell (RBC) casts accompanied by at least two of the following clinical findings: edema (periorbital in most of the cases), azotemia, oliguria, and hypertension.

AGN can be classified etiologically into four main clinical categories (*Table 293.1*): (1) postinfectious AGN, (2) AGN associated with systemic diseases, (3) idiopathic glomerulonephritis, and (4) familial nephritis.

In children, the majority of cases of AGN are postinfectious, which include bacterial, viral, and parasitic causes (*Table 293.2*). The most common postinfectious AGN cases are those following infection of the throat or skin with group A β hemolytic streptococci. Poststreptococcal acute glomerulonephritis (PSAGN) occurs in two forms, the epidemic form and the sporadic form.

Incidence and Prevalence

Streptococcal infection continues to be the most common cause of AGN in children living in Thailand, China, India, South Africa, South America, Southeast Asia, Turkey, and Arab countries. Environmental conditions that can explain the difference in incidence in different countries include:

(a) the density in terms of number of people per unit area of living space (i.e., the number of residents per household is much higher in countries with high incidence compared to Europe and North America) and (b) the prevalence of nephritogenic strains of streptococcus in the population.

Data on the incidence of AGN following documented infection with group A β hemolytic streptococci reveal attack rates as low as 1% to as high as 20%.

Age and Sex Distribution and Familial Cases

The disease occurs most commonly in children between the ages of 3 and 7 years. It is rare in infants and children younger than 2 years of age, and is more common in boys by a ratio of 2:1. In a study of 302 children with sporadic PSAGN (*Table 293.3*), the mean age was 7.1 years, 85% were 4 years or above, and the ratio of boys to girls was 1.6:1. Cases of PSAGN frequently cluster in an individual family. One study reported that 20% of the sibling contacts of patients with PSAGN developed clinical or subclinical glomerulonephritis. In a study of 302 patients (*Table 293.3*), seven of 302 patients (2%) had siblings who were admitted to the hospital with symptomatic PSAGN within 3 weeks of their own diagnosis.

Association with Pharyngitis and Pyoderma

PSAGN may follow group A streptococcal infection of either the skin or pharynx. Unlike rheumatic fever, only certain M types are associated with this sequelae. Distinct M types are associated with each site of infection: types 1, 3, 4, 12, and 25 are associated with pharyngitis-related PSAGN and types 2, 6, 49, 55, and 57, are associated with pyoderma-related PSAGN. Pharyngitis-related PSAGN tends to peak in the winter and spring month, whereas pyoderma-related PSAGN is more prevalent in the summer and fall. The interval between the preceding streptococcal infection and the development of PSAGN is 1–2 weeks (average 10 days) in pharyngitis-related PSAGN; the interval is longer (4–8 weeks) in pyoderma-related PSAGN.

Pathogenesis

The exact mechanism by which renal injury is produced in this disease is not completely understood. It was suggested that circulating immune complexes that traverse the glomerular basement membrane activate the complement system, which leads to release of substances that attract neutrophils; lysosomal enzymes released by neutrophils are at least in part responsible for the damage to the

Familial Nephritis (Alport Disease)

glomeruli. However, similar circulating immune complexes have also been found in patients with rheumatic fever without glomerulonephritis and may occur in normal individuals.

Previous studies have shown elevated levels of plasma interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF alpha), and urinary IL-6 and IL-8, in patients with PSAGN. Increased renal expression of IL-8 and transforming growth factor-beta (TGF-B) has also been reported in this disease. The streptococcal erythrogenic exotoxin type B (ETB) and its precursor (ETBP) have been shown to be involved in the pathogenesis of PSAGN. ETB has been found in renal biopsies from patients with PSAGN.

In a recent study, it has been reported that there was a significant increase in IL-6, IL-8, TNF alpha, and TGF-B1 in ETB- or ETBP-treated human mononuclear leukocytes culture.

Clinical Features

Subclinical cases occur about four times more frequently than easily recognized cases; however nearly all the patients have abnormal urine analysis.

The initial clinical manifestations of 302 children with sporadic PSAGN are shown in (*Table 293.3*).

Table 293.2
Infectious agents associated with postinfectious acute glomerulonephritis

Bacterial
• Group A β hemolytic streptococci
• Streptococcus viridans (subacute bacterial endocarditis nephritis)
• Staphylococcus aureus
• Staphylococcus albus (shunt nephritis)
• Streptococcus pneumoniae (pneumococcus)
• Salmonella typhi
• Klebsiella pneumoniae
• Brucella
• Treponema pallidum (syphilis)
• Mycoplasma pneumoniae
Viral
• Hepatitis A
• Hepatitis B
• Hepatitis C
• Epstein-Barr virus
• Mumps virus
• Varicella-zoster virus
• Coxsackievirus
• Rubeola virus
• Human immunodeficiency virus
Parasitic
• Plasmodium malariae and falciparum
• Schistosoma mansoni
• Toxoplasma gondii
• Echinococcus (hydatid disease)
• Loa loa
• Onchocerca volvulus
• Leishmania

Edema

Edema is the most common clinical finding in patients with PSAGN, present in 90% and constituting the chief complaint in 62% of children with PSAGN. Characteristically, early morning periorbital edema is an initial clinical manifestation. The lower extremities are the second site for fluid retention. Usually there is no ascites or pleural effusion except in patients who presented with nephrotic syndrome. The degree of edema depends on

Table 293.3
Epidemiologic and clinical presentations of 302 children with sporadic poststreptococcal acute nephritis

Mean age (range) (year)	7.1 (2–14)
Male:female ratio	1.6:1
Average residents per household	8.2
Familial occurrence	2%
Edema	98%
Gross hematuria	60%
Hypertension	64%

the sodium content of the diet. Patients without obvious edema at presentation often lose 1–2 kg of body weight during recovery.

Hematuria

Gross hematuria is a common presentation in children with PSAGN. Usually the parents describe the urine as tea colored or cola colored. The brown color is caused by hemolysis with liberation of hemoglobin, which is then transformed to hematin in an acid urine.

Hypertension

Hypertension occurs in 70–82% of patients, and can be severe in over half of these patients. Hypertension is usually present at the onset of PSAGN. Hypertension in patients with PSAGN has been related to expansion of intravascular or extravascular volume and to vasospasm resulting from neurogenic or hormonal factor. Results of previous studies suggest that renin secretion is not the primary cause of hypertension in patients with PSAGN.

These data indicate that hypertension in PSAGN is "volume-dependent hypertension"; therefore, prompt fluid and sodium restriction, diuretics, and addition of a vasodilator (e.g., hydralazine) can control the hypertension optimally.

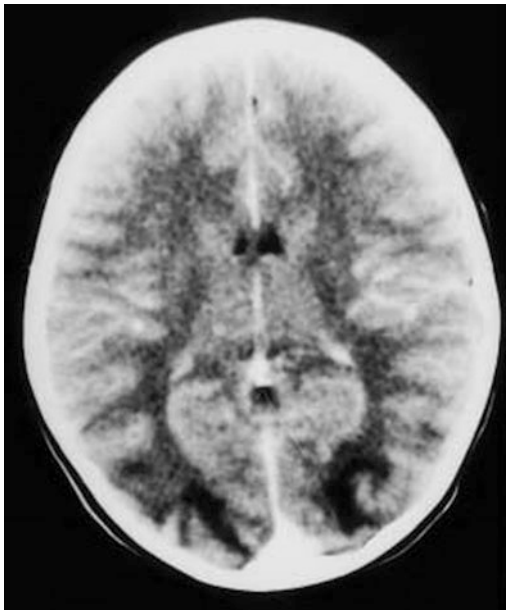

Figure 293.1
Axial computed tomography section demonstrating hypodensity in the occipital lobes (Reproduced from [20])

Hypertensive Encephalopathy/Reversible Posterior Leukoencephalopathy Syndrome (RPLS)

Cerebral symptoms are usually related to an acute increase in the blood pressure ("hypertensive encephalopathy"). These symptoms have been reported to occur in 5–10% of patients. The most frequent acute cerebral manifestations are headache, nausea, vomiting, disturbances of consciousness, and convulsions.

Posterior reversible encephalopathy syndrome (PRES), other name reversible posterior leukoencephalopathy syndrome (RPLS), is a recently described clinico-imaging related entity; this syndrome has been reported in patients with PSAGN.

The clinical manifestations include sudden visual loss, seizures, and specific magnetic resonance imaging. MRI reveal areas of hyperintensities in the bilateral, parietal, and occipital lobs; these hyperintensities resolve in 2 weeks (*Figs. 293.1–293.3*).

Congestive Heart Failure/Pulmonary Edema

Clinical evidence of congestive heart failure (i.e., tachycardia, tachypnea, respiratory distress, gallop rhythm, hepatic enlargement) and radiologic evidence of pulmonary

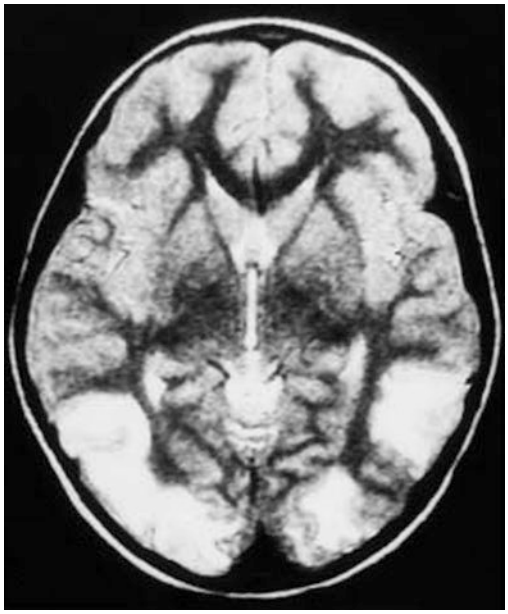

Figure 293.2

edema (pulmonary alveolar infiltrates, cardiomegaly, and prominent septal thickening) are manifestations that occur in 20% of patients.

Hypertension and hypervolemia are the primary factors producing symptoms of congestive heart failure. In previous studies, it has been shown that the plasma volume of patients with PSAGN is increased and that a correlation exists between the blood volume and signs or symptoms of pulmonary edema.

In children who present with respiratory distress and chest X-ray showing cardiomegaly and pulmonary edema, blood pressure recording and urine analyses should be performed immediately to rule out acute glomerulonephritis.

Hemoptysis (pulmonary hemorrhage) has been reported to occur with PSAGN.

Laboratory Findings

1. Microscopic hematuria usually present in all patients. Urine examination reveals numerous RBCs with evidence of glomerular hematuria, and RBC casts can be seen in fresh urine specimens.
2. Proteinuria is present in 80% of patients with PSAGN; however, massive proteinuria (i.e., nephrotic-range proteinuria) is present in only 4–10% of patients.
3. Serum complement C3 level was found to be decreased in 80–95% of patients if measurements were made during the first 2 weeks of illness. The complement levels usually returned to normal within 6–8 weeks. Persistently low complement levels beyond 8 weeks indicate the need to investigate other possible causes of glomerular nephritis, which include membranoproliferative glomerulonephritis and lupus nephritis.
4. Renal function: Azotemia is present in PSAGN; usually there is a mild to moderate reduction in glomerular filtration rate. The serum creatinine usually does not exceed 150 micromole/L in the majority of patients; however, a few patients (up to 8%) can present with acute renal failure, with very high serum creatinine as clinical evidence of rapidly progressive glomerulonephritis (RPGN). In a follow-up study 1–16 years of the acute episode of PSAGN, it was found that these patients has basal creatinine clearance similar to normal control; however, the renal function reserve (RFR) was significantly reduced compared to control group.
5. Anemia is usually mild and related to the degree of plasma volume expansion (i.e., dilutional anemia). Recently, in three cases of PSAGN reported associated with autoimmune hemolytic anemia, (AIHA) the

patients had a positive direct antiglobulin test (DAT). Patients with PSAGN and significant anemia should have a DAT performed.
6. Sedimentation rate is usually increased during the cute phase of the disease.

Evidence of Streptococcal Infection

Isolation of streptococci from the throat or skin and/or evidence of host response are confirmatory of streptococcal infection. Cultures of the throat and any skin lesions may yield a β hemolytic streptococcus. Humoral antibodies to specific streptococcal extracellular products can be demonstrated by neutralizing assays. The antistreptolysin o (ASO) assay is the most commonly used. Eighty percent of untreated children will have a fourfold rise in ASO titer.

After pyoderma, response to ASO is frequently slight or absent. In contrast, the antideoxyribonuclease B (antiDNAse B) and the antihyaluronidase (AH) assays are useful after skin as well as throat infection. The streptozyme agglutination slide test can detect five antibodies (ASO, antiDNAse B, AH, and antistreptokinase) within 7–10 days. It was demonstrated that increased streptococcal zymogen antibody titers are the best available marker for streptococcal infection associated with AGN.

In a recent study, it was reported that the combination of ASO and AntiDNAse B was a very sensitive and specific combination for identifying non-suppurative post streptococcal disease (sensitivity 95.5%, specificity 88.6%).

Pathology

The characteristic pathologic findings of PSAGN include light microscopic demonstration of diffuse exudative proliferative glomerulonephritis. The glomeruli are enlarged, with a pronounced lobular configuration. There is endothelial and mesangial cell proliferation. Capillary lumens are extensively obliterated. Inflammatory cells are commonly present in the glomeruli; they are mainly polymorphonuclear leukocytes (*Fig. 293.4*), but occasionally eosinophils, lymphocytes, F macrophages, and plasma cells are identified as part of the exudative component. Focal and segmental crescents are common, but diffuse crescentic glomerulonephritis involving more than 50% of the glomeruli (i.e., RPGN) is rare. On immunofluorescence microscopy, there is fine granular staining for immunoglobulin G, C3, and C1q along the capillary loops and within the mesangium. On electron microscopic examination, the most characteristic change seen ultrastructurally is the presence of subepithelial discrete electron-dense, dome-shaped "humps" that project outward from the epithelial side of the basement membrane.

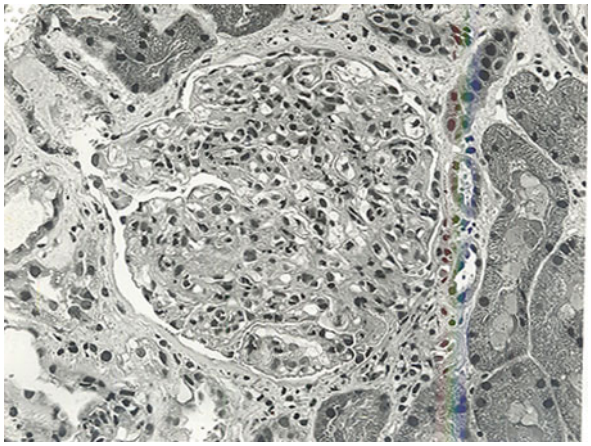

Figure 293.4
Glomerulus in postinfetious glomerulonephritis. The glomerulus is hypercellular due to increased mesangial and endothelial cells along with infiltration by polymorphonuclear cells (courtesy of Dr. M. Akhtar)

Clinical Course

The natural course of PSAGN in children is as follows:

Oliguria and azotemia resolve within 7–14 days, hypertension resolves within 7–21 days, gross hematuria resolves within 3 weeks, C3 becomes normal within 6 weeks, proteinuria may persist for 6 months, and microscopic hematuria may persist for 1–2 years.

Diagnosis and Differential Diagnosis

The diagnosis of PSAGN can be established by the following clinical and laboratory criteria:

1. Clinical diagnosis of acute nephritis (i.e., acute onset and presence of hematuria, edema, hypertension, azotemia)
2. Decreased serum level of C3
3. Bacteriologic or serologic evidence of streptococcal infection
4. Spontaneous improvement in the clinical and laboratory indicators as stated above in "Clinical Course"

Other causes of acute nephritis, including systemic diseases affecting the kidney and primary renal disease, should be considered in the differential diagnosis:

1. Henoch–Schonlein nephritis: presence of purpuric rash, abdominal pain, gastrointestinal bleeding, arthritis, normal C3, elevated immunoglobulin A
2. Systemic lupus erythematosus: systemic manifestations that include rash, fever, arthralgia/arthritis, positive antinuclear antibodies, persistently depressed C3 and C4
3. Hereditary nephritis: family history of renal disease, sensorineural hearing deficit of patient or family member, normal C3
4. Membranoproliferative glomerulonephritis: persistent depressed C3, intractable hypertension

Treatment

The management of the child with PSAGN centers on adequate treatment of hypertension and reducing the volume expansion. In a study of 302 children with sporadic PSAGN, the management included fluid and sodium restriction, diuretics (furosemide), and other antihypertensives, including hydralazine and propranolol; there was no mortality and there was a clinical complete recovery. A few patients may develop RPGN. The latter group may require dialysis and pulse methylprednisolone therapy and eventually may recover completely.

Prognosis

Most of the follow-up studies of children with PSAGN have shown that short- and long-term outcome is excellent, with complete recovery and no progression to chronic renal failure.

PSAGN rarely recurs.

294 IgA Nephropathy

Rosanna Coppo

Case

A previously healthy 10-year old boy developed a cough, clear nasal discharge, and a temperature of 101°F. Approximately 12 h after the onset of symptoms, the mother became alarmed when the boy's urine turned brown. The boy was playing normally and did not appear ill. The amount of urine was normal. The boy had grown normally and had had excellent primary medical care; he had had no previous urinary problems or urinalyses. Because his urine remained brown, the mother and child visited a pediatrician. At the pediatrician's office, he appeared healthy except for the upper airway congestion. His blood pressure and other physical examination were normal. A urinalysis demonstrated large amounts of hemoglobin, 1+ protein, a high red blood cell count, and many red blood cell casts. Serum creatinine and complete blood count were normal.

What is your differential diagnosis? Could this be IgA nephropathy?

Definition

IgA nephropathy (IgAN) is a glomerular disease characterized by renal IgA deposits, prevalent over other classes of immunoglobulins, mostly in the mesangial area (*Fig. 294.1*). It can be observed in association with features of systemic vasculitis in Henoch-Schoenlein purpura or can be limited to the kidney, as described by Berger (primary IgA nephropathy). IgAN is common in children and adolescents presenting with persistent isolated microscopic hematuria or hematuria associated with moderate proteinuria.

Epidemiology

Primary IgAN is more frequent in males than in females. Its prevalence in children is variable around the world. In Japan, Korea, and Taiwan, all children are screened annually, and those thought to have glomerular hematuria have a renal biopsy. In these countries, the prevalence of IgAN is about 30% of all the glomerular diseases. The prevelance of IgAN in the USA is unknown, although it is less common in Afro-Americans. In Europe, IgAN represents almost 20% of all the renal biopsies in children. In South America, IgAN represents 25% of biopsies for suspected glomerular disease.

Etiology

A role for mucosal infections in IgAN has been hypothesized due to the typical manifestation of gross hematuria coincident with upper respiratory tract infections. Several experimental models have reproduced IgA mesangial deposits with pathogen administration, including intranasal delivery of Sendai virus, a common respiratory pathogen, immunization with Hemophilus parainfluenzae antigens, Coxsackie B4, Staphylococcus Aureus cell envelope, and others. IgAN was reproduced in experimental animals also by oral immunization with gliadin or other alimentary antigens. In humans, relationships between IgAN and infection have been claimed for Staphylococcus antigens, Cytomegalovirus, Epstein virus, Enterovirus, Helicobacter pylori, and others. All these data suggest that exogenous antigens derived from pathogens or environmental antigens could play a role in pathogenesis of IgAN, however the mechanism is still unclear.

Pathogenesis

The accumulation within glomeruli of IgA-containing immune material together with complement fractions, usually C3, was initially ascribed to deposition of IgA immune complexes (IgAIC) formed in response to mucosal pathogens. This hypothesis offered a simple explanation of the relationship between mucosal infections and gross hematuria. High levels of IgAIC are detectable in 30–70% of patients, mostly containing polymeric IgA1. However, no specific viral or alimentary antigens have been found in renal mesangial deposits, which suggests a role for a dysregulated IgA immune response.

Attention has been focused on the properties of the IgA produced by patients with IgAN, particularly IgA1

Structure of immunoglobulin A1

subclass (*Fig. 294.2*), the most representative of deposits in glomeruli of patients with this disease. An insertion of 18 aminoacids in the hinge region between CH1 and CH2 domains represents the major structural difference between IgA1 and IgA2. In this insertion three threonine and three serine residues are bound to five short O-linked oligosaccharide chains. The O-glycosylation consists of a core N-acetyl galactosamine (GalNAc) which occurs alone or extended with β1, 3 linked Gal or further with sialic acid in α2, 3 and / or α2, 6 linkage. In healthy subjects, serum IgA1 consists of a mixture of molecules with different O-glycoforms, whereas an abnormal IgA1

O-glycoform pattern has been detected in IgAN by using different techniques which demonstrated a high frequency of O-glycans consisting of GalNAc defective in β1,3 Gal. Such aberrantly glycosylated IgA1 can circulate as a monomer or participate in macromolecular self-aggregates; they can elicit an IgG autoimmune response forming IgG/IgA1IC or react with antigens and form true IgAIC. IgAIC constituted by aberrantly glycosylated IgA1 likely escape clearance by hepatic receptors and have a preferential renal deposition by virtue of enhanced lectinic reactivity with fibronectin, laminin, and collagen within the mesangial matrix. Currently, genetic and immunological studies support a hypothesis that IgA nephropathy is a multifactorial disease in which one or more genes, probably in combination with the effects of environmental factors, may be responsible for the onset of the disease.

Among other pathogenetic influences, increased production of IL-4 and IL-5 by Th2 subset lymphocytes in IgAN may explain the production of abnormally glycosylated IgA1 molecules which deposit in the glomeruli and could reduce terminal galactosylation and sialylation. The interaction with Fcα receptors on mesangial cells results in cellular activation and flogistic mediator synthesis including a variety of cytokines (IL6, PDGF, IL1, TNF-α, TGFβ), vasoactive factors (prostaglandins, thromboxane, leukotrienes, endothelin, PAF, NO), or chemokines (MCP-1, IL-8, MIP-1, RANTES). The influx of monocytes and lymphocytes into the mesangium is enhanced by the C3 codeposition. The activation of mesangial cells leads to cell contraction, hemodynamic modifications, and activation of the Renin-Angiotensin System (RAS). Angiotensin II enhances the activation of cytokines and chemokines and potentiates the actions of PDGF and TGFβ as growth factors for mesangial cells, favoring proliferation and accumulation of extracellular matrix, ultimately promoting sclerosis. Particular attention has been recently devoted to genes possibly involved in IgAN progression, as the polymorphism of RAS genes, due to a correlation between angiotensin II levels in tissue and the activity of the gene encoding ACE. In IgAN, there is no clear evidence of a significant alteration in the ACE genotype frequency, but several reports associate one genotype (DD) with a greater rate of progression in IgAN.

Pathology

The changes observed by light microscopy are not specific for this nephropathy, and IgAN is identified by the detection of predominance of IgA deposits in mesangial areas with codeposition of IgG and C3 in one third of the cases (Fig. 294.1). At light microscopy, primary IgAN presents with focal or diffuse proliferation of mesangial cells and expansion of the extracellular matrix. Other glomerular lesions are frequently associated, including focal or diffuse endocapillary proliferation, extracapillary proliferation with crescent formation, glomerular hyalinosis, and segmental or global sclerosis. Limited areas of tuft necrosis, indistinguishable from those seen in association with small vessel vasculitis, are detectable in IgAN with particularly acute disease. Rapidly progressive forms with crescents involving more than 50% of glomeruli are very rare. Interstitial and arteriolar changes are infrequently found.

Several authors have proposed classifications of IgAN grouping and stratifying the lesions. A new classification has recently been produced by a consensus of pathologists and nephrologists. This Oxford clinicopathological classification consists of a combined report of scores related to four lesions (mesangial and endocapillary hypercellularity, segmental glomerulosclerosis, and tubular atrophy/interstitial fibrosis) that were found to be predictive of outcome independently of clinical assessment. Cross-sectional correlations between pathology and clinical features, including proteinuria at the time of biopsy, were similar in adults and children. Although children with IgAN displayed more proliferative lesions and fewer chronic changes than adults, the predictive value of each lesion in the Oxford IgAN clinicopathological classification on renal survival was not modified by age at biopsy.

Clinical Features

The most typical clinical feature of IgAN is macroscopic hematuria concomitant with upper respiratory tract infections or other mucosal inflammatory processes; it rarely occurs after vaccination or heavy physical exercise. Symptoms and/or urinary signs before the age of 3 years; are rare but increase with age. Gross hematuria affects 30–40% of children with IgAN. The interval between the precipitating event and the appearance of macrohaematuria is very short (12–72 h). The macrohaematuria persists for few days (usually less than 3 days), infrequently accompanied by flank and loin pain and fever. The color of the urine is red or brown (coke-colored); red blood cell casts are common. These episodes can recur and microscopic hematuria of various degree isolated or associated with low amounts of proteinuria can be residual between episodes of macroscopic hematuria. Thirty to fifty percent of the children biopsied for persistent microscopic hematuria with or without proteinuria have a diagnosis of IgAN. Proteinuria may

be found in 3–13% of chilren with asymptomatic hematuria and IgAN. A transient increase in proteinuria occurs coinciding with episodes of gross hematuria. In some children (6%), the clinical onset of IgAN can appear as nephrotic syndrome.

In a few cases, at the onset of disease, there is an acute nephritic syndrome, similar to poststreptococcal glomerulonephritis. In these children, macrohaematuria is associated with increased serum creatinine and urea, and also hypertension. In rare cases, the onset may be severe nephritic syndrome progressing to chronic renal failure due to crescentic lesions. Furthermore, in a few patients acute oliguric failure, usually spontaneously reversible, accompanies the episodes of macrohaematuria, attributed to tubular obstruction by red blood cells. Hypertension usually develops during a follow-up of several years or in severe cases.

Diagnosis

The hallmark of this nephritis is glomerular deposition of IgA; hence the diagnosis is possible only after renal biopsy, using immunofluorescence or immunohistochemistry investigations.

High serum levels of IgA are found in 35–50% of patients. This marker, particularly in cases with typical and recurrent macroscopic hamaturia, may suggest the possible presence of the disease, as well as the more sophisticated detection of high levels of aberrantly glycosylated serum IgA1, but the diagnosis is made on a histological basis only. It is common to find high levels of macromolecular IgA (IgAIC, mixed IgA/IgGIC, IgA/fibronectin aggregates), particularly during the phases of clinical activity.

Complement values are generally within the limits when C3 or C4 are measured, while signs of subclinical complement activation can be detected by measuring the C3d breakdown product.

Serial measurement of 24 h protein excretion or urinary protein/creatinine ratio is highly recommended as one of the most useful parameters to follow over the years. Urinary excretion of cytokines, mostly MCP-1 and IL6, is increased in patients with progressive course, but not generally available for clinical use.

Differential Diagnosis

As mentioned above, the diagnosis is histological only, performed on renal biopsy.

Other conditions presenting with gross hematuria should be considered to assess the need for renal biopsy, mostly postinfectious acute glomerulonephritis. The interval between upper respiratory tract infection and macrohematuria in IgAN is very short (hours or 1–3 days), compared with 1–3 weeks in postinfectious acute glomerulonephritis.

Besides renal biopsy features, the diagnosis is made in the absence of any recognizable systemic disease (lupus erythematosis, Henoch–Schönlein purpura, cryoglobulinemia), or chronic liver disease, which may present IgA mesangial deposits as well.

Treatment

Attempts to intervene in the pathogenic sequences leading to IgAN would consider a reduction in antigen challenge and since tonsils are frequent source of infections, interest has been focused on tonsillectomy. Abandoned as a routine approach in Europe and North America, tonsillectomy is still favored in some regions of the world, notably in Japan. This procedure may be of some value in preventing episodic gross hematuria in the short term, but the long-term effects are uncertain. Tonsillectomy is supported by two large retrospective studies from Japan and China, which reported that the benefit on renal function decline is evident in a follow-up longer then 10 years. Tonsillectomy has a clear indication when tonsils are a true infectious focus, otherwise the benefit is unclear. Other attempts to reduce the antigen exposure include long term antibiotics and gluten-free diet, which resulted not effective on functional decline, even though the latter significantly reduces the IgA immunological abnormalities.

Current therapeutic strategies for IgAN have been directed toward modulating the glomerular response to immune deposits, in order to decrease the resultant tissue damage and progression toward sclerosis.

Patients at risk for progressive renal injury should be detected. Therapeutic intervention must be attempted in rapidly progressive IgAN (i.e., with florid crescent formation involving more than 50% of glomeruli, hypertension, and/or severe proteinuria). The protocols include a cycle of 10 plasmaphereses, cyclophosphamide 3 mg/kg/day, and prednisone 1 mg/kg/day for 8 weeks or a course of high dose methylprednisolone pulses alone or in association with 2 mg/kg/day cyclophosphamide for 8 weeks. In a cohort of children with severe IgAN and slowly progressive course, the treatment with prednisone and azathioprine for 1 year reported favorable outcome. A similar protocol in association with heparin-warfarin and

dipyridamole may be used for children with histologic signs of diffuse mesangial proliferation.

Children with IgAN and high levels of proteinuria are at risk for progressive disease. Patients with severe proteinuria >3 g/day/1.73 m^2 even if they still have normal renal function should be treated. Prednisone 1 mg/kg/day for 4 weeks, with a progressive reduction over the following 8 weeks, and then small doses for a total time period of 1–3 years has a good indication for patients with nephrotic-range proteinuria and eicosapentanoic acid (fish-oil) for 2 years in those with high or moderate proteinuria (>1<2 g/m^2 day) with initial contraction in glomerular filtration rate. In adults, three pulses of methylprednisolone at months 1,3,5, followed by low doses of prednisone, provided a significant protective effect on the functional decline. It is of interest that the benefit of this therapy last for several years after the pulses, protecting the treated patients from proteinuria and even more from loss of renal function. No controlled study is available in children. Results of a randomized, placebo-controlled, double-blind trial in North America using prednisone (60 mg/m^2 every other day for 3 months, followed by 40 mg/m^2 every other day for 9 months, and then 30 mg/m^2 every other day for 12 months) or fish oil (4 g/day for 2 years) found no benefit in treatments groups versus the placebo group.

ACE inhibitors (ACE-I) have a strong basis for use in the treatment of IgAN, not only because they improve two principal progression factors (hypertension and proteinuria) but because their use may inhibit the long series of potentially negative Angiotensin II effects.

In a European multicenter controlled trial including children and young subjects (3–35 years old) with a constant level of moderate proteinuria (>1<3.5 g/day/1.73m^2 over the 3 months before enrollment) and normal or moderately reduced renal function, patients were randomized to receive benazepril 0.2 mg/kg/day or placebo. The primary outcome of renal disease progression, defined as >30% decrease in baseline creatinine clearance and/or worsening of proteinuria to nephritic range, found significant differences between the two groups. A stable remission of proteinuria (<0.5g/day/1.73 m^2) was observed in 56% of ACE-I patients versus 8% of placebo patients. The multivariate Cox analysis showed that treatment with ACE-I was the independent predictor of prognosis, while no influence on the progression of renal damage was found for gender, age, baseline glomerular filtration rate, systolic or diastolic blood pressure, and proteinuria.

Vitamin E, used as anti-oxidant drug, showed significant reduction in proteinuria, with a statistically non-significant trend toward a better preservation of renal function in one trial. Cyclosporine A does not provide protective effects on the recurrence of IgAN in transplanted kidneys, indirectly indicating no benefit on the original disease. The effectiveness of mycophenolate mofetil is still debated.

Prognosis

The prognosis of IgAN was initially considered to be more benign in children than in adults, but long-term studies have failed to confirm this assessment. The natural history of IgAN in children represents, with few exceptions, the early phase of a chronic disease. Severe clinical signs usually develop after 5–15 years requiring the need for long follow-up including adult life in order to define the history and the progression of IgAN in an individual patient. In the first report by Levy et al., a follow-up of 13 years in 90 French children demonstrated that only 9% progressed to renal failure. However, persistent signs of active renal disease develop at long-term follow-up as reported in 47% of Swedish children after 10 years, including proteinuria in 35%, hypertension in 9%, and decreased glomerular filtration rate in 3%. In a report from Japan in 200 children who were followed for a mean period of 5 years, urinary abnormalities were detected in 38%, persistent heavy proteinuria in 10%, and progression to chronic renal failure in 5%. A Finnish study reported that subjects with IgAN originated in childhood after 2 decades may have no signs of urinary disease in one third of the cases, and minor urinary abnormalities in another third, but the last third had chronic kidney disease and 10% needed renal replacement treatment.

In short-term follow-up studies in both adults and children, a better prognosis is observed in children, while a 20 year survival analysis showed that IgAN in children was as progressive as in adults. In a cohort of 103 American children mostly of Caucasian or Afro-American race, a report in 1995 predicted a kidney survival rate from the time of biopsy of 85% at 10 years and 73% at 20 years. The Caucasian American cohort data have been recently updated and the survival at 10 years now results to be 91% and at 20 years 80%, similar to a Finnish report, predicting renal survival rates of 93% and 87% at 10 and 20 years respectively. An investigation from Japan that followed 181 IgAN patients for a mean of 7 years from onset, reported 50% in clinical remission and a predicted survival rate of 92% at 10 years and 89% at 20 years. A multicenter study in the USA reviewed clinical and pathological features in 80 children with primary IgAN,

who were followed for at least 4 years. Seven markers were found to be predictive of end-stage kidney disease in children: the presence of glomerular sclerotic changes, especially when these were associated with proliferation or when sclerosis affected 20% or more of the glomeruli; Afro-American race; hypertension at biopsy; proteinuria at biopsy; age at presentation; crescents; male gender.

Some children, usually those presenting with moderate microscopic hematuria without proteinuria and displaying the mildest lesions, do not progress to end-stage renal failure over decades of observation. In children with progressive IgAN, the clinical course is often slow and indolent. Proteinuria is a relevant risk factor for progression both in children and adults. As for adults, follow-up proteinuria (percent duration of massive proteinuria) or proteinuria at 1 year have the strongest predictive value for disease progression. The composition of proteinuria also has been correlated with clinical outcome. An elevated excretion of tubular proteinuria (low molecular weight proteins and particularly α1 microglobulin) has been found to be a negative prognostic index. Similarly, an increased excretion of cytokines and chemokines, such as IL-6 or chemokines (MCP-1), with reduced excretion of EGF were found to be significant risk factors. Gross hematuria does not carry an increased risk of progression.

In conclusion, IgAN in children should be considered to be potentially progressive over decades, and life-long follow-up is needed in order to detect progressive disease and determine the need for therapy.

Prevention

As the disease is thought to originate from an abnormal response of the immune system to common antigens, no prevention is presently envisaged.

295 Alport Syndrome

Clifford E. Kashtan

Definition

Alport syndrome (AS) is an inherited disorder of basement membranes that affects a type IV collagen network composed of α3, α4, and α5(IV) chains. Functional and structural abnormalities of basement membranes result in hematuria and progressive renal disease, sensorineural deafness, and ocular abnormalities. Risk of progression to end-stage renal disease is virtually 100% in affected males.

Etiology

The defects in type IV collagen characteristic of AS arise from mutations in the COL4A3, COL4A4, and COL4A5 genes, which encode the α3, α4, and α5 chains of type IV collagen, respectively.

Epidemiology

It has been estimated that 1 in 50,000 European infants have AS. The gene frequency in the United States is approximately 1 in 5,000 to 1 in 10,000. AS accounts for about 2% of children with chronic renal failure and about 2% of children who receive renal transplants, according to the 2008 report of the North American Pediatric Renal Trials and Collaborative Studies.

Pathogenesis

There are three genetic forms of AS. X-linked AS (XLAS) is caused by mutations in the COL4A5 gene and is the predominant form of the disease, accounting for approximately 80% of patients. Affected males are hemizygotes carrying a single mutant COL4A5 allele. Affected females carry a normal COL4A5 allele as well as a mutant allele and are therefore heterozygotes. About 15% of patients with AS have the recessive form of the disease (ARAS) due to mutations in both alleles of the COL4A3 or COL4A4 gene, located on chromosome 2. These patients are either homozygotes who have the identical mutation in both alleles of the affected gene (and who may have consanguineous parents) or compound heterozygotes who have inherited different mutations in the affected gene. About 5% of patients have autosomal dominant AS (ADAS) caused by heterozygous mutations in COL4A3 or COL4A4. Most individuals with heterozygous COL4A3 or COL4A4 mutations are asymptomatic or exhibit isolated, nonprogressive microscopic hematuria associated with thin glomerular basement membranes (thin basement membrane nephropathy or TBMN). Why some people with heterozygous mutations in COL4A3 or COL4A4 have a progressive course leading to chronic renal failure or end-stage renal disease is uncertain.

Several hundred different mutations in the COL4A5 gene have been identified in patients and families with XLAS. Reported mutations include large rearrangements (∼20%), small deletions and insertions (∼20%), missense mutations that alter a glycine residue in the collagenous domain of the α5(IV) chains (∼30%), other missense mutations (∼8%), nonsense mutations (∼5%), and splice-site mutations (∼15%).

The α3, α4, and α5 chains of type IV collagen form a distinct network in several basement membranes of the kidney, cochlea, and eye. Mutations causing AS prevent deposition of normal α3α4α5(IV) networks in basement membranes, triggering incompletely understood pathologic processes that result in the clinical manifestations of AS.

Pathology

Renal. Light microscopic changes are unusual before 5 years of age. Mesangial hypercellularity and matrix expansion, and eventually focal segmental glomerulosclerosis, are common in older children and adolescents, especially boys. Increasing tubular atrophy and interstitial fibrosis develop after age 10.

Electron microscopy may reveal pathognomonic changes depending on the patient's age and gender. The earliest abnormality is diffuse attenuation of the glomerular basement membrane (GBM). During childhood and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_295,

adolescence, the great majority of boys with XLAS and both boys and girls with ARAS develop the classic Alport GBM lesion, consisting of diffuse thickening accompanied by "basket-weave" transformation of the lamina densa, intramembranous vesicles and densities, scalloping of the epithelial surface of the GBM and foot process effacement. The percentage of GBM displaying this lesion increases progressively with age in boys with XLAS. Females with XLAS display a range of GBM alteration, from focal GBM attenuation to diffuse thickening and basket weaving, with no consistent correlation of GBM findings and age.

Routine immunofluorescence is normal or shows nonspecific immunoprotein deposition. Because disease-causing mutations result in abnormal expression of type IV collagen in basement membranes of most AS patients, specific immunostaining for type IV collagen α chains is useful for both diagnosis and differentiation of XLAS and ARAS. Expression of α3(IV), α4(IV), and α5(IV) chains is completely absent in approximately 80% of XLAS males, and 60–70% of XLAS females exhibit mosaic expression of these chains. In most ARAS patients, GBM is nonreactive with antibodies to α3(IV), α4(IV), and α5(IV) chains, and Bowman's capsules and tubular basement membranes are also negative for the α3(IV) and α4(IV) chains. However, immunostaining for α5(IV) chains in Bowman's capsules and tubular basement membranes is positive. It is important to note that the altered immunostaining for the α3(IV)–α6(IV) chains in patients with XLAS and ARAS is not age dependent. Therefore, this method can provide diagnostic information even in patients who are too young to display characteristic abnormalities in GBM ultrastructure.

Normal epidermal basement membranes (EBM) express α5(IV) chains. EBM staining for α5(IV) chains is negative in about 80% of XLAS males, and mosaic expression of α5(IV) is observed in 60–70% of XLAS females, allowing diagnosis of XLAS by skin biopsy. Skin biopsy is not useful for the diagnosis of ARAS, since expression of α5(IV) in EBM is normal.

Cochlear. The hearing loss of AS arises from cochlear dysfunction. Normal cochleae express type IV collagen α3α4α5 networks in the spiral limbus, spiral ligament, and in the basement membrane interposed between the organ of Corti and the basilar membrane. However, expression of these networks is absent in AS cochleae. Careful examination of well-preserved cochleae from men with XLAS and deafness revealed a zone of separation between the organ of Corti and the underlying basilar membrane, and cellular infiltration of the tunnel of Corti and the spaces of Nuel. These changes are not observed in similarly well-preserved cochleae obtained from normal individuals or patients with other causes of deafness. The structural changes observed in AS cochleae may be associated with defective attuning of basilar membrane motion and hair cell stimulation, resulting in reduced acuity of hearing.

Ocular. Type IV collagen α3α4α5 networks are normal components of several basement membranes in the eye, including corneal basement membrane, Descemet's membrane, lens capsule, internal limiting membrane of the retina, and retinal pigment epithelium basement membrane. The ocular manifestations of AS likely arise from the absence or the abnormality of α3α4α5(IV) networks in eye basement membranes. Lens capsules of AS patients with anterior lenticonus exhibit marked attenuation and focal areas of dehiscence, suggesting that the lens capsule lacks the mechanical strength to maintain the normal lens shape.

Clinical Manifestations

Renal. Persistent microscopic hematuria starting in early childhood is the cardinal clinical feature of AS, occurring in all XLAS males, 95% of XLAS females, and in all ARAS patients. Episodic gross hematuria is not unusual, especially during childhood. Some children with AS have virtually constant gross hematuria.

Overt proteinuria typically appears during later childhood or adolescence in XLAS males and in ARAS patients and increases progressively, often into the nephrotic range. About 75% of XLAS females ultimately develop proteinuria of some degree. Most children with AS have normal blood pressures, but hypertension is common in adolescent males with XLAS and teenaged ARAS patients.

Glomerular filtration rate is typically well preserved during childhood and begins to decline during adolescence. The impacts of gender and genotype on the rate of loss of renal function are discussed below under Prognosis.

Cochlear. Hearing is normal at birth and during early childhood. Symmetrical deficits in sensitivity for high frequency sounds often become detectable by audiometry in late childhood. In XLAS males, the probability of hearing loss is 50% by age 15, 75% by age 25, and 90% by age 40. In XLAS females, the probability of hearing loss is 10% by age 40 and 20% by age 60. Most ARAS patients develop deafness, although precise data on timing is not available.

Over time, the hearing deficit progresses into the frequency range of conversational speech. Because the deficit typically does not exceed 60–70 dB and speech discrimination is preserved, hearing aids are effective in most affected individuals.

Ocular. Anomalies of the lens, retina, and cornea are common in AS, especially among XLAS males and ARAS

patients, often becoming apparent during adolescence and young adulthood. About 15% of XLAS males exhibit anterior lenticonus, in which the central portion of the lens protrudes into the anterior chamber. While this lesion may be asymptomatic, it may be associated with reduced visual acuity and cataracts, and even rupture of the lens may occur. Abnormal retinal pigmentation, consisting of whitish-yellow perimacular flecks, occurs in about 15% of XLAS males, often in association with lenticonus. Corneal abnormalities include recurrent corneal erosions and posterior polymorphous dystrophy.

Other. The association of XLAS with smooth muscle tumors (leiomyomas) of the esophagus, tracheobronchial tree, and in women, with the external genitalia, has been described in several dozen families. Symptoms such as dysphagia, postprandial vomiting, epigastric or retrosternal pain, recurrent bronchitis, dyspnea, cough, and stridor often appear in late childhood. The Alport syndrome-diffuse leiomyomatosis complex arises from X-chromosomal deletions involving COL4A5 and the proximal portion of the adjacent COL4A6 gene.

Mental retardation, midface hypoplasia, and elliptocytosis have been described in a small number of XLAS males who carry deletions that extend downstream of the 3' end of the COL4A5 gene.

Diagnosis

Diagnosis of AS depends on the presence of hematuria associated with one of the following:

1. Mutation(s) in COL4A3, COL4A4, or COL4A5
2. Diagnostic abnormalities of immunostaining for type IV collagen in skin or kidney biopsy
3. Confirmed AS in a first-degree relative
4. Anterior lenticonus or perimacular flecks

AS should be strongly suspected when hematuria is associated with bilateral high frequency sensorineural deafness and/or pathognomonic ultrastructural changes in GBM, and the diagnosis should be confirmed by genetic testing or type IV collagen immunostaining.

Differential Diagnosis

Differentiation of AS from other causes of familial and sporadic glomerular hematuria is based upon careful clinical evaluation, reliable pedigree data, and thoughtful consideration of the relative merits of skin biopsy, kidney biopsy, and molecular analysis. In a child with isolated hematuria, a positive family history of hematuria in the absence of a history of ESRD suggests a diagnosis of thin basement membrane nephropathy (TBMN). Two rare causes of familial hematuria associated with macrothrombocytopenia, Epstein and Fechtner syndromes, can be excluded if the platelet count is normal. Familial IgA nephropathy and membranoproliferative glomerulonephritis are uncommon causes of familial hematuria.

In the absence of a family history of hematuria, the differential diagnosis of glomerular hematuria includes AS, TBMN, IgA nephropathy, membranoproliferative glomerulonephritis, membranous nephropathy, lupus nephritis, postinfectious glomerulonephritis, and Henoch–Schonlein nephritis. Associated clinical findings (e.g., rash, arthritis) or laboratory findings (e.g., hypocomplementemia) will suggest diagnoses other than AS in many patients.

While the results of hearing evaluation are likely to be normal in young children with AS, audiometry may be very useful in children over 6–8 years of age. Ophthalmologic assessment may also provide valuable information, although ocular lesions are more prevalent in those with advanced disease and less common in young patients in whom differentiation of AS from TBMN is more difficult.

Tissue studies can complement clinical and pedigree information. Skin biopsy with immunostaining for the α5(IV) chain may be diagnostic, especially when clinical and pedigree data strongly suggest XLAS. Normal expression of the α5(IV) chain in EBM may indicate that (1) the patient has XLAS, but his or her COL4A5 mutation does not change the α5(IV) expression; (2) the patient has ARAS or ADAS, in which expression of α5(IV) in EBM is not affected; or (3) the patient does not have AS. Whereas skin biopsy is useful only if it provides definitive confirmation of a diagnosis of XLAS, renal biopsy carries the advantage of enabling the diagnosis of XLAS, ARAS, and non-Alport kidney disease.

Mutation detection rates of 80–90% are attainable in XLAS males by COL4A5 sequencing. Comparable data for detection of COL4A3 and COL4A4 mutations in patients with ARAS are lacking. Information about laboratories providing type IV collagen gene sequencing can be found on the web sites of GeneReviews (www.genereviews.org) and the Alport Syndrome Foundation (www.alportsyndrome.org).

Treatment

As there have been no controlled therapeutic trials in human AS, treatment recommendations must be derived

from animal studies and anecdotal reports. In murine ARAS, several interventions have improved renal outcomes, including angiotensin antagonism, TGFβ-1 inhibition, chemokine receptor 1 suppression, administration of bone morphogenic protein-7, blockade of matrix metalloproteinases, bone marrow transplantation, and irradiation. Inhibition of angiotensin converting enzyme (ACE) resulted in an improved survival in dogs with XLAS. In uncontrolled studies of human AS, ACE inhibition reduced proteinuria, at least transiently. Cyclosporine treatment also resulted in prolongation of survival in male XLAS dogs. Cyclosporine treatment diminished proteinuria and appeared to stabilize renal function in a small, uncontrolled study of AS males. However, apparent acceleration of renal fibrosis was suggested by the results of another study of cyclosporine treatment in AS patients.

At present, angiotensin antagonism aimed at suppression of proteinuria appears to be the least risky of available treatment options. With advancing disease, management of hypertension, nephrotic syndrome, and chronic renal failure is required.

AS patients typically have excellent renal transplant outcomes. Two issues require special attention: First, evaluation of potential related donors must identify affected individuals. Second, monitoring after transplant must allow early diagnosis of post-transplant anti-glomerular basement membrane antibody-mediated glomerulonephritis (anti-GBM nephritis), a complication of transplantation that is unique to AS.

Familiarity with the genetics and clinical features of AS is required for informed donor evaluation. Since 100% of males with XLAS have hematuria, absence of hematuria excludes AS in male relatives of XLAS patients. About 95% of females with XLAS have hematuria, so there is only a 5% chance that a female without hematuria is affected. Given that by age 60 there is an estimated risk of ESRD of 30% in women with XLAS, female members of XLAS families who have hematuria should generally be discouraged from kidney donation.

Anti-GBM nephritis occurs in approximately 3% of transplanted AS males, typically occurs during the first year after transplantation, and usually results in irreversible graft failure. There is a high rate of recurrence in subsequent allografts. In XLAS males, the primary target of anti-GBM antibodies is the α5(IV) chain. Females with XLAS who require transplantation are at little or no risk of developing anti-GBM nephritis. However, both males and females with ARAS can develop anti-GBM nephritis after transplantation. The α3(IV) chain is the primary target of anti-GBM antibodies in ARAS patients.

Prognosis

Gender and genotype are the main determinants of prognosis in AS. Although virtually 100% of males with Alport syndrome will ultimately develop ESRD, the pace of progression is heavily influenced by genetic factors. Men with ADAS exhibit relatively slow loss of renal function, with a half-life of renal survival that is about twice that of men with XLAS.

In XLAS males, the probability of ESRD is 50% by age 25, 80% by age 40, and 100% by age 60. Those with major rearrangements or premature stop codons in COL4A5 progress about twice as rapidly to ESRD as those with missense mutations. Large deletions, nonsense mutations, and small mutations that alter the translational reading frame are associated with a 90% probability of progression to ESRD by age 30. The risk of ESRD by age 30 is 70% in patients with a splice-site mutation and 50% in those with a missense mutation.

The timing of deafness and the occurrence of ocular lesions are also influenced by COL4A5 genotype. The risk of developing deafness before age 30 is 90% in those with deletions, nonsense mutations, or splice-site mutations, compared to 60% in those with missense mutations.

These genotype–phenotype correlations are not apparent in XLAS females perhaps because of the overwhelming influence of random X-chromosome inactivation on disease course in XLAS females. The risk of ESRD in women with XLAS is 12% by age 45, 30% by age 60, and 40% by age 80, and is substantially higher in XLAS females who have proteinuria.

Prevention

Prevention of AS depends on the reproductive decisions of affected individuals. Information regarding prenatal diagnosis is available at genereviews.org.

296 Henoch Schönlein Purpura Nephritis

Richard S. Trompeter

Definition

Henoch Schönlein Purpura (HSP) is primarily a disease of childhood and is one of the most common forms of systemic vasculitis diagnosed in children. The clinical manifestations are legion, but most characteristic is the triad of a purpuric rash affecting the lower extremities, gastrointestinal symptoms principally abdominal pain, and arthritis. The majority of patients recover completely within a month of the onset of the initial symptoms.

Historical Note

Schönlein is usually credited with the original description of a characteristic rash and arthralgia, and Henoch with the association of a similar rash with abdominal symptoms and subsequently with renal disease. However, as early as 1801, Heberden had described repeated attacks of purpuric rashes with painful swelling, abdominal discomfort, and hematuria.

> ▶ Another boy, five years old, was seized with pains and swellings in various parts and the penis in particular was so distended, though not discoloured, that he could hardly make water. He had sometimes pains in his belly, with vomiting, and at the time some streaks of blood were perceived in his stools, and the urine was tinged with blood. When the pain attacked his leg, he was unable to walk; and presently the skin of his leg was all over full of bloody points. After a truce of three to four days the swelling returned, and the bloody dots, as before.

Epidemiology

The majority of patients are Caucasian or oriental, and contributions to the literature over the past decades give the impression that the condition is more common in Europe and Japan than in North America. The estimated annual incidence of Henoch Schönlein Purpura Nephritis (HSPN) is 20 per 100,000 children. Ethnicity may be an important etiopathological factor with a preponderance of Caucasian children affected, 17 per 100,000, compared to African American 6 per 100,000, or Asian children 5 per 100,000.

HSP mainly affects children between the ages of 3 and 10 years and boys are affected more often than girls (1.5:1). In about two thirds of children, an upper respiratory tract infection precedes the onset of HSP by 1–3 weeks. The incidence shows a seasonal variation with a peak around November to January in the Northern Hemisphere. In general, children are ill and pyrexial with a temperature usually not higher than 38°C.

Pathogenesis

The etiology remains unknown. At the beginning of the last century, Osler likened the condition to serum sickness and other anaphylactoid reactions. The term "anaphylactoid purpura" was introduced by Frank. Since then the idea that HSP is caused by hypersensitivity reaction has developed into the concept that HSP is due to an allergy to antigens derived from microorganisms, food, or drugs.

HSP is now generally considered to be an immune complex-mediated disease characterized by the presence of polymeric IgA contained in dermal, gastrointestinal, and glomerular capillaries. Capillary IgA immune complexes are probably the result of either circulating immune complex deposition or in situ formation. It is known that patients with HSP and IgA nephropathy demonstrate abnormalities of IgA glycosylation leading to mesangial cell deposition and injury.

The pathognomonic IgA and C3 deposits in the mesangial cells of the kidney are indistinguishable from those seen in IgA nephropathy. Although there is evidence that the glomerular injury may be attributable to the deposition of C3 complement and activation of the alternate pathway of complement the role of a biological mediator for inflammation has as yet not been identified.

In healthy subjects, IgA is found abundantly in mucosal fluids but the serum concentration is low. Both increased IgA synthesis and reduced clearance have been implicated in the pathogenesis of IgA immune complex deposition. Antigens presenting to the mucosa may be the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_296,

stimulus to the increased production of IgA and thus be the trigger for the development of HSP. Many viruses, bacteria, medications, and food hypersensitivity have been implicated in precipitating HSP but no exogenous antigen has been consistently identified in either the circulating immune complexes or in mesangial deposits in the kidney.

Clinical Manifestations

Skin

The characteristic skin rash is purpuric and is symmetrically distributed over the extensor surfaces of the lower legs and arms and over the side of the buttocks. It is invariably present in the area of the lateral malleolus and sometimes is present only at that site. Pressure areas, e.g., beneath the waistband are commonly affected and spots may appear on the penis. The onset is usually as a red maculopapular rash that becomes purpuric and eventually takes on a fawn color as it fades. The rash is not itchy and may not always have a purpuric stage. Patches of purpura may vary in size. In young children under 5 years of age, the illness may start with a generalized urticarial rash that becomes purpuric. Edema of the dorsa of the hands and feet, scalp, and face are not uncommon and correlate with the vasculitic activity and not with any degree of proteinuria. Subcutaneous bleeding can occur at any site and is frequently seen in the eyelids and conjunctiva and in the scrotum mimicking torsion of the testis.

Joints

The joints are affected in up to 75% of cases. The arthralgia most commonly affects the knees and ankles and less frequently the wrists and hands. The joints may become painful and swollen because of periarticular edema. Joint effusions are rare and the arthralgia recovers without residual damage.

Gastrointestinal Tract

Abdominal pain is common affecting at least two thirds of patients with HSP. The pain may be sufficiently severe to mimic an acute abdominal emergency. Abdominal symptoms may precede the rash and joint manifestations in up to 30% of cases. Vomiting, diarrhea, periumblical pain mimicking acute appendicitis, hematemesis, and malena are the main symptoms. Major gastrointestinal disease occurs in approximately 5% of patients, intussusception being the most common. Petechiae and ecchymoses have been observed endoscopically in the stomach, duodenum, sigmoid colon, and rectum. In recent years, ultrasonography has been extremely valuable for diagnosing intra-abdominal pathology particularly intussusception, bowel wall edema and dilatation, and ileus.

Kidney

Renal manifestations are found in 20–100% of patients with HSP and tend to be more common and severe in older children. The reported variable incidence of renal involvement can be accounted for by the differing criteria used to define renal involvement as well as by different methods used to detect microscopic hematuria. In the majority of patients with a nephropathy, urinary abnormalities follow the onset of the typical rash within 4 weeks. However, urinary abnormalities may also precede the onset of the rash or follow it by many months. In older patients severe gastrointestinal system involvement, frequent relapses of and late skin lesions beyond 3 months have been associated with an increased risk of renal involvement.

At presentation, microscopic hematuria with or without proteinuria, occurs in 70–80% of cases of HSP nephropathy, only 20% will have macroscopic hematuria. Variable proteinuria may be present even in urine that does not contain blood, and the patient may develop nephrotic syndrome. The child who presents with a severe acute nephritic syndrome is more likely to develop nephrotic syndrome and or renal insufficiency. Varying degrees of renal failure, often transient is found in approximately 20% of cases. Long-term renal morbidity, i.e., progression to end-stage disease is rare and observed in 2–5% of patients with HSPN.

Laboratory Investigations

Blood

No laboratory test has been found to be diagnostic for HSP. The peripheral blood may show a neutrophil leukocytosis. The erythrocyte sedimentation rate can be elevated. Platelet count and clotting times are normal. Positive throat cultures, elevated ASO, anti-DNase B and anti-NADase titers are of no diagnostic significance. Tests for antinuclear antibodies and rheumatoid factor are negative.

Serum IgA levels may be elevated in approximately 50% of children with HSP. About half of the children with HSP have cryoglobulins in their sera. Analysis of the cryoglobulins reveals IgA and properidin suggesting activation of complement via the alternative pathway. IgA containing immune complexes have been detected in patients with HSP whether or not they developed acute nephritis.

Although recently identified genetic polymorphisms may not contribute to the susceptibility to HSP, there is the potential that their presence could be a risk factor for the development of nephrotic syndrome.

Histopathology

Light Microscopy

The lesion most typical of HSPN consists of a leucoblastic vasculitis characterized by a transmural and perivascular infiltration with polymorphonuclear leucocytes, histiocytes, and sometimes eosinophils in association with fibrinoid necrosis, nuclear debris, and extravasation of erythrocytes. This lesion is frequently found in the superficial postcapillary venules in the skin.

The predominant renal lesion is found in the glomerulus and is characterized by focal and or segmental mesangial injury or a mesangial proliferative glomerulonephritis with varying degrees of hypercellularity. The lesions are similar to those found in IgA nephropathy. The development of epithelial cell crescents represents an extension of the severity of the disease and may result in glomerular tuft necrosis and segmental capillary thrombosis. The International Study of Kidney Disease in Children classification of HSPN describes a broad correlation between the clinical presentation and the renal histopathology (*Table 296.1*). Those with hematuria and insignificant proteinuria generally have less severe histological changes that are likely to resolve spontaneously whereas those with heavy proteinuria and a refractory nephritic or nephrotic syndrome will have more severe changes unlikely to resolve.

Immunofluorescence

In contrast to the more focal and segmental changes observed on light microscopy, the striking feature on immunofluorescent staining of the renal biopsy is the global glomerular involvement with mesangial deposition of IgA.

Table 296.1
Histological classification of Henoch Schönlein Purpura Nephritis (HSPN)

1. Minimal change
2. Mesangial cell proliferation
3. Focal/diffuse proliferation or sclerosis with >50% crescents
4. Focal/diffuse mesangial proliferation or sclerosis with 50–75% crescents
5. Focal/diffuse mesangial proliferation or sclerosis with >75% crescents
6. Membranoproliferative type lesion

Electron Microscopy

Electron-dense IgA containing deposits are predominantly mesangial but are also seen in subendothelial areas. The latter are frequently associated with glomerular basement membrane disruption and these changes correlate well with the severe glomerular injury seen on light microscopy and associated with heavy proteinuria.

Treatment

For decades, prediction of outcome of HSPN has been the focus of attention and the challenge has been to find good prognostic criteria in order to make educated decisions concerning treatment. Can HSPN in patients with HSP be prevented is a tantalizing question and has been the subject of much study. Similarly in patients with HSPN, prevention of progression to end-stage renal disease remains the principal objective when considering a therapeutic intervention.

Prevention of HSPN

Retrospective and prospective reviews of patients with HSP with no signs of nephropathy at the time of presentation and treated with corticosteroid therapy, usually oral prednisone or intravenous methylprednisolone have been reviewed. Although some patients with unpleasant symptoms may have benefited from early treatment, there is little evidence to support the hypothesis that prophylaxis with prednisone treatment for 2–4 weeks can prevent renal involvement.

Immunosuppression

The large majority of children with HSP are mild and are associated with a good prognosis. Immunosuppressive therapy is therefore not indicated and patients should be managed symptomatically. There are few prospective data describing the treatment of renal disease associated with HSP. Dudley et al. reported data from a prospective double-blind placebo-controlled trial of 353 children who presented with HSP and were randomized to treatment with prednisolone (2 mg/kg for 7 days followed by 1 mg/kg for 7 days) compared to placebo. At 1 year of follow-up, there was no difference in the incidence of proteinuria between the two groups. This study provides compelling evidence of absence of a beneficial effect of early treatment with prednisolone in the development of HSPN.

It is very difficult to assess any beneficial effect of multiple drug therapy prescribed to treat severe HSPN usually associated with a rapidly progressive glomerulonephritis. Most studies describing the combination of corticosteroids plus cyclophosphamide or cyclosporine A or azathioprine or mycophenolate mofetil are all hampered by limitations. The majority of studies contain very small numbers of patients and contain patients with varying severity of disease. Similarly, there are insufficient data to support treatment with intravenous immunoglobulin, angiotensin-converting enzyme inhibitors, and tonsillectomy.

Plasma Exchange

The use of early plasma exchange either alone or in combination with immunosuppressive therapy cannot be recommended in view of the paucity of available data.

General Management

As in the treatment of any patient with an acute nephritic syndrome, careful attention must be paid to the treatment of hypertension with salt and water restriction in combination with a loop diuretic and if the blood pressure does not reduce specific antihypertensive therapy may be required. A nephrotic syndrome may require similar fluid restriction and diuretic therapy with careful attention to avoid hypovolemia.

Long-Term Outcome

The overwhelming majority of the long-term morbidity in HSP is associated with a nephropathy. The risk of developing acute or chronic renal impairment is greatest in those children who have a nephritic/nephrotic clinical presentation and in those who have evidence of a crescentic glomerulonephritis on renal biopsy. The incidence of long-term chronic renal disease is subject to center bias in that tertiary renal centers report up to 20% versus 2–5% from unselected general pediatric centers.

All patients with significant renal impairment at presentation require follow-up for life. It is recognized that in women who as children had HSPN there is a risk of developing hypertension in pregnancy. Children with no evidence of a nephropathy at presentation should be reviewed for at least 6 months following resolution of the rash in order to ensure no late presentation of a nephropathy, i.e., proteinuria or hypertension. Those children who remain with persistent microscopic hematuria or nonnephrotic range proteinuria must be followed up until the urinalysis becomes clear.

Transplantation

In the very small number of children who progress to end-stage renal disease, renal transplantation may become necessary. There is no contraindication to either deceased donor or living related transplantation. There is a risk of recurrence of HSPN in the engrafted kidney. However, the observed mesangial cell IgA deposits can occur in the transplanted kidney where the original cause of renal failure was neither HSPN nor IgA nephropathy.

297 Hemolytic Uremic Syndrome

Sandra L. Watkins

Definition

Hemolytic uremic syndrome (HUS) was first described by Conrad von Gasser in 1955. Today HUS is a frequent cause of acute renal failure in children, most commonly preceded by a diarrheal illness, and termed Typical or D+ HUS. The classic triad is thrombocytopenia, nonimmune hemolytic anemia, and renal failure. Although other organs such as the brain, heart, gut, and pancreas can be involved, the kidney is the principal site of major damage. D+ HUS is the most common form of HUS, while atypical HUS (D-HUS) is much rarer and is beyond the scope of this review.

Etiology

D+ HUS generally occurs following gastrointestinal infection with Shiga toxin (Stx)-producing *Escherichia coli* (STEC), organisms first incriminated by Karmali et al. as an etiological factor in the development of HUS. The diarrheal prodrome is caused by ingestion of foods contaminated with an STEC, most commonly *E. coli* 0157:H7. Other less common serotypes have also been described. Undercooked ground beef is often the contaminated food, although other sources, such as unpasteurized apple cider or milk, salad greens, and water, have also been identified as the source of infection.

Epidemiology

The incidence of D+ HUS in North America is one to three new cases per 100,000 population per year. However, the incidence appears to be greater in northern climes and in rural areas. In 1992, a massive outbreak of *E. coli* O157:H7 infections caused by consuming poorly cooked ground beef at a fast-food restaurant chain in the western United States brought public awareness to this entity. However most cases are endemic, sporadic infections. Most D+ HUS occur in the summer and fall, with rural populations more often involved than urban.

Pathogenesis

The gastroenteric infections preceding D+ HUS are almost never bacteremic but systemic complications arise from circulating Stx, with bloody diarrhea caused by mesenteric vascular ischemia initiated by circulating Stx. Interactions between Stx and circulating leukocytes and platelets may also play a role in pathogenesis. Stxs bind to the glycosphingolipid globotriaosylceramide (GB_3), which can be demonstrated on renal glomerular endothelial, mesangial, and tubular epithelial cells. Profound hematological abnormalities during HUS and histopathologic analyses demonstrate the thrombotic basis of HUS. The plasma of patients with HUS demonstrates elevated levels of plasminogen activator inhibitor (PAI)-1 activity, elevated levels of circulating D-dimers, and generation of thrombin.

Pathology

The classic renal lesion of D+ HUS is a glomerular thrombotic microangiopathy with capillary and arteriolar wall thickening.

Clinical Manifestations

The interval between ingesting contaminated food and the first day of diarrhea ranges between 2 and 12 days. Typically, *E. coli* O157:H7 infections cause 1–3 days of nonbloody diarrhea after which the diarrhea becomes bloody. It is the bloody diarrhea, which occurs in about 90% of cases, that usually prompts patients or their families to seek medical advice. Fever is usually absent and fecal leukocytes are rarely detected. The colon can be quite severely affected with edema and thickening causing severe cramping, abdominal pain, and rectal prolapse. Diarrhea resolves with no sequelae in 85% of infected patients, but in 15%, as the diarrhea resolves the hematologic abnormalities, heralded by thrombocytopenia, becomes manifest closely followed by renal involvement. HUS findings occur between days 5 and 13 of illness with

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_297,

the median time of onset approximately 1 week after the onset of diarrhea.

Some infected children develop "partial" or "incomplete" HUS with thrombocytopenia, with or without anemia, while maintaining a normal serum creatinine, leading to complete resolution in a few days. However, once renal failure has developed resolution can be delayed by several days to months.

Diagnosis

The diagnosis of D+ HUS is made by demonstrating hemolytic anemia with hematocrit less than 30% and evidence of erythrocyte destruction on peripheral blood smear; platelet count less than 150,000 platelets per mm^3; and serum creatinine greater than the upper limit for age. Fibrinogen is normal or elevated, and the prothrombin time is only modestly prolonged, unlike classic disseminated intravascular coagulation. Hematuria or proteinuria may also be present.

Differential Diagnosis

A clinical microangiopathic picture similar to D+ HUS without the preceding diarrhea can be seen in systemic vasculitis, malignant hypertension, pregnancy, idiopathic thrombotic thrombocytopenia, various forms of D-HUS, including pneumococcal pneumonia and familial HUS, and drug-induced HUS associated with cyclosporine A, mitomycin-C, and oral contraceptives.

Management of D+ HUS

Fluid management is often difficult in early HUS. In the face of prolific diarrhea, vomiting, and poor intake, it is important to maintain intravascular volume to support renal perfusion. However, as azotemia develops one must avoid fluid overload. Accurate assessment of intravascular volume is difficult as patients are often hypoalbuminemic due to the diarrhea and develop vascular leakage due to endothelial damage, leading to edema despite being intravascularly depleted. Thus one must carefully determine daily weights and fluid balance. As oligoanuria develops fluids must be restricted at the first indication of cardiopulmonary overload. Diuretics should be avoided. Their use should be restricted to severe central volume overload in a non-oliguric patient, but dialysis is likely to be more effective. Vasodilators are useful for the treatment of hypertension. Angiotensin-converting enzyme inhibitors should be avoided because of concern that they might exacerbate kidney injury by diminishing renal perfusion.

Nephrotoxic medications should be avoided and the dosages of all medications that are renally excreted should be adjusted accordingly. Antibiotics should not be given to patients with STEC infections as antibiotic use has been associated with an increased risk of developing HUS. Similarly, antimotility agents should be avoided and narcotics should be used with caution, because there may be an increased risk of HUS or neurological complications. Nonrenal complications of HUS should be anticipated and treated appropriately. Neurological complications are the most worrisome and can include irritability, lethargy, confusion, stroke (thrombotic or hemorrhagic), seizures, and coma, with severe complications occurring in about 10% of patients. Cardiac dysfunction and congestive heart failure can develop. The most common pulmonary consequence is fluid overload and pleural effusions, but adult respiratory distress syndrome can also occur. Intestinal complications during acute HUS include rectal prolapse, colon perforation, and necrosis. Acidosis that does not correct easily with dialysis suggests ischemic or necrotic bowel. Clinically significant pancreatitis and glucose intolerance can occur during HUS, but mildly elevated amylase and lipase are generally asymptomatic. Oligoanuric patients should have potassium and phosphate restriction. Sodium restriction may be necessary to reduce edema and hypertension. With initiation of dialysis diets can be liberalized.

Eighty percent of HUS patients develop severe anemia, some without renal failure. The usual indications for erythrocyte transfusion should be followed with vigilance for rapid volume expansion causing hypertension or volume overload. Blood products should be volume- and leuko-reduced and administered on dialysis in the oliguric patient. Platelet transfusions should be avoided unless there is clinically significant hemorrhage or invasive procedures are planned because platelets could conceivably exacerbate thrombosis. Hemolysis and anemia can be the last abnormality to correct as HUS resolves, often requiring late transfusions. Iron is generally not needed as iron from hemolyzed cells is available for erythropoiesis. Erythropoietin may be useful in some cases.

Indications for dialysis in HUS are similar to those in other forms of acute renal failure and include hyperkalemia, uremia, persistent acidosis, hypertension, volume overload leading to respiratory compromise, and oligoanuria when limiting nutritional support and blood product administration. While hemodialysis (HD), peritoneal dialysis (PD), and continuous venovenous

hemodialfiltration (CVVHD) are all effective, cardiac instability may preclude HD and severe intestinal involvement may restrict the use of PD. CVVHD generally offers the most effective clearances and volume control while allowing parenteral nutrition and transfusions.

Multiple therapies, including corticosteroids, heparin, aspirin, dypyridamole, streptokinase, Synsorb Pk, plasmapheresis, and plasma infusions, have been unsuccessful in HUS and are not generally recommended, although anecdotal evidence supports the use of plasma infusions and/or pheresis in severe neurological complications.

Prognosis

Oligoanuria, volume depletion, severe leukocytosis, and Hct <23% at presentation predict morbidity and mortality in the acute phase. Five to ten percent of patients with HUS die in the acute phase, but most survivors appear to demonstrate full recovery from the acute episode. However, recent long-term follow-up studies suggest a high incidence of sequelae, perhaps up to 50%. The most concerning sequelae are related to renal dysfunction and include hematuria, proteinuria, chronic renal failure, including ESRD, and hypertension. Rarely, insulin-dependent diabetes mellitus can persist or develop as a late sequela. In cases with severe neurologic complications, permanent deficits can occur. Clinicians should be alert for late gastrointestinal complications including stricture and cholelithiasis. The severity of the initial illness and the need for and length of dialysis are risk factors for long-term renal sequelae.

Prevention

D+ HUS can largely be prevented by preventing infection with STEC bacteria, through thorough cooking of ground beef, washing fruits and vegetables, and avoiding unpasteurized liquids. Upon occurrence of STEC colitis, avoidance of antimotility agents and antibiotics, and early intravascular volume support may prevent or reduce the severity of HUS.

298 Lupus Nephritis

Jochen H. H. Ehrich · Lars Pape · Doris Franke

Definition/Classification

Systemic lupus erythematosus (SLE) is a chronic life-threatening disease with autoantibody-induced organ damage. The long-term prognosis depends mainly upon kidney involvement, which is observed in 50–90% of children. The gravity of lupus nephritis (LN) depends as much on the clinical progress (i.e., bad prognosis in acute kidney failure with rapidly escalating loss of function) as on the histological changes (i.e., poor prognosis in class IV LN). In the long term, the avoidance of renal replacement therapy is paramount in cases with the development of chronic kidney insufficiency. LN is the heterogeneous renal manifestation of SLE and is characterized by a high variability of clinical and histological presentations with an unpredictable course of renal disorders and extrarenal comorbidity.

Etiology

The etiology of SLE is unclear. UV light, viral infections, and drugs may trigger the initial attack and relapses of SLE. The causes for different organ manifestations of SLE are unclear. Almost 90% of all pediatric patients with SLE develop renal involvement.

Epidemiology

There are considerable regional differences in the epidemiology of SLE, with the lowest incidence rates observed in Caucasian populations. More severe courses of SLE and LN were reported in the African and Afro-American population. One third of patients with SLE develop the first symptoms during childhood. The incidence of SLE in children under 19 years of age was in the range of 0.6/100,000 children and year. There has been a trend toward an increased incidence and prevalence of SLE for Caucasians in the USA, while the incidence has been stable in Sweden. The female to male ratio was 4.5:1.

Pathogenesis

Many pathogenetic pathways have been implicated in SLE. The racial and a familial component to SLE susceptibility were suggested by data demonstrating familial clusters of SLE, concordance among twins, and a fourfold increased risk for SLE in first-degree relatives of women with SLE. More than 25 genes are now known to contribute to the mechanisms that predispose individuals to lupus reasoned that functional inherited genetic variation in pathways deranged in SLE may alter susceptibility or be associated with severity of disease.

The following mechanisms, cells, and proteins were linked to SLE: B cells, altered antibodies, immune complexes (IC), T cells, dendritic cells, apoptosis, cytokines, hormones, and complement components. However, their SLE-specific interaction is unclear, and there is currently no spectrum of immunological markers that may predict the clinical or histopathological course of SLE. For many years circulating IC or in situ IC were regarded as the main pathogenetic factors of LN. In fact, especially LN has been regarded as the prototype for IC-mediated glomerular disease. It was argued that the morphologic spectrum of glomerular pathology represented an entity that depended mainly on the severity of IC-induced damage. Hence, the broad clinical spectrum of LN disease ranging from isolated hematuria and proteinuria to nephrotic syndrome (NoS), nephritic syndrome (NiS), and finally chronic renal insufficiency has been interpreted as being the result of the same IC-mediated process. Furthermore, focal segmental LN has been interpreted as being the localized result of the same IC-mediated process than the more extensive lesions in diffuse proliferative LN. The pathogenetic explanation of the IC-induced variability of renal involvement in SLE must be questioned. It is unclear if all deposited IC are nephritogenic in LN and whether they are "Goodies or Baddies." There may be cases where the mesangial area is full of IC, and the inflammatory reactions may be scarce.

Controversial results were reported on the role of anti-nucleosome, high-avidity anti-dsDNA antibodies, and anti-alpha-actinin antibodies in the pathogenesis of LN. The role of B cells in SLE has historically focused on their

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_298,

autoantibody production; however, Stohl et al. suggested that B cells have multiple autoantibody-independent roles in SLE as well. B cells can efficiently present antigens and activate T cells. They can augment T cell activation through co-stimulatory interactions, and they can produce numerous cytokines that affect inflammation, lymphogenesis, and immune regulation. Not surprisingly, B cells have become attractive therapeutic targets in SLE. In summary, LN is not a disease entity in terms of pathogenesis and clinical picture, but instead is a group of lesions of unknown pathophysiological mechanisms that are treated with immunosuppressive drugs of which the mechanisms of renal and systemic interactions are poorly understood.

Pathology

All children with SLE and renal involvement such as proteinuria and/or hematuria should undergo a renal biopsy after associated coagulation disorders were excluded or treated. Triple diagnosis using light, immune, and electron microscopy should be performed to identify the histopathological type of LN-associated glomerulopathies as well as associated vascular and tubulointerstitial involvement. The role of renal biopsy in the evaluation of LN in childhood-onset SLE remains controversial. Historically, the principal criteria for the staging of lupus nephritis are glomerular abnormalities. Tubular dysfunction and pathology was mostly not routinely assessed in LN patients, despite the fact that SLE may be associated with a variety of tubular defects. There are children with SLE in whom LN is not suspected due to the absence of hematuria, glomerular proteinuria, hypertension, and decrease in GFR but who may have tubulointerstitial nephritis (TIN).

Based on the 1982 WHO classification, the revised classification of 2004 proposed that class I and II LN be used for purely mesangial involvement (class I = mesangial immune deposits without mesangial hypercellularity; class II = mesangial immune deposits with mesangial hypercellularity); class III for focal glomerulonephritis (involving $<$50% of total number of glomeruli) with subdivisions for active and sclerotic lesions; class IV for diffuse glomerulonephritis (involving $\geq$50% of total number of glomeruli) either with segmental (class IV-S) or global (class IV-G) involvement, and also with subdivisions for active and sclerotic lesions; class V for membranous LN; and class VI for advanced sclerosing lesions (*Table 298.2*). Tubulointerstitial inflammation and fibrosis was usually found in patients with class III, IV, and VI LN.

Renal biopsies should be examined by electron microscopy to identify glomerular podocytopathy with diffuse epithelial cell process effacement in the absence of peripheral glomerular immune deposits. A "full house" immunofluorescence pattern with the presence of IgA, IgG, IgM, C1q, C3, and tubular reticular structures by electron microscopy and mesangial deposits in an otherwise typical membranous nephropathy may indicate LN in seronegative SLE patients.

SLE patients may rarely have isolated tubulointerstitial nephritis. The most common intrarenal vascular lesions were nonspecific sclerotic changes. The other common vascular lesions were immunoglobulin microvascular casts (IMCs). IMCs ("lupus vasculopathy") were characterized by the presence of immunoglobulin deposition within the glomerular capillaries and small arterioles. Vasculitis and thrombotic microangiopathy were rare lesions.

The clinicopathological correlation demonstrated a significant relationship between histopathology and clinical course in LN; however, the biopsy findings did not uniformly correlate with the clinical features. The predominant histological type was class IV LN in patients with NiS. Active and chronic lesions were more likely to occur in patients of class III/IV LN; these patients were also more likely to have evidence of clinical renal disease than patients in class II. There was a significant association between NoS and class V LN. The status prediction of LN patients based on clinical information alone was significantly enhanced by information obtained from renal biopsy.

The classes of glomerular pathology may change during follow-up. It is unclear to what extent these changes are due to immune-modulating effects of treatment or reactivation of the disease. Repeat biopsies are indicated especially in patients with class II LN if renal function is deteriorating. The role of protocol biopsies in the management of patients with LN is unclear because neither the time point of renal biopsy nor their superiority have been identified in controlled studies.

Clinical Manifestations

The initial clinical manifestation of LN is characterized mostly by glomerular dysfunction ranging from isolated glomerular proteinuria and hematuria (in ca 20% of patients) to nephritic syndrome (in ca 40%) or nephrotic syndrome (in ca 40–50%) and chronic renal failure (CRF $<$ 10%) (*Table 298.1*). SLE patients rarely develop nonoliguric renal failure and tubular proteinuria as a consequence of isolated tubulointerstitial nephritis (TIN). Approximately one third of children with LN suffer from arterial hypertension at onset of the disease.

One third of lupus patients may develop the antiphospholipid syndrome (APS) nephropathy that is

Table 298.1
Clinical classification of lupus nephritides

1. Isolated glomerular hematuria
2. Isolated proteinuria
3. Combined hematuria/proteinuria
4. Nephritic syndrome (NiS) with hematuria, proteinuria >500 mg/day, arterial hypertension and with or without a decrease in glomerular filtration rate (GFR)
5. Nephrotic syndrome (NoS) with a proteinuria >1.66 g/m^2/day, low serum albumin <25 g/L, edema and hypercholesterolemia, with or without a decrease in glomerular filtration rate
6. Acute kidney failure with a reversible decrease of GFR <60 mL/min/1.73 m^2
7. Chronic kidney failure with an irreversible decrease of GFR <60 mL/min/1.73 m^2
8. Antiphospholipid antibody syndrome nephropathy
9. Hemolytic-uremic syndrome (HUS)

characterized by arterial hypertension, proteinuria, hematuria, and renal insufficiency. Renal artery occlusion is reported in patients with SLE and antiphospholipid antibodies. Thrombosis of the inferior vena cava and the renal veins are also described in SLE with APS.

Thrombotic thrombocytopenic purpura (TTP) is observed in patients with SLE. TTP may be difficult to identify because of the overlapping manifestations with SLE. Hemolytic anemia, thrombocytopenia, renal impairment, fever, and neurological abnormalities are characteristic of each disease process. The role of ADAMTS 13 activity in SLE-induced TTP remains to be clarified. The association of a hemolytic-uremic syndrome (HUS) with SLE is occasionally reported.

Laboratory Diagnosis

The erythrocyte sedimentation rate is usually increased in children with SLE indicating disease activity. By contrast, CRP is mostly normal. The complement system is consisting of three pathways and more than 30 proteins play a major role in the pathogenesis of SLE. On the one hand, the complement system appears to have protective features in that hereditary homozygous deficiencies of classic pathway components are associated with an increased risk for SLE. On the other hand, immune complex–mediated activation of complement may be responsible for pathological features of LN.

Immunological tests should look for hypocomplementemia (low C3 and low C4). C3 complement usually normalizes after remission; however, C4 mostly remains decreased. Double-strand DNA autoantibodies are usually elevated and normalized when LN comes into remission. All patients should be examined for a rise of antiphospholipid antibodies. Severity of LN should be clarified by estimating glomerular filtration rate (GFR), e.g., by cystatin C-based equations. Screening for renal involvement in patients with SLE is mandatory; however, the use of urinary dipsticks to detect proteinuria is inadequate and all lupus patients should be tested quantitatively for albumin excretion. Glomerular and tubular proteinuria can be differentiated by measuring urinary albumin and α-1-microglobulin. Glomerular hematuria can be distinguished from post-renal hematuria by microscopy. The renal function should be measured at regular intervals (e.g., every 3 months during the first 3 years) testing for proteinuria, hematuria, and GFR. B-cell-attracting chemokine CXCL13 was found to be a marker of disease activity and renal involvement in SLE. Urinary TNF-like weak inducer of apoptosis (TWEAK) has been implicated as a candidate clinical biomarker for LN. It is unclear which clinical biomarkers will turn out to be the most suitable ones for measuring disease activity before the appearance of renal dysfunction.

Differential Diagnosis

Other types of hypocomplementemic glomerulonephritides, other vasculitides and bacterial sepsis associated renal failure should be differentiated from LN. Inborn complement deficiencies (e.g., C1q deficiency, factor H disorders) may be associated with NiS, NoS, or atypical HUS.

Controversy and Consensus

The treatment of LN in children and adolescents is up to now, evidence-based, barely feasible. Contrary to adult medicine, there is no data from prospective controlled treatment studies in pediatric patients with LN. It is, e.g., unclear if the presently propagated oral treatment of mycophenolate mofetil (MMF) to induce remission of a severe LN in adults is also equally effective as intravenous Cyclophosphamide (IV-CYC) treatment in adolescents in view of the often inadequate medication compliance rate within this age group. Many of the drugs used in the treatment of LN and mentioned in this article are not licensed for children and adolescents in indications of SLE (off-label use). Due to the low case numbers of children and adolescents, controlled conclusive studies were just not possible in most countries. On the other

hand, the attending pediatrician is responsible for medical regularity and possible side effects. Off-label medication should therefore only be prescribed in light of currently applicable guidelines, recommendations, or from renowned scientific literature. The following treatment recommendations in LN in children and adolescents are mostly opinion-based.

The stratification of treatment modalities of LN was based on severity of LN pathology (mild, moderate, or severe glomerular involvement). However, pathological classification may not detect pathogenetic or clinical differences among patients with severe LN. Therefore, it is proposed that the choice of immunosuppressive agents for the treatment of the heterogeneous group of types of LN should include the main three clinical pictures such as NoS, NiS, or none of these two. Treatment of LN was controversially discussed in the literature and there was no universally accepted treatment protocol in 2009 for all classes of LN. The target cells for treatment and the precise mechanisms of anti-glomerulonephritic action of drug-induced immunosuppression in LN were unclear. Theoretically, all treatment modalities should aim at reducing the amount of deposited glomerular immune complexes. Podocytes have been identified as the target cell for immunosuppressive therapy of NoS of idiopathic focal segmental glomerulosclerosis suggesting that treatment of NoS may benefit especially from cyclosporine A (CSA) and predniso(lo)ne (PRED). In analogy, mesangial cells, endothelial cells as well as invading mononuclear cells and granulocytes may play a more important role in the development of NiS leading to a decrease of GFR. Thus, SLE patients having steroid-resistant NoS may benefit from other immunosuppressive agents than patients with NiS, irrespectively of the underlying histological type of glomerulonephritis. Unfortunately, there are no controlled studies available that attributed the patients to specific modes of therapy after combining both the clinical and histopathological appearance of LN. It may be argued that there is some correlation between the type of clinical involvement and histological alteration; however, this correlation is not a close one. NoS, for instance, is the major clinical manifestation of class V LN; however, almost all other histological types of LN may also be associated with a NoS, e.g., class IV diffuse LN may be characterized by a severe NoS and a reduced GFR. In summary, the purpose of future studies should be to further investigate the evidence of disparate mechanisms of glomerular injury in the inflammatory glomerular lesions and pathophysiologies of renal dysfunction.

There is a consensus that – for classification of LN – baseline data of SLE should be recorded including patients' demographics, renal function, and extrarenal comorbidity such as antiphospholipid syndrome and validated activity indices, as well as current medication. Renal biopsies using light, immunofluorescence, and electron microscopy should show 20 glomeruli on histology to allow a safe histopathological classification according to *Table 298.2*.

The categorization of different classes of LN has helped considerably to decide upon treatment options. Most guidelines recommend the use of combination therapy with intravenous PRED and other immunosuppressants to induce remission in proliferative LN class III and IV. Class I and II LN may not require the use of immunosuppressants in addition to oral PRED.

Most experts agreed that *induction therapy* should be given for at least 3–6 months. Expanded induction treatment may be necessary in those patients who have not yet entered a complete remission of LN. Serological measurements were not regarded as key markers of LN activity. No single renal marker has been identified for measuring response to treatment. Instead, the combination of a GFR >90 mL/min/1.73 m^2, with proteinuria <0.2 mg/mg creatinine and absence of hematuria defines a complete remission. Repeat renal biopsies are not required to define a complete remission. In fact, there may be a discrepancy between biopsy results and clinical markers, the meaning of which is unclear. Some nephrologists preferred the term "response" over "remission" in assessing the effects of LN treatment as some patients showed major benefit from treatment without reaching a complete remission. A more useful term is probably "partial response," however, this term was only well defined for NoS (partial response = proteinuria between 166 mg/1.73 m^2/day and 2 g/1.73 m^2/day, and serum albumin >25 g/L) and not for NiS. A sustained remission was defined as a complete remission for more than 6 months. A relapse of LN was defined as a reappearance of clinical symptoms of SLE and a new episode of renal involvement in those children reaching a complete remission during induction therapy or after relapse therapy. Some nephrologists preferred the term "flare" over relapse because patients with a partial remission may develop a new episode of disease activity requiring a new course of therapy or an intensified maintenance therapy. Flares of SLE may not be accompanied by flares of LN; however, recurrent episodes of LN may also be accompanied by a change of the histological class of LN. Likewise, a patient with an initial NoS of LN may reach a complete remission and may later on develop a NiS while on maintenance therapy or after stopping all treatment. This "nephritic flare" should not be regarded as a relapse of the NoS but as a new manifestation of LN with

Histopathological classification of lupus nephritides (International Society of Nephrology/Renal Pathology Society 2003, according to Weening et al.)

Classification of lupus nephritis	
Class I	Minimal mesangial lupus nephritis
	Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence
Class II	Mesangial proliferative lupus nephritis
	Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits
	May be a few isolated subepithelial or subendothelial deposits visible by immunofluorescence or electron microscopy, but not by light microscopy
Class III	Focal lupus nephritis[a]
	Active or inactive focal, segmental, or global endo- or extracapillary glomerulonephritis involving $<$50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations
Class III (A)	Active lesions: focal proliferative lupus nephritis
Class III (A/C)	Active and chronic lesions: focal proliferative and sclerosing lupus nephritis
Class III (C)	Chronic inactive lesions with glomerular scars: focal sclerosing lupus nephritis
Class IV	Diffuse lupus nephritis[b]
	Active or inactive diffuse, segmental, or global endo- or extracapillary glomerulonephritis involving $\geq$50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) lupus nephritis when $\geq$50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) lupus nephritis when $\geq$50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation
Class IV-S (A)	Active lesions: diffuse segmental proliferative lupus nephritis
Class IV-G (A)	Active lesions: diffuse global proliferative lupus nephritis
Class IV-S (A/C)	Active and chronic lesions: diffuse segmental proliferative and sclerosing lupus nephritis
	Active and chronic lesions: diffuse global proliferative and sclerosing lupus nephritis
Class IV-S (C)	Chronic inactive lesions with scars: diffuse segmental sclerosing lupus nephritis
Class IV-G (C)	Chronic inactive lesions with scars: diffuse global sclerosing lupus nephritis
Class V	Membranous lupus nephritis
	Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations
	Class V lupus nephritis may occur in combination with class III or IV in which case both will be diagnosed
	Class V lupus nephritis show advanced sclerosis
Class VI	Advanced sclerosis lupus nephritis
	$\geq$90% of glomeruli globally sclerosed without residual activity

Indicate and grade (mild, moderate, severe) tubular atrophy, interstitial inflammation and fibrosis, severity of arteriosclerosis, or other vascular lesions
[a]Indicate the proportion of glomeruli with active and with sclerotic lesions
[b]Indicate the proportion of glomeruli with fibrinoid necrosis and/or cellular crescents

a possible change of renal histology. Thus, the *relapse therapy* may have to differ from the initial induction therapy. Several types of "flares" can be differentiated: (1) isolated proteinuria, (2) combined hematuria and proteinuria, (3) NoS, and (4) NiS. Flares of LN may rarely manifest as a HUS.

Maintenance is the period of less intensive immunosuppressive therapy following induction therapy. *Maintenance therapy* of LN is poorly defined and randomized controlled studies are lacking. It can be given to patients in remission to prevent relapses and it can be applied to patients in partial remission or with stable baseline

measurements to prevent progression of the disease. Maintenance therapy with long-term oral PRED should be avoided to prevent steroidal toxicity. Low doses of MMF, Azathioprine (AZA), or CSA should be given to sustain remission. The duration of maintenance therapy is unclear and it may last for many years in patients with multiple relapses of LN. Symptomatic maintenance therapy includes treatment of arterial hypertension and hyperlipidemia.

Rescue therapies were poorly defined in children with LN unresponsive to known types of immunosuppressive therapies. Some rescue therapies included "new" drugs that had not yet been tested before or they consisted in new combinations of known drugs thus increasing the "immunological attack" during treatment. As rescue therapies such as Rituximab (RIT) have a considerable risk of side effects, they should be restricted to specialized pediatric nephrology centers.

Treatment recommendations have taken into account that therapeutic decisions are substantially influenced by the costs of drug treatment. There may be no "right and wrong" when deciding upon a treatment regimen because "availability and nonavailability" will decide upon "how and when" to treat. Several countries may lack the financial resources for offering expensive drugs such MMF, CSA, and RIT to all patients. As intravenous prednisolone (IV-PRED), IV-CYC, and AZA are available in most countries, these drugs may be the most frequently used in LN worldwide.

There is a risk of doctors' noncompliance to standardized treatment protocols, and in addition patients' nonadherence to long-term drug treatment severely influences outcome of LN. Therefore, a team of caregivers should be responsible for psychosocial care and for a guided transfer from pediatric into adult care.

The treatment of LN is typified by popular misconceptions: that there is a standard of care, that treatment has well-defined aims, and that the optimum length of treatment is established. In conclusion, level 1a evidence was not achieved for any therapy of LN. In reality, uncertainties still exist and the evidence base remains weak. Most studies on the outcome of LN are difficult to interpret because the choice of combination treatment, the dosage of different immunosuppressive agents, and the duration of induction and maintenance therapy were poorly standardized. Moreover, the response to treatment was analyzed according to different criteria such as normalization of GFR, and/or reduction of proteinuria, etc.; however, response to treatment thus is not the same as disease remission. Proteinuria can take a long time to reach baseline levels, and normalization of urine is not the same as loss of histological disease activity.

Several standardized treatment protocols were tested in controlled and uncontrolled trials on LN; however, very few have gained an international acceptance. It is also unclear if children with LN should be treated by individualized treatment modalities because the individual needs of lupus patients are ill defined. In fact, many pediatric nephrologists will have to treat less than 50 children with LN during their professional life span, which will not lead to a "proper learning curve." Ideally, all pediatric nephrologists should include their patients in multicenter therapeutic trials to test the best possible treatment and control of disease activity. However, there were no such international trials available in 2009.

Drug Alternatives

Several multicenter, randomized, open-label trials were conducted in adult patients to analyze the therapeutic response to different immunosuppressive regimen. However, most studies were inadequately powered with small number of patients, short-term follow-up, inclusion of heterogeneous mixtures of patients in terms of race and severity. Eligibility criteria included (1) the SLE meeting for classification criteria of the American College of Rheumatology (*Table 298.3*), (2) renal biopsy documenting LN according to the classification of the World Health Organization (*Table 298.2*), and (3) clinical activity as defined by one or more of the following: incident decrease in renal function as defined by GFR, PU, and HU (*Table 298.1*) or serologic abnormality such as anti-DNA antibodies or hypo-complementemia (*Table 298.4*).

Because therapeutic responses may differ depending on the pattern of renal histological features, the patients were stratified according to renal biopsy as having proliferative glomerulonephritis as compared with membranous glomerulonephritis and other types. Permuted blocks of patients of variable size were used within each subgroup. The primary end point was (1) complete remission at different intervals (12–24 weeks), (2) partial remission, (3) maintenance of baseline measurements, or (4) progression of renal dysfunction. The clinical studies were conducted in adults to analyze the efficacy of induction therapy to achieve a complete remission or of maintenance therapy to prevent relapses. Studies on relapse therapy or rescue therapy were rarely systematically performed. The stratification of most studies was based

Table 298.3

Lupus erythematosus disease activity index (SLEDAI)

Wtd score	Descriptor	Definition
8	Seizure	Recent onset. Exclude metabolic, infectious, or drug-related causes
8	Psychosis	Altered ability to function in normal activity due to severe disturbance in the perception of reality. Includes hallucinations; incoherence; marked loose associations; impoverished thought content; marked illogical thinking; bizarre, disorganized, or catatonic behavior. Exclude the presence of uremia and offending drugs
8	Organic brain syndrome	Altered mental function with impaired orientation or impaired memory or syndrome other intellectual function, with rapid onset and fluctuating clinical features. Includes a clouding of consciousness with a reduced capacity to focus and an inability to sustain attention on environment, and at least two of the following: perceptual disturbance, incoherent speech, insomnia or daytime drowsiness, increased or decreased psychomotor activity. Exclude metabolic, infectious, and drug-related causes
8	Visual	Retinal changes from systemic lupus erythematosus: cytoid bodies, retinal hemorrhages, serous exudates or hemorrhages in the choroid, optic neuritis (not due to hypertension, drugs, or infection)
8	Cranial nerve	New onset of a sensory or motor neuropathy involving a cranial nerve
8	Lupus headache	Severe, persistent headache; may be migrainous; unresponsive to narcotics
8	Cerebrovascular accident	New syndrome. Exclude arteriosclerosis
8	Vasculitis	Ulceration, gangrene, tender finger nodules, periungual infarction, splinter hemorrhages. Vasculitis confirmed by biopsy or angiogram
4	Arthritis	More than two joints with pain and signs of inflammation
4	Myositis	Proximal muscle aching or weakness associated with elevated creatine phosphokinase/aldolase levels, electromyographic changes, or a biopsy showing myositis
4	Casts	Heme, granular, or erythrocyte
4	Hematuria	More than five erythrocytes per high-power field. Exclude other causes (stone, infection)
4	Proteinuria	More than 0.5 g of urinary protein excreted per 24 h. New onset or recent increase of $>$0.5 g/24 h
4	Pyuria	More than five leukocytes per high-power field. Exclude infection.
2	New malar rash	New onset or recurrence of an inflammatory type of rash
2	Alopecia	New or recurrent. A patch of abnormal, diffuse hair loss
2	Mucous membranes	New onset or recurrence of oral or nasal ulcerations
2	Pleurisy	Pleuritic chest pain with pleural rub or effusion, or pleural thickening
2	Pericarditis	Pericardial pain with at least one of rub or effusion. Confirmation by electro- or echocardiography
2	Low complement	A decrease in CH50, C3, or C4 level (to less than the lower limit of the laboratory-determined normal range)
2	Increased DNA binding	More than 25% binding by Farr assay (to $>$ the upper limit of the laboratory-determined normal range, e.g., 25%)
2	Fever	More than 38°C after the exclusion of infection
2	Thrombocytopenia	Fewer than 100,000 platelets
2	Leukopenia	Leukocyte count of $<$3,000/mm^3 (not due to drugs)

Adapted from Bombardier (1992)

Table 298.4
Lupus criteria

Clinical Criteria
1. Acute or subacute cutaneous lupus
2. Chronic cutaneous lupus
3. Oral/Nasal ulcers
4. Nonscarring alopecia
5. Inflammatory synovitis with physician-observed swelling of two or more joints or tender joints with morning stiffness
6. Serositis
7. Renal: urine protein/creatinine (or 24-h urine protein) representing at least 500 mg of protein/24 h or red blood cell casts
8. Neurologic: seizures, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, cerebritis (acute confusional state)
9. Hemolytic anemia
10. Leukopenia ($<$4,000/mm^3 at least once) or Lymphopenia ($<$1,000/mm^3 at least once)
11. Thrombocytopenia ($<$100,000/mm^3) at least once
Immunologic Criteria
1. ANA above laboratory reference range
2. Anti-dsDNA above laboratory reference range (except ELISA: twice above laboratory reference range)
3. Anti-Sm
4. Antiphospholipid antibody Lupus anticoagulant False-positive test for syphilis Anticardiolipin – at least twice normal or medium-high titer Anti-b2 glycoprotein 1
5. Low complement Low C3 Low C4 Low CH50
6. Direct Coombs test in absence of hemolytic anemia

on renal histology and interestingly not so much on the clinical presentation of LN, e.g., NiS or NoS. Most studies concentrated on moderate or severe lupus nephritis including gross proteinuria, decrease of GFR, hematuria, and arterial hypertension. Treatment protocols for induction and maintenance therapy included PRED, CYC, MMF, AZA, CSA, RIT, and others. Monotherapeutic trials were seldom, most studies included a combination therapy using more than one immunosuppressive agent.

Predniso(lo)ne

Once the diagnosis of a LN has been established, the child should be admitted to hospital and an immunosuppressive treatment including daily oral PRED should be started with the aim to induce remission. One of the most widely used initial regimen consists of 60 mg/day/m^2 body surface area (BSA) PRED, not exceeding the total daily dose of 80 mg. The dosage of PRED may be referred to BSA or to body weight: 60 mg/day/m^2 BSA will correspond approximately to 2 mg/day/kg body weight. There is no data available to compare the efficacy of PRED with other corticosteroids in LN. PRED is generally given in three divided doses with the highest dose in the morning and the lowest dose in the evening, e.g., 30–20–10 mg in a child with one square meter BSA. There is no data available addressing the efficacy of the time intervals of PRED dosage during daytime, e.g., once or twice instead of three times daily.

Intravenous prednisolone of methylprednisolone therapy (IV-PRED) has been shown to be effective in children with either NoS or NiS in increasing the steroid-induced immune attack if given in addition to oral steroids. However, neither the number of pulses, nor the intervals or dosages have been standardized in pediatric nephrology nor it is clear if IV-PRED has to be adjusted to different causes of glomerulonephritides. Six pulses on alternate days with 300 mg/m^2 PRED is recommended. Oral PRED should be given on the IV-PRED free days. Pulses of IV-PRED should be given to patients with class III–V LN. Continuous steroidal treatment is an essential part of combination therapies using CYC or MMF; however, the duration of high-dose PRED should be limited to 6 weeks because of threatening steroidal side effects. The risk–benefit effect of low-dose continuous PRED – though being part of many protocols – is unclear.

In order to sustain remission and to prevent an early relapse, continuous oral PRED treatment is usually followed by alternate-day PRED (40 mg/48 h/m^2) given in a single morning dose.

It is the aim of corticosteroid therapy to induce a complete and long-lasting remission. There are, however, many patients with LN who will only enter a partial or short-term remission after receiving PRED monotherapy and therefore a combination therapy of PRED with other immunosuppressive drugs is recommended in all types of LN.

Cyclosporine A

Apart from class V LN the positive role of CSA in the induction treatment of the other types of LN has never

been clarified. Several authors reported an effective induction of remission in patients with different histological types of LN using CSA in addition to PRED. It is impossible to calculate the exact remission rate from the pooled data of 63 articles found in Pub Med because some of these were lacking an analysis on the rate of patients with a complete remission. Last but not least, the positive effect of additional immunosuppressive agents given concomitantly to CSA could not always be differentiated from the CSA effect itself. In summary, the pooled data on the articles for "CSA and LN" reveal that CSA had a steroid sparing effect during induction therapy and that it had a proven effect on decreasing proteinuria in patients with LN.

In our center, 11 children with an initial attack of nephrotic LN (class II LN = 4, IV = 4, V = 3 patients) with normal GFR received CSA (150 mg/m^2/day) and continuous PRED (60 mg/m^2/day) as induction therapy. Three patients had been previously unresponsive to oral PRED + CYC pulses given at monthly intervals. Maintenance therapy included a tapering of PRED over 5–8 months to 5 mg/m^2/48 h followed by a switch to alternate-day PRED (10 mg/m^2/48 h), and CSA dosage was given to achieve target trough levels between 80 and 120 ng/mL. All 11 patients entered complete remission of NoS after induction therapy with CSA + PRED. Maintenance therapy with CSA plus alternate-day PRED effectively prevented a relapse in 7/11 children. Four of 11 patients developed 1 or 2 relapses while having CSA trough levels below 60 ng/mL. From our own data and from the literature it is concluded that the combination of CSA + PRED is a safe treatment in patients with NoS and a normal GFR at onset of LN.

The role of CSA in the induction treatment of nephritic LN is unclear. In those patients with LN achieving a partial remission with persistent proteinuria after PRED and CYC or MMF the additional use of CSA may effectively contribute to inducing a complete remission. CSA has also been shown to prevent relapses and flares during maintenance therapy if combined with AZA or PRED.

The role of Tacrolimus in the treatment of LN in children is unclear because of lacking data.

Cyclophosphamide

A decisive advancement in the treatment of LN was brought about by the long-term studies carried out in the early 1990s by the National Institute of Health with an observation period of up to 20 years. These studies showed that CYC led to a better renal survival over a long period (10–20 years) than that achieved with the exclusive use of PRED. Furthermore it could be shown that IV-CYC pulse therapy (7 pulses of 500–1,000 mg/m^2 in monthly intervals) was equivalent to a daily oral CYC dose with regard to preservation of remission and with lower toxicity. Boumpas et al. showed that the continuation of IV-CYC pulse treatment (three-monthly dose) over a period of 3 years led to a better remission rate and found that CYC plus additional monthly IV-PRED pulses produced an improved long-term outcome in patients with proliferative LN if compared to CYC monotherapy.

Altogether in these studies, a remission in approximately 80% of patients was achieved. Regardless of the type of maintenance therapy, approximately one third of the responsive patients showed relapses under continued immunosuppression. End-stage kidney failure insufficiency developed in 10–20% of the patients within 5–10 years.

A major problem of the treatment with IV-CYC and IV-PRED pulses was the high rate of serious side effects (30–50%) such as gonadal and gastrointestinal toxicity, alopecia, bone marrow depression, hemorrhagic cystitis, lymphoproliferative diseases as well as life-threatening infections. CYC-induced gonadal toxicity was observed in cumulative dosages exceeding 250 mg/kg body weight. Because of the high proportion of postpubertal male patients developing a disturbed spermatogenesis, it is advisable to perform a cryo-conservation of sperm before cytotoxic drug treatment of LN patients. A secondary amenorrhea was found in female patients with increasing age, ranging in the order of 13% at the age of 20 years, 50% from the age of 20–30 years, and almost 100% in patients over 30 years of age. There are positive reports on the use of GnRH agonists such as Leuproreline acetate to protect the ovaries.

The Euro-Lupus trial evaluated a reduced dosage of CYC pulses giving a maximum of 500 mg (6 mini-pulses every 2 weeks) compared to the classical NIH protocol using 500 mg/m^2 per month (7 pulses followed by and then one pulse after 3 and 6 months). Thus, the cumulative dosage in a patient of 70 kg and 175 cm was 3 g CYC in the Euro-LN trial and approximately 8 g CYC in the NIH protocol. Both groups of patients received AZA after stopping CYC. A total of 90 patients were included having class III or IV LN and a proteinuria above 500 mg per day. After a mean follow-up of 5 years, the results of both groups were comparable and approximately 80% of patients were in remission after 5 years. However, the rate of side effects was twice as high in the high-dose CYC group if compared with the low-dose CYC group.

Mycophenolate Mofetil

Several controlled studies were performed in adult patients with LN to test the hypothesis that MMF may be more efficient than the previous gold standard using IV-CYC and IV-PRED to induce and sustain remission of LN. Most studies had a short follow-up of less than 12 months, a small number of patients, or no patient with a severe decrease of GFR below 30% of the norm.

The authors Zhu B et al. and Chan TM et al. analyzed 24 patients with class IV LN and MMF/PRED versus oral CYC/PRED followed by AZA/PRED after 6 months. Eighty-one percent of patients in the MMF group achieved complete remission within 12 months compared to 76% of patients in the CYC group. After a mean follow-up of 5 years, there were no statistical differences concerning the remission and relapse rates. However, the number of patients was less than 20 after follow-up of 3 years and the long-term results of the study may have to be interpreted with great care. The rate of side effects was one third of patients in the CYC group compared to 10% in the MMF group. End-stage renal disease developed in 5% of patients of both groups after 5 years.

Hu et al. reported on 46 patients with class IV LN; group 1 received MMF and group 2 IV-CYC pulses in addition to PRED. After a short follow-up of 6 months, proteinuria decreased by 70% in the MMF group and by 48% in the CYC group, and hematuria by 90% versus 65%, respectively. MMF induced a more rapid decrease in dsDNA antibodies in the blood and a more pronounced regression of glomerular immune complex deposits in the control biopsy than CYC.

Ginzler et al. studied 140 adult patients with LN (15% class III, 55% class IV, 20% class V, 10% mixed membrano-proliferative GN) giving MMF to group 1 and monthly IV-CYC to group 2 B in addition to PRED. Complete remission was achieved in 22% of the MMF group and 5.8% in the CYC group within 6 months. A partial remission was found in 30% of patients receiving MMF and in 25% of patients receiving CYC. Side effects such as severe infections and hospitalizations were less frequent in the MMF group; however, the MMF patients had a higher rate of diarrhea. Patients had been submitted to a high dosage of MMF (3 g per day) exceeding dosages of MMF in other studies. The efficacy of CYC was dose dependent.

The ALMS trial studied 370 patients with an initial attack of class III or IV LN for 24 weeks comparing MMF/PRED with IV-CYC/PRED. MMF was not superior to IV-CYC as induction therapy. The incidence of serious adverse events was similar in both groups. Race, ethnicity, and geographical region were shown to affect treatment response; more Black and Hispanic patients responded to MMF than to IV-CYC.

Contreras et al. performed a study on MMF maintenance therapy in LN. After a 6-month induction therapy using IV-CYC in patients with severe LN, MMF maintenance therapy had a lower rate of side effects than three-monthly IV-CYC pulses. Fujinaga et al. reported that four children with severe LN experienced no flares during maintenance therapy with MMF and tapered PRED. Maintenance therapy with MMF is efficacious and safe for the treatment of high-risk patients with proliferative LN. The dose of MMF during maintenance should be reduced if patients receive a co-medication with CSA to avoid MMF toxicity.

Azathioprine

The induction therapy with AZA was inferior to IV-CYC pulses and PRED. During a follow-up of 5.7 years, patients receiving AZA had a fourfold increased risk of developing chronic renal insufficiency with a doubling of serum creatinine and a ninefold increased relapse rate of LN. In conclusion, AZA induction therapy should not be given to patients with severe class IV LN. Maintenance therapy with AZA is efficacious and safe for the treatment of high-risk patients with proliferative LN. AZA should be started after end of induction therapy at a dosage of 1–3 mg/kg/day. Azathioprine is a prodrug of mercaptopurine, a substance that is subsequently metabolized by thiopurine methyltransferase (TPMT). Approximately 6 in 1,000 people have deficiency of TPMT because of genetic mutations. These people are at great risk of developing life-threatening bone marrow toxicity. It is recommended to test LN patients for TPMT activity before starting AZA.

Rituximab

The monoclonal antibody RIT is directed against CD 20 positive cells, and in more than 30 retrospective studies, in small numbers of patients, it was shown to induce a complete remission in more than 50% of patients if used as a combination therapy with PRED and CYC or MMF. The French multicenter retrospective study of childhood-onset SLE reported eight girls with class IV or V LN. Patients received 2–12 intravenous infusions of RIT (350–450 mg/m^2/infusion) with PRED. Six patients also received different standard immunosuppressive agents.

Remission was achieved in six of eight patients. It was concluded that RIT may be an effective rescue or co-therapy. Caution is necessary with respect to minimizing the number of doses and treatments with RIT. The treatment with RIT is an off-label use and parents should be informed about possible side effects and complications, such as life-threatening infections and leukencephalopathy syndrome.

Plasmapheresis and Immunoglobulins

The large differences that exist in the use of plasmapheresis/immunoadsorption in the treatment of LN practiced in different centers/countries seem to be based on the local habits or national character and not so much on scientific findings. Although not proven, plasmapheresis might be beneficial as rescue therapy in patients with acute life-threatening disease, for which high-dose immunosuppressive therapy may not be possible, or as an adjunct procedure for patients not responding to conventional therapy. Clear-cut recommendations regarding type of adsorption column, intensity and duration of treatment, and accompanying immunosuppressive treatment cannot be given.

The role of intravenous immunoglobulin infusions in the rescue therapy of LN is unclear. High sucrose immunoglobulin preparations should be avoided because they may be associated with acute renal failure due to tubular damage.

Recommendations for Induction Therapy of Different Clinical and Pathological Types of Lupus Nephritis

The following four therapeutic protocols are taking into account both the clinical and histopathological heterogeneities of LN:

Protocol 1. Severe nephritic LN including a decrease of GFR ($<$90 mL/min/1.73 m^2), proteinuria above 500 mg/m^2/day, arterial hypertension, and hematuria showing class III or IV LN on renal biopsy.

Protocol 2. Nephrotic LN and normal or mildly reduced GFR (60–90 mL/min/1.73 m^2) with classes II, III, IV, or V on renal biopsy.

Protocol 3. Mild or moderate nephritic class II–IV LN with proteinuria above 500 mg/m^2/day, hematuria, with or without hypertension and normal GFR.

Protocol 4. Other groups of LN.

The rationale of these treatment recommendations is based on the following findings and conclusions:

1. Children with LN should receive a combination therapy of several drugs instead of monotherapy.
2. The initial immunosuppressive attack should be massive. A start with a mild immunosuppression followed by a slowly escalating intensity with successively added drugs should be avoided.
3. PRED has been shown to be an effective component of all combination therapies in LN; IV-PRED is more effective than oral PRED.
4. CYC has been shown to be an effective part of combination therapy; IV-CYC pulses being more efficient than oral CYC, however, high cumulative dosages may lead to persistent side effects.
5. MMF has been shown to be an effective part of combination therapy in adult patients with LN and should be tested in children because of a lower rate of side effects than CYC. Furthermore, MMF is an integrated part of maintenance therapy.
6. CSA is a useful component of combination therapy for children with LN and NoS both during induction and maintenance therapy.
7. AZA is a steroid-sparing agent and its use is limited to maintenance therapy.
8. RIT has been shown to be effective as part of a combination rescue therapy in those patients who have previously been unresponsive to the above-mentioned drugs.
9. The choice of four different protocols for all types of LN may be criticized because less or more than four regimen may be offered to patients to allow either a standard procedure for all or a more individually tailored treatment for some patients. Unfortunately, the published guidelines did not allow to develop a uniform approach.

It is unclear to what extent the lessons from the treatment of adult patients with LN can be transferred from adults to children. Several authors have emphasized that a LN in children and adolescents had a more severe course than in adults. Anecdotal reports indicate that there seems to be a similarly good efficacy of IV-CYC pulses and IV-PRED in children with severe LN; however, the side effects on growth and on pubertal development were poorly studied. The gold standard for the induction treatment of patients with severe class IV LN includes initial IV-PRED pulses, oral PRED, and monthly IV-CYC pulses for at least 3–6 months. Patients with milder LN were treated by several combination therapies using either PRED + AZA, or PRED + MMF, or PRED + CYC, or PRED + CSA as induction therapy.

Many authors give MMF or AZA and low-dose PRED as maintenance therapy. Maintenance therapy is mostly individually tailored according to presence or absence of side effects.

Protocol 1. Severe Lupus Nephritis

Induction therapy of severe nephritic LN should include a combination therapy of IV-PRED pulses, oral PRED, and IV-CYC pulses or alternatively MMF (Fig. 298.1). Maintenance therapy in responders includes MMF and oral PRED. Partial responders should be put on maintenance therapy if renal dysfunction is mild such as proteinuria less than 1 g/day to wait for a late complete response. Nonresponders should undergo rescue therapy. Relapse therapy should be given to relapse patients and to patients with flares using MMF and IV-PRED plus oral PRED. The intensity and duration of relapse therapy with PRED depends on the severity of corticosteroid toxicity.

Induction Therapy

Corticosteroids: 3–6 IV-PRED pulses (300 mg/m^2 on alternate days) plus oral PRED (60 mg/m^2/day, a maximum dose of 80 mg/day) are given for 4 weeks. Patients entering complete remission should be switched from continuous PRED to alternate-day PRED (starting with 40 mg/m^2/day with a tapering of PRED to reach a baseline alternate-day PRED dosage of 5–10 mg/m^2/48 h). Side effects of PRED should be studied at regular intervals and alternate-day PRED may be stopped completely in responsive patients during the first year after initial treatment.

Cyclophosphamide: IV-CYC (500–750 mg/m^2) should be given 1 day after the initial IV-PRED pulse. Anuric children should receive a lower dosage of 250–500 mg/m^2/day. Further IV-CYC pulses are given in monthly intervals. As the response to IV-CYC pulses was shown to be dose dependent, patients with very severe LN may be treated with high doses of CYC reaching 1,000 mg/m^2. The IV-CYC dosage has to be reduced in those patients developing leukopenia below 4,000/μL. Patients receiving IV-CYC pulses should also be treated with a prophylaxis to prevent hemorrhagic cystitis and vomiting. Mesna (400 mg/m^2 iv) can be given prior to and following CYC pulses. Anti-emetics like Ondansetrone (5 mg/m^2 iv) should be given prior to IV-CYC pulses and may be repeated at lower dosages.

Intravenous volume loading with half-isotonic sodium chloride solutions will depend on the GFR and on the hydration of the child. Severe edema should be avoided.

Mycophenolate mofetil may be given as an alternative to IV-CYC: MMF is given orally at a dosage of 1,000–1,200 mg/m^2/day (maximum 2 g/day). MMF dosage should be adjusted according to the results of a Mini-AUC requiring three blood samples: C_0, $C_{0.5}$, and C_2 according to the equation: MPA-AUC (area under the curve) = $10.01 + 3.94 \times C_0 + 3.24 \times C_{0.5} + 1.01 \times C_2$. The MPA-mini-AUC should aim at levels ranging between 60 and 80 mg × h/L. Patients developing leucopenia should receive a lower MMF dosage. Patients developing diarrhea while on MMF may be switched to enteric-coated mycophenolate sodium.

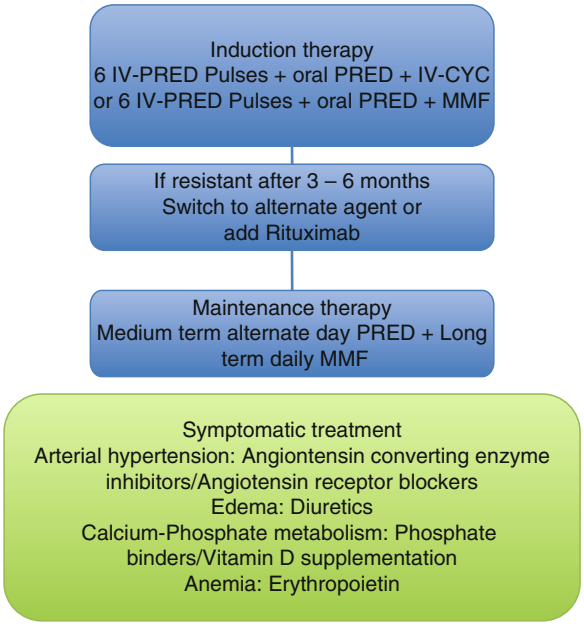

Figure 298.1
Treatment protocol for severe lupus nephritis (LN) with nephritic syndrome (Nis)

Maintenance Therapy

PRED should be switched from continuous application to alternate-day therapy as soon as the patient has entered a remission to prevent steroidal side effects. Tapering of PRED dosage is mostly individually tailored; however, the criteria for this maneuver are poorly standardized. AZA should be started after end of induction therapy at a dosage of 1–3 mg/kg/day. MMF should be started with 1,000/m^2/day and MMF dosage should be adjusted to MPA-mini-AUC levels ranging between 60 and 80 mg × h/L.

Rescue Therapy

There is no universal definition of treatment resistance in LN. If patients with severe LN do not respond to induction therapy after 6 months, or if LN progresses during the initial 6-month treatment period, patients should be treated by a rescue therapy. This triple therapy includes IV-PRED pulses + oral PRED, MMF, and RIT. The treatment protocol for PRED and MMF is similar to the general induction therapy. RIT (375 mg/m^2 BSA) should be given on day 0 and 15. Further injections may be given to relapsing patients. Paracetamol and antihistamines should be given prior to RIT.

Protocol 2. Nephrotic Syndrome with Class II–V LN

Glomerular podocytopathy with 80% foot process effacement is specific for patients with SLE-induced NoS regardless of the underlying class of LN. The development of nephrotic range proteinuria in patients with LN without peripheral immune deposits was described to be a manifestation of SLE in the podocytes. It is concluded from therapeutic studies on FSGS and NoS that CSA may also effectively reduce proteinuria in patients with LN and NoS. Children with class V LN and those children with other class II–IV LN who did not achieve complete remission of proteinuria after other types of immunosuppression should receive a combination therapy of IV-PRED, oral PRED, and CSA.

Induction therapy should be started with 3–6 IV-PRED pulses on alternate days (300 mg/m^2 PRED) (*Fig. 298.2*). Oral PRED (60 mg/m^2) should be given on the IV-PRED free days for 4–6 weeks and should be switched to alternate-day PRED in those patients entering remission. Continuous PRED may be prolonged and tapered in nonresponders for a maximum of 6 months.

CSA (150 mg/m^2/day) is started together with IV-PRED and the CSA dosage should be adjusted to achieve target trough levels between 100 and 140 ng/mL until remission. Patients with a NoS and an initial GFR below 60 mL/min/1.73 m^2 may develop a transient decrease in GFR during CSA therapy. Therefore, these patients may be switched from CSA to MMF.

As soon as the patients have achieved a complete remission, the oral prednisone therapy should be switched to alternate-day PRED and maintenance therapy should consist of alternate-day PRED + CSA (or MMF if given successfully for induction therapy). Therapeutic trough levels of CSA should aim at C_O concentrations of

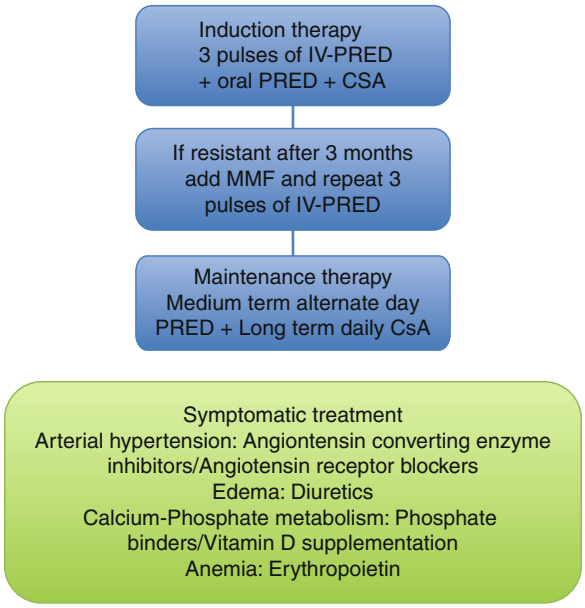

Figure 298.2
Treatment protocol for lupus nephritis with nephrotic syndrome (Nos)

80–120 ng/mL during maintenance therapy. Patients experiencing a relapse during CSA maintenance therapy should receive a second course of IV-PRED pulses + oral PRED. Patients developing CSA nephrotoxicity during maintenance therapy may be switched from CSA to MMF maintenance therapy. Frequent relapses may receive a maintenance therapy with a combination of CSA + MMF. Those patients who did not respond to induction therapy with PRED + CSA may be switched to IV-CYC, or MMF.

Class V LN may be further differentiated into subclasses Va to Vd LN. There is presently no finding supporting the finding that patients with membranous LN should be treated differently according to these subclasses.

Protocol 3. Mild or Moderate Nephritic Syndrome and Class II–IV LN with Proteinuria Above 500 mg/m^2/day, Hematuria, With or Without Hypertension and Normal GFR

Induction therapy should be started with 3 pulses IV-PRED and low-dose IV-CYC or MMF (*Fig. 298.3*). Oral PRED (60 mg/m^2/day, a maximum dose of 80 mg/day) is given for 4 weeks and then tapered to lower dosages. Patients entering complete remission should be switched

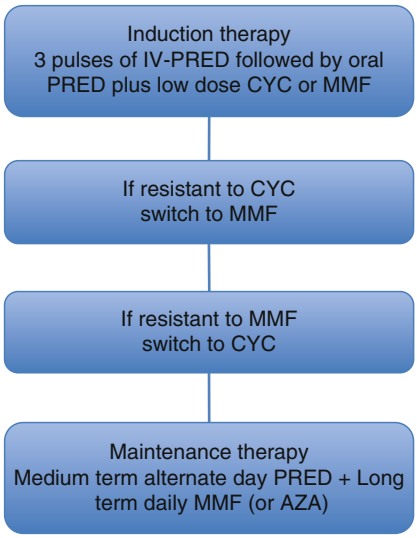

Figure 298.3
Treatment protocol for mild and moderate lupus nephritis with nephritic syndrome

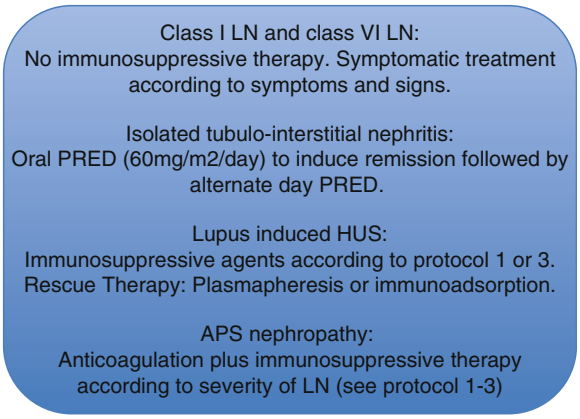

Figure 298.4
Treatment options for other types of lupus nephritis

from continuous PRED to alternate-day PRED (starting with 40 mg/m^2/day with a tapering of PRED to reach a baseline alternate-day PRED dosage of 5–10 mg/m^2/48 h. Side effects of PRED should be studied at regular intervals and alternate-day PRED may be stopped completely in responsive patients during the first year after initial treatment. Six "low-dose" IV-CYC pulses (500 mg/m^2) should be given at monthly interval starting 1 day after onset of PRED. MMF may be given orally at a dosage of 1,000 mg/m^2/day as an alternative to IV-CYC.

Maintenance therapy may include MMF, AZA, or CSA in addition to low-dose alternate-day PRED.

Protocol 4. Other Groups of Lupus Nephritis

Patients with class I LN need no immunosuppressive therapy as long as there is no progressive renal dysfunction. On the other side of the severity spectrum is class VI LN, which should be regarded as the final stage of renal involvement with little inflammatory lesions and mostly scarring. These patients should neither undergo induction therapy nor rescue therapies to avoid unnecessary side effects. Nephroprotection including antihypertensive and antiproteinuric treatment is indicated in these patients.

Children with lupus-induced isolated tubulointerstitial nephritis should be treated with oral PRED (60 mg/m^2/day) to induce remission (*Fig. 298.4*).

Patients with lupus-induced HUS or TTP should be treated by immunosuppressive agents and anticoagulation and may receive plasmapheresis or immunoadsorption.

Patients with APS nephropathy will require anticoagulation in addition to immunosuppressive therapy.

Prognosis

SLE can be a lifelong disease. The prognosis of different LN depends on the underlying classes and also on the different therapeutic regimen. Under-immunosuppression may lead to progression of CKD and overtreatment to an increase of side effects such as severe infections.

All published data on the follow-up of different classes of LN in children suffer from the missing standardization of immunosuppressive therapies and the lack of long-term evaluation of children into adult life. Factors indicating a poor prognosis are persistent proteinuria, hypertension, and an increase in serum creatinine.

Approximately one fifth of all Caucasian children with LN have class I and II LN and a good prognosis, however, class II LN may deteriorate to the higher classes, thus worsening the initial prognosis.

The prognosis of LN class III representing one fifth of all LN patients in childhood depends on the percentage of affected glomeruli, and those patients having fewer than 20% damaged glomeruli may have a 95% 5-year renal survival.

Class IV is the most severe type of LN and is usually found in approximately 40–50% of all children with LN. The prognosis depends substantially on the intensity of

immunosuppressive treatment and 5-year renal survival rates of 80% were achieved by intensified treatment protocols.

Class V lesions can be found in approximately one tenth of children with LN. It has a good prognosis if treated properly and less than 20% of patients will develop a renal failure after 5 years.

Class VI LN is defined by more than 90% of sclerosed glomeruli. The renal prognosis is poor and the kidneys do no longer benefit from immunosuppressive treatment.

In Europe, 0.7% of all children on renal replacement therapy suffered from LN, this percentage was 5% in the US American population. Those patients entering terminal renal failure will require transplantation with or without prior dialysis. Recurrence of LN in the graft was rarely reported. Patients with LN and an APS nephropathy have a high risk to develop a graft thrombosis.

SLE is a systemic disease with wide-ranging effects on physical, psychological, and social well-being. Comprehensive assessment of quality of life and economic costs in addition to disease activity and disabilities is important. New outcome measures are needed to allow for improvement of patient care.

Prevention

Maintenance therapy should aim at preventing relapses and progression of renal dysfunction. It is unclear how soon immunosuppressive treatment can be stopped after a successful induction therapy. Avoidance of intense UV-light exposure should be kept lifelong. In patients lacking a complete response after induction therapy, immunosuppressive agents may have to be given for many years. Maintenance therapy should especially aim at preventing long-term side effects of PRED, CYC, and CSA.

299 Goodpasture Syndrome

Karyn Yonekawa

Definition

In 1919, EW Goodpasture described an 18-year-old male who initially presented with the clinical manifestations of influenza. His course was atypical however and his post-mortem evaluation discovered evidence of systemic disease with massive alveolar hemorrhage and glomerular cell proliferation. Stanton and Tange, in 1958, summarized the literature to date reporting 12 cases plus 9 of their own with the same clinical presentation. They suggested that the syndrome of pulmonary hemorrhage and glomerulonephritis be given the eponym of Goodpasture's syndrome. The etiology was unknown until the link between glomerulonephritis and anti-glomerular basement membrane (anti-GBM) antibodies was suggested in the years to follow. Although pulmonary-renal syndrome is now recognized to have many causes, the presence of anti-GBM antibodies, pulmonary hemorrhage, and a proliferative glomerulonephritis is the triad that defines Goodpasture's syndrome.

Incidence and Risk Factors

Most references to incidence are describing the occurrence of anti-GBM disease with or without pulmonary involvement, not specifically to the incidence of Goodpasture's syndrome as defined above. Anti-GBM disease is estimated by most to be responsible for less than 2% of all glomerular diseases. There is a bimodal distribution of incidence with respect to age, with the peak during the third decade of life in males and during the sixth in females. Goodpasture's syndrome seems to occur more commonly in males under the age of 50. However, patients of all ages and either sex can be affected. Although there are reports of Goodpasture's syndrome in children as young as 4.5 years, the diagnosis is rare in pediatrics. It is also less frequently reported in Asians and Africans; Caucasians are predominantly affected. The Maori, the indigenous Polynesian people of New Zealand, may be particularly susceptible as well. Familial cases have been reported including identical twins.

Potential risk factors for developing Goodpasture's syndrome include smoking, inhaling cocaine, and being exposed to hydrocarbons such as toluene. Of note, an upper respiratory infection has been reported as preceding the onset of symptoms in 20–60% of cases.

Pathogenesis

Goodpasture's syndrome is an autoimmune disease characterized by the presence of anti-GBM antibodies directed at type IV collagen. The specific targets of most anti-GBM antibodies are epitopes in the non-collagenase domain (NC1) of type IV collagen's α3 chain. However, a significant proportion of patients express antineutrophil cytoplasmic antibodies (ANCA) in addition to anti-GBM. In these patients, the range of autoantibodies is broader, including antibodies to the α1(IV), α4(IV), and α5(IV) NC1. Rarely, antibodies are found against α2(IV) NC1. As the NC1 epitopes are normally sequestered, it is proposed that an oxidant, environmental or endogenous, exposes the hidden antigen.

Kidney injury occurs directly from the antigen–antibody interaction, with secondary mediators inflicting further damage. Complement and leukocytes invade causing cellular proliferation within the glomeruli. Bowman's capsule is often compromised and cells enter into the urinary space resulting in crescent formation.

A similarly destructive capillitis affects the alveolar basement membranes. Neutrophils enter the pulmonary interstitium and disrupt the alveolocapillary barrier allowing blood to extravasate into the alveoli.

Genetics

There is a strong link between human leukocyte antigen (HLA) types and Goodpasture's. HLA DR15 (DRB1-1501 and DRB1-1502 alleles) and DR4 are positively associated with the development of Goodpasture's disease. HLA-DR7 and DR1 may be protective.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_299,

Pathology

Renal biopsy demonstrates a proliferative glomerulonephritis usually with crescent formation. Segmental and global glomerular sclerosis and interstitial fibrosis can be seen if the biopsy is done late in the disease course. Immunofluorescence shows a linear pattern of immunoglobulin G (IgG) staining in the glomerular capillary basement membrane with frequent incorporation of C3 in a more granular or discontinuous distribution (*Fig. 299.1*). Less frequently found are codeposits of IgM, IgA, or C1q. Electron microscopy reveals widening of the basement membrane with some distortion of glomerular capillaries and endothelial cell hypertrophy plus hyperplasia.

Lung biopsy sections on light microscopy reveal red blood cells and hemosiderin laden macrophages. Electron microscopy shows a thickened basement membrane with hyperplasia of type I and type II pneumocytes. Immunofluorescence demonstrates characteristic linear deposits of IgG along alveolar septa.

Clinical Features

Most patients with Goodpasture's syndrome present with pulmonary involvement either preceding or concurrent with glomerulonephritis. The pulmonary manifestations may include cough and dyspnea with hemoptysis ranging from mild to massive hemorrhage. Blood or hemosiderin laden macrophages may be seen in the bronchiole alveolar lavage fluid. Although non-specific, chest radiograph is usually abnormal demonstrating interstitial or alveolar infiltrates. A microcytic anemia may be present even without clinically apparent pulmonary hemorrhage.

Renal manifestations include microscopic hematuria or gross hematuria, proteinuria and decreased renal function. A rapidly progressive glomerulonephritis resulting in renal failure within days or weeks may occur. Alternately, cases of normal creatinine at presentation have been reported.

Systemic complaints of fever, fatigue, weakness, rashes, and arthralgias are more commonly seen in patients with coexistent positive ANCA titers. Hypertension is possible, but a minority have high blood pressure at onset. Anti-GBM antibodies are demonstrated in the serum in most patients. Serum complements and an anti-nuclear antibody titer are usually normal.

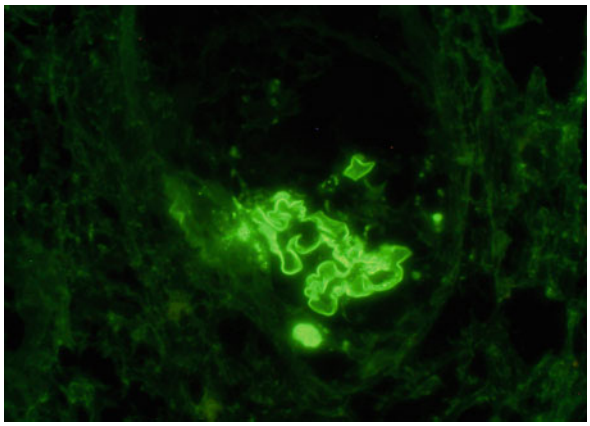

Figure 299.1
Immunofluorescence of a partial glomerulus demonstrates intense linear staining for IgG, characteristic of the renal biopsy findings in Goodpasture's syndrome (Photo courtesy of Laura Finn, MD)

Treatment

High dose corticosteroids appear to be effective in controlling symptoms of alveolar hemorrhage, but as monotherapy, they are not effective in restoring renal function. Plasmapheresis in combination with an immunosuppression regimen, such as prednisone and cyclophosphamide, has been shown to control pulmonary hemorrhage and decrease the progression of renal disease. Immunosuppressive therapy suppresses de novo rebound antibody production while plasmapheresis removes the circulating antibodies. Intensive plasmapheresis may be used for weeks depending on the clinical response. Immunosuppression can continue for up to a year.

Prognosis

Most patients with a significantly elevated creatinine, oliguria, and interstitial fibrosis on renal biopsy progress to end-stage renal disease. Those with a serum creatinine above 8 mg/dL (704 µmol/L) are unlikely to respond to therapy although some have been able to come off dialysis with an aggressive approach commenced early. Transplantation can be safely considered once the patient's anti-GBM antibody titer normalizes for a sustained period. Rarely, Goodpasture's can recur in the transplanted kidney.

In contrast to the renal outcomes, patients are generally left with little pulmonary deficit, regardless of the amount of lung hemorrhage they have experienced.

Additionally, overall morbidity and mortality have improved tremendously compared to the preplasmapheresis era, which was associated with a mortality of 75–90%. Now with early and aggressive therapy, it is 1 year survival that is 75–90%.

300 Congenital Nephrotic Syndrome

Patrick Niaudet

Congenital nephrotic syndrome is present at birth or appears during the first 3 months of life. Onset of nephrotic syndrome between 3 months and 1 year defines infantile nephrotic syndrome. Most cases have a genetic basis (*Table 300.1*) and a poor outcome. The diagnosis of the disease responsible for the nephrotic syndrome is based on clinical, biological, histological, and genetic studies.

Congenital Nephrotic Syndrome of the Finnish Type (CNF)

This type of congenital nephrotic syndrome initially described by Hallman et al. is more frequent in Finland with an incidence of 1.2 per 10,000 births. It has also been reported in various ethnic groups around the world.

Genetics

The disease is inherited as an autosomal recessive trait. The gene was mapped to chromosome 19q13.1 in 17 Finnish families and other families around the world, and no genetic heterogeneity has been reported. The gene, called *NPHS1*, has a 26 kb size and contains 29 exons. It encodes for a 1,241-residue transmembrane protein of the immunoglobulin superfamily of cell adhesion molecules named "nephrin." Many different mutations of *NPHS1* have been reported. In Finnish patients, the two most common mutations, Fin-major and Fin-minor account for 90% of all patients, as homozygous mutations or compound heterozygous mutations. Fin-major mutation is a two base pair deletion in exon 2 that causes a frameshift and a translation stop in the same exon. Fin-minor is a nonsense mutation in exon 26.

The same gene is responsible for the disease in non-Finnish patients with CNF. The mutation-carrying chromosomes descend from different ancestors without evidence of a founder effect. Beside the two "Finnish mutations," more than 50 other mutations have been detected mainly outside Finland. The mutations including deletions, insertions, nonsense, missense, and splicing mutations are scattered along the entire gene. Interestingly, eight out of nine patients with an atypically mild disease (of which five were in remission) were homozygous for R1160X, a mutation also associated with the classical form suggesting the presence of genetic or other modifying events.

By immunoelectron microscopy, it has been shown that nephrin is specifically located at the slit diaphragm between the podocyte foot processes. Two decades ago, electron microscopic observations revealed a zipper-like structure at the slit diaphragm, with a width between 20 and 50 nm. It has been hypothesized that nephrin molecules extending between two opposite foot processes may interact with each other in the slit diaphragm through homophilic interactions. Since nephrin mutations are associated with massive proteinuria, it can be concluded that this protein is crucial for the maintenance of the glomerular filtration size-selective barrier.

Pathology

The kidneys are enlarged in the initial stages of the disease. Light microscopic examination early in the course of the disease show mild mesangial hypercellularity and increased mesangial matrix in the glomeruli. Irregular microcystic dilatation of proximal tubules is the most striking feature, although this change is not specific. No immune deposits are detected by immunofluorescence studies. Later in the course, interstitial fibrosis, lymphocytic and plasma cell infiltration, tubular atrophy, and periglomerular fibrosis develop in parallel with glomerular sclerosis.

Clinical Features

Massive proteinuria occurs in utero and the symptoms at birth are related to the protein deficiency. Most infants are born prematurely (35–38 weeks), with a low birth weight for gestational age. The placenta is enlarged, being more

Pierson syndrome	3p21	AR	*LAMB2*	Laminine beta 2
Nail–patella syndrome	9q34.1	AD	*LMX1B*	Transcription factor
Mitochondrial cytopathies	mtADN	Maternal	mtADN	Respiratory chain protein

than 25% of the total birth weight. Fetal distress is frequent. The cranial sutures are widely separated due to delayed ossification. Infants often have a small nose and low ears. Flexion deformities of the hips, knees, and elbows are frequent.

Edema is present at birth or appears during the first week of life. The nephrotic syndrome is severe with marked ascites. The proteinuria is highly selective early in the course of the disease and hematuria is uncommon. The urinary protein losses are accompanied by profound hypoalbuminemia and severe hypogammaglobulinemia. As a result, nutritional status and statural growth are poor, and affected infants are highly susceptible to bacterial infections (peritonitis, respiratory infections) and to thromboembolic complications due to the severity of the nephrotic syndrome. Hypothyroidism due to urinary losses of thyroxine-binding protein is also common. Cholesterol and triglycerides are markedly elevated. The blood urea and creatinine concentrations are initially normal.

Renal ultrasonography shows enlarged hyperechogenic kidneys without the normal corticomedullary differentiation.

End-stage renal failure usually occurs between 3 and 8 years of age. However, some *NPHS1* mutations are associated with end-stage renal failure occurring much later in life.

Prenatal Diagnosis

CNF can be diagnosed prenatally as it becomes manifest during early fetal life, beginning at the gestation age of 15–16 weeks. Fetal proteinuria leads to a more than tenfold increase in the amniotic fluid alpha-fetoprotein (AFP) concentration. A parallel, but less important increase in the maternal plasma AFP level is observed. However, positive results may occur in heterozygous carriers leading to false diagnosis.

Genetic linkage and haplotype analyses may diminish the risk of false positive results in informative families. The four major haplotypes, which cover 90% of the CNF alleles in Finland, have been identified, resulting in a test with up to 95% accuracy. When the mutation responsible for the disease has been identified in a child, antenatal diagnosis may be proposed for a sibling following trophoblast biopsy.

Treatment

The nephrotic syndrome in CNF is always resistant to corticosteroids and immunosuppressive drugs. Furthermore, these drugs may be harmful due to the already high susceptibility to infection.

Standard conservative treatment includes daily or every other day albumin infusion, gamma globulin replacement, nutrition with a high-protein, low-salt diet, vitamin and thyroxine substitution, and prevention of infections and thrombotic complications. The diet is often provided by tube feeding. The rate of intercurrent complications remains high and growth and development are usually retarded. Some patients may require bilateral nephrectomy to prevent continued massive protein losses before the development of renal failure.

A possible medical alternative to nephrectomy is the combination of an angiotensin converting enzyme inhibitor and indomethacin therapy, which in some children lead to a decrease in protein excretion and improvement in nutritional status and growth.

If nephrectomy is performed, dialysis is provided until the patient reaches a weight of 8–9 kg. At this stage, renal transplantation can be considered. Nephrotic syndrome

can develop after transplantation. This occurred in 13 of 51 allografts (25%), but only in children with the Fin-major/Fin-major genotype, which is associated with the absence of nephrin in the native kidneys. Anti-nephrin antibodies were observed in most affected patients. Plasma exchanges and oral cyclophosphamide may induce a remission.

Idiopathic Nephrotic Syndrome and *NPHS2* Mutations

Idiopathic nephrosis rarely occurs at birth, more commonly presenting during the first year of life. All the morphological variants of idiopathic nephrotic syndrome seen in older children can occur at this time including minimal change disease, diffuse mesangial proliferation, and focal and segmental glomerular sclerosis.

Steroid-responsiveness with a favorable course can be seen. However, most affected infants are resistant to therapy and many progress to end-stage renal disease. *NPHS2* mutations have been detected in some of these cases. *NPHS2* encodes an integral membrane protein, podocin, which is found exclusively in glomerular podocytes. Some patients with congenital nephrotic syndrome were found to lack *NPHS1* mutations. In two of five such patients, Koziell et al. found homozygous *NPHS2* mutations. Schulteiss et al. found homozygous or compound heterozygous *NPHS2* gene mutations in 11 out of 27 (41%) patients with CNS. Two additional cases had similar findings in terms of mutations in *NPHS2*, but not NPHS1, were also reported in a study of 13 unrelated patients from Japan.

In addition, some patients have both *NPHS1* and *NPHS2* mutations, resulting in a triallelic abnormality (homozygous mutations in one gene and a heterozygous mutation in the other). These findings demonstrate the genetic heterogeneity of congenital nephrotic syndrome and the absence of genotype/phenotype correlations.

Diffuse Mesangial Sclerosis

Diffuse mesangial sclerosis is the second cause of early nephrotic syndrome progressing to end-stage renal failure. It is seen exclusively in young children. Homozygous truncating mutations of the *PLCE1* gene, which encodes phospholipase C epsilon, was reported in eight children out of 12 children from six families with isolated diffuse mesangial sclerosis. Other patients have a Pierson syndrome, a Denys–Drash syndrome or an isolated form of diffuse mesangial sclerosis.

Clinical Features

Nephrotic syndrome may be present at birth or even detected in utero on the finding of elevated maternal alpha-fetoprotein serum level. The antenatal discovery of large hyperechogenic kidneys mimicking polycystic kidneys may be the first symptom of the disease. Most often, the patients are normal at birth and have a normal birth weight. Nephrotic syndrome develops progressively during the first or the first 2 years of life after a period of increasing proteinuria. Renal insufficiency may be present from the onset of renal symptoms. Various types of extrarenal signs have been reported in a few patients: nystagmus, nystagmus with mental retardation, cataract, mental retardation with microcephaly and myocarditis, severe myopia with cardiac arrhythmia, muscular dystrophy and dysmorphic features of the face.

Pathology

The glomerular lesions are characterized in the early stages by a fibrillar increase in mesangial matrix without mesangial cell proliferation. The capillary walls are lined by hypertrophied podocytes. The fully developed lesion consists of the combination of thickening of the glomerular basement membranes and massive enlargement of mesangial areas, leading to reduction of the capillary lumens. The mesangial sclerosis contracts the glomerular tuft into a sclerotic mass within a dilated urinary space (Fig. 300.1). There is usually a corticomedullary

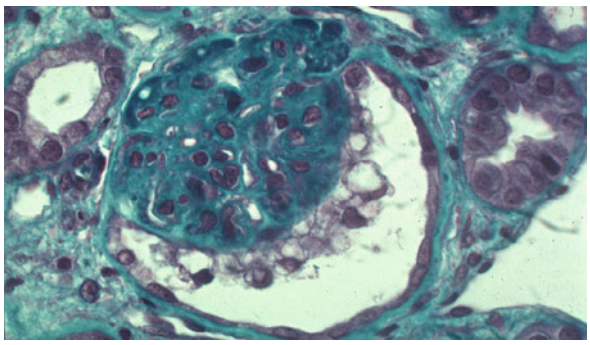

Figure 300.1

gradient of involvement, with the deepest glomeruli being less affected. Tubules are severely damaged, especially in the deeper cortex where they are markedly dilated and often contain hyaline casts.

Electron microscopy reveals hypertrophic mesangial cells surrounded by an abundant mesangial matrix, which often contains collagen fibrils. The podocytes are hypertrophied and contain many vacuoles. There is also irregular effacement of foot processes with focal detachment of the epithelial cell from the glomerular basement membrane.

Immunofluorescence shows mesangial deposits of IgM, C3, and C1q in the least affected glomeruli, while deposits of IgM and C3 outline the periphery of the sclerosed glomeruli. These deposits are probably nonspecific, occurring in areas of previous injury.

Therapy

Nephrotic syndrome secondary to diffuse mesangial sclerosis is always resistant to corticosteroids and immunosuppressive drugs. The nephrotic syndrome is usually less severe than in the CNF. Treatment is supportive and consists of maintenance of electrolyte and water balance and adequate nutrition, prevention and treatment of infectious complications, and management of renal failure. Bilateral nephrectomy is considered at the time of transplantation because of the theoretical risk of developing a Wilms' tumor. It is mandatory if a *WT1* mutation has been identified. Recurrent disease does not develop in the transplant.

Denys–Drash Syndrome

Denys–Drash syndrome (DDS) is characterized by the triad of severe glomerulopathy with diffuse mesangial sclerosis progressing rapidly to end-stage renal disease, male pseudohermaphroditism, and Wilms' tumor.

Genetics

The Denys–Drash syndrome is usually sporadic, and heterozygous germline mutations in the Wilms' tumor predisposing gene are observed in nearly all affected patients.

The *WT1* gene, located on chromosome 11p13, encodes a transcription factor presumed to regulate the expression of a series of target genes through DNA binding. It plays a critical role in kidney and gonad development and, when mutated, in the occurrence of kidney tumor and glomerular nephropathies. The target genes potentially regulated, most often negatively, by *WT1* include genes which code for transcription factors as well as for growth factors or their receptors.

WT1 is strongly expressed during embryofoetal life. In the mature kidney, *WT1* expression persists only in podocytes and epithelial cells of the Bowman's capsule. Disruption of *WT1* gene in mice results in the absence of both kidneys and gonads suggesting a crucial role of *WT1* in the development of the genitourinary tract. *WT1* play a major role in the induction of the ureteric bud, the mesenchymal to epithelial differentiation, the progression of nephrogenesis, and the maintenance of podocyte function.

More than 60 germline mutations have been reported in patients presenting with complete or incomplete DDS. They are de novo mutations, most of them missense mutations located within exons 8 or 9 encoding zinc fingers 2 and 3, respectively. The most common *WT1* lesion is a missense 1180 C to T transition converting the arginine located at the top of the third zinc finger (ZF3) to tryptophan (R394W). These *WT1* mutations change the structural organization of the respective zinc fingers and, consequently, result in loss or alteration of their DNA binding ability as confirmed by in vitro experiments. DDS mutations appear to act in a dominant negative fashion. *WT1* gene mutations, identical to those observed in DDS, have been reported in a few patients with isolated diffuse mesangial sclerosis.

Clinical Features

The nephropathy is usually discovered after several months of life, sometimes at birth. Proteinuria is accompanied by nephrotic syndrome. There is no hematuria. Blood pressure is often elevated. Progression to ESRD before the age of 4 years is the rule. Some patients progress rapidly within a few weeks to end-stage renal failure. There is no recurrence of the original disease after renal transplantation. Diffuse mesangial sclerosis is a constant feature of the Denys–Drash syndrome. It is associated with the two other components of the triad in the complete form, but with only one of the two in the incomplete forms. Wilms' tumor may be the first clinical manifestation of the syndrome. Thus, careful renal ultrasonography should be performed, looking for nephroblastoma, in any patient found to have diffuse mesangial sclerosis. The tumor may be unilateral or bilateral. Male

pseudohermaphroditism, characterized by ambiguous genitalia or female phenotype with dysgenetic testis or streak gonads, is observed in all 46 XY patients. In contrast, 46 XX children appear to have a normal female phenotype.

Pierson Syndrome

Pierson syndrome is an autosomal recessive syndrome with congenital nephrotic syndrome with diffuse mesangial sclerosis and ocular malformations (microcoria, abnormal lens with cataracts, and retinal abnormalities). This disorder is due to mutations in the *LAMB2* gene, which encodes laminin beta 2. Laminin beta 2 is abundantly expressed in the glomerular basement membrane where it plays a role in anchoring and in the development of podocyte foot processes. *LAMB2* knockout mice exhibit congenital nephrotic syndrome in association with anomalies of the retina and neuromuscular junction. *LAMB2* mutations have also been found in patients with congenital nephrotic syndrome and either no or less severe ocular abnormalities.

Galloway Syndrome

The Galloway syndrome is characterized by microcephaly, mental retardation, hiatus hernia, and the nephrotic syndrome of early onset with a mean age at discovery of 3 months. It appears to be transmitted as an autosomal recessive trait. The nephrotic syndrome is usually severe, resistant to steroid therapy, and progresses to end-stage renal failure. Renal biopsy reveals minimal changes or focal and segmental glomerulosclerosis. The underlying defect is not known.

Congenital Nephrotic Syndrome Secondary to Infections

Congenital syphilis can cause membranous nephropathy. Histological examination often shows a mixed pattern with membranous nephropathy and mesangial proliferation. Penicillin treatment leads to the resolution of the syphilis and the renal abnormalities.

The nephrotic syndrome may be induced by congenital toxoplasmosis. Proteinuria may be present at birth or may develop during the first 3 months, in association with ocular or neurologic symptoms. Histological examination often shows mesangial proliferation with or without focal glomerulosclerosis. Treatment of toxoplasmosis or steroid therapy usually leads to remission of the proteinuria.

Congenital or infantile nephrotic syndrome has been reported in association with cytomegalovirus, rubeola virus, human immunodeficiency virus, and mercury intoxication.

Other Causes of Congenital Nephrotic Syndrome

Congenital nephrotic syndrome has been reported in association with type I carbohydrate-deficient glycoprotein syndrome in a neonate with neurologic abnormalities and diffuse mesangial sclerosis. It has also been reported in association with infantile sialic acid storage disease and more recently in association with mitochondrial respiratory chain deficiency.

Antenatal nephrotic syndrome due to membranous nephropathy has been reported in infants whose mothers have mutations in the metallomembrane endopeptidase gene, which encodes the podocyte protein neutral endopeptidase (NEP). During pregnancy, the absence of NEP protein induces an alloimmunisation against NEP presented by fetal cells, resulting in a fetal podocyte injury which may lead to chronic renal failure.

301 Nephrotic Syndrome in Children

Patrick Niaudet

Nephrotic syndrome is defined by a proteinuria higher than 50 mg/kgBW/day and hypoalbuminemia <30 g/l. A nephrotic syndrome is always secondary to a glomerular disease.

Different mechanisms have been described in the nephrotic syndrome: circulating nonimmune factors in idiopathic nephrotic syndrome, circulating immune factors in several types of glomerulonephritis, mutations in podocyte, or slit diaphragm proteins in inherited forms of nephrotic syndrome.

Proteinuria in glomerular disease is due to increased filtration of macromolecules (such as albumin) across the glomerular capillary wall. The latter consists of three components: the fenestrated endothelial cell, the glomerular basement membrane (GBM), and the epithelial cell foot processes. The pores between the foot processes are closed by a thin membrane called the slit diaphragm. The filtration of macromolecules across the glomerular capillary wall is normally restricted by charge-selectivity and size-selectivity. The GBM have a net negative charge which creates a barrier to the filtration of anions such as albumin. In comparison, circulating IgG is predominantly neutral or cationic and its filtration is not limited by charge.

In minimal change disease, the most common cause of nephrotic syndrome in children, there is a loss of anionic charge without structural damage by light microscopy. However, electron microscopy demonstrates epithelial foot processes effacement. In glomerular diseases other than idiopathic nephrotic syndrome, structural injury seen by light microscopy results in an increase in the number of large pores in the GBM. This structural damage allows movement of normally restricted proteins of varying sizes (including large neutral proteins, such as IgG) across the filtration barrier.

Clinical Features

The nephrotic syndrome is responsible for edema which increases gradually and becomes detectable when fluid retention exceeds 3–5% of body weight. It is often initially apparent around the eyes and misdiagnosed as an allergy. Edema is gravity dependent. During the day, periorbital edema decreases while it localizes to the lower extremities. In the reclining position, it localizes to the back. It is white, soft, and pitting. Edema of the scotum and penis or labiae may also be observed. Anasarca may develop. The abdomen may bulge with umbilical or inguinal hernias. When ascitis build up rapidly, the child complains of abdominal pain and malaise. Abdominal pain may also result from severe hypovolemia, peritonitis, pancreatitis, thrombosis, or steroid-induced gastritis. Blood pressure is often normal, but may be elevated depending on the underlying disease. Shock is not unusual after sudden fall of plasma albumin as observed in idiopathic nephrotic syndrome.

The nephrotic syndrome may be discovered during routine urine analysis or during the evaluation of a patient with hematuria. It may also be revealed by a complication such as peritonitis, deep vein or arterial thrombosis, or pulmonary embolism.

Laboratory Findings

Urine Analysis

Nephrotic range proteinuria is defined as urinary protein excretion greater than 50 mg/kg/day or 40 mg/m^2/h. It is higher at onset and decreases as plasma albumin concentration falls. In young children, it may be difficult to obtain a 24-h urine collection, and urinary protein to creatinine ratio or albumin to creatinine ratio in untimed urine specimens is useful. For these two indices, the nephrotic range is 200–400 mg/mmol. The selectivity of proteinuria may be appreciated by polyacrylamide gel electrophoresis or by the evaluation of the Cameron index that is the ratio of IgG to transferrin clearances. A favorable index would be below 0.05 and 0.10; a poor index is above 0.15 or 0.20. Proteinuria is most often highly selective, consisting of albumin and lower-molecular-weight proteins in case of minimal change disease whereas a poor Cameron index is often associated with more severe histologic lesions. However, there is a considerable overlap in results, and the test has limited value.

The urine sediment often contains fat bodies. Hyaline casts are also usually found in patients with massive

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_301,

proteinuria, but granular casts are not present unless there is associated acute renal failure and acute tubular necrosis. Urinary sodium is low, 1–2 mmol/day, resulting in sodium retention and edema

Blood

Plasma protein levels are markedly reduced, less than 50 g/l, due to hypoalbuminemia. Plasma albumin level is lower than 30 g/l and may be less than 10 g/l. Electrophoresis shows a typical pattern with low albumin, increased α2-globulins, and, to a lesser extent, β-globulins, whereas the level of γ-globulins depends on the cause of the nephrotic syndrome. For example, IgG levels are markedly reduced in minimal change disease and elevated in systemic lupus erythematosus. Lipid abnormalities include high levels of cholesterol, triglyceride, and lipoproteins. The result is that prolonged nephrotic syndrome contributes to the development of atherosclerosis and possibly to theprogression of renal damage. Total cholesterol and low-density lipoprotein cholesterol are elevated, whereas high-density lipoprotein cholesterol remains unchanged or low, particularly high-density lipoprotein 2, leading to an increased low-density lipoprotein to high-density lipoprotein cholesterol ratio. Patients with severe hypoalbuminemia have increased triglycerides and very-low-density lipoprotein. Apoproteins and apolipoproteins B, CII, and CIII are also elevated. The levels of lipoprotein (a) are elevated in nephrotic patients.

Serum sodium is often reduced due in part to hyperlipemia and in part to the dilution from renal retention of water due to hypovolemia and inappropriate antidiuretic hormone secretion. Hyperkalemia may be observed in cases of renal insufficiency. Hypocalcemia is related to hypoalbuminemia, and the level of ionized calcium is usually normal.

Hemoglobin levels and hematocrit are increased in patients with plasma volume contraction. Thrombocytosis is common and may reach 5×10^8/l or 10^9/l. Fibrinogen and factors V, VII, VIII, and X are increased, whereas antithrombin III, the heparin cofactor, and factors XI and XII are decreased. These abnormalities contribute to a hypercoagulable state.

Complications

Acute renal failure: Some patients with idiopathic nephrotic syndrome have a reduction of the glomerular filtration rate (GFR) attributed to hypovolemia, with complete return to normal after remission. A reduced GFR may be found despite normal effective plasma flow. This reduction is transitory, with a rapid return to normal after remission.

Renal failure may be secondary to bilateral renal vein thrombosis that can be diagnosed by sonography. Acute renal failure has also been reported with interstitial nephritis. Skin rash and eosinophilia are suggestive of this diagnosis, which is often associated with furosemide or other medication

Acute renal failure is usually reversible, often with intravenous albumin and high-dose furosemide-induced diuresis.

Renal failure may be related to severe histologic lesions in patients with primary or secondary glomerulonephritis.

Infections: Bacterial infections are frequent in nephrotic children. Sepsis may occur at the onset of the disease. The most common infection is peritonitis, often with *S. pneumoniae*. Other organisms may be responsible: *Escherichia coli*, *Streptococcus bovis*, *Haemophilus influenzae*, and other Gram-negative organisms. Apart from peritonitis, children may develop meningitis, pneumonitis, or cellulitis. Viral infections may be observed in patients receiving corticosteroids or immunosuppressive agents. Varicella is often observed in young children and may be life threatening if acyclovir therapy is not promptly initiated.

Thrombosis: Nephrotic patients are at risk of developing thromboembolic complications. Several factors contribute to this increased risk of thrombosis: a hypercoagulable state, hypovolemia, immobilization, and infection. The incidence of thromboembolic complications in nephrotic children is reported to be approximately 3%. However, this percentage may underestimate the true incidence. In one series, systematic evaluation by ventilation-perfusion scans showed defects consistent with pulmonary embolism in 28% of all patients with steroid-dependent minimal change disease. Pulmonary embolism should be suspected in cases with pulmonary or cardiovascular symptoms and may be confirmed by angiography or angioscintigraphy. Renal vein thrombosis should be suspected in patients with nephrotic syndrome who develop sudden macroscopic hematuria or acute renal failure. In such cases, Doppler ultrasonography shows an increase in kidney size and the absence of blood flow in the renal vein. Thrombosis may also affect the arteries (e.g., pulmonary arteries) or other deep veins (cerebral veins).

Hypovolemia: Hypovolemia is common and typically observed at onset of idiopathic nephrotic syndrome or early during a relapse. Sepsis, diarrhea, or diuretics may precipitate hypovolemia. Hypovolemic children often

have abdominal pain, low blood pressure, and cold extremities. Hemoconcentration with a raised hematocrit accompanies hypovolemia.

Symptomatic Treatment

Diet: Diet includes a protein intake of 130–140% of the normal daily allowance according to statural age. Salt restriction is necessary for the prevention and treatment of edema. A very-low-salt diet is necessary in case of edema. Fluid restriction is recommended for moderate to severe hyponatremia (plasma sodium concentration <125 mmol/l). A reduction of saturated fat is advisable. Carbohydrates are given preferentially as starch or dextrin-maltose, avoiding sucrose, which increases lipid disturbances.

Hypovolemia: Hypovolemia, a consequence of rapid loss of serum albumin may be aggravated by diuretics. When symptomatic, this complication requires emergency treatment by rapid infusion of plasma (20 ml/kg) or albumin 20% (1 g/kg) administrated with monitoring of heart rate, respiratory rate, and blood pressure.

Diuretics: Diuretics should only be used in cases of severe edema, after hypovolemia has been corrected. Patients with anasarca may be treated with furosemide (1–2 mg/kg) or, if necessary, furosemide and salt-poor albumin (1 g/kg infused over 4 h) to increase the rate of diuretic delivery to the kidney. This approach is immediately effective, but not long lasting. Moreover, respiratory distress with congestive heart failure has been observed in some patients. Spironolactone (5–10 mg/kg) may be prescribed, provided serum creatinine is normal. Amiloride may also be used in combination with furosemide. Diuretics may induce intravascular volume depletion with a risk of thromboemboli and of acute renal failure. Refractory edema with serous effusions may require drainage of ascites and/or pleural effusions. Head-out immersion has been reported to be helpful in these cases.

Thromboemboli: Patients with severe hypoalbuminemia are at risk for thromboembolic complications. Prevention includes mobilization, avoiding hemoconcentration and treating early sepsis or volume depletion. Prophylactic warfarin may be given to patients with a plasma albumin concentration below 20 g/l, a fibrinogen level >6 g/l, or an antithrombin III level <70% of normal. Patients at risk may be treated with low-dose aspirin and dipyridamole, although no controlled trials have been performed to demonstrate their efficacy for preventing thrombosis.

Heparin is given initially if thrombosis occurs, alone or with thrombolytic agents. The heparin dose necessary to obtain a therapeutic effect is often greater than normally, due to decreased antithrombin III levels.

Antihypertensive drugs: Hypertension is treated, using a β-blocker or a calcium channel blocker during acute episodes. In cases of permanent hypertension, an angiotensin converting enzyme inhibitor or an inhibitor of angiotensin II receptor is preferred.

Infections and immunizations: Prophylaxis of *S pneumoniæ* with oral penicillin is often prescribed to children during initial corticosteroid treatment. Vaccination with the conjugated pneumococcal vaccine (7vPCV) is recommended. In cases of peritonitis, antibiotics against both *S pneumoniæ* and Gram-negative organisms are started after peritoneal fluid sampling. Varicella is a serious disease in patients receiving immunosuppressive treatment or daily corticosteroids. Varicella immunity status should therefore be assessed. In case of exposure, early prevention by acyclovir must be instituted. Immunization with the varicella vaccine is effective and safe in children on low-dose alternate day steroid therapy.

Reduction of proteinuria: There is evidence that proteinuria per se is toxic for the tubules and can favor the progression of renal fibrosis. Therefore, reduction of proteinuria should be a goal in patients with persistent proteinuria. The best results are obtained with ACE inhibitors and AT1 receptor antagonists, alone or in combination. Several studies have demonstrated the renoprotective effects of ACE inhibitors in proteinuric patients, suggesting that this strategy is appropriate in patients with prolonged nephrotic syndrome.

Causes of Nephrotic Syndrome in Children

Idiopathic Nephrotic Syndrome

It is the main cause of nephrotic syndrome in children (INS) representing more than 90% of cases before age 10 years and 50% after 10 years. INS is defined by the association of a nephrotic syndrome with minimal glomerular changes (Fig 301.1) or nonspecific histological lesions such as focal and segmental glomerular sclerosis or diffuse mesangial proliferation. Most often, no immunoglobulin or complement deposit is seen on immunofluorescent examination. However, IgM deposits may be observed and the clinical significance of such deposits is controversial. Electron microscopy shows an effacement of the podocyte foot processes.

Most patients with minimal change lesions respond to corticosteroids with complete remission. Conversely,

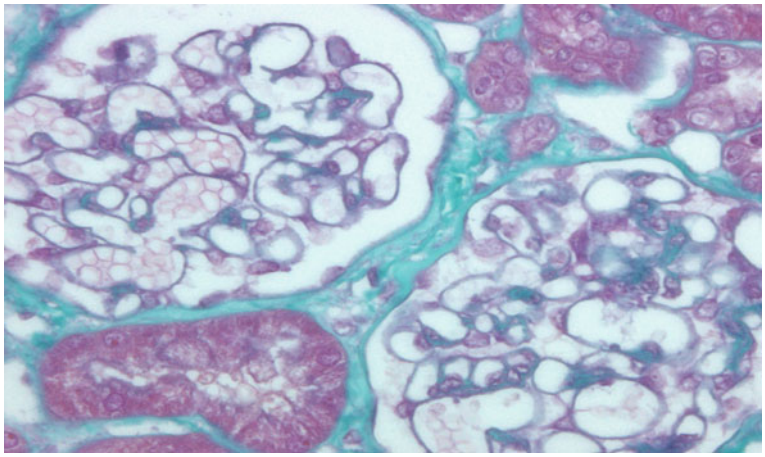

Figure 301.1

patients in whom the renal biopsy shows FSGS or diffuse mesangial proliferation often do not respond to corticosteroids. This is the reason why several authors believe that minimal change disease is a distinct entity, and FSGS, diffuse mesangial proliferation, and IgM nephropathy are also distinct entities. However, serial renal biopsies show that some patients with minimal changes on initial biopsy may later develop FSGS. Furthermore, some patients with FSGS respond to corticosteroids and have a favorable long-term outcome. Experience has shown that response to steroid therapy carries a greater prognostic weight than the histological features on initial biopsy. Therefore, two types of INS are described according to the response to corticosteroids; steroid sensitive INS in which proteinuria rapidly resolves and steroid-resistant INS in which proteinuria persists despite corticosteroids.

Initial Treatment

Steroid therapy is started when the diagnosis of INS is most likely in a child older than 1 year and younger than 11 years of age, without hypertension, gross hematuria or extra-renal symptoms, and normal complement levels. In some cases, the treatment is started after a renal biopsy has been performed. Prednisone remains the reference drug. Prednisolone has the advantage of being soluble in water, making treatment easier in young children. The ISKDC regimen consists of prednisone, 60 mg/m^2/day with a maximum of 80 mg/day, in divided doses for 4 weeks followed by 40 mg/m^2 on alternate days for 4 weeks. A response occurs in most cases within 10–15 days. Approximately 90% of responders enter in remission within 4 weeks after starting steroids, whereas less than 10% go into remission after 2–4 more weeks of a daily regimen or three to four pulses of methylprednisolone (1 g/1.73 m^2). This latter regimen seems to be associated with fewer side effects than prolongation of daily high-dose steroids.

The number of children with frequent relapses is decreased with a longer course of prednisone. A longer duration is more important than the cumulative dose of prednisone in reducing the risk of relapse. This relative risk decreases by 0.133 (13%) for every additional month of treatment up to 7 months.

Steroid-responsive INS

In the majority of children, INS is steroid responsive. Approximately 30% of them have only one attack and are definitively cured after a single course of steroids. Ten to 20% of patients experience relapses several months after stopping treatment and most of them are cured after three to four relapses which respond to a standard course of steroids. The remaining 50–60% relapse as soon as steroid therapy is stopped or when the dosage is decreased. These steroid-dependent patients often raise difficult therapeutic problems. As long as the nephrotic syndrome responds to therapy, there is very little risk of progression to chronic renal failure.

Treatment of Relapses

Fifty to sixty percent of children experience relapses as soon as steroid therapy is stopped or when dosage is

decreased. Steroid-dependent patients may be treated with repeated courses of prednisone. Another option consists of treating relapses with daily prednisone, 40–60 mg/m^2, until proteinuria has disappeared for 4–5 days. Thereafter, prednisone is switched to alternate days and the dosage is tapered to 15–20 mg/m^2 every other day, according to the steroid threshold. Treatment is then continued for 12–18 months. This regimen is associated with less steroid side effects as the cumulative dosage is lower. The risk of relapse during upper respiratory tract infections is decreased when steroid therapy is given daily for 5–7 days rather than on alternate days.

Alternative Treatments

An alternative treatment is indicated in children who develop severe side effects of steroid therapy such as statural growth impairment, in children at risk of toxicity (diabetes or during puberty), in children with severe relapses accompanied by thrombotic complications or severe hypovolemia, and in those with poor compliance.

Levamisole at a dose of 2.5 mg/kg every other day reduces the risk of relapse in steroid-dependent patients. However, the beneficial effect of levamisole is not sustained after stopping treatment. Side effects occasionally include neutropenia, agranulocytosis, vomiting, cutaneous rash, vasculitis, and neurological symptoms including insomnia, hyperactivity, and seizure.

Alkylating agents such as cyclophosphamide and chlorambucil can induce long-lasting remissions in patients who are frequent relapsers or steroid dependent. Data from the literature show a remission rate of 67–93% at 1 year and 36–66% at 5 years following a course of cyclophosphamide. The therapeutic effect is related to the duration of treatment. The response to cyclophosphamide is also related to the pattern of response to steroids. The duration of remission is higher in frequent relapsers as compared to steroid-dependent patients. Cyclophosphamide is given at a dose of 2 mg/kg/day (cumulative dose 168 mg) to patients with steroid dependency who have evidence of steroid toxicity.

Remissions may also be obtained with chlorambucil. The recommended dosage is 0.2 mg/kgBW for 2 months.

Side effects of alkylating agents limit their use. Bone marrow toxicity requires regular blood cell counts. The treatment should also be discontinued in case of infection. The risks of varicella should be explained to the parents in order to rapidly start acyclovir treatment. Alopecia and hemorrhagic cystitis rarely occurs with the dosage used in these patients. Gonadal toxicity is well established and the risk is greater in boys than in girls. The gonadal toxicity threshold is between 200 and 300 mg/kgBW for cyclophosphamide and 8–10 mg/kgBW for chlorambucil.

Mycophenolate mofetil (MMF) treatment has a beneficial effect in children with steroid-dependent INS and allows to decrease or stop steroid therapy in 40–75% of children. However, relapses are nearly constant after cessation of treatment. Doses of 450–600 mg/m^2 day in two divided doses are usually given. Side effects including gastrointestinal disturbances (abdominal pain, diarrhea) and hematologic abnormalities are rare. Many authors now recommend the use of MMF rather than alkylating agents in children with steroid-dependent INS who suffer from side effects of steroid therapy.

Cyclosporine is effective in inducing or maintaining remission in 85% of patients with frequently relapsing or steroid-dependent NS, thereby allowing withdrawal of prednisone. The dose should preferably not exceed 5 mg/kg/day in two oral doses. Most patients relapse within the few months following cessation of treatment. Thus, cyclosporine may have to be administered for long periods of time, exposing patients to its potential nephrotoxicity. As a result, the plasma creatinine concentration should be monitored regularly. Serial renal biopsies after 18 months of therapy can demonstrate histologic lesions of nephrotoxicity without clinical evidence of renal function impairment. Other side effects include hypertension, hyperkalemia, hypertrichosis, gum hypertrophy, and hypomagnesemia.

Rituximab has been reported to be effective in patients with severe steroid-dependent nephrotic syndrome. In a multicenter series, 22 children with severe steroid-dependent nephrotic syndrome or steroid-resistant but cyclosporin-sensitive INS were treated with two to four infusions of rituximab. Rituximab was effective in all patients when administered during a proteinuria-free period in association with other immunosuppressive agents. Remission was induced in three of the seven proteinuric patients. One or more immunosuppressive treatments could be withdrawn in 19 patients (85%), with no relapse. When relapses occurred, they were always associated with an increase in CD19 cell count. Adverse effects were observed in 45% of cases, but most of them were mild and transient.

Steroid-resistant INS

It represents 10% of cases of INS and is a heterogeneous entity as different diseases are included under the same denomination.

During the recent years, there have been several reports on the molecular basis of familial cases of FSGS.

Mutations in several genes such as NPHS2, NPHS1, or WT1 may be responsible for steroid-resistant nephrotic syndrome with FSGS (Table 301.1). Podocin mutations are found in more than 40% of autosomal recessive steroid-resistant INS and 10–20% cases of sporadic steroid-resistant INS. Because immunosuppressive therapy has not been shown to be effective in treating children with SRNS due to NPHS2, NPHS1, or WTI mutations, identifying these patients can avoid unnecessary exposure to these medications and their side effects. Thus, screening for such mutations should be performed in those with a familial history of SRNS and children with steroid-resistant disease

The optimal approach to the treatment of steroid-resistant INS not due to a genetic defect is uncertain. A treatment with cyclosporine and prednisone may be given provided the glomerular filtration rate is normal. There is evidence that tacrolimus is effective in a significant proportion of patients with steroid-resistant INS. A course of methylprednisolone pulses with alkylating agents may be another option. There is no evidence that mycophenolate mofetil is beneficial to these patients.

The long-term prognosis of steroid-resistant INS is dominated by the risk of progression to end-stage renal failure. Renal survival rate in Caucasian children is approximately 50% at 10 years. Progression to ESRF has been reported to be more frequent and more rapid in patients with African or Hispanic descent when compared to Whites.

About 30% of patients with steroid-resistant INS who progress to renal insufficiency present a recurrence of proteinuria after renal transplantation. Several risk factors for recurrence have been identified: onset of disease after 6 years of age, a rapid progression to renal failure, diffuse mesangial proliferation on initial renal biopsy, and a recurrence on a first graft.

Primary Glomerulonephritis

Membranous glomerulonephritis (MGN) is characterized by a diffuse thickening of the capillary walls due to immune deposits on the epithelial side of the GBM. By immunofluorescence, these deposits are granular and peripheral. They are stained mainly with anti-IgG serum. Patients with MGN develop proteinuria which may be asymptomatic and responsible for a nephrotic syndrome. Microscopic hematuria is frequent. Hypertension and renal insufficiency are exceptional early in the course of the disease. The prognosis is often good with a disappearance of proteinuria within a few months or years. Less than 10% of cases progress to renal failure. MGN may be secondary to systemic lupus erythematosus, an infection (hepatitis B, congenital syphilis), or to the administration of drugs such as penicillamin or gold salts. The treatment depends on the underlying disease and the severity of the clinical manifestations.

Membranoproliferative glomerulonephritis (MPGN) is characterized by mesangial hypercellularity, an increase of mesangial matrix, and a thickening of the capillary walls secondary to subendothelial extension of the mesangium. MPGN have been subdivided in three types according to morphological features. Type I MPGN, with subendothelial deposits, the most frequent, is associated with classical complement pathway activation. Type II MPGN or dense deposit disease is associated with an alternate complement pathway activation and intramembranous dense deposits and represent 10–20%

Table 301.1
Genetic forms of nephrotic syndrome with FSGS

Disease	Locus	Transmission	Gene	Protein
SRNS + FSGS	1q25–31	AR	*NPHS2*	Podocine
SRNS + FSGS or DMS	10q23	AR	*NPHS3*	Phospholipase C ε 1
CNS ou SRNS	19q13.1	AR	*NPHS1*	Nephrin
Susceptibility to FSGS	2q34–36	AR	*CD2AP*	CD2 associated protein
SRNS + FSGS	9q13	AD	*ACTN4*	α-Actinine
SRNS + FSGS	11q	AD	*TRPC6*	Calcium channel
Schimke syndrome	6p12	AR	*SMARCAL1*	Regulator of chromatin
Frasier syndrome	11p13	AD	*WT1*	WT1 protein
Mitochondrial cytopathies	mtADN	Maternal	mtADN	Respiratory chain protein

of cases. Type III MPGN, observed in less than 5% of cases, is characterized by subenthothelial and subepithelial deposits and by complex alterations of the GBM. More than 50% of patients have a low concentration of C3 due to the activation of the C3 convertase by autoantibodies, called nephritic factors (NeF). The C3NeF of the amplification loop is an IgG autoantibody which reacts with activated factor B of the C3 convertase and is observed in dense deposit disease with or without partial lipodystrophy. The C3NeF of the terminal pathway is observed in type III MPGN and also in some patients with Type I MPGN. Patients may present with acute nephritic syndrome, asymptomatic proteinuria, or nephrotic syndrome. Hematuria, macroscopic or microscopic, is most often present. MPGN may occur in patients with HBV or HCV infection. In the long term, more than 50% of patients progress to renal failure. Some children with MPGN respond to steroid therapy.

IgA nephropathy (Berger disease) is a frequent glomerular disease which affects boys more often than girls. The age at discovery is variable, but more often between 7 and 13 years. Macroscopic hematuria is the presenting symptom in 75% of cases. Recurrent episodes of macroscopic hematuria occur often within 2 days following an episode of upper respiratory tract infection. In other children, the disease is discovered at routine urine analysis because of microscopic hematuria and proteinuria. Blood pressure is usually normal. Serum IgA levels are increased in 50% of cases. Renal biopsy shows moderate histological lesions with mesangial deposits and mesangial hypercellularity, and less frequently segmental and focal glomerulonephritis (*Fig 301.2*) or endo-extracapillary glomerulonephritis. Mesangial deposits stains mainly for IgA, and less for IgG and C3. The presence of permanent proteinuria with or without nephrotic syndrome is a factor of poor prognosis with a possible progression to renal failure which occurs in 10% of cases after 10–15 years.

Anti-GBM nephritis is rare in children. It may be isolated or present with pulmonary hemorrhage (Goodpasture syndrome). Renal symptoms consist of hematuria, proteinuria with nephrotic syndrome, and renal failure. The diagnosis is confirmed by the presence of circulating IgG antibodies to the GBM by ELISA assay or by indirect immunofluorescence on normal kidney. Renal biopsy shows crescentis glomerulonephritis with linear deposits of IgG along the GBM by immunofluorescence. A prompt diagnosis is mandatory as only an early treatment with steroids, cyclophosphamide, and plasma exchanges may prevent the progression to end-stage renal failure.

Renal vasculitis the most frequent type of glomerulonepritis is microscopic polyangiitis involving glomerular capillaries. ANCA are present in most cases and are directed against myeloperoxydase (P-ANCA). In children, Wegener's granulomatosis is rare. Upper-respiratory symptoms are frequent and ANCA are directed against proteinase 3 (C-ANCA). Renal biopsy shows

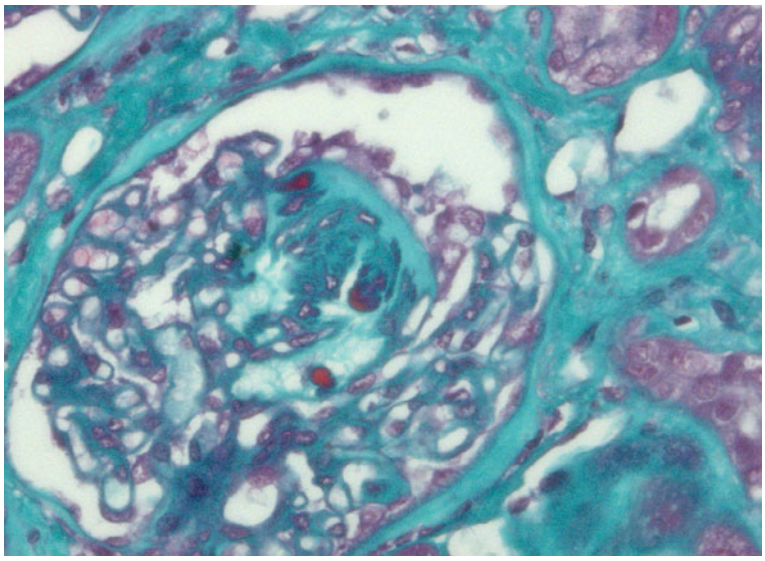

Figure 301.2

necrotizing glomerulonephritis with extracapillary proliferation without immune deposits. Corticosteroids and cyclophosphamide have greatly improved the prognosis.

Secondary Glomerulonephritis

Acute post-infectious glomerulonephritis occurs most often 10–20 days after a streptococcal infection. The child presents with an acute nephritic syndrome including hematuria, proteinuria, hypertension, and renal failure. Some patients develop nephrotic syndrome. Complement abnormalities include low CH50 and low C3. Renal biopsy, when performed, shows proliferative glomerulonephritis with infiltrating neutrophils and subepithelial humps. In severe cases, cellular crescents develop. C3 deposits are present in the mesangium and along the capillary walls. Most patients recover normal renal function within 3 weeks with supportive therapy. Steroid-pulse therapy is proposed to patients with rapidly progressive glomerulonephritis and extensive crescent formation.

Schönlein-Henoch purpura (SHP) nephritis is observed in 30–50% of children with SHP and manifests most often during the first 3 months. Hematuria, almost constant, may be accompanied by proteinuria and nephrotic syndrome. Renal biopsy shows IgA deposits and variable mesangial and extracapillary cell proliferation. Patients with nephrotic syndrome often have severe histological lesions with crescentic glomerulonephritis and a risk of progression to end-stage renal failure. In such cases, steroid therapy may be proposed.

Systemic lupus erythematosus renal disease is frequent in children with SLE. Nephrotic syndrome is observed in patients with more severe renal involvement, often in association with acute renal failure. Renal biopsy may show diffuse proliferative glomerulonephritis or membranous nephropathy with immunoglobulin and complement deposits. The presence of anti-DNA antibodies is highly suggestive of SLE and low C3 concentration is suggestive of an active disease.

Bacterial infections infective endocarditis may be associated with glomerulonephritis. The clinical manifestations are similar to those observed in acute glomerulonephritis. Nephrotic syndrome is unusual. Nephrotic syndrome is more frequent in shunt nephritis secondary to infected ventriculoatrial shunt. C3 and C4 levels are reduced in both conditions, and renal biopsy may show a pattern of membranoproliferative glomerulonephritis or acute post-streptococcal glomerulonephritis.

Other Causes

Amyloidosis

In children, amyloidosis is most often secondary to chronic inflammatory diseases (chronic juvenile arthritis, Crohn disease), to prolonged infections (tuberculosis, osteomyelitis, bronchestasis), to cystic fibrosis or familial Mediterranean fever. Amyloid deposits are present in the mesangium, the capillary walls, and the tubular basement membranes. In case of glomerular deposits, patients often present with proteinuria and nephrotic syndrome. The treatment of the cause, if possible, may prevent the progression to renal failure.

Alport Syndrome

Alport syndrome is an inherited renal disorder characterized by a progressive hematuric nephritis with ultrastructural changes of the glomerular basal membrane and sensorineural hearing loss. Mutations in the *COL4A5* gene are responsible for the more frequent X-linked form of the disease. All affected males progress to renal failure, whereas in most female patients, the course is considered to be benign. Mutations in the *COL4A3* or *COL4A4* genes are responsible for an autosomal recessive form of the disease observed in approximately 15% of patients. The disease is as severe in male as in female. The presence of massive proteinuria with nephrotic syndrome is suggestive of a poor prognosis and is associated with a progression to ESRD.

Nail–Patella Syndrome

The nail–patella syndrome or osteo-onychodysplasia is an autosomal dominant disorder characterized by hypoplastic or absent patella, dystrophic fingernails and toenails, and dysplasia of elbows and iliac horns. Renal symptoms are present in approximately 50% of patients. The most frequent symptoms are proteinuria, sometimes with a nephrotic syndrome, and hematuria. End-stage renal disease develops in approximately 30% of cases. The abnormal gene, located at the distal end of the long arm of chromosome 9, encodes a transcription factor of the LIM-homeodomain type named *LMX1B*, which plays an important role for limb development in vertebrates.

Hemolytic Uremic Syndrome

Hemolytic and uremic syndrome is characterized by the association of hemolytic anemia, thrombopenia, and renal disease secondary to thrombotic microangiopathy. The typical form is the most frequent in children occurring after an episode of diarrhea caused by *Escherichia coli*. Other germs may be responsible for HUS such as *Shigella dysenteriae* or *Streptococcus pneumoniae*. Children present with acute renal failure which is reversible in most cases. Atypical HUS is less frequent but of poorer prognosis. The patients may develop nephrotic syndrome and renal failure. Atypical HUS may be associated with mutations in the genes for complement proteins including C3, factors H, B, and I, and CD46. It is estimated that approximately 50 percent of cases of atypical HUS result from mutations in these genes. Atypical HUS may also be associated with von Willebrand factor-cleaving protease deficiency, congenital intracellular defects of vitamine B12 metabolism, or may be of unknown origin. Familial forms are frequent.

Sickle Cell Disease

Proteinuria with nephrotic syndrome and sometimes renal failure may develop in patients with sickle cell disease. Renal biopsy shows glomerular enlargement and focal and segmental glomerular sclerosis and less often a picture of membranoproliferative glomerulonephritis with IgG and C3 deposits.

Renal Hypoplasia and or Dysplasia

Children with renal hypoplasia or renal dysplasia usually do not have signs of glomerular involvement. The occurrence of proteinuria is often related to lesions of focal and segmental glomerular sclerosis secondary to severe nephron reduction and is observed in association to chronic renal failure.

302 Juvenile Nephronophthisis

Abdelaziz Y. Elzouki · Laurel Steinmetz

Renal cysts are derived from tubular epithelium that proliferates abnormally to generate the wall delineating the cyst; fully developed renal cysts are, in fact, tumor masses that are filled with liquid rather than with cells. Cysts may occur in cortex, medulla, or both regions. Hereditary renal cystic disorders are a diverse group of clinical categories having in common only the presence of cystic structures in renal parenchyma. The following two chapters focus on the major hereditary renal cystic diseases that have clinical importance in the pediatric population, including juvenile nephronophthisis (NPH), medullary cystic kidney disease (MCD), autosomal recessive polycystic kidney disease (ARPKD), and autosomal dominant polycystic kidney disease (ADPKD).

Juvenile Nephronophthisis

Juvenile NPH is responsible for 10–20% of chronic renal failure in children and is the most common genetic cause of end-stage renal disease in children. The onset of NPH is insidious, and the condition is usually not clinically diagnosed until the patient is in advanced renal failure. MCD is clinically and histologically indistinguishable from NPH; nevertheless, the two forms can be distinguished on the basis of inheritance and evolution – NPH is an autosomal recessive disorder while MCD is autosomal dominant disorder, in NPH end-stage renal failure is encountered during early adolescence while it occurs after fourth decade of life in MCD.

Epidemiology

NPH affects girls and boys equally.The incidence is approximately 0.13 for 10,000 live births in Finland, whereas in Canada, it is 1 per 50,000 live births and in United States 9 per 8.3 million. The disorder has been reported worldwide.

Genetics

These disorders include juvenile nephronophthisis, Senior-Loken syndrome, Joubert syndrome, Meckel-Gruber syndrome, and medullary cystic kidney disease. While renal imaging and histology are similar, there is a diverse phenotypic range in both renal disease progression and extrarenal manifestations. Several different gene mutations have been implicated in this heterogeneous group of disorders. Amongst those are NPHP1-9 and AHI1 in nephronophthisis (*Table 302.1*) and MCDK1-2 in MCDK. NPHP1 was the first gene mutation identified and the most prevalent. NPHP1 homozygous deletion is present in 20–40% of nephronophthisis cases. The other mutations are much less common accounting for less than 2% of the cases individually. While most of these mutations have been associated with retinitis pigmentosa, NPHP5 and 6 are often associated with more severe retinal disease such as Leber's congenital amaurosis.

Etiology

Through recognition of these genes and others implicated in cystic kidney diseases, a new unifying theory of renal cystogenesis has emerged. This theory states that proteins implicated in renal cyst development are expressed in the centrosome, basal body, or primary cilia. Cilia are hair-like structures found on almost every type of vertebrate cell explaining the extrarenal involvement associated with these disorders. The proteins involved in ciliary function are highly conserved amongst organisms and many of the gene products implicated in renal cystic disease interact with each other in the ciliary complex. These findings support reclassification of many cystic kidney diseases as ciliopathies. Several potential mechanisms for renal cyst development in nephronophthisis exist. They include: (1) the mechanosensory mechanism whereby ciliary bending defects lead to changes in calcium influx altering cell

signaling pathways, (2) defective membrane and centrosome proteins lead to disruption of normal cell–cell and cell–matrix signaling, (3) improper planar polarity of tubules due to dysregulation of the WNT pathway, (4) abnormal apoptosis of normal renal cells leading to proliferation of cystic lesions at the expense of normal kidney tissue which is unique to nephronophthisis compared to the polycystic kidney diseases with enlarged kidneys.

Pathology

The disease is characterized by the presence of cysts in the medulla and corticomedullary junction. The size of the cysts ranges from less than 0.5 mm to 2 cm in diameter. The characteristic pathologic feature in renal biopsy is the presence of chronic tubulointerstitial inflammation and fibrosis (*Fig. 302.1*).

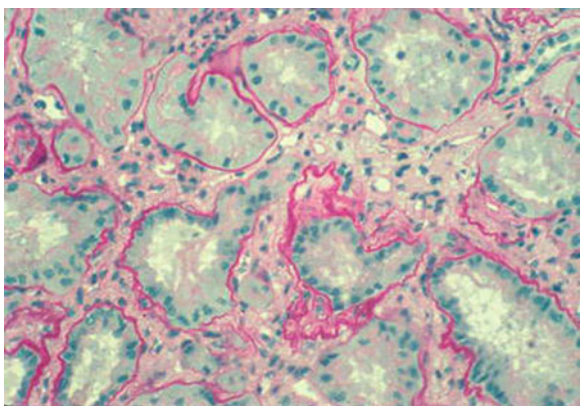

Figure 302.1
Renal histology of nephronophthisis showing diffuse interstitial fibrosis and various tubular changes (Reproduced from Salomon R, Saunier S, Niaudet P (2009) Nephronophthisis. Pediatr Nephrol 24(12):2333–2344, fig. 1)

Clinical Features

Usually the child presents with clinical and laboratory findings of chronic renal failure at the age of 10–12 years. Other characteristic clinical features include history of polyuria and polydipsia, history of salt craving, failure to thrive, normal blood pressure, parental consanguinity, and the presence of retinal abnormalities. Urinalysis is unremarkable, but urinary concentrating ability is impaired.

Extrarenal manifestations (*Table 302.2*):

1. A retinopathy known as a tapetoretinal degeneration also known as retinitis pigmentosa (*Fig. 302.2*) (Senior-Loken syndrome), seen in 18% of cases.

Table 302.2
Extrarenal manifestations in nephronophthisis

Ectodermal dysplasia (Sensenbrenner syndrome)

Reproduced from Salomon R, Saunier S, Niaudet P (2009) Nephronophthisis. Pediatr Nephrol 24(12):2333–2344, Table 2
[a]Personal data

Retinitis pigmentosa(RP) has been observed in association with mutations in most NPHP genes (except NPHP7), but whereas RP is always present and severe in patients with NPHP 5 and NPHP 6 mutations, the symptoms are in general mild in patients with mutations in the other NPHP genes.

2. Leber congenital amaurosis. In the early-onset form, affected children are blind from birth, have specific electroretinogram findings, and develop retinitis pigmentosa. In the late-onset type, blindness occurs later in childhood. Other eye abnormalities include coloboma, cataracts, amblyopia, and nystagmus.
3. Neurologic associations such as cerebellar ataxia, developmental delay (Joubert syndrome) JS is autosomal recessive neurological disorders can be associated with NPH and is characterized by complex cerebellar and brain stem malformation the so called "molar tooth sign" observed by MRI (*Fig. 302.3*).

   Other neurological associations with NPH include recurrent seizures and mental retardation.
4. Congenital hepatic fibrosis.
5. Skeletal abnormalities, including cone-shaped epiphyses in the hand phalanges, metaphyscal chondrodysplasia of the femoral necks (Saldino-Mainzen syndrome), and Jeune asphyxiating thoracic dysplasia.
6. Other syndromes that feature NPH are described in *Table 302.3*.

Diagnosis

Medullary cysts, although regarded as the hallmark of this condition, are seldom seen in percutaneous renal biopsy specimens, even though medullary tissue may be present, presumably because of their uneven distribution. Ultrasonography has been used, but there are many other medical causes of chronic renal failure that show parenchymal heperechogenicity and loss of corticomedullary differentiation echogenic, and cysts may be too small to be detected by ultrasonography. Computerized tomography (CT) scan has been underutilized as a diagnostic tool in this disease entity. The recommended technique for CT scan examinations is contrast-enhanced 1- to 2-mm sections throughout the kidneys. Lesions are usually shown as multiple cysts, typically located at the medulla and corticomedullary region (*Fig. 302.4*). The thin 1- to 2-mm sections recommendation is based on the fact that the size of the cysts ranges from less than 0.5 mm to 2 cm in diameter.

The detection of homozygous mutations by polymerase chain reaction (PCR) amplification permit fast and accurate diagnostic evidence. When a deletion has been demonstrated in one child, it should be sought in siblings to determine those who are affected.

Management

Usually the patient presented with clinical features of chronic renal failure. The immediate and long-term

management is as for children with chronic renal failure (see Chap. 313, "Chronic Renal Failure"), which includes correction of metabolic acidosis and electrolyte imbalance, treatment of osteodystrophy, nutritional support, and dialysis or kidney transplant.

Infantile Nephronophthisis

A chronic autosomal recessive tubulointerstitial nephritis with cortical microcysts progressing to end-stage renal disease before 2 years of age, severe hypertension is common. Ultrasonography usually shows moderately enlarged kidneys.

303 Autosomal Dominant Polycystic Kidney Disease/Autosomal Recessive Polycystic Kidney Disease

Abdelaziz Y. Elzouki · Laurel Steinmetz

Autosomal Dominant Polycystic Kidney Disease

ADPKD, the most prevalent hereditary renal cystic disorder, affects approximately 1:400 to 1:1,000 persons in the United States and is the fourth leading cause of chronic renal failure throughout the world. ADPKD is rarely diagnosed in infancy and childhood. Most reported cases present at birth with an abdominal mass or are found through screening members of families with ADPKD.

Genetics

ADPKD is inherited in an autosomal dominant fashion with full penetrance. A family history of ADPKD is elicited in approximately 60% of affected persons. A lack of family history is probably related to the variability of expression of the disease. ADPKD is a genetically heterogeneous disease with multiple different mutations in two genes, PKD1 and PKD2. PKD1 mutations tend to lead to end-stage renal disease at a younger age than mutations in PKD2. However, no specific mutations have been correlated with disease phenotype. PKD1 is a large gene on chromosome 16p13.3 and its mutations account for 85% of cases. PKD2 is a smaller gene on 4q21–23 and accounts for 14% of cases.

Only 5–10% of mutations are sporadic.

Preliminary evidence indicates that a third genotype, PKD3, has been identified in 1% of patients, but no genomic locus has been assigned.

Etiology

Cystogenesis in ADPKD is related to defects in polycystins, proteins, which localize to the cell membrane and cilia. Specifically defects in polycystin 1, coded for by PKD1, and polycystin 2, coded for by PKD2 contribute to cyst development. Polycystin 1 is expressed in heart, brain, bone, and muscle while polycystin 2 is expressed in reproductive organs, vascular smooth muscle, kidney, heart, and small intestine. Evidence suggests that these two proteins form a complex in the primary cilia contributing to its mechanosensory ability and that disruption of this ability contributes to cystogenesis. Polycystin 1 is also involved in cell–cell signaling, mechanosensory machinery, intracellular signaling including cell cycle regulation and proliferation, fluid production, and cell polarity. Polycystin 2 is responsible for intracellular calcium influx thought to alter gene expression. Evidence suggests that cystogenesis in ADPKD requires a two hit hypothesis where a patient inherits one mutation and then later develops a second somatic mutation leading to cyst development. The two hit hypothesis would explain why the cyst pattern in ADPKD is focal. This theory may also explain why cysts form at different times even amongst individuals who inherit the same genetic mutations.

Pathology

Renal architecture is distorted by multiple cysts whose number and size increase with increasing age. Cysts may be seen in liver and pancreas. Approximately 10% of patients develop berry aneurysms of the cerebral circulation, and hepatic fibrosis occurs occasionally.

Clinical Features

There are four ways in which ADPKD presents in childhood: (1) prenatal or neonatal presentation, which resembles the clinical presentation of ARPKD (i.e., bilateral renal mass, hypertension, respiratory distress, and renal insufficiency; (2) evaluation of asymptomatic siblings of families with ADPKD; (3) symptomatic children with a family history of ADPKD; and (4) symptomatic patients

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_303,

with no family history of polycystic kidney disease (PKD) for whom a parent is found to have PKD as a result of the evaluation of the parents. Usually these symptomatic children present with gross hematuria or hypertension and renal cysts on ultrasonography.

Extrarenal complications include cardiac valve abnormalities, cerebral berry aneurysms, hepatic, pancreatic, and spleen cysts.

Many studies in adults have been shown that patients with mutations in the PKD2 gene have a better prognosis than do PKD1 patients: In a study on genotype–phenotype correlation in children with ADPKD, PKD1 children had more and larger renal cysts, larger kidneys, and higher ambulatory blood pressure than PKD2 children. Prenatal finding of renal cysts or postnatal enlarged kidneys were observed only in patients with mutations in PKD1 gene.

Diagnosis

The renal ultrasonography of a neonate with ADPKD demonstrates large kidneys with hyperechoic parenchyma and no differentiation between cortex and medulla. It is possible to diagnose ADPKD prenatally with the use of DNA obtained from amniocentesis or chorionic villus sampling by the gene linkage techniques, but clinicians do not think this late-onset disease warrants interruption of pregnancy. In older children the renal ultrasonography demonstrates the cyst (*Fig. 303.1*). The sensitivity of CT scan is greater than that of ultrasonography (*Fig. 303.2*).

In adult patients younger than 30 years of age, the presence of two cysts, either unilateral or bilateral, is sufficient to make the diagnosis. In patients 30–59 years old, at least two cysts in each kidney are essential for the diagnosis. DNA linkage analysis testing is useful in determining the disease status of relatives with normal kidneys who wish to be considered as potential donors for living kidney transplantation.

Treatment

Early disease detection has traditionally led to problem with insurability and later employment but has offered these individuals little benefit if any in term of treatment option. New potential targets for therapies stemming from animal and bench research have been surfaced these include:

1. Clinical trials to explore the role of inhibition of renin-angiotensin-aldosterone system(RAAS), utilizing combination therapy ACEI and ARB in treatment of hypertensive individuals with ADPKD.
2. Agents that inhibit cell growth and proliferation utilizing an inhibitor of the mammalian target of rapamycin mTOR, treatment studies are now underway in adults with ADPKD to determine if Sirolimus that is widely used in transplant recipients is effective in slowing the progression of the disease.
3. Vasopressin V2 receptor antagonists are also demonstrating potential therapeutic benefits in APKD.

Although the translation of these new potential targets for therapies into meaningful safe remedies in human will

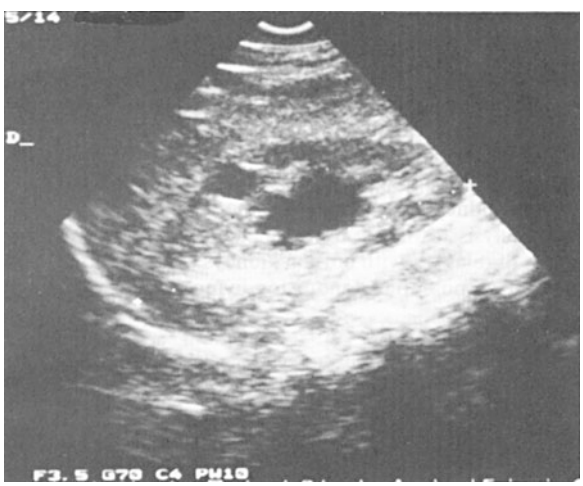

Figure 303.1
Renal ultrasonography in a child with a diagnosis of ADPKD. Note the large cyst (Reproduced from chap. 108, first edition, fig. 2)

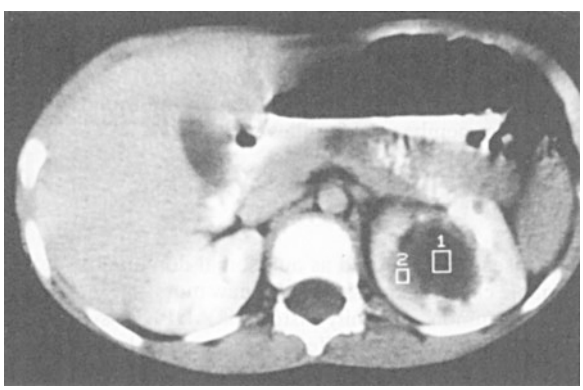

Figure 303.2
Contrast-enhanced computerized tomography scan demonstrates large cyst in left kidney in a child with a diagnosis of ADPKD (Reproduced from chap. 108, first edition, fig. 3)

take time and scrutiny, it is likely that children with ADPKD will benefit from those outstanding scientific contributions in near future.

Autosomal Recessive Polycystic Kidney Disease

ARPKD has previously been referred to as "infantile polycystic kidney disease"; however, the disease can present at any age, from the prenatal period through adolescence, and in a few patients ARPKD is not recognized until adulthood.

The pathologic findings of the disease include varying degrees of cystic dilation of the distal tubules and collecting ducts throughout the cortex and medulla, varying degrees of biliary dysgenesis, and hepatic fibrosis.

Epidemiology

The reported prevalence varies from 1:600 to 1:55,000 live births. Gene frequency is in a range from 1:40 to 1:100.

Genetics

This disease is inherited in an autosomal recessive pattern. Mutations have been found in the PKHD1 gene on chromosome 6p21. This gene is large and multiple different types of mutations have been found. Variability in age of onset is related to different expression of mutation and modifier genes. Patients with two truncating mutations will die in the perinatal period. Missense mutations tend to cause less severe phenotypes. PKHD1 encodes the protein fibrocystin, also known as polyductin.

Etiology

Fibrocystin is thought to contribute to normal ciliary development. However, its precise function has not been elucidated. Studies suggest that it complexes with polycystin 1 and 2 and plays a role in intracellular calcium signaling. It also may contribute to normal tubule morphogenesis. In addition, cyclic AMP and epidermal growth factor receptor also play a role in cystogenesis in ARPKD models.

Clinical Presentation

Prenatally the findings of oligohydramnios, bilateral enlarged kidneys that are diffusely echogenic, and the absence of fluid in the fetal bladder are consistent with a diagnosis of ARPKD. Elevation of α-fetoprotein levels in maternal serum and amniotic fluid may complement the prenatal ultrasonographic diagnosis.

The newborn usually presents with bilateral massively enlarged kidneys and respiratory distress, which is a complication of pulmonary hypoplasia or pneumothorax. Severely affected neonates may demonstrate the Potter phenotype (i.e., deep-set eyes, flat beaked nose, micrognathia, low-set ears, and joint deformities). Later in infancy and childhood, those who survive the neonatal period will develop the sequelae of renal insufficiency (i.e., failure to thrive, anemia, and renal osteodystrophy). The majority of patients have a concentrating defect with polyuria and polydipsia. Hyponatremia and metabolic acidosis have been described.

Hypertension occurs in nearly all patients with ARPKD. It was reported that all affected infants who had blood pressure measurements at 3 months of age were hypertensive. The degree of hypertension has been noted to be most severe in the first year of life and may be responsible for early death in many of these patients.

Extrarenal manifestations include:

Liver Disease. The liver disease in ARPKD is primarly manifest by two major types of pathophysiology biliary disease and portal hypertension.There is considerable variability in the severity of liver disease in ARPKD.

The complications of hepatic fibrosis and portal hypertension are seen more frequently in older children. These complications include hepatosplenomegaly, bleeding esophageal varices, and hypersplenism sequelae (i.e., anemia, thrombocytopenia, and leukopenia).

The most common manifestations of biliary disease are sepsis/cholangitis and or complication of cholelithiasis.

Standard liver biochemical testing is typically normal in children with ARPKD with liver disease and thus may not necessary be useful as screening tools.

A combination of physical examination (finding of splenomegly) and CBC (finding of cytopenia) and abdominal ultrasonography is a reliable method for screening for evidence of portal hypertension.

Intracranial Aneurysm. The incidence of intracranial aneurysm is well-known extrarenal manifestation of ADPKD, the incidence is about 10%; there are reported cases of intracranial aneurysm in patients with ARPKD (*Fig. 303.3*).

Diagnostic Imaging

The abdominal ultrasound usually shows enlarged kidneys with hyperechoic parenchyma and no differentiation

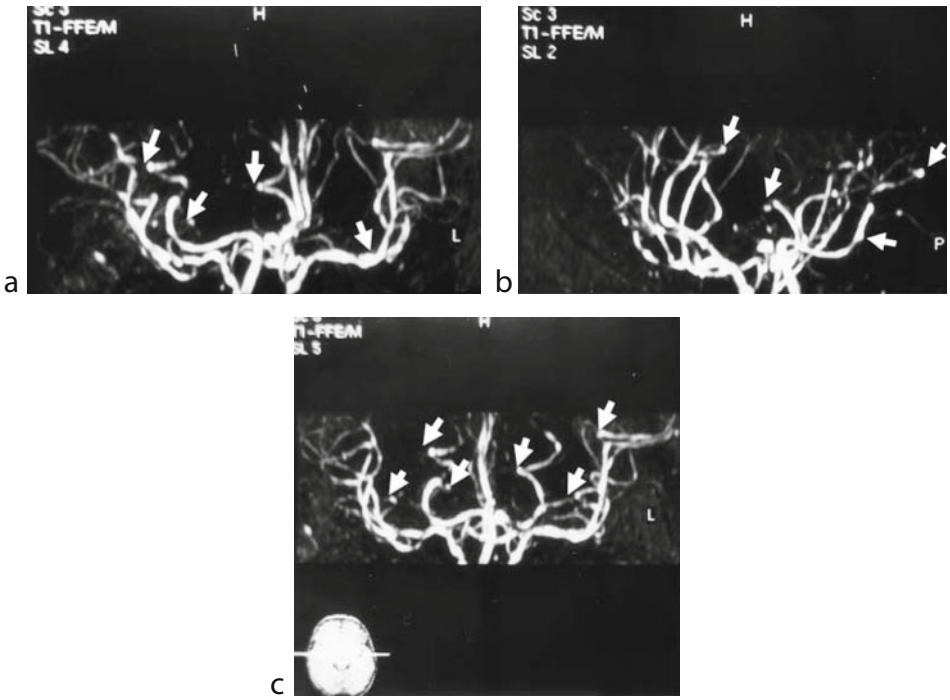

Figure 303.3
Magnetic resonance of brain angiography of multiple intracranial aneurysms in the branches of middle and posterior cerebral arteries (Reproduced from Lilova MI, Petkov DL (2001) Intracranial aneurysm in a child with Autosomal Recessive Polycystic Kidney Disease. Pediatr Nephrol 16:1030–1032)

between cortex and medulla (*Fig. 303.4*). The liver is usually normal in size and less echogenic than the kidney; dilated intrahepatic biliary ducts may be demonstrated. The presence of portal hypertension on Doppler ultrasonography indirectly indicates the presence of hepatic fibrosis. The intravenous pyelogram usually shows the classic findings of enlarged kidneys, and delayed nephrogram with medullary streaking (accumulation of contrast in dilated medullary collecting ducts). The intravenous pyelogram is not essential for diagnosis and certainly not recommended.

Magnetic Resonance (MR) cholangiography is more sensitive test for identifying biliary ectasia, recommended the MR cholangiography be performed at least once in children with ARPKD.

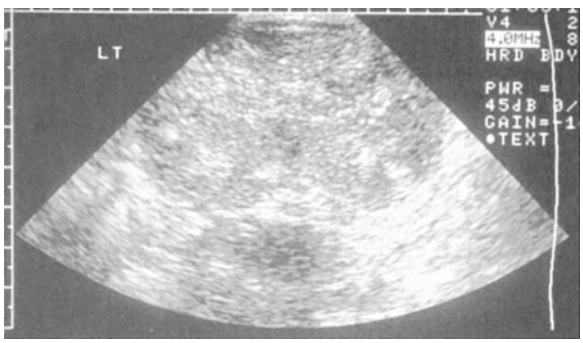

Figure 303.4
Renal ultrasonography in a child with a diagnosis of ARPKD. Note enlarged kidney with hyperechoic parenchyma and no differentiation between cortex and medulla (Reproduced from chap. 108, first edition, Fig. 4)

Management

Hypertension can be treated with calcium-channel blockers, β blockers, angiotensin-converting enzyme inhibitors, and vasodilators. Hypertension may require multiple antihypertensive agents for effective control. Supplemental bicarbonate therapy is needed for those with metabolic acidosis. The same treatment as that used for chronic renal failure (see Chap. 313, "Chronic Kidney Disease"), as well as dialysis and/or transplant, are indicated when children with ARPKD reach end-stage renal disease. For hepatic involvement, close

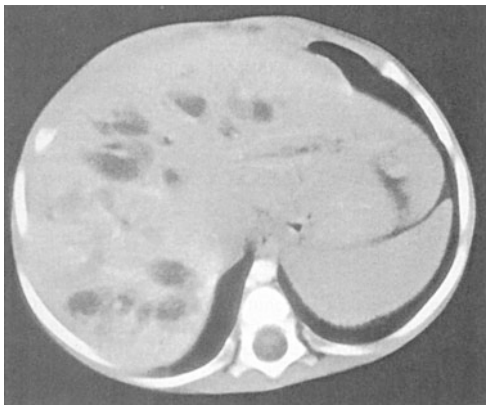
monitoring for the complications of portal hypertension and hypersplenism is necessary. Surgical intervention with portocaval and splenorenal shunts may be needed. Appropriate antimicrobial therapy should be given to those patients with a suspected diagnosis of cholangitis.

Caroli Syndrome

Caroli syndrome is characterized by the presence of autosomal recessive polycystic kidney disease, congenital hepatic fibrosis, and nonobstructive dilation of the intrahepatic bile ducts. On hepatic ultrasonography, there are saccular dilated bile ducts containing intraluminal protrusions and crossbridges, and contrast-enhanced CT scan reveals liver cysts with a "central dot sign" (◉ *Fig. 303.5*).

How to Differentiate Between ADPKD and ARPKD

Distinguishing between ADPKD and ARPKD based on clinical findings may be unreliable. Both ADPKD and ARPKD produce renal masses and hypertension in childhood. Ultrasonography may show enlarged hyperechoic kidneys in both entities; conversely, macroscopic cysts may be detected in older patients with ARPKD. The use of liver biopsy has been proposed as a means of distinguishing between ADPKD and ARPKD. The diagnosis of ARPKD cannot be supported in the presence of a normal liver. The presence of hepatic fibrosis, however, does not exclude a diagnosis of ADPKD. Congenital hepatic fibrosis has occurred in association with ADPKD. The single most useful investigation in the evaluation of a child with early onset of cystic renal disease is ultrasound of the parents and/or genetic analysis, the detection of homozygous mutations by polymerase chain reaction (PCR) amplification permit fast and accurate diagnosis evidence.



◘ Figure 303.5
Computerized tomography scan demonstrates liver cysts with a "central dot sign" in a child with a diagnosis of Caroli syndrome (Reproduced from chap. 108, first edition, Fig. 5)

304 Proximal Renal Tubular Disorders

Sami A. Sanjad

Definition and Classification

Diseases affecting the renal tubules occur due to structural or functional abnormalities in the different segments of the nephron. From a quantitative point of view the proximal tubular cells perform a remarkable job in reabsorbing the filtered plasma and its accompanying solutes. The distal tubules continue that process but are more involved in fine tuning operations, acidification of the urine, and diluting or concentrating it as necessary. In diseases of the proximal tubules, variable qualitative and quantitative degrees of aminoaciduria may be present with or without bicarbonaturia, glucosuria, uricosuria, or phosphaturia. Any combination of abnormal solute excretion is theoretically conceivable and may be found in different syndromes of proximal tubular dysfunction.

Etiology: General

Disorders of proximal tubular function may be secondary to congenital or hereditary diseases or due to acquired defects. The hereditary or congenital defects are much more prevalent and may be due to: (a) absent or defective Na-solute cotransport system in the proximal tubular cells, as seen in cystinuria, Hartnup disease, renal glucosuria, vitamin D resistant rickets, and proximal renal tubular acidosis; (b) altered gene affecting more than one transport system – adult Fanconi syndrome; (c) mutant genes resulting in endogenous tubulotoxic substances accumulated from extra renal metabolic pathways (cystinosis, galactosemia, tyrosinemia, hereditary fructose intolerance, Wilson's disease); (d) abnormal solute transport due to structural changes associated with congenital renal and urinary tract malformations (cystic diseases, nephronophthisis, and hydronephrosis).

Acquired defects of proximal tubular function are usually drug induced or related to intrinsic renal diseases (see below). This chapter covers three major disease entities associated with proximal tubular dysfunction: (1) Fanconi syndrome, (2) proximal renal tubular acidosis, and (3) disorders of phosphate transport.

Fanconi Syndrome

Also known by many other eponyms (Lignac-Fanconi, de Toni-Debré-Fanconi syndrome), the Fanconi syndrome represents a heterogeneous group of disorders which may be hereditary or acquired with a common denominator being abnormalities in the transport of multiple solutes by the proximal tubular cells. Solutes normally reabsorbed by the proximal tubules are lost in the urine in variable proportions. These include glucose, amino acids, phosphate, bicarbonate, uric acid, and low-molecular-weight proteins and cations. Most cases of Fanconi syndrome in children are secondary to inherited metabolic diseases associated with specific enzyme defects, or due to transport abnormalities across the tubular cells. Acquired Fanconi syndrome is usually due to tubulotoxic effect of several drugs and toxins or due to intrinsic renal diseases with a significant tubulointerstitial component (*Table 304.1*). When no identifiable cause is found, the Fanconi is known as primary or idiopathic and may be familial or occur sporadically.

Clinical Findings

The clinical manifestations of the Fanconi syndrome and the onset of symptoms vary with the underlying etiology. Most patients with inherited disorders present in the first year of life with failure to thrive, frequently with anorexia and vomiting. Polyuria and polydipsia with bouts of fever and dehydration may also be present. Rickets is invariably seen at some stage of the disease and may be the presenting manifestation in some children.

Pathogenesis

The pathogenesis of the Fanconi syndrome is incompletely understood and probably varies with the underlying

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_304,

etiology. It is quite possible that a dysfunction of the basolateral membrane Na-K-ATPase pump, brought about by an endogenous or exogenous toxin, would result in impaired energy production for solute reabsorption by the proximal tubule. This has been observed in several clinical and experimental disorders associated with the Fanconi syndrome.

Diagnosis

The diagnosis of the Fanconi syndrome is easily made when the above constellation of findings are seen in association with euglycemic glucosuria and mild proteinuria on routine urinalysis. Proteinuria is primarily tubular in origin and is characterized by low-molecular-weight proteins, usually less than 30,000 Da. They include lysozyme and beta$_2$-microglobulin but also a small amount of filtered albumin that escapes reabsorption by the proximal tubule. Serum analysis reveals hyperchloremic metabolic acidosis, normal urea and creatinine levels (unless severe dehydration is present), hypophosphatemia, hypokalemia, hypouricemia, and hyponatremia. This low plasma solute concentration is a reflection of their losses in the urine as a result of decreased reabsorption by the proximal tubular cells. Urine amino acid analysis reveals generalized, nonspecific aminoaciduria. Once the diagnosis of Fanconi syndrome has been reached on clinical grounds, every effort should be made to obtain an etiologic diagnosis.

Etiology of Specific Forms of the Fanconi Syndrome

Hereditary Causes of the Fanconi Syndrome

Cystinosis

Cystinosis is cited in the western literature as the most common cause of the Fanconi syndrome with an incidence of 1:200,000 live births. It is not to be confused with cystinuria which (a) does not cause the Fanconi syndrome; (b) is predominantly associated with increased urinary excretion of cystine, ornithine, lysine, and arginine; and (c) is frequently associated with cystine urolithiasis.

Cystinosis is an autosomal recessive lysosomal storage disease characterized by the accumulation of cystine in several organs including the kidney, liver, gut, spleen, bone marrow, lymphatic system, leukocytes, cornea, thyroid, and other organs. The biochemical defect is unknown but a defective transport of cystine across the lysosomal membrane appears to be the most likely cause. Three forms of cystinosis are recognized: (1) infantile or nephropathic form being the most common, (2) adolescent or late form, and (3) adult or benign ocular cystinosis.

Clinical Findings in Cystinosis

The clinical and laboratory manifestations of nephropathic cystinosis are those of the Fanconi syndrome described above and they usually become apparent in early infancy. Polyuria and polydipsia are particularly common early manifestations. Some patients may present with severe hypokalemia and alkalosis mimicking Bartter's syndrome. Growth failure is severe and associated with hypophosphatemic rickets and hyperchloremic acidosis. Although glomerular filtration rate is normal in the early phases of the disease, progressive deterioration is the rule. By the end of the first decade most children with nephropathic cystinosis will develop end stage renal disease necessitating dialysis and renal transplantation.

The extra renal manifestations of cystinosis are secondary to the accumulation of cystine crystals in different organs. Thus, corneal deposition is responsible for photophobia, excessive tearing, and blepharospasm. Hypothyroidism, characterized by high TSH levels, is a frequent occurrence, particularly in older children, but clinical hypothyroidism is uncommon. Muscular weakness and hypotonia secondary to hypokalemia and carnitine deficiency are commonly observed. Testicular deposition of

cystine crystals may explain the incomplete pubertal development frequently seen in males with cystinosis. This is associated with reduced plasma levels of testosterone but normal pituitary function. The central nervous system, initially thought to be spared in cystinosis, is now a well-known site of involvement in older patients with the disease. Symptoms vary from difficulty in walking to dysphagia, speech difficulty, and dementia. Cranial nerve involvement and pyramidal tract signs may also be seen. Retinopathy develops in a few patients and may be progressive and lead to blindness.

Adolescent and adult type cystinosis are less frequent. The clinical manifestations are insidious and the Fanconi syndrome is usually milder, occurring after the age of 8 years in the adolescent form. In the adult form of cystinosis, also known as ocular cystinosis, there is no renal involvement, but patients may complain of photophobia due to cystine deposition in the cornea.

Diagnosis

Cystinosis may be diagnosed by slit lamp examination of the cornea where cystine crystals may be seen. Bone marrow, liver or kidney biopsy may also reveal cystine crystals. Unequivocal diagnosis is made by demonstrating increased cystine content in leukocytes or rectal mucosa from affected individuals. The leukocyte cystine content is 5–15 nmol of ½ cystine/mg protein in the infantile form and less than 0.2 in normal individuals. Prenatal diagnosis is now possible by measuring amniotic fluid or cultured fibroblasts for cystine content. Molecular genetic studies have shown mapping of the cystinosis gene to chromosome 17p13. The *CTNS* gene encodes a 367-amino acid protein called cystinosin which is widely expressed in many organs, particularly pancreas, kidney and muscle. All patients with cystinosis tested have had mutations in the CTNS gene with no evidence thus far of genetic heterogeneity.

Glycogen Storage Disease (GSD)

The proximal tubular dysfunction associated with GSD is referred to as Fanconi-Bickel syndrome (GSD type 11) and was first described in 1949. Patients present typically in early infancy with failure to thrive, hypotonia, hepatomegaly, and rickets. Hyperchloremic acidosis with bicarbonate wasting is usually severe. The kidneys are usually enlarged and are loaded with glycogen. Many patients develop hypoglycemia with prolonged fasting and show impaired galactose utilization. One of the most striking abnormalities that characterizes this syndrome is the massive glucosuria, which may reach 100 g/m^2/day in some patients.

GSD appears to be relatively common in certain parts of the world. In Saudi Arabia it was diagnosed in more than one half of the cases of Fanconi syndrome (15 of 29) referred to a tertiary care center. In our experience many of these patients have a decreased or absent activity of the enzyme phosphorylase b kinase (pbk) involving liver and kidney. This was documented on liver homogenates from several patients with GSD and Fanconi syndrome who also had renal glycogen storage documented by histochemical assay. It has been subsequently shown, however, that mutations in the facilitative glucose transporter GLUT2 are causative of this syndrome and the low pbk activity detected in our patients is probably a secondary phenomenon that contributes to the deposition of glycogen in response to the intracellular glucose retention caused by GLUT2 deficiency.

Proximal tubular dysfunction has been described in a few patients with GSD type 1 (von Gierke's disease) but these are usually mild and not associated with a complete Fanconi syndrome. A more prevalent and serious finding in these patients who now are living longer than before is focal glomerulosclerosis with proteinuria and at times progressive renal failure.

Tyrosinemia Type I

Also known as hepatorenal tyrosinemia, this autosomal recessive disorder is characterized clinically by early onset of nodular hepatic cirrhosis, failure to thrive, and Fanconi syndrome. Rickets may be severe and crippling in untreated patients (*Figs. 304.1* and *304.2*). Abdominal ultrasonography reveals hepatosplenomegaly and enlarged kidneys which, combined with the biochemical findings of the Fanconi syndrome, should arouse suspicion of tyrosinemia. A presumptive diagnosis of tyrosinemia is made when the urinary excretion of succinyl acetone (SA) is elevated. Delta aminolevulenic acid (DALA) is also excreted in large amounts in the urine of patients with tyrosinemia. The metabolic defect is related to deficiency of the enzyme fumaryl acetoacetate hydrolase (FAH) which leads to accumulation of toxic precursors including SA and DALA. The FAH gene has been cloned recently and mapped to chromosome 15 (15q23–q25). Several missense mutations have been described with no evidence of phenotype genotype correlation with different clinical manifestations sometimes observed

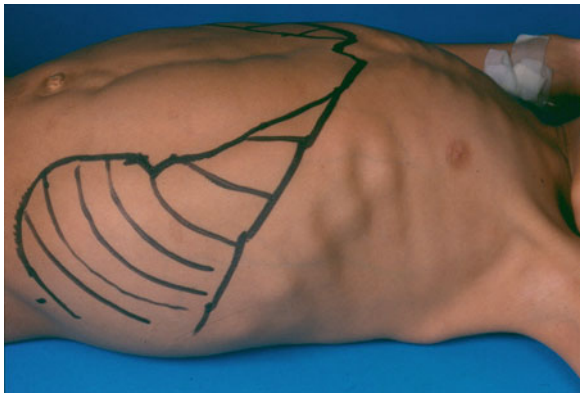

Figure 304.1

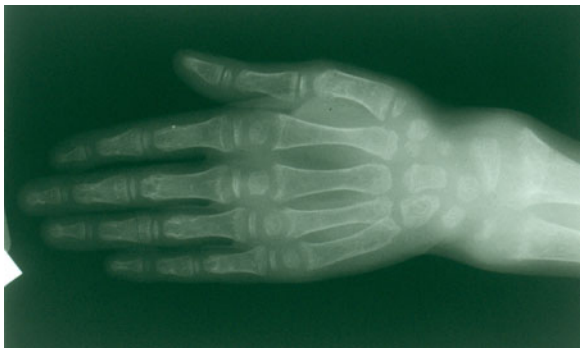

Figure 304.2
Severe rachitic changes in a patient with hepatorenal tyrosinemia

within the same family. This phenomenon may due to mutation reversion which has been described in patients with tyrosinemia.

Galactosemia

Galactosemia may result from many inherited enzyme deficiencies. Only that associated with Gal-1-PO_4 uridyl transferase deficiency results in the Fanconi's syndrome, which is incomplete, in that glucosuria is absent and phosphaturia is seldom severe to result in hypophosphatemia. Renal tubular acidosis is probably of the proximal type and associated with bicarbonaturia. Galactosemia and galactosuria are invariably seen. The diagnosis should be suspected in any infant with a history of failure to thrive, jaundice, hepatomegaly with or without cataracts, and non-glucose reducing substance in the urine. Definitive diagnosis is made by determining red blood cell Gal-1-PO_4 uridyl transferase activity. The molecular diagnosis of galactosemia has been identified recently by mutations in the GALT gene located on chromosome 9p13. The most common of these is a missense mutation of *Q188R* (replacement of glutamine-188 by arginine) but several other mutations have been identified as well.

Hereditary Fructose Intolerance

Hereditary fructose intolerance is an autosomal recessive inborn error of fructose metabolism caused by deficiency of fructose-1-phosphate (F1-PO_4) aldolase B activity in the liver, renal cortex, and small intestine. Several mutations in the human aldolase *B* gene have been identified, the most common being the A149P mutation in exon 5 located on chromosome 9_q 21.3_q 22.2. The clinical manifestations that develop following fructose ingestion are acute in nature and consist of nausea, vomiting, and diarrhea. Liver failure may develop within days. An acute Fanconi syndrome with *hyperuricemia*, hyperlactic acidemia, and hypermagnesemia develops within 30–60 min of ingestion of a large amount of fructose. In extreme cases, seizures, lethargy, and coma may develop. Ingestion of small amounts of fructose is not associated with symptoms.

The renal tubular abnormalities as well as the other manifestations of the disease are probably secondary to accumulation of F-1-PO_4 with depletion of inorganic phosphate, thus limiting ATP regeneration. This may lead to reduced transport of multiple solutes across the proximal tubular epithelial cell characteristic of the Fanconi's syndrome. Fructose withdrawal promptly reverses the acute changes and the renal tubular dysfunction. In patients with chronic fructose ingestion, however, liver damage may be irreversible.

Lowe's Syndrome (Oculocerebrorenal Syndrome)

Lowe's syndrome is an X-linked recessive disease characterized by congenital cataracts, glaucoma, developmental and growth retardation, hypotonia, and a renal Fanconi syndrome. The gene locus (OCRL) has been mapped to X 25–26 by linkage analysis. More specifically the gene product is a 105 kD protein localized to the Golgi complex.

The Fanconi syndrome is usually mild or incomplete but it may be quite severe in some cases. In many patients glomerular insufficiency develops later in childhood in spite of adequate symptomatic treatment for the tubular abnormalities. Dialysis and transplantation are usually not prescribed because of the moderate to severe mental retardation seen in most patients with Lowe's syndrome.

Dent's Disease

This is a rare X-linked disorder characterized by hypercalciuria, hyperphosphaturia, low-molecular-weight proteinuria, and aminoaciduria, and an incomplete Fanconi syndrome. If untreated, many patients develop nephrolithiasis and renal failure. In addition, one third of the patients develop rickets or osteomalacia. The gene has been localized to chromosome Xp11.22 and has been identified as a chloride channel gene *CLCN5*. There are actually four diseases associated with mutations in this gene: Dent disease, X-linked recessive nephrolithiasis (XRN), X-linked recessive hypophosphatemic rickets (XLRH), and idiopathic low-molecular-weight proteinuria of Japanese children (ILMWP). All share many similarities as described above but patients with Dent disease and XLRH develop rickets while the others do not. Renal failure is only seen in patients with Dent disease and XRN. Female carriers are asymptomatic but frequently have low-molecular-weight proteinuria.

Wilson's Disease

Wilson's disease is an autosomal recessive disease primarily affecting the liver and brain where marked amounts of copper are deposited. It is caused by mutations in the *ATP7B* gene located on chromosome 13 (13q14.3) and is expressed primarily in the liver, kidney, and placenta. The gene codes for a P-type (cation transport enzyme) ATPase that transports copper into bile and incorporates it into ceruloplasmin. Mutations can be detected in 90% of patients and most of these are homozygous.

The classical triad of hepatic cirrhosis, Kayser-Fleischer rings in the cornea, and neurological symptoms are pathognomonic findings. Renal involvement appears later with more advanced liver disease but it may precede hepatic failure. It is characterized by tubular dysfunction as seen in other cases of the Fanconi syndrome, but glucosuria is infrequent.

Other Hereditary Causes of the Fanconi Syndrome

The Fanconi syndrome has been described in association with several other rare inborn errors of metabolism including mitochondrial cytopathies, metachromatic leukodystrophy, pyruvate carboxylase deficiency (Leigh's syndrome), and glutathione synthetase deficiency. *Table 304.2* outlines some of the inherited disorders of proximal tubular function with and without the Fanconi syndrome. It includes some of the salient clinical findings, enzymatic defects, and inheritance pattern.

Acquired Disorders Causing the Fanconi Syndrome

These are primarily disorders associated with heavy metal exposure (lead, mercury, platinum), drug induced lesions as with ifosfamide, outdated tetracycline, aminoglycosides, toluene inhalation, and with abnormalities in protein metabolism as in amyloidosis, Sjögren's syndrome, and the nephrotic syndrome. The development of Fanconi syndrome in a child with nephrosis is an ominous sign indicating tubulointerstitial nephropathy, usually in association with focal segmental glomerulosclerosis. The Fanconi syndrome may also be acquired following renal transplantation where the mechanism is probably immune mediated.

Of all the drugs causally related to the Fanconi syndrome, ifosfamide is probably the most predictable since tubular dysfunction occurs in a relatively high percentage of treated patients. Ifosfamide is a cyclophosphamide analog used to treat several solid tumors. The Fanconi syndrome develops acutely during treatment and is usually heralded by glucosuria and hypophosphatemia. Both proximal and distal RTA may be observed in addition to aminoaciduria and uricosuria. Hypokalemia may be severe and beta$_2$-microglobulinuria is quite pronounced. The tubular toxicity is thought to be due to chloracetaldehyde, one of the metabolites of ifosfamide. Glomerular toxicity and reduced GFR may also occur with ifosfamide toxicity. Hemorrhagic cystitis occurs with much less frequency than with cyclophosphamide.

General Treatment of the Fanconi Syndrome

Metabolic Acidosis and Electrolyte Abnormalities

Patients with Fanconi syndrome frequently require large doses of bicarbonate or citrate to replace the ongoing losses

Table 304.2
Inherited disorders of proximal tubular function

Disorder	Clinical findings	Biochemical defect	Urine abnormalities	Inheritance, gene locus, mutations
Fanconi syndrome Cystinosis	Progressive renal failure; cystine storage in multiple organs	Defective cystine transport across lysosomal membrane	Usual for FS	AR 17p13, D17S1584, CTNS
GSD 11 Fanconi-Bickel syndrome	Hepatomegaly Nephromegaly Hypoglycemia	Phosphorylase b kinase deficiency in some patients due to massive glycogen accumulation secondary to impaired glucose transport	Massive glucosuria	AR 3q26.1–26.3 Mutations in *GLUT2*
Tyrosinemia	Nodular cirrhosis Portal hypertension Liver failure, hepatosplenomegaly nephromegaly	Fumaryl acetoacetate hydrolase deficiency	SA, DALA	AR 15q23–q25
Galactosemia	Jaundice Hepatosplenomegaly Cataracts Mental retardation	Gal-I-PO_4 uridyl transferase deficiency	Galactose No glucosuria	AR *GALT* gene on 9p13 Mutation of *Q188R*
Hereditary fructose intolerance	Hypoglycemia, seizures, jaundice, hyperuricemia, ↑Mg	F-I-PO_4 aldolase B deficiency	Fructose	AR chromosome 9q213–q22.2 *A149P* mutations
Lowe's syndrome	Mental retardation, cataracts, glaucoma	Abnormal inositol PO_4 metabolism	Usual for FS	XLR Xq25–26 OCRL-1 is 105 kD protein located in Golgi complex
Other P.T. disorders Proximal RTA with osteopetrosis	Growth failure Mental retardation Cranial nerve abnormalities Fractures	↓T_{HCO3} CAII deficiency	Bicarbonaturia Bicarbonaturia	AD, AR 8q22 – several mutations – intron 2
HVDRR	Rickets, hypophosphatemia	↓TRP Impaired calcitriol synthesis	Phosphaturia	XLD, AD *Hyp* gene Xp22.1 *PHEX, FGF23*
Cystinuria	None, urolithiasis, renal failure from obstructive uropathy	Defective transport of cystine and dibasic amino acids in proximal tubules and intestine	Cystine, ornithine, lysine, arginine	Chromosome 2p Mutations in *SLC3A1* gene

AD autosomal dominant, *AR* autosomal recessive, *XLD* X-linked dominant, *XLR* X-linked recessive, *SA* succinyl acetone, *DALA* delta aminolevulenic acid, *FS* Fanconi syndrome, *TRP* tubular reabsorption of phosphate, *CA* carbonic anhydrase, T_{HCO3} tubular reabsorption, bicarbonate

through the urine. If the fractional excretion of bicarbonate is very high the alkali requirement is proportionately larger. Some patients require 10–20 mEq/kg/day in four or more divided doses. If higher doses are needed, the large amount of sodium may lead to ECV expansion and further bicarbonate wasting. In such cases, salt and water should be restricted and a thiazide diuretic (2 mg/kg/day hydrochlorothiazide) administered to produce a mild ECV contraction and enhance bicarbonate reabsorption. Potassium supplements are frequently needed to replace renal potassium wasting and treat hypokalemia. Potassium citrate or lactate is ideally suited for treatment because they will also help in correcting metabolic acidosis. Calcium and magnesium supplements may be needed in patients with hypocalcemia and renal magnesium wasting. A prostaglandin synthetase inhibitor such as Indomethacin

(1–3 mg/kg/day) may be useful in reducing the urinary sodium, potassium, and water losses that are frequently seen in many patients with the Fanconi syndrome. Their use is contraindicated in the face of deterioration of renal function as seen in later stages of nephropathic cystinosis.

Hypophosphatemia and Bone Disease

While hypophosphatemia plays a major role in the bone disease in Fanconi syndrome, other factors including reduced calcitriol synthesis, chronic acidosis, and hypercalciuria are also important. Vitamin D therapy in the form calcitriol or one-alpha hydroxy-D3 is frequently needed to correct rickets. Doses vary from 0.25 to 3.0 μg/day. Phosphate supplements are always needed in high and frequent doses, depending on the severity of the phosphaturia. Most patients require 1–2 g/day in four divided doses. With adequate phosphate supplementation it is possible to promote bone healing with smaller doses of vitamin D.

Specific Treatment of the Fanconi Syndrome

Cystinosis

The use of the aminothiols cysteamine or phosphocysteamine has shown promising results in depleting cystine from the lysosome of affected cells. This is accomplished by an intralysosomal reaction between cystine and cysteamine to form a cysteine-cysteamine disulfide that exits the cell via a lysine carrier system. Treatment should be started as soon as the diagnosis of cystinosis is confirmed. The starting dose is 10 mg/kg/day in four divided doses. This is raised progressively to 60 mg/kg/day and titrated against leukocyte cystine content. Cysteamine treatment has been associated with improvement in the Fanconi syndrome and possible delay in the onset of renal failure. If and when renal failure develops, dialysis and transplantation offer the only hope for prolonged survival. The results of renal transplantation in patients with cystinosis are more successful than renal transplantation performed for other chronic renal diseases. This may be due to reduced immune responsiveness induced by intracellular cystine accumulation. The Fanconi syndrome does not recur but interstitial and mesangial accumulation of cystine has been reported.

Tyrosinemia Type 1

Until recently the only effective therapy for tyrosinemia type 1 was liver transplantation, preferably prior to the development of severe liver failure and hepatocellular carcinoma, known complications of nodular cirrhosis. An experimental drug that underwent clinical trials over the past 10 years or so appears to have stood the test of time and has shown promising results for patients with tyrosinemia type 1. The drug, 2-nitro-trifluoromethylbenzoyl-1, 3-cyclohexanedione (NTBC), inhibits 4-OH-phenylpyruvate dioxygenase, the second enzyme in the degradation pathway of tyrosine which is two steps proximal to the enzyme defect in tyrosinemia. The drug was recently approved for commercial use as an orphan drug and marketed as Nitisinone. Studies with NTBC therapy show an impressive reduction in the plasma level and the urinary excretion of SA and DALA and alpha-fetoprotein levels with a marked reduction in hepatosplenomegaly. Tubular dysfunction also improves significantly with NTBC treatment.

Other

In some cases of the Fanconi syndrome where the underlying cause is known, withdrawing the offending agent will reverse the tubular dysfunction. This is true for galactose in galactosemia and fructose in hereditary fructose intolerance. A diet low in tyrosine and methionine in patients with tyrosinemia results in moderate improvement in the Fanconi syndrome associated with the disease. Cornstarch therapy for GSD may cause regression of hepatomegaly but has no effect on the tubular dysfunction. Chelating agents such as Penicillamine-D and Zinc therapy for Wilson's disease are associated with significant reduction in serum copper levels as well as clinical improvement.

Prognosis in Fanconi Syndrome

Prognosis depends on the underlying etiology of the Fanconi syndrome. For patients with cystinosis, the most common cause of the syndrome, long term treatment with cysteamine improves long term patient outcome, but even in patients who have undergone successful renal transplantation a significant number of extra renal abnormalities persisted or worsened over time. These included hypothyroidism, pulmonary insufficiency, myopathy, diabetes mellitus, and others. One third of the transplanted patients died at a mean age of 28 years or 16 years post

transplant. In tyrosinemia, long term outcome has improved appreciably with early institution of Nitisinone therapy (see above) which should be started prior to development of nodular cirrhosis.

Proximal Renal Tubular Acidosis (Type II, PRTA)

Definition

Defective bicarbonate reclamation by the proximal tubule is referred to as proximal RTA. It is usually seen in association with other proximal tubular transport defects as part of the Fanconi syndrome, but it may also be observed less commonly as an isolated condition where it is referred to as primary proximal RTA.

Etiology/Pathophysiology

The basic defect in PRTA is impaired renal bicarbonate reabsorption by the proximal tubules. Hypothetically, any of the mechanisms responsible for the reclamation of bicarbonate from the proximal tubular cells could be implicated in the etiology of PRTA. For a better understanding of PRTA a brief review of the mechanisms involved in bicarbonate reabsorption is in order (Fig. 304.3).

In the proximal tubular cells, a specific electroneutral Na^+–H_+ exchanger (NHE-3) at the luminal basement membrane, together with basolateral transport of bicarbonate by an electrogenic Na^+-HCO_3^- cotransporter (NBC-1), accounts for the reabsorption of 85% of the filtered bicarbonate back to the plasma. The remaining 15% of the filtered bicarbonate is reabsorbed in the more distal segments of the tubule, primarily by the thick ascending limb of Henle's loop (TALH). *NHE-3* is the main isoform of the NHE family responsible for the Na^+ exchange with H^+. It is localized exclusively in the apical cells of the proximal tubules and the cells of the TALH. The human *NHE-3* gene (*SLC9A3*) maps to chromosome 5p15.3.

Filtered bicarbonate combines with hydrogen (exchanged for sodium) to form carbonic acid (H_2CO_3) which is rapidly dehydrated to CO_2 and water, a process catalyzed by luminal carbonic anhydrase (CA IV) in the brush border of the proximal tubular cell. Luminal CO_2 diffuses freely into the cell and is rehydrated by cellular carbonic anhydrase (CA II) to form carbonic acid, which dissociates into H^+ and HCO_3^-. Both CA IV and CA II are maximally stimulated in chronic metabolic acidosis. The regenerated bicarbonate is returned to the blood via the NBC-1 to maintain normal bicarbonate levels. About one third of the hydrogen secreted and exchanged for sodium is derived from an electrogenic H-ATPase pump in the luminal basement membrane. PRTA (type 2 RTA) could occur if any of the forces involved in bicarbonate reabsorption, singly, or in combination became defective.

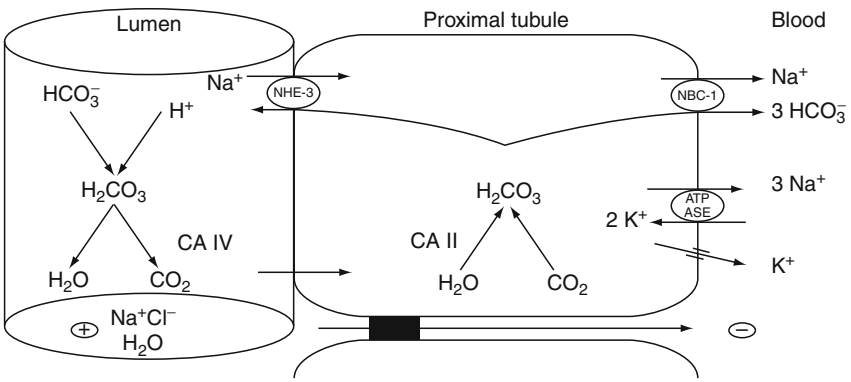

Figure 304.3

Bicarbonate reabsorption in proximal tubular cell. About two third of H^+ secreted is counter-transported with Na (NHE-3) and one third by a H^+-ATPase pump in the luminal membrane. HCO_3^- transport at the basolateral membrane is via a 1 Na^++3HCO_3 cotransporter (NBC-1). Cellular carbonic anhydrase II (CA II) and membrane-bound carbonic anhydrase IV (CA IV) are necessary for HCO_3^- reabsorption

These might be secondary to mutations in NHE3, NBC-1, carbonic anhydrase II or IV, or the H-ATPase pump. An abnormality in the Na-K-ATPase pump causes impaired reabsorption of all solutes ordinarily cotransported with sodium and results in the Fanconi syndrome. Bicarbonate reabsorption in the proximal tubule is a high capacity, low gradient process that bears an inverse proportion to changes in extracellular fluid volume. Other factors influencing HCO_3^- reabsorption include intraluminal flow rate, tubular and peritubular HCO_3-concentration, parathyroid hormone, pCO_2, chloride and potassium concentrations.

Incomplete bicarbonate reabsorption results in a large excretion of the filtered load of bicarbonate causing a fall in the plasma bicarbonate level. This excess bicarbonate will flood the distal tubules and impair urinary acidification. The urine pH will be alkaline and remain so until plasma bicarbonate falls below the renal threshold, after which it becomes bicarbonate free and properly acidified by the intact distal secretion of hydrogen ion. During acidemia in untreated patients, the urine pH is always less than 5.5.

PRTA in Association with the Fanconi Syndrome

The hereditary forms of the renal Fanconi syndrome are usually secondary to autosomal recessive metabolic diseases, the most common being cystinosis, tyrosinemia type 1, and glycogen storage disease (below). Renal bicarbonate wasting in the Fanconi syndrome occurs as part of a generalized proximal tubular transport defect. This is the result of a dysfunctional basolateral Na-K ATPase pump which is the driving source of energy for solute reabsorption. Glycogen storage disease appears to be a relatively common cause of the Fanconi syndrome in the Middle East, particularly in Saudi Arabia. This form of GSD, known as the Fanconi-Bickel syndrome, is due to mutations in the glucose transporter gene GLUT2. Other disease entities associated with the Fanconi syndrome and PRTA are listed in *Table 304.1*.

Isolated PRTA

This is a rare disease entity. The clinical features of isolated PRTA are those of failure to thrive and vomiting usually detected in early infancy, but the disease may not be diagnosed until early childhood. Unlike patients with the Fanconi syndrome, rickets, hypercalciuria are not features of this disease but hypokalemia has been observed in some patients. Most reported cases have been (a) sporadic, (b) autosomal dominant, and (c) autosomal recessive with ocular abnormalities.

Sporadic PRTA

Most cases of sporadic PRTA occur in early infancy and may be explained on an immature NHE3 or NBC1 transporter systems. Patients with this condition require therapy with alkalinizing agents but the majority outgrows the disease with time.

Autosomal Dominant PRTA

This variant of PRTA must be extremely rare and was reported once in a Costa Rican family about 30 years ago. All affected members had moderately severe hyperchloremic acidosis associated with growth retardation. Family pedigree in these patients was compatible with an autosomal dominant pattern of inheritance. Molecular studies have not been performed but the gene encoding the NHE3 appears to be a good candidate. Studies in knockout mice lacking the gene encoding NHE3 (*SLC9A3*) reveal significant reduction in proximal tubular reabsorption of bicarbonate but with only a mild degree of metabolic acidosis.

Autosomal Recessive PRTA

This entity was first described about 30 years ago by Donckerwolcke et al. This is another rare disorder which is invariably associated with ocular abnormalities including glaucoma, cataracts, and band keratopathy and, at times, physical and mental retardation, basal ganglia calcification, and enamel defects. The metabolic abnormalities reveal a fairly severe hyperchloremic, hypokalemic metabolic acidosis. The few patients described with this disease have been mostly from Europe and Japan. At the molecular level, several inactivating mutations in the gene encoding NBC-1 (*SLC4A4*) have been identified. These include nonsense mutations R298S, R510H, and a stop codon Q29X. The ocular abnormalities can be explained by the fact that the *NBC1* gene is expressed in several ocular tissues.

PRTA with Osteopetrosis

A unique syndrome of PRTA associated with osteopetrosis, cerebral calcification, and carbonic anhydrase II deficiency has been reported in several families from the Arab world. The syndrome is inherited as an autosomal recessive trait and is characterized clinically by failure to thrive, recurrent fractures, mental retardation in the majority of patients, and cranial nerve abnormalities. Over two third of the cases have been from Middle Eastern and North African countries where genetic heterogeneity is suggested by a more severe variant of the disease. In addition to the PRTA, a distal acidification defect has been suggested in many of these patients. The gene locus has been mapped to chromosome 8q22. Several mutations have been identified in patients with carbonic anhydrase II deficiency, but the most common is the Arabic one, which is a splice junction mutation in intron 2. More recently, mutations in the gene OC16, encoding the a3 subunit of the osteoclast V H^+-ATPase, have been shown to cause infantile malignant osteopetrosis.

Acquired PRTA

Drugs inhibiting carbonic anhydrase such as acetazolamide will cause a reduction in bicarbonate reabsorption in the proximal tubular cell (*Fig. 304.3*) resulting in a mild form of PRTA. More recently, Topiramate, a drug initially approved as an antiepileptic agent, is being increasingly used in the treatment of several neurologic and metabolic disorders. The drug also inhibits renal carbonic anhydrase activity, resulting in a proximal acidification defect similar to that observed with acetazolamide. The drug also causes hypocitraturia, hypercalciuria, and increased urine pH, all conducive to increased risk for kidney stone disease.

Diagnosis of PRTA

The diagnosis of PRTA should be considered in any infant (male > female) with failure to thrive and unexplained hyperchloremic acidosis. A urinary pH below 5.5 is strong evidence against distal RTA. If urinary pH falls in the equivocal zone (5.5–6.0) an acute acid load test with ammonium chloride should clarify the issue. This test is not necessary, and could be hazardous, if moderate to severe acidosis is present to begin with. The urine pH in PRTA is variable and depends on the plasma bicarbonate concentration. The diagnosis is confirmed by demonstrating a fractional excretion of bicarbonate (FE_{HCO3}) in excess of 15%. FE_{HCO3} is calculated during intravenous bicarbonate infusion or oral bicarbonate therapy by simultaneous measurement of urine and plasma bicarbonate and levels after ensuring an adequate rise in plasma bicarbonate:

$$FE_{HCO3} = \frac{U_{HCO3} \times P_{Cr}}{U_{Cr} \times P_{HCO3}}$$

where U and P represent urine and plasma concentration of bicarbonate (HCO_3) and creatinine (Cr) respectively.

Treatment of Proximal RTA

Treatment of PRTA usually requires large and frequent doses of sodium bicarbonate or citrate (5–20 mEq/kg/day). Potassium supplements may be necessary especially with large doses of bicarbonate, as this will aggravate potassium wasting by the kidney. In patients requiring large doses of alkali therapy, a thiazide diuretic may be used to reduce ECV expansion and enhance bicarbonate reabsorption by the proximal tubules.

Prognosis of PRTA

The prognosis of PRTA depends on the underlying etiology. If associated with the Fanconi syndrome, as the majority of cases are, the outcome will vary with the specific etiology of the Fanconi syndrome and its response to therapy (see above).

Disorder of Renal Phosphate Transport

Several disease entities have been described in association with hypophosphatemia, some are heredofamilial and some are acquired.

Heredofamilial Hypophosphatemia

Several terms have been used to describe this entity: vitamin D resistant rickets, X-linked hypophosphatemic rickets, primary hypophosphatemic rickets, familial hypophosphatemia, and phosphate diabetes. The disease represents the most common form of rachitic bone disease in North America, Western Europe, and in industrialized countries where nutritional rickets is no longer a significant problem.

Heredofamilial hypophosphatemia is transmitted as an X-linked dominant (XLH) or autosomal dominant trait (ADHR) with the former being much more prevalent (1 in 20,000). A rare autosomal recessive variant (ARHR) was also described recently.

XLH

In XLH, affected males (hemizygotes) will always manifest the disease, whereas females (heterozygotes) have a milder form of hypophosphatemia with mild bowing of the legs.

Etiology, Genetics, and Pathogenesis

The mutant gene of XLH has been mapped recently to the short arm of the X chromosome (Xp 22). One third of cases occur sporadically and may represent new mutations. Two murine homologues, *Hyp* and *Gy*, have helped significantly in detecting the mechanisms for renal phosphate wasting in XLH. The gene responsible for XLH was identified recently by positional cloning and designated *PHEX* (*PH*osphate regulating gene with homology to *E*ndopeptidases on the *X* chromosome). Several inactivating mutations in this gene have been identified in patients with XLH and in the murine models as well. It is thought that under normal circumstances, *PHEX* is involved in the inactivation of a phosphaturic hormone or the activation of a phosphate conserving hormone. Therefore loss *of PHEX* function is associated with either an excess of this phosphaturic hormone or a deficiency in the phosphate conserving hormone. In either case, renal other Na/P cotransporter would be down regulated and phosphaturia would ensue. However, endogenous *PHEX* substrates have not yet been identified. Recently it has been shown that *FGF23* gene expression is increased in Hyp mouse bone and Hyp osteoblast cultures, suggesting that *PHEX* normally inhibits FGF23 expression. Thus, an inactivating PHEX mutation results in abnormal regulation of FGF23 and possibly other molecules, resulting in the phenotype of XLH.

Clinical Findings

Children with XLH present at the onset of walking or later when weight bearing will lead to the classical bone deformities and growth failure. Genu varum occurs more frequently than genu valgum. Coxa vara is common, leading to the typical waddling and unsteady gait. Craniotabes and rachitic rosary, commonly seen with vitamin D deficiency rickets, are seldom observed with XLH. Tooth eruption may be delayed, but unlike in hypocalcemic forms of rickets, the enamel is normal. Sensorineural deafness appears to be relatively common. Radiologically, the findings are those of rickets with loss of provisional zone of calcification, widening of the epiphyseal plate, and coarse trabecular pattern. These changes are more pronounced in the lower extremities. Long bones are short and thickened, resulting in short and stubby appearance.

Pathophysiology

The pathophysiology of bone disease in XLH remains a controversial issue. It is possible that the primary genetic defect (*PHEX* mutations) causes (a) decreased renal tubular transport of phosphate leading to phosphaturia and hypophosphatemia (b) defective renal 1-alpha hydroxylase activity leading to inappropriately low levels of 1,25 $(OH)_2D_3$ relative to the low serum phosphate. This latter defect could be acquired since calcitonin stimulation of 1-alpha hydroxylase is normal in patients with HVDRR. This combination (a and b) is synergistic in causing the bone disease characteristic of XLH. The inadequate levels of 1, 25 $(OH)_2$ D_3 will also lead to reduced calcium and phosphate absorption from the gut, further contributing to the pathogenesis of the disease. Although PTH levels in XLH are usually normal, increased proximal tubular sensitivity to PTH may contribute to the renal phosphate wasting.

Diagnosis

The clinical manifestations described above are usually suggestive of the diagnosis. This is confirmed Biochemically where XLH is characterized by variable degrees of hypophosphatemia with normal serum calcium, elevated alkaline phosphatase and normal or slightly elevated PTH levels. The urinary findings reveal evidence of hyperphosphaturia with urinary phosphate excretion exceeding 20 mg/kg/day. Tubular reabsorption of phosphate (TRP) is derived by simultaneous measurement of urine and plasma phosphate and creatinine and calculated by the formula:

$$\mathrm{TRP} = 1 - \frac{U_p \times P_{Cr}}{U_{Cr} \times P_p}$$

where U_p and U_{Cr} indicate urine phosphate and creatinine concentrations, respectively, and P_{Cr} and P_p represent

plasma creatinine and phosphate concentrations. Normally, TRP ranges between 0.80 and 0.90. In patients with XLH, TRP is frequently below 0.50 (0.40–0.70). The test should be done while the patient is receiving adequate phosphate supplements for a few days.

ADHR

Patients with ADHR have similar clinical findings as those with XLH but differ in their mode of inheritance. The *ADHR* gene locus was mapped to chromosome 12p13.3. The gene responsible for ADHR has been found by positional cloning to be a fibroblast growth factor, *FGF23*. It has been subsequently shown that infusion of FGF23 in experimental animals results in phosphaturia and hypophosphatemia. At the renal proximal tubule brush border, FGF23 infusion rapidly decreases expression of Na/P cotransporter. Parathyroid hormone (PTH) also directly decreases Na/P cotransporter at the renal proximal tubule brush border *via* a cAMP/protein kinase A–mediated pathway, but infusion of FGF23 in thyroparathyroidectomized rats causes hypophosphatemia suggesting that the action of FGF23 on renal phosphate reabsorption is independent of PTH and may be complementary.

Treatment and Prognosis of XLH and ADHR

Since rickets in XLH and ADHR is primarily due to hypophosphatemia the goal of therapy is directed at raising plasma phosphate to normal levels. Phosphate supplements, in large and frequent doses, were recommended in the past to compensate for the ongoing urinary losses. Large doses of phosphate are usually associated with gastrointestinal complaints (vomiting and diarrhea) which may be a limiting factor in the treatment. Another drawback of raising plasma phosphate is the simultaneous lowering of the plasma ionized calcium which will lead to secondary hyperparathyroidism that can further aggravate the bone disease and increase the phosphaturia. For these reasons the addition of calcitriol to the therapeutic regimen offers the following advantages: (1) less phosphate will be needed and less gastrointestinal complications; (2) calcium and, to a lesser degree, phosphate absorption from the gut are enhanced leading to bone healing and improved linear growth; and (3) low incidence of hyperparathyroidism. The recommended dose for oral phosphate supplement is 1–2 g/day in four to five divided doses. Calcitriol in a dose of 0.25–1.0 μg/day is usually sufficient but some patients may require higher doses. Lower limb deformities appear to correct better if treatment is started before the age of 6 years, but final adult height remains significantly lower than the expected mean for age. Many patients require unilateral or bilateral corrective osteotomies for severe and persistent rachitic changes in the lower extremities. Some patients may benefit from growth hormone therapy.

Recent data suggest that adjunctive therapy with thiazide diuretics in combination with salt restriction will enhance proximal tubular reabsorption of phosphate. We have tried this combination in 6 patients with XLH but were not encouraged with the results, but thiazides may be effective in reducing the hypercalciuria and nephrocalcinosis associated with vitamin D therapy.

Other Hypophosphatemic Syndromes

Hypophosphatemic rickets or osteomalacia may be seen with chronic intake of phosphate binding gels.

Oncogenic hypophosphatemia with osteomalacia also known as tumor induced osteomalacia (TIO) has been reported with certain tumors of mesenchymal origin, usually sclerosing hemangiomas. Patients with TIO may present with fatigue, bone pain, fractures, and proximal muscle weakness. Children develop rickets and lower extremity deformities similar to those in ADHR and XLH. Many of these tumors are small and may be difficult to locate. Multiple imaging techniques including, magnetic resonance imaging, and positron emission tomography may be required to localize the tumor, which when found and removed reverses the phosphate, vitamin D, and bone abnormalities. The vast majority of these tumors are benign. Tumors that cause TIO usually overexpress FGF23, a known phosphaturic substance. Pathologic samples of patients with TIO have detected FGF23 in more than 80% of specimens tested.

The syndromes of hereditary hypophosphatemia with hypercalciuria must be differentiated from HLH and ADHR. Two forms are recognized. One is a rare autosomal recessive with phosphaturia and hypophosphatemia but appropriately elevated calcitriol levels. Hypercalciuria is probably due to increased intestinal absorption of calcium. Phosphate supplement without vitamin D reverses the rickets and osteomalacia. The other form is known as Dent's disease and is associated with X-linked nephrolithiasis and hypophosphatemic rickets. Hypercalciuria, uricosuria, and renal potassium wasting with progression to chronic renal failure is frequently observed.

Hyperphosphatemic Syndromes

Disorders associated with hypoparathyroidism, whether congenital or acquired are associated with hyperphosphatemia and hypocalcemia. The various conditions associated with these abnormalities are discussed in the section of endocrinology. A new syndrome of congenital hypoparathyroidism, dysmorphic features, severe growth failure, and mental retardation was reported recently in Arabian infants with normal cardiovascular systems and normal cellular immunity. Their dysmorphic features are quite distinctive from those of DiGeorge's syndrome and consist of deep-set eyes, microcephaly, thin lips, beaked nose tip, external ear anomalies, depressed nasal bridge, micrognathia, and other minor anomalies. The mode of inheritance of this syndrome is autosomal recessive as suggested by the very high rate of consanguinity (11 of 12 patients), equal occurrence in both sexes, and familial incidence. Molecular studies have recently identified the genetic basis of this disease. Mutations in the tubulin-specific chaperone, *TBCE*, have been found consistently in these patients. Treatment with pharmacologic doses of vitamin D and calcium supplements improves their biochemical abnormalities but growth retardation shows no response.

305 Disorders of Distal Tubular Transport of Sodium and Potassium

Sami A. Sanjad · John W. Foreman

Under normal circumstances, the urinary excretion of sodium matches the dietary intake such that a zero external balance is maintained. The factors that control sodium balance have been briefly alluded to in the section on renal function. A detailed account of the different factors modulating sodium balance are beyond the scope of this chapter, but suffice it to say that after the first year of life, the kidney is able to reduce urinary excretion of sodium to negligible values if the need arises (low-salt diet, ECV contraction).

Disorders Associated with Isolated Renal Salt Wasting

Etiology

Solute Diuresis Associated with Nephron Hyperfiltration

This is typically seen in patients with chronic renal failure, particularly those with a significant tubulointerstitial component. Renal salt wasting is usually mild but occasionally can be severe enough to cause ECV contraction, hypotension, and further deterioration of renal function. The diagnosis is made from the history and physical examination and tests of renal function which reveal increasing azotemia, hyponatremia, hyperkalemia, and metabolic acidosis. Urinary sodium is usually in excess of 60–120 meq/L in spite of ECV contraction.

Impaired Tubular Sodium Transport

Both congenital and acquired defects in sodium transport along different segments of the nephron may be associated with variable degrees of renal salt wasting.

Acute and chronic interstitial nephritis – Various segments of the nephron may be involved in abnormalities of sodium transport. Many renal diseases with a prominent tubulointerstitial involvement may be associated with renal salt wasting. These include obstructive uropathies, nephrocalcinosis, analgesic nephropathy, allergic interstitial nephritis, amyloidosis, and others.

Medullary cystic disease/Juvenile nephronophthisis – Renal salt wasting may be a prominent feature in children and adolescents with this disease.

Drugs – Several drugs known to cause interstitial nephritis may cause some degree of salt wasting. Prominent among these are *cis*-platinum and Amphotericin B.

Renal tubular acidosis – Patients with both proximal and distal RTA exhibit variable degree of salt wasting. In proximal RTA, this occurs only with sodium bicarbonate treatment when plasma bicarbonate exceeds the renal tubular threshold. In distal RTA, a mild degree of renal salt wasting occurs at all levels of plasma bicarbonate, and fractional excretion of sodium is usually between 2% and 5% (normal $<1\%$).

Transient Pathophysiologic States Associated with Renal Salt Wasting

Transient renal salt wasting may be seen during the recovery phase of acute tubular necrosis. In children recovering from acute post streptococcal glomerulonephritis, a mild degree of salt wasting may occur for a few months following recovery, but this is of no clinical significance. Massive renal salt wasting may occur in the early post renal transplant period, and to a lesser degree following relief of urinary tract obstruction. Diuretics, by definition, interfere with sodium reabsorption at different sites of the nephron and thus will cause reversible renal salt wasting.

Conditions Associated with Deficient Mineralocorticoid Activity

These are typically observed in patients with Addison's disease, isolated hypoaldosteronism, and pseudohypoaldosteronism type 1. Congenital adrenal hyperplasia,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_305,

due to 21-α-hydroxylase deficiency is one of the most common extra renal causes of renal salt wasting. This entity is discussed separately in the section on endocrinology.

Treatment

Treatment of isolated renal salt wasting states will depend on the underlying mechanism and the severity of the renal sodium losses, its effect on renal function, blood pressure, serum sodium, potassium, and acid–base balance (see below). Liberalizing salt intake, parenterally, or orally if tolerated, will usually reverse these abnormalities. If concomitant metabolic acidosis is present, sodium bicarbonate or citrate should be used in addition to sodium chloride.

Disorders Associated with Renal Salt Wasting and Hypokalemia

Bartter's Syndrome

Since Bartter and colleagues' original description of two patients with severe hypokalemic metabolic alkalosis and hyperaldosteronism in 1962, there have been several series and case reports describing a similar clinical presentation.

Clinical Manifestations

Older patients with Bartter's syndrome present typically with hypokalemia, fatigue, muscle weakness and cramps, neuromuscular irritability, polyuria, and polydipsia. The hypokalemia is usually moderate to severe and is secondary to renal potassium wasting, with urinary potassium concentrations frequently exceeding 40 meq/L. Serum bicarbonate values usually exceed 30 meq/L and are accompanied by arterial pH values that are often above 7.50. This metabolic alkalosis is chloride resistant as urine chloride levels exceed 20 meq/L with resultant hypochloremia.

Many other abnormalities have been described in patients with Bartter's syndrome. Urine concentrating ability is impaired, presumably from the long-standing hypokalemia. Hyperplasia of the juxtagomerular cells is common but this is not pathognomonic of Bartter's syndrome as originally thought because it may be seen in other conditions associated with extracellular volume contraction and hyperreninemia, such as Addison's disease, laxative or diuretic abuse. Hyperplasia of renal medullary interstitial cells, the probable source of the increased prostaglandin secretion typically observed in this syndrome, has also been described. In children, growth retardation is common and may be the presenting complaint. Mild mental retardation and facial dysmorphism has also been noted in some patients. A more severe and common variant of Bartter's syndrome is seen in the neonate or early infancy and is referred to as antenatal Bartter's syndrome. These babies have a history of maternal polyhydramnios and are usually born prematurely and small for gestational age. Hypercalciuria is invariably present in association with nephrocalcinosis. Prostaglandin E2 is markedly elevated and has led to the name hyperprostaglandin E2 syndrome. These infants have been reported to respond especially well to cyclooxygenase inhibitors.

Etiology and Pathogenesis

The past 12 years have witnessed major developments in the fields of molecular and cell biology that have led to our understanding of the pathogenesis of Bartter's syndrome. Until the mid-1990s, the pathogenesis of this syndrome remained elusive and pathophysiologic constructs of the syndrome were circular making the initiating event difficult to define.

Because the biochemical and physiologic changes in Bartter syndrome are similar to those seen in patients receiving loop diuretics, the Bumetanide-sensitive Na–K-2Cl cotransporter, *NKCC2*, was sought as a candidate gene due to its role in Cl and Na reabsorption in the TALH segment. This transporter is the site of action for loop diuretics where they inhibit sodium, potassium, and chloride reabsorption. Thus, chronic administration of loop diuretics will result in hypokalemia, metabolic alkalosis, hyperreninemia, hyperaldosteronism, chloride wasting, hypercalciuria, and hyperprostaglandinism which are findings typically observed in patients with Bartter's syndrome (*Fig. 305.1*). Also, physiologic studies with hypotonic saline or water diuresis had clearly demonstrated impaired sodium chloride reabsorption in the thick ascending limb of Henle's loop in the majority of patients studied.

The etiology of Bartter's syndrome has been characterized recently at the molecular level. Simon and associates demonstrated linkage of Bartter's syndrome to the renal Na–K-2Cl cotransporter gene *NKCC2* and identified several inactivating mutations for this gene that cosegregate with the disease – Bartter's type 1. Genetic heterogeneity was demonstrated subsequently by the

same group of investigators who identified mutations in two additional genes that act as regulators of the Na–K-2Cl cotransporter. The first is ROMK, an ATP-sensitive K channel, which recycles reabsorbed K back to the tubular lumen to allow sustained cotransport activity – Bartter's type 2. The second is a chloride channel gene *CLCNKB* which is important in Cl absorption across the basolateral membrane to the peritubular blood – Bartter's type 3. A fourth genotype of Bartter's syndrome was identified by positional cloning in ten families with the usual abnormalities but in association with sensorineural deafness. The gene encodes a protein called Barttin, a beta subunit of the *CLCNKB,* which is also expressed in the potassium-secreting epithelial cells of the inner ear. Thus, inactivating mutations of the gene impair function of the chloride channel, causing Bartter's syndrome and sensorineural deafness – Bartter's type 4. All these variants of Bartter's syndrome are inherited by autosomal recessive genes and disease prevalence is more common in communities with high rate of consanguineous marriages. Lastly, a fifth variant of Bartter's syndrome was discovered in association with another rare syndrome of autosomal dominant hypocalcemia. The mutated gene is the Calcium Sensor Receptor, *CASR,* which is also expressed in the TALH. When maximally activated due to gain of function mutations, this results in decreased sodium and chloride reabsorption primarily due to inhibition of the ROMK channel. With the advent of the molecular identification of the various types of Bartter's syndrome, it is now possible to develop phenotype–genotype correlations, although considerable overlap remains. *Table 305.1* and *Fig. 305.2* summarize the various phenotypes and genotypes of Bartter's syndrome.

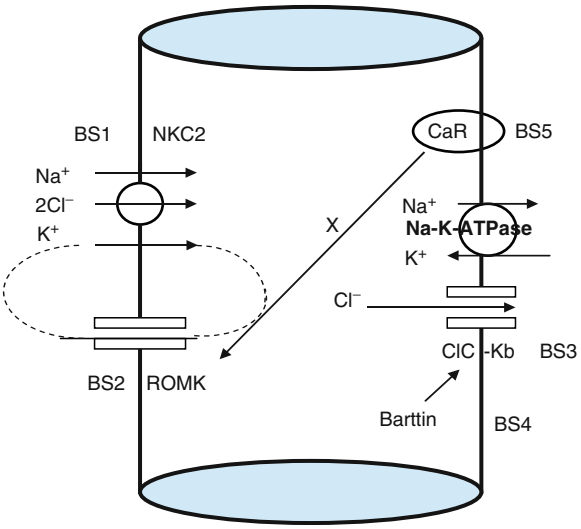

Figure 305.2
The main transport proteins and ion channels in the TALH. Mutations in the NKCC2, ROMK, CLC-KB, Barttin, and CaR cause Bartter's syndrome (BS) types 1, 2, 3, 4, 5, respectively

Table 305.2
Hypokalemic, metabolic alkalosis in children

Non-hypertensive	Hypertensive
Pyloric stenosis	Renal artery stenosis
Gastric suction	Primary aldosteronism
Cystic Fibrosis	Cortisol synthesis enzyme defects
Diuretics – laxatives	11-Beta-hydroxylase

Bartter's syndrome	Cortisol degradation enzyme defect
Gitelman's syndrome	11-Beta-cortisol dehydrogenase
Neonatal Bartter's – hyperprostaglandin E syndrome	Glucocorticoid remediable hypertension
	Liddle's syndrome
Congenital chloride diarrhea	Licorice abuse

Differential Diagnosis

The differential diagnosis of Bartter's syndrome and other forms of hypokalemic, metabolic alkalosis in children is shown in *Table 305.2*.

Gitelman's Syndrome

In 1966, Gitelman and Welt described a familial disorder characterized by hypokalemia, metabolic alkalosis, and hypomagnesemia. Most patients presented in late childhood, or as young adults, frequently with tetany. Compared to Bartter's syndrome, they have less pronounced hypokalemia, hyperreninemia, and hyperaldosteronism. Hypocalciuria and hypomagnesemia are other distinguishing features and they usually have normal stature. Genetic studies of patients with Gitelman's syndrome have identified several inactivating mutations in the thiazide-sensitive Na–Cl cotransporter (NCCT) in the early distal tubule. Impaired function of this transporter would increase sodium delivery to the more distal portions of the nephron leading to increased potassium and hydrogen ion secretion. The cause of the increased magnesium excretion seen in this syndrome is unclear, but it may also be seen in patients receiving thiazides chronically. *Table 305.3* shows some of the salient features that differentiate Bartter's from Gitelman's syndromes.

Treatment and Prognosis

The major goal in treating Bartter's syndrome is to normalize the serum potassium. However, this is usually difficult to achieve and patients require large doses of supplemental KCl. "Potassium sparing" agents, such as amiloride, spironolactone, and triamterene, are helpful but many of these patients remain hypokalemic in spite of large doses of KCl and potassium sparing drugs. Nonsteroidal anti-inflammatory drugs (NSAIDS) are somewhat useful in correcting the hypokalemia and volume contraction, presumably by inhibiting prostaglandin synthesis and their effect on blocking the tubuloglomerular feedback caused by decreased chloride reabsorption. Prostaglandin inhibitors also reduce the hypercalciuria and are reported to be especially useful in "neonatal Bartter's" or hyperprostaglandin E2 syndrome. In many patients, these agents are useful initially, but not on a long-term basis. Angiotensin converting enzyme inhibitors have been shown to improve the hypokalemia, but many patients cannot tolerate their hypotensive effects. In spite of the severe and long-standing potassium depletion, cardiac arrhythmias are infrequent and these patients tolerate general anesthesia relatively well. In Gitelman's syndrome, magnesium supplementation is especially important, in addition to potassium. In contrast to Bartter's syndrome patients,

Table 305.3
Differentiation between Bartter's and Gitelman's syndromes

	Bartter's syndrome	Gitelman's syndrome
Age of presentation	Early (may be neonatal)	Anytime – often as adults
Presenting complaint	Polyuria, polydipsia, FTT	Tetany
Inheritance	Autosomal recessive or sporadic	Autosomal recessive
Maximal urine concentration	Decreased	Usually normal
Serum magnesium	Normal	Low
Urinary calcium	>4 mg/kg/day	Low or normal
Defect	Mutations in cotransporter NKCC2, ROMK, CLCNKB/A Channels, Barttin, CaSR	Mutations in thiazide-sensitive NaCl transporter in renal distal tubule

Gitelman's syndrome patients require relatively modest doses of KCl to correct the potassium defect and NSAIDS are not required.

Disorders Associated with Renal Salt Wasting and Hyperkalemia

Autosomal Recessive Pseudohypoaldosteronism Type 1 (AR PHA1)

This is a rare autosomal recessive disorder characterized by life-threatening dehydration in neonatal life and early infancy secondary to severe renal salt wasting, hypotension, hyponatremia, and hyperkalemic metabolic acidosis. There is also marked elevation of plasma renin activity and aldosterone levels. Genetic analysis of affected offspring showed linkage to chromosomes 12p13 and 16p13 which contain genes encoding different subunits of the sodium epithelial channel, ENaC. Several inactivating homozygous mutations in the three subunits (α-, β-, and γ-ENaC) of this gene have been identified. These mutations are associated with persistent and longer open probability of the channels leading to renal salt wasting from the distal collecting tubules and a secondary defect in hydrogen and potassium ion secretion with resultant hyperkalemia and metabolic acidosis (*Figs. 305.3* and *305.5*). Since the ENaC is also expressed in the respiratory epithelial cells, from the nose to the terminal bronchioles and alveoli, patients with the PHA1 frequently present with increased airway secretions and lower respiratory infections.

The differential diagnosis of PHA1 includes (1) salt wasting congenital adrenal hyperplasia with mineralocorticoid deficiency, (2) isolated hypoaldosteronism (very rare), and (3) autosomal dominant PHA1.

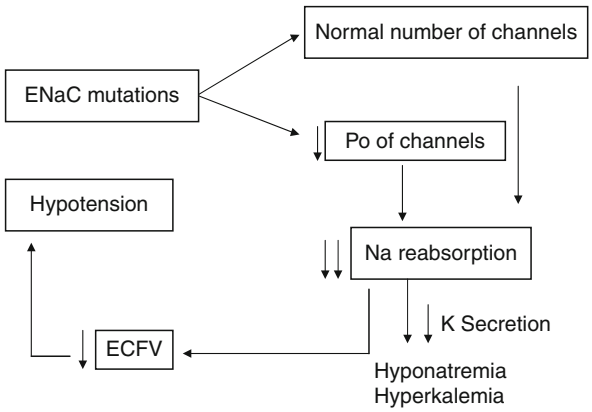

Figure 305.3
Pathophysiology of AR pseudohypoaldosteronism type 1. *ENaC* sodium epithelial channel, *Po* open probability

Autosomal Dominant Pseudohypoaldosteronism Type 1 (AD PHA1)

This entity has a similar but, usually, a less severe clinical presentation than the recessive type. Heterozygous mutations in the gene (*NR3C2*) encoding the mineralocorticoid receptor are found in 75% of reported families as well as in some sporadic cases. In many patients, the symptoms related to renal salt wasting remit with time.

Treatment of PHA1

In order to keep up with high urinary losses of sodium, a high salt intake is an essential aspect of the management of patients with PHA1 with some requiring as much as 20–30 mmol of sodium/kg/day. In addition, most infants

and children will require K-binding resins to prevent hyperkalemia which may be lethal at times.

Disorders with Renal Salt Retention and Hypokalemia

Liddle's Syndrome

Liddle and colleagues described a family with hypokalemia and hypertension in which the clinical manifestations resembled primary aldosteronism, but the serum and urine aldosterone levels were suppressed. It was also noted that an inhibitor of the aldosterone receptor was not effective in treating hypertension, but triamterene, which inhibits potassium secretion through a mechanism other than aldosterone receptor blockade, was effective. Several kindreds have been described to date and this syndrome is inherited as an autosomal dominant disorder. The signal feature, besides hypertension, is hypokalemia, occurring in 50% of patients. Hypertension typically begins in adolescence, but has been noted in infants. The severity of the hypertension varies between patients, but there is an excess of cerebral hemorrhage and premature death in most kindreds.

Pathogenesis

Linkage analysis of the original kindred showed complete linkage of the disease to the beta subunit of the amiloride-sensitive epithelial sodium channel (β-ENaC). This sodium channel resides on the luminal membrane of the renal cortical collecting duct and plays an important role in sodium reabsorption in this nephron segment. It has been subsequently shown that activating, gain of function, mutations in both β and γ subunits of the ENaC are causative of Liddle's syndrome presumably, the defective subunit increases the number of open channels and maintains the distal nephron in a sodium avid state, even when the patients are salt repleted and aldosterone is inhibited. The avid sodium reabsorption maintains a lumen negative electrical gradient, which enhances potassium and hydrogen ion excretion. This leads to hypokalemia, volume expansion, hypertension, and metabolic alkalosis (*Figs. 305.4* and *305.5*).

Diagnosis

The diagnosis of Liddle's syndrome should be suspected in patients with hypertension and hypokalemia. The finding of suppressed aldosterone levels confirms this suspicion, especially if there is a strong family history of hypertension. A urine aldosterone to potassium ratio of <60 (ng/mmol) appears to be the most sensitive measure of aldosterone suppression. Patients with Liddle's syndrome usually have high TTKG values (greater than 9–10) which fall to low levels following treatment with sodium channel blockers (see below).

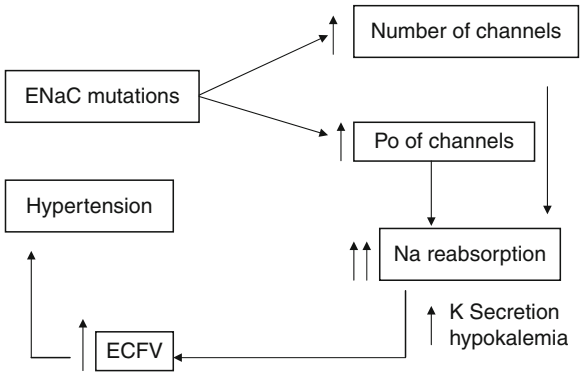

Figure 305.4
Pathophysiology of Liddle' Syndrome. *ENaC* sodium epithelial channel, *Po* open probability

Differential Diagnosis

Other causes of hypokalemic hypertension include renal artery stenosis, renin secreting tumor, primary hyperaldosteronism, and glucocorticoid remediable aldosteronism (GRA). All of these can be distinguished from Liddle's syndrome by the presence of hyperaldosteronism. Enzymatic deficiencies that lead to hypokalemic hypertension include 11-beta-hydroxylase and 17-alpha-hydroxylase in the cortisol and aldosterone biosynthetic pathway. Deficiency of 11-beta-hydroxylase is characterized by virilization and deficiency of 17-alpha-hydroxylase with hypergonadotropic hypogonadism. Both are also associated with decreased cortisol levels that stimulate corticotropin release. This stimulates steroid formation proximal to the block, including deoxycorticosterone that has mineralocortoid effects through the aldosterone receptor. These patients have low cortisol levels and abnormal levels of steroid metabolites in their urine. They respond to spironolactone, unlike patients with Liddle's syndrome. The enzyme, 11-beta-hydroxysteroid dehydrogenase, protects the aldosterone receptor from interacting with cortisol by converting it to cortisone. Patients with 11-beta-hydroxysterone dehydrogenase deficiency have low levels of aldosterone and abnormal levels

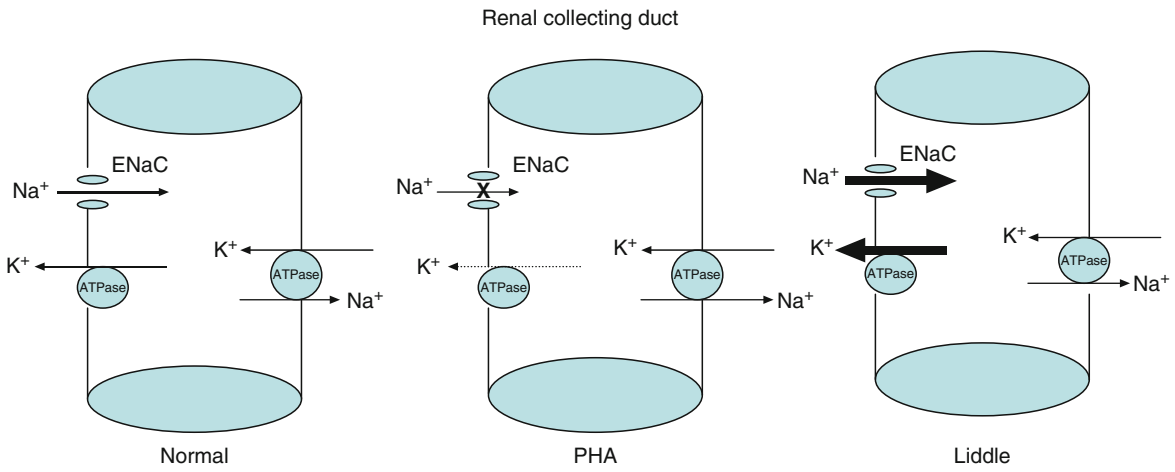

Figure 305.5
Pathophysiology of Pseudohypoaldosteronism type 1 and Liddle's syndrome

of cortisol to cortisone metabolites in their urine. Glycyrrhetinic acid found in licorice inhibits this enzyme mimicking 11-beta-hydroxysterone dehydrogenase deficiency. GRA results from an abnormal gene that consists of the ACTH responsive portion of the gene coding 11-beta-hydroxylase to aldosterone synthetase gene. This gene fusion mutation confers ACTH regulation to aldosterone synthesis, leading to excess aldosterone. All these enzyme defects demonstrate a reduction in blood pressure with physiologic doses of dexamethasone.

Treatment

The first aspect of Liddle's syndrome treatment is to block the open sodium channel with the potassium sparing diuretics, amiloride or triamterene. Spironolactone, acting through the aldosterone receptor is not useful. However, sodium restriction may still be necessary in some patients to reduce the volume expansion and maintain blood pressure control. In spite of maximal doses of amiloride and sodium restriction, some patients will require additional antihypertensive agents.

Disorders with Salt Retention and Hyperkalemia

Pseudohypoaldosteronism Type 2 (Gordon Syndrome)

In 1970, Gordon and associates described a 10-year-old girl with hypertension, severe hyperkalemia, acidosis, suppressed renin and aldosterone activity, and normal GFR. At least 40 patients with similar findings have been reported since then. Many of these have been members of the same family and an autosomal dominant inheritance has been suggested, but a clear-cut mode of transmission has not been determined in most cases. The syndrome is very rare and has been reported in both children and adults, and represents the prototype of pseudohypoaldosteronism type II. Hyperkalemia may be quite severe and is associated with hyperchloremic acidosis, moderate to severe hypertension, and ECV expansion, with secondary suppression of renin, aldosterone, and prostaglandins. These findings are diametrically opposite to those of Bartter's and Gitelman's syndromes. The proximate cause of this rather unique salt-sensitive syndrome of hypertension and hyperkalemic acidosis has been found recently to be due to activating, gain of function, mutations in the novel genes *WNK1* and *WNK4* both of which enhance the activity of the thiazide-sensitive NaCl cotransporter, NCC, in the distal collecting tubule. In addition, these mutated genes have an inhibitory effect on the potassium channel ROMK thus leading to avid sodium chloride reabsorption and potassium retention.

Treatment

Treatment consists of moderate salt restriction alone, or in combination with furosemide or thiazides. This completely reverses the hyperkalemic acidosis, restores renin, aldosterone, and prostaglandins, and normalizes blood pressure. In some patients with refractory hyperkalemia, cation exchange resins may be necessary.

306 Distal Renal Tubular Acidosis (TYPE I, DRTA)

Sami A. Sanjad

Introduction

The kidney plays a major role in acid–base homeostasis. This is accomplished by two essential mechanisms, both involving the exchange of filtered sodium from the tubular lumen with secreted hydrogen from the tubular cells. The first mechanism is quantitatively more important and occurs primarily in the proximal tubule. It accounts for the reabsorption or reclamation of 85–90% of the filtered bicarbonate back to peritubular capillaries, thus maintaining the concentration of bicarbonate in the plasma fairly constant. This process is catalyzed both by: (a) luminal carbonic anhydrase IV, which causes the dehydration of carbonic acid; and (b) cellular carbonic anhydrase II, which rehydrates the absorbed CO_2 to form carbonic acid. The latter dissociates into H^+ and HCO_3. This regenerated bicarbonate is returned to the blood and maintains normal bicarbonate levels (Fig. 288.2, Chap. 288, "Overview of Renal Function").

The second mechanism also involves the exchange of luminal sodium for cellular hydrogen ions secreted in the distal tubule. The hydrogen ions combine with filtered buffers (mainly phosphate) and are excreted in the final urine as titratable acid. As this is not enough to excrete all the daily acid load, a new buffer, NH_3, derived from the deamination of glutamine in the tubular cells, diffuses passively into the lumen and combines with hydrogen ion, also secreted from the tubular cells. The resulting NH_4^+ ion is "trapped" (does not diffuse back into the cell) and is excreted in the final urine (Fig. 288.3, Chap. 288, "Overview of Renal Function"). Net acid excretion (NAE) is the term used to express the sum of TA and NH_4^+ minus any HCO_3 (negligible) that may be excreted. The steady state net acid excretion is equal to hydrogen ion generated from endogenous and exogenous (diet) sources. This is also equal to the net addition of bicarbonate by the kidneys to the body fluids (40–60 meq/m^2/day).

Definition

DRTA is a rare renal tubulopathy characterized by persistent hyperchloremic (normal anion gap) metabolic acidosis due to impaired secretion of hydrogen ion from the distal collecting duct cells to the tubular lumen resulting in relatively high urine pH in the face of systemic acidosis. Although frequently considered in the differential diagnosis of infants and children with failure to thrive, it is seldom detected as the cause.

Pathophysiology of DRTA

Until recently, all patients with DRTA were thought to have a single underlying pathogenetic mechanism: an inability of the distal nephron to generate and maintain steep pH gradients between peritubular blood and urine. The implication was that the distal tubular cells were capable of proton secretion but, because of a leaky membrane, hydrogen ions back diffused to the circulation leaving behind a relatively alkaline urine. This was referred to as gradient defect RTA. The prototype of such a defect in acidification is seen in patients treated with Amphotericin B.

Three types of cells in the distal nephron contribute to acid–base homeostasis: (1) the alpha-intercalated cells, which contain a luminal H^+-ATPase pump and an H^+–K^+-ATPase pump; (2) the principal cells, which have an indirect but important effect in urine acidification (see below, Voltage-dependent DRTA); and (3) the beta intercalated cells, which have a limited role in acidification but may be involved in bicarbonate secretion in vegetarians ingesting an alkaline ash diet. With this background, it is now possible to characterize DRTA from a mechanistic point of view (*Fig. 306.1*).

The alpha-intercalated cell of the distal collecting ducts plays a pivotal role in the fine regulation of acid–base balance by the human kidney. This is accomplished by the H^+-ATPase pump at the luminal membrane, which

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_306,

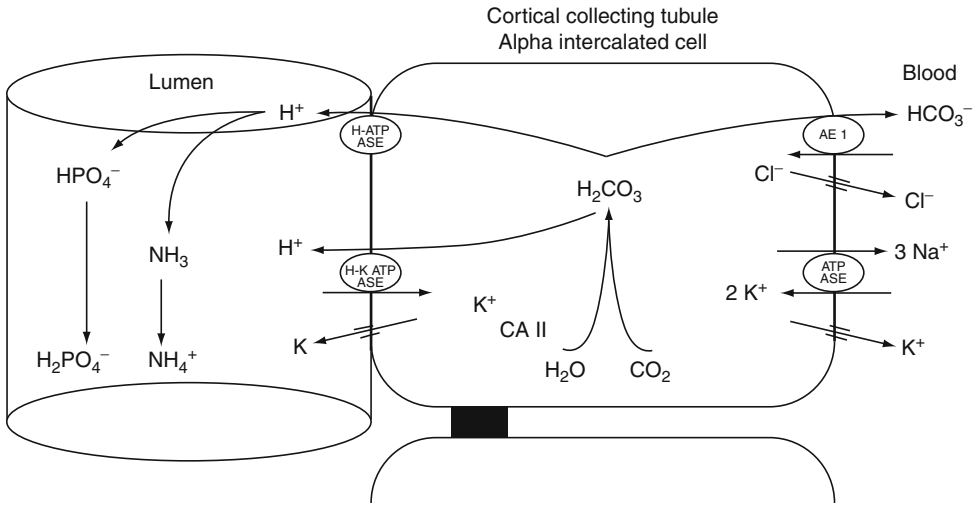

Fig. 306.1

Excretion of fixed acids in the distal nephron. Hydrogen secretion by the alpha-intercalated cells takes place via the H^+-ATPase pump in the luminal basement membrane. About 40% of the secreted hydrogen ions combine with filtered phosphate to form titratable acid. Most of the remaining hydrogen secreted combines with NH_3 to form NH_4^+, but a small amount remains as free hydrogen ions and regulates urinary pH. Bicarbonate reclamation occurs by Cl^-/HCO_3^- exchanger AE1 at the basolateral membrane

secretes H^+, and by the HCO_3^-/Cl^- (AE1) exchanger at the basolateral membrane, which is responsible for bicarbonate regeneration. Failure of either mechanism underlies the cellular and molecular etiology of distal RTA. Several mutations in the genes responsible for these transport systems have been identified recently, revolutionizing our understanding of the molecular basis of DRTA. Both hereditary and acquired forms are recognized in patients with DRTA, but this chapter will deal primarily with the hereditary forms of DRTA that prevail in infants and children.

Etiology of DRTA

Hereditary DRTA

The past 10 years have witnessed major advances in molecular biology that have allowed for a better understanding and classification of the hereditary forms of DRTA at the cellular and subcellular level. In infants and children, the autosomal recessive forms of RTA are more prevalent, whereas in adults the less severe, dominant forms are more common.

Autosomal Dominant Distal RTA

Randall and Targgart were the first to report RTA with nephrocalcinosis and osteomalacia in successive generations suggesting an autosomal dominant transmission. Subsequent reports confirmed this mode of transmission in several families. Clinical manifestations and the degree of acidosis in reported patients have been milder and therefore detected much later in life than in those with autosomal recessive distal RTA.

Chaabani and colleagues reported on large kindred with RTA with evidence of autosomal dominant transmission. As in previously reported cases, metabolic acidosis was well tolerated and often asymptomatic. Only 3 of 28 patients, with both parents affected, developed hypercalciuria, nephrocalcinosis, and growth retardation.

More recently, molecular studies in several kindreds with autosomal dominant RTA have consistently revealed mutations in the *SLC4A1* gene encoding the Cl^-/HCO_3^- exchanger AE1. These have been mostly missense mutations in codon Arg 589 suggesting an important role for this residue in the normal acidification process. It has been shown that these mutations in the *AE1* gene are not associated with loss of function of the Cl^-/HCO_3^- exchanger and that they probably affect the acidification process by targeting of *AE1* from the basolateral to the luminal membrane of the alpha-intercalated cell. Mutations in the erythrocyte isoform of the *AE1* are associated with hemolytic anemias due to ovalocytosis or spherocytosis, but seldom with RTA.

Autosomal Recessive DRTA

This entity appears to be relatively common in Middle Eastern countries. Karet et al. have elucidated the mechanisms responsible for the acidification defect in patients with recessive distal RTA. Molecular studies involving genome-wide linkage analysis in a cohort of several, mostly consanguineous, kindreds with distal RTA localized two genes: one on chromosome 2p13 associated with sensory-neural deafness (SND) and another on chromosome 7q33–34 associated with normal hearing. Both genes encode kidney-specific subunits of the proton pump of the alpha-intercalated cell. The majority of patients in both groups were of Arab or Turkish descent. Patients with distal RTA and SND were found to have several mutations in the gene encoding the B-1 subunit of the H^+-ATPase, *ATP6V1B1*, which is localized on chromosome 2p. Most of these mutations were found to disrupt the structure or alter the production of the normal B-1 subunit protein. It was also demonstrated that *ATP6V1B1* messenger RNA was expressed in the fetal and adult cochlea as well as the endolymphatic sac, findings that may explain the SND in these patients.

In patients with distal RTA and normal hearing, linkage analysis led to a defective gene on chromosome 7. This gene (*ATP6V0A4*) encodes a newly identified kidney-specific a4 isoform of the H^+-ATPase pump subunit. The clinical and biochemical manifestations are indistinguishable from patients with RTA with SND. Long-term follow-up, however, has revealed that many patients in this group develop mild hearing loss in later life. Stover and colleagues have recently demonstrated that the *ATP6V0A4* gene is also expressed within the human cochlea, again providing an explanation for the hearing defect. Recent reports from the Far East have identified different mutations in the AE1 in association with autosomal recessive distal RTA with or without ovalocytosis. This appears to be confined to Thailand and has not been documented in Caucasians.

Mixed RTA (Type 3)

Renal tubular acidosis combining features of both proximal and distal acidification defects may be observed in infants and children as a transient defect (previously known as type 3 RTA) and could be related to immaturity of one or more of the several transport systems described above. A syndrome of mixed RTA associated with osteopetrosis, cerebral calcification, and carbonic anhydrase II (CA II) deficiency has been reported in several families from the Arab world (Chap. 304, "Proximal Renal Tubular Disorders"). The syndrome is inherited as an autosomal recessive trait and is characterized clinically by failure to thrive, recurrent fractures, mental retardation, and cranial nerve abnormalities. Over 70% of the cases have been from Middle Eastern and North African countries where genetic heterogeneity is suggested by a more severe variant of the disease. More than 70 cases have been documented in the literature, with more than half from Saudi Arabia. A recent study by Fathallah and colleagues documents evidence for a founder effect in 24 patients with osteopetrosis and CAII deficiency from 14 Tunisian families. A filiation study led to the tracing of a gene to a common Arabic tribe that settled in the Maghreb in the tenth century. The gene locus for CAII has been mapped to chromosome 8q2 with several mutations identified, the most common being the Arabic one, which is a splice junction mutation in intron 2. More recently, mutations in the gene *OC16*, encoding the a3 subunit of the osteoclast V-H^+-ATPase, have been shown to cause infantile malignant osteopetrosis.

Clinical Findings in DRTA

In infants and children the clinical manifestations of proximal and DRTA are similar, namely, growth failure, vomiting, and recurrent bouts of dehydration. Hypokalemia occurs in about 30% of patients with DRTA. Muscle weakness, sometimes progressing to skeletal or respiratory muscle paralysis may occur if hypokalemia is severe. Potassium depletion will also cause impaired urinary concentration resulting in polyuria and polydipsia with a tendency for extracellular fluid volume contraction and secondary hyperaldosteronism, which will further aggravate renal potassium wasting. Rickets or osteomalacia are frequently observed in untreated DRTA. Hypocitraturia, together with the alkaline urine, and hypercalciuria in patients with DRTA play an important role in the pathogenesis of nephrocalcinosis, which is found in more than two thirds of the cases (*Fig. 306.2*). Nephrocalcinosis is seldom observed in patients with PRTA. The sequelae of impaired hydrogen ion secretion by the distal tubule are illustrated in *Fig. 306.3*

Differential Diagnosis of DRTA

Table 306.1 lists the different clinical entities considered in the differential diagnosis of DRTA. In infants the hereditary forms should be suspected in the face of a positive family history and consanguineous parents. The acquired

forms of DRTA may be seen at any age and should be considered in patients with tubulointerstitial renal diseases such as chronic pyelonephritis, obstructive uropathies, and post-renal transplantation.

Fig. 306.2
Medullary nephrocalcinosis in an infant with dRTA

Hyperkalemic DRTA (Type 4)

The hereditary forms of hyperkalemic RTA are extremely rare and are usually seen in association with pseudohypoaldosteronism of which two types are recognized (see Chap. 305, "Disorders of Distal Tubular Transport of Sodium and Potassium").

Type I Pseudohypoaldosteronism

Clinically, these patients present in early infancy with renal salt wasting, hypovolemia, hyperchloremic acidosis, and hyperkalemia. Plasma and urinary aldosterone are elevated. Two modes of inheritance are recognized. The autosomal dominant is relatively mild and the defect is restricted to the kidneys. It is caused by heterozygous mutations in the mineralocorticoid receptor gene. The autosomal recessive form is much more serious and associated with severe renal salt wasting and potentially lethal hyperkalemia. The disease has been characterized recently at the molecular level and found to be due to loss of

function mutations in the alpha, beta, and gamma subunits of the sodium epithelial channel, ENaC. In addition to the kidney, the salivary glands, the gastrointestinal and pulmonary systems may be also affected.

Type II Pseudohypoaldosteronism

This is a rare autosomal dominant disease with few case reports having appeared in the literature since the original description by Gordon and associates (see Chap. 305, "Disorders of Distal Tubular Transport of Sodium and Potassium"). It is characterized by hyperkalemic acidosis, hypertension secondary to plasma volume expansion, and suppression of renin and aldosterone. The proximate cause has been discovered recently to be secondary to gain of function mutations in the WNK1 and WNK4 kinases, which may enhance transcellular and paracellular chloride conductance as well as decreasing potassium efflux by inhibition of the potassium channel ROMK.

Voltage-Dependent RTA

Electronegativity of the distal luminal fluid is maintained by the principal cell that is involved in sodium absorption and potassium secretion. A lumen negative voltage due to reduced sodium reabsorption will indirectly impair hydrogen secretion by the alpha-intercalated cells and potassium secretion by the principal cells. Loss of sodium uptake into the cells of the distal nephron reduces the transepithelial potential for potassium and proton secretion, explaining the hyperkalemia and metabolic acidosis. The urinary pH is greater than 5.5, but will be appropriately acidic if the defect in sodium reabsorption is reversible. Voltage-dependent RTA may be observed in children with severe ECV contraction in which distal sodium delivery is significantly reduced. It may also be seen with urinary obstruction, sickle-cell disease, and lupus nephritis and as a side effect of several drugs, such as amiloride, triamterene, lithium, and trimethoprim.

Combined Voltage and Secretory Defects

Such a combined defect might explain the distal RTA observed in clinical states associated with reduced nephron mass and aldosterone deficiency or resistance. Patients with type IV RTA fall into this category and may be classified under various syndromes of hypoaldosteronism. In this subtype there is substantial reduction in renin production usually associated with chronic interstitial nephropathy. As a result, renin-dependent aldosterone secretion falls leading to low circulating levels with subsequent hyperkalemia and hyperchloremic acidosis. The condition is usually seen in adult patients with mild azotemia due to diabetic nephropathy, gout, chronic pyelonephritis, and interstitial nephropathy. It may also be seen in children with hydronephrosis and as a side effect of several drugs including nonsteroidal anti-inflammatory drugs, heparin and spironolactone.

Aldosterone Deficiency

This may occur with glucocorticoid deficiency as in adrenogenital syndrome and Addison's disease or as an isolated defect due to reduced aldosterone biosynthesis. Salt wasting is usually severe and hyperkalemia may be life threatening.

Infantile Type IV RTA (Partial Aldosterone Resistance)

This represents a relatively common type of hyperkalemic RTA in infants and young children. In this condition there seems to be partial resistance to the action of aldosterone with hydrogen and potassium retention, but normal sodium reabsorption and therefore no renal salt wasting. The clinical presentation is like that of other types of RTA, with failure to thrive and vomiting. There is no sex predilection and familial occurrence has been reported. This condition tends to be self-limited and most patients will no longer require alkali therapy by the age of 5 years. It is quite possible, therefore, that the condition represents a maturational defect in distal tubular physiology that may be related to the mineralocorticoid receptor gene or the sodium epithelial channel. A transient post-receptor defect remains a possibility. Some of the clinical findings and differential diagnosis of hyperkalemic RTA are outlined in *Table 306.2*.

Other Types of DRTA

Rate-Dependent DRTA

This is a rather mild defect in acidification also involving the alpha-intercalated cells of the collecting ducts and is due to a decreased number of H^+-ATPase pumps or their rate of operation. Patients with rate-dependent RTA are able to lower urine pH when properly challenged but have a reduced maximal rate of hydrogen ion excretion. Rate-dependent RTA is typically seen in patients with mild renal transplant rejection and in some cases of interstitial nephritis.

Incomplete DRTA

This entity is rare in children and is defined as an inability of the distal nephron to acidify the urine maximally with an exogenous acid load in the absence of systemic acidemia. It is often discovered in patients being investigated for nephrolithiasis and nephrocalcinosis. Incomplete RTA may also be seen in some patients with familial renal magnesium wasting and hypercalciuria.

With any of the above defects, excretion of titratable acid and ammonium (net acid excretion) will be reduced resulting in positive hydrogen ion balance. In patients with type IV hyperkalemic RTA, urinary pH is appropriately acidic and titratable acid is usually normal, but ammoniagenesis and ammonium transport are suppressed

by the high serum potassium resulting in decreased ammonium and net acid excretion. A mild degree of renal bicarbonate wasting may be seen in patients with distal RTA. Moderate bicarbonaturia (up to 15% of the filtered load) is commonly seen in infants with a secretory defect but tends to improve with time.

The clinical and laboratory findings that help distinguish the different types of RTA, including PRTA, appear in ❯ *Table 306.3*.

Diagnostic Evaluation of Patients with DRTA

1. Determine serum anion gap: $Na-[Cl+HCO_3]=12-16$ mmol/L. In the absence of diarrhea or carbonic anhydrase inhibitors, a normal anion gap acidosis establishes the presence of RTA.
2. Measure capillary pH and pCO_2 and serum potassium to establish the severity of acidemia and the degree of respiratory compensation and diagnose hypo- or hyperkalemia.
3. Urine pH on a freshly voided specimen. If less than 5.5 and serum potassium is normal or low in the presence of acidemia, proximal RTA is the most likely diagnosis. This is confirmed if urine anion gap is negative (see below).
4. Assess glomerular function by blood urea and creatinine levels, creatinine clearance, and radionuclide scan if indicated. These are usually normal.
5. Assess global tubular function by measuring urine osmolality, glucose, amino acids, phosphate, uric acid, sodium, potassium, calcium, and magnesium to rule out Fanconi syndrome.
6. Radiologic evaluation to rule out nephrocalcinosis and rickets.
7. Determine urine anion gap (U_{AG}) by subtracting urine chloride from the sum of urine sodium and potassium concentrations: $U_{AG}=[U_{Na}+U_K]-U_{Cl}$. A negative value indicates that there is another unmeasured cation, ammonium (NH_4^+), signifying a normal distal acidification and ruling out distal RTA. A positive U_{AG} with a normal or low serum potassium and urine pH of >5.5 is highly suggestive of a secretory or gradient defect RTA. This can be substantiated by simultaneous determination of urine and blood pCO_2 (U-B pCO_2) during bicarbonate loading or following carbonic

Table 306.3
Clinical and laboratory findings in RTA

	Proximal RTA (Type II)	Distal RTA		
		Type I		Type IV
		Secretory or gradient defect	Voltage defect	Hypoaldosteronism Pseudohypoaldosteronism
Age	Infancy, childhood	Infancy	Any age	Any age

Alkali requirement (mg/kg/day)	5–20	2–14	2–3	2–3

NAE net acid excretion=(NH_4^+ titratable acid), *Urine AG* urine anion gap, *U-BpCO₂* simultaneous measurements of pCO_2 in urine and blood during intravenous bicarbonate infusion and urine alkalization (U pH>7.5), *FE_{HCO3}* fractional excretion of HCO_3 – or percentage of filtered load of bicarbonate excreted in the urine

anhydrase inhibition and urine alkalinization. If distal hydrogen ion secretion is intact, hydrogen will combine with bicarbonate to form H_2CO_3. Due to the absence of luminal carbonic anhydrase IV in the distal tubule, H_2CO_3 will be dehydrated slowly to CO_2, and will raise tubular urine pCO_2 levels (*Fig. 306.4* and *Table 306.3*).

Because of the impermeant nature of the uroepithelial membranes, this rise in pCO_2 will be reflected in the final urine. With normal distal hydrogen ion secretion, urine pCO_2 values rise above 70 or 80 mmHg and the U-B pCO_2 is greater than 20 mmHg. If the U_{AG} is positive (low NH_4^+) in the presence of hyperkalemic RTA, a urine pH above 5.5 is indicative of a voltage-dependent RTA. If urine pH is below 5.5, the diagnosis of hypoaldosteronism or any of the syndromes of pseudohypoaldosteronism should be considered.

8. Ammonium Chloride Load: (100 meq/m^2 po)/ Furosemide-Fludrocortsone. This test of urine acidification should be used only in equivocal or borderline cases of suspected RTA when plasma bicarbonate is above 16–17 mmol/L and the urine pH is greater than 5.5. A normal test will result in lowering of the urine pH to less than 5.5 (usually less than 5.0) and yield a net acid excretion in excess of 40 μeq/min/m^2. Many patients tolerate NH_4Cl ingestion poorly because of gastric irritation and develop nausea and vomiting.

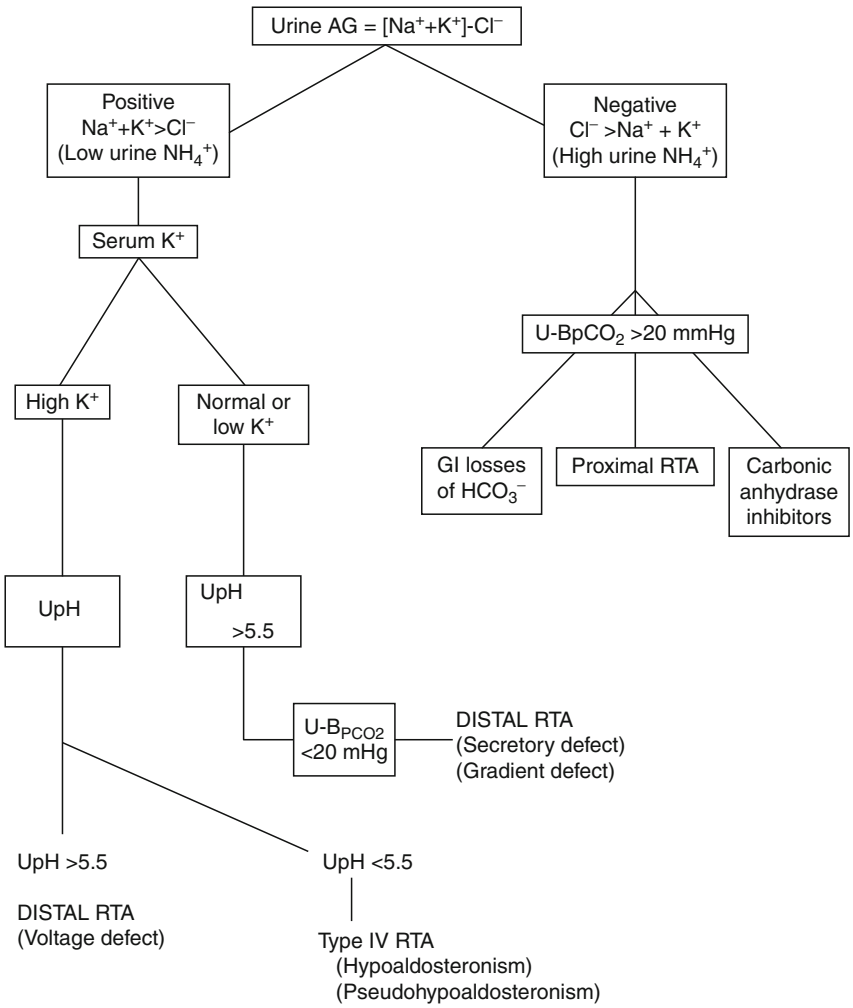

Fig. 306.4
Urine anion gap in the differential diagnosis of RTA (Modified from Lash and Arruda (1993)

An alternative way to test the capacity for distal acidification is to administer furosemide and mineralocorticoid fludrocortisone simultaneously. The combination of both, increased distal Na^+ delivery and mineralocorticoid effect, will stimulate distal H^+ secretion by both increasing the luminal electronegativity and having a direct stimulatory on H^+ secretion.

Treatment and Prognosis of DRTA

The treatment of distal RTA consists of adequate alkali replacement to normalize plasma bicarbonate. Infants with the classical variety require 2–3 meq/kg/daily in three divided doses. This corresponds to the endogenous acid production. Those with renal bicarbonate wasting may require higher doses of alkali (3–14 meq/kg/day) in four or more divided doses depending on the extent of their urinary losses. For patients with moderate or severe hypokalemic RTA, potassium citrate alone or in combination with sodium citrate (Polycitra) is the treatment of choice. One milliliter of Polycitra yields 2 meq of bicarbonate, 1 meq of sodium, and 1 meq of potassium. With correction of acidosis a "catch-up" growth is seen within a few months and normal stature is eventually attained. Correction of acidosis also corrects the hypocitraturia and prevents nephrocalcinosis and deterioration in renal function, if treatment is instituted before the age of 3 years. Partial correction of metabolic acidosis with inadequate alkali replacement will not prevent the development of nephrocalcinosis and possible chronic renal failure. The sensorineural deafness associated with autosomal recessive DRTA does not improve with treatment, even if initiated early in the course of the disease.

In the secondary forms of distal RTA, the therapy will depend on the underlying disease. Most patients will require 2–3 meq/kg/day of sodium bicarbonate in divided doses. In patients with severe rachitic bone disease a short course of vitamin D will accelerate the healing process.

In patients with hyperkalemic RTA, treatment is tailored to the underlying disease process. In voltage-dependent hyperkalemic RTA, a high sodium and low potassium intake with or without a thiazide or loop diuretic will lower serum potassium and raise bicarbonate to normal levels, but alkali therapy may be required in some patients. For patients with the various syndromes of hypoaldosteronism, and pseudoaldosteronism, treatment will consist of adequate salt intake to replace urinary losses and a mineralocorticoid supplement if necessary (Florinef .05–0.1 mg/day). In patients with hyporeninemic hypoaldosteronism, the use of Furosemide 1–2 meq/kg/day may be sufficient to correct the hyperkalemia and acidosis, but alkali therapy may also be necessary in some patients.

307 Nephrogenic Diabetes Insipidus

Deborah P. Jones

Definition/Classification

Diabetes insipidus (DI, *insipidis*, from Greek, "to pass through" and Latin, "without taste") is a disorder characterized by inability of the kidney to concentrate urine. It is complicated by polyuria, polydipsia, and increased risk for hypertonic dehydration. DI may result from defects in the central nervous system, which impair production/release of antidiuretic hormone (ADH, also known as vasopressin), a condition known as central DI, or from inability of the kidney to respond to ADH, known as nephrogenic DI (NDI). In central DI, because the kidney's response to ADH is preserved, ADH is used as therapy.

Etiology

Proper concentration of urine requires a hypertonic renal medulla (the result of normal function of the ascending limb of the loop of Henle) and normal function of the collecting duct, which controls water excretion. In the collecting duct, ADH increases luminal permeability to water by its action on the membrane abundance of apical water channels (aquaporin 2 channels, AQP2). Activation of the vasopressin 2 receptor (V2R) stimulates an intracellular signaling cascade, which stimulates the recruitment of previously synthesized water channels contained in endocytic vesicles to be inserted into the luminal membrane thus allowing the passive movement of water into the cell; water exits via other aquaporin channels (type 3 and 4) found on the basolateral membrane of the collecting duct cell.

Pathogenesis

In childhood, NDI is most often the result of congenital disease resulting from mutations of the transport systems required for active water reabsorption in response to vasopressin. (❯ *Fig. 307.1*) Genetic mutations of the vasopressin receptor are responsible for 90% of affected individuals with NDI, and mutations of the aquaporin 2 channel account for 10%. The X-linked form of NDI resulting from mutations in the AVPR2 gene, located on the X chromosome, explains the male predominance of this disorder. The incidence of X-linked NDI in the province of Quebec, Canada is estimated at 8.8/million live male births. In Nova Scotia, another Canadian province, the incidence is much higher (58/million male births) due to a founder effect from those who arrived to the region on the Ship Hopewell. Although most affected individuals are able to translate the V2R protein, it is not properly folded and thus not translocated to its proper location on the basolateral membrane; thus, absence of receptor or abnormal receptor interrupts the G-protein coupled cellular response following V2R activation.

Autosomal dominant and recessive modes of inheritance result from mutations of the AQP2 gene located on chromosome 12. Affected individuals with this form of NDI also appear to have intracellular trafficking abnormalities, which lead to retention of the protein within the endoplasmic reticulum instead of endosomes ready for recruitment to the apical membrane. The lack of apical AQP2 on the apical membrane prevents normal water movement in response to a normal vasopressin-induced intracellular signaling cascade. To date, there are no clinical characteristics that allow distinction between the two major underlying genetic forms of NDI. In addition, some individuals with clinical NDI have not been found to have either of these known defects in collecting duct water transport.

Case

A 2-year-old WM was referred by his pediatrician for polyuria and polydipsia. His mother reports that he drinks 200–300 oz of water each day. He wakes up every night to drink water and requires numerous diaper changes during the night due to a large urinary volume. When deprived of fluids, his lips become red and dry; he has been seen drinking water from the garden hose, gutter downspout drain, toilet, and pet bowl. He was the 8 lb product of an uneventful pregnancy. He was nursed until the age of

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_307,

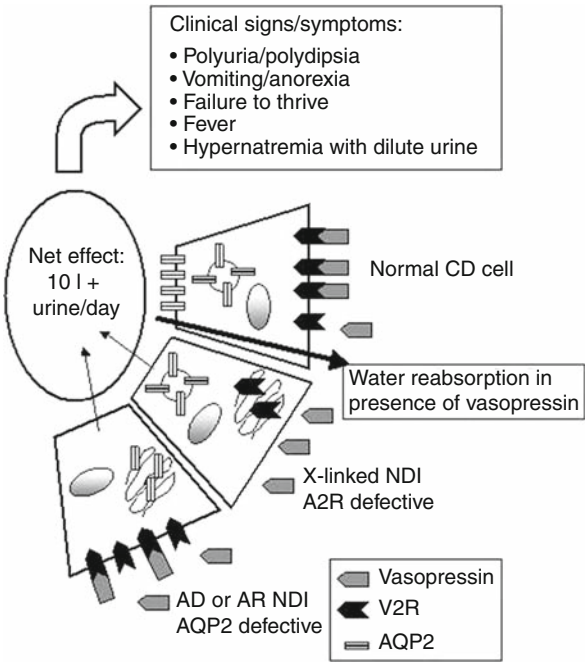

Figure 307.1
Cellular events involved in the vasopressin-induced water reabsorption in the normal collecting duct cell and in those resulting from mutations of either the V2R or AQ2 gene are represented. Common clinical symptoms/signs that accompany the underlying defect in water transport (reabsorption) are listed

6 months. Mother was often told that she was feeding him too much as he nursed constantly and also had vomiting during early infancy. Past medical history is without serious illness or hospitalization. Developmental milestones have been met. Family history is negative for kidney disease, specifically conditions with polyuria. Physical exam reveals an active and well-appearing boy who is drinking water directly from the exam room faucet. Weight was at the 50th and height at the 10th percentile.

Clinical Manifestations

The clinical presentation of NDI can be nonspecific particularly in infancy. The most common symptoms and signs at presentation are vomiting/anorexia (72%), failure to thrive (52%), fever (41%), constipation (34%), polydipsia (14%), and psychomotor retardation (3%). In a recent case series of genetically confirmed cases (30 males) the median age at diagnosis was 9 months, and mean age was 25 months. More than half were diagnosed by 12 months of age, and 87% were diagnosed by 18 months. Serum sodium is often increased, along with signs of dehydration and inappropriately dilute urine is found. Interestingly, family history was present in 25% of cases and six previous infant deaths were discovered to have likely been the result of undiagnosed NDI among families of identified cases. Given the nonspecific symptoms and often the lack of family history, diagnosis of NDI may be delayed. Previous case series indicated that up to 80% of affected individuals had signs of mental retardation. This is suspected to have been the result of repeated episodes of dehydration, fever, etc. With the trend toward earlier diagnosis in the past 2 decades, the prevalence of psychomotor retardation in children with NDI appears to be decreasing. Infants who receive mother's milk, which has a lower solute load, may also be somewhat protected. In the experience of this author, parents often give impressive histories describing extraordinary water craving: i.e., drinking from the outdoor waterspout, from the dog's bowl, and from the toilet. In, addition, infants with NDI often prefer water to milk or food in contrast to otherwise healthy children.

Case, continued: Laboratory evaluation sent at referral included a sodium level of 140 mmol/L, creatinine 0.5 mg/dL, urine specific gravity 1.005, and urine osmolality was 72 mOsm/kg. He underwent an abbreviated water deprivation test. At 4 h, the plasma osmolality was 309 mOsm/kg, sodium 149 mmol/L, and urine osmolality was 118 mOsm/kg. An ADH level was drawn and he was given DDAVP 1.5 mg/m^2 by subcutaneous injection; the highest urine osmolality obtained was 141 mOsm/kg, and at 1 h post ADH, the test concluded. His plasma ADH level was high – 38.1 pg/mL.

Differential Diagnosis

Polyuria, which is the clinical manifestation of inability to concentrate urine, may result from disorders other than DI. These disorders include other congenital renal tubular disorders such as Bartter/Gitelman syndrome and Fanconi syndrome. In contrast to NDI, these conditions are characterized by abnormalities in electrolyte handling, which are accompanied by hypokalemic metabolic alkalosis with or without hypomagnesemia (Bartter/Gitelman syndrome) and by hypokalemic, hypophosphatemic acidosis often with rickets (Fanconi syndrome). In addition, primary polydipsic syndromes may also cause polyuria. Acquired forms of NDI include lithium intoxication, hypercalcemia, protein malnutrition, sickle cell

nephropathy, hypokalemia, juvenile nephronopthisis, and obstructive uropathy.

Diagnosis is dependent upon demonstration of inappropriately dilute urine in the setting of hyperosmolar plasma. In the case of individuals who present with hypernatremia and hyperosmolality, water deprivation is not required. In such a clinical setting, documentation of a urine osmolality of less than 300 mOsm (should be >800 in a normal child) is sufficient to indicate a significant concentrating defect. Administration of vasopressin is followed by measurement of urinary osmolality; individuals with central DI are able to increase the urine osmolality by at least 200 mOsm. Those with NDI show no significant increase in urine osmolality after vasopressin. In some cases in which the primary complaint is polydipsia and polyuria in the presence of normal serum sodium and plasma osmolality a short water deprivation test may be performed under close supervision. It is advised that this test be performed by those experienced in its procedure and interpretation. Measurement of plasma vasopressin may also be helpful in differentiating central from nephrogenic DI, as levels are lower than normal in central DI and elevated in NDI. Although NDI is much more common among males, females may be affected. The mutation may be expressed in females depending upon which X chromosome becomes inactivated in early embryogenesis. Therefore, the presence of clinical symptoms and signs suggestive of a concentrating defect in a female does not eliminate the possibility of NDI.

Given that 10 L of urine may be required to be excreted by the urinary tract, urologic complications of NDI are not uncommon. These complications include severe hydronephrosis, renal pelvic dilation, transient ureteral dilation, acute urinary retention, urinary infection, and nocturnal enuresis. Therefore, interval renal ultrasounds are recommended in the management of these patients. Growth may also be abnormal particularly in the first year of life. This aspect may be related to the feeding intolerance and the need to consume large volumes of water rather than food.

Case, continued: Imaging of the kidneys and bladder by ultrasound was normal. He was started on hydrochlorothiazide and amiloride. His mother reported a marked decrease in urine volume and increased appetite after initiation of treatment. A de novo mutation in the patient's vasopressin receptor gene was confirmed; his mother was not a carrier. Renal imaging studies at 5 years of age were still normal. At last follow-up, at 5 years of age, his height was at the 50th and weight at the 75th percentile. He continues to have polyuria and polydipsia, which is manageable during the day. Nighttime urine volume continues to be challenging.

Treatment

Treatment starts with access to water at all times. For infants, this may require creative methods. The mother of one of the author's patients fashioned a nipple attached to a large water bottle, which traveled wherever the child went – in stroller or bed. Dietary therapy is aimed at reduction of renal solute load. Previously prescribed low-protein diets are no longer recommended as they result in protein malnutrition. Low dietary salt is still recommended. Drug therapy most often initiates with thiazide diuretics (HCTZ 3 mg/kg/day, divided BID) in combination with the potassium sparing diuretic amiloride (0.3 mg/kg/day) and/or potassium supplementation. Although administration of diuretics to patients with polyuria seems counter intuitive, the thiazide diuretic hydrochlorothiazide reduces urine volume. This effect was initially attributed to increased proximal tubular water and solute reabsorption; however, recent studies indicate that thiazide diuretics increase water permeablility in the inner medullary collecting duct. In addition, hypokalemia should be avoided due to its potential contribution to abnormal urinary concentration. Nonsteroidal anti-inflammatory drugs such as indomethacin (2–3 mg/kg/day, divided BID) have also proven useful for NDI. These agents increase proximal tubular fluid and solute reabsorption; they seem to be tolerated fairly well. Unfortunately, they may be accompanied by gastrointestinal and renal toxicity. Although reduced by as much as 70% below baseline values with pharmacologic therapy, urine volumes and water intake are still excessive: one case series reported that despite therapy with HCTZ/amiloride, oral intake ranged from 125 mL/kg/day to 250 mL/kg/day and urine output from 3 mL/kg/h to 10 mL/kg/h. Most children continue to awaken at night to drink water and continue to demonstrate nocturnal enuresis despite optimal drug therapy. An algorithm for evaluating a child with polyuria is found in *Fig. 307.2*.

Although rare, the diagnosis of NDI should be considered in any child with polyuria and polydipsia, and in the setting of hypertonic dehydration in which dilute urine is found. Molecular characterization of the results of genetic mutations in the V2R and AQP2 have allowed a much better understanding of the underlying defects commonly found in children with NDI. Drug therapy is available which appears to be well tolerated and to support near normal growth. Unfortunately, most affected children

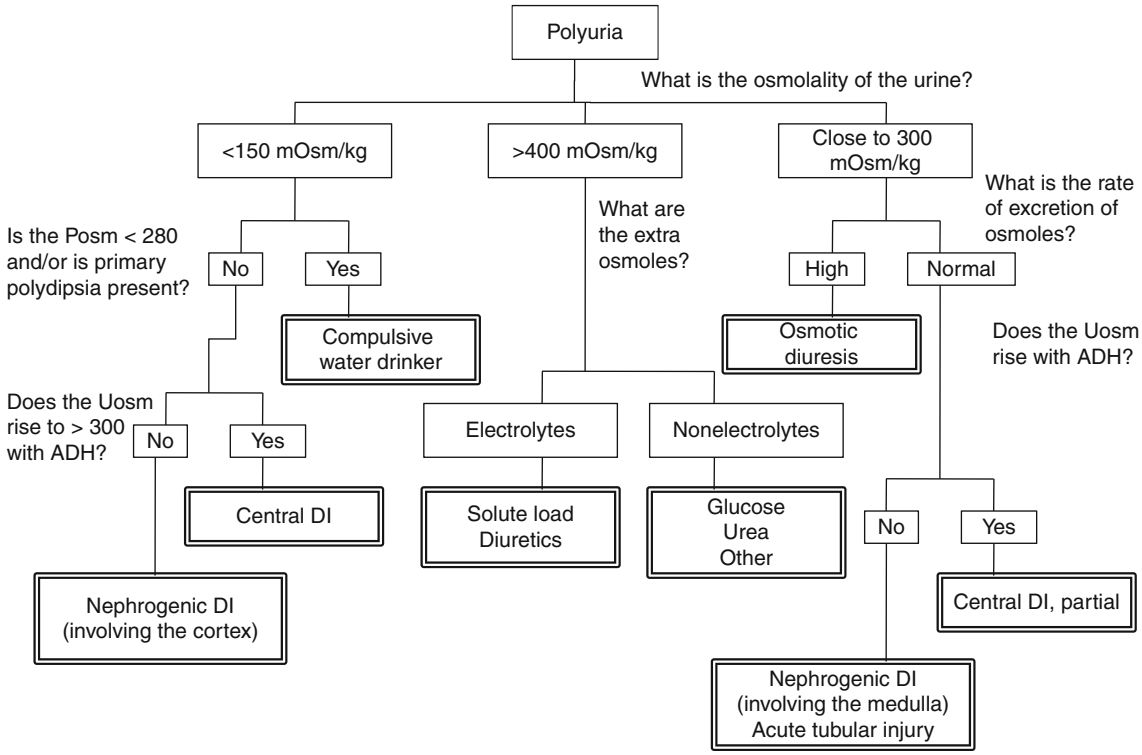

Figure 307.2
An algorithm for evaluating a child with polyuria

continue to display some symptoms and signs of excessive urinary volume.

Treatment: Future Development

Given that both V2R and AQP2 mutations have been associated with protein trafficking abnormalities, the potential for specific drug therapies aimed at escorting the miss-targeted proteins to their appropriate location on the basolateral or apical membrane of the collecting duct may eventually be available.

308 Urinary Stone Disease

Burhan Edrees · Soud Al Rasheed

Overview

Definition

Nephrolithiasis is the formation of stones in the kidney, while urolithiasis is stone in the urinary system. The existence of nephrolithiasis was known to Hippocrates, who described the symptoms of renal colic: "An acute pain is felt in the kidney, the loins, the flank and the testis of the affected side; the patient passes urine frequently; gradually the urine is suppressed. With the urine, sand is passed."

Nephrocalcinosis, when there is generalized increase in Calcium content of the kidney, which can be microscopic or macroscopic when you can see abnormal renal tissue using radiologic evaluation.

Epidemiology

Geographical Distribution

The incidence of urolithiasis in a given population is dependent on the geographic area, racial distribution, and socioeconomic status of the community.

Changes in socioeconomic conditions over time, and the subsequent changes in dietary habits, have affected not only the incidence but also the site and chemical composition of calculi.

In different series of patients of all ages with renal stone, prevalence in children ranges from 2 to 2.7%, can go up to 17% in some countries like Turkey, where urolithiasis is considered to be endemic. In the pediatric population, recent studies have shown that the annual incidence in children may be increasing in the West. In a series from Iceland, the annual incidence of kidney stones was 5.6 and 6.3 per 100,000 children under 18 and 16 years of age. The overall probability that an individual will form stones varies in different parts of the world. In view of adult literatures, the risk of developing urolithiasis in adults appears to be higher in the western hemisphere (5–9% in Europe, 12% in Canada, 13–15% in the USA) than in the eastern hemisphere (1–5%), although the highest risks have been reported in some Asian countries such as Saudi Arabia (20.1%). In Europe, it is reported that the occurrence of urolithias in the nineteenth century population was quite similar to that of the twentieth century in Asia. The rate of hospital admissions due to renal stone disease varies widely in different geographic regions, from 0.001 to 0.1% in the USA to 7% in Asia. This rate is one tenth of that seen in the adult population. Boys show a mild preponderance for stone disease, with a male to female ratio of 1.4:1 to 2.1:1, with more preponderance in white children in USA, and with African American and Asian children only rarely affected.

Renoureteral calculosis featuring mainly calcium oxalate and phosphate is currently more frequent in economically developed countries, whereas vesical calculosis (urinary bladder stone) is fairly widespread in Asia, with calculi composed of ammonium urate and calcium oxalate.

Stone composition has changed substantially over the past decades, with a progressive increase in frequency of calcium oxalate and calcium phosphate stones. Recent epidemiology studies from different continents and countries report that calcium oxalate accounts for 60–90% of stones in children, followed by calcium phosphate (10–20%), struvite (1–14%), uric acid (5–10%), cystine (1–5%), and mixed or miscellaneous (4%). Hypercalciuria is recognized worldwide as the most frequent underlying factor in calcium oxalate stones, although, in some countries of the eastern hemisphere, hypocitraturia has been reported as the leading cause. Other less frequent metabolic risk factors are hyperuricosuria and hyperoxaluria. However, increased urinary oxalate excretion might be underestimated and might even be a more prevalent risk factor than hypercalciuria for stone disease in some populations. Struvite or infection-related stones, which were very common in children until the last century, are rarely seen today in industrialized countries, possibly due to improved management of both pediatric obstructive uropathy and urinary tract infections. Bladder stones based on malnutrition during the first years of life are currently a frequent finding in various areas of Turkey,

Iran, India, China, Indochina, and Indonesia. Although the incidence is proportionally decreasing as social conditions improve. This trend defined as "stone wave" has been explained in terms of changing social conditions and the consequent changes in eating habits. In Europe, Northern America, Australia, Japan, and, more recently, Saudi Arabia, affluence has spread to all social classes and with it the tendency for individuals to increase protein intake in large quantities.

The Afro-Asian stone-sucess forming belt stretches from Sudan, the Arab Republic of Egypt, Saudi Arabia, the United Arab Emirates, the Islamic Republic of Iran, Pakistan, India, Myanmar, Thailand, and Indonesia to the Philippines (*Fig. 308.5*). In this area of the world, the disease affects all age groups, from less than 1 year old to more than 70 years old, with a male-to-female ratio of 2 to 1. The prevalence of calculi ranges from 4% to 20%. The higher prevalence of urolithiasis in many of those countries is possibly determined by the high consanguinity that prevails among ethnic groups that live in those geographical areas.

Other risk factors involved in this geographical pattern are cultural practices such as the chewing of betel quid, which is common in many countries of the world, particularly in Southeast Asia. The quid consists of a preparation of areca nut, betel leaf, and calcium hydroxide "lime" paste, which produces a high incidence of hypercalciuria and hypocitraturia.

In the north Indian population, the absence of Oxalobacter formigenes, an intestinal oxalate degrading bacteria, can lead to a significant increase in the risk of absorptive hyperoxaluria.

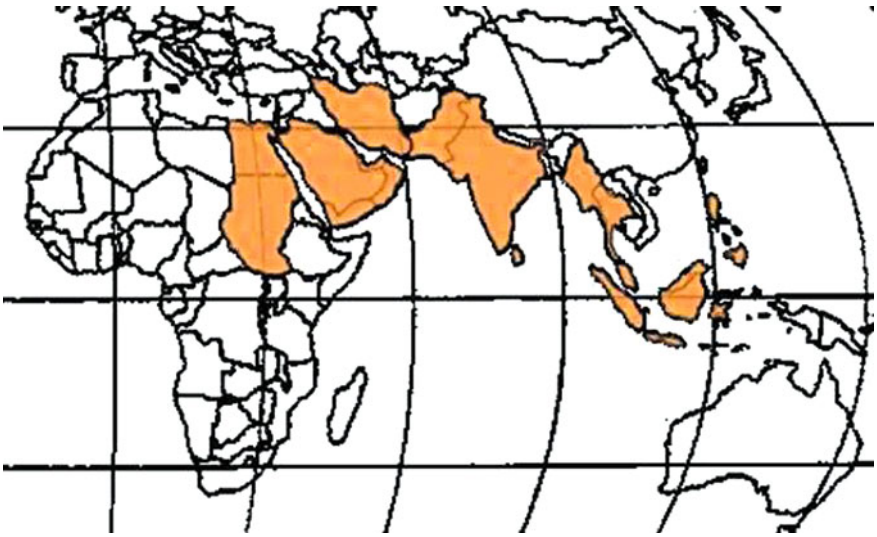

Figure 308.5
North African–Asian stone belt

Urolithiasis is most common in the southeastern region of USA, where the states of Virginia, North Carolina, Georgia, Tennessee, and Kentucky are described collectively as the North American "stone belt" (*Fig. 308.6*).

In summary, the epidemiology of renal stones with regard to stone composition is continuing to change all over the world toward a predominance of calcium oxalate stones. Major differences in the frequency of the other constituents, particularly uric acid and struvite, reflect particular eating habits and infection risk factors specific to certain population.

Pathogenesis

Stone formation is due to imbalance between *promoter* (which increases the tendency to form stone) and *inhibitor* (which increases solubility of stone constituents).

Figure 308.6
North American stone belt

The first step in the pathogenesis of nephrolithiasis is the formation of crystal nuclei. This occurs when the concentration of a salt exceeds the solubility limit "supersaturation." This is sometimes accompanied by a deficit of the protective substances known as crystallization inhibitors (e.g., citrate, magnesium, potassium etc.) The term "urinary stone risk factor" refers to conditions that promote the crystallization of a salt.

Widely recognized urinary stone risk factors are low urinary volume and increase in salt urinary excretion, and an excessively alkaline urinary pH (>7.0), or excessively acid urinary pH (<5.5), according to the type of stone. Alternatively if the urine is very concentrated due to decreased fluid intake a stone is most likely to be produced, and this is why a stone is most likely to occur in hot weather or in people who do not drink much fluid.

Etiology

There are different causes of renal stone, majority in children being metabolic causes. We can elaborate some of those causes as follows:

1. Hypercalciuria:

   Hypercalciuria is the most important pathophysiologic risk factor in calcium stone formation.

   Types of hypercalciuria:

   Absorptive hypercalciuria:

   Occurs in approximately 20–40% of stone formers, and is characterized by increased intestinal absorption of calcium. The positive calcium balance suppresses parathyroid hormone (PTH) secretion and increases the renal filtered load of calcium, leading to increased urinary calcium excretion. It was deduced that the 4q33-qter segment contains the putative gene for absorptive hypercalciuria.

   A severe form of absorptive hypercalciuria has been mapped to chromosome 1q23.3-q24.

   It is classified as Type I or II, according to the response to dietary calcium restriction. Type I is diet-unresponsive and Type II, urinary calcium normalizes in response to a low calcium diet.

   Renal Hypercalciuria:

   Secondary to Impaired renal tubular reabsorption of calcium. Renal loss of calcium reduces serum calcium and secondarily stimulates PTH secretion. Consequently, increased intestinal calcium absorption caused by enhanced 1,25-[OH]2D synthesis and mobilization of calcium from bone caused by increased PTH lead to hypercalciuria. The pathogenesis of renal calcium leak is unknown. Renal hypercalciuria is relatively uncommon, occurring in approximately 5–8% of stone formers.

   Resorptive hypercalciuria:

   Rare cause of stone disease, 3–5%, that is most commonly associated with primary hyperparathyroidism. Excessive PTH secretion from a parathyroid adenoma leads to bone resorption, increased renal synthesis of 1,25-[OH]2D (calcitriol), and enhanced intestinal absorption of calcium.

   Other causes of hypercalciuria

   A number of conditions like hypercalciuria associated with special inherited diseases, see *Table 308.3*,

Table 308.1
Frequency of urolithiasis according to age, stone location, gender, and stone composition in populations of different socioeconomic levels

Variable	Socioeconomic level	
	Low	High
Overall frequency in children	High	Low
Bladder stones (%)	>40	<10
Female patients (%)	<20	>25
Calcium oxalate (%)	<40	>60
Uric acid (%)	>30	<20

History, epidemiology and regional diversities of urolithiasis
Source: López M, Hoppe B (2010) Pediatr Nephrol doi: 10.1007/s00467-008-0960-5

granulomatous diseases, including sarcoidosis, tuberculosis, and histoplasmosis, have been reported to cause hypercalcemia; bedridden patients like cerebral palsy if not discovered early will have bone resorption and hypercalciuria, in which conditions weight bearing exercises and increased fluid intake can be of help.

2. Hypocitraturia
Citrate is the most abundant organic anion in human urine, and is a well-recognized inhibitor of stone formation. Hypocitraturia is a well-known risk factor for calcium nephrolithiasis, and has been identified in 20–60% of calcium stone formers.

Citrate complexes with calcium in solution forms a soluble complex and decreases urinary saturation of stone-forming calcium salts (CaOx and calcium phosphate).

By that it inhibits crystallization, aggregation, and agglomeration of CaOx and calcium phosphate, thereby further reducing stone formation. Acid load promotes proximal tubular reabsorption of citrate and reduced citrate synthesis, leading to hypocitraturia, whereas alkali load reduces tubular reabsorption and enhances citrate synthesis, thereby increasing urinary citrate excretion. A variety of pathology associated with acidosis leads to hypocitraturia. Distal renal tubular acidosis (RTA) is associated with systemic acidosis, and is characterized by high urine pH, and low serum bicarbonate and potassium.

Chronic diarrhea is associated with systemic acidosis because of alkali loss in the stool. Excessive animal protein provides an acid load that promotes bone loss and causes hypocitraturia. Other causes of acidosis associated with hypocitraturia are thiazide-induced hypokalemia, which produces intracellular acidosis, and vigorous exercise, which produces lactic acidosis. Overweight status in children might be associated with an elevated risk of stone formation in both sexes owing to the alterations in urine composition, with status of hypocitraturia. Finally, idiopathic hypocitraturia may represent an isolated abnormality, unrelated to an acidotic state.

3. Hyperoxaluria
Is thought to increase the risk of stone formation by increasing urinary saturation of CaOx. The effect of oxalate on stone formation depends on the interaction between calcium and oxalate that takes place in the intestine and urine.

In the intestine, oxalate absorption is modulated by dietary oxalate and the formation of a poorly absorbed calcium-oxalate complex. In the setting of dietary calcium restriction, calcium-oxalate complex formation is reduced, thereby increasing luminal free oxalate that is absorbed from the intestine and excreted in the urine.

Hyperoxaluria can be associated with primary disorders in biosynthetic pathways (primary hyperoxaluria), or high substrate levels (excessive vitamin C).

Primary hyperoxaluria is caused by a rare inherited autosomal recessive disorder in glyoxalate metabolism by which the normal conversion of glyoxalate to glycine is prevented, leading to oxidative conversion of excess glyoxalate to oxalate, an end product of metabolism. Systemic oxalosis ensues, and leads to excretion of markedly high levels of urinary oxalate. The risk of stone formation is increased when urine oxalate exceeds 0.4 mmol/L, especially if urine calcium concentration is elevated (i.e., more than 4 mmol/L), leading to the formation of monohydrated calcium oxalate (whewellite) crystals, causing stone formation and nephrocalcinosis (*Fig. 308.7*). At diagnosis, 54% of hyperoxaluric patients have had stones and 30% had nephrocalcinosis. Without treatment, end stage renal failure occurs in 50% of patients by age 15 years, with an overall mortality ~30%.

Two forms of primary hyperoxaluria have been identified: primary hyperoxaluria type 1 (PH1) [online Mendelian Inheritance in Man (MIM) 259900] is an autosomal recessive disorder (~1:120,000 live births per year in Europe), and alanine-glyoxalate aminotransferase (AGT) activity is either absent or mistargeted to the mitochondria. Primary hyperoxaluria type 2 (PH2) (MIM 260000) has been documented in fewer than 50 patients, which differ in the enzyme defect responsible for the disease,

Table 308.2

Genetics of disorders presenting with urolithiasis and/or nephrocalcinosis

Group of defects	MIM	Locus, gene	Inheritance	Gene product	Phenotype
Hypercalciuria-induced urolithiasis/nephrocalcinosis					
Autosomal dominant hypocalcemic hypercalciuria	146200; 601199	3q13.3-q21, CASR	AD	CASR	Hypercalciuria Hypocalcemia CRF
Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC)	248250; 603959	3q27, 1p34.2, CLDN16, CLDN 19	AR	Paracellin 1, (Claudin 16, 19)	Hypercalciuria, hypercalcemia, hypomagnesemia, dRTA, CRF, hypermagnesuria, polyuria, tetany seizures

glyoxylate reductase/hydroxypyruvate reductase (GR/HPR), and absence of GR/HPR activity both in the liver and lymphocytes. The median age at onset is 1–2 years, and the classical presentation is urolithiasis (whewellite), including hematuria and obstruction, but stone-forming activity is lower than in PH1. GFR is usually maintained during childhood, and systemic involvement is exceptional. The biochemical hallmark is the increased urinary excretion of L-glycerate, but the definitive diagnosis requires DNA analysis and screening of the most frequent mutation (c.103delG). PH1 is the most common and the most challenging form. The median age of patients when symptoms first appear is 5–6 years, and end-stage renal disease (ESRD) is reached between 25 years and 40 years of age in half of the patients. It is responsible for less than 0.5% of ESRD in children in Europe and 10–13% in countries with a high rate of consanguineous marriages. Along with progressive decline of glomerular filtration rate (GFR $<$ 30–50 mL/min per 1.73 m^2) due

to renal parenchymal involvement, continued overproduction of oxalate by the liver and reduced oxalate excretion by the kidneys lead to systemic involvement (oxalosis), bone becomes the major compartment of the poorly soluble oxalate pool. The combination of both clinical and sonographic signs is a strong argument for PH1, i.e., the association of renal calculi, nephrocalcinosis, and renal impairment; in addition, family history may bring additional information. PH1 grossly fits five presentations: (1) infantile form with early nephrocalcinosis and kidney failure; (2) recurrent urolithiasis and progressive renal failure, leading to a diagnosis of PH1 in childhood or adolescence; (3) late-onset form with occasional stone passage in adulthood; (4) diagnosis given by post-transplantation recurrence; and (5) presymptomatic subjects with a family history of PH1. Crystalluria and infrared spectroscopy are of major interest for identification and quantitative analysis of crystals and stones showing whewellite (*Fig. 308.7*).

Currently, a polymerase chain reaction using a serum sample can identify the three most common mutations in the involved genes. The AGXT gene is located on chromosome 2q37.3; numerous mutations and polymorphisms have been identified. Prenatal diagnosis can be performed from DNA obtained from chorionic villi or amniocytes. Indeed, one study reported that 66% of patients who had hyperoxaluria were diagnosed without the need for liver biopsy. The diagnosis of primary hyperoxaluria should be suspected in any calcium stone-forming child, because nephrolithiasis is the most common presenting symptom of the disease. Transplantation of the kidney and/or liver is generally required.

Malabsorptive state is the most common cause of hyperoxaluria with intestinal disease–associated stone formers. In the setting of fat malabsorption, saponification of fatty acids with luminal calcium reduces

Table 308.3
Steps in diagnosis

Steps	Diagnostic findings
History including family history	Diet, fluid intake, medications, vitamin supplementation, chronic disease? Malabsorption syndrome? immobilization?
Clinical findings	Pain, hematuria, vomiting, UTI, passage of stones, gravel
Imaging	Ultrasonography, plain film, non-contrast-enhanced CT, (MRI) intravenous urography
Urine	Density, specific gravity, osmolality, pH, glucose, protein, sediment, culture, spot urine (molar creatinine ratio of calcium, oxalate, uric acid, citrate, magnesium, cystine screening {nitroprusside test, amino acid screen}), 24 h urine (volume, pH, lithogenic and stone-inhibitory parameters, calculation of urinary saturation).
Blood/serum	Electrolyte, calcium, phosphorus, magnesium, creatinine, urea, uric acid, alkaline phosphatase, (PTH, Vitamin D/A, plasma oxalate, serum Vitamin B6 level)
Stone analysis	Infrared spectroscopy or X-ray diffraction
Indication for metabolic stone valuation	Recurrent stone formers
	Intestinal disease (particularly chronic diarrhea)
	Pathologic skeletal fractures
	Osteoporosis
	History of urinary tract infection with calculi
	Personal history of gout
	Infirm health (unable to tolerate repeated stone episodes
	Solitary kidney
	Anatomic abnormalities
	Renal insufficiency
	Stones composed of cystine, uric acid, or struvite

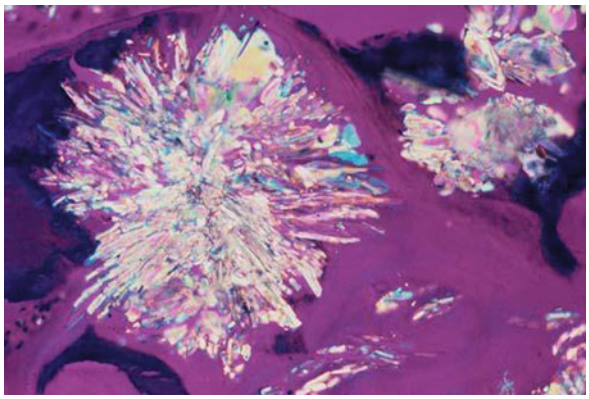

Figure 308.7
Bone biopsy in an adolescent with primary hyperoxaluria type 1. Examination under polarized light shows calcium oxalate crystals

calcium-oxalate complex formation in the gut, increasing the pool of unbound oxalate available for absorption.

Hyperoxaluria can occur from excessive dietary intake of oxalate-rich foods such as nuts, chocolate, brewed tea, spinach, and rhubarb. Severe calcium restriction may reduce intestinal oxalate binding, thereby increasing intestinal oxalate absorption. Excessive vitamin C intake has also been shown to increase oxalate excretion by in vivo conversion of ascorbate to oxalate. Oxalate-degrading bacteria such as Oxalobacter formigenes have been shown to colonize the intestine of normal individuals, and may reduce intestinal oxalate; absence of these bacteria has been linked to increased urinary oxalate levels.

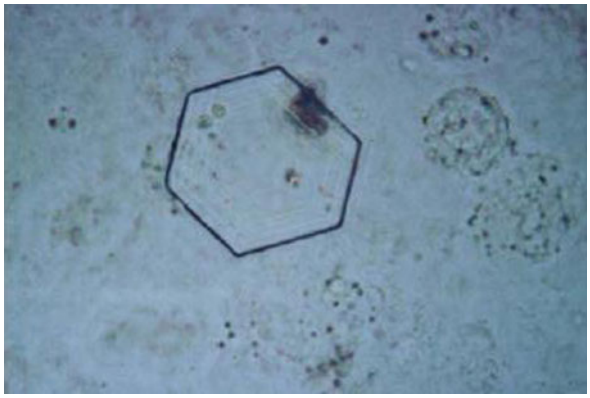

Figure 308.8
Examination of urinary sediment discloses a hexagonal crystal of cystine

4. Hyperuricosuria
Hyperuricosuria can lead to CaOx stone formation by heterologous nucleation on the surface of monosodium urate crystals. The most common cause of hyperuricosuria is increased dietary purine intake, as uric acid is the end product of purine metabolism.

Numerous hereditary (see *Table 308.3*) and acquired diseases can lead to hyperuricosuria, including gout, myelo- and lymphoproliferative disorders, multiple myeloma, hemolytic disorders, and hemoglobinopathies. The pathophysiology of hyperuricosuric CaOx nephrolithiasis is intimately related to urinary pH. At pH less than 5.5, poorly soluble undissociated uric acid precipitates, leading to uric acid or CaOx stone formation. At pH greater than 5.5, uric acid is found predominantly in its dissociated form. In special cases of excessive uric acid formation, increased urinary saturation of monosodium urate ensues, promoting CaOx stone formation through heterogeneous nucleation.

5. Cystinuria:
Cystinuria (MIM 220100) is an autosomal recessive inherited aminoaciduria that leads to recurrent nephrolithiasis, accounting for approximately 6% of metabolic stones in the pediatric population with prevalence varying throughout different global locations but is approximately 1 in 7,000 in the general population of Europe and the United States. Newborn screening programs have estimated the disease frequency at 1:100,000 in Sweden. On the other hand, high frequency of the disease has been reported for Libyan Jews living in Israel with a prevalence rate of 1/2,500. In Turkey in Sivas province, the prevalence of cystinuria is 1/772; this prevalence ratio is the highest ever among those

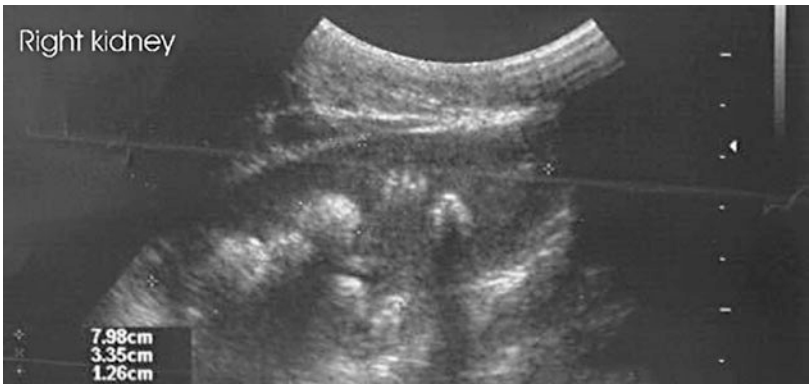

Figure 308.9
Ultrasound: staghorn urolithiasis of the right kidney

Figure 308.10
CT scan: staghorn urolithiasis of the right kidney and stones in the left ureter (*arrow*). Stones within the left kidney are not visible on this scan

reported for other countries. Three different types of cystinuria (types I, II and III) have been described. This classification has been modified as type I and non-type I (divided clinically as types II and III). In1994, a cystinuria gene (*SLC3A1*) was cloned and mapped on chromosome 2p16.3. The gene encodes the protein rBAT, a b0, +AT transporter-related protein expressed in the renal and intestinal epithelium. The glycoprotein rBAT causes cystinuria type I. It is thought that b0, +AT represents the catalytic subunit of the transporter complex and that rBAT is mainly involved in the trafficking and possible stabilization of the transporter in the brush border membrane. rBAT may also modify the functional transport properties of the complete transporter complex. The transporter functions as a tertiary active exchanger taking up cystine, arginine, lysine, and ornithine from urine in exchange for neutral amino acids. To date, more than 80 mutations in *SLC3A1* have been documented as cited by Škopková et al. The International Cystinuria Consortium has described a new classification system based on the chromosomal localization of the mutation, with type A cystinuria (45% of patients with cystinuria), mutations of the SLC3A1 gene on chromosome arm 2p encoding the rBAT protein called (type I) before.

Type B cystinuria (53% of patients with cystinuria), mutations of the SLC7A9 gene on chromosome 19, was called (non-type I) previously.

Type AB with mutations on both chromosomes is found in 2% of patients with cystinuria. Homozygous, compound heterozygous, and obligate heterozygous subtypes have been described, with homozygotes excreting the greatest amount of cystine; affected individuals demonstrate excretion of cystine and the dibasic amino acids ornithine, arginine and lysine in the proximal tubule. Due to a pH drop in the collecting duct, cystine (soluble at normal urinary pH) exceeds the solubility limit in urine and forms typical crystals and eventually kidney stones; diminished reabsorption of these amino acids in the intestine is not pathologic because these are not essential amino acids and their di-peptide forms are still transported.

By 1 year of age, a homozygous patient's urinary excretion of cystine is usually more than 1,000 mmol/g creatinine with a mean excretion rate of 4,500 mmol/g creatinine. At usual urine volumes, this excretion rate exceeds its solubility. Life-long recurrent stone formation is a characteristic of patients with the homozygous forms of cystinuria.

Heterozygote carriers may also form stones because they have been shown to excrete up to 2,400 mmol/g creatinine; parents of cystinuria Type A have normal levels of cystine and lysine excretion. Therefore, this type was also referred to as the fully recessive form. In type B, elevated levels of cystine and lysine are observed in obligate heterozygotes. It is currently well established that the clinical manifestations of cystinuria are exclusively renal. Their early recognition is important for timely treatment and genetic counseling.

Cystinuria may be diagnosed by the finding of hexagonal crystals (*Fig. 308.8*).

A prenatal approach to cystinuria has been suggested by the presence of hyperechoic colon during the third trimester of pregnancy, which may be due to the presence of large amounts of cystine in the colon wall.

The follow-up of these patients is based on urine volume (urine specific gravity target <1,010), urine pH (target ~7.5 – < 8), free urine cystine concentration (target < 1 mmol/L or < 100 μmol/mol creatinine), renal ultrasonography and, sometimes, urinary sodium (in order to estimate sodium intake), and crystal volume assessment (target < 3,000 $\mu m^3/mm^3$).

6. Infection:
   Children with a history of multiple urinary tract infections may be at risk of nephrolithiasis (struvite stones), especially if the organisms contain the enzyme urease, which results in a high urine pH that promotes the supersaturation of urine with struvite and calcium phosphate apatites. Patients with surgically augmented bladders are at risk of developing bladder stones, most commonly struvite stones.

Clinical Manifestations

The most common findings of urolithiasis in pediatric age groups are abdominal pain and hematuria; they might have vomiting and dysuria. The observation of a 33% hematuria rate in the metabolic group and a 26% dysuria rate in the infection group is clinically significant. Many studies reported that urine oxalate, uric acid, and calcium cause hematuria by damaging the uroepithelium, and in these cases urinary N-acetyl-glucoseaminoglycan (NAG) levels, as a marker of tubular injury, were elevated . These previous findings support the association of metabolic etiology and hematuria. Recent studies from various countries reported a mean age for urolithiasis of 4.2–8.2 years. The mean ages of the groups with metabolic etiology and infectious etiology were found to be lower compared with the other groups; a family history of urolithiasis was reported in 11.8–21.9% of patients. Diagnosis is often only made when nephrocalcinosis is incidentally noted on an imaging study performed for other reasons or when symptoms of reduced concentrating capacity of the renal tubules are obvious. The underlying pathological condition is not always evident and requires a detailed history and workup. Renal colic has been reported in some infants with nephrocalcinosis, but it is more likely due to passage of tiny calculi than to nephrocalcinosis per se. It is not unusual for nephrocalcinosis to be diagnosed during systematic renal ultrasound examination of high-risk infants or as part of the diagnostic evaluation of urinary tract infection. The first clinical symptoms, if any, are gross or microscopic hematuria and/or sterile leukocyturia that may be misdiagnosed as urinary tract infection. Single family member involvement was found more than multiple involvements. Stone occurrence was more in the immediate family members than distant relatives, especially brothers of affected patients. Study of stone risk in the family members should be centered on brothers and sons of stone patients.

Diagnosis

We should start with good history including immediate close relatives (brothers and sons), medications, possible risk factors like malabsorption, and immobilizations.

Clinical findings may not be very informative, but finding of hematuria, leukocyturia, passage of stone, abdominal pain, and dysuria may be of some help.

Laboratory evaluation can help especially in metabolic caused stones:

Serum levels of uric acid, electrolytes, creatinine, calcium, phosphorus, and bicarbonate should be measured. Serum parathyroid hormone level should be obtained in children who have hypercalciuria, hypercalcemia, or hypophosphatemia, vitamin A (for patients with hypercalciuria), serum vitamin B6 levels, and plasma oxalate (for patients with primary hyperoxaluria) and, of course, molecular genetic testing will later be necessary (*Table 308.3*).

Elevated serum alkaline phosphatase may indicate possible bone resorption. Twenty-four hour urine collection for sodium, calcium, urate, oxalate, cystine, citrate, and creatinine [determine tubular reabsorption of phosphate (TRP) or tubular maximum for phosphate corrected for glomerular filtration rate (TmP/GFR)] should be evaluated. Since many urinary components are influenced by dietary intake, 24 h urine collections (to exclude diurnal fluctuations related to intake of food and beverages) provide the best information and also provide an objective assessment of the child's daily intake of fluid. Advise the patient or the parent to maintain the normal fluid intake and the normal dietary habits, before 24 h urine collected (avoid urine sampling under parenteral infusions). Also keep in mind that stones in situ may diminish the excretion of urinary lithogenic material, as these substances may concurrently be absorbed by the stone. For urine collection, a preservative should ideally be placed directly into the sampling bottle; however, urine may be collected without initial preservation, so long as it is kept cool (at 4°C) and adequately preserved within 24 h. Ideally, the urine collection is to be obtained at least 6 weeks after the passage of a stone. Collecting two 24-h samples may be recommended. Determination of urinary supersaturation for calcium oxalate, calcium phosphate, and urate may be helpful (*Table 308.4*). Most children with elevated supersaturation values had urine volumes ≤ 1 mL/kg/h. The urinary creatinine excretion rate may be used to verify an adequate urine collection, with most children excreting ~15 to 20 mg/kg/24 h. If the creatinine

excretion is significantly more or less, it may indicate either an over- or undercollection.

If a 24-hour collection is difficult, especially in younger children, urinary standards based on single specimens, corrected to urine creatinine concentration, have been developed (*Tables 308.4* and *308.5*).

The calcium-to-creatinine ratio changes with age. If hypercalciuria is suspected on a single random sample, confirmation with 24-hour urine collection is needed.

A urine culture should be considered to exclude the possibility of acute or chronic urinary tract infection. Urinalysis may be helpful, particularly if crystals are noted. Cystine crystals are colorless, flat, and hexagonal, and if they are found in the urine, they are diagnostic for cystinuria. Cystine is screened for by nitroprusside test or by chromatography for amino acids.

Since the pH of the urine is a major factor in the formation of many stones, its measurement, preferably by glass electrode, or, if a pH electrode is not available, by pH paper with the specific and adequately distinguishable range of pH 2 to 9, is of utmost importance. Sometimes, it is advisable to determine a daily profile of both the pH and the density (specific gravity or osmolality) of the urine. This may also be used for follow-up, e.g., to assess the effect of the administration of alkali or to check the patient's compliance regarding sufficient fluid intake. To discriminate the primary from the secondary forms of hyperoxaluria, a [13 C2] oxalate absorption test can be performed, which is safe and reliable in children, as in adults. Intestinal oxalate absorption is normal in patients with primary hyperoxaluria and would be significantly increased in those with dietary or enteric hyperoxaluria. Also, a stool analysis for the absence of oxalate-degrading

Table 308.4
Normal values for 24 h urine

Chemical component	Value
Calcium	<4 mg (0.1 mmol)/kg per 24 h
Sodium	<3 mEq (3 mmol)/kg per 24 h
Potassium	>3 mEq (3 mmol)/kg per 24 h
Magnesium	>88 mg (44 mmol)/1.73 m^2 per 24 h
Citrate	>180 mg (94 μmol/g (8.84 mmol) creatinine

bacteria, especially Oxalobacter formigenes, will give further evidence of the existence of a secondary reason for hyperoxaluria.

Qualitative analysis of the stone obtained after intervention or spontaneous stone passage is one of the most important diagnostic measures. The methods of choice are infrared spectroscopy or X-ray diffraction. Even amounts of $\leq$ 1 mg can be analyzed. Chemical stone analysis is inappropriate, as it is prone to errors and is obsolete. The analytic principle of X-ray diffraction is based on the crystal structure of the stone substances. With infrared spectroscopy the loss of energy in the infrared spectrum due to the circulation of the activated chemical molecules is determined.

Recurrent stones should be analyzed again, since the stone composition may change. After lithotripsy only stone fragments are available, and these can be recovered by straining the urine. All fragments should be sent for analysis to allow additional tests, if needed.

Radiologic Evaluations

Ultrasound of the kidney and bladder can show nephrocalcinosis and renal or pelvic stone; KUB does not add significant diagnostic utility above clinical evaluation with symptoms of renal colic; helical CT is the best method of testing for urinary tract stones, more sensitive and safer method than IV pyelography (IVP). The appearance on imaging studies depends upon the stone's composition. Those composed of calcium oxalate or calcium phosphate have a very dense image on conventional radiographs and on CT scans. Struvite (magnesium ammonium phosphate) and cystine stones are of intermediate density, and small stones of all compositions can be difficult to appreciate by conventional radiography. Uric acid stones are radiolucent on radiographs, requiring the administration of contrast agents for adequate visualization, and have a low density image on CT scans. Stones of all composition, with the exception of drugs (e.g., indinavir) and matrix (protein), have distinguishing characteristics of echogenicity and shadowing on ultrasonography.

Ultrasonography has the additional advantages of wide availability, avoidance of ionizing radiation, ready detection of hydronephrosis, and ability to define some aspects of the anatomy of the urinary tract; it is not as sensitive as CT is for the detection of small (smallest size between 1.5–2 mm in diameter) stones in the ureter.

Most stones can be imaged without the use of contrast agents. However, when obstruction is a concern, when radiolucent or low density stones require careful delineation, or when details of urinary tract anatomy are needed (such as confirmation of a duplicated collecting system), contrast agents (CT urography, intravenous pyelography, or retrograde ureteroscopy/pyelography, or orthograde pyelography) are usually required.

For the detecting and monitoring of nephrocalcinosis, high-resolution ultrasonography is the optimal imaging method (◉ *Fig. 308.11*).

Some pitfalls in the renal ultrasonography of neonates, and especially preterm infants, have to be noted: Tamm–Horsfall protein (THP) deposits within the renal calyces may look like nephrocalcinosis (◉ *Fig. 308.11*). THP deposition, however, disappears within 1–2 weeks, and follow-up will show completely normal kidneys. Furthermore, the echogenicity of the renal cortex in neonates is physiologically increased, hence detection of cortical nephrocalcinosis can be difficult and may become evident only some weeks later when a rim of cortical calcification becomes visible. However, diffuse cortical nephrocalcinosis may already be detectable shortly after birth in patients with suspected primary hyperoxaluria, and it is directly visible both by US and X-ray.

Treatment

Non-specific Treatment

Acute episode: During the acute phase when the stone is being passed, management is directed toward pain control, and facilitating passage or removal of the stone(s).

The acute management of nephrolithiasis depends upon the severity of the pain, and the presence of obstruction or infection. In some patients, outpatient medical management with oral analgesics and hydration is possible. However, in others, especially those with nausea, vomiting, and severe pain, hospitalization is required for parenteral fluid and pain medication. Other indications for hospitalization include urinary obstruction and infection.

Pain control: Both nonsteroidal antiinflammatory drugs (NSAIDs) and opioid therapy are used to control pain associated with nephrolithiasis. In studies of adult patients, both classes of analgesics are effective in pain relief. Combination therapy of the two has also been reported to be effective and in some cases superior to either agent alone.

Urologic removal of stones may be required in patients with unremitting severe pain that is refractory to analgesic therapy, or in those with obstruction or infection.

Prevention of recurrent disease: Aim for medical treatment is to decrease or prevent stone formation or growth,

Table 308.6
Diet variables with different sodium concentrations

Category	High sodium food	Low sodium alternative
Meats, poultry, fish, eggs	Burritos, pizzas, canned meat, ham, salted nuts	Fresh beef, fish or pork; Low sodium peanut butter; dry beans
Dairy products	Butter milk, cottage cheese, regular cheese	Milk, mozarella cheese, ice cream
Bread, grains, cereals	Salted bread, biscuits, pancakes, pasta	Non-salted breads, muffins; unsalted popcorn, pretzels
Soups	Canned and dehydrated soup	Low sodium canned soup; home-made soup without salt
Desserts and sweets	Bottled salad dressings, salted butter, instant cake	Unsalted butter, low sodium salad dressings, homemade cake

and decrease need for surgical intervention. This includes an evaluation to identify any underlying cause or risk factors for stone formation. Based upon this assessment, interventions are tailored to reduce the risk of recurrent stone formation.

Dietary and Fluids Management

Dietary management can reduce urinary excretion of stone constituents or increase urinary inhibitors. In low-risk stone formers, dietary measures alone may be sufficient to prevent stone recurrence without the need for drug therapy. A number of factors have been shown to influence stone formation, including fluids, sodium, potassium, animal protein, calcium, and oxalate.

Fluids

A high fluid intake will cause increased urine output, which will reduce urinary saturation of stone-forming calcium salts. Keeping urine flow of >1 mL/kg per hour is needed to decrease risk of supersaturation for calcium oxalate, calcium phosphate, and uric acid, thus protecting from the formation of the corresponding kidney stones. Long-term compliance with an increased fluid regimen is often poor. Coffee and tea were shown in observational studies to reduce the risk of stone formation. Potassium-rich fruit juices such as orange or lemonade juice but not potassium-poor juices, like cranberry juice, provide organic anions that are metabolized to

alkali, thereby increasing urinary pH and citrate. Grape fruit juice may cause concomitant increase in urinary oxalate.

Approximate fluid per day at different ages are as follows:

Infants – $\geq$ 750 mL
Small children below 5 years of age – $\geq$ 1,000 mL
Children between 5 and 10 years of age – $\geq$ 1,500 mL
Children greater than 10 years of age – $\geq$ 2,000 mL

Sodium

A high salt intake increases stone risk by reducing renal tubular calcium reabsorption and increasing urinary calcium.

High urinary sodium increases urinary saturation of monosodium urate, and reduces urinary citrate via sodium-induced bicarbonate loss. Consequently, inhibitory activity against CaOx and calcium phosphate is reduced, monosodium urate-induced CaOx crystallization is enhanced, and urinary saturation of CaOx and calcium phosphate is increased.

Furthermore, high urinary sodium reduces the efficacy of thiazide treatment for hypercalciuria by blunting the hypocalciuric effect.

A low sodium diet is allowing less than 1 teaspoon per day. The majority of sodium consumed comes from sodium chloride (NaCl), better known as salt. The average American gets 6% of their total salt added at the table, 5% added during cooking, and natural sources in food another 11%, and the remaining comes from prepared foods. Many packaged meats, canned and frozen foods, contain a surprising amount of salt, as a preservative, adds flavor to foods, and helps to keep foods from drying out. Most canned vegetables have a much higher salt content than the same fresh vegetable, in general, salt intake should be limited.

Optimal daily intake of sodium according to ages is as follows: 1.2–1.9 g for ages 4–8 years and, 1.5–2.3 g for ages 9–18 years.

Most Americans consume between 3,000 and 5,000 mg of sodium per day. The National Academy of Sciences' Institute of Medicine advises that children under the age of 11 should not be given more than 2.4 g of sodium in a day. There are few rules to be followed when following a low sodium diet for children.

Start the diet by removing salty foods (packaged foods) from the child's diet.

Lower the amount of seasoning salt used in cooking.

Use different herbs and spices like black pepper or basil to enhance the taste of certain eatables.

For few dishes, natural fruit juices can also enhance the flavor of certain meals.

Use moderate amount of soy sauce and ketchup. They contain high amounts of sodium

Measuring the urine sodium/potassium ratio, which optimally should be below 2.5, assesses compliance with the dietary recommendations related to sodium and potassium.

Potassium

High potassium intake decreases urine calcium. The optimal daily potassium intake, provided mostly in the form of fruit, vegetable, and dairy products is 3.8 g at ages 4–8 years and 4.5 g at ages 9–18 years.

Animal Protein

Animal protein provides an acid load because of the sulfur-containing amino acids. A high protein intake reduces urine pH and citrate, and enhances urinary calcium excretion via bone resorption and reduced renal calcium reabsorption; the purine load potentially increases urinary uric acid. Restriction of animal protein (red meat, fish, poultry) to two servings daily is recommended.

Calcium

Hypercalciuric patients may be optimally treated with a program of modest calcium and oxalate restriction, along with pharmacologic therapy. Severe calcium restriction should always be avoided so as to prevent a negative calcium balance; however, mild calcium restriction (less than one serving of dairy daily) should be part of a program of broad dietary modification in patients who have hypercalciuria. Normocalciuric patients do not benefit from dietary calcium restriction, and therefore, a liberal calcium intake is recommended in this group of patients.

Oxalate

The relative contribution of dietary oxalate and endogenous oxalate production to urinary oxalate is controversial. Dietary oxalate has been estimated to account

Table 308.9
Suggested therapy for urolithiasis caused by metabolic abnormalities

Metabolic abnormality	Initial treatment	Second-line treatment
Hypercalciuria	Reduction of dietary Na+	Potassium citrate
	Dietary calcium at RDA	Neutral phosphate
		Thiazides
		Alendronate (bisphosphonate) esp. in resorptive hypercalciuria
Hyperoxaluria	Adjustment of dietary oxalate	Neutral phosphate
		Potassium citrate Magnesium
		Pyridoxine
		Oral ingestion of Oxalobacter formigenes
Hypocitric aciduria	Potassium citrate	Bicarbonate
Hyperuricosuria	Alkalinization	Allopurinol
Cystinuria	Alkalinization	Tiopronin (Thiola)
	Reduction of dietary Na+	D-penicillamine (+pyridoxine)
		Captopril
		The goal of treatment is to keep urinary cystine concentration $\leq$ 250 mg (1 mmol/L.)

Source: From Milliner DS (2004). Urolithiasis. In: Pediatric nephrology. Lippincott Williams & Wilkins, Philadelphia, p 1104

for 10–50% of urinary oxalate, depending on dietary calcium and oxalate intake, and the bioavailability of oxalate in foods. In general, restriction of oxalate-rich foods, such as nuts, chocolate, tea, and dark roughage is recommended. Vitamin C has been implicated in calcium stone formation because of in vivo conversion of ascorbic acid to oxalate. Limitation of vitamin C supplements is recommended.

Other Diet Components

Other nutrients, such as sucrose, fructose, may be associated with higher risk for kidney stone disease, whereas phytate and magnesium may decrease it.

Drug Therapy

For those patients in whom conservative dietary measures fail or those who have more aggressive stone disease or identifiable metabolic abnormalities, pharmacologic therapy, along with dietary management, should be initiated.

Thiazide Diuretics

Thiazide diuretics are reserved for patients who have severe hypercalciuria not responding to conservative measures.

Doses can be divided according to ages: <6 months: 1–3 mg/kg/day in 2 divided doses;

>6 months to 2 years: 1–3 mg/kg/day in 2 divided doses; maximum: 37.5 mg/day

>2–17 years: Initial: 1 mg/kg/day; maximum: 3 mg/kg/day (50 mg/day).

Its mechanism resorts in enhancing sodium and calcium reabsorption in the distal renal tubule leading to a reduction in urinary calcium excretion. The diuresis induced may be accompanied by a fall in urinary calcium excretion of as much as 50–150 mg (1.3–3.8 mmol) per day This hypocalciuric effect is reduced if sodium intake is not limited. Stone recurrences can decrease from 50% (untreated) to 20% (treated) over 5 years. Thiazides have many other effects on the body. They increase serum calcium and uric acid levels while decreasing urinary citrate levels. Hyperuricemia or acute gout rarely develops in individuals receiving thiazides. A risk of dehydration, hypokalemia, and hyponatremia exists. They can cause magnesium loss and increase cholesterol. Adverse effects occur in about one third of patients but are usually mild. The most bothersome clinical adverse effect is lethargy, but muscle aches, depression, decreased libido, generalized weakness, and malaise also can occur. About 20% of patients stop thiazide therapy because of these adverse effects. These medications originally were intended solely for use as diuretics for hypertension. They have become the primary medical treatment for hypercalciuria because of their unique ability to remove calcium from the urine and return it to the general circulation. They can be used in virtually any type of hypercalciuria, with the possible exception of resorptive hypercalciuria, in which they can exacerbate hypercalcemia.

Potassium Citrate

Potassium citrate is effective in the treatment of patients who have calcium stones providing an alkali load,

(potassium or sodium citrate, 100–150 mg/kg per day in 3–4 divided doses) increased urinary pH and citrate, thereby increasing urinary inhibitory activity especially for urate stone, cystine, and also Hypercalciuric patients. Potassium citrate can reduce stone recurrence rates by 75% among hypocitraturic stone former. It is recommended that the urine pH should not exceed 8.5, a high alkaline urine promotes formation of calcium phosphate stones.

Allopurinol

In calcium stone formers, who have moderate to severe hyperuricosuria and in whom other conservative measures fail, including high fluid intake, alkalinaization of urine and in older children diet modification, allopurinol has been shown to reduce urinary uric acid levels and prevent recurrent stone formation. Allopurinol is a xanthine oxidase inhibitor that prevents the conversion of hypoxanthine to xanthine, the precursor of uric acid, which decreases in about 2 to 3 days, in both serum and urine. Allopurinol should be discontinued at first appearance of skin rash or any sign of adverse reactions.

The skin rash may be followed by more severe hypersensitivity reactions such as exfoliative, urticarial, or purpuric lesions, as well as Stevens-Johnson syndrome (erythema multiforme) and, very rarely, a generalized vasculitis that may lead to irreversible hepatotoxicity and death. There have been occasional reports of reduction in the number of circulating-formed elements of the blood, including bone marrow suppression, granulocytopenia, and thrombocytopenia, usually in association with renal and/or hepatic disorders or in whom concomitant drugs have been administered that have a potential for causing these reactions.

Periodic liver function tests, renal function tests and complete blood cell counts should be performed in all patients on allopurinol.

Observe patients with impaired renal or hepatic functions carefully during the early stages of allopurinol administration and withdraw the drug if increased abnormalities in hepatic or renal function appear.

In cases of patients using diuretics, such as Thiazides and ethacrynic acid, when given with allopurinol, it may increase serum oxypurinol concentrations and may thereby increase the risk of serious allopurinol toxicity, including hypersensitivity reactions, particularly in patients with decreased renal function.

Allopurinol should not be given to children except those with hyperuricemia secondary to malignancy or with Lesch–Nyhan syndrome, because safety and effectiveness have not been established in other conditions.

Since allopurinol and its metabolites are excreted by the kidney, drug accumulation can occur in renal failure and the initial dose of allopurinol should consequently be reduced. In children with recurrent renal stone >10 years and adults – Oral dose: 200–300 mg daily is divided or single daily dosage.

Pyridoxine

Promotes the conversion of glyoxalate to glycine, thereby reducing the substrate for oxalate production. Pyridoxine is used for treatment of PH1, not all patients of PH1 respond to Pyridoxine, a test dose of 5–10 mg/kg per day is given. It is likely to be of limited value in patients of enteric hyperoxaluria.

Specific Treatment

Stone Removal

Indications for stone removal – severe pain, infection, severe obstruction, growth of calculus, nonprogression, interference with lifestyle, any stone can be removed by open procedure (rarely done), percutaneous nephrostomy (for kidney and upper ureter), large calculi fragmented first by ultrasound, electrohydraulic (EHL, spark in water tub) or laser lithotripters, (more effective for simple renal stones than branched or ureteral calculi), transurethral removal (calculi below pelvic rim) use basket for removal.

Extracorporeal Shock Wave Lithotripsy (ESWL)

According to the guidelines of the European Association of Urology, ESWL should be the first surgical choice for most renal pediatric stones. The underlying function of all types of ESWL machines is to generate and focus shock-wave energy at a focal point that is clustered at the calculus. Ideally, the impact of the shock wave disintegrates the stone so the fragments can pass the ureter.

ESWL may not be as effective as ureteroscopic management of ureteric stones, but associated with fewer complications, comparing ESWL versus ureteroscopic management, 73% vs. 90% stone-free rate. ESWL is

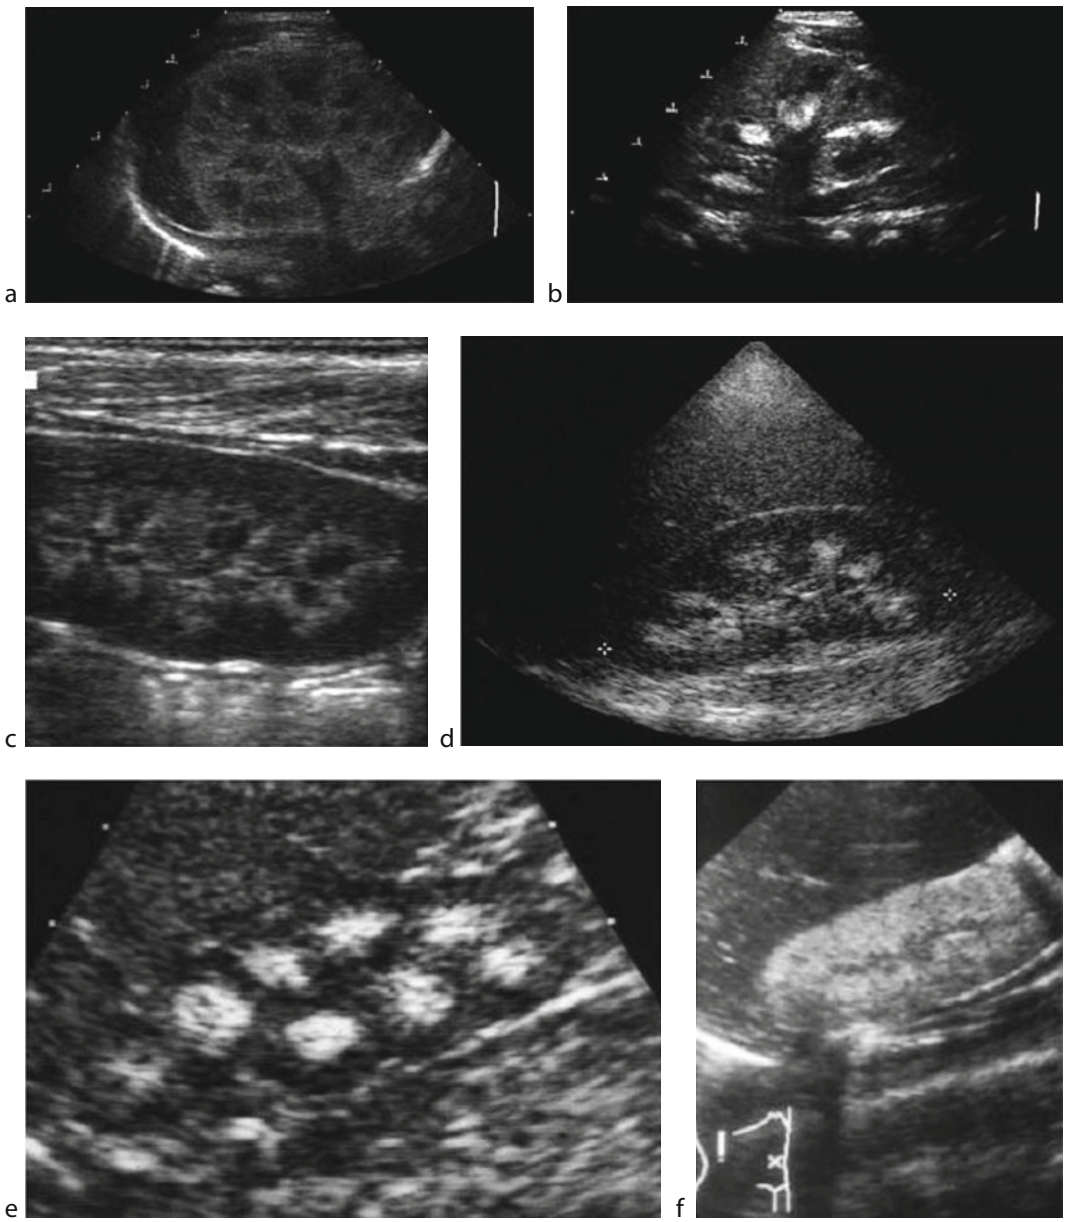

Figure 308.11
(a) Normal, still hyperechoic kidney of a preterm infant. (b) Tamm–Horsfall kidney. (c)Medullary nephrocalcinosis (NC) grade I (mild increase of echogenicity around the pyramidal border). (d) Medullary NC grade II (mild increase of echogenicity at whole pyramid). (e) Medullary NC grade III (more severe hyperechogenicity of entire pyramid). (f) Diffuse corticomedullary NC

associated with shorter length of hospital stay. Studies demonstrated that there are short-term effects such as perirenal hematomas, hematuria, and reduced GFR directly after ESWL therapy. However, there has been no evidence for long-term damage in children.

It is of utmost importance that no stone material is left behind, no matter what therapy is employed, as recurrence rates are higher than in adults. Thirty-three percent of patients with small remaining stone fragments after extracorporeal shock-wave lithotripsy (ESWL) (<3 mm),

which were formerly called clinically insignificant residual fragments (CIRFs) in the early era of ESWL, had an increasing stone mass on median follow-up of 24 months.

Compared with stone-free individuals, patients with residual fragments had an increased risk for adverse clinical outcome, with an odds ratio (OR) of 3.9.

If an underlying metabolic disorder was existent, the OR for growth of residual fragments was 11.4.

Before choosing the appropriate treatment, it is indispensable to know the number, size, location, and composition of a stone, and in addition, any information about the urinary tract below the stone.

ESWL is the preferred treatment in pediatric urolithiasis patients with calculi <20 mm. Stone-free rates after ESWL in children range between 57% and 92%.

In suspected cystine stones, the maximum diameter should not exceed 15 mm because of the hardness of the stone. Hardness of cystine stones, a ureteroscopic or minipercutaneous nephrolithotomy approach is coequal, if not the new first-line therapy. Thus, large and hard stones, such as cystine and whewellite, decrease ESWL success rates.

Another important aspect in treatment planning is urinary tract anatomy and stone location. ESWL treatment of stones in lower calices has a lower success rate due to the special anatomy and gravity situation.

Minipercutaneous Nephrolithotomy

A percutaneous approach (PCNL) could be used for bigger and more complex calculi.

Although there are no international guidelines as to when PCNL should be the primary treatment in children, there are relative indications, such as large stones (>1.5 cm) or >1 cm for lower-pole concrements. Especially if there are anatomical abnormalities that prevent good fragment clearance (i.e., ureteropelvic junction obstruction, calyceal diverticulum, ureter stricture), and depending on stone composition, PCNL can be the treatment of choice. Although PCNL is an invasive treatment, it achieves excellent stone free rates and comes with a relatively low risk in experienced hands.

Ureterorenoscopy

URS is ideally suited for calculi in the mid and distal ureter; this procedure has become a first-line treatment for ureteral stones and can even be considered a good treatment option for renal calculi.

Laparoscopic Surgery/Open Surgery

In developed countries, open surgery remains the treatment of choice for 0.3–5.4% of children. In general patients with anatomical abnormalities i.e., ureteropelvic junction obstruction, obstructive megaureter, urolithiasis will receive open surgery if stone removal and anatomical correction can be combined in one operation. In developing countries, open surgery is used in 14% of cases, which is likely due to the fact that open surgery is more cost-effective in those countries.

Prevention

The best treatment both for calcium containing stones and for other stones remains prevention. A stone requires supersaturation, a nidus, and time to form. Thus, ample hydration, avoidance of infection, and good voiding habits minimize the chance of stone formation, whether initial or recurrent.

Once a stone has formed, however, there is more than a 50% chance that a second stone will form at some point.

Based upon these observations, prevention of recurrent stone disease should be a major clinical goal. Preventive measures are directed toward reducing risk factors associated with stone formation. In all children with nephrolithiasis, adequate fluid intake is a key component to reducing the risk of recurrent stones. High fluid intake increases the urine flow rate and lowers the urine solute concentration, thereby reducing the likelihood of new stone formation. The therapeutic preventive interventions are based upon the underlying metabolic condition.

Surgical success based on less complication and complete removal of the stone to reduce risk of recurrence.

Prognosis

Ninety percent of patients will pass the stone if < 4 mm in distal ureter, 50% 4–6 mm, only 20% > 6 mm pass stones. Small non-uric acid stones in upper pole appear least likely to progress; most lower pole calyceal stones < 20 mm can be adequately cleared with extracorporeal shock wave lithotripsy (ESWL); asymptomatic lower pole caliceal stones may be safe to observe.

In recent articles a recurrence rate of 67% during a mean follow-up of 59 months is quoted. Despite the excellent response to treatment noted in most children with urolithiasis, long-term nephrologic care is indicated, particularly for children who have more complex forms of

renal stone disease, because renal insufficiency or end-stage renal disease may develop.

In general, increased water intake can be used for primary prevention of urinary calculi; reducing soft drink consumption reduced risk of stone recurrence among men; greater increase in urine volume associated with reduced risk of recurrence among patients who had stones, low-animal-protein, low-salt diet may prevent recurrent stones in selected patients, thiazides and allopurinol reduced 3-year recurrence rate from 55% to 15–25% in randomized trials. Restricted animal protein and salt with normal calcium intake is more effective than low-calcium diet in preventing recurrent stones in men with recurrent calcium oxalate stones and hypercalciuria.

309 Interstitial Nephritis and Primary Hyperoxaluria

Pierre Cochat

Tubulointerstitial Nephritis

The definition of tubulointerstitial nephritis (TIN) is based on histopathological findings, so kidney biopsy remains the only definitive diagnostic investigation. TIN may be due to various causes and is probably underdiagnosed both in adults and children.

Acute Tubulointerstitial Nephritis (ATIN)

Presentation

Children with ATIN usually present with non-oliguric acute renal failure without edema, sometimes with loin pain, which develops over a period of days to several weeks; in case of drug-induced ATIN, symptoms typically begin 3–5 days after drug (re)exposure. Renal presentation may also include leukocyturia, and various degree of tubular impairment (polyuria, glucosuria, tubular proteinuria). Blood pressure is normal and there is neither hematuria nor heavy proteinuria. Renal ultrasonography may show normal or enlarged kidneys with increased echogenicity.

According to the primary disease, extrarenal signs such as low-grade fever, maculopapular rash, mild arthralgias, anemia, weight loss, and malaise may be associated (in 50% of cases). In the case of drug-induced ATIN, hypereosinophilia and eosinophiluria may be found. More specific organ involvement may be of major interest, and ophthalmologic examination should be recommended in most cases looking for uveitis. However it is likely that many patients with mild ATIN are often clinically silent.

Etiology

ATIN accounts for 5–10% of acute renal failure in the pediatric setting, and may have various causes, which are summarized in ❯ *Table 309.1*. However, the role of drug-related ATIN seems to be increasing during the recent years both in children and adults.

A few biological investigations are of interest: erythrocyte sedimentation rate, urinary β-2 microglobulin, antitubular cell antibodies, serum immunoglobulins, etc. In difficult cases, serum sample should be stored at −20°C for further immunological assessment.

Pathology

Renal biopsy may be useful in some patients but is not required for all. ATIN prevalence was 11.3% of biopsy-confirmed acute renal failure in a recent large series that included both children and adults.

Light microscopy shows interstitial edema with inflammatory cellular infiltrate (majority of T cells, together with macrophages and plasma cells), sometimes with granulomatous lesions or eosinophils according to etiology (mainly drug-induced ATIN). Patients with diffuse infiltrate had a worse prognosis than those with focal interstitial infiltrate. Tubes and capillaries may be sometimes involved.

Immunofluorescence staining for antibodies and complement uses to be negative, but linear or granular deposits of immunoglobulin G or M may be occasionally present along the tubular basement membranes.

Treatment

The overall outcome of ATIN is usually good without any specific treatment; the mean recovery time to the nadir creatinine level is 1–2 months. When drug-induced ATIN is suspected, the presumed causative drug should be withdrawn first, and rechallenge must be excluded.

In adults, 58% of cases require acute renal replacement therapy. According to pathological features and etiology, early short course oral corticosteroid therapy may be indicated but results are controversial. The best results have been obtained with TINU syndrome and some drug-induced (antibiotics, non-steroidal anti-inflammatory drugs) ATIN.

Table 309.1
Etiologies of acute tubulointerstitial nephritis

Drugs and toxins +++	Hypersensitivity to drugs (acyclovir, indinavir, tenofovir; beta-lactams, cephalosporins, ciprofloxacin, rifampicin, isoniazid, sulfonamides, vancomycin, macrolides; non-steroidal anti-inflammatory drugs; frusemide, thiazides, triamterene; allopurinol; phenytoin, carbamazepine; ranitidine, cimetidine; omeprazole; bisphosphonates; alpha interferon; azathioprine)
	Mushrooms (*Cortinarius*)
	Creatine
Crystal-induced ATIN	Drugs (acyclovir, indinavir, triamterene)
	Uric acid
	Calcium salt (phosphate, oxalate)
Infections ++	Acute pyelonephritis (*Escherichia coli*)
	Systemic bacterial infection (streptococcus, staphylococcus, leptospirosis)
	Mycoplasma infection
	Viral infection (Epstein-Barr, HIV, Hantaan, BK polyoma, adenovirus)
Systemic disorders	Sarcoidosis, Sjögren syndrome, systemic lupus, inflammatory bowel disease
	Vasculitides
	"TINU" syndrome (idiopathic TubuloInterstitial Nephritis with Uveitis)
	Lymphoma, leukemia
Primary ATIN	Isolated idiopathic tubulointerstitial nephritis

Chronic Interstitial Nephritis (CTIN)

CTIN develops over months or years and is a common unspecific feature, which may also have specific causes.

Presentation

CTIN is often diagnosed late because clinical signs are usually limited. Patients present with progressive chronic kidney disease, variable degrees of arterial hypertension, tubular dysfunction (tubular proteinuria, polyuria, enzymuria, increased natriuresis, acidosis), leukocyturia, hematuria, and hyporeninemic hypoaldosteronism. Small kidneys with increased echogenicity and anemia are suggestive of a long-standing process.

Etiology

CTIN may have various causes, which are summarized in *Table 309.2*. Some specific biological investigations may be of interest: erythrocyte sedimentation rate, urinary β-2 microglobulin, antitubular basement membrane antibodies, anti-tubulointerstitial nephritis antibodies, serum immunoglobulins, etc. In difficult cases, serum should be stored at −20°C for further immunological assessment.

Pathology

CTIN associates various degrees of interstitial inflammatory infiltrate (lymphocytes, monocytes, macrophages), tubular involvement (tubular atrophy, flattened epithelial cells, tubular dilation, tubular basement membrane thickening), glomerulosclerosis, and interstitial fibrosis; vessels may also be involved.

Immunofluorescence microscopy is usually negative, except in systemic diseases. The extent of disease on renal biopsy inversely correlates with renal function and may accurately predict renal prognosis.

Treatment

In case of drug- or toxin-induced nephropathy, the causative agent should be ruled out. In most other cases, nephroprotection is recommended, such as conservative management of electrolyte disturbances, blood pressure control, angiotensin-converting enzyme inhibitor, and angiotensin-2 receptor antagonist.

Primary Hyperoxaluria

Hyperoxaluria may be either a secondary or a primary disease. Two autosomal recessive inherited enzyme defects of glyoxylate metabolism are related to type 1 and type 2 primary hyperoxalurias (PH), that is, alanine: glyoxylate aminotransferase (AGT; *AGXT* gene located on chromosome 2q37.3) and glyoxylate reductase/hydroxypyruvate reductase (GRHPR; *GRHPR* gene on chromosome 9q11), respectively. A gene for PH3 has been recently identified. Among all PH patients, type 1 accounts for ∼80%, type 2 for ∼10%, and non-type 1 non-type 2 for ∼10%.

	Anorexia nervosa (hypokalemia due to diuretic and/or laxative)
	Heavy metals (cadmium, lead, lithium)
	Aristolochic acid (Chinese herbs, Balkan nephropathy) [adult]
	Radiation nephritis
Immunological disorders	CTIN due to anti-tubular basement membrane antibodies
	Systemic lupus and other immune-mediated glomerulonephritis
	T cell-induced CTIN (renal allograft rejection, TINU syndrome)
Genetic diseases	Nephronophthisis
	Cystinosis
Nephrocalcinosis	Inherited (hypercalciuria, distal tubular acidosis, hyperoxaluria)
	Acquired (drug-induced, cortical necrosis, HIV)

Primary Hyperoxaluria Type 1

Pathophysiology

The functional defect of AGT leads to oxalate overproduction by the liver. Since calcium oxalate is insoluble in urine, PH1 usually presents with symptoms referable to the urinary tract. The median age at initial symptoms is 5–6 years and end-stage renal disease (ESRD) is reached between 25 and 40 years of age in half of the patients. Along with progressive decline of glomerular filtration rate (GFR), oxalate deposition occurs in many organs, leading to systemic involvement (named "oxalosis") and bone is the main compartment of the insoluble oxalate pool.

Presentation

The combination of both clinical and renal sonographic findings is a strong argument for PH1, that is, the association of renal calculi, nephrocalcinosis, and renal impairment; in addition, family history may bring additional information.

PH1 grossly fits five presentations: (i) infantile form with early nephrocalcinosis and kidney failure, (ii) recurrent urolithiasis and progressive renal failure, leading to a diagnosis of PH1 in childhood or adolescence, (iii) late-onset form, with occasional stone passage, in adulthood, (iv) diagnosis given by post-transplantation recurrence, and (v) presymptomatic subjects with a family history of PH1.

Diagnosis

The diagnosis is based on urine crystals analysis (calcium oxalate monohydrate, i.e., whewellite), infrared spectroscopy and concomitant hyperoxaluria (urine oxalate >1 mmol/1.73 m^2/day, normal <0.5). In patients with well-defined phenotype, genotyping (DNA sequencing) can be further proposed in order to screen the most common mutations according to local background. Prenatal diagnosis can be performed from DNA obtained from crude chorionic villi or amniocytes.

The assessment of oxalate burden is a major issue when GFR falls to below 30–50 mL/min/1.73 m^2. It is mainly based on repeated plasma oxalate assessment, fundus examination, bone imaging and sometimes bone biopsy examination.

Management

Conservative measures should be started as soon as the diagnosis has been suspected. The aims are to increase urinary solubility of calcium oxalate and to decrease oxalate production (*Table 309.3*).

The treatment of stones should avoid open and percutaneous surgery because further renal lesions will alter renal function, so that the use of extracorporeal shock wave lithotripsy is an available option in selected patients. In patients with repeated renal colic, stone removal can be

Table 309.3

Supportive treatment for patients with primary hyperoxaluria type 1 with preserved renal function

Mode of action	Compound	Dose (per 24 h)
Urine dilution +++	Water	2–3 L/m^2
Crystallization inhibitor	Potassium/sodium citrate	100–150 mg/kg
Normalize urine calcium	Hydrochlorothiazide	0.5–2.0 mg/kg
Decrease oxalate production	Pyridoxine (AGT cofactor)	5–10 mg/kg

attained by ureteroscopy and a ureteral JJ stent may be helpful for pain control and protection of renal damage.

Dialysis is unsuitable for patients who have reached ESRD because it cannot overcome the continuous excess production of oxalate by the liver in spite of its small molecular mass. Peritoneal dialysis alone is unable to clear enough oxalate and is rather contraindicated in such patients. Conventional maintenance long-term hemodialysis is also associated with unacceptable quality of life and may be a life-threatening option in the long term. Therefore, daily hemodialysis is currently the preferred option despite technical challenges in infants, and it may be combined with PD in most children in order to enhance overall oxalate clearance and therefore minimize systemic involvement prior to transplantation.

There are different approaches to organ transplantation strategy, which may be influenced by the local allocation system. The largest experience has been obtained with a one-step combined liver-kidney transplantation leading to acceptable results. The option of a two-step procedure (liver transplantation followed by renal transplantation) should be kept in mind according to local experience and when the prospective waiting time is long enough to jeopardize both patient quality of life and survival. Patient survival after combined liver and kidney transplantation approximates 80% at 5 years and 70% at 10 years. Isolated kidney transplantation is not recommended due to ~100% disease recurrence, and preemptive isolated liver transplantation has limited indications due to ethical reasons.

Non-type-1 Primary Hyperoxaluria

In patients with overt hyperoxaluria, the pattern of urinary metabolites is indicative but no longer a diagnosis of PH. In patients with a clinical picture of PH1, 10–30% have normal AGT activity that may lead to a diagnosis of PH2 or of another inherited disorder causing hyperoxaluria. The overall long-term prognosis is better than for PH1.

310 Urinary Tract Infection

Sean E. Kennedy · Andrew R. Rosenberg

Background

Urinary tract infection (UTI) is one of the commonest bacterial infections in children. A single UTI may lead to significant acute morbidity and often recurs. Rare but serious long-term sequelae of UTI include hypertension and chronic kidney disease. The knowledge that a significant number of young children with UTI will have an underlying anomaly of the urinary tract, most commonly vesicoureteral reflux (VUR), and that those with more severe anomalies are more likely to suffer recurrent infections and chronic injury, has led to considerable research and ongoing debate. Whilst much progress has been made in understanding the links between UTI, VUR, and chronic kidney injury, many unanswered questions remain.

Definitions

The term urinary tract infection (UTI) is used to describe both symptomatic infections as well as situations when bacterial growth is detected in children who lack any other signs or symptoms of UTI. This latter situation, known as asymptomatic bacteriuria, is a benign condition that does not require treatment unless the patient has a kidney transplant or is pregnant. In the rest of this chapter UTI refers to growth of microorganisms in the urinary tract coexistent with signs and/or symptoms of infection.

UTI can be further classified based on site of infection. Pyelonephritis is the term used for infections involving one or both kidneys. Cystitis is a lower urinary tract infection confined to the bladder.

The distinction between pyelonephritis and cystitis is usually based on clinical signs and symptoms. The classical features of pyelonephritis are fever, loin pain, and tenderness. However pain and tenderness can only rarely be elicited in young children and infants. Therefore the clinical diagnosis of pyelonephritis rests upon the presence of fever $\geq$38°C in a child with a UTI. The presence of infection in the kidney is suggested by elevated circulating inflammatory markers such as procalcitonin and may be confirmed by dimercaptosuccinic acid (DMSA) scanning at the time of infection (see below).

A recurrent UTI is any UTI occurring after an initial infection has been fully treated.

Etiology

Gram-negative organisms cause the majority of UTI, with *Escherichia coli* accounting for at least 75% of first infections. Other common organisms include *Klebsiella* and *Proteus* species. Less common pathogens include *Enterobacter*, *Citrobacter*, and *Enterococci*.

Staphylococcus saprophyticus has been reported to cause between 7% and 15% episodes of cystitis in young women but is only rarely isolated in young children.

Staphylococcus aureus and *Pseudomonas* species are uncommon causes of UTI that are more likely to be found in children with anatomical or functional abnormalities of the urinary tract.

Chronic or recurrent infections with urease producing organisms, particularly *proteus*, may lead to precipitation of struvite (magnesium ammonium phosphate) which can form stag horn calculi. *Proteus mirabilis* can be grown from the periurethral areas of >22% of uncircumcised male infants.

Other uncommon causes of UTI in children include viruses (e.g., adenovirus) and fungi (e.g., *Candida* spp.). Adenovirus typically causes a haemorrhagic cystitis that may present as macroscopic haematuria. Fungal UTI usually occurs in association with risk factors such as long-term urinary catheterization and immunosuppression.

Tuberculous infection should be considered in a child from an area where TB is endemic who has otherwise unexplained pyuria. Tuberculous infections of the kidney and urinary tract usually occur as a result of haematogenous spread of mycobacteria. The renal infection begins in the glomeruli and, although usually asymptomatic, can cause progressive renal injury and scarring. Lower tract infection may arise secondary to shedding of mycobacteria in urine.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_310,

Chronic infection with *schistosoma haematobia* is associated with bladder granulomata and may present as dysuria, frequency, and terminal haematuria.

Epidemiology

The incidence of UTI differs according to age and gender. Up to 10% of girls will have had a UTI by adulthood with the majority of cases occurring after the age of 2 years. On the other hand, only 2–3% of boys will be diagnosed with a UTI during childhood and more than 60% of these occur before the age of 2. UTIs are an uncommon occurrence in boys older than 4 years of age.

UTI is the cause of up to 10% of all episodes of fever without focus in children younger than 2 years of age. Uncircumcised male infants have a higher incidence of UTI than circumcised boys and UTIs cause up to 20% of febrile episodes in uncircumcised boys less than 3 months of age.

Children with UTI are more likely to have a family history of UTI in first-degree relatives than children without UTI.

Other risk factors for UTI include previous UTI, constipation, voiding dysfunction, neurogenic bladder, and structural anomalies of the urinary tract including vesicoureteral reflux (VUR). VUR is present in at least 20–30% of children having their first UTI compared to only 1–3% of the general pediatric population.

Voiding dysfunction is a broad term used to describe a urination pattern abnormal for the child's age. It may present with symptoms, including urgency, frequency, and incontinence, with onset after daytime continence has been achieved at about 4–5 years of age. Voiding dysfunction is associated with VUR but often occurs independently.

Voiding dysfunction is caused by abnormal (or immature) regulation of bladder filling and emptying, and can be classified as:

- Overactive bladder (also known as unstable bladder, or urge incontinence)
- Underactive bladder
- Dysfunctional voiding, marked by uncoordinated relaxation of the muscles of the external sphincter

Voiding dysfunction may be suggested by a history of incontinence or urgency. Overactive bladder typically is seen in young girls who have urgency and often adopt postures to prevent micturition, such as crossing of legs or squatting. It is frequently associated with constipation, and the presence of the two conditions is labelled dysfunctional elimination syndrome.

Underactive bladder is also more often seen in girls than boys and is characterized by infrequent voiding often associated with constipation. Incomplete bladder emptying may result from hypoactive detrussor function and UTI may ensue.

Neurogenic dysfunction of the bladder is most commonly due to spinal dysraphism, often as an open myelomeningocoele (*spina bifida*). Closed or occult spinal lesions may also affect bladder function. Other spinal causes of neurogenic bladder include sacral agenesis, tethered spinal cord associated with imperforate anus, cloacal malformations, and spinal cord injuries from sporting injuries. Neurogenic bladder is infrequently due to a central nervous system abnormality such as cerebral palsy.

Nonneurogenic neurogenic bladder (or Hinman's syndrome) is a term used to describe the most severe form of dysfunctional voiding. It is often associated with recurrent UTI and constipation and may lead to chronic kidney injury. The mechanisms underlying the detrusor–sphincter incoordination are not fully understood. Management may include bladder training; however, intermittent catheterization is often required.

Pathogenesis

The urinary tract above the distal urethra is usually sterile. Most infections are caused by bowel organisms that have ascended via the urethra to colonize the bladder. Uropathogenic *E. coli* characteristically have surface fimbriae (Type II or P fimbriae) that promote attachment to urinary epithelium allowing colonization. The process of attachment involves adherence of bacterial fimbriae to specific receptors expressed on the surface of urinary epithelium. The receptor for certain uropathogenic *E. coli* is a glycosphingolipid that is also expressed on red blood cells.

The urinary tract relies on several defense mechanisms to prevent infections. The primary defense is regular and complete emptying of the bladder. Other protective mechanisms include the systemic innate immune response and inherent antibacterial properties of normal bladder cells. Toll like receptor-4 (TLR4) is intricately involved in the innate immune response to UTI.

Infants may be more susceptible to UTI because of immaturity of their immune defenses, both systemic and local to the urinary tract. Other reasons for high rates of UTI during infancy include altered gut flora and colonization of periurethral areas by pathogenic organisms.

Breast fed infants have a reduced incidence of UTI relative to formula fed infants. The reasons for the

protective effect of breast milk have not been elucidated but may include the transfer of secretory IgA and other immunoactive molecules.

The presence of UTI caused by organisms that usually have a low virulence for the urinary tract, such as *S. aureus*, *Enterococci* and *Pseudomonas* species, suggests that normal host defenses have been altered. The commonest reasons for this are incomplete emptying of the urinary tract due to obstruction, high-grade VUR, or dysfunctional voiding.

UTIs are rarely the result of haematogenous spread of organisms. However this should be suspected in children with UTI secondary to an atypical organism, particularly *S. aureus*, and an otherwise normal urinary tract.

Clinical Manifestations: Symptoms, Signs

Fever is the most common presenting feature of UTI in infants and young children. Children younger than 3 months of age with UTI are more prone to develop septicaemia and severe illness including meningitis. Neonates with UTI may not develop a high fever and at times may be hypothermic.

Other clinical features of UTI differ according to age and site of infection. Nonspecific signs of UTI in the first weeks of life include drowsiness, vomiting, poor feeding, lack of weight gain, and prolonged jaundice.

Infants and young children typically do not present with localizing signs of infection, consequently fever may be the only sign. Parents will occasionally notice malodorous urine and children who are out of nappies may show urinary frequency or enuresis and, rarely, dysuria.

Older children, particularly those who are verbal and fully toilet trained are more likely to present with specific symptoms such as urinary frequency and dysuria or abdominal pain.

The physical examination of a child with a suspected or proven UTI should be thorough and aim to assess for predisposing factors and complications. Hypertension may be a sign of underlying renal disease or may be a consequence of renal scarring secondary to previous UTI. Abdominal or flank masses may indicate hydronephrosis, urinary retention, or other renal pathology. *Constipation* may be identified by finding palpable feces in the left iliac fossa. Periurethral inflammation, balanitis, or phimosis may either be a source of ascending infection or alternatively may give rise to dysuria and pyuria and masquerade as a UTI. Spinal anomalies may be suggested by midline pits, dimples, birthmarks, and hairy patches, as well as reduced anal tone, an abnormal gait, and abnormal lower limb reflexes.

Diagnosis

The diagnosis of a UTI depends on collection of an uncontaminated urine sample. An older child or adolescent may be able to provide a mid stream urine (MSU) with or without the assistance of a parent; however, the majority of children with suspected UTIs will be too young to collect an uncontaminated sample for themselves. *Table 310.1* lists the methods by which urine can be collected in young children and babies.

Prompt collection of an uncontaminated urine specimen is necessary in acutely unwell babies and children to allow empiric treatment while awaiting culture results. In these situations either suprapubic aspiration (SPA) or perurethral catheterization should be used to collect a specimen. SPA is a simple and safe procedure. It can be performed in children under 2 years of age as a full bladder in this age group normally sits above the bony pelvis. The likelihood of urine being in the bladder is increased by timing the procedure to be at least 60 min from the last void and after a feed. Many centers use an ultrasound bladder scan beforehand to confirm that urine is present in the bladder.

Urine collected by an adhesive plastic bag will be contaminated by skin or bowel flora in up to 50% of cases, therefore bag collections (even if the skin has been carefully washed beforehand) should not be used to diagnose a UTI. Another simple, noninvasive method of urine collection from babies is use of a urine collection pad, but again this method is prone to contamination and should generally not be relied upon. The usefulness of these two methods is in their ability to exclude a UTI, that is, if urine collected by bag or pad does not grow a significant growth of bacteria, then a UTI is not present.

Table 310.1
Methods of urine collection for microbiological culture

Method	Diagnostic criteria
Clean catch	$>10^5$ cfu/mL of a single organism
Suprapubic aspiration	Any growth of bacteria
Transurethral catheterization	>10,000 cfu/mL of a single organism
Adhesive bag	A negative culture excludes a UTI
Absorbant pad	A negative culture excludes a UTI

UTI is defined by a significant growth of a single organism in a clean catch urine, MSU, SPA, or catheter urine. Because each of these techniques has its own risk of contamination, the diagnostic criteria for UTI depends on collection method (Table 310.1). Urine collected by SPA should be sterile unless a UTI is present, therefore any growth of bacteria should be considered to be significant. A significant growth of bacteria from an MSU or clean catch urine is 10^5 cfu/mL of a single organism. A mixed growth or a lower colony count (10^4–10^5 cfu/mL) may also be indicative of infection if the clinical features support a diagnosis and collection of a further specimen for culture may be warranted. The laboratory should always be informed of the method used for collection.

Urine microscopy and biochemical dipstick analysis can be used to guide decisions on initial management and the need for urine culture (Table 310.2). The presence of organisms on microscopic examination of unspun urine and/or on Gram stain of urine is strongly suggestive of a UTI. Therefore urgent microscopy of urine should be utilized if available to diagnose UTI in young children with fever without focus.

The presence of urinary nitrites detected by dipstick in a child with a fever suggests the presence of a UTI. Urinary nitrites are produced by urease splitting organisms; however, not all UTI causing organisms convert nitrate to nitrite and urease splitting bacteria may take up to 4 h to produce detectable nitrites in urine. A positive test for nitrites is therefore highly specific but lacks sensitivity to allow the diagnosis of all UTIs (Table 310.2).

Urinary leukocytes are usually present during a UTI, but they may also be present in a large proportion of febrile children without UTI as well as in otherwise healthy children. The diagnostic utility of urinary dipsticks is maximal when the results of leukocyte esterase and nitrite tests are considered together. If both tests are negative then it is unlikely that a UTI is present. If nitrites are present then the likelihood of a UTI being present is high (>95% positive predictive value) and this likelihood is increased further if the leukocyte esterase test is also positive (Table 310.2). The least useful result is positive leukocyte esterase with negative nitrites, as this finding is nonspecific (Table 310.2).

Confirmation of UTI by culture is important not only for management of the current illness but also as young children with a confirmed UTI should undergo further investigation. Culture and sensitivity results will guide antibiotic management.

Blood tests are not required to make the diagnosis of UTI but may be useful to guide management, detect complications, and possibly localize the infection. Electrolyte abnormalities (e.g., *hyponatremia*, *hyperkalemia* and *acidosis*) may complicate infections in infants or children with urological anomalies and require judicious management. Leucocytosis is commonly seen in febrile children. C-reactive protein and plasma procalcitonin levels may both be elevated and higher levels (procalcitonin >0.5 ng/mL) are more likely in instances of pyelonephritis.

Differential Diagnosis of UTI in Children

The differential diagnosis of febrile UTI in young children is broad and includes both minor and life threatening infections. The differential diagnosis of acute cystitis in older children and adolescents includes dysfunctional voiding, urethritis, vulvovaginitis, prostatitis, epididymoorchitis, and *nephrolithiasis*.

Treatment

Any symptomatic UTI should be treated with antibiotics. Parenteral antibiotics are indicated in children less than 3 months of age or any child who appears toxic. Parenteral antibiotics should also be considered in any child who is vomiting or who is unable to tolerate oral antibiotics for any reason, and in older children with high fever and

Table 310.2
Utility of urine microscopy and dipstick analysis for guiding decisions about management and investigations of a child with a suspected UTI

Test result	Sensitivity (%)	Specificity (%)	Interpretation
Gram stain +	93	95	UTI likely
Leukocyte −, nitrite +	50	98	UTI likely
Leukocyte +, nitrite −	83	84	UTI possible
Leukocyte +, nitrite +	72	96	UTI likely
Leukocyte −, nitrite −			UTI unlikely

marked loin tenderness. Parenteral antibiotics should be continued until the defervescence occurs and the patient is able to tolerate oral medications.

In children older than 6 months there is good evidence to suggest that oral antibiotics are as efficacious as parenteral. There is less evidence to guide the duration of antibiotic therapy. Pyelonephritis is usually treated with 7–10 days of antibiotics. Antibiotic therapy should be reviewed in any child with a UTI whose fever does not settle after 48 h of appropriate therapy or if fever recurs later in the course of therapy.

Empiric antibiotics should be commenced promptly in infants that appear toxic, generally after a collection of specimens for culture, which may include cerebrospinal fluid.

Older children and those with less severe presentation should have empiric antibiotics commenced if there is a strong clinical suspicion of UTI based on presenting features, risk factor assessment, and/or urinary dipstick analysis or microscopy (*Table 310.2*).

Empiric antibiotics should be active against *E. coli* and other common uropathogens (*Table 310.3*). The choice of specific antibiotics should be guided by local patterns of bacterial resistance. Uropathogenic *E. coli* in most areas have a high degree of resistance to amoxicillin; therefore this antibiotic should generally be avoided for empiric use. The susceptibility of *E. coli* to first generation cephalosporins and trimethoprim/sulphamethazole varies widely.

Empiric parenteral therapy should include agents with good tissue penetration. In seriously ill young children a second agent should be added to broaden antibacterial coverage. Antibiotics that are likely to be active against *enterococci* (e.g., ampicillin) should be used empirically in children less than 3 months or those with known urological anomalies. Oral antibiotics that are excreted in the urine but do not achieve therapeutic serum levels (e.g., nitrofurantoin) should not be used to treat UTI in febrile infants and young children in whom pyelonephritis is likely.

Antibiotic therapy should be rationalized once culture results and antibiotic sensitivities are known.

The clinical condition of most patients, including normalization of temperature, improves within 24–48 h of initiation of appropriate antibiotic therapy. Repeat urine culture to confirm the success of therapy is not required if a child responds well to antibiotics and completes the full course. Non-adherence with a full course of therapy is common and may lead to inadequate treatment and relapsing infection.

Table 310.3
Empiric antibiotics for suspected UTI

Clinical features	Suitable empiric antibiotics[a]	Management guide
Age <6 months or toxic at any age	Cefuroxime 50 mg/kg 8 hourly	Parenteral antibiotics until afebrile for 48 h. Then continue appropriate oral antibiotic for a total of 7–10 days
	Cefotaxime 50 mg/kg 6 hourly	
	Ceftriaxone 100 mg/kg 24 hourly	
	Gentamicin 2.5 mg/kg 8 hourly[a] with the addition of Ampicillin 25 mg/kg 6 hourly	
Age >6 months and fever ≥38°C or other signs/symptoms of pyelonephritis	Parenteral agents as above or the following oral agents	Continue appropriate antibiotic for a total of 7 to 10 days
	Cefixime 8 mg/kg 24 hourly	
	Amoxycillin/clavulanate 12.5 mg/kg 12 hourly[b]	
	Cefuroxime 15 mg/kg 12 hourly	
	Cephalexin 12.5 mg/kg 6 hourly	
	Sulphamethoxazole/trimethoprim 4 mg/kg[c] 12 hourly	
Temp <38°C and symptoms of cystitis	Oral agents as above	Oral antibiotics for 3–5 days in total

[a]Choice of empiric antibiotics should be based on local patterns of antibiotic resistance
[b]Once daily gentamicin 7 mg kg^{-1} day^{-1} may be an alternative
[c]Dosage based on amoxicillin component
[d]Dosage based on trimethoprim component

Suppurative Complications

One uncommon complication of pyelonephritis is acute focal bacterial nephritis (also referred to as lobar nephronia or focal pyelonephritis) – a well-localized renal infection without frank abscess formation. If inadequately treated it may progress to abscess formation. At least a 3-week course of appropriate antibiotic therapy is recommended for treatment.

The presence of acute focal bacterial nephritis or abscess should be suspected if fever persists after 4 days of appropriate antibiotic treatment. The diagnosis is usually made by ultrasonography. Findings on ultrasound include appearance of an ill-defined mass with disruption of the corticomedullary junction and lack of vascularity (*Fig. 310.1*).

CT scanning (with and without contrast) may be used to confirm the diagnosis and potentially to discriminate between a complex abscess and a malignancy. Findings suggestive of renal abscess include a poorly defined, wedge-shaped, hypodense area that may involve liquefaction and does not enhance after contrast administration.

Renal Scarring

Renal scarring is the primary sequelae of pyelonephritis. A scar is a discrete area of tubular atrophy, tubulointerstitial fibrosis, and chronic inflammation. Between 5% and 30% of young children will develop a renal scar after an initial febrile UTI. Risk factors for scarring include: age less than 4 years, recurrent febrile UTI, delay in treatment of UTI, dysfunctional elimination, and VUR.

New scars rarely develop in children older than 4 years of age, except in those with neurogenic bladder, severe anatomical anomalies, or transplanted kidneys. Studies of kidney transplants suggest that scarring is possible if VUR is present, regardless of age.

The most sensitive imaging technique for diagnosis of scarring is the 99m-dimercaptosuccinic acid (DMSA) scan (*Fig. 310.2*). A scar is shown by diminished radioisotope uptake in a discrete area. Acute pyelonephritis is also associated with photopenia on DMSA scanning, which will resolve over time. Therefore a scar should only be diagnosed if an abnormality is detected on DMSA scan performed after a wait of at least 3 months from the time of UTI (6 months is generally preferred).

More severe degrees of renal scarring may be evident on renal ultrasonography. A clue to scarring is an unusually small kidney or a discrepancy in size between left and right kidney on ultrasound. A left kidney longer than the right by more than 10 mm or a right kidney longer than the left by 7 mm or more suggests the presence of a DMSA abnormality.

The reported long-term consequences of renal scarring are variable. Small discrete scars do not cause an appreciable impairment of renal function but may increase the risk of hypertension. Early studies suggested that up to 10% of children with renal scars will develop hypertension by early adulthood. However these studies were small and probably included more severely damaged kidneys detected by intravenous pyelograms. Larger long-term studies, including children with lesser degrees of

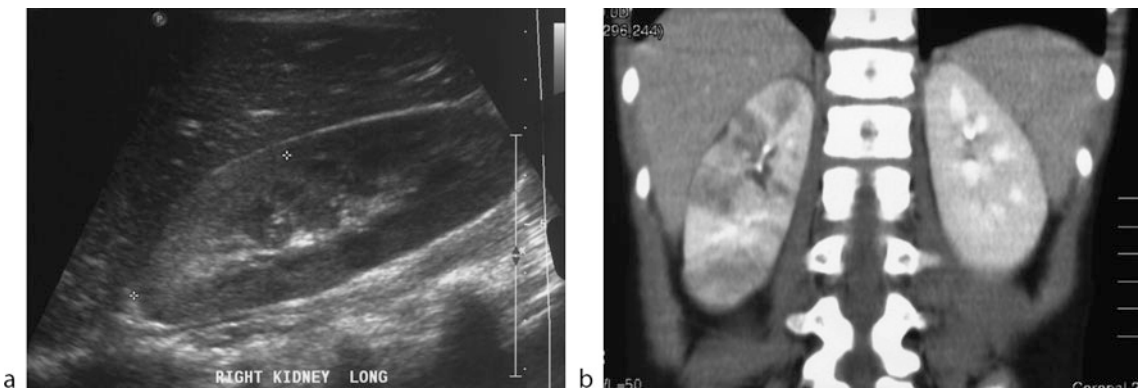

Figure 310.1

Acute focal bacterial nephritis due to E. coli in a 7 year old girl who presented with fever, right iliac fossa pain and psoas muscle spasm. (a) Ultrasound of right kidney showing a focal area of increased echogenicity and poor corticomedullary differentiation in the upper pole between markers. (b) Post-contrast CT scan of same patient showing patchy enhancement of right kidney particularly involving the lateral aspect of the upper pole, the lower pole is also affected

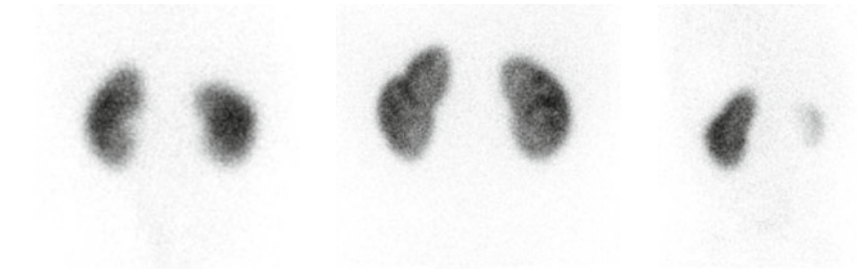

Figure 310.2

Renal DMSA Scans performed 6 months after UTI. (a) Normal scan showing symmetrical renal function and smooth renal outlines. (b) Abnormal scan of a 5-year-old girl with a history of recurrent UTIs showing a discrete cortical scar in the upper pole of the left kidney. (c) Abnormal scan from a 15-month-old boy who had a febrile UTI at age 9 months. Scan shows a small right kidney with an irregular outline and poor function. This appearance is consistent with congenital reflux nephropathy. Further investigations revealed grade IV right sided vesicoureteral reflux

scarring detected by DMSA, have failed to show similar rates of hypertension. Renal scarring increases the risk of complications during pregnancy including hypertension and pre-eclampsia.

Children with severe scarring may develop chronic kidney disease; this outcome is known as reflux nephropathy and is described below.

Vesicoureteral Reflux

VUR is the retrograde flow of urine from the bladder into one or both ureters. It is diagnosed by micturating cystourethrogram (MCUG) and is stratified into five grades of severity, depending on the radiological appearance (*Fig. 310.3*). Radionucleotide cystourethrogram is an alternative imaging modality with less radiation exposure but it provides less anatomical detail. VUR cannot be reliably diagnosed by ultrasonography.

VUR is usually an isolated finding which occurs because the submucosal tunnel through which the ureter attaches to the bladder is short and does not close on voiding.

VUR has a genetic basis and can be detected in 30% of first-degree relatives of an index case; the concordance rate in monozygotic twins is 80–100%. Inheritance patterns are usually consistent with autosomal dominant transmission with incomplete penetrance, but a causative gene/s has not been identified.

Children with neurogenic bladder, dysfunctional voiding, or bladder outlet obstruction (e.g., *posterior urethral valves*) are at risk for developing secondary VUR.

VUR is detected in 25–40% of preschool children who have had a UTI. The true prevalence of VUR in the normal population is uncertain; the most often quoted figure is 1% of all infants, but the true frequency may be higher. The prevalence of VUR is increased in children with the dysfunctional elimination syndrome.

Most children diagnosed with VUR after a UTI have low-grade reflux (grades 1 and 2) and the natural history is for resolution over time. Most low-grade cases and up to 50% of higher-grade cases will resolve by 4 years of age. VUR is less likely to resolve if it is associated with other anomalies of the urinary tract.

VUR potentially increases the risk for UTI by allowing incomplete voiding and may increase the risk of pyelonephritis by promoting passage of infected urine to the upper tract. The presence of VUR is probably the strongest single determinant of whether a child will develop a scar after pyelonephritis. However, VUR is not a prerequisite for scarring.

Surgical correction of VUR has traditionally been by ureteral re-implantation, with the aim of producing a longer intramural segment of ureter. The success rate of this surgery is 95–99%. Re-implantation surgery may reduce the risk of recurrent pyelonephritis. Whether or not this confers protection from scarring has not been established.

An alternative approach to antireflux surgery is the endoscopic injection of a bulking agent into the subureteral region of the bladder wall (subureteric transurethral injection [STING]). The rate of reflux correction overall may be less than with re-implantation surgery and the procedure appears best suited to less severe cases. A recent multicenter randomized controlled trial showed that endoscopic antireflux treatment reduced the recurrence rate of febrile UTI in young girls with high grade VUR.

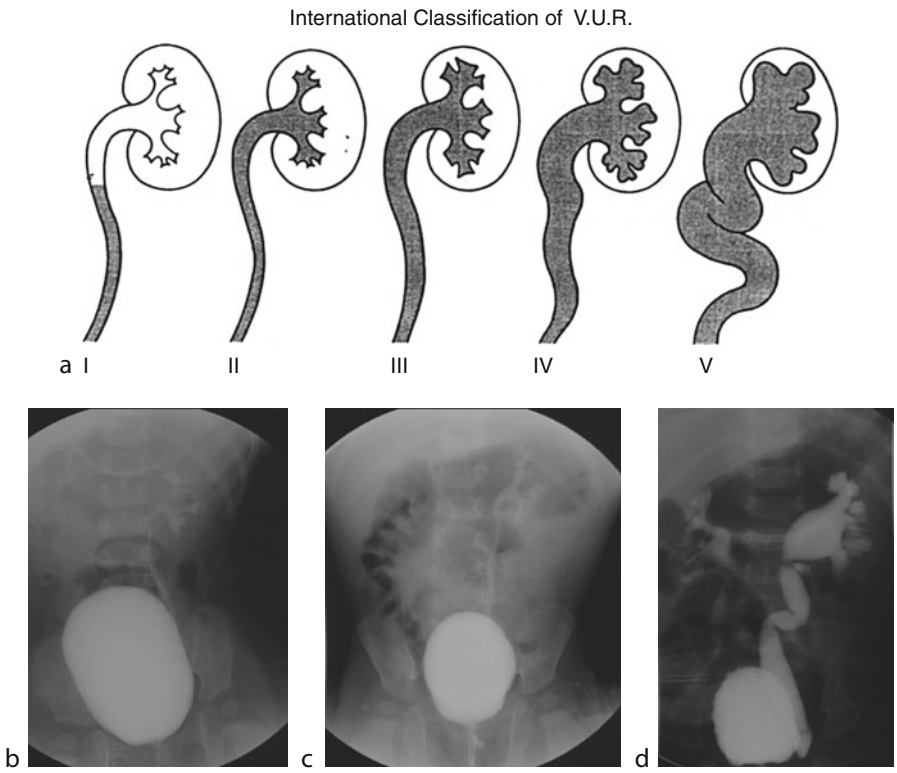

Figure 310.3

Vesicoureteral reflux. (a) Grading system proposed by the International Reflux Study Committee 1981 (Report of the International Reflux Study Committee: Medical versus surgical treatment of vesicoureteral reflux: a prospective international reflux study in children. (1981) Pediatrics 67: 392). (b) Micturating cystourethrogram (MCUG) performed after a febrile UTI in a 9 month old girl. Left sided grade II VUR. The renal ultrasound was normal. (c) MCUG performed after a febrile UTI in another 9-month-old girl. Left sided grade III VUR is demonstrated by reflux of radiocontrast into a dilated ureter. The renal ultrasound was normal. (d) MCUG performed after a febrile *Escherichia coli* UTI in a 2-week-old male infant. Bilateral high-grade VUR, grade IV on *right* and grade V on *left*. Ultrasound demonstrated bilateral ureteric dilation and mild left pelvicalyceal dilatation. DMSA showed scarring of right kidney

Reflux Nephropathy

Reflux nephropathy is the term originally proposed to describe renal scarring associated with VUR and UTI and replaced the misleading label of chronic pyelonephritis. Reflux nephropathy itself is something of a misnomer, as it is now recognized that scarring can develop after UTI without VUR being present. On the other hand, children with high-grade reflux may have abnormal kidneys without ever having a UTI.

Reflux nephropathy causes 2–5% of cases of end-stage kidney disease (ESKD). However the vast majority of children with UTI do not proceed to ESKD, reflecting the fact that reflux nephropathy includes a wide range of pathology, from small functionally insignificant scars through to badly damaged kidneys and ESKD.

The more severe end of the spectrum of reflux nephropathy includes children who have dysplastic and/or hypoplastic kidneys at birth, coexistent with VUR that is usually high grade.

Proteinuria and hypertension may be signs of reflux nephropathy. Strict blood pressure control and treatment with Angiotensin converting enzyme inhibitors may delay progression of kidney impairment.

Investigations After UTI

Most occurrences of UTI will occur in children with anatomically normal urinary tracts and will not lead to any significant complications. However, up to 30% of children will develop irreversible renal damage (scar) after a UTI

and in a significant minority UTI will be the first sign of a serious urological anomaly, early detection of which may allow appropriate management and limit further renal damage. Furthermore, approximately one third of children will have recurrent UTI and detection of risk factors such as VUR can be used to direct preventative therapy. Therefore, investigation of children after an initial or recurrent UTI has two main goals:

1. Detection of underlying urological anomalies
2. Detection of complications

Several guidelines and consensus statements have been published advising on investigations after an initial UTI, these have been developed in light of considerable uncertainties about the significance of renal scarring and a lack of evidence with regard to the effectiveness of preventative strategies. Therefore the advice has ranged from the interventional approach proposed by the American Academy of Pediatrics (perform ultrasound and micturating cystogram in all young children after an initial UTI) to the relatively minimalist approach of the United Kingdom's National Institute of Clinical Excellence (www.nice.org.uk/cg54).

Routine imaging with ultrasound should be performed in any child after an initial UTI with the possible exception of adolescent girls who have cystitis on clinical grounds. Ultrasound may be avoided if a good quality antenatal ultrasound, performed after 30-week gestation, did not detect any renal anomaly. Renal ultrasound should be performed during the initial course of antibiotics to assess for obstruction or acute focal bacterial nephritis if there is a lack of response to appropriate antibiotics.

The approach to further investigation of any child should be guided by the ultrasound appearance as well as the child's age, clinical features and local resources. Urological anomalies are more likely to be present in children with UTI caused by pathogens other than *E. coli* and in children who would otherwise be considered to have a low risk of UTI (e.g., boys older than 2 years).

An MCU is often performed after resolution of the acute infection to assess for VUR. VUR is more likely to be present and significant in children who are younger, have infection with an organism other than *E. coli*, have had recurrent infections, have pyelonephritis, and/or have an abnormal ultrasound (e.g., ureteric or pelvicalyceal dilatation, or abnormal size kidneys). Evidence of pyelonephritis is provided by high plasma procalcitonin levels and by an abnormal DMSA scan at the time of infection; if either of these are present there is a greater chance of grade 3–5 VUR.

Two suggested approaches to imaging after UTI in young children are outlined in ❯ *Fig. 310.4*. Imaging of older children should be individualized based on risk factors for recurrent infections, renal scarring, and VUR.

Prevention

Recurrent UTI occurs in between 15% and 40% of children after a first infection. The majority of recurrences occur during the following 2 years after the initial UTI. Factors that are associated with recurrence include young age at first UTI, female gender, anomalies of the urinary tract including VUR, and voiding dysfunction.

Voiding dysfunction can be managed by encouraging regular and complete bladder emptying (e.g., scheduled voiding every 2–3 h) with or without the addition of anticholinergic agents. Older children may be amenable to bladder training. *Constipation* should be treated by dietary and behavioral modifications as well as laxatives as required.

Prophylactic Antibiotics

The results of two large randomized controlled trials in children recently published confirm that prophylactic antibiotics confer a small but significant degree of protection from recurrent UTI. Antibiotic prophylaxis may be of particular benefit in young girls with high grade VUR as a recent study found prophylactic antibiotics reduced the rate of recurrent febrile UTI and new scar development in this population. Once-daily therapy with antibiotics such as cotrimoxazole, trimethoprim, or nitrofurantoin has been found to be safe; however, there is some concern about prophylactic antibiotics promoting growth of resistant organisms.

Prophylactic therapy is usually discontinued when the risk of severe infection and scarring is judged to be low.

Cranberry Juice

Cranberry juice may prevent recurrent UTI in women and older girls but as yet there is no evidence to show it is effective in younger children. The mechanism of action of cranberry juice is uncertain; it appears that substances in the berries may interfere with the adherence of *E. coli* to uroepithelium. The most effective dose and formulation of cranberry juice have not been established. Cranberry juice should not be used for treating a UTI.

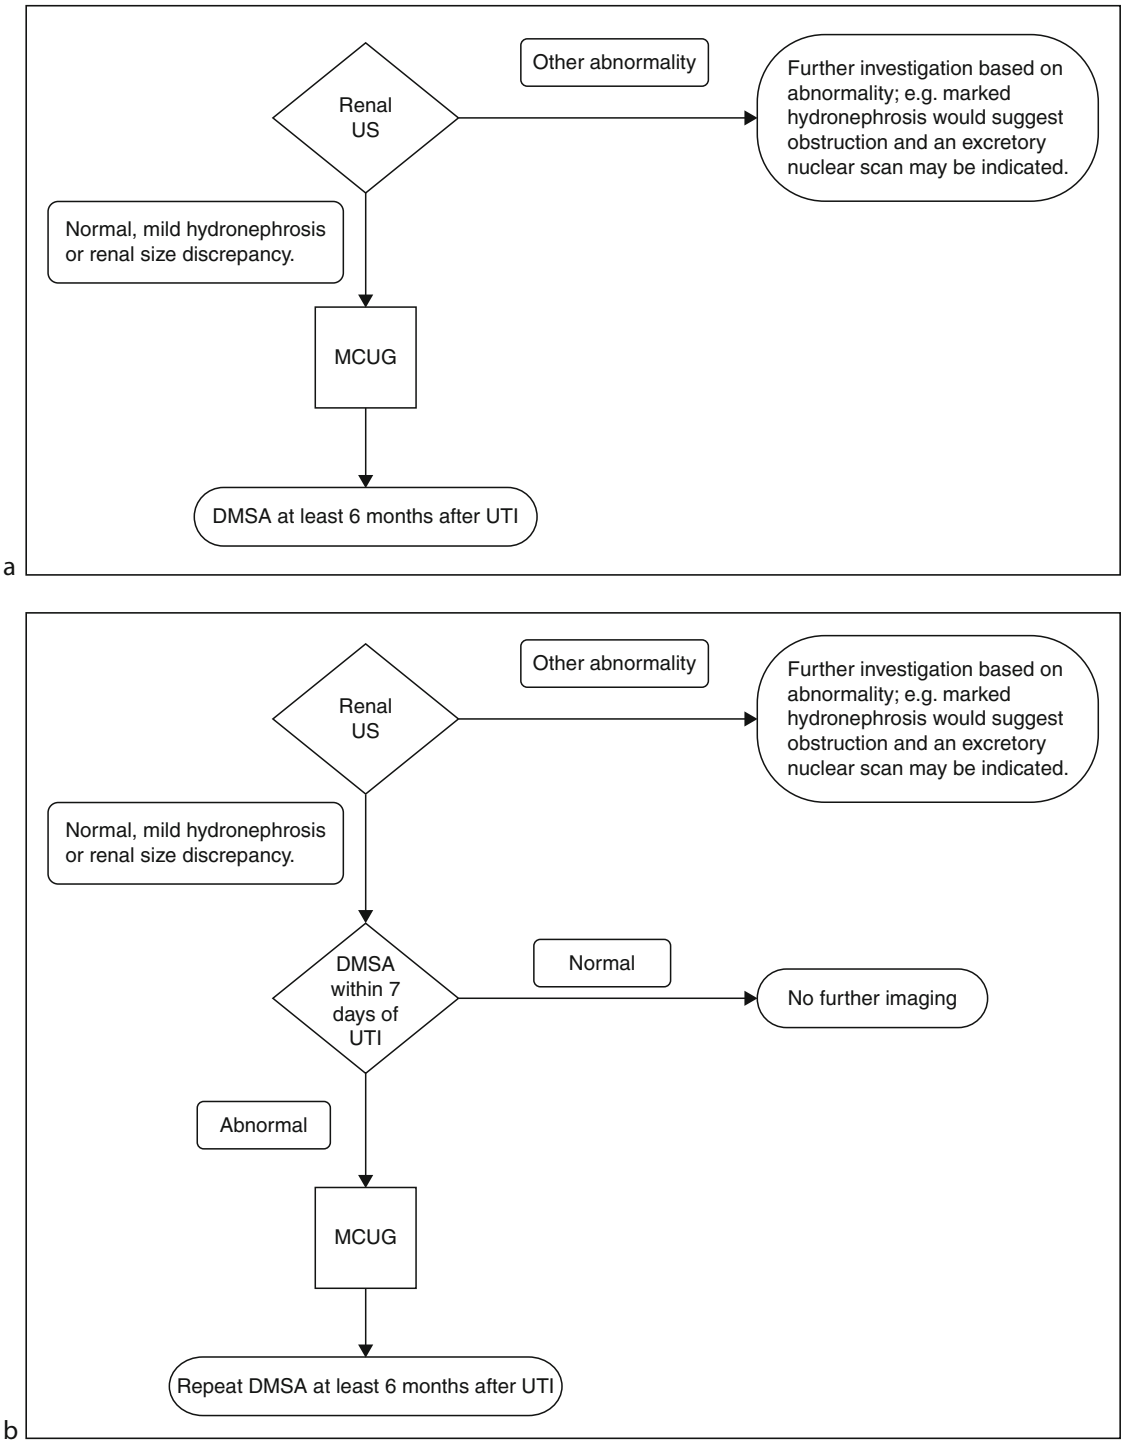

Figure 310.4

Investigation after UTI of children less than 2 years of age. (a) Suggested approach to screen all young children with UTI for vesicoureteral reflux (VUR). (b) Alternative approach using an acute DMSA as a screening modality. Such an approach could lead to about a 50% reduction in MCUG rates. An abnormal acute DMSA will be present in >90% of cases of dilating VUR

Probiotics

There is no good evidence to support the use of probiotics as a preventive strategy for UTI.

Circumcision

Circumcised males have a lower rate of UTI during childhood than uncircumcised males. Given the low incidence of UTIs in boys, the vast majority of uncircumcised boys will not develop a UTI and more than 100 circumcisions would be needed to prevent one UTI. The risk: benefit ratio does not justify circumcision of all boys, but circumcision could be considered as a means to prevent UTI in boys with recurrent UTI or those at high risk of recurrence and scarring because of underlying urological abnormalities.

Antireflux Surgery

Surgical intervention to correct VUR should be considered in children with VUR, recurrent infections (despite prophylactic antibiotics), and renal damage.

Prognosis and Follow-up

Parents of children who have had a UTI should be educated about the signs of UTI to allow prompt treatment of any recurrences.

The overall prognosis for children after UTI is favorable; however, a small number, particularly those with high-grade VUR and bilateral renal damage, are at risk of *hypertension* and *chronic kidney disease*. Any child with renal scarring should have annual review for blood pressure measurement. Children who have bilateral renal scarring should be monitored for signs of progression of renal disease including proteinuria and appropriate management should be initiated for hypertension or impaired glomerular filtration rate.

311 Obstructive Nephropathy

Stephanya Shear · Martin A. Koyle

Introduction

Congenital obstructive nephropathy represents a spectrum of disease from the partially obstructive ureteropelvic junction to severe bilateral disease associated with posterior urethral valves (PUVs). In this latter situation, the renal manifestations can lead to the extreme situation of bilateral renal dysplasia, oligohydraminos, and resultant pulmonary dysplasia resulting in Potters syndrome and fetal demise. In between these extremes lie the majority of patients who may or may not have long-term renal function deterioration. We are challenged in determining those patients who will have long-term renal damage, especially those where this deterioration can be minimized by appropriate investigation and therapy.

To date, we have no markers or studies that indicate which children will benefit from early intervention, especially in utero. In fact, many studies would argue that intervention does not change the natural history of the disease; indeed damage is more likely to have occurred during renal development and has early in gestation, determined that the kidney will carry on a path of dysplasia.

As the clinical use of prenatal ultrasound has increased to at least 80% of pregnancies in the United States, the incidence of early detection of urinary anomalies has increased. Only 1% of prenatal ultrasounds will have any anomaly, with all genitourinary anomalies composing only 20% of that 1%. The overall percentage of obstructive urinary abnormalities is thus more likely to be present in 0.04–0.3% of all antenatal evaluations by ultrasound.

As noted earlier, there is very little evidence that fetal intervention improves outcomes in renal units or infant pulmonary morbidity. However, if intervention for antenatal hydronephrosis is to be considered, the following parameters would need to be present: (1) normal chromosomes in a male fetus, with (2) no other existing urologic or non-urological abnormalities, and (3) evidence of increasing hydronephrosis with corresponding decreases in amniotic fluid level late in pregnancy. This scenario is most often associated in a male with PUV and the goal of intervention is to restore amniotic fluid with the hope of allowing improved lung maturation.

Obstructive nephropathy describes renal damage and pathology secondary to obstruction and is distinct from hydronephrosis. Hydronephrosis is a "generic" radiographic finding, meaning "water on the kidney," that can be a sign of obstructive renal damage; however hydronephrosis is not synonymous with obstructive nephropathy. Most cases of hydronephrosis are associated with a benign clinical course. The majority of fetuses will fall into the category of mild hydronephrosis; with renal pelvis diameters less than 1 mm or Society for Fetal urology (SFU) grade I-2see (*Table 311.1*). Very few of these kidneys will require intervention after birth. Thirty percent of infants with AP diameters greater than 7 mm at 33 weeks gestation will have normal renal ultrasounds at 5 days of age.

Renal Damage and Hydronephrosis

The pathogenesis of renal damage after obstruction has been the subject of many well-crafted animal studies; however the natural history is poorly understood in humans, although there has been increasingly more knowledge regarding the cellular changes in renal units after obstruction.

Renal Damage, Renal Insufficiency, and Hypertension

In obstructed units, it is not the delay in emptying or hydronephrosis per se that is the primary concern. Instead, it is the resulting compromise of renal function that might lead to renal insufficiency and possibly renal failure.

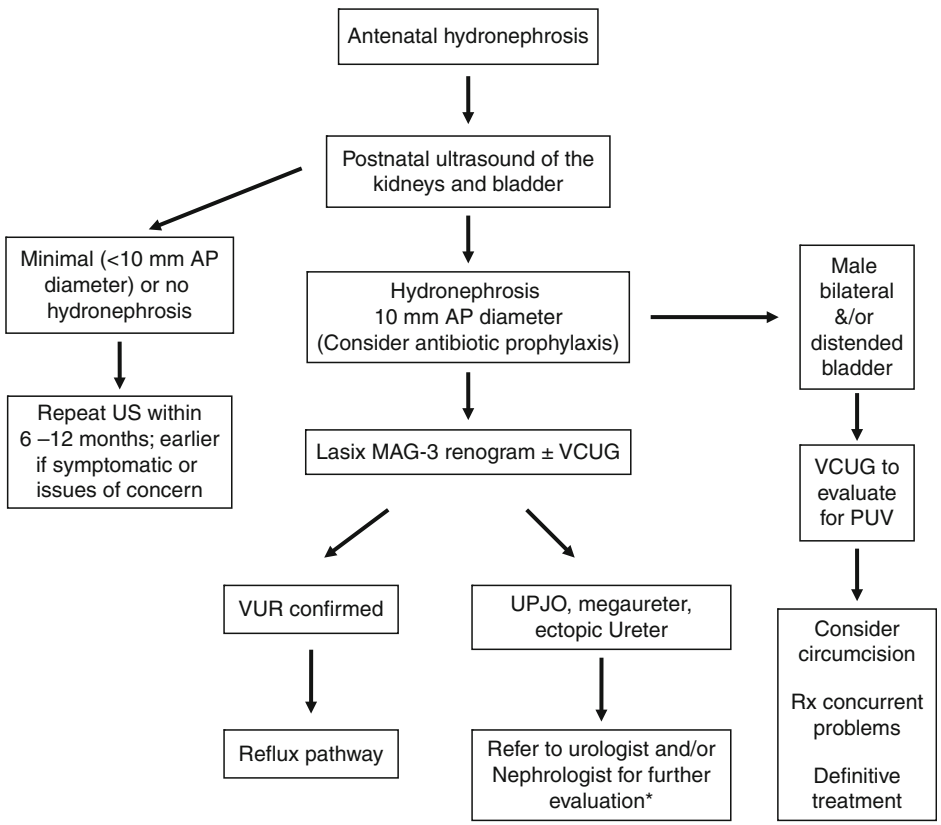
The consequences of obstruction on renal function have been elucidated using animal models. When counseling patients and families, it may be useful to answer questions regarding the types of damaged obstructed

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_311,

Table 311.1
Society for Fetal Urology (SFU) grading system for Antenatal Detected Hydronephrosis (ANH) J Pediatr Urol (2010) 6, 212–231

Grade	Description
0	No hydronephrosis
1	Slight dilation of renal pelvis; normal calyces
2	Moderate renal pelvis dilation; mild caliectasis
3	Large renal pelvis with calyceal dilation but preserved renal parenchyma
4	Very large renal pelvis with severe caliectasis and thinning of renal parenchyma

kidney can incur, but care must be made when translating animal models to the human patient. Animal models differ from human natural history of the disease in time of the obstruction and species specific variations in gene expression. Chronic partial urinary obstruction has been shown to cause tubular atrophy, interstitial fibrosis, and retarded renal growth. Marked inflammation is also seen. Early relief of obstruction can restore nephrogenesis and reduce progression of renal damage with the potentially greatest ability before nephrogenesis is complete in the antenatal period. However some damage, such as fibrosis, may continue even after obstruction is alleviated. Results from these studies have both supported early intervention in the infant period as well as theories that damage in



utero has already destined those poorly functioning kidneys to fail and intervention postnatally does not alter their course.

Since congenital obstruction is thought to be particularly damaging to the maturing kidney, researchers have looked for evidence of renal dysplasia in children affected with obstruction. It is still unknown to what extent obstruction in utero results in the parenchymal maldevelopment and what histological finding predicts renal function. Huang et al. performed 70 biopsies on 61 patients undergoing open pyeloplasty for ureteropelvic junction obstruction. They found epithelial proliferation, glomeruli sclerosis, and cystic dilatation; however, the degree of these changes did not correlate with hydronephrosis, age, or renogram split function levels. When comparing obstructed kidneys to autopsy controls that found in obstructed kidneys decreased proximal tubules size and a decrease concentration of distal tubules independent of glomeruli injury. Tubules were seen to have atrophy with and without overt fibrosis. The decrease in size of the proximal tubule may represent immaturity of these structures and they found a correlation between smaller proximal tubule size and longer washout times. Other studies while showing histological changes at the time of pyeloplasty, these changes correlate poorly to the differential function of the affected kidney.

Renal insufficiency is a worrisome complication in patients with congenital urinary obstruction. The true incidence of renal insufficiency is difficult to obtain since many studies of obstruction use surrogate marker such as wash out times or split function of renograms as a measurement of renal function before or after intervention. In one study, of the most severe cases of PUV, a quarter of boys have chronic renal insufficiency. In recent long-term studies, again 25% of patients may have renal insufficiency and some of those boys progress to ESRD by young adulthood. It is also true that in children with PUV with initial normal renal function from ages 5 to 11 may progress to renal insufficiency and ESRD. The degree to which this deterioration may be ameliorated by surgery is debated. One study showed no significant difference in renal outcomes based on initial surgical technique. Looking at 100 patients, chronic renal disease was seen in 51% of the boys by the age of 20 years and 40% had ESRD. Similar proportions in each surgical group had evidence of chronic disease and renal failure. Childhood cases of ESRD were rare, and insufficiency before the age of 10 was seen only in one third of patients. These results speak to theories that in utero obstruction of the kidneys sets up a path toward significant renal impairment. It also underscores the need for long-term follow-up in these children to assess renal function.

Some patients, especially those with PUV, can have hypertension. Those patients with bilateral obstruction more commonly have hypertension. Although several studies of PUV found evidence of chronic renal insufficiency (CRI), no study reports significant numbers of children with hypertension. In spite of the relatively large numbers of studies in the ureteropelvic junction obstruction (UPJO) and PUV populations, no study has directly studied the incidence of hypertension as predictive of clinical outcome.

Radiological Evaluation

Patients with suspected obstructed renal systems will be evaluated radiographically. The timing of these studies, as well as which studies are performed, may differ depending on the clinical and radiological evaluations. Although some general comments can be made, there is great variability in the frequency of studies and the merits of the various imaging modalities differ see (*Fig. 311.1*) (*Table 311.2*).

Unless PUV or severe obstruction is suspected, a renal and bladder ultrasound is usually performed after 72 h following birth, and in healthy infants, initial studies can be deferred until the second month of life. The delay in the neonate allows for the improved hydration and lessens the chance of missing hydronephrosis due to depleted volume status. Serial ultrasounds can be performed thereafter, depending on the diagnosis and patient's clinical picture. Ultrasounds are components of the routine management and are advantageous in that they are easy to perform, noninvasive, tolerated well by children, do not expose the child to radiation, reproducible, and relatively inexpensive.

A voiding cystourethrogram might be considered if dilatation is seen on the initial ultrasounds is suggestive of obstruction due to PUV; voiding cystourethrogram (VCUG) can also diagnose ureteroceles and ectopic ureters. Unfortunately, a VCUG exposes the patient to radiation and catheterization. Sedation is usually not required in infants but may be considered in older children.

Nuclear renal scans are used to measure obstruction, evaluate renal scars, and determine relative split renal function, and are currently the most commonly used studies used to evaluate obstruction. Current nuclear scans employ technetium-99. A comparison of the various nuclear renal scans is shown below (*Table 311.3*). As

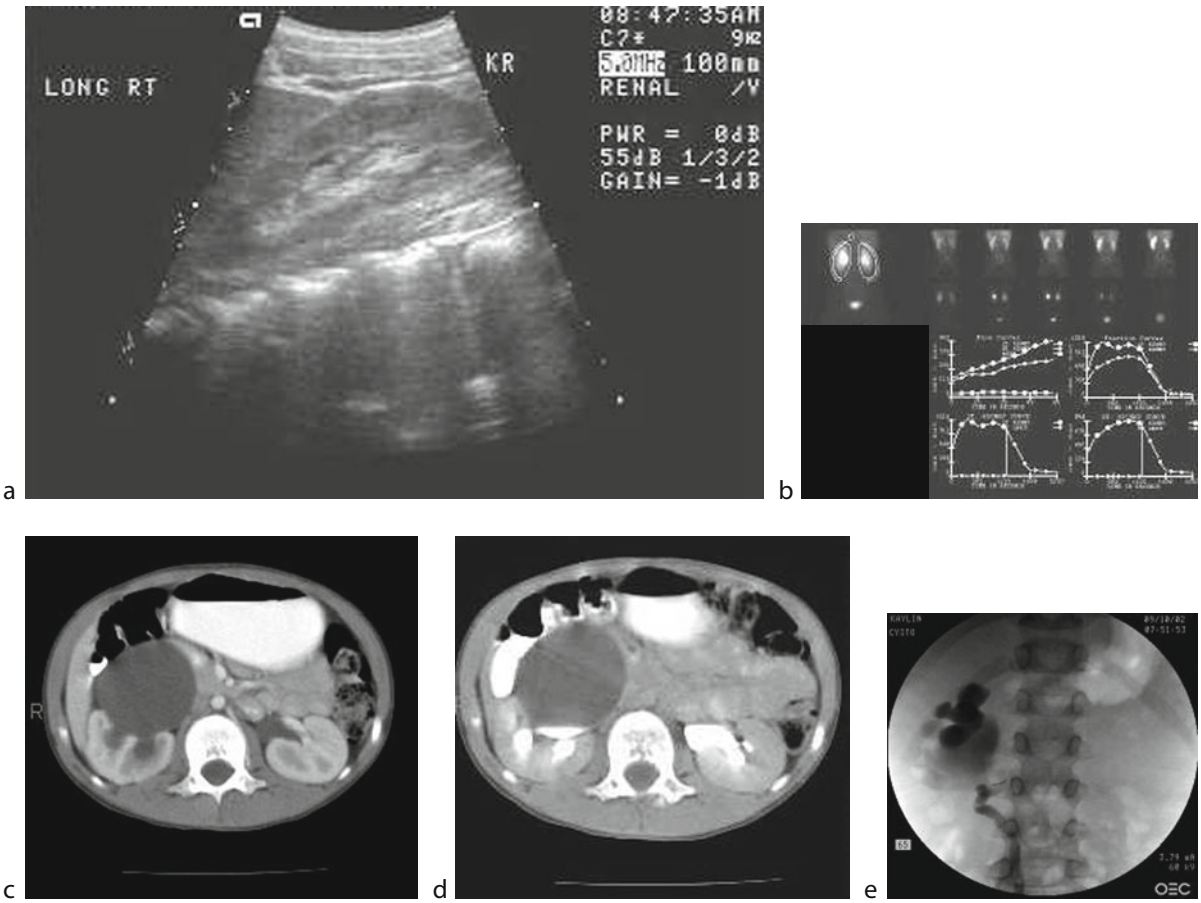


Figure 311.1

This case illustrates the imperfection of imaging in detecting intermittent obstruction. This 3-year-old child had been seen for repeated bouts of abdominal pain. The ultrasound (a) and nuclear imaging study (b) demonstrate a normal right kidney, without hydronpehrosis, and with excellent function and drainage. The CT scan performed without (c) and with contrast (d) 2 weeks later when the child presented with abdominal pain, reveals marked pelviectasis and moderate caliectasis. A retrograde pyelogram (e) performed at the time of pyeloplasty further substantiates a ureteropelvic junction

with ultrasounds, there is significant variability in the use of these scans and there is significant variability in interpretation. All nuclear renal scan expose the child to significant radiation exposure and some require bladder catheterization. The child does not require sedation. Different radiopharmaceuticals are utilized depending on the information desired. When evaluating for obstruction, MAG-3 (mercaptoacetyltriglycine), which is predominately excreted by the tubules, is the preferred agent (*Table 311.3*). If MAG-3 is unavailable, DTPA or GC can be used (*Table 311.3*).

CT scans are ideal for imaging the parenchyma. Excretory CT scans can be used as a method to detect obstruction. However, CT scans have considerable higher radiation exposure that plain radiography and require children unable to lie still for 20 min be sedated. They also do not provide quantitative measurements regarding relative renal function.

MRI renograms are not used routinely for baseline or follow-up studies. Although they do not expose the child to radiation, they require sedation, are expensive, and like CT scans do not provide quantitative information. They do offer information about detailed anatomy but can be extremely helpful in complex circumstances, such as diagnosing ectopic ureters and duplex collecting systems. Ongoing work with this modality has been promising in

Table 311.2
Imaging techniques utilized in the evaluation of suspected obstructed hydronephrosis

Study	Utility
VCUG	Selectively utilized to diagnose posterior urethral valves, reflux and intravesical abnormalites such as diverticulcum and ureterocele.
IVP	Rarely utilized today.
Ultrasound	Almost always the initial anatomical *screening test* due to lack of radiation, rapidity of study, reproducibility, and cost. Very little functional information provided.
Renography	May be *dynamic* (MAG-3 with furosemide), to study for obstruction, or *static* (DMSA), where more precise determination of function can be elucidated. DMSA may require sedation.
CT scanning	May be useful because of anatomical detail but suffers because of significant radiation dose.
MR urography	Provides superb anatomic detail and can also provide functional information. In younger patients it may require sedation or general anesthesia and hence cost is an issue that prohibits routine use.
Invasive techniques	Cystoscopy and retrograde pyelography can be used to more clearly define an anatomical problem such as ectopic ureter, ureterocele, ureterovesical or ureteropelvic junction obstructions, and are generally performed at the time of definitive repair. Interventional radiology can be helpful in the diagnosis and treatment of come complicated obstructive pathologies. The Whithaker or pressure- flow study is rarely used in selective cases of obstructive uropathy.

Table 311.3
Basic technetium scans and their characteristics

	Technetium-99 (^{99m}TC) nuclear renal scans	
Scan	Agent	Characteristics
MAG-3	Mercaptoacetyltriglycine	Tubular clearance
		Lower radiation exposure
		High quality
		Not influenced by GFR
DPTA	Diethylenetriamine pentaacetic acid	Requires the highest concentration of ^{99m}TC
		Rapidly cleared from system
		Measures GFR
		Poor quality to measure obstruction
DMSA	Dimercaptosuccinic acid	Binds tightly to tubular cells
		Best study to assess renal cortex
		Reflect renal mass
		Partially influenced by GFR
GC	Glucoheptonate	Influenced by GFR but cannot measure
		Tubular secretion
		Visualizes cortex
		Cannot measure obstruction

not only demonstrating complex anatomy with extraordinary clarity, but also as a functional, dynamic instrument that might ultimately surpass the current nuclear medicine studies.

With modern imaging, it is rare that cystoscopy and retrograde pyelography are utilized as a routine, separate diagnostic procedure. If performed, it is often done by some pediatric urologists at the time of a definitive

procedure. Likewise, the intravenous pyelogram or urogram is rarely useful.

Use of Antibiotics and Circumcision

Prescribing of antibiotic prophylaxis for all uropathies has undergone scrutiny and many question the utility of antibiotic use, even in cases of reflux. In patients with obstruction and concomitant vesicoureteral reflux, antibiotics may be of some benefit in reducing febrile urinary tract infections in some cases. Until better controlled trials yield results that define their true role, antibiotic prophylaxis should be utilized after assessing the pros and cons with the family, for those children with obstruction and reflux, ureteroceles, and/or megaureters. In essence, until studies clarify the currently conflicting data, practitioners should question their utility of prophylactic antibiotics and should manage each child individually.

Another area of practice variation is routine circumcision. Historically, in the United States, all boys with signs of neonatal uropathies, obstruction included, underwent routine neonatal circumcision as a prophylactic measure. Just as the use of antibiotics has been scrutinized, so has circumcision. The PUV population has generated the most information on the value of circumcision. It is more difficult to make statements of benefit in cases of ureteropelvic junction obstruction, megaureter, or ureterocele. Urinary tract infections can be reduced by circumcision, and the clinical benefit of the procedure is the greatest in patients with a high risk for febrile infection such as boys with PUV. The incidence of urinary tract infection may be reduced by as much as 83%. Families should be counseled in order to make an informed decision regarding circumcision, as with antibiotic prophylaxis, as part of the management options.

Major Causes of Obstruction

Ureteropelvic Junction Obstruction

Ureteropelvic junction obstruction (UPJO) is the most common cause of congenital urinary obstruction. Current theories to the cause of obstruction include deposition of collagen causing internal constriction, presence of crossing vessels that compress the pelvis, or obstructing polyps. Inherited differences in peristaltic function may contribute to the range of disease phenotypes seen in UPJO. Regardless of the cause of UPJO, the significant outcomes are hydronephrosis and presumed impact on renal function due to back pressure from the obstruction.

Prior to the widespread use of prenatal ultrasounds, children with UPJO presented in infancy with palpable abdominal masses, failure to thrive, urinary tract infections, and/or renal failure. Older children presented with flank pain usually accompanied with emesis. Although infants and children continue to present for evaluation in this manner, an increasingly greater number of children are diagnosed as a result of prenatal ultrasounds.

The use of prenatal ultrasound in the early detection and diagnosis of obstruction has increased over the last 3 decades as the use of ultrasound has become a routine part of prenatal care in the United States. Sensitivity for detection increases as ultrasounds are performed in later trimesters resulting in 1% of pregnancies indicating urinary abnormalities. Hydronephrosis is the most common finding. Most cases of prenatally detected hydronephrosis do not persist post partum. Large series indicate up to 50% of cases of prenatal hydronephrosis will resolve within 16 months of the postnatal period.

Ureteropelvic junction obstruction accounts for over 65% of the cases of prenatal hydronephrosis. Prenatal ultrasound has become the primary mode of diagnosing UPJO. Concerns arose that widespread use of prenatal ultrasound would lead to an increase in unnecessary surgery. Indeed, early detection and diagnosis has lead to earlier intervention. It is debatable to whether early detection has manifested in significant long-term outcomes. Patients with prenatal diagnosis have similar outcomes in regards to renal function when compared to patients presenting with symptoms. Both groups have similar gain of renal function, and pyeloplasty did not significantly improve renal function.

Indications for surgical intervention are a subject of debate with practitioners using consistent but different criteria for surgical correction. The use of diuretic (Lasix) renal scans has provided additional information for the clinician but interpretation and execution of tests may be confusing. Mercapto-acetyl tri glycine (MAG-3), a technetium-99 labeled compound that is secreted by the renal tubules, has significant fidelity regardless of underlying renal function, and is considered the best current agent for estimating renal obstruction and function. Since these studies are open to interpretation, these studies are best conducted as part of a comprehensive management strategy by surgeons or nephrologists.

Many children can be followed conservatively with 10–25% ultimately requiring surgical correction usually within the first 2 years of life. And some studies show that

even when requiring surgical correction, delay in surgery does not impair recovery of renal function.

Important to the practicing general pediatrician is that these children need to be followed closely in order to detect clinical and radiographic changes that may indicate renal deterioration. Blood pressure measurements, urine analysis, and repeated ultrasounds or renograms maybe recommended while under the care of an urologist and/or a nephrologist. Early consultation with these specialties will insure close follow-up. It is controversial whether children without a history of UTIs or vesicoureteral reflux need to be maintained on prophylactic antibiotics and many current physicians will not routinely use them.

Posterior Urethral Valves

Posterior urethral valves (PUV) are a congenital urethral anomaly seen in boys due to an obstructing membrane. PUV accounts for 3–9% of all cases of hydronephrosis. The degree of obstruction varies and the resulting phenotype can be from mild dilation to severe obstruction affecting both the bladder and kidneys. Obstructing urine can produce a distended, poorly contractile bladder and significant bilateral vesicoureteral reflux that dilates ureters and the renal collecting system. Oligohydraminos can be associated with sever obstruction that ultimately impacts lung maturity of the developing fetus. Although less common than UPJO, it represents a significant cause of morbidity and mortality from obstruction from both a respiratory and renal perspective. Mortality was as high as 35% in the 1960s. Now, 90% of boys with PUV survive infancy. Improved outcomes are due both to aggressive antenatal care in intensive care units as well as the developments of renal dialysis and transplantation. Sever obstruction is a neonatal medical emergency requiring urinary tract drainage respiratory support, and when indicated, correction of electrolyte imbalances. Severely affected newborns may require some form of renal replacement therapy. Presence of PUV is often suspected antenatally, but is confirmed by a postnatal voiding cystourethrogram (VCUG). Bladder drainage via the urethral catheter remains in place until the child is both stable and large enough to undergo endoscopic resection of the valves or urinary diversion.

Endoscopic ablation of the valves has a high rate of success; however ablation must be confirmed by post-procedure VCUG. Boys, especially those of low birth weight, with presumed small urethras drainage can also be managed by performing a cutaneous vesicostomy that allows the bladder to drain through the abdominal wall bypassing the obstructed urethra or cutaneous ureterostomies where the ureters are brought out to the skin. Some groups suggest a stepwise approach to treat as many patients with valve ablation and then proceed to diversion if decompression of the urinary system is not achieved by ablation alone; however limited evidence exists that this alters the progression of renal damage.

Patients with significant sequela from PUV require close follow-up usually with both nephrologists and urologists. However, with aggressive management of the newborn and experience in renal dialysis and transplantation, mortality for all children with PUV is less than 5% (Parkhouse). Early aggressive measures have not changed the rate of renal insufficiently or renal failure. Ureteral dilatation and reflux are often present even after valve ablation and patients are maintained on prophylactic antibiotics. The degree of obstructive nephropathy can be significant ranging from chronic renal insufficiency, requirements for dialysis, and potential end-stage renal disease culminating in renal transplantation. As many as 35% of boys with PUV may go onto renal failure. Risk factors for renal failure include late diagnosis of PUV and bilateral reflux. Many patients have small, poorly compliant bladders that lack adequate contractile capability. Patients have varying degrees of bladder dysfunction and may need to perform clean intermittent catheterization to empty their bladders, require bladder augmentation for an adequate capacity, or need the creation of catheterizable channels. Progression of bladder dysfunction will require urodynamic evaluation as part of ongoing urological follow-up.

Bladder function remains an ongoing challenge in the management of these patients and contributes to both significant morbidity and reduced quality of life. Without aggressive management of the valve bladder, renal transplantation is associated with lower graft survival. The increasing success of renal transplantation has been one of the major factors in the recent lower mortality rates for patients with PUV.

Obstructing Megaureter

Megaureter is a descriptive term applied to all ureters that have significant dilatation (greater than 0.7–1 cm). Only a small portion of megaureters are truly obstructing. Distinguishing dilated ureters that are obstructed from those that are merely dilated is an important step. Some

clinicians rely on drainage pattern from diuretic renograms. However, dilated ureter empty less efficiently and thus a delayed time to empty could potentially represent only a capacious ureter. Ultrasound findings of a progressively increasing hydronephrosis or dilatation to a level near the bladder that then sharply tapers off, is also used by some for evidence for obstruction. Those megaureters that are both obstructing and refluxing can be diagnosed by voiding cystourethrograms where the ureter is seen to taper significantly as it approaches the bladder. And as with UPJO, the insult potentially resulting in the obstruction has been linked to increased collagen deposition. In the cases of megaureter, the location of collagen deposition is near or at the ureterovesical junction. As with other causes of obstruction, many megaureters are diagnosed by prenatal ultrasounds. Prior to the widespread use of ultrasound, children presented with failure to thrive, urinary track infections, and hematuria. Although the true natural history of megaureters is unknown, many prenatally detected megaureters can be managed conservatively, at least initially. Management is similar to ureteropelvic junction obstruction in that patients are followed expectantly with serial ultrasounds and renograms. Greater controversy exists on what modality to use to determine obstruction in the cases of megaureter. Given the tortuousity and dilation of the megaureter, there is often delayed emptying of the ureter such that time to emptying becomes a less reliable marker of obstruction. Instead many physicians will use serial split renal function or sonographic evidence of thinning parenchyma as indication for intervention. Many patients are maintained on prophylactic antibiotics. Patients are more likely to undergo surgical correction when high grades of hydronephrosis are seen in combination with diminished renal function. Break through urinary tract infections while on prophylaxis is also a reason for intervention; however it is unclear if surgery decreased the incidence of further infections. Prior studies do not show significant regain of renal function after surgical correction.

Surgical repair of obstructing megaureters has consisted of separation of the ureter from the bladder, removal of the affected segment, tapering of the ureter and reimplantation into the bladder. Although the ureter may empty more efficiently after surgical correction, dilatation of the ureter may persist. Goals of the surgery are focused on alleviating obstruction so as to disrupt the continued pressure on the renal segment. As with other patients with obstructing nephropathy, these patients with megaureters are followed long term to assess their renal function and urinary tract function.

Ureteroceles

Ureteroceles are seen when the distal portion of a ureter is dilated sometimes distorting the bladder. Obstruction is thought to be caused by an anomaly at the ureteral orifice. It is not clear if this anomaly represents a partially obstructing membrane or an error in the normal development of the ureteric bud in utero. The anomaly is found four times more often in females and is associated with ureteral duplication in 80% of the time. In cases of renal duplication, the upper pole moiety is most often associated with the ureterocele. Ureteroceles are often associated with ectopic insertion of the ureteral orifice. In girls insertion can occur at the bladder neck, vagina, or urethra. In boys, ectopic insertion occurs in the urethra, seminal vesicles, prostate, or vas deferens. Up to 50% of children with ectopic ureters will have reflux into the ipsilateral lower pole kidney. Even those ureteroceles that are not ectopic can be quite large and may obstruct the bladder neck. A patient with an ureterocele most commonly presents with urinary tract infections and/or sepsis. Patents can present with urinary obstruction due to the extension of ureterocele beyond the bladder neck, or incontinence in the case of ectopic insertion. In recent years, more ureterocele are diagnosed with prenatal ultrasounds, but still a significant number are detected symptomatically. Although early detection has not altered renal function, it has been shown to decrease the morbidity associated with ureteroceles by instituting early use of antibiotic prophylaxis and resulting lower rates of UTI.

Treatment of the ureterocele is tailored to the individual patient in regards to symptoms, age, presence or absence of duplication, relative function of the upper pole moiety if present, presence or absence of reflux, location of insertion of the ureter, renal function, and history of infection. Asymptomatic patients, most often those diagnosed prenatally, can be managed conservatively with serial renal ultrasounds; however limited information is available to whether this represents a course for most patients. Various surgical options are available with the goal of treatment being assuring adequate drainage, minimizing the risk for infection, preservation of renal function, and management of reflux if present. Surgical techniques include endoscopic incision of the ureterocele, upper pole heminephrectomy with or without lower tract reconstruction, ureteroureterostomy, and complete nephroureterectomy. Increasingly, treatment plans have maintained renal tissue by performing ureteroureterostomies with only limited indications for heminephrectomy.

312 Acute Kidney Injury

Hui-Kim Yap

Definition

Acute renal failure occurs when there is a rapid decline in glomerular filtration rate, resulting in impairment of excretion of nitrogenous waste product, and loss of water and electrolyte regulation as well as acid-base regulation. This is reflected clinically by an abrupt increase in serum creatinine, and/or an abrupt decrease in urine output. Although oliguria, defined as urine volume less than 400 mL/m^2 per day, is common in acute renal failure, non-oliguric renal failure in which urine volume is normal is a well-recognized entity occurring in conditions such as aminoglycoside toxicity.

More recently, the Acute Kidney Injury Network (AKIN) proposed to use the term "acute kidney injury" (AKI) to redefine the entire spectrum of acute renal dysfunction, encompassing early and mild forms all the way to severe forms requiring renal replacement therapy. In adults, a classification system known as the RIFLE criteria, to define the severity of AKI, has been proposed by the Acute Dialysis Quality Intitiative. This defines risk, injury, and failure based on changes in serum creatinine and/or urine output, combined with the clinical outcome classes based on persistence of renal failure, namely, loss and end-stage kidney disease. Studies in the adult intensive care setting suggest that use of the RIFLE criteria conveys significant prognostic information, and may therefore aid in clinical decision making, especially the timing to institute renal replacement therapy. Similarly, modified criteria for pediatric patients have been proposed based on estimated creatinine clearances and urine output (*Fig. 312.1*), although there are concerns regarding the validity of estimated glomerular filtration rates when plasma creatinine is not in equilibrium as is the case in AKI.

Etiology

Causes of acute kidney insufficiency in children can be broadly classified into pre-renal, renal, and post-renal causes (*Table 312.1*).

Pre-renal vasomotor causes are potentially reversible if hypoperfusion can be corrected before tubular damage is established. Hypoperfusion may result from intravascular volume depletion as seen in blood loss, severe dehydration, or "third-spacing" in intestinal obstruction, as well as hypotension following sepsis or shock, and ineffective circulatory volume as in cardiac failure or states of severe hypoproteinemia. Failure to adequately reverse these predisposing conditions will result in hypoxic-ischemic AKI. Recognizing that various "toxins" can cause AKI is important, as there is evidence that preventive measures may be effective. These nephrotoxic compounds include intravascular radiocontrast agents, aminoglycoside antibiotics, amphotericin B, chemotherapeutic agents such as ifosfamide and cisplatin, acyclovir, acetaminophen, and calcineurin inhibitors.

Renal causes include the rapidly progressive forms of glomerulonephritis, including post-infectious glomerulonephritis, lupus nephritis, Henoch-Schönlein nephritis, membranoproliferative glomerulonephritis, anti-neutrophil cytoplasmic antibody-associated glomerulonephritis, and anti-glomerular basement membrane disease. Thrombosis of the renal vessels, especially in the critically ill neonate, may lead to AKI. Hemolytic-uremic syndrome which may follow diarrheal illnesses or pneumococcal infection is not uncommon in young children. Other renal causes include acute pyelonephritis; acute tubulointerstitial nephritis, which may be secondary to infections or drugs such as ampicillin; and tumor infiltration such as that seen in lymphoid malignancies.

In tropical countries, infections such as falciparum malaria which cause pigment injury secondary to intravascular hemolysis, and leptospirosis associated with hepatorenal failure, are important causes of AKI. Additionally, in populations where glucose-6-phosphate dehydrogenase deficiency is prevalent, drug-induced acute intravascular hemolysis may result in renal failure. Heat stroke and exercise-induced rhabdomyolysis must be considered in adolescents presenting with AKI.

Post-renal causes especially obstructive uropathies should be excluded as these are potentially reversible causes of AKI. Bladder outlet obstruction, such as that seen in posterior urethral valves in boys and neurogenic bladder, is an important cause. Ureteral obstruction of a single functioning kidney must be considered, unless

The pediatric-modified RIFLE (pRIFLE) criteria for the diagnosis of AKI. RIFLE: Risk, Injury, and Failure with the outcome classes Loss and End-stage kidney disease (Modified from Ackan-Arikan A et al., Kidney Int 10:963–964)

Table 312.1
Causes of acute kidney injury in children

Pre-renal (vasomotor nephropathy)	Renal	Post-renal
Ischemic • Hypovolemia including hemorrhage, gastrointestinal losses, burns, renal salt-wasting conditions • Hypotension • Hypoxia • Cardiac failure • Sepsis • Intestinal obstruction • Hepatorenal syndrome Toxic • Aminoglycosides • Wasp sting • Plant toxins • Snake-bite • Pigments eg hemoglobin or myoglobin • Radiocontrast agents	Glomerulonephritis (GN) • Post-infectious GN • Systemic lupus erythematosus • Henoch-Schönlein nephritis • Membranoproliferative GN • Anti-neutrophil cytoplasmic antibody-associated GN • Anti-glomerular basement membrane disease • Idiopathic rapidly progressive GN Vascular • Hemolytic-uremic syndrome • Renal artery thrombosis • Renal vein thrombosis Acute tubulointerstitial nephritis • Infections, e.g., Ebstein Barr virus and leptospirosis • Drugs including herbal preparations Acute pyelonephritis Tumor infiltration	Structural • Posterior urethral valve • Ureteric obstruction • Neurogenic bladder Crystalluria • Tumor lysis syndrome • Melamine Calculi Blood clot

obstruction occurs bilaterally. Another cause of significant obstruction in children is crystal precipitation in the renal tubules. Children with acute lymphoblastic leukemia and B-cell lymphoma are at the highest risk of AKI due to tumor lysis syndrome following chemotherapy. This results in tubular precipitation of uric acid crystals and its precursors, xanthine and hypoxanthine, as well as calcium phosphate crystals.

Epidemiology

Epidemiological data on the incidence and prevalence of AKI in children is difficult to ascertain. A retrospective review from England estimated a yearly incidence for AKI in children as 0.8 per 100,000 population. Geographic differences in the causes of AKI do exist (*Fig. 312.2*). In developing countries, primary renal diseases such as post-infectious glomerulonephritis and hemolytic-uremic syndrome are important causes of AKI. Although survival is generally better in children with primary renal disease, lack of access to medical care coupled with the poor socio-economic conditions in these countries contribute to the poor outcomes in these patients. Unfortunately the real tragedy in these areas is that AKI secondary to pre-renal causes such as gastroenteritis would have been preventable if they were able to have timely volume replacement.

Recent pediatric AKI epidemiological data for critically ill children demonstrate a shift from primary renal disease to injury secondary to other systemic illnesses and/or their treatment. With the development of pediatric intensive care in tertiary hospitals catering for specialties such as cardiac surgery, oncology, and solid organ and bone marrow transplant, a larger proportion of pediatric AKI is due to ischemic or toxic injury (*Fig. 312.2*). The mortality in this group of infants and children is higher, ranging from 33% to 78%, due to the concomitant presence of multiorgan failure. The most important predictors

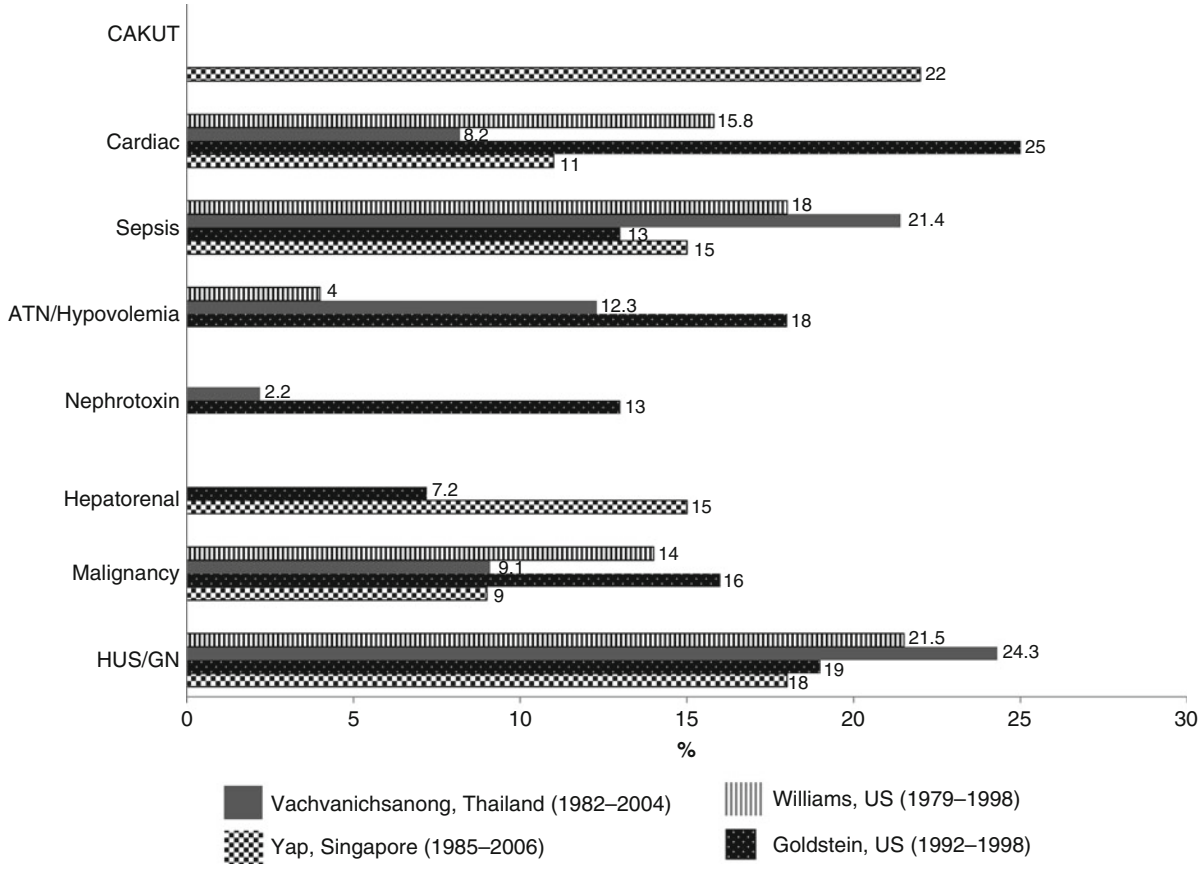

Figure 312.2
Causes of AKI worldwide. CAKUT: congenital abnormalities of the kidney and urinary tract. ATN: acute tubular necrosis

of mortality among these critically ill children include the severity of the underlying systemic illness, hemodynamic stability, and the degree of fluid overload at initiation of renal replacement therapy.

Similarly AKI affects approximately 8–24% of severely ill newborns treated in the neonatal ICU, with a mortality rate of between 10% and 61%. Data from the literature suggest that the incidence of AKI in asphyxiated newborns is high, and portends a poor outcome. Other factors associated with development of AKI in neonates include very low birth weight (less than 1,500 g), a low Apgar score, persistent arterial duct, and maternal use of antibiotics and nonsteroidal anti-inflammatory drugs.

Pathogenesis

Molitoris proposed a mechanistic classification that delineates four distinct phases in AKI: initiation, extension, maintenance, and recovery (*Fig. 312.3*). In the "initiation phase," numerous ischemic insults, alone or in synergistic combination with nephrotoxins, initiate epithelial and vascular cell injury, resulting in patchy tubular necrosis and a rapid decline in glomerular filtration rate. Hypoxic or ischemic AKI is characterized by early vasoconstriction followed by patchy tubular necrosis. Following reperfusion, loss of endothelial cell function with distorted peritubular pericapillary morphology occurs. Possible mechanisms of cellular injury include perturbation in endothelin or nitric oxide regulation of vascular tone, ATP depletion with resultant cytoskeletal alterations, changes in heat shock proteins, induction of the systemic inflammatory response, and the generation of reactive oxygen and nitrogen molecules.

The "extension phase" immediately follows the "initiation phase," where multiple interrelated events lead to a worsening of epithelial and endothelial cell injury and cell death, primarily in the cortico-medullary region. A phase of stabilization of injury known as the "maintenance phase" precedes the "recovery phase" where cellular repair, division, and redifferentiation occurs, resulting in improved epithelial and endothelial cell function and recovery of the glomerular filtration rate. Previously, it was thought that recovery from hypoxic-ischemic and nephrotoxic AKI was complete with normalization of renal function; however, recent studies have shown that recovery may be partial and patients may be at higher risk for chronic kidney disease.

This pathogenetic concept provides an important framework upon which therapy can be based. (*Fig. 312.3*). Utilizing this approach, it is easy to understand why studies that initiate therapy during the maintenance phase have proven uniformly unsuccessful. On the other hand, significant progress has been made in the prevention of ischemic AKI, especially with regards to the high-risk population, defined as children with conditions associated with hypovolemia or underlying renal disease. Finally, renal replacement therapy should be appropriately instituted in established AKI.

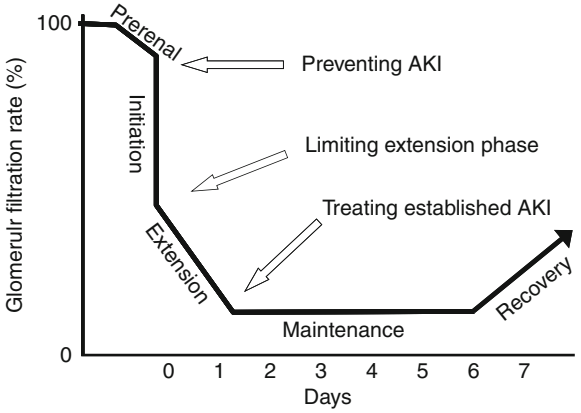

Figure 312.3
Mechanistic basis for the treatment of AKI (Modified from Molitoris J (2003) J Am Soc Nephrol 14:265–267)

Clinical Manifestations

A high index of suspicion is required to diagnose AKI. There are typically four scenarios where AKI should be considered in infants or children with oliguria.

Children Presenting with Conditions Associated with Severe Hypovolemia

Children who present with vomiting, diarrhea, and decreased oral intake are at risk of developing severe hypovolemia and AKI. On the other hand, in some conditions associated with polyuria, such as diabetic ketoacidosis, renal tubular acidosis and chronic tubulopathies, these children can develop severe hypovolemia and pre-renal AKI if their fluid intake is insufficient for any reason to keep up with the urine loss. Physical signs of hypovolemia are prominent, such as tachycardia, poor capillary refill, decreased skin turgor, dry mucous membranes, sunken eyes, and orthostatic blood pressure changes.

Children Presenting Acutely with Symptoms Suggestive of Renal Disease

Acute onset of oliguria, edema, and gross hematuria, with a preceding history of pharyngitis or impetigo, is consistent with post-infectious glomerulonephritis, where AKI requiring dialysis occurs in less than 1%. Bloody diarrhea with oliguria or anuria suggests diarrhea-associated hemolytic-uremic syndrome, whereas in children with pneumonia, development of oliguria accompanied by anemia and thrombocytopenia is indicative of pneumonia-associated hemolytic-uremic syndrome. In children with nephrotic syndrome, AKI though uncommon, should be suspected if there is severe hypovolemia with hypotension and tachycardia, accompanied by marked decrease in urine output. Systemic signs and symptoms of vasculitis, such as purpuric or malar rash, joint pain or swelling, and hemoptysis, suggest the possibility of rapidly progressive glomerulonephritis associated with systemic vasculitis.

Critically Ill Children with Predisposing Factors for Multiorgan Failure

Critically ill children with sepsis and hypotension frequently have multiorgan failure resulting in AKI with oligoanuria, especially with the use of inotropes such as noradrenaline or adrenaline. Often these children are immunosuppressed or neutropenic such as in oncology patients undergoing chemotherapy or bone marrow transplantation. A history of nephrotoxic medications is often present, including antibiotics such as aminoglycosides or amphotericin-B, chemotherapeutic agents such as cisplastin, and calcineurin inhibitors.

Newborn Infants with Oliguria or Anuria

Oliguria in the newborn beyond 72 h is worrying and should be investigated. In the absence of ischemic injury, anuria or oliguria suggests a major congenital malformation such as posterior urethral valves, or genetic disease such as autosomal recessive polycystic kidney disease. In the sick neonate with hematuria, bilateral renal vein thrombosis should be suspected.

Diagnostic Approach

The modified RIFLE criteria for pediatric patients (*Fig. 312.1*) will help in standardizing the definition of AKI so that the appropriate therapeutic decisions can be made. These criteria are based importantly on either the degree of oliguria over a timed period or a change in the estimated creatinine clearance.

Having defined the presence of AKI, the next step is to differentiate the various causes using several noninvasive methods. Early diagnosis of pre-renal and obstructive causes is important as prompt corrective measures may prevent the onset of established renal injury.

Urinary Sediment

The urinary sediment should be examined for the presence of cells, crystals, cellular debris, and casts. The presence of hematuria associated with dysmorphic red cells and red cell casts suggests a diagnosis of glomerulonephritis, while renal tubular epithelial cells, tubular cell casts, or coarsely granular pigmented casts suggest acute tubular necrosis. Pyuria may suggest pyelonephritis, although tubulointerstitial disorders may present with sterile pyuria. Moreover, the presence of eosinophils is highly suggestive of acute allergic interstitial nephritis. Crystals in the urine such as uric acid or calcium oxalate crystals may be useful indicators of the underlying etiology in the appropriate clinical setting with AKI, namely, tumor lysis syndrome and ethylene glycol poisoning, respectively. If there are scant findings on microscopy examination of the urine, this may be consistent with pre-renal or obstructive causes of AKI.

Blood and Urinary Indices to Differentiate Between Pre-renal and Established Renal Failure

Blood and urinary indices used to differentiate between pre-renal and established acute renal failure are based on the premise that the proximal renal tubular transport mechanisms are still able to respond to the hypovolemic stimulus in pre-renal failure, as compared to the failure of these transport mechanisms in acute tubular necrosis. The serum urea/creatinine ratio has been used to distinguish between pre-renal and established renal failure, in older children and adolescents with hypovolemia. This ratio is usually high in pre-renal disease due to increased urea reabsorption following enhanced proximal transport of sodium and water. A ratio greater than 20:1 for urea and creatinine measured in mg/dL or 0.10 for urea measured in mmol/L and creatinine in μmol/L is seen in pre-renal disease. Unfortunately, in conditions of increased catabolism,

gastrointestinal hemorrhage and corticosteroid administration, the ratio can be elevated. Conversely, a normal ratio can be seen in liver disease or protein malnutrition.

Urinary indices derived from measurements on simultaneous random urine and plasma specimens, in the absence of diuretic use, can help differentiate pre-renal versus established renal failure (*Table 312.2*). In hypovolemia, there is marked urinary sodium reabsorption and concentration of the urine, whereas in irreversible tubular injury, the tubules are unable to appropriately conserve sodium. As urinary sodium concentration can also be low as a result of dilution, the fractional excretion of sodium (FeNa) is a better index to take into account renal water handling. In conditions where there is relative renal hypoperfusion such as hypovolemic dehydration, nephrotic syndrome, congestive cardiac failure, or cirrhosis, the FeNa is less than 1%. In contrast, tubular damage results in FeNa ranging from 2% to 3%. As the renal tubules in newborns are relatively immature compared to older infants and children, the corresponding FeNa in newborns with hypovolemia is less than 2.5%. However, in patients given diuretics, and in salt-losing conditions, such as Bartter's syndrome, interstitial nephritis, and chronic renal disease, urinary sodium may be high, thus obviating the value of indices based on urinary sodium excretion. In these situations, the fractional excretion of urea (FeUN) has been proposed as a better index to distinguish between pre-renal failure and established tubular necrosis. The FeUN should be less than 35% in conditions of hypovolemia, whereas in acute tubular necrosis, the value is greater than 50%.

Table 312.2
Use of urinary indices to differentiate pre-renal and intrinsic renal causes of AKI

	Pre-renal cause*	Intrinsic renal cause*
Urine sodium (mmol/L)	<20 (<20)	>40 (>50)
Urine osmolality (mOsm/kg)	>500 (>400)	<350 (<400)
Urine/plasma urea	>8	<3
Urine/plasma osmolality	>1.15 (>1.2)	<1.1 (<1.2)
Urine/plasma creatinine	>40	<20
Fractional sodium excretion (FeNa)	<1 (<2.5)	>1 (>2.5)
Fractional urea excretion (FeUN)	<35%	>50%

FeNa = (urine sodium/plasma sodium) × (plasma creatinine/urine creatinine) × 100%
FeUN = (urine urea/plasma urea) × (plasma creatinine/urine creatinine) × 100%
These indices must be used with caution in premature neonates less than 32 weeks gestation, since a high urinary sodium excretion is commonly observed
*Values in parenthesis are the criteria for neonates

Other Laboratory Tests

Other laboratory tests may provide some clues as to the underlying etiology of the AKI. The complete blood count is important to look for anemia and thrombocytopenia, suggestive of hemolytic-uremic syndrome or a vasculitis-associated glomerulonephritis. The peripheral blood smear should also be done to look for schistocytes in hemolytic-uremic syndrome, or spherocytes in lupus nephritis. The urine should be tested for hemoglobin or myoglobin to exclude pigment nephropathy, if the history is suggestive of intravascular hemolysis or rhabdomyolysis. Decreased serum complement levels (C3 with or without C4), elevated anti-nuclear antibodies, anti-neutrophil cytoplasmic antibodies, and anti-glomerular basement membrane antibodies are useful to distinguish the various glomerular diseases resulting in AKI. The serum complement C3 is low at presentation in post-infectious glomerulonephritis, lupus nephritis, and membranoproliferative glomerulonephritis. Specific patterns of biochemical abnormalities may be seen in certain causes of AKI. Hypocalcemia, hyperphosphatemia, and hyperuricemia occur in tumor lysis syndrome, while in rhabdomyolysis, there is additional elevation of the serum creatine kinase levels. An increase in anion and osmolar gaps in the presence of AKI is suggestive of ethylene glycol poisoning.

Novel Biomarkers of AKI

Serum creatinine is a poor marker of early renal dysfunction, especially in AKI where the patients are not in steady state. Substantial elevation in serum creatinine is often not witnessed until 48–72 h after the initial insult to the kidney. The tools of modern science have provided promising novel plasma and urinary biomarkers for AKI, with potentially high sensitivity and specificity. These include a plasma panel comprising neutrophil gelatinase-associated lipocalin (NGAL) and cystatin C, and a urine panel comprising NGAL, interleukin-18 (IL-18), and kidney injury molecule-1 (KIM-1).

Cystatin C is a cysteine protease inhibitor that is produced at a constant rate, freely filtered by the kidneys, and

is almost completely reabsorbed by the proximal renal tubular cells. Prospective studies have shown that an increase in cystatin C levels occurred 1½ days before AKI developed.

Circulating NGAL is normally reabsorbed in the proximal tubule. Following kidney injury, NGAL is secreted in the thick ascending limb of the loop of Henle, and is found in the urine, and the NGAL protein is detected in the blood and urine very early in the course of AKI. In a prospective study of children undergoing cardiopulmonary bypass, plasma and urinary NGAL levels were elevated within 2–6 h of surgery, and was able to predict the development of AKI, compared to serum creatinine levels which rose by at least 50% only 1–3 days after surgery. However, NGAL is also increased in infections, inflammatory conditions, and malignancies, and thus may have limited value in predicting AKI in these clinical situations.

Urinary IL-18 is a pro-inflammatory cytokine that is induced and cleaved in the proximal tubule. It is detected in the urine following ischemic AKI, but not in chronic kidney disease, urinary tract infections, nephrotic syndrome, or pre-renal failure. In the intensive care setting, urine IL-18 measurements were able to predict AKI about 2 days prior to the rise in serum creatinine, and was an independent predictor of mortality in these critically ill children with AKI.

KIM-1 is a type 1 transmembrane protein that is not detectable in normal kidney tissue or urine, but is expressed at very high levels in dedifferentiated proximal tubule epithelial cells in human kidneys after ischemic or toxic injury. Earlier studies have shown that KIM-1 measurement was able to distinguish between ischemic AKI from pre-renal azotemia and chronic kidney disease. More recently, urinary KIM-1 levels were shown to be predictive of AKI in children undergoing cardiopulmonary bypass. In fact, urinary KIM-1 performed best as an early marker of AKI compared to other urinary biomarkers such as N-acetyl-beta-D-glucosaminidase (NAG), NGAL, IL-18, cystatin C, and alpha-1 microglobulin. However, urinary KIM-1 measurements may be also induced in a variety of chronic proteinuric, inflammatory, and fibrotic disease states, as well as upregulated by nephrotoxins, including cyclosporine, cisplatin, and gentamicin, thus limiting its value in predicting AKI in the presence of these confounding factors.

Imaging

Imaging of the urinary tract is important in the diagnostic workup of children with AKI, as it is crucial for the exclusion of obstructive uropathies. In addition, assessment of kidney size is a useful indicator of the chronicity of the renal failure. Enlarged kidneys standardized to patient's age and size is suggestive of AKI, whereas small contracted kidneys suggest chronic renal failure. These imaging modalities include ultrasonography, CT urogram, radionuclide imaging, magnetic resonance imaging, and, occasionally, plain film of the abdomen.

Ultrasonography should be the initial imaging modality in the diagnostic workup of children with AKI to detect bilateral upper tract obstruction, bladder outlet obstruction, or obstruction of a solitary functioning kidney. Dilatation of the pelvicalyceal system can be detected within 24–36 h of the onset of acute urinary obstruction. It is important to realize that dilatation of the upper tract may not be seen in the acute stage of ureteral obstruction if this is accompanied by a decrease in urine output. In lower tract obstruction, ureteral dilatation, bladder size, and wall hypertrophy, as well as the presence of associated lesions such as ureterocele can be identified by ultrasonography. An increase in echogenicity is seen in both acute and chronic kidney disease. In neonates with renal vein thrombosis, Doppler flow scanning will be able to demonstrate decreased blood flow.

Radionuclide imaging using ^{99m}Tc mercaptoacetyltriglycine (MAG3) or ^{131}I-iodohippurate is used to assess blood flow and the severity of functional obstruction. Noncontrast CT scans are able to demonstrate the renal pelvis and proximal ureter, and may be helpful in identifying sites of ureteral obstruction, stones, tumors, or congenital abnormalities. Contrast-enhanced scans will add functional information of the individual kidney; however, this should be avoided in AKI due to the risk of contrast nephropathy. Magnetic resonance urogram, both static and gadolinium enhanced, is a useful study to identify collecting system morphology in obstructive uropathies, regardless of excretory fuction. Unfortunately, infants and young children require sedation for this study. Moreover, the risk of nephrogenic systemic fibrosis following gadolinium-based contrast agents in patients with renal failure limits the use of the dynamic scan in AKI.

Renal Biopsy

Renal biopsy should be considered if there is clinical suspicion of a rapidly progressive form of glomerulonephritis or acute allergic interstitial nephritis. A definitive histological diagnosis in these instances will be important as immunosuppressive therapy can alter the outcome of the disease.

Clinical Management

Medical Management

The main aim in managing AKI is to maintain homeostasis, while awaiting improvement in renal function, either spontaneously or while the underlying cause is being treated. Because of the availability and efficacy of dialysis, patients with AKI often succumb not due to AKI, but to other comorbidities. The main goals in medical management are therefore to maintain adequate renal perfusion, prevent fluid overload and hypertension, maintain normal electrolytes and acid-base status, and ensure adequate nutrition.

Maintaining Adequate Renal Perfusion

In severely ill patients who are at risk of ischemic AKI, correction of pre-renal factors such as dehydration, poor cardiac output, hypovolemia, and acid-base and electrolyte abnormalities is important to prevent development of AKI (*Fig. 312.4*). Unless contraindicated due to fluid overload or cardiac failure, a child with clinical evidence of hypovolemia and oliguria should be administered an intravenous fluid challenge over 20–30 min, with either crystalloid solutions such as normal saline (10–20 mL/kg) or colloid solutions such as 5% albumin if hypotensive. This can be repeated if the child is still hypovolemic. Restoration of adequate urine flow and improvement in renal function with fluid resuscitation is consistent with pre-renal disease. However, if urine output does not increase and renal function fails to improve with restoration of intravascular volume, invasive monitoring may be required to adequately assess the child's fluid status and help guide further therapy.

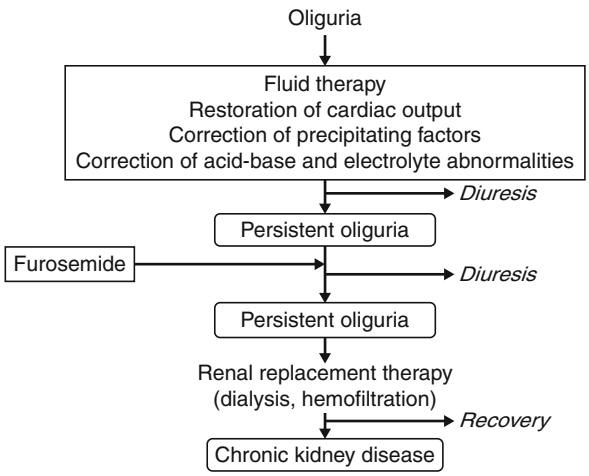

Figure 312.4
Algorithm for intervention in vasomotor nephropathy

If oliguria persists despite adequate correction of pre-renal factors, a trial of loop diuretics such as furosemide (2–5 mg/kg) may be attempted to promote diuresis, converting the child from oliguric to non-oliguric renal failure, thus facilitating fluid balance without the need for dialysis. Low dose dopamine infusion (1–5 mcg/kg per hour) is thought to promote renal vasodilatation, however, the evidence that this has a beneficial effect in limiting or preventing established AKI is lacking. Fenoldopam, a potent, short-acting, selective, dopamine-1 receptor agonist that decreases vascular resistance while increasing renal blood flow, has been shown in a meta-analysis to decrease the incidence of AKI and the need for renal replacement therapy in critically ill adults. Although there are some good results with its use in children, additional studies need to be performed to determine its value. On the other hand, use of vasoactive agents in hypotensive patients to maintain adequate blood pressure may improve renal perfusion.

Preventing Fluid Overload and Hypertension

In general, infants and children with AKI are not severely uremic, but their major problem is fluid overload following oliguria or anuria. Fluid overload is potentially fatal in AKI due to pulmonary edema, and the first line of treatment in these oliguric or anuric patients is fluid restriction and intravenous diuretics. Fluid volume should be restricted to insensible water loss calculated at 400 mL/m^2 per day, in addition to replacing urine, gastrointestinal, and other losses. Therapy should be aimed at decreasing the body weight by 0.5–1% daily.

Fluid overload may aggravate hypertension in patients with glomerulonephritis, resulting in hypertensive urgencies or emergencies. These children are symptomatic with complaints of nausea, headache, and blurred vision. Uncontrolled hypertension often leads to acute end-organ injury such as posterior reversible encephalopathy syndrome with altered mental state and seizures, cerebral infarction, cerebral hemorrhage, left heart failure, and grade III–IV retinopathy with exudates, hemorrhage, and papilledema. It is important to treat these hypertensive emergencies with intravenous antihypertensive agents that can produce a controlled reduction of blood pressure in order to avoid worsening of the cerebral edema due to disruption of cerebral autoregulation.

Maintaining Normal Electrolytes and Acid-Base Status

The common electrolyte disorders in AKI are hyperkalemia, hyponatraemia, hypocalcemia, and hyperphosphatemia. Hyperkalemic emergencies, where serum potassium levels are greater than 7 mmol/L accompanied by electrocardiographic changes such as peaked T waves, flattened P waves, increased PR interval, and widening of the QRS complex, can be managed with intravenous calcium (0.5 mL/kg up to a maximum of 20 mg given slowly over 15 min) to stabilize the cardiac membrane, followed by nebulized (2.5 mg for body weight less than 25 kg or 5 mg for body weight 25 kg or more) or intravenous salbutamol (4 mg/kg) or intravenous insulin (1 IU/5 g dextrose) and dextrose (0.5 g/kg) to temporarily lower the serum potassium levels, prior to dialysis. Less urgent elevations of serum potassium (6–7 mmol/L) can be managed with oral or rectal kayexylate (1 g/kg to a maximum of 30 g) or other ion exchangers, and correction of concomitant acidosis. Hyponatraemia due to fluid overload can be corrected with fluid restriction and loop diuretics. If there is renal salt wasting, then sodium supplementation may be necessary. Hypocalcemia and hyperphosphatemia can be managed with calcium-based phosphate binders. Severe metabolic acidosis where serum bicarbonate is less than 15 mmol/L or pH less than 7.2 may be corrected with oral sodium citrate or intravenous sodium bicarbonate. The latter has the adverse effect of hypernatremia, and exacerbating fluid overload, necessitating dialysis.

Ensuring Adequate Nutrition

Ensuring adequate nutrition is often a real challenge in the critically ill patient. Energy balance studies on patients with AKI have demonstrated that cumulative energy deficits are associated with increased mortality. In infants and children with AKI, given their limited reserves, these nutritional issues will be further amplified. Because of the necessity for fluid restriction, increasing the concentration of the enteral feeds or parenteral hyperalimentation will improve caloric delivery. However, this is often limited by the consequent increase in osmolarity of the feeds. Early institution of dialysis will allow better optimization of nutrition in these patients.

Acute Renal Replacement Therapy

The traditional indications for renal replacement therapy in AKI include severe hyperkalemia unresponsive to conservative therapy, uncontrolled acidosis that cannot be safely corrected because of risk of sodium or volume overload, severe volume overload with uncontrolled hypertension, pulmonary edema or cardiac failure, progressive uremia with deterioration in the general condition, and hypercatabolic states with increase in blood urea by greater than 10 mmol/L per day.

The critically ill child is often on a downward spiral, with sepsis, shock, acute respiratory distress syndrome, often leading to multiorgan failure which forms the final common pathway of lethal infective and non-infective complications. In this setting, where there is hypotension, effective hypovolemia, hypoxemia, hypercapnia, and hypothermia, coupled with the use of a multitude of vasoactive and nephrotoxic drugs, AKI is inevitable. This is often associated with a poor outcome. In general, these children may not be severely uremic, but their major problem is fluid overload and electrolyte perturbations especially acidosis, hyponatremia, and hyperkalemia. Conservative management with severe fluid restriction is not the answer, as this has its attendant problems of inadequate nutrition, propensity to hypoglycemia, insufficient volume space for blood products, and difficulty in drug delivery, such as inotropic support and antibiotic infusions. Therefore, early institution of dialysis is important in these critically ill children with AKI to maintain homeostasis and create enough volume space so that the nutritional and therapeutic needs may be met.

There are various strategies for the dialytic treatment of children with AKI, including peritoneal dialysis (PD), intermittent hemodialysis (HD), and continuous renal replacement therapy (CRRT). Choice of dialysis modality is largely influenced by the age and size of the child or infant, clinical presentation, presence or absence of multiorgan system failure, indication for renal replacement therapy, experience of the center, and the available resources (*Table 312.3*).

Acute Peritoneal Dialysis

Acute PD is still the modality of choice in many countries, especially in the developing world. It is a relatively cheap form of dialysis, and does not require sophisticated equipment or complicated technical expertise. Acute PD is associated with less hemodynamic instability, and has the advantage of avoiding the need for vascular access and blood priming. It can be done in very young infants, and does not require anticoagulation in the child with disseminated intravascular coagulopathy.

Table 312.3
Comparison of different dialytic modalities in AKI

Variable	PD	HD	CRRT
Continuous therapy	Yes	No	Yes
Hemodynamic stability	Yes	No	Yes
Fluid balance achieved	Variable	Yes (intermittent)	Yes
Optimal nutrition	No	No	Yes
Metabolic control	Yes	Yes (intermittent)	Yes
Easy to perform	Yes	No	No
Anticoagulation	Not required	Heparin anticoagulation or heparin free	Heparin or citrate anticoagulation
Vascular access required	No	Yes	Yes

Although PD has certain advantages over filter dependent procedures, there are several problems that make PD difficult especially in the small infant. Catheter problems are common such as leakage into the subcutaneous tissue and hernia sites, especially inguinal. Drainage is frequently a problem because of catheter malposition, kinking, omental wrapping, and fibrin clot. In young infants, it is often not possible to increase the dwell to the desired volume due to splinting of the diaphragm in the critically ill infants with acute respiratory distress syndrome. The slow and relatively inefficient removal of all types of molecules, as well as unreliable ultrafiltration, represents a considerable drawback compared to other modalities of acute dialysis, especially in patients with hypotension and poor peritoneal perfusion. Hence, acute PD may not provide adequate clearances in the hypercatabolic patient with severe hyperkalemia and hyperphosphatemia. Moreover, acute PD is contraindicated in patients with recent abdominal surgery, necrotizing enterocolitis, and presence of ventriculo-peritoneal shunts. Therefore acute PD is currently best for "uncomplicated" or medical causes of AKI.

Intermittent Hemodialysis

Intermittent HD is still the mainstay of dialysis for AKI in older children and is performed in adult centers in many countries. Its main advantage is the rapid removal of uremic toxins and fluid volume. Therefore it is indicated in the emergency treatment of hyperkalemia, lactic acidosis and myoglobinuria. However, HD in young children is notoriously difficult in view of the smaller blood volumes. This is especially accentuated in the critically ill child, where inotropes are usually required to support the systemic blood pressure. Moreover, these children often have acute respiratory distress syndrome, and are hypoxemic, resulting in hemodynamic instability during intermittent HD. Rapid HD may also result in dialysis dysequilibrium. In view of the difficulties of HD in the critically ill pediatric patient, this dialytic modality is generally limited to children with "uncomplicated" AKI.

Continuous Renal Replacement Therapy (CRRT)

This decade has seen much enthusiasm for the use of CRRT for the critically ill child. CRRT encompasses a wide range of strategies, which include slow continuous ultrafiltration, continuous venovenous hemofiltration, continuous venovenous hemodialysis, to a combination of continuous venovenous hemodiafiltration. There are many advantages of continuous modalities of dialysis in the critically ill patient. Despite removal of large volumes of fluid by ultrafiltration, the critically ill patient on CRRT remains hemodynamically stable. In a large randomized controlled trial comparing CRRT with intermittent HD in critically ill patients, CRRT resulted in more efficacious solute clearances. Studies have also shown that inflammatory mediators, cytokines, and toxins may be removed by continuous hemofiltration in patients with sepsis, not only by adsorption to certain hemofilter membranes, but also through the ultrafiltrate, providing a rationale for the use of high volume ultrafiltration.

Some of the disadvantages of CRRT include bleeding complications following the use of heparin. Citrate anticoagulation is now widely used to circumvent this problem. Other problems include temperature instability, requiring warming of either the dialysate or blood

returning to the patient. Small molecular sized nutrients such as oligosaccharides, peptides, and amino acids, and electrolytes such as phosphate and magnesium can be lost through the hemofilter, and therefore need to be replaced. The bradykinin release syndrome is an important complication seen specifically with the commonly used polyacrylonitrile (AN69) membranes. Blood contact with the AN69 membrane results in generation of bradykinin, especially in the presence of acidosis. Hence priming of the dialysis lines with banked blood should be avoided.

Prognosis

The prognosis of AKI is highly dependent on the underlying etiology. Mortality is high in critically ill children with multiorgan failure. Recovery from intrinsic renal disease is also highly dependent on the underlying etiology. Children with nephrotoxic AKI and hypoxic/ischemic AKI usually recover normal renal function; however, those who have suffered substantial nephron loss, such as in hemolytic-uremic syndrome or rapidly progressive glomerulonephritis, may progress to chronic kidney disease. Therefore these children need to be followed up in the long-term for blood pressure monitoring and development of proteinuria.

313 Chronic Kidney Disease (CKD)

Lesley Rees

Definition

Chronic kidney disease (CKD) means any abnormality of the renal parenchyma that will not recover. A progressive decline in kidney function may occur, but only if both kidneys are abnormal.

Classification

Staging of CKD

CKD is divided into stages according to its severity (*Table 313.1*). As renal function declines, uremia, electrolyte disturbances and anemia become more common, and lead to uremic complications such as lethargy and poor appetite, sodium retention and hypertension, acidosis, bone disease and vascular calcification. By CKD stage 5, renal replacement therapy (RRT) may become necessary, but some children who maintain good urine output may manage without for many years with a glomerular filtration rate (GFR) as low as this. Renal function may remain stable or even show some improvement in infancy and early childhood. Decline in renal function occurs thereafter, particularly, in the peripubertal years.

Etiology

The commonest cause of CKD in childhood is renal dysplasia, representing up to 70% of cases. Renal dysplasia is due to abnormal renal development, either because of intra uterine obstruction or in association with vesicoureteric reflux, syndromes, genetic defects such as branchio-oto-renal syndrome or renal coloboma syndrome, or causes as yet undefined. In boys, most cases are due to a posterior urethral valve. Abnormal urinary tract drainage will predispose to urinary tract infection (UTI), which can cause further renal damage.

Renal cystic diseases are the second commonest cause. Autosomal recessive polycystic kidney disease (ARPKD) is often diagnosed antenatally or is recognized in infancy when palpable kidneys, hepatosplenomegaly and hypertension are found. Autosomal dominant PKD (ADPKD) rarely causes problems in childhood, unless there is disruption of TSC2 and the adjacent PKD1 gene (contiguous gene syndrome), as in 2% of patients with tuberose sclerosis. Patients with Bardet–Biedel Syndrome may have cystic kidney disease and there may be (but not always) cysts with nephronophthisis. Nephronophthisis may occur in isolation or in association with retinitis pigmentosa (Senior-Loken Syndrome). Glomerulocystic disease is becoming a more frequent diagnosis with the identification of the renal cysts and diabetes syndrome due to HNF1β gene mutations.

The next commonest causes are the nephrotic syndromes (NS), including congenital NS, which presents in infancy, and focal segmental glomerulosclerosis (FSGS). FSGS is a unifying term used to describe steroid resistant NS with a particular histological appearance that is due to different genetic abnormalities. Another NS, membranoproliferative glomerulonephritis, is a less common cause of CKD.

Other causes include renal vascular events (particularly neonatal arterial and venous thromboses), atypical Hemolytic Uremic Syndrome (HUS), renal stone diseases, subsequent to acute kidney injury (AKI) due to any cause (including rapidly progressive glomerulonephritis, HUS, dehydration with cortical necrosis), hereditary nephropathies, systemic diseases such as SLE and the vasculitides, renal diseases that occur in association with syndromes, and in some patients the cause is not known. As time goes by, more and more genes that cause CKD are being identified.

Epidemiology

Although the identification of CKD in children has improved due to antenatal screening programs, the true incidence is unknown and may be higher than suspected. Studies suggest an annual acceptance rate for new pediatric patients with a GFR < 75 ml/min.1.73 m^2 of around 12 cases per million child population. It is easier to be more precise about the incidence of children needing to enter RRT programs because such data are collected by national registries, being 9 per million child population per year in the UK, 10 in Australia and New Zealand, and 15 in the USA.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_313,

Table 313.1
Staging of CKD

Stage	GFR ml/min/1.73 m^2	Features
1	>90	Renal parenchymal disease present
2	60–90	Usually no symptoms but may develop biochemical abnormalities at the lower end of the GFR range
3	30–60	Biochemical abnormalities and anemia and in addition may develop poor growth and appetite
4	15–30	Symptoms more severe
5	<15	Renal replacement therapy may be required

Pathogenesis

Although the etiologies of CKD are multiple, progressive destruction of renal tissue occurs through a common pathway regardless of the cause. Intrarenal pathology leads to abnormal hemodynamics, chronic hypoxia, inflammation, cellular dysfunction and the activation of fibrogenic biochemical pathways. The end result is the replacement of normal structures with extracellular matrix, culminating in fibrosis.

Clinical Manifestations

Presentation of CKD: Symptoms and Signs

The commonest way for CKD to present is during antenatal scanning. Around 50% of children are diagnosed antenatally; some can be missed if there has not been a third trimester ultrasound scan. The next commonest way is with a complicating episode of AKI, which can be precipitated by infection or dehydration. Children may also present with nonspecific symptoms, such as anorexia and lethargy, which may be severe enough to cause failure to grow normally. Diseases that predominantly affect the renal tubular concentrating mechanisms, such as juvenile nephronophthisis or renal dysplasia, may present with polydipsia and polyuria. Less commonly, children may present with hypertension or with an incidental finding of proteinuria, or to orthopedic surgeons with bony abnormalities such as knock knees or bow legs. They may be detected by screening because of another affected family member.

Case No 1

A male infant was diagnosed antenatally with one bright kidney and one hydronephrotic kidney with oligohydramnios. He was delivered prematurely due to the spontaneous onset of labor and developed respiratory distress and a pneumothorax. Subsequent imaging showed a posterior urethral valve, which was ablated urethrally. He had bilateral renal dysplasia. His renal function progressively declined throughout childhood and declined rapidly during puberty, so that he needed a renal transplant at the age of 16.

Diagnosis

Investigations

Assessment of Renal Function

The easiest way to assess renal function on a day-to-day basis is to use the plasma creatinine. Creatinine is produced at a constant rate from the breakdown of creatine phosphate from muscle and is excreted by filtration without reabsorption; therefore, it is a good representation of renal function. There are pitfalls in the interpretation of the plasma creatinine: first, plasma levels do not rise until renal function has halved; second, as creatinine levels increase progressively with muscle bulk and, therefore growth, the level has to be interpreted according to age; third, levels will be lower than expected in a child who is malnourished. This means that formulae used to calculate the GFR may give results that are higher than the true result. One such formula is shown below:

$$\text{GFR} = \frac{40 \times \text{height (cm)}}{\text{creatinine } (\mu\text{mol/l})}$$

GFR can be more accurately assessed by measuring the rate of disappearance from the plasma of a substance that is freely filtered by the glomerulus but not reabsorbed by the tubules, but in practice this is rarely needed. It can also be calculated by measuring the clearance of creatinine, but as a timed urine collection is needed for this, it is not often undertaken in childhood.

Investigation of the Cause of CKD; Differential Diagnosis

The History and Examination

It is always important to find out the results of antenatal scans, amniotic fluid status (as this represents fetal urine

production), and the neonatal and family history. The physical examination should include a general examination, but should focus on growth, the BP, and look for evidence of bone disease.

Investigations

There are two investigations that are crucial for the diagnosis of the cause of CKD: ultrasound (US) and urine stick testing for protein. The appearances of the kidneys (i.e., renal sizes, the presence of cysts, and evidence of obstruction or calculi) on US (*Table 313.2*) will then guide further more selective investigations. Additional imaging may be necessary if a structural or cystic lesion or calculi are the cause and will depend on the US appearances.

Urine stick testing can also be very helpful: heavy proteinuria suggests a nephrotic syndrome; proteinuria and hematuria suggest a glomerulonephritis or familial nephropathy; and no proteinuria may be present with cystic diseases and dysplasias. However, proteinuria may result from any cause due to hyperfiltration, when reduced nephron number leads to increased glomerular pressure within the remaining glomeruli. Proteinuria may be tubular in cases of tubulopathy, when urinary retinol binding protein and N-acetyl glucosaminidase levels will be raised.

Complement levels, anti-DNA antibodies, anti-neutrophil cytoplasmic antibodies and IgA levels should be measured if glomerulonephritis is suspected; plasma and urine calcium, oxalate and purines if calculi; and urine pH and white cell cystine if a tubulopathy is suspected. Genetic analysis may be available for some conditions. Renal biopsy may be necessary if the cause of CKD remains unclear.

Case No 2

A 12 year old boy presented with a 3 month history of bone pain, loss of appetite, lethargy, and vomiting. He had a long history of polydipsia and polyuria. His younger brother was taller than him. On examination he was on the second centile for height, he was pale, his BP was normal, and there were no other abnormalities. Investigations showed his hemoglobin to be 8 gm/dl, creatinine 1,200 mcmol/l, potassium normal, calcium low, and phosphate high. He had no proteinuria. His kidneys were normal sized and bright with poor cortico-medullary differentiation and some small cysts at the corticomedullary junction. Nephronophthisis was suspected and this was confirmed by DNA analysis for the presence of the commonest gene for this condition, which has been designated NPHP1, rendering renal biopsy unnecessary.

Measurements to be Made at Each Clinic Visit

Height and weight, and head circumference in young children and pubertal stage in older ones, should be plotted on a growth chart and BP checked at each clinic visit. Early morning urine should be tested for albumin to creatinine ratio. Routine blood tests include a full blood count, urea, electrolytes, bicarbonate, creatinine, calcium,

Table 313.2
Appearance of kidneys on renal ultrasound

Cystic	Small	Normal sized	Obstruction	Calculi
Dysplasia	Dysplasia ± vesico-ureteric reflux	Glomerulo-nephritides	Dysplasia with posterior urethral valves	Recurrent UTIs ± obstruction/reflux
Autosomal recessive polycystic kidney disease	Vascular insults (venous or arterial)	Familial nephropathies	Dysplasia with VUJ obstruction	Calcium disorders
Autosomal dominant polycystic kidney disease	All causes may result in small kidneys by Stage 5 CKD	Nephrotic syndromes	Dysplasia with PUJ obstruction	Hyperoxaluria
Tuberose Sclerosis		Nephronophthisis (may be cystic)	Neuropathic bladder	Purine disorders
Glomerulocystic diseases		Tubulopathies		Cystine

phosphate, alkaline phosphatase, intact PTH, and albumin. Fasting HDL and LDL cholesterol and triglycerides and iron status may be checked less often.

One very important aspect of the management of the child with CKD is care of the blood vessels. The use of antecubital veins should be avoided when possible as they will be needed in the future for fistula formation. Similarly damage resulting in stenosis of the subclavian veins would preclude creation of a fistula in that arm.

Treatment

Prevention of Progression of CKD

The first aim of management of CKD is to reduce its progression as far as is possible. Progression can be attenuated by the maintenance of the BP within the normal range for age and height, and by the use of an ACE inhibitor (e.g., ramipril) ± an AT1 receptor blocker (e.g., losartan) to dilate the glomerular afferent arteriole, reduce intraglomerular pressure and, therefore, reduce proteinuria, which is thought to contribute to the development of fibrosis. Dyslipidemia may play a role in the progression of CKD. Increased LDL cholesterol is a particular problem for children with nephrotic syndrome. Hypertriglyceridemia and abnormal apolipoprotein metabolism is a feature of CKD. Dietary intervention may be necessary, and some children (particularly those with nephrotic syndrome) may need lipid lowering agents.

Growth, Nutrition, and Electrolytes

Growth retardation occurs in up to 50% of children with CKD stages 3–5. Children with congenital nephropathies are particularly severely affected. This is because growth in the first 2 years of life is as high as 25 cm/year at birth, falling to 18 cm/year at 1 year and 10 cm/year at the age of 2, by which time half of the final adult height has been achieved. It is, therefore, possible to lose considerable height potential at that age, which can be as much as 2SD in the first 6 months of life in infants with severe CKD. The calorie and protein requirement is extremely high during this period of rapid growth, and an adequate nutritional intake can be very difficult to maintain. After this age, when the role of growth hormone (GH) becomes more important, the rate of growth can be normal. Growth may also be adversely affected at the time of puberty, which may be delayed, with an attenuated pubertal growth spurt. Growth retardation increases with the severity of CKD. However, it has to be remembered that there are children with CKD who have associated syndromes that in themselves affect growth. Successful renal transplantation can normalize growth in some children, but may be counteracted by corticosteroid therapy used as immunosuppression and poor transplant function.

There are many different causes for poor nutritional intake: CKD is characterized by a predisposition to anorexia and vomiting. Poor appetite may be due to abnormal taste sensation, the requirement for multiple medications, the preference for water in the polyuric child, and elevated circulating cytokines such as leptin, TNF-α and IL-1 and -6, which act through the hypothalamus to affect appetite and satiety. Vomiting may result from gastroesophageal reflux and delayed gastric emptying in association with increased polypeptide hormones, and may be so profound that as much as one third of feed can be lost. Other factors that contribute to insufficient nutrition include episodes of fasting surrounding surgical procedures and episodes of sepsis, which may have a significant effect on growth, principally in the infant. Importantly, many children with severe CKD have associated co-morbidities that influence feeding and growth in their own right.

The child on dialysis has even more issues that affect their nutritional intake. They are likely to be on a fluid restriction, appetite may be affected by the presence of a full abdomen and constipation in patients on peritoneal dialysis (PD), and there may be considerable losses of protein in the dialysate in PD and amino-acids in hemodialysis (HD).

Ensuring adequate nutrition is one of the most important aspects of care of the child with CKD. As well as its obvious importance in promoting adequate growth, nutritional manipulation can control symptoms and prevent complications, particularly uremia and bone disease, such that it is possible to delay the need for dialysis.

Case No 3

A boy was referred at age 2 with prune belly and CKD stage 5 (creatinine 400 mcmol/l). He was lethargic and refusing food and was on the second centile for height. A gastrostomy was placed and provision of adequate calories and protein allowed catch-up growth to the 25th centile. He continued to grow along that centile and symptomatically improved. Dialysis was not needed until nearly 6 years of age despite a creatinine in the high 500s mcmol/l.

The type of diet recommended depends on the cause and severity of CKD and mode of RRT. If dietary intake

is inadequate, the first thing is to try an oral dietary supplement in addition to a normal diet. There are various types of supplements, with different ratios of calories and protein. In the young child with vomiting it is possible to increase the feed concentration and, therefore, decrease the feed volume. However, the rate-limiting step for this is that vomiting may worsen and diarrhea can occur with increasing feed density. Medications such as prokinetic agents (domperidone), H2-receptor antagonists (ranitidine), proton pump inhibitors (lansoprazole), and 5HT3 receptor antagonists (ondansetron) may be of benefit. The stress on the family of trying to feed an anorexic child cannot be overestimated, and this, along with a declining rate of growth, can only be resolved by the use of enteral feeding.

A nasogastric tube is acceptable for a short time, and is the method of choice in the infant weighing <4 kg, but most families prefer the placement of a gastrostomy as it is hidden under clothing. Enteral feeding via any route, but particularly gastrostomy, is associated with decreased vomiting and improved appetite, nutrition, and growth. The tube has the additional benefit of its potential use in the administration of medications, and the large fluid volumes that may be prescribed post transplant.

Overall, calorie and protein allowances should be the same as for the normal child. However, as CKD progresses it may become necessary to ensure that the protein intake is not above requirements, aiming to keep the serum albumin in the normal range with a plasma urea below 20 mmol/l. Above this level of urea, nausea, lethargy, itching, and worsening anemia may occur. The child on PD absorbs up to 12 kcal/kg/day from the dialysate, but may lose protein in the dialysate effluent. The child on HD may lose amino acids in the same way. Supplements of protein of up to 50% of the dietary requirements may, therefore, be needed in very young children on PD, who have the highest protein losses.

Structural renal diseases have a predominant effect on the renal tubule, so that reabsorption of sodium bicarbonate and water from the glomerular filtrate is inadequate. Therefore, these children are often polyuric and polydipsic, and need salt and bicarbonate supplementation and free access to water. However, children with CKD due to predominantly glomerular disease may retain salt and develop hypertension. Such children should be managed with a salt restricted diet and medications as necessary. A low potassium diet is usually only necessary at CKD stage 5.

Recombinant human growth hormone is effective in some children with CKD, and can be considered when growth has failed to respond to correction of inadequate diet and biochemical abnormalities and optimization of dialysis, and, for children on steroid therapy, when the dose of steroids has been reduced to the lowest possible.

Anemia

The anemia of CKD is normochromic and normocytic, with a low reticulocyte count. It is important to exclude iron, vitamin B12, or folate deficiency, which may play a role due to the anorexia of CKD. However, when the GFR falls below 35 ml/min/1.73 m^2, decreased production of erythropoietin is common and responds well to subcutaneous injection of this hormone, which can usually be administered weekly or even less often with some newer erythropoietin preparations. Uremia itself may cause decreased red cell survival and bone marrow inhibition. Bone marrow fibrosis occurs with severe hyperparathyroidism (osteitis fibrosa). Blood loss occurs during HD and the anticoagulation required during the HD process can result in chronic blood loss from the gastro-intestinal tract.

Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD)

Effects of CKD on Mineral Metabolism

CKD leads to abnormal calcium, phosphate, parathyroid hormone (PTH), and vitamin D metabolism resulting not only in disordered bone turnover, mineralization and growth, but also cardiovascular and soft tissue calcification. For this reason, the term CKD-MBD is now used to encompass all these abnormalities, and the term renal osteodystrophy should be reserved for the bony abnormalities that are seen on histology.

Calcium absorption and, therefore, plasma calcium levels are usually low in untreated CKD. Calcium absorption is under the control of vitamin D, levels of which are also usually low in CKD. This is for two reasons. First, there is deficiency of the substrate 25(OH)D due to poor appetite and protein and dairy food restriction, reduced production in the skin due to reduced outdoor activity and, therefore, sunlight exposure, and loss of vitamin D binding protein in the urine. Second, there is decreased 1α hydroxylation in the kidney of 25(OH)D to the active form of vitamin D, 1,25-dihydroxyvitamin D ($1,25(OH)_2D$). Another contributory factor is that dietary calcium is reduced for similar reasons to vitamin D.

Conversely, it would be expected that phosphate levels would be high, due to decreased renal phosphate excretion. Although this is the case as CKD progresses, in early

CKD normophosphatemia is maintained. This is because the high phosphate load stimulates the production of fibroblast growth factor 23 (FGF23), a phosphaturic hormone produced by the osteocyte. FGF23 induces a negative phosphate balance in two ways: it decreases renal tubular phosphate reabsorption, and decreases the production of 1,25 $(OH)_2D$; 1,25$(OH)_2D$ increases gut phosphate absorption as well as calcium.

As CKD progresses, FGF23 is no longer able to prevent hyperphosphatemia, so phosphate levels rise. This, along with low plasma calcium and 1,25$(OH)_2D$ levels, stimulate PTH secretion through the calcium sensing receptors and vitamin D receptors in the parathyroid gland. All the actions of PTH are to restore the plasma calcium to normal. It effects this by mobilizing calcium from bone, increasing tubular reabsorption of calcium, increasing hydroxylation of 25(OH)D, thereby promoting gut absorption of calcium and decreasing tubular reabsorption of phosphate.

The Role of PTH in CKD-MBD

PTH is thought to be the main player in the evolution of CKD-MBD: persistent stimulation of the parathyroid glands leads to hypertrophy, progressing to nodular hyperplasia, and culminating in the need for parathyroidectomy. The logic, therefore, has to be that prevention of the process starting must be beneficial.

PTH and Renal Osteodystrophy

The effect of PTH on the skeleton is to increase the activity of osteoclasts and osteoblasts such that high PTH levels cause high turnover (osteitis fibrosa), and low levels low turnover (adynamic) bone disease. Both types lead to bone pain, fractures, and growth problems. They can also lead to cardiovascular and soft tissue calcification because of hypercalcemia and hyperphosphatemia: in high turnover bone disease, calcium and phosphate are removed from bone into the circulation, and in low turnover, bone is unable to buffer changes in plasma calcium and phosphate.

Aims of Management of CKD-MBD

The aim of management of CKD-MBD is to maintain normal bone turnover and, therefore, prevent symptoms of bone pain and fractures, allow normal growth and prevent vascular disease and soft tissue calcification. It is important to intervene early in the course of CKD to prevent escape of the parathyroid glands from normal control mechanisms.

Phosphate Control

Plasma phosphate levels fall progressively from birth to the age of 3 and then remain stable. Maintenance of a normal age-related plasma phosphate is crucial to the prevention of hyperparathyroidism. Dietary phosphate is principally in protein containing foods, and dairy products in particular, and these foods should be restricted if the phosphate is above normal.

Reduction in phosphate load results in a reduction in FGF23 and an increase in 1,25$(OH)_2D$, which increases calcium absorption and plasma calcium and, therefore, suppresses PTH. However, 1,25$(OH)_2D$ increases phosphate absorption to as much as 80–90% of dietary intake, so it is usually the case that phosphate binders, which latch on to phosphate in the gut and prevent its absorption, are needed. The principal phosphate binders contain calcium Calcium carbonate is the cheapest and most used, followed by calcium acetate. If required in large quantities such binders present a large calcium load; calcium free phosphate binders are available if there are problems with hypercalcemia. Phosphate, being predominantly intracellular, is poorly removed by dialysis. It is one of the most toxic molecules that circulates in excess in CKD, and plays an important role in vascular calcification. Maintenance of the plasma phosphate well below the upper limit of the age-related normal range is, therefore, crucial.

Calcium

The requirement for calcium varies with age, from 0.4 to 1 g daily, and is relatively higher when growth is fastest, that is, in the first 2 years of life. Plasma calcium is, like phosphate, age dependent, falling over the first 3–4 years of life. Interpretation of the plasma calcium requires adjustment for the albumin and pH, or ionized calcium can be used.

Vitamin D

The benefits of vitamin D extend beyond its effect on bone disease, as it has anti-inflammatory properties and beneficial effects on the cardiovascular system. Conversely, this has to be balanced against the risks of hypercalcemia and its depressive effect on the chondrocyte. If it is possible to measure 25(OH)D, and this proves to be low, ergo, or cholecalciferol should be prescribed. If the PTH remains high, the smallest possible dose of 1,25$(OH)_2D$ to suppress the PTH can then be added. If hypercalcemia develops, the 1,25$(OH)_2D$ should be stopped.

PTH

Guidelines for the management of CKD-MBD hinge on the need to keep the PTH level within a fixed range, which is one that maintains normal bone turnover. European guidelines recommend maintaining the PTH in the normal range until dialysis, when up to 3 × the upper limit of normal (ULN) is acceptable. KDOQI recommends the normal range until CKD 4, when 1–2 × ULN is recommended and then 3–5 × ULN for patients on dialysis, in order to allow for skeletal resistance to PTH as CKD evolves. These guidelines were written as the understanding of the interplay with cardiovascular disease was emerging. They are predominantly opinion-based as they are extrapolated from adult studies and a small number of pediatric studies, and are largely out-of-date. When hyperparathyroidism becomes tertiary, with persistent hypercalcemia and radiological changes, new therapies that block the calcium sensing receptor are beneficial in adults and have been successfully used in children. Severe, uncontrolled hyperparathyroidism may necessitate parathyroidectomies.

Radiological Changes

Radiological changes of CKD-MBD include rickets, hyperparathyroidism, and osteosclerosis. Features include periosteal erosions and elevation and widening of the zone of provisional calcification with a coarse trabecular pattern. Vertebral collapse, alternating with areas of osteosclerosis, gives the appearance called rugger jersey spine. Radiological changes occur late and may be normal even with moderate hyperparathyroidism.

Vascular Calcification

Vascular calcification has been demonstrated in children on dialysis. Disorders of phosphate, calcium, PTH, and vitamin D have all been shown to contribute. Large epidemiological studies in adults have shown that mortality rises exponentially as the plasma phosphate rises; the risk of death increases by 6% for every 0.3 mmol/l rise in plasma phosphate. Mortality also increases exponentially as the calcium × phosphate product rises above 5 $mmol^2/l^2$. PTH itself is a risk actor for vascular disease in several studies of children on dialysis. The most risk is when the level is >2 × ULN. Vitamin D has a bimodal effect, such that vitamin D levels above and below the normal range are associated with vascular calcification.

Prognosis

The diagnosis of CKD implies progressive decline in renal function, but whether mild impairment progresses, is unknown. Studies have shown that the probability of kidney survival at 20 years of age with a diagnosis of a GFR in early childhood of 51–75 ml/min.1.73 m^2 is 63%, 30% in those with a GFR of 25–50, and 3% in those with a GFR <25 mL/min/1.73 m^2. The diagnosis of CKD has implications for survival: the overall mortality rate has been estimated to be 1.4% for children before RRT is needed, but much higher for children on dialysis, when lifespan is reduced by 40–60 years.

Prevention

Prevention of CKD is the Holy Grail for the nephrologist. At present, however, there are only a few situations where prevention is possible, such as relief of urinary tract obstruction or prevention of infection. It is important to identify children with CKD as early as possible because the mainstay of treatment is to attenuate the rate of progression of CKD by normalization of BP and reduction of proteinuria. Careful attention to nutrition, electrolytes, and anemia is essential to maintain well-being and growth.

314 Dialysis in Children

Bradley A. Warady

Incidence, Prevalence and Causes of End-Stage Renal Disease in Children

End-stage renal disease (ESRD) is an uncommon disorder in children, with an incidence rate in the USA of approximately 14 patients per million children of similar age. The incidence varies within the pediatric population with a rate of 29 per million for children 15–19 years, in contrast to a rate of 9 per million for children 0–4 years. The incidence in children is also significantly different from that which is experienced by adults in whom rates of 127 per million and 625 per million characterize the 20–44 and 45–64 year age groups, respectively. Similarly, pediatric patients only account for a small percentage of the total dialysis population. In 2007, of a total of 354,753 patients on dialysis in the USA, only 2,177 (0.6%) were younger than 20 years (*Table 314.1*). Approximately one-half of children who initiate chronic dialysis have a congenital or hereditary disorder, such as aplastic/hypoplastic/dysplastic kidneys or obstructive uropathy (e.g., posterior urethral valves), whereas the remainder have an acquired cause of ESRD such as focal segmental glomerulosclerosis (FSGS). In all cases, the development of ESRD, as defined by an estimated glomerular filtration rate (eGFR) of 8 mL/min/1.73 m^2 or the development of treatment-resistant signs and symptoms of uremia (e.g., lethargy, recurrent emesis, poor growth, anemia, elevated blood pressure, acidosis, fluid overload, poor school performance), mandate the provision of renal replacement therapy in the form of dialysis or transplantation. Although kidney transplantation is the nearly universal goal for children who develop ESRD, approximately 75% of patients initially receive chronic peritoneal dialysis (CPD), hemodialysis (HD), or both, prior to receipt of a kidney transplant.

Choice of Dialysis Modality in Children

The percentage of children that receive one form of chronic dialysis versus the other varies globally. For instance, nearly 80% of prevalent pediatric (0–19 years) dialysis patients in Russia receive HD, in contrast to Spain where almost 60% receive CPD. The choice is most often made based on patient age and size, dialysis center experience and philosophy, family preference, assessment of whether the individual patient and family can be adherent with a home dialysis regimen, and the availability of the specific modality. Careful evaluation of the family's social, psychological, and economic background, ideally by a multiprofessional team including the family physician and nephrologist, dialysis nurse, psychologist, and social worker, is mandatory if a fully informed decision regarding modality selection is to be made. The quality of life (QOL) of the patient and family and the potential impact of the dialysis modality on this parameter also assumes great importance in the decision process. In all cases, HD is the modality of choice when the family is unwilling or unable to conduct dialysis at home. Although few in number, absolute contraindications to CPD include the presence of the following:

- Omphalocele
- Gastroschisis
- Bladder extrophy
- Diaphragmatic hernia
- Obliterated peritoneal cavity and peritoneal membrane failure

At present, there is no clear evidence that one form of dialysis is preferable over another for most children with ESRD. In all cases, patients and families should understand that, at some point during the clinical management with dialysis, a change in modality may be necessary as a result of compromised efficacy and/or the development of complications associated with their current therapy.

Chronic Peritoneal Dialysis

Peritoneal dialysis is frequently the preferred initial dialysis modality in pediatric programs, primarily for psychosocial reasons. CPD, which is characteristically performed at home following the training of patients/parents/caregivers by dialysis staff, permits flexibility of the treatment schedule and normal attendance at school, does not

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_314,

Table 314.1
Prevalent dialysis patients (Data from US patients in 2007)

Age	HD	PD
0–19	1,253	860
20–44	46,105	5,842
45–64	133,637	11,510
65–74	74,674	4,748
75+	72,084	3,122

require venipuncture during the dialysis procedure, and allows for a reasonable fluid intake because dialysis is conducted on a daily basis.

Peritoneal dialysis makes use of the peritoneal membrane as a natural dialyzing membrane. The dialysis solution is instilled and dwells within the peritoneal cavity, during which time bloodstream derived solutes (e.g., urea, creatinine) move down a concentration (electrochemical) gradient based on the principle of diffusion. At the same time, the osmotic component of the dialysis solution, typically glucose, causes fluids to move from blood to dialysate (e.g., ultrafiltration) as a result of the osmotic gradient. Peritoneal dialysis solutions are commercially available in standard dextrose concentrations of 1.5%, 2.5%, and 4.25%. The inflow, dwell, and drainage of dialysate characterize a single dialysis cycle or exchange.

A reliable peritoneal catheter is the cornerstone of successful CPD. Most long-term catheters are constructed of either silastic or polyurethane. The Tenckhoff catheter is the one most commonly used and, like all CPD catheters, is comprised of an intraperitoneal and an extraperitoneal portion. The former contains holes through which the dialysis solution flows into the peritoneal cavity and then subsequently drains. A portion of the extraperitoneal segment of the catheter is tunneled subcutaneously within the abdominal wall and has one or two Dacron cuffs that primarily fix the catheter's position at its exit site.

The CPD prescription takes into account the amount and dextrose concentration of the dialysis solution to be used for each cycle and the length of the cycle. In part, the prescribed cycle length is determined by the time it takes for solute and osmotic equilibration to take place between plasma and dialysate such that the infusion of fresh dialysis solution would be advantageous. The speed with which solutes and water move across the peritoneal membrane (e.g., transport capacity) can be determined clinically by performance of the peritoneal equilibration test (PET). Continuous ambulatory peritoneal dialysis (CAPD) is a manual form of CPD in which the patient or caregiver attaches and instills a bag of sterile dialysis solution into the peritoneal cavity four times per 24 h, with each of the three daytime exchanges lasting approximately 5 h and the nighttime exchange, 9 h. In contrast, the most frequently used CPD modality for children in many countries, automated peritoneal dialysis (APD), uses an automated device which can measure, heat, deliver, drain, remeasure, and discard dialysate in patterns determined by the prescribing team. The greatest percentage of children receiving APD utilize a regimen consisting of 6–12 exchanges over 8 to 10 h per night with a daytime dwell consisting of approximately 50% of the nocturnal exchange volume. Guidelines for the performance of CPD in children recommend an individual exchange volume of 1,000–1,200 mL/m^2 for patients >2 years of age; younger patients should be prescribed a lower initial volume (600–800 mL/m^2) to promote tolerance. The efficacy or "adequacy" of CPD has historically been characterized by the measurement of small solute clearance, most commonly in terms of the Kt/V_{urea}. However, recently published guidelines by the National Kidney Foundation emphasize the clinical status of the patient as an important qualitative target and state that "adequate dialysis is likely provided if the patient's clinical status is characterized by adequate growth, blood pressure control, and nutritional status; avoidance of hypovolemia (or hypervolemia) and sodium depletion; and adequate psychomotor development." Factors that might contribute to inadequate CPD include:

- Loss of residual native kidney function
- Reduced peritoneal surface area caused by intra-abdominal adhesions
- Loss of membrane solute transport capacity/ultrafiltration capacity because of peritonitis
- Noncompliance with CPD prescription
- Poorly functioning PD catheter

Complications of CPD

The single most common complication that occurs in children maintained on CPD is peritonitis. Peritonitis contributes to significant morbidity and can lead to irreversible technique failure. The frequency of peritonitis in children regularly exceeds that in adults. The most recent annual report of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) includes information on 3,999 episodes of peritonitis in 6,008 years of follow-up for an annualized rate of 0.67 (one episode every 18.0 months). Young patient age and catheter

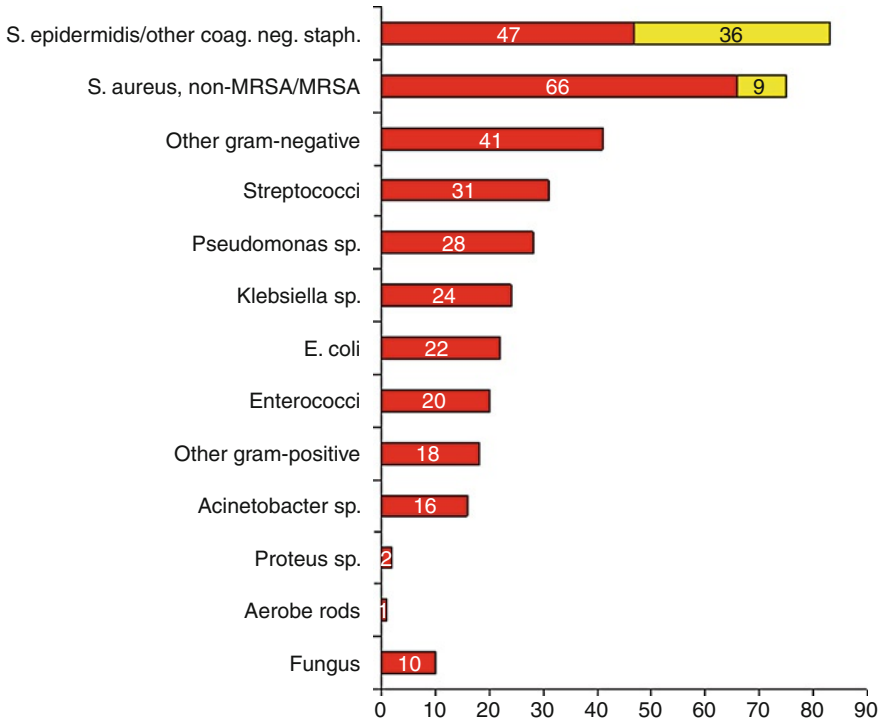

Figure 314.1
Distribution of peritonitis (n = 350) causative organisms in children receiving peritoneal dialysis

exit-site and tunnel infections, often secondary to *Staphylococcus* or *Pseudomonas*, are important risk factors for peritonitis. Approximately 50% of peritonitis episodes are caused by Gram-positive bacteria, particularly *Staphylococcus epidermidis* and *Staphylococcus aureus*, 20–30% by Gram-negative organisms, with the cultures remaining negative in a substantial percentage (<20%) of episodes (*Fig. 314.1*). Peritoneal dialysis patients presenting with abdominal pain and/or cloudy drained dialysis fluid (effluent) should be presumed to have peritonitis and should be evaluated for this infection. The diagnosis is confirmed when the effluent white blood cell (WBC) count is $>100/mm^3$ and at least 50% of the WBCs are polymorphonuclear leukocytes. When peritonitis is suspected and following collection of dialysate effluent for culture and cell count, empiric antibiotic therapy should be administered through the intraperitoneal route and consist of a combination of a first generation cephalosporin or a glycopeptide, with a third-generation cephalosporin or an aminoglycoside. To minimize the risk for antibiotic-related toxicity associated with the use of either vancomycin or an aminoglycoside, maintenance antibiotic therapy with alternative choices should be instituted as soon as the antibiotic susceptibilities are known.

Chronic Hemodialysis

Hemodialysis is currently the dialysis modality used by nearly 60% of prevalent pediatric patients in the USA and in almost all cases, is performed in a dialysis center. A HD system consists of a blood circuit, a dialysate circuit, and a dialyzer. Blood is pumped from the patient's vascular access to the dialyzer (the "arterial segment") and uremic toxins and water are removed. A separate pump delivers anticoagulants to prevent clotting within the extracorporeal circuit. The clearance of solutes is a function of the blood and dialysate flow rates and the permeability of the dialyzer's membrane to the solutes as clearance occurs by diffusion down a concentration gradient between plasma and dialysate. Ultrafiltration occurs because a transmembrane hydrostatic gradient is created from the blood to the dialysate compartment. The dialyzed blood is subsequently recirculated to the patient through the "venous segment" of the circuit. Throughout this process, ultrafiltration control systems and monitors that evaluate pressures within the blood lines and airleaks are engaged and alert the dialysis staff if adjustments are needed.

The vascular access is a crucial aspect of the blood circuit as the efficiency of HD is in large part dependent

on access function and blood delivery. HD access is divided into two categories: permanent access in the form of an arteriovenous fistula (AVF) or arteriovenous graft (AVG) and semipermanent access in the form of catheters with a subcutaneous cuff. Catheters currently serve as the most common form of access for children receiving HD, being present in more than 60% of patients at dialysis initiation. While these devices allow for the blood flow necessary for HD in patients who have relatively small vessels that do not permit the surgical connection between the native artery and vein necessary for an AVF or AVG, catheters have a much greater complication rate than either of the permanent accesses. For this reason, it is recommended that children more than 20 kg who are expected to receive HD for more than 1 year should be evaluated for permanent vascular access placement.

The HD prescription incorporates the size of the dialyzer to be used, the blood and dialysate flow rates and the length of the treatment. To prevent hemodynamic instability, the extracorporeal circuit should not exceed 10% of the patient's blood volume, a requirement that often dictates dialyzer size. Blood flow rates are generally less than 400 mL/min/1.73 m^2 to minimize the risk for cardiovascular compromise and the dialysate rate is >1.5 times the blood flow rate to prevent dialysate saturation and the associated limitation of clearance. In most cases, HD is provided three times weekly, with each session lasting 3.5–4 h. Recent positive experiences with frequent HD (e.g., >5 days weekly) suggest that this approach may become more common. The urea reduction ratio is an approximation of the fraction of blood urea nitrogen (BUN) removed in a single dialysis session and is a method of quantitating HD adequacy. It is determined in the following manner:

$$\text{URR} = (\text{preBUN} - \text{postBUN})/\text{preBUN} \times 100\%$$

Although simplistic, the URR has a number of shortcomings: most importantly, the inability to provide any information about a patient's nutritional status. As a result, Kt/V has become the preferred method for measuring delivered dialysis as it more accurately reflects urea removal than does URR, and it provides information on patient nutrition by allowing for the calculation of the protein catabolic rate. Like in adults, the Kt/V in children should be >1.2 per dialysis session. Factors that might contribute to inadequate HD include:

- Underprescription
- Inadequate vascular access
- Shortened treatment time
- Dialyzer clotting

Complications of HD

Hypotension is the most common acute complication of HD and often arises as a result of the removal of large volumes of fluid by ultrafiltration and depletion of the intravascular volume during the dialysis session. At times, this may be accompanied by muscle cramps, nausea, dizziness, or headache. Noninvasive monitoring of the hematocrit within the dialysis circuit may help "predict" this complication since changes in hematocrit are inversely proportional to changes in intravascular volume. Treatment consists of stopping (or slowing) ultrafiltration, providing saline as deemed necessary to maintain blood pressure and minimize symptoms, and placing the patient in the Trendelenburg position. Adjusting the timing of antihypertensive medications on dialysis days and decreasing fluid gain between dialysis sessions are often effective preventative measures.

The most common complication associated with dialysis catheter usage is infection and sepsis. Infection rates of catheters are 60% higher than the rates for AVF and AVGs and often require removal/replacement of the access along with systemic antibiotic therapy. Catheter usage can also be complicated by the development of vascular stenosis and the inability to create a permanent vascular access.

Additional Clinical Issues for the Pediatric Dialysis Patient

Optimal management of the dialysis patient requires attention to a variety of clinical manifestations for which treatment guidelines do exist. Issues to be addressed include anemia management with iron and erythropoiesis stimulating agents (ESA), nutrition, growth and the possible use of recombinant growth hormone therapy (rhGH), bone-mineral management with phosphate binders and vitamin D therapy, blood pressure management, education, and health-related quality of life (HRQOL). In all cases, centers providing chronic dialysis to children should have access to the expertise needed to address these important concerns.

315 Pediatric Kidney Transplantation

Peter F. Hoyer

Introduction

Dr. Murray performed the first successful kidney transplantation more than 50 years ago among identical twins. At that time immunological and immunosuppressive concepts did not exist. About 15 years later, transplantation became an accepted treatment modality for adults with renal failure but was regarded as unethical for children. Today kidney transplantation is the preferred treatment for renal replacement therapy in children.

Major side effects of chronic renal failure like growth retardation, developmental delay, anemia, renal osteodystrophic bone disease as well as poor school attendance improve dramatically after successful kidney transplantation. Contraindications against kidney transplantations are few, i.e., malignancies or chronic infections. A major problem is still shortage of suitable and compatible organs. Unsolved challenges remain the preservation of renal function, prevention of infections, long-term cardiovascular problems, side effects of chronic drug administration, and long-term rehabilitation.

Underlying Diseases Leading to Kidney Transplantation

Underlying diseases leading to kidney transplantation are in one-third urinary tract malformations, one-third nephronophthisis and cystic kidney disease, and one-third acquired diseases like non genetic hemolytic uremic syndrome (HUS) and other glomerulopathies (*Table 315.1*). Multiorgan diseases, which may deteriorate after transplantation, are important for the prognosis after transplantation. Syndromatic diseases with mental retardation require very intensive and long-term care.

Pretransplant Assessment and Preparing for the Waiting List

Outcome after transplantation clearly depends on careful pretransplant evaluation and preparation. Infections after transplantation are a major problem due to chronic immunosuppression. Therefore, care must be given to get all information about previous vaccinations and to complete missings recommended vaccinations. Especially life-attenuated vaccines should be completed before immunosuppression starts.

Complete assessment of the recipient includes a general physical status, evaluation of organ functions, mental and cognitive status. The immunological status includes blood groups and human leukocyte antigens, i.e., HLA antigens, and in case of autoimmune disease activity parameters including complement, anti-DNA antibodies or ANCAs. Chronic infections like tuberculosis must be excluded. In case of urinary tract malformation, a careful planning together with the pediatric urologist is mandatory; this may include nephrectomy of chronic infected kidneys as well as evaluation of the bladder by urodynamic studies. A miction cysturethrogram is recommended for almost all patients in order to diagnose a relevant vesicoureteral reflux.

Attention must be given to medications, which inhibit or enhance the drug metabolizing system cytochrome p450 of the liver, because this might have a tremendous effect on doses and drug levels of calcineurin inhibitors (*Table 315.2*).

Living Transplantation Versus Deceased Donor Organ Transplantation

Nowadays most families wish to contribute to the treatment of renal failure by offering living transplantation to their children. It is important to inform the families as early as possible about such options, but very balanced information about the pros and cons is necessary. The pros for living-related transplantation are a short waiting time or even a preemptive transplantation, optimal timing of the transplantation, early and excellent graft function, almost no delayed graft function and fewer rejection episodes (*Fig. 315.1*). In general, in the long-term run the prognosis of a living-related kidney is superior to a deceased donor organ (*Fig. 315.2*). On the other hand, ethical issues have to be addressed. It is absolutely mandatory, that the transplantation is self-motivated and

Rifampicin	Fluconazole
Gluco-corticosteroids	Itraconazole
St. John´s wort etc.	Verpamil
	Diltiazem
	Grapefruit etc.

a free decision without any coercion. A careful clinical, laboratory and radiological evaluation of the donor is a prerequisite for transplantation. The safety of the donor has a high priority and donors with diseases that are occasionally unknown before evaluation must be excluded from living donation. In general, 30–50% of parents are acceptable as donors. Unrelated living donor transplantation has become an option if a clear relationship among donor and recipient is granted but any commercial organ transplantation has to be rejected.

Access to Transplantation and the Waiting List

In almost all countries, possible transplant recipients have to be registered on a waiting list in a local organ sharing network like in the *Eurotransplant foundation, UK Transplant, Scandinavian Transplant* network, or in the *UNOS* network in the United States. Waiting time for a transplant is by no means uniform and several factors are taken into consideration for an algorithm for organ allocation. ABO blood types continue to have a major effect and also HLA typing and histocompatibility are still considered as a major predictor for transplant success. Specific cytotoxic antibodies have to be measured on a regular basis. In case of competing for a same organ because of equal histocompatibility, time on a waiting list and medical urgency play a major role. Patients with special medical risk factors get some priority. In some countries, children get a preference on the waiting list, while in other countries this is not the case. Recently, data from UNOS suggest that children should preferentially receive organs from donors younger than 35 years and that HLA matching has less impact on outcome for a first transplant.

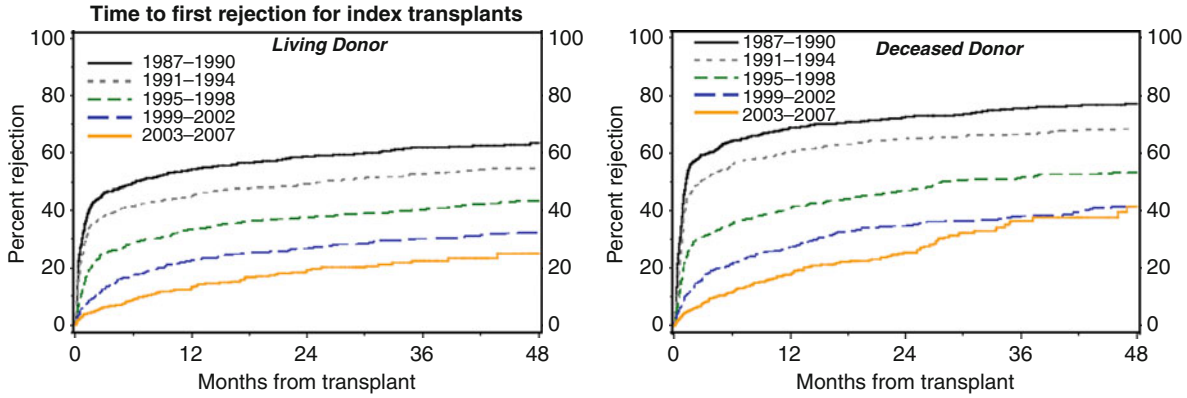

Figure 315.1

Time to first rejection episode in living donor transplantation and in deceased donor transplantation. There is a remarkable improvement over time (NAPRTCS 2008)

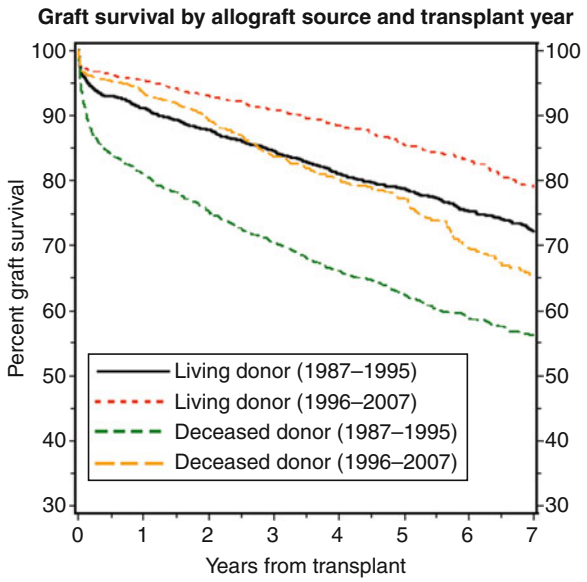

Figure 315.2

Improvement of graft survival over time in living and deceased donor transplantation. Five year graft survival after living donor transplantation is now in the order of 90% (NAPRTCS 2008)

Technical Aspects of Kidney Transplantation

In most children, the transplant kidney is placed like in adults in the right or left fossa iliaca with an anastomosis to the iliac artery and iliac vein. However, in the very young, large kidneys have not enough space and blood supply from the iliac artery may be insufficient. Therefore, the vascular anastomosis should be placed between the aorta and caval vein in the middle of abdomen (*Fig. 315.3*). Careful consideration has to be given to the kidney size and the recipient's size because a large transplanted kidney may require a high blood supply, which will not be achievable in very small recipients. Therefore, most centers recommend to transplant a kidney to a recipient with a minimum weight of 8–10 kg and to take into consideration the diameter of the aorta.

Perioperative Management

The perioperative management of kidney transplantation is standardized. Successes are clearly related to a center experience, which includes pretransplant preparation, experienced anesthesiology, specially trained transplant surgeons, as well as postoperative care. Adequate hydration should be measured by a central venous line, and fluid and electrolytes have to be balanced according to circulatory parameters and urine output. Most centers have a standard operation procedure with the administration of diuretics such as furosemide and infusion of mannitol before the anastomoses are opened. Dopamine infusion is widely accepted to enhance kidney perfusion and to maintain blood pressure adequately high; however, this recommendation has never been tested in a prospective trial in children.

Postoperative application of Doppler sonography in the operation room is important in order to exclude organ compression or early thrombosis. Urine output via transurethral catheter or suprapubic catheter should be checked hourly and any obstruction must be detected early in order to prevent a leakage of the vesicoureteral anastomosis.

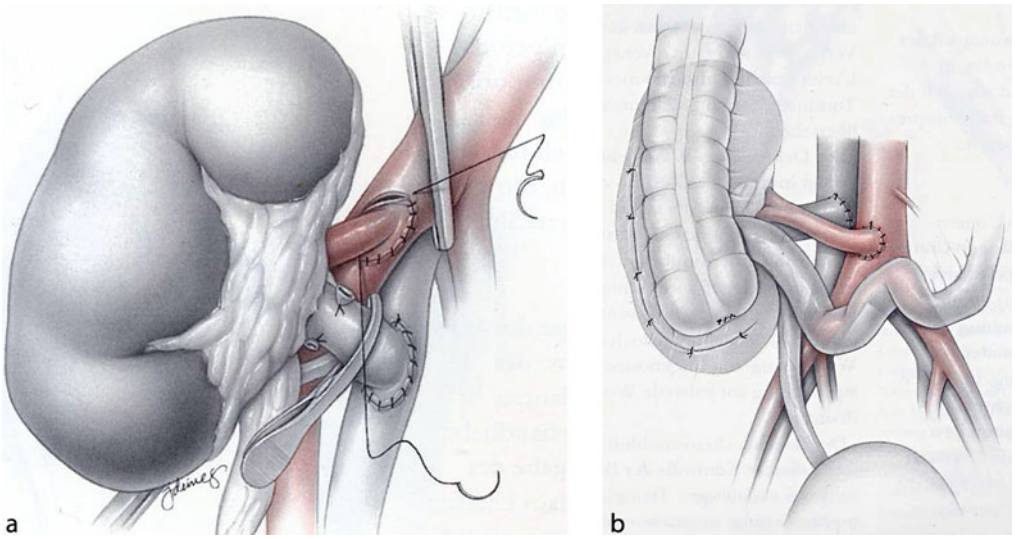

Figure 315.3
Surgical technique in the standard situation panel a and in small children panel b. In panel b, the renal artery is anastomosed to the aorta and the renal vein to the caval vein (Courtesy of Professor Paul, Clinic for Transplantation Surgery University Clinic Essen)

Immunosuppression

Immunosuppressive drugs can be classified in different categories:

- Steroids
- Lymphocyte-directed antibodies such as ATG, OKT3, thymoglobulin or IL2 receptor antibodies
- Calcineurin inhibitors like cyclosporine or tacrolimus
- mTOR-inhibitors (mammalian target of rapamycin): sirolimus and everolimus
- Antiproliferative agents like azathioprine or mycophenolic acid

Newer agents like co-stimulatory pathway blocking agents are used in adults but have not been tested in children so far. Major side effects of immunosuppressive drugs are listed in *Table 315.3*.

Steroids have been used as a basic drug in transplantation long time before newer drugs were developed. Most protocols still include steroids. Because of the major side effects, especially on growth in pediatric transplantation a search for steroid avoidance protocols or steroid withdrawal is going on. First trials without steroid treatment seem promising; however, a translation into daily routine outside from studies needs further confirmation.

The monoclonal antibodies OKT3 and ATG have been recommended as induction therapy by the NAPRTCS registry some years ago, but the superiority to treatment without the induction antibodies have not been demonstrated. The monoclonal antibody basiliximab, which is directed against the alpha chain of the interleukin 2 receptor on activated lymphocytes, should be in theory synergistic to treatment with calcineurin inhibitors. In large trials and meta-analysis, a reduction in early acute rejection episodes has been demonstrated but no benefit with

Table 315.3
Major specific side effects of immunosuppressive drugs

Steroids	Obesity, arterial hypertension, growth retardation
Cyclosporine A	Nephrotoxicity, hypertrichosis, gingival hyperplasia, elevated lipids

regard to long-term outcome. In a prospective randomized double blind trial basiliximab was tested versus placebo with a standard immunosuppression consisting of cyclosporine steroids and mycophenolate mofetil. In this trial, no benefit with regard to rejection episodes was visible for basiliximab, however, the overall data were extremely good compared to results which are analyzed by registries (◉ *Fig. 315.1*) and which are much inferior. Therefore, a benefit of a monoclonal antibody against the IL2-receptor cannot be excluded under standard situation.

Cyclosporine A has become a corner stone in kidney transplantation in the late 1980s. Major side effects are nephrotoxicity, hypertrichosis, gingival hyperplasia, and elevated lipids. The calcineurin inhibitor tacrolimus is more powerful in terms of dosis and blood levels, but has the same nephrotoxic side effects. In addition to that, some beta cell toxicity has been reported in trials with adult patients and higher doses are associated with PTLD, especially in patients who are EBV naïve before transplantation. With regard to cosmetic side effects and compliance in young adolescents, tacrolimus is gaining preference by many centers.

mTOR inhibitors were introduced with the promise to lead to less nephrotoxicity and improved kidney function. However, high lipids early after transplantation, wound healing problems, and enhanced cyclosporine toxicity has reduced the enthusiasm. A recent trial by NAPRTCS combining sirolimus with tacrolimus has lead to unacceptable high PTLD rates. Nevertheless, mTor inhibitors with their specific profile have a place in a subgroup of patients with special problems. Mycophenolate mofetil (MMF) and the compound mycophenolic acid are the most widely used immunosuppressive drugs in about 80% of patients. Generally, they are used in combination with calcineurin inhibitors allowing a substantial reduction of these nephrotoxic compounds. MMF has become a substitute for azathioprine over the last 15 years. However, in terms of cost-effectiveness and long-term benefit azathioprine needs new consideration.

Due to the importance of the immunosuppressive therapy most drugs require a pharmacokinetic monitoring. The therapeutic window is rather small; undertreatment may lead to rejection and graft loss while overtreatment to toxicity or severe infections. In addition to that, many drugs may interfere with metabolism of calcineurin inhibitors (◉ *Table 315.2*) and also mycophenolate acid. The average dose of drugs used in various combinations after transplantation has been evaluated by NAPRTCS (◉ *Fig. 315.4*). It is of note that a combination of tacrolimus and MMF requires about half the dose of MMF, which is required with the combination of cyclosporine and MMF. Drug levels are measured as predose trough level or at certain time points to calculate drug exposure as area under the curve (AUC). This is essential to adjust drug dosing.

Reasons for Graft Failure

Under the current immunosuppressive therapies, graft loss due to rejection has become less important. The NAPRTCS registry reported in 2006 that the leading cause of graft failure are thrombosis with 21%, chronic rejection 20%, acute rejection 10%, death 8%, recurrence of original disease 9%, and all other different reasons 32%. Therefore, prevention of graft thrombosis has the major impact on outcome. Although there are no prospective trials, several factors may reduce the risk for thrombosis: meticulous surgical techniques with anastomosis guarantee in high kidney perfusion are of major importance. Identification of a hypercoagulable state with APC resistance, or a previous history of multiple thrombotic events may point to an increased risk after transplantation. While some centers report almost no graft thrombosis by prophylactic use of heparin, others have not seen a benefit. However, these results are difficult to interpret, because immediate postoperative monitoring of anticoagulation is not always reported and some publications are biased by large historical data.

Acute Rejection Episodes

Most acute rejection episodes are observed during the first 3 months after transplantation. The percentage of patients who are treated for acute rejections during the first year after transplantation has continued to decline from 30% to 20–15%. An acute rejection is defined as an acute deterioration of the graft function associated with specific pathologic changes. These pathologic changes have been classified by the Banff consortium (◉ *Table 315.4*).

The gold standard for diagnosing a rejection episode is a kidney biopsy. An ultrasound-guided kidney biopsy is a safe procedure and has the advantage to provide a clear diagnosis and to prevent unnecessary treatment. Other causes for functional deterioration of the graft can also be described by a kidney biopsy, i.e., drug toxicity (◉ *Fig. 315.5a*), unspecific tubular injury, recurrence of original diseases, and chronic allograft nephropathy (◉ *Fig. 315.5b*).

In case of acute rejection, steroid therapy usually can reverse rejection episodes. Steroid-resistant rejection is a rare event, which may require intensified immunosuppression

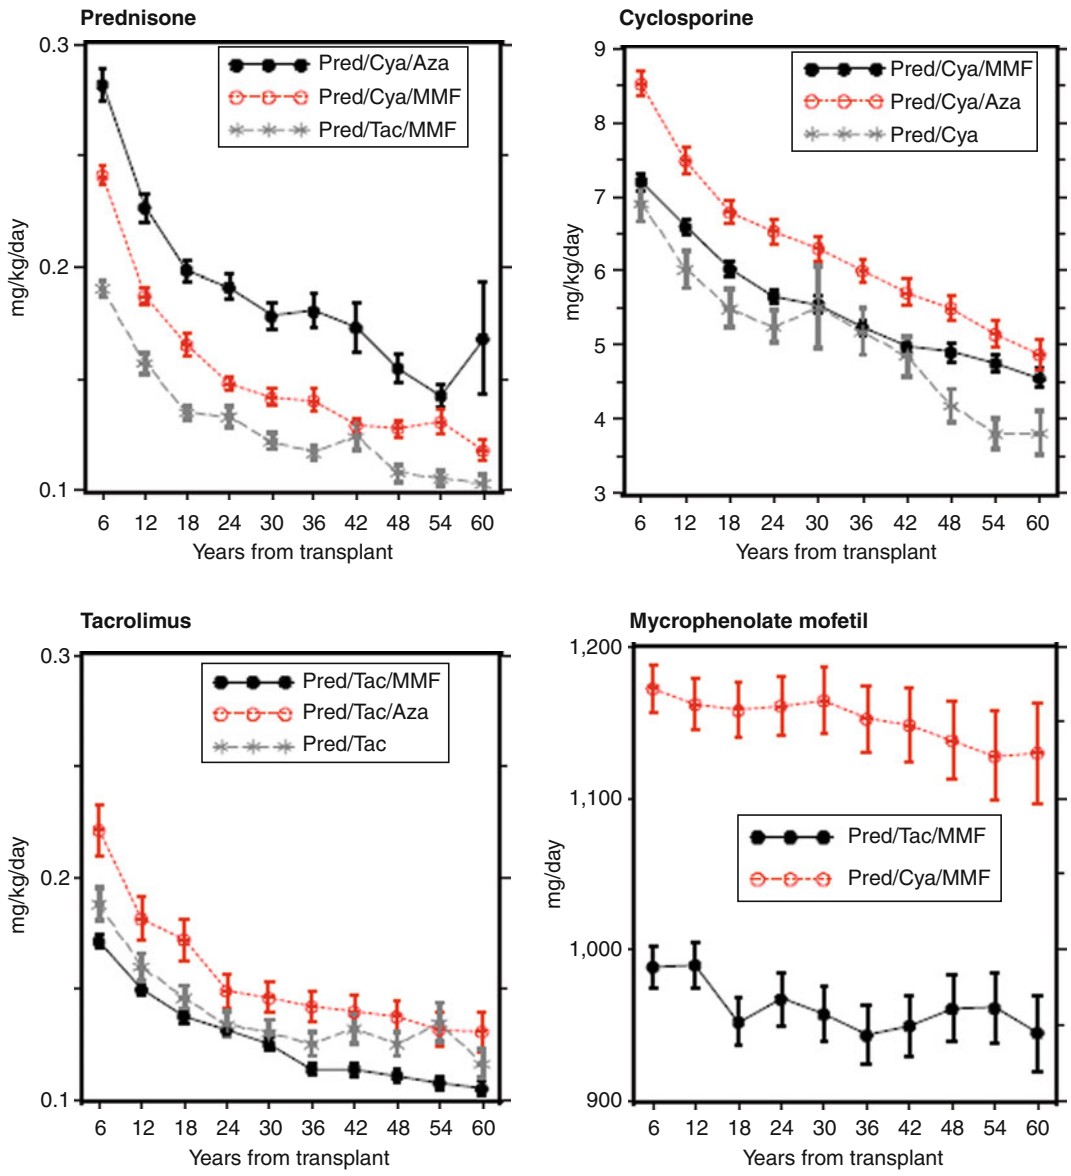

Figure 315.4

Mean drug concentrations used after transplantation in relation to combined drug therapies (NAPRTCS 2008)

with antibody therapy. In case of acute rejection, inadequate immunosuppression induced by poor drug absorption or noncompliance must be excluded. Switching to other drug combinations may be advisable.

Chronic Allograft Dysfunction

Chronic allograft dysfunction is an unsolved problem in kidney transplantation. While rejection episodes are rare events in younger children, poor compliance in adolescence may lead to chronic inadequate immunosuppression. Other reasons for chronic allograft nephropathy are not well-defined chronic immunologically mediated injury, arterial hypertension, chronic calcineurin inhibitor toxicity, the senescence of renal cells, and de novo diseases in the kidney such as transplant glomerulopathy or tubular interstitial nephritis by recurrent urinary tract infection.

Table 315.4
Banff 2005 diagnostic categories for renal allograft biopsies (2005 revision)[a]

1. Normal
2. AMR
Acute AMR ($C4d^+$) type
(a) ATN-like
(b) Capillary margination and/or thrombosis
(c) Arterial
Chronic active AMR[b]
glomerular double contours, peritubular capillary basement membrane multilayering. interstitial fibrosis, tubular atrophy, fibrous intimal thickening
3. Borderline changes
4. T cell–mediated rejection
Acute
• (a) Significant interstitial infiltration (<25% of parenchyma) and moderate tubulitis
(b) Significant interstitial infiltration (>25% of parenchyma) and severe tubulitis
• (a) Mild to moderate intimal arteritis
(b) Cases with severe intimal arteritis comprising >25% of the luminal area
• Transmural arteritis
Chronic active T cell–mediated rejection[b]
5. Interstitial fibrosis and tubular atrophy, no evidence of any specific cause
Grade
(a) Mild (<25% of cortex)
(b) Moderate (26–50% of cortex)
(c) Severe (>50% of cortex)
6. Other: Categories not considered to be due to rejection; may coincide with categories 2 through 5

[a]Adapted from reference
[b]Changes in the updated Banff 2005 schema
AMR = antibody mediated rejection

Infections After Transplantation

Infections after transplantation may be related to the disease of organs, to the recipient's immune status or to the immunosuppression itself. In a recent prospective trial with cyclosporine, MMF and basiliximab almost any infection was encountered in 95.4%, a cytomegalovirus infection in 12.8%, EBV virus infection in 9.2%, gastroenteritis in 23.9%, herpes simplex 10.1%, pyelonephritis 9.2%, rhinitis 21.1%, upper respiratory tract infection in 34.9%, and urinary tract infection 34.9%. Since CMV infection has an impact on graft function, the CMV recipient donor constellation is of great importance. In general, studies suggest a prophylactic gancyclovir therapy for at least 3 months in case of CMV mismatch, i.e., a positive donor in a negative recipient. In addition to that, monitoring of cytomegalovirus replication by measuring PP65 is established in many pediatric transplant programs.

EBV infection has also an impact on outcome. EBV infection rates increases with the amount of immunosuppression. EBV naïve children are at risk to develop an infection with a high viral DNA load and a prolonged course. Some studies reported coincidence with a cyclomegalovirus infection. A primary EBV infection in an EBV naïve recipient is a risk factor for the development of posttransplant lymphoproliferative disease (PTLD). The EBV viral load is measured in many centers, since it may point to a risk for PTLD, but there seems to be no definite correlation.

Urinary tract infections are common problems in patients with obstructive uropathy or bladder dysfunction. There is a high risk that this problem continues after transplantation. Operative removal of the recipient's diseased kidney and ureters, evaluation of the bladder

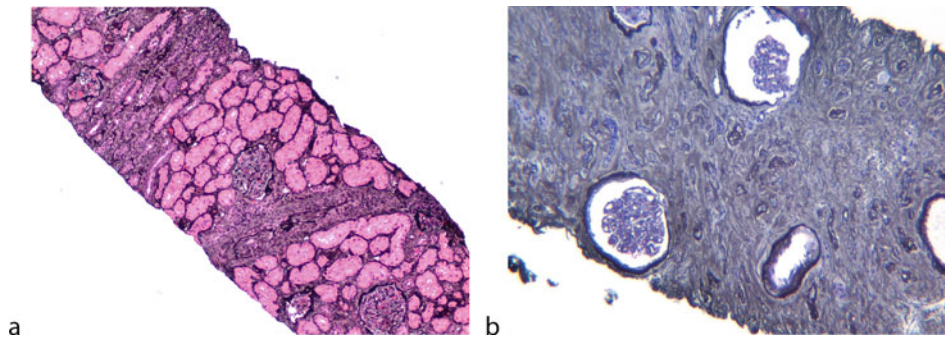

Figure 315.5
(a) Kidney biopsy with a striped form of interstitial fibrosis as can be seen as sign of calcineurin inhibitor toxicity or perfusion injury. (b) Chronic allograft dysfunction. Biopsy with severe interstitial fibrosis

function as well as treatment of bladder dysfunction should ameliorate the situation. Some cases can only be managed by continuous prophylactic antibiotic therapy.

Besides these classical infections, chronic immunosuppression may pose the patients to the risk of fungal infections or pneumocystis carini pneumonia (PCP). Due to a high fatality rate of PCP, intensive immunosuppressive protocols should get PCP prophylaxis with trimethoprim sulfamethoxazole.

Long-Term Problems After Organ Transplantation

After successful organ transplantation many problems may interfere with a good rehabilitation. These problems may be categorized as follows:

- Recurrence of original disease
- Progress of extra renal complications of the disease
- Consequences of chronic immunosuppression, i.e., direct toxicity of immunosuppressive drugs or consequences of over immunosuppression
- Cardiovascular diseases
- Progressive deterioration of the graft function

Recurrence of Original Diseases

With a transplantation of a new organ as a substitute to a failing organ, there is a hope, that the problem is cured. A look to the underlying diseases leading to renal transplantation makes clear, that different original diseases may not be cured in the same way by renal transplantation. A recurrence of original diseases after kidney transplantation is a relevant problem (Table 315.5).

FSGS has been described for a long time to have a considerable risk to reoccur in a transplanted organ. Up to 30% have been reported to lose their organ due to recurrent FSGS. Treatment options that have been tried are intensified immunosuppression and plasmapheresis. The increasing knowledge about the etiology of FSGS allows a new perspective on this problem. In pediatric patients, about one-third of cases with FSGS may have an underlying gene mutation in genes that have been described to lead to FSGS, i.e., *NPHS1*, *NPHS2* (podocine), *NPHS3*, *Wt1*, *CD2AP*, *TRPC6*, *Laminin beta 2*, etc. By discriminating genetic and non-genetic FSGS it has been demonstrated, that genetic FSGS has a very low risk to reoccur in a transplanted organ while the rate of recurrence in non-genetic FSGS is high. These findings are very important for counseling parents who wish to donate a kidney.

Table 315.5
Recurrences of original diseases after kidney transplantation in children

	Recurrence (%)	Grade	Loss of kidney transplant (%)
HUS, atypic	>40	++	>50
FSGS	25–30	++	>50
MPGN I	70	+	12–30
MPGN II	100	(+)	10–20
Lupus erythematodes	5–40	(+)	5
IgA nephritis	55–85	+	5–20

HUS hemolytic uremic syndrome, *FSGS* focal segmental glomerulosclerosis, *MSGN* membrano proliferative glomerulonephritis

In Alport syndrome, mutations in the collagen gene (*X-linked Col4A5 and autosomal Col4A3/Col4A4*) have been described. After successful transplantation, deafness may progress. Some rare cases may develop a picture like a Goodpasture syndrome. An explanation for this is that a patient with a mutated collagen will receive a new antigen by a transplanted kidney which then causes anti-GBM antibodies.

Hemolytic uremic syndrome is one of the most common causes for acute renal failure. While the shigatoxine-associated HUS has a good chance for full recovery, the so-called atypical HUS, which is not caused by shigatoxine, may have a high risk for recurrence after transplantation. Various mutations in the complement/factor H system have been described to cause atypical HUS. In these cases, the kidney is a target for uncontrolled complement activation. While the transplantation procedure itself may activate the complement system, an insufficient inhibitory potential may then lead to the recurrence of the HUS in the transplanted kidney. Therefore, patients with atypical HUS should have an intensive workup to look for mutations in factor H, factor I, and factor B or to detect antibodies against factor H. The prognosis of recurrent HUS after transplantation is poor. Intensive plasmapheresis and plasma infusion may be an option in some patient. Besides recurrence of atypical HUS, a de novo HUS in a transplanted kidney has been described and explanations point toward a possible rule of calcineurin inhibitors.

In lupus nephritis, recurrence of the original disease is a rare event. Other immunological diseases like Wegner's

granulomatosis or pauci-immune glomerulonephritis may have some risk for relapses after transplantation.

Data on the recurrence of Henoch Schönlein Purpura after transplantation are not conclusive.

In IgA nephropathy, IgA deposits in the mesangium can be demonstrated in almost all transplanted kidneys. However, this cannot be correlated with a further deterioration of the graft function.

In primary hyperoxaluria, the transplanted kidney may still be a target for continuous calcium oxalate deposition and early graft failure. In patients with primary hyperoxaluria, combined kidney liver transplantation should be considered, before a high oxalate load may worsen the general prognosis.

Progress of extra renal manifestation of systemic diseases is important in patients with autosomal recessive polycystic kidney disease (ARPKD). A liver involvement with liver fibrosis is obligatory. In addition to that, some patients have cholangiodysplastic features. The consequence of liver fibrosis is the development of portal hypertension, splenomegaly, and hypersplenism. Cholangiodysplasia may lead to cholangitis. Some patients with ARPKD may need a liver transplantation later in their course after kidney transplantation, in other patients; the liver involvement requires early combined liver kidney transplantation.

Patients with autosomal dominant polycystic kidney disease (ADPKD) rarely need a renal replacement therapy during childhood or adolescence phase. Some patients may develop liver cysts or mitral ballooning. Cerebral aneurisms have not been reported in pediatric patients.

Juvenile nephronophthisis is a common cause for chronic renal failure and transplantation in children. The disease may be very complex and many subtypes have been described. Major problems due to the progress of underlying disease are liver involvement with cholangiodysplasia and liver fibrosis, or tapetoretinal degeneration like in Senior–Loken syndrome.

Rare diseases with multiorgan involvement, which continue to be a problem after transplantation, are Joubert syndrome, Jeune syndrome, spondyloepiphyseal dysplasia, Bardet–Biedl syndrome, or juvenile cystinosis. Long-term problems are cerebellar ataxia, mental retardation, failure to growth, cerebral ischemia, or vision loss in case with tapetoretinal degeneration. Patients with cystinosis suffer from crystal deposition in the cornea, diabetes, and hypergonadotropic hypogonadism.

Malignancies After Organ Transplantation

The rate of malignancy is correlated to the intensity of immunosuppression. Lymphoproliferative diseases have been described in 2–5% of patients. First infection with EBV early after transplantation may be a risk for further development of PTLD (*Fig. 315.6a*). PTLD may appear as polymorphic or monomorphic lymphoma (*Fig. 315.6b*). While in milder cases, stopping of calcineurin inhibitor therapy may lead to tumor regression, others with monoclonal elements and CD20 expression (*Fig. 315.6c*) improve after therapy with rituximab. Patients with undifferentiated lymphoproliferative diseases have a much less favorable prognosis despite intensive chemotherapy. Lymphomas, which appear beyond the early transplant phase after 1 or 2 years, are more likely to be Non-Hodgkin lymphomas. Then a standard chemotherapy is required. All children with chronic

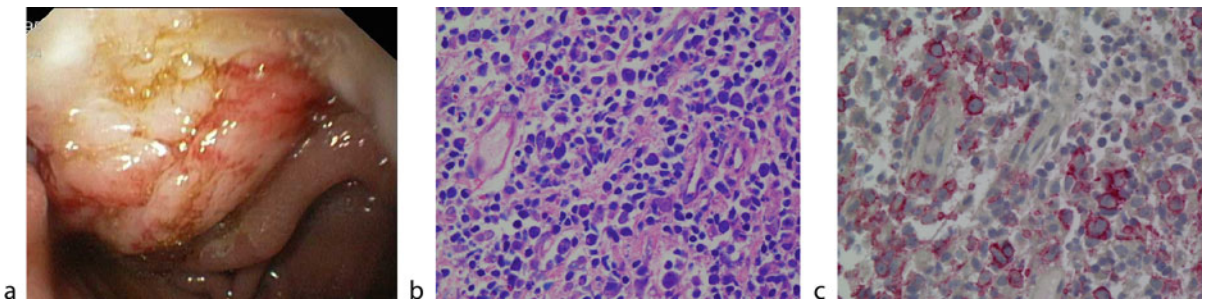

Figure 315.6

(a) Six years old boy 8 months after transplantation. Endoscopy of the distal esophagus: polypous swelling in the cardia region. (b) HE staining of the biopsy reveals a monomorphic lymphoma. (c) Biopsy of the lymphoproliferation with positive staining for the marker CD20

immunosuppressive therapy have an increased risk to develop skin cancer. Therefore, special attention must be given to suspicious skin lesions.

Cardiovascular Problems

An unsolved problem after solid organ transplantation is a high cardiovascular mortality. Major risk factors for that are long time on dialysis, chronic hyperphosphatemia, hyperlipidemia, arterial hypertension, and long-term administration of steroids and calcineurin inhibitors. Recent studies have shown calcifications in the coronary arteries in young adults and an increased arterial stiffness in patients with renal insufficiency on dialysis and also after transplantation. Future research for long-term rehabilitation for patients with chronic renal failure and transplantation should address the high impact of cardiovascular disease on patient's survival.

Noncompliance

Worldwide there are reports of high rejection rates and up to 20% of organ losses in young adolescents. Patients who are transferred to adult units are at highest risk. This age group has been described not to follow the multidrug regimes. Adolescents have an increased readiness for risks and decreased capability to estimate the future consequences of their acts and omissions. They are teenagers and they want to behave like teenagers. Pediatrics transplant centers pay increasing attention to this problem and many programs are under development to improve the noncompliance in young adolescents.

Summary

Pediatric kidney transplantation is a well-established therapy for chronic renal failure. Sophisticated surgical techniques and modern drug combinations lead to excellent short-term results; however, long-term problems like deterioration of graft function, infections, and cardiovascular morbidity beyond the child and adolescent phase remain challenges for future research activities.

316 Practical Approach to Anemia in Children

Ahmad A. Mallouh

Introduction

Like any other health problem, the etiologic diagnosis of anemia depends on interpreting information obtained from history, physical examination, and appropriately ordered laboratory tests. Before embarking on an extensive and expensive "laundry list" of laboratory testing, the physician needs to determine if the patient is truly anemic, taking into consideration the normal values for age, sex, and ethnicity (*Table 316.1*).

Classification of Anemia in Children

Anemia is classified into two ways: erythrokinetic (physiologic) and morphologic classification.

Erythrokinetic (Physiologic) Classification

This classification utilizes the pathophysiology of anemia, whether it resulted from (a) underproduction (bone marrow suppression or infiltration), (b) shortened red blood cell (RBC) survival (hemolysis), (c) blood loss, or (d) the combination of more than one factor. A normal or low reticulocyte count indicates bone marrow suppression (aplasia or hypoplasia), infiltration (malignancy or storage disease), replacement (myelofibrosis or osteopetroses), deficient or poor utilization of iron (iron deficiency, anemia of chronic disease) or acute blood loss or early acute hemolysis (before the bone marrow has the time to respond), while a high reticulocyte count and/or the presence of nucleated RBCs in the peripheral circulation indicate an active bone marrow, such as hemolysis, recovery from transient aplasia, response to anemia caused by acute blood loss, or response to iron therapy in iron deficient patients (*Table 316.2*).

Morphologic Classification

Based on the RBC morphology, anemia is classified according to the RBC size (mean corpuscular volume or MCV), mean hemoglobin concentration (MCHC), or mean hemoglobin content (MCH). Morphologically, anemia can be classified as normocytic (normal MCV), microcytic (low MCV), or macrocytic (high MCV). Depending on the hemoglobin concentration and content, anemias can be classified as normochromic (normal MCHC and MCH) or hypochromic (low MCHC and MCH). Development changes of these parameters should be taken in to consideration (*Tables 316.1* and *316.3*).

Clinical Findings

History, physical examination, results from a complete blood count (CBC), and inspection of a well-prepared blood smear are the essential first steps in the workup for anemia. A systematic analysis of the information obtained in such a way enables the physician to establish a correct diagnosis in some cases and narrow the differential diagnosis for others, thus limiting the number of the needed specific tests.

History

Age, gender, ethnicity, dietary history, history of acute or repeated blood loss, dark colored stools, history suggestive of associated or causative diseases (fever, arthritis, skin rash, weight loss), history suggestive of inflammatory bowel disease, prolonged menstruation in teenaged girls, history of pica, history of drug or toxin exposure, past history of blood transfusion, present or past history of jaundice and red colored urine, family history of anemia, blood transfusion, splenectomy, or cholecystectomy represent only a short list of important information which direct the workup of children with anemia. These factors, alone or in various combinations, can direct the investigation toward or away from a possible diagnosis. Inherited anemias usually present early in childhood. RBC membrane disorders (hereditary spherocytosis, hereditary elliptocytosis, hereditary pyropoikilocytosis, etc.),

Women	14.0	4.80	42	87	29	34	1.0

RBC red blood cells, *MCV* mean corpuscular volume, *MCH* mean corpuscular hemoglobin, *MCHC* mean corpuscular hemoglobin concentration

disorders of alpha globin chain (α-thalassemia), and RBC enzymopathies (G6PD, pyruvate kinase deficiency) may present in the neonatal period, while beta globin chain disorders (sickle cell disease, β-thalassemia) do not manifest clinically until at least 2–3 months of age. X-linked anemias, such as G6PD deficiency, affect mainly boys. However, it should be kept in mind that homozygous females are not uncommon in communities with high rates of consanguineous marriage. Race and ethnicity help in directing the investigations toward certain disease entities. Sickle cell disease is common in people of African origin, parts of the Arabian Peninsula, and parts of India. β-thalassemia is common in people of Mediterranean origin. α-thalassemia is common in people of African origin, Arabs in the Gulf area and in Southeast Asia. Hemoglobin E is common in Southeast Asian origin and parts of the Indian subcontinent. G6PD deficiency is common in people of Mediterranean origin (Greek, Arabs, Sardinians), in people of African origin, and in Southeast Asia. Nutritional anemia (iron deficiency, folate deficiency) and chronic lead poisoning are more common in children of low socioeconomic class. Iron deficiency is common in exclusively breast-fed infants and those taking non-iron-fortified formulas. Folate deficiency may occur in infants exclusively fed on goat's milk. Vitamin B12 deficiency may occur in vegetarians. Acute blood loss is usually evident and can be a cause of significant anemia depending on the amount of the lost blood. Chronic and repeated blood loss, on the other hand, can be missed without a specific and detailed history. Heavy menstrual periods, upper or lower gastrointestinal tract bleeding, manifesting as hemopytisis, melena, or fresh blood in the stools (esophageal varices, peptic ulcer, Meckle's diverticulum, intestinal hemangioma) might be the cause of iron deficiency anemia. A history of jaundice and/or dark colored urine suggests an acute hemolytic anemia. Hemolytic anemia after ingestion of fava beans, sulfa drugs, or antimalarial medications suggests the diagnosis G6PD deficiency. Aplastic anemia may result from ingestion of benzene, chemotherapeutic drugs, or myelosuppresive medication, i.e., chloramphenicol. Exposure to certain "folk medications" may lead to chronic lead poisoning.

Table 316.2
Erythrokinetic classification of anemia

Decreased or absent production of red blood cells
Aplastic/hypoplastic anemia
Congenital aplastic/hypoplastic anemia
Fanconi anemia
Diamond–Blackfan anemia
Dyskeratosis congenital
Schwachman–Diamond syndrome (pancreatic insufficiency and bone marrow failure syndrome)
Paroxysmal nocturnal hemoglobinuria, acquired aplastic/hypoplastic anemia
Acquired constitutional aplastic anemia (idiopathic or secondary to known causes, i.e., post hepatitis)
Transient erythroblastopenia of childhood (TEC).
Aplastic anemia secondary to Parvovirus B 19 in patients with chronic hemolytic anemia
Bone marrow failure due to drugs, toxins, irradiation, or infection
Bone marrow replacement malignancies (leukemia, lymphoma, disseminated solid tumor)
Myelofibrosis
Osteopetrosis
Myelodysplasia
Deficiency syndromes due to deficiency of substance needed for red blood cell production
Iron deficiency
Vitamin B12 deficiency
Folate deficiency
Copper deficiency
Zinc deficiency
Pyridoxine deficiency
Thiamine deficiency
Protein deficiency
Anemia secondary to erythropoietin deficiency
Chronic renal failure
Anemia of prematurity
Chronic malnutrition
Hypothyroidism, hypopituitarism
Ineffective erythropoiesis
Dyserythropoietic anemias
Vitamin B12 and folate deficiencies
Sideroblastic anemia
Chronic lead poisoning
Thalassemia syndrome
Thiamine-responsive megaloblastic anemias
Orotic aciduria with megaloblastic anemia
Ineffective utilization of iron by bone marrow
Chronic inflammatory diseases
Acute or chronic infection
Viral diseases
Excessive red blood cell destruction (shortened red blood cell survival)
Hemolytic anemias
Congenital hemolytic anemias
Hemoglobinopathies (sickle cell disease, hemoglobin C, hemoglobin E, etc.)
Thalassemia syndrome (α and β thalassemia)
Unstable hemoglobin mutation
Red blood cell membrane disorders (hereditary spherocytosis, hereditary elliptocytosis, hereditary pyropoikilocytosis, hereditary pyknocytosis, hereditary stomatocytosis, and paroxysmal nocturnal hemoglobinuria)
Red blood cells, enzyme deficiency (glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency)
Acquired hemolytic anemias
Immune hemolytic anemia
Autoimmune hemolytic anemia
Allo-immune hemolytic anemia
Drug-induced immune hemolytic anemia
Immune hemolytic anemia associated with collagen-vascular diseases, lymphoma, or infections
Nonimmune acquired hemolytic anemia
Disseminated intravascular coagulopathy (DIC)
Hemolytic–uremic syndrome (HUS)
Thrombotic thrombocytopenic purpura (TTP)
Kasabach–Merritt syndrome (KMS)
Hemolytic anemia associated with bacterial or parasitic infection
Microangiopathic hemolytic anemia associated with congenital heart disease or prosthetic heart valves
Hypersplenism
Acute splenic sequestration (in sickle cell disease)
Anemia due to blood loss

Associated symptoms can direct investigation to certain diagnostic entities. History of recurrent painful attacks suggests sickle cell disease. History of petecheal rash, echymosis, epistaxis, or easy bruisability may indicate thrombocytopenia. History of severe or recurrent infection may indicate the presence of severe neutropenia

Table 316.3
Morphologic classification of anemia

Microcytic anemias
Iron deficiency anemia
Thalassemia syndromes
Chronic lead poisoning
Sideroblastic anemia
Pyridoxine deficiency/dependency
Anemia of chronic inflammatory disease
Some anemias associated with unstable hemoglobins
Macrocytic anemia
A. With megaloblastic features
Vitamin B1 deficiency
Folate deficiency
Orotic aciduria
Thiamine-responsive megaloblastic anemia
Drug-induced megaloblastic anemia (methotrexate, 6MP, anticonvulsants, Bactrim)
B. Without megaloblastic features
Reticulocytosis
Aplastic/hypoplastic anemia (may be normocytic or macrocytic)
Dyserythropoietic anemia
Liver disease
Hypothyroidism
Normocytic anemia
Aplastic anemia
Hemoglobinopathies
Red blood cell membrane disorders
Red blood cell enzymopathies
Immune hemolytic anemia
Microangiopathic hemolytic anemia
Acute blood loss
Hypersplenism
Anemia associated with acute infection
Anemia of chronic renal failure

either as a separate entity or in association with pancytopenia, i.e., aplastic anemia or hypersplenism. A history of systemic disease may give a clue to the etiologic diagnosis of the anemia. A history of chronic disease may cause anemia either by improper utilization of iron by the bone marrow, malabsorption, poor diet intake, or occult blood loss. A past history of blood transfusion suggests a chronic or recurrent process. A history of neonatal jaundice and/or anemia may suggest an inherited disease. A past history of cholelithiasis suggests a chronic hemolytic process. A family history of a specific type of anemia suggests a similar diagnosis in the child. Family history of splenectomy or cholelithiasis at a young age suggests an inherited chronic hemolytic anemia. Family history of a hypochromic microcytic anemia not responding to iron therapy in a parent or sibling suggests the diagnosis of thalassemia.

Physical Examination

The clinical manifestations of anemia are nonspecific. They are related to the severity and acuteness of the anemia. Pallor, tachycardia, and lethargy may be present in severe anemia; however, these are not sensitive, especially in chronic anemia. Anemia is often diagnosed on routine CBC done prior to a surgical procedure, routine clinic visit, or on hospitalization for other medical problems. Associated findings may suggest the etiologic diagnosis:

- Hepatosplenomegaly and chronic hypochromic microcytic hemolytic anemia together with family history or certain ethnic background suggests the diagnosis of β-thalassemia major
- Splenomegaly with chronic hemolytic anemia and family history of splenectomy or cholecystectomy suggest hereditary spherocytosis
- Lymphadenopathy with or without hepatosplenomegaly associated with a petecheal rash may suggest hematologic malignancy
- Jaundice and/or dark colored urine suggest a hemolytic process
- A petecheal rash and/or ecchymoses suggest pancytopenia
- Various dysmorphic features may suggest a specific type of anemia, i.e., Fanconi anemia, Blackfan–Diamond syndrome, or thalassemia major

Complete Blood Count and Inspection of the Blood Smear

The physician needs to look at and try to interpret every item in the CBC. RBC indices form the bases of the morphologic classification of anemia (*Table 316.3*). The degree of bone marrow activity forms the basis of the erythrokinetic classification of anemia (*Table 316.2*). Some types of anemia can be diagnosed

simply by inspecting a peripheral blood smear (RBC membrane disorders and microangiopathic anemias). Target cells are suggestive of hemoglobinopathies. The presence of hypersegmented neutrophils is suggestive of folic acid or vitamin B12 deficiency. Abnormal malignant cells (blasts) are suggestive of leukemia. Basophilic stippling of the RBCs suggests chronic lead poisoning (although, it must be remembered that basophilic stippling may be present in other disease entities such as congenital nonspherocytic hemolytic anemias and unstable hemoglobins). Thrombocytopenia and/or neutropenia indicate involvement of other cellular blood elements rather than isolated anemia.

Diagnosis of Anemia

Once it is decided that a patient has anemia, several questions must be answered prior to a plan for specific laboratory testing is pursued:

- Does the patient have isolated anemia or pancytopenia?
- Is the anemia due to underproduction (bone marrow failure), hyperdestruction (hemolysis) or underproduction on top of hyperdestruction (aplastic crisis in patients with chronic hemolytic anemia)?
- Is the anemia acute or chronic?
- Is there a family history of a similar condition?
- Are there any dysmorphic features present on physical exam?
- Are the RBCs microcytic, normocytic, or microcytic?

Further investigations should be planned using the answers to these questions and using the morphologic and erythrokinetic classification.

Hypochromic Microcytic Anemia

For practical purposes, the differential diagnosis of hypochromic microcytic anemia in children includes: iron deficiency anemia, β-thalassemia trait, hemoglobin E disease, α-thalassemia trait, chronic lead poisoning, anemia of chronic disease, and the sideroblastic anemias (*Tables 316.4* and *316.5*). Hemoglobin electrophoresis is the preferred diagnostic test for β-thalassemia trait. A high hemoglobin A2 level is diagnostic. Hemoglobin A2, however, can be normal if β-thalassemia trait is associated with severe iron deficiency, δ/β-thalassemia, or α-thalassemia. Hemoglobin F is also often elevated in β-thalassemia trait. Hemoglobin electrophoresis also is diagnostic for other hemoglobinopathies with microcytic anemia, i.e., Hb E, Hb C, Hb D, and Hb H. Low serum iron, high total iron binding capacity (TIBC), and low serum ferritin are characteristic of iron deficiency. The serum ferritin level is the most sensitive and specific none invasive test, as it is a reflection of iron stores. Serum

Table 316.4
Differential diagnosis and expected laboratory values for microcytic hypochromic anemia

Laboratory value[a]	Iron deficiency	β-thalassemia trait	α-thalassemia trait	Hemoglobin H disease	Chronic lead poison	Sideroblastic anemia	Chronic disease
MCV	↓	↓	↓	↓	↓	↓ or N	↓ or N
RDW	↑	N	N	↑	N	↑	N
Parents' MCV	N	↓ One parent	↓ One parent	↓ One parent	N	N	N

Table 316.5
Laboratory values in iron deficiency anemia versus anemia of chronic disease

	Normal range	Iron deficiency (mean)	Chronic disease (mean)
Iron (μg/dl)	70–190	≤30	>30
TIBC (μg/dl)	250–400	≥450	>200
Transferrin saturation	30	≤7	≤14
Ferritin	20–220	≤10	≤150
Macrophage iron in marrow	2+	0	3+

TIBC total iron-binding capacity

ferritin, however, is an acute phase reactant and can be normal if iron deficiency is associated with inflammatory disease, infection, hepatitis, or pregnancy. A therapeutic trial of iron therapy can be used as a diagnostic and therapeutic test. A significant rise in the reticulocyte count after 5–7 days or a significant rise of hemoglobin (1–1.5 gms/dl) after one month of oral iron therapy are diagnostic of iron deficiency. Failure to respond almost always exclude iron deficiency. It should be remembered; however that noncompliance is one of the most causes of failure to respond. Isolated iron malabsorbtion is extremly rare. The RDW and Mentzer index (MCV/RBC) are useful in differentiating iron deficiency from thalassemia trait. A higher RDW (>20) and high Mentzer index (>13) are suggestive of iron deficiency. α-thalassemia is diagnosed by exclusion, except for hemoglobin H disease which can be diagnosed by supravital stain (brilliant cresyle blue) and hemoglobin electrophoresis. The presence of high levels of hemoglobin Barts in newborn blood is diagnostic of α-thalassemia trait.

Chronic lead poisoning is characterized by hypochromic microcytic anemia and basophilic stippling of the RBCs. High whole blood lead level is diagnostic. The sideroblastic anemias are rare in children. Bone marrow examination is required for diagnosis. The presence of ringed sideroblasts in the bone marrow is diagnostic. Anemia of chronic disease can be differentiated from iron deficiency by (in addition to the clinical picture) normal to high serum iron and serum ferritin and normal TIBC.

Macrocytic Anemias

Macrocytosis denotes large red blood cells (high MCV). While megaloblastic anemia is the most common cause of macrocytosis and while megaloblasts are by definition macrocytes, not every macrocyte is a megaloblast. Megaloblastic anemia results from impaired DNA synthesis resulting in large RBCs. Bone marrow RBC precursors are dysblastic with the maturation of the nucleus, and cytoplasm is asynchronous. Macrocytic anemias can be divided into two subtypes: the megaloblastic anemias and the non-megaloblastic macrocytic anemias.

Megaloblastic Anemia

Megaloblastic anemias are characterized by macrocytic RBCs, macro-ovalocytes, hypersegmented neutrophils, and megaloblastic erythroid precursors in the bone marrow. The most common causes of megaloblastic anemia are folate deficiency (diagnosis is confirmed by low RBC folate level) and vitamin B12 deficiency (diagnosis is made by low serum vitamin B12 level).

Further studies are needed to confirm the diagnosis of megaloblastic anemia and to identify an etiology (e.g., the Schilling test, anti-parietal cell antibodies, anti-intrinsic factor antibody). Several drugs interfere with DNA synthesis and cause megaloblastic changes in the RBC precursors with or without anemia. These drugs include anticonvulsants (phenytoin, phenobarbital), chemotherapeutic agents (methotrexate, 6-mercaptopurine, hydroxyurea), and trimethoprim-sulfamethoxazole. Diagnosis in these cases is clearly based on the history of drug intake. Several inborn errors of metabolism can cause megaloblastic anemia (orotic aciduria, homocystinuria, methylemalonic aciduria). Patients affected by these conditions have complex clinical manifestations. The diagnosis depends on the clinical picture and specific tests for the suspected disease. Thiamine-responsive anemia is usually associated with sideroblastc anemia. The diagnosis is suggested by the exclusion of other causes of megaloblastosis and response to thiamine therapy.

Non-megaloblastic Macrocytic Anemia

Macrocytic anemia without megaloblastic bone marrow changes can be due to reticulocytosis, aplastic anemia, Blackfan–Diamond anemia, myelodysplastic syndromes, and dyserythropoietic anemias. Reticulocytes are large cells. A high reticulocyte count can be the cause of an elevated MCV. The diagnosis of aplastic anemia is suggested by reticulocytopenia and is confirmed by the examination of bone marrow biopsy. Myelodysplastic syndromes and dyserythropoietic anemias require bone marrow examination for diagnosis.

Normocytic Anemias

Normocytic anemias are due to either RBC underproduction or hyperdestruction (hemolysis):

1. Anemias due to underproduction (bone marrow failure): This group includes the aplastic anemias (congenital or acquired), bone marrow infiltration (leukemia, lymphoma, disseminated malignant solid tumors etc.), myelofibrosis, and osteopetrosis. In addition to the clinical picture, which may suggest the diagnosis in some cases, these anemias are characterized by a low reticulocyte count. The diagnosis is confirmed by bone marrow examination.
2. Anemias due to hyperdestruction (hemolytic anemias): These anemias are characterized by laboratory evidence of hyperactive bone marrow (high reticulocytes count and/or the presence of nucleated RBCS in the peripheral circulation). They include:
   (a) Red blood cells membrane disorders such as hereditary spherocytosis, hereditary elliptocytosis, and hereditary pyropoikilocytosis. A family history of one of these diseases, a family history of splenectomy and/or cholelithiasis at a young age may suggest the diagnosis. These diagnoses are confirmed by inspection of a well-prepared blood smear. Specific tests such as the osmotic fragility may be required to confirm the diagnosis.
   (b) Hemoglobinopathies (sickle cell disease, Hb C, Hb D) are diagnosed by hemoglobin electrophoresis.
   (c) Red blood cells enzymopathies (G6PD deficiency, pyruvate kinase deficiency) are diagnosed by specific enzyme assays.
   (d) Autoimmune hemolytic anemia is diagnosed by a positive direct anti-globulin test.
   (e) The microangiopathic hemolytic anemias (DIC, hemolytic uremic syndrome) are diagnosed by inspection of the peripheral blood smear. Thrombocytopenia and schistocytes (fragmented RBCs) are often present.

317 Immune Hemolytic Disease of the Newborn

Jason Glover · Bill H. Chang

Definition/Classification

Hemolytic disease of the newborn (HDN) is a form of IgG-mediated red blood cell (RBC) destruction whereby maternal antibodies cross the placenta and cause hemolytic anemia in the newborn. It is classified as a congenital anemia due to peripheral destruction of the red blood cells.

Etiology

The first description of HDN is thought to have been in 1609 by a French midwife named Louyse Bourgeois about a twin birth. The first infant died of hydrops fetalis and the second died of jaundice and opisthotonis a few days later. It was not until 1932 when Diamond et al. coined the term "erythroblastosis fetalis" as a syndrome linking congenital anemia, jaundice, and hydrops fetalis with evidence of extramedullary hematopoiesis and erythroblastemia. During the 1930s and 1940s, Landsteiner and Weiner described the Rhesus (Rh) blood groups, while Levine and associates described the link between the Rh groups and HDN. This description involved a case of a woman who had a recent delivery of a hydropic stillborn then had a severe transfusion reaction to her husband's blood. Levine postulated that she had become sensitized to her husband's blood from the fetus. They later showed that the mother was Rh-negative and her husband was Rh-positive. Later, Chown's description of how Rh-negative mothers could be sensitized by a transplacental hemorrhage led to clinical trials in both the UK and the US suppressing allo-immunization. Women given anti-D IgG intramuscularly at the time of delivery had a dramatic decrease in the risk of HDN. Therefore, the history and management of HDN have led to many breakthroughs including immunoprophylaxis using human antibodies and development of screening programs for maternal blood group antibodies.

Epidemiology

Prior to immunoprophylaxis, HDN due to the Rh was a major source of long-term morbidity and early mortality in the developing fetus and newborn. Since the majority of HDN is due to Rh allo-immunization, the incidence is closely linked with the proportion of a population who are Rh-negative. For example, about 10% of live births in the UK were of Rh-positive children to Rh-negative mothers. It is thought that about 1 pregnancy in 200 is susceptible to hemolytic disease of the newborn with a historical mortality rate of 1 in 400. Prior to the use of immunoprophylaxis, approximately 16% of Rh-negative women became sensitized in their first ABO compatible Rh-positive pregnancy and one half would have detectable anti-D immunoglobulin 6 months after delivery. This usually occurs as a result of exposure to fetal antigens during pregnancy. Although fetal cells can be detected in maternal blood during all trimesters of most pregnancies, the largest exposure to fetal blood occurs in the third trimester and delivery. Interestingly, about 25% of D-negative women will either not become sensitized or will become tolerant. Partial protection can also come from ABO incompatibility by unknown mechanisms. By their fifth pregnancy the probability of sensitization is about 50%. With the advent of Rh immunoprophylaxis, the incidence of HDN due to Rh has decreased to approximately 1.8% of susceptible pregnancies.

Pathogenesis

The Rh blood group system is a complex system comprised of a tetramer of several proteins. Rh-positive blood type is mainly comprised of one D subunit, one CE subunit, and two RhAg subunits, whereas Rh-negative blood type consists only of two CE subunits and two RhAg subunits. Therefore, sensitization occurs due to exposure of the RhD subunit. At first exposure a primary

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_317,

weak IgM response will not affect the fetus because IgM does not cross the placenta. The subsequent IgG response will then affect the fetus causing hemolysis. After a primary response, a subsequent exposure produces a rapid IgG response that then crosses the placenta. Therefore, repeated exposures increase the severity of HDN in subsequent pregnancies. The fundamental cause of erythroblastosis is an immune-mediated red cell destruction causing increased erythropoiesis. Due to peripheral red cell destruction, extramedullary erythropoiesis can be found in the liver, spleen, kidneys, skin, intestines, and adrenal glands with subsequent immature nucleated RBCs found in the peripheral blood.

Other rare causes of varying degrees of HDN are due to at least 26 other blood group systems. These molecules include transporter and channels such as Diego or Kidd, pathogen receptors such as Duffy, adhesion molecules, enzymes such as ABO and Kell, structural proteins, and complement receptors. With the advent of immunoprophylaxis and decreasing family sizes, the incidence of HDN due to Rh has been decreasing whereas other causes appear to be slightly increasing. Of the multitude of antibodies that have been reported to cause HDN, most have been single case reports or cause a mild form of the disease. In contrast, disease caused by antibodies to Kell has been described as severe. It is second to RhD in its immunizing potential. Since this antigen is expressed in early erythroid progenitors, it may suppress erythrogenesis causing early hydrops. HDN due to ABO incompatibility accounts for approximately 5% of infants with jaundice. It usually causes a milder form of HDN except in southeast Asia, Africa, and Latin America for unknown reasons.

Pathology

Once sensitization occurs, the factors affecting the severity of HDN include the placental transfer of antibody, the characteristics of the antibody and antigen, the maturation of the spleen, and fetal erythropoiesis. All four IgG subclasses can be transported across the placenta with fetal levels reaching the mother's levels by 17–20 weeks' gestation. Typically, in Rh HDN, antibodies do not fix complement. Instead, Fc-mediated pathways lead to opsonization of the RBCs. Anti-D coated RBCs adhere to macrophages in rosettes, especially in the spleen. The RBCs are then consumed by the macrophages, or their membranes become damaged and fragile leading to lysis. Antibody-dependent cellular toxicity also accounts for some RBC destruction through myeloid and NK cell activity.

On occasion antibodies that bind to the RBCs can fix complement (as in ABO incompatible transfusion reactions). If a high enough concentration fixes complement, red cell extravascular destruction occurs which can lead to hemoglobinemia, shock, and disseminated intravascular coagulopathy. End products of red cell destruction are then predominantly cleared by the liver. Antigens such as Rh and Kell are restricted to the erythroid cells expressed in the fetus and neonate. Therefore, infants with this disease can present in hydrops due to early severe anemia.

Clinical Manifestation

Since the 1950s, degrees of severity of HDN have been used to assist in classification, research, and treatment of the disease. Mild HDN is described as having antibody-coated red cells that are identifiable by Coomb's test, without an associated anemia. This group accounts for close to 50% of the affected fetuses and requires almost no treatment. Infants with moderate HDN have elevated bilirubin and are at risk for neural toxicity and kernicterus without treatment. They will have signs of anemia without acidosis or signs of hydrops. Peripheral blood will show polychromasia, anisocytosis, and reticulocytosis. This group accounts for approximately 30% of affected fetuses and requires intensive phototherapy and exchange transfusion to manage the jaundice. Severe HDN present with severe anemia, hydrops, or impending hydrops and can die before, during, or after birth without intensive management (including intrauterine transfusion). If untreated, one half will develop hydrops between 18 and 34 weeks' gestation with polyhydramnios. Ascites, pleural, and pericardial effusions may develop with subsequent compression hypoplasia of the lungs making respiration difficult at birth.

Diagnosis

Initial prenatal diagnosis for infants at risk of Rh-mediated HDN can be performed by blood type and antibody screen on the mother. A thorough prenatal history should include whether the mother had previous pregnancies and/or blood transfusions. Maternal antibody screening and typing for both ABO and D-antigen is the standard of care at the first prenatal visit. This should include elective abortions, due to the sensitization of the mother and risk of HDN to complicate future

pregnancies. In a mother who is Rh-negative and an initial antibody screen is weak or negative, testing should be repeated at 24–28 weeks into the pregnancy, prior to the administration of anti-D immunoglobulin. Mothers with maternal serum red cell antibody titers $\geq$1:16 should then undergo Doppler ultrasound for peak systolic blood flow of the middle cerebral artery to predict moderate to severe anemia. Fetuses diagnosed with early anemia should undergo prenatal treatment.

In 1997, Lo et al. were able to identify the presence of free fetal DNA from a maternal blood sample. This discovery had obvious implications in reducing the need for invasive procedures such as chorionic villus sampling and amniocentesis to determine a fetus' blood type. The fetal DNA obtained from the mother's serum can be used to determine the fetal blood group phenotype for the D-antigen as well as the minor antigens c, E, C, K. Prenatal determination of fetal D-antigen status may reduce the rate of unnecessary anti-D immunoglobulin injections (40% of D-negative mothers will have a D-negative fetus). Typing of all D-negative mothers has been determined to be feasible and will likely become standard of care.

HDN in the newborn is typically diagnosed through clinical symptoms and laboratory tests that are common to any hemolytic process. Clinical symptoms include jaundice, pallor, hepatosplenomegaly, and may progress to tachycardia. The jaundice associated with HDN often presents within the first 24 h of life. A thorough laboratory evaluation would include complete blood counts with differential, manual examination of the smear for schistocytes, and increased reticulocytes. An elevated unconjugated serum bilirubin can aid in establishing the diagnosis of HDN from other types of jaundice, assessing the degree of hemolysis, and estimating the risk of developing kernicterus. Microspherocytes may be seen in HDN due to ABO incompatibility but is usually not seen in HDN due to Rh incompatibility.

Either the direct antiglobulin test (Coomb's) or the indirect antigen test may be used to detect an antibody-mediated HDN. The direct antiglobulin test is utilized to show the presence of maternal antibody on the child's red blood cells. The maternal antibody will cause agglutination of the child's red blood cells in a standard serum that is known to contain antibodies to IgG. An indirect antiglobulin test is used to screen for very low concentrations of IgG antibodies present in the mother's serum that can cross the placenta. The Kleihauer-Betke test can be used to estimate the degree of fetal hemoglobin transferred from either placental hemorrhage, or the normal transfer of the fetal components of the placenta.

Differential Diagnosis

The differential diagnosis of HDN is dependent on the severity of the disease. Causes of hydrops fetalis in the fetus or newborn include other blood disorders such as severe iron deficiency anemia; alpha thalassemia; cardiac dysrhythmias such as supraventricular tachycardia; metabolic disorders such as lysosomal storage diseases; genetic disorders such as Turner's (XO) Syndrome; maternal infections such as syphilis and parvovirus B19; and tumors such as teratomas.

Neonatal jaundice can be subdivided into indirect (unconjugated) and direct (conjugated) hyperbilirubinemia. Causes of unconjugated hyperbilirubinemia, if left untreated may develop into kernicterus, including HDN, bacterial and viral sepsis, normal physiologic jaundice, dehydration, cephalohematomas, hypothyroidism, or metabolic disorders such as Crigler–Najjar syndrome and Gilbert's Syndrome. The etiology of hemolysis in a newborn (*Table 317.1*) should also include the broad categories of sepsis/infection, red blood cell membrane defects, red blood cell enzyme deficiencies, hemoglobinopathies, and medication associated red cell destruction.

Treatment

Maternal Treatment

Attempts to suppress the maternal immune response in cases with a prior history of HDN have been attempted. Although Rh-immune globulin is effective in preventing the mother's immune response, it is known to be ineffective in stopping a response once it has begun. Plasma exchange of the mother has also been attempted to lower the maternal antibody levels. However, this decrease is only transient, and higher rebound can occur. The procedure is costly, can be painful, and vascular access is necessary. Administration of pooled IVIG to the mother has also been attempted in cases of expected severe disease, although the exact mechanism of action is not well defined. Clinical research trials are continuing to investigate IVIG's safety and efficacy.

Fetal Treatment

Prior to immunoprophylaxis, 8% of fetuses would develop hydrops before 32 weeks making early intervention important for the outcome of the fetus. Early attempts at intraperitoneal fetal transfusion proved to be efficacious.

Table 317.1
Causes of hemolytic anemias in the newborn

General etiologies	Specific etiologies	Special features
Immune-mediated	– Rh incompatibility – ABO incompatibility – Minor antigen mismatch: Kell, Duffy	– The most common cause of severe early jaundice
Sepsis	– Bacterial – Viral sepsis (such as herpes simplex viremia)	Jaundice may be conjugated and unconjugated, due to hemolysis- and endotoxin-mediated reduction of bile secretion
RBC membrane defect	– Hereditary spherocytosis – Hereditary elliptocytosis – Hereditary stomatocytosis – Hereditary ovalocytosis	– Family history may be positive for anemia and gallstones at an age <40 years
RBC enzyme deficiency	– Glucose-6-phosphate – Pyruvate kinase – Hexokinase – Glucose-6-phosphate isomerase – Phosphofructokinase – Aldolase – Triose phophate – Glyceraldehyde-3-phophate isomerase – Phosphoglycerate	– Rare other than G6PD – Associated with metabolic and severe neurologic disorders
Hemoglobinopathies	– Thalassemias – Sickle cell diseases	β-thalassemia may present with significant severe hemolysis
Drug-induced	– Oxytocin – Drugs that cause oxidative stress in G6PD	– May be worsened by drug passage in the breast milk – May increase the hemolysis in G6PD

Later, fetal intravascular transfusion became the preferable procedure as it dramatically reversed hydrops and increased survival. This procedure is usually performed under ultrasound guidance into the umbilical vein at its insertion into the placenta. Intraperitoneal fetal transfusion remains a technique used for the severely affected fetus with small cord vessels, or more commonly, the older fetus where fetal size and placement of the placenta preclude access to the umbilical vessels.

Neonatal Treatment

General Care

Fortunately, in the post-Rh-immunoprophylaxis era, cases of severe hydrops fetalis are rare. This has made the study of interventions in the management of severe HDN in clinical trials difficult. Many of the procedures such as drainage of pleural and peritoneal effusions, and what level to perform exchange transfusion remain studied in small numbers. Standard treatment of issues from prematurity such as surfactant administration need to be more aggressive in the child with HDN as they may compound systemic problems. Top-up transfusions should be considered in anemic neonates who are acidotic, hypoxic, and hypotensive. However, if multiple top-up transfusions are needed then iron studies should be followed for signs of overload, especially in cases of liver dysfunction.

Infants with mild to moderate disease should undergo early and aggressive phototherapy with both spotlights and a fiber-optic blanket. A bilirubin level at which to institute phototherapy is largely arbitrary; however, it is accepted that premature infants should start phototherapy at a much lower level. The rate of rise of the bilirubin may be more concerning than a stably high level. Although dehydration is a potential risk of phototherapy, it is less compared to the risks associated with exchange transfusion.

Feeding should be encouraged early as long as exchange transfusion is not anticipated, given exchange transfusion's increased risk of necrotizing enterocolitis.

Although breast milk and colostrum contain Rh antibodies, very little antibody is absorbed across the intestine of the infant. Folate supplementation may be necessary in children who have had exchange transfusion from adult sources which have a lower folate level. Folic acid supplementation (100–200 μg/day) is recommended for several weeks after exchange transfusion. Iron supplementation is not needed in cases of HDN as the iron will be reabsorbed, and additional transfusion may cause overload. Vitamin B12 is usually adequate in the mother's breast milk.

Exchange Transfusion

Originally performed in the 1920s through the anterior fontanelle, exchange transfusion is now performed using umbilical catheterizations. This technique not only replaces the antigen-coated RBCs of the newborn with fresh RBCs, but also corrects the anemia, prevents hyperbilirubinemia, and modestly removes unbound anti-D antibody. Exchange transfusion can produce a significant drop in neutrophil levels and a reduction in platelets that are both generally well tolerated. Other complications include apnea and bradycardia, hypocalcemia, bleeding, and catheter-associated thrombosis. These complications are mostly mild and asymptomatic but rarely can be catastrophic leading to the death of the patient. Because of these risks, there are no specific thresholds for the indication of exchange transfusion. Instead, most providers will perform the procedure on their experience for significant anemia or when conservative measures do not control the bilirubin. Since the risk of serious complications are higher in the ill patient versus the mildly symptomatic patient, early exchange may be warranted.

IVIG

Several small studies have examined the use of IVIG on the infant to potentially treat HDN. However, there is a lack of evidence to indicate the safety and efficacy of IVIG. Therefore, IVIG should only be recommended in a well-defined clinical trial.

Prognosis

Both the morbidity and mortality of the disease is dependent on the successful treatment of the hemolysis and anemia. With successful prevention and treatment there should be minimal long-term effects from this disease. Patients with mild HDN (about 50% of cases) will most likely suffer no long-term effects. Newborns with moderate disease (about 30% of cases), however, are at risk for kernicterus if they do not receive treatment. Again, with successful treatment of the anemia and hyperbilirubinemia, minimal sequelae should occur. The maternal anti-D-titers of these infants are usually $>$1:64. They will have some degree of a symptomatic anemia but are not usually hydropic. In the past they would have received exchange transfusion, however, with current aggressive management with intense phototherapy this may be avoided. Cases of severe HDN have hydrops or are progressing toward hydrops in utero. They will die in utero or shortly after birth if aggressive interventions such as fetal intravascular transfusion are not undertaken. Polyhydramnios may be the first sign in utero of a hydropic infant. Anasarca, ascites, pleural, and peritoneal effusions may develop and cause hypoplasia of crucial organ formation such as the lungs.

Prevention

Prevention of Rh sensitization hinges on immunoprophylaxis by injecting anti-RhD immunoglobulin to the recipient. Originally tested to prevent sensitization in males, successful trials were undertaken in which Rh-negative, unsensitized females were given anti-D intramuscularly after delivery of an Rh-positive infant. Post-natal Anti-D prophylaxis of 200–300 μg given within 72 h of pregnancy lowered the incidence of RhD alloimmunization 6 months after delivery and in subsequent deliveries. Further, prenatal administration of 100 μg (500 international units) of anti-D at 28 weeks and 34 weeks' gestation to women in their first pregnancy can reduce the risk to about 0.2%. Therefore, most guidelines recommend routine administration of Rh immunoglobulin to all D-negative pregnant women in the early and mid-third trimester. Both pre- and post-natal prophylaxis will prevent 96% of RhD isoimmunization. Earlier antenatal prophylaxis for women who are likely to abort or undergo amniocentesis or chorionic villus sampling is safe and may reduce further sensitization. Although small amounts of anti-D may cross the placenta, there appears to be no adverse effects to the fetus. In rare occasions, a large fetal-to-maternal transplacental hemorrhage may occur at the time of delivery needing prompt assessment and a titrated dose of anti-D.

318 Iron Metabolism and Iron Deficiency Anemia

Heather Bradeen · Samir Shehab · Michael Recht

Background

Anemia is defined as a reduction in red blood cell mass or blood hemoglobin concentration. In practice, these are most often signaled by reductions of either the hemoglobin, a measure of the concentration of hemoglobin in the whole blood expressed as grams per 100 mL (dL), or hematocrit, the fractional volume of a whole blood sample occupied by red blood cells. The age variation for the hemoglobin and hematocrit varies widely in the pediatric population. It is particularly important to use age- and sex-adjusted norms when evaluating a pediatric patient for anemia. Iron deficiency is the most common nutritional deficiency in children. The World Health Organization estimates that anemia, largely caused by iron deficiency, affects between 500 million and two billion people worldwide. In some developing countries, up to 50% of preschool children and pregnant mothers have iron deficiency anemia (IDA). In the United States, the prevalence of IDA among children has been declining as a result of improved dietary iron supplementation.

Iron Metabolism

Iron is an abundant element in the natural world. Iron plays a critical role in mammalian cells. It is essential for oxygen delivery as well as numerous enzymatic systems. However, excess iron is toxic to cells and a deficiency of iron impairs cellular functions. Iron homeostasis is tightly regulated. Its excretion from the body is limited either through blood loss or sloughing of mucosal cells of the gastrointestinal lining. There are no known pathways for regulated iron excretion. Complex systems control iron absorption from dietary sources. Efficient recycling of iron is necessary to maintain its balance in the body. Disturbances to iron homeostasis have a significant impact on children's health. Insufficient iron intake leads to iron deficiency anemia, the most common pediatric hematology disorder worldwide. An excess of iron also causes problems particularly in children receiving chronic blood transfusions. Iron overload causes serious chronic organ dysfunction particularly in the liver, the heart, and the endocrine glands.

Normal Iron Endowment

Full term infants are born with approximately 350 mg of total body iron. By adulthood, an individual's iron endowment increases to 3–5 g. Normal adult men usually absorb 0.5–1 mg of iron each day from the diet. Menstruating women absorb more, approximately 1–2 mg of iron each day, to account for iron losses through blood loss. In pregnancy, iron absorption increases to approximately 2–4 mg daily to support the iron needs of the developing fetus. Approximately 75% of the total iron is within the erythrocyte and erythrocyte precursor population, and 10–20% is in storage form in the body. The remaining iron is utilized iron-dependent enzymatic pathways and biochemical reactions.

Iron Absorption

Total iron absorption depends on the bioavailability of dietary iron as well as regulation of iron absorption from the intestinal cells (*Fig. 318.1*).

Dietary Iron

Animal sources provide iron in the form of heme iron. Heme iron is a component of hemoglobin and myoglobin. It is the most bioavailable form of iron and is efficiently absorbed from the diet. Heme iron passes into the cytoplasm unchanged, where the iron molecule is then released. Nonheme iron, in the form of an insoluble ferric salt, is less bioavailable than heme iron. Nonheme iron is absorbed using a different cellular pathway. The ferric iron must first be converted to ferrous form, and then it is transported through the intestinal cell membranes with

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_318,

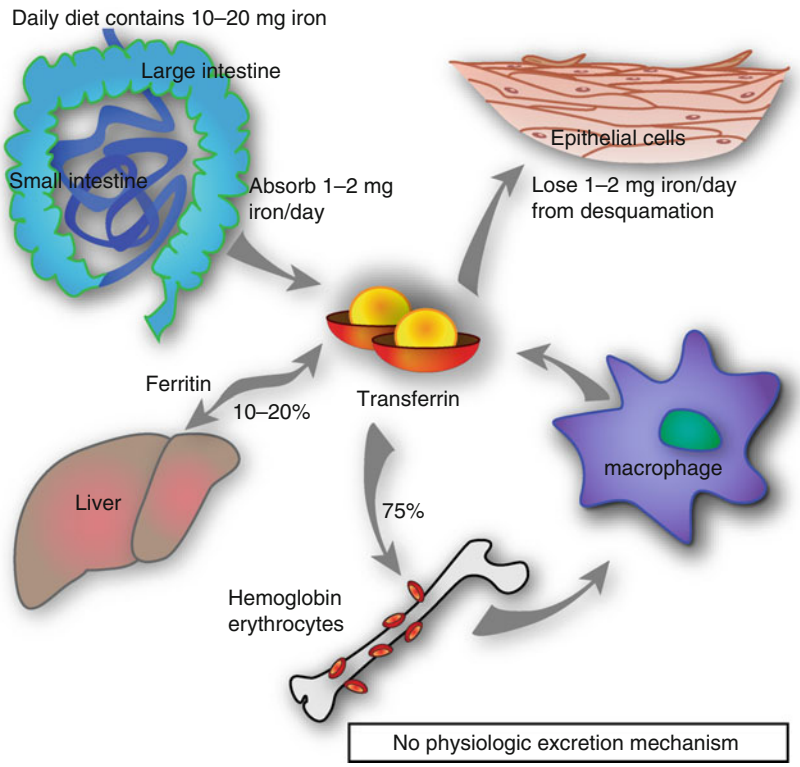

Fig. 318.1
Iron absorption

iron transport proteins. A variety of factors influence the absorption of nonheme iron. Acidic foods such as food rich in vitamin C enhance conversion of iron in the ferric form to the soluble ferrous form. The presence of dietary meat proteins in the intestinal lumen also enhances the absorption of nonheme iron. On the other hand, certain foods can impede absorption, such as tannates (tea and coffee), phosphates, antacids, and egg yolks. The decreased bioavailability of nonheme iron puts the vegan at risk for developing iron deficiency. Human breast milk, although low in total iron content, contains iron in a highly bioavailable form.

Intestinal Iron Absorption

Iron is absorbed in the proximal duodenum. Intestinal iron absorption is controlled at the level of mucosal transport and absorption. When total body iron stores are low, iron absorption is increased. Hypoxia and increased erythropoietic demand increase intestinal iron absorption. Both inflammation and increases in body iron have an opposing effect and decrease iron absorption.

Iron Storage and Recycling

Most of the body's iron is within a closed loop involving circulating transferrin, the erythroid bone marrow, senescent erythrocytes, and the reticuloendothelial macrophages. There is additional gain and loss through the intestinal mucosa. Excess iron is stored as ferritin in the liver. Smaller amounts of iron are utilized in muscle by myoglobin (not shown). The potential reactivity of iron molecules necessitates mechanisms for its safe transport and storage. Several important proteins are required for the safe handling of iron.

- Transferrin is the plasma transport protein for iron. Transferrin binds iron with extremely high affinity and prevents iron from reacting with other molecules so that iron may be delivered to tissues in a nontoxic form.
- Ferritin is a protein that stores iron and prevents it from reacting with other molecules. Iron stored as ferritin is relatively available for iron metabolism when iron needs arise. The liver is the primary location for ferritin. Plasma ferritin measurement is related to cellular iron stores.

- Hemosiderin is another form of stored iron, but its iron is much less available and is difficult to mobilize in the regulation of iron hemostasis. Its primary role is probably to keep iron from causing damage to surrounding molecules.

Iron Deficiency Anemia

Prevalence

In the United States, about 9% of toddlers have iron deficiency, with 3% affected by iron deficiency anemia. Rates decrease with advancing age until adolescence, when up to 16% of girls develop iron deficiency and 3% have iron deficiency anemia. The overall rate of iron deficiency in young children has declined only slightly during the past 4 decades. In the United States, iron deficiency is higher among children living at or below the poverty level, and in Black and Hispanic children. Other risk factors for IDA include childhood obesity and a history of prematurity or low birth weight. These findings demonstrate the need for ongoing surveillance and early intervention to prevent iron deficiency during infancy and early childhood, particularly among high-risk groups.

Clinical Features

Although iron deficiency anemia is often asymptomatic, the ability to recognize its clinical signs and symptoms is essential to preventing long-term neurodevelopmental delay. Additionally, appropriate therapy for those who are otherwise symptomatic has been shown to effectively treat symptoms as well as correct the underlying deficiency. Although its correlation with the severity of anemia is poor, pallor is the most easily recognizable sign of iron deficiency anemia. It is most prominent in the conjunctivae, gingiva, palmar creases, and nailbeds. Physical exam often also reveals tachycardia and systolic flow murmurs, and, less commonly, glossitis, stomatitis, koilonychias, and blue sclerae.

Children with mild to moderate iron deficiency anemia, defined as having hemoglobin concentrations of 6–10 g/dL, may be asymptomatic as a result of effective compensatory mechanisms. However, when iron deficiency becomes severe, with hemoglobin concentrations <5 g/dL, irritability, fatigue, and anorexia are common. Pica (which may also be a sign of lead toxicity) and pagophagia (craving and eating ice) are relatively common behavioral indicators of iron deficiency anemia. Older children and adolescents may present with exercise intolerance and shortness of breath. Of note, iron replacement therapy has been shown to improve symptoms even before laboratory values reflect changes.

In early infancy, iron deficiency anemia has been correlated with lower scores on mental and motor developmental assessments, although the exact mechanism by which this occurs has yet to be fully elucidated. Evaluations of toddlers have demonstrated similar results. Adolescent females are at a particularly high risk for iron deficiency. Poor dietary intake in this population as well as increased iron demand due to menstruation, rapid growth, and vigorous exercise contribute to this phenomenon. Anemia in teenage girls has been linked to impairments in verbal memory and learning, which can improve with iron replacement therapy, and girls with iron deficiency with and without anemia have been shown to score below average in math assessments. Of note, the cognitive sequelae of iron deficiency may precede the anemia itself as CNS iron is decreased before red blood cell production is impaired.

Populations at Risk for Iron Deficiency Anemia

Neonatal and Infant Iron Deficiency Anemia

Neonates of mothers with iron deficiency are at increased risk for IDA in early infancy. During the first 5–6 months of life, the normal term infant is iron replete. However, several conditions in the newborn period can lead to the development of IDA:

- Prematurity
- The administration of erythropoietin for anemia of prematurity
- Fetal-maternal hemorrhage
- Twin–twin transfusion syndrome
- Other perinatal hemorrhagic events
- Insufficient dietary intake

Premature infants are at increased risk for IDA in early infancy because of a smaller total blood volume at birth, increased loss through phlebotomy, and poor gastrointestinal absorption. Dietary issues contribute significantly to the evolution of IDA in infancy and early childhood. Common factors leading to IDA include the following:

- Insufficient iron intake
- Decreased absorption because of poor dietary sources of iron

- Early introduction of whole cow's milk
- Occult blood loss secondary to cow's milk intolerance
- Medications
- Malabsorption states

Recommendations for the prevention of iron deficiency in infants include the following:

- Encourage breast-feeding for the first 4–6 months; after this time, consider adding iron-fortified cereals. Two or more servings a day meet an infant's requirement for iron.
- For breast-fed preterm or low-birth weight infants, begin iron supplementation (1–2 mg/kg/day) at 1 month and continue until 12 months.
- For infants younger than 12 months of age who are not breast-fed or are partially breast-fed, use only iron-fortified formulas.
- At 6 months of age, encourage one feeding per day of foods rich in vitamin C.
- After 6 months of age, or when developmentally ready, consider introducing pureed meats, which increase the absorption of nonheme iron.
- Avoid low iron formulas or cow's milk until 12 months of age.
- Children aged 1–5 years should consume no more than 600 mL (20 oz) of milk daily. They should consume an adequate amount of iron-containing foods to meet daily requirements.

Toddler Iron Deficiency Anemia

Although the rapid growth rates of infancy are complete, iron deficiency anemia is most prevalent at this stage of development, particularly between 1 and 2 years of age. Many children have low iron stores early in the toddler years, particularly those who have received whole cows' milk throughout many months of infancy. Further, the dietary forms of iron consumed during these ages are often the nonheme forms of iron salts, iron that is much less bioavailable. Although insufficient stores and poor dietary intake are common in this age group, microcytic anemia presenting after the age of 3 years must be further investigated. Further investigation should aim to exclude malabsorption, bleeding, or chronic illnesses with true or apparent iron deficiency. Inflammatory bowel disease may occasionally present in toddlers. Ulcerative colitis presents as bloody diarrhea with incidental anemia. Crohn's disease is often more insidious, sometimes only vague ill heath and anemia are found.

Adolescent Iron Deficiency Anemia

The Third National Health and Nutrition Examination Survey (NHANES III) found a 9% incidence of iron deficiency and a 2% incidence of iron deficiency anemia among American females between the ages 12 and 15 years; the respective values were 11% and 3% in girls between the ages of 16 and 19 years. Less than 1% of adolescent males had iron deficiency. Studies in other countries have found higher rates of iron deficiency in male and female adolescents. Adolescents with chronic illness, heavy menstrual blood loss (>80 mL/month), or who are underweight or malnourished are at increased risk for iron deficiency and should be screened during health supervision or specialty clinic visits. Overweight and obese adolescents also appear to be at increased risk for iron deficiency and should undergo screening. Obesity was a risk factor for iron deficiency anemia in both boys and girls, but rates were approximately three times higher in girls. In addition, adolescent athletes, particularly those participating in endurance training, following alternative diets (vegetarian), or females at menarche, appear to be at risk for iron deficiency and should be screened as part of the pre-sport physical examination.

Differential Diagnosis

The differential diagnosis of microcytic anemia must be considered when iron deficiency anemia is suspected. Most commonly, microcytosis results from either iron deficiency, alpha or beta thalassemia trait, or heterozygous hemoglobin E disease. Hemoglobin electrophoresis is useful in differentiating and diagnosing thalassemias and hemoglobinopathies. Less common causes include inflammation, lead toxicity, thalassemia major, and sideroblastic anemia. Infection and anemia of chronic disease, while usually associated with normocytic anemia, may cause a mild microcytic anemia as well.

Blood loss must also be ruled out in children presenting with features of anemia. Most frequently, a dietary history of foods not fortified with iron and/or excessive cow's milk intake (>24 oz/day) may be elicited in these patients, especially those between the ages of 6 months and 2 years. Cow's milk iron is poorly absorbed in comparison to human breast milk, and excessive consumption results in early satiety and delayed gastric emptying. This, in turn, leads to decreased intake of iron-rich foods. Additionally, cow's milk often causes microscopic blood loss and may cause gross blood loss

if a significant milk-protein inflammatory colitis develops. It is therefore recommended that children ideally consume <16 oz of cow's milk daily and eat iron-fortified foods. Other sources of blood loss, such as gastrointestinal abnormalities or infections, should also be considered. Peptic ulcers, polyps, Meckel diverticula, hemangiomas, and inflammatory bowel disease may present with anemia. Hookworm infestation and *Helicobacter pylori* infection are important infectious causes of iron deficiency anemia and should be considered in geographic areas in which these infections are prevalent. Consideration of the patient's ethnicity may be useful in differentiating the causes of anemia. Alpha thalassemia is found in children of African, Chinese, and Southeast Asian descent. Beta thalassemia occurs in those of Mediterranean, African, and Asian origins. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is more commonly found in children of Mediterranean descent. Hemoglobinopathies, such as sickle cell disease and sickle cell thalassemia, are found more frequently in those of African descent.

Laboratory Features

Red Blood Cell Indices

Even before anemia occurs, the red cell indices fall and they fall progressively as the anemia becomes more severe. The blood film shows hypochromic, microcytic cells with occasional target cells. The reticulocyte count is low in relation to the degree of anemia. The platelet count is often moderately raised in iron deficiency, particularly when hemorrhage is ongoing.

Serum Iron and Total Iron-Binding Capacity

The serum iron falls and the total iron-binding capacity (TIBC) rises so that the TIBC is less than 10% saturated. This contrasts both with the anemia of chronic disorders when the serum iron and TIBC are both reduced and with other hypochromic anemias, where the serum iron is normal or even raised.

Serum Transferrin Receptor

Transferrin receptor is shed from cells into plasma. The level of serum transferrin receptor is increased in iron deficiency anemia but not in the anemia of chronic conditions or thalassemia trait. The level is also raised if the overall level of erythropoiesis is increased.

Serum Ferritin

A small fraction of body ferritin circulates in the serum, the concentration being related to tissue, particularly reticuloendothelial, iron stores. The normal range in men is higher in men than in women. In iron deficiency anemia, the serum ferritin is low. A raised serum ferritin indicates iron overload. Other causes of increased ferritin include excess release of ferritin from damaged tissues or an acute phase response (e.g., inflammation). The serum ferritin is normal or increased in the anemia of chronic disorders.

Therapy

For infants and children presenting with a mild microcytic anemia and a presumptive diagnosis of IDA, the most cost-effective strategy is a therapeutic trial of oral iron supplementation. Ferrous sulfate (3–6 mg/kg of elemental iron, once or twice daily between meals) should produce a rise of more than 1 g/dL in patients with IDA. For infants with confirmed IDA, ferrous sulfate (3–6 mg/kg/day of elemental iron) remains the standard therapy. Iron-fortified formulas and iron supplementation at these doses are infrequent causes of gastrointestinal symptoms. In children with severe IDA, a reticulocyte response may be seen within 72 h. If a child does not respond to adequate oral iron supplementation, potential causes for refractory IDA include the following:

- Failure to adhere to recommendations
- Intolerance to medication
- Ongoing gastrointestinal blood loss
- Chronic inflammatory disease
- Pulmonary hemosiderosis
- Incorrect diagnosis

Parenteral iron therapy should be reserved for patients with severe, persistent anemia who have proven intolerance to oral supplements, malabsorption, or poor compliance to oral therapy. Parenteral iron should be used with caution because there is a 2–3% risk for anaphylaxis, some cases of which result in death. Iron dextran is the parenteral form most commonly used preparation for pediatric patients. Sodium ferric gluconate and iron sucrose are also available, but these were developed for use in dialysis patients and are not

approved by the US Food and Drug Administration for use in children.

Transfusion therapy is rarely necessary for severe IDA, even with hemoglobin concentrations of 4–5 g/dL. Transfusions should be reserved for patients in distress (heart rate greater than 160/min, respiratory rate greater than 30/min, lethargy, not feeding well). Transfusions should be administered with caution to such patients, giving transfusion volumes of 5 mL/kg over 3–4 h to avoid inducing heart failure.

Follow-up

Follow-up is essential because of the effects of iron deficiency on neurodevelopment. Unfortunately, failure to follow up is a common occurrence, even among children who present with severe anemia. It is essential that the health care provider develop a proactive plan to ensure adequate compliance and follow-up of these patients during a critical time of neurodevelopment.

319 Autoimmune Hemolytic Anemia

Veronica H. Flood · Michael Recht

Definition/Classification

Autoimmune hemolytic anemia (AIHA) is a condition in which red blood cell (RBC) destruction occurs due to antibody formation directed against self RBC antigens. In children, AIHA typically occurs following viral infection. AIHA can be due to either warm or cold antibodies, with the temperature referring to the optimal binding temperature of the antibody. AIHA is less likely to be chronic in children than in adults, but the anemia may be severe on initial presentation. In adults, the incidence of AIHA is approximately 1–3/100,000. Warm AIHA is more common than cold AIHA, accounting for about 90% of adult cases. The prevalence of cold AIHA in adults is 16/million. In children, the incidence is unknown, but mild AIHA may be more frequent, with some cases never coming to medical attention.

Pathology

Warm AIHA is due to IgG antibodies directed against RBC membrane proteins (*Table 319.1*). These antibodies bind maximally at body temperature (37°C), causing extravascular hemolysis. Most RBC destruction occurs via splenic macrophages, although liver sequestration may occur. Pediatric AIHA is thought to result from antecedent viral infection inducing anti-RBC antibodies, possibly through molecular mimicry as has been described for infection-associated ITP. Additional mechanisms include self-ignorance, loss of tolerance, polyclonal T or B cell activation, and immunoregulatory disorders.

Antibodies may be directed against any RBC antigen, but anti-Rh antibodies are the most common, usually anti-e or anti-c. Epitope mapping studies performed for the Rh D autoantigen have identified specific peptides important in IL10-mediated T cell response, although the clinical significance is not yet defined. Glycophorin is another common antigenic site. In addition, antibodies have been reported against Wr^b, En^a, LW, U, Ge, Sc1, Kell, and band 3. Warm AIHA antibodies are usually polyclonal.

Evans syndrome refers to those patients with both AIHA and ITP. The disorders may occur sequentially or simultaneously, and relapse is frequent. Underlying immune dysregulation may be present, with new evidence suggesting Evans syndrome is part of a spectrum with autoimmune lymphoproliferative disease (ALPS). Seif and colleagues studied 45 children with Evans syndrome and diagnosed 47% with ALPS. Treatment of refractory Evans syndrome and ALPS differs from that of isolated pediatric AIHA in that these patients may require additional immune modulatory agents. Many, however, do respond to corticosteroids.

Cold AIHA is due to IgM antibodies, also referred to as cold agglutinins. These antibodies bind at lower temperatures, with maximal reactivity typically at 4°C. Mycoplasma infection is the most frequent triggering agent for cold AIHA in children. Antibody specificity is usually anti-I or anti-i. Cold AIHA antibodies are usually monoclonal and hemolysis is primarily intravascular.

Paroxysmal cold hemoglobinuria (PCH) is caused by IgG antibodies that bind at cold temperatures but cause RBC lysis at warmer temperatures. These are often referred to as Donath-Landsteiner antibodies. The Donath-Landsteiner antibody is directed against the P antigen. The classic presentation of PCH in adults is associated with syphilis, but in children viral infections are the most common cause. Many different viral and bacterial pathogens have been reported in childhood PCH, including *Staphylococcus aureus*, *Haemophilis influenzae*, and adenovirus.

Clinical Manifestations

Hemolytic anemia is the hallmark of AIHA. Patients may present with fatigue or pallor due to the anemia. Dizziness, headache, and shortness of breath are signs of more severe anemia. Jaundice or scleral icterus may be noted due to elevated bilirubin from extravascular hemolysis. Dark, cola colored urine occurs in the presence of intravascular hemolysis. Fever may also be seen, particularly with viral illnesses as the precipitating factor. On exam, patients may demonstrate splenomegaly, but spleen size may also be

Haptoglobin	
Urinalysis	

normal. Tachycardia may be present, particularly if the anemia is of recent onset. Lymphadenopathy is common in patients with viral infections. Cold AIHA may present with acrocyanosis similar to that seen in Raynaud's syndrome.

Diagnosis

Diagnosis of AIHA involves a variety of laboratory tests, with the typical workup summarized in *Table 319.2*. A complete blood count will show anemia, typically with a normal MCV. The RDW is usually high due to concurrent elevation in the reticulocyte count. Except in the setting of marrow suppression due to parvovirus, there is usually a brisk reticulocytosis. Review of the peripheral blood smear should show spherocytes, formed when part of the antibody-coated RBC membrane is removed by the spleen, resulting in spherocytes rather than the classic biconcave disk shape. Increased hemolysis will result in increased spherocytosis. Cold AIHA may result in RBC agglutination on the peripheral smear. Erythrophagocytosis may also be observed (*Fig. 319.1*).

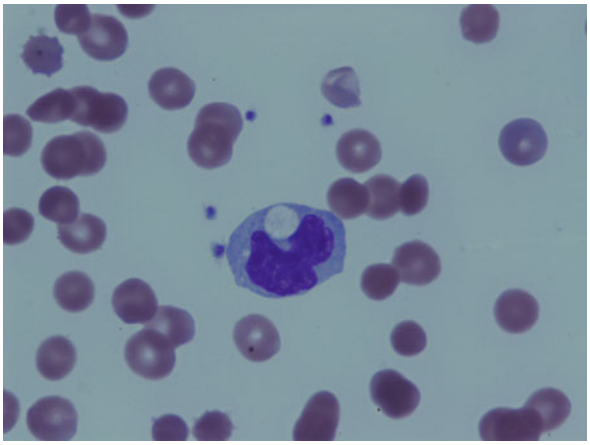

Figure 319.1
Peripheral smear demonstrating spherocytes and erythrophagocytosis (courtesy of Dr. Gabriela Gheorghe, Medical College of Wisconsin)

Blood chemistries will show elevated unconjugated bilirubin levels. Conjugated bilirubin should be normal in AIHA. Lactate dehydrogenase is also elevated due to increased RBC turnover. Haptoglobin will be decreased due to scavenging of free hemoglobin. Hemoglobinuria is uncommon in warm AIHA but frequently seen in cold AIHA and paroxysmal cold hemoglobinuria.

The pathognomonic test for AIHA is the direct Coombs test, or direct antiglobulin test (DAT). The DAT detects IgG antibodies or complement (C3) bound to the patient's RBCs. In warm AIHA, the IgG DAT will be positive, while in cold AIHA, the complement DAT will be positive, demonstrating the presence of complement on the RBC surface. The DAT is performed by incubating patient RBCs with reagents containing either anti-IgG or anti-complement to detect bound antibodies. Occasionally, symptoms of AIHA will be present with a negative DAT. Rare patients will have a positive DAT without symptoms. Thermal amplitude testing may be helpful, particularly for cold AIHA. Testing is performed at 4°, 22°, 30°, and 37°C to determine at what temperature maximal agglutination occurs.

Donath-Landsteiner testing should be performed when paroxysmal cold hemoglobinuria is suspected. If patient serum is incubated with normal RBCs at 0°C or 37°C, no lysis is observed, but when the incubation first occurs at 0°C and is then moved to 37°C, lysis will occur. Thermal amplitude may vary, with some antibodies binding at intermediate temperatures.

Table 319.3
Treatment options for AIHA

First line treatment	Second line treatment	Third line treatment
Corticosteroids	Rituximab	Plasmapheresis
Transfusion	Splenectomy	Cytotoxic agents Cyclophosphamide 6-Mercaptopurine Azathioprine 6-Thioguanine Danazol
IVIG		Immune suppressive agents Cyclosporine Mycophenolate mofetil

Differential Diagnosis

AIHA is due to antibody-mediated RBC destruction. Other causes of hemolysis should be considered and excluded on the basis of patient and family history as well as laboratory testing. Hereditary spherocytosis (HS) can present with anemia and spherocytosis, although the DAT should be negative in HS. Enzymopathies and other RBC membrane defects may also present with anemia and hemolysis. Family history may be useful in evaluation for the presence of inherited RBC defects, as many patients will have affected parents or other family members. Dark urine due to intravascular hemolysis is common in cold AIHA, but may also be a presenting feature of paroxysmal nocturnal hemoglobinuria (PNH). Anemia and hemolysis are also seen in microangiopathic disorders such as hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) although thrombocytopenia and schistocytes on the peripheral blood smear should help to differentiate these from the anemia of AIHA.

In addition, AIHA may be secondary to other underlying disorders. Systemic lupus erythematosis has been associated with AIHA as has lymphoma. Infections such as HIV may also be responsible for AIHA. Hemolytic anemias may occur following solid organ or bone marrow transplant when there is an ABO mismatch between donor and recipient, with antibodies produced either by the grafted marrow or organ against recipient RBCs, or by the recipient against the donor RBCs. Adults are more likely to have AIHA secondary to an underlying condition than young children.

Drug-induced hemolytic anemia has been reported following administration of numerous medications, including penicillins, cephalosporins, and methyldopa. While original reports of drug-induced immune hemolysis were common with penicillin and methyldopa, cephalosphorins are now responsible for the majority of cases. Reactions have been reported with other frequently used medications, including NSAIDs and trimethoprim.

Treatment

Transfusion may be required in severe AIHA. Symptomatic patients should receive the least incompatible unit available, but extensive testing should not delay transfusion when clinically indicated. Most children with AIHA are previously healthy, and are unlikely to have previous exposures such as pregnancy or transfusions that could have led to the development of an underlying alloantibody. Since most AIHA antibodies are directed against common RBC antigens such as the Rh epitope, finding a perfectly compatible unit may be impossible. In such instances, slow RBC transfusion is acceptable, with close monitoring for a possible transfusion reaction. Survival of the transfused cells will likely be affected by the autoantibody as well, but may suffice to reduce symptoms while other therapeutic measures are employed. Some clinicians recommend using the "least incompatible" unit but transfusion guidelines at present support transfusion regardless of the crossmatch results once a significant alloantibody has been ruled out. Hemoglobin levels less than four merit transfusion, as do children with significant symptoms, particularly with concurrent reticulocytopenia. For cold AIHA, a blood warmer should be used to maintain a temperature of 37°C. Additional treatment options are summarized in *Table 319.3*.

Steroids are the mainstay of AIHA treatment. In warm AIHA, steroids decrease RBC sequestration and antibody formation. Glucocorticoids are thought to inhibit clearance of RBCs via the Fc receptors. Their effect, however, is not instantaneous, as improvement in symptoms usually takes several days. Dosing varies widely in pediatrics, with typical dosing of prednisone at 1–4 mg/kg/day given for at least 5 days or until the hemolysis slows. Most clinicians will then wean steroids over several weeks but no standard protocol exists. IV methylprednisolone may be used in severe cases. Response rates to oral steroids are excellent, with typical response rates of 80% in both adults and children. Relapses are infrequent in children, but may occur, so close monitoring following recovery is

warranted. Parents should be counseled regarding signs and symptoms of anemia.

Cold avoidance is important in paroxysmal cold hemoglobinuria. Since these antibodies bind only at cold temperatures, preventing binding will reduce hemolysis. Room temperature should be raised as high as comfortable. In addition, patients should avoid cold foods, such as ice cream and popsicles, as these may precipitate a bout of hemolysis. Warm clothes, including hats and gloves, should be worn when outside, and extreme cold temperatures avoided if possible. IV fluids and medications, including RBC transfusions, should be administered via a blood warmer.

IVIG may be useful, either alone or in combination with steroids. Trials of IVIG in adult patients demonstrated a response rate of 40%. Early pediatric trials showed a response in 3 of 4 children. A larger study demonstrated a response rate of 40%, but children tended to fare better than adults. IVIG may work by several mechanisms, including Fc receptor blockade or decrease in antibody production. Cold AIHA is thought to be generally less responsive to IVIG than warm AIHA.

Splenectomy is generally reserved for those children refractory to medical therapy for two reasons. First, the risk of infection following splenectomy in children is not insubstantial, and therefore should be avoided in younger children if at all possible. Second, the response rate to splenectomy is only about 60%, with at present no clear indication of which patients will respond best to splenectomy. In theory, removing the spleen will remove the site of RBC destruction, but some patients have continued hemolysis, suggesting that alternate sites of RBC removal are present.

Recently, the monoclonal anti-CD20 antibody rituximab has been used for a variety of autoimmune conditions, including AIHA. Rituximab is a chimeric antibody composed of human IgG heavy and light chains fused to a murine variable region. It binds to CD20, removing B cells from circulation and thus decreasing antibody production. Reactivation of hepatitis B has been reported following rituximab treatment. The risk of serious infection, however, appears to be low despite B cell depletion. Some clinicians administer IVIG following rituximab, but there are no strong data to support its use. Adult trials suggest approximately 50% will respond to rituximab, and those who relapse following rituximab may respond to retreatment. One pediatric trial showed response in 13 of 15 patients, although 3 of the responders later relapsed. Response rates in children appear to be greater than those in adults, with over 90% remission in a collection of case reports. Publication bias, however, must be taken into account, as it is likely there are many non-responders that have not shown up in case reports. At present, rituximab and splenectomy are both considered second line treatment following steroids and/or IVIG.

Plasmapheresis may be of some utility in cold AIHA to remove the inciting IgM antibody. A blood warmer should be utilized to keep blood products at 37°C. Plasmapheresis has also been utilized in warm AIHA. No clinical studies exist, but case reports in adults with severe AIHA suggest a response rate of around 65%. The necessity of catheter placement limits this procedure to pediatric intensive care units in most hospitals, and plasma exchange may not be rapidly available for small children, limiting the use of this therapeutic modality. However, it may be beneficial in refractory cases.

Numerous other cytotoxic agents have been utilized in refractory AIHA, including cyclophosphamide, 6-mercaptopurine, azathioprine, 6-thioguanine, and danazol. Immune suppressants such as cyclosporine or mycophenolate mofetil have been tried with some success. In pediatric AIHA patients, a recent study by Sobota and colleagues in 29 refractory AIHA patients demonstrated an 83% response rate to 6-mercaptopurine. Consideration of immune suppressive agents for refractory patients should take into account cost and convenience of administration as there is at present no clear order of precedence given the limited data available on these medications in pediatric AIHA.

Summary

AIHA is not uncommon in children. Although warm AIHA is observed most frequently, cold AIHA and PCH may also occur in this age group. Viral infections are thought to be the initiating agent in pediatric AIHA. Children typically present with anemia, reticulocytosis, and signs of hemolysis. The diagnosis of AIHA relies on the ability to demonstrate the presence of anti-RBC antibodies, typically through a positive DAT. Treatment may be required, with steroids the mainstay of AIHA therapy. Alternate treatment options are available for refractory patients.

320 Glucose-6-Phosphate Dehydrogenase Deficiency

Hassan M. Yaish

> The indiscriminate selection of a battery of hematologically oriented tests, such as obtaining a Coomb's test and levels of serum iron, Vitamin B12, and folic acid in every anemic patient is wasteful, unwise, and unnecessary.
>
> Maxwell Wintrobe, 1930

Among the various red cell enzymes disorders, glucose-6-phosphate dehydrogenase (G6PD) deficiency is by far the most common and most significant clinical entity. The several disorders resulting from this enzymopathy affect more than 400 million people worldwide and probably twice as many heterozygous girls. The highest incidence is encountered in the tropics or the subtropics where malaria was endemic in the past. A highest incidence of G6PD deficiency is found around the Mediterranean region, affecting Southern Europeans, Middle Easterners, and North Africans. Both the rate of incidence and the type of G6PD may vary from one region to another in the same country. More than 50% of the populations of certain oases in the Eastern Province of Saudi Arabia, for instance, were found to have G6PD deficiency, in contrast to less than 2% in the central region. G6PD deficiency is also encountered in certain parts of India and Southeast Asia.

G6PD Function

This enzyme catalyzes the first reaction in the oxidative pentose phosphate pathway, through which less than 5% of the red cells' glucose is metabolized. It is clear, therefore, that the main function of this pathway is not glucose metabolism but to provide a continuous supply of the reduced nicotinamide dinucleotide phosphate (NADPH) necessary for conversion of the oxidized form of glutathione (GSSG) to the reduced form (GSH), in a second reaction mediated by glutathione reductase (*Fig. 320.1*). Reduced glutathione, in turn, plays a critical role in the detoxification and reduction of the various oxidants accumulating in the red cells, such as hydrogen peroxide and other oxygen radicals. For this reason, G6PD was classified as a "housekeeping" enzyme. The last reaction in this pathway is usually mediated by glutathione peroxidase and is crucial for the protection of the integrity of the red cell, which is already handicapped by the lack of a nucleus and mitochondria that render it unable to produce G6PD. In addition, the red cell's oxygen load represents an occupational hazard for the cell itself. It acts as a continuous source for oxidants with damaging potential for the cell integrity. These red cell characteristics explain why, among all cells that lack G6PD activity, red blood cells are the most vulnerable. Many children with G6PD deficiency develop episodic hemolysis upon exposure to oxidants.

G6PD Polymorphism

The G6PD gene (Gd) is located on the long arm of chromosome X in close proximity to the color blindness and the classic hemophilia A genes. Inherited as an X-linked disorder, it affects primarily hemizygous boys (Gd−), homozygous girls (Gd−/Gd−), and occasionally heterozygous girls (Gd−/Gd+). More than 400 different variants of G6PD have been identified so far. Almost all such variants are the results of point mutations rather than actual deletions. Amino acid substitutions at different points of the G6PD gene's polypeptide chain characterize the various mutants, similar to the substitutions encountered in the different hemoglobinopathies. The G6PD enzyme mutants include:

G6PD B+: Refers to the normal enzyme found in most populations.

G6PD A+: Designation for another normal enzyme mutant present in people of African origin.

G6PD A−: The designation for the African mutant once activity drops to 5–15% of normal.

G6PD B− (Mediterranean): Designation for the variant exhibited by people of Mediterranean, North African, and Far East descent with activity less than 5% of normal.

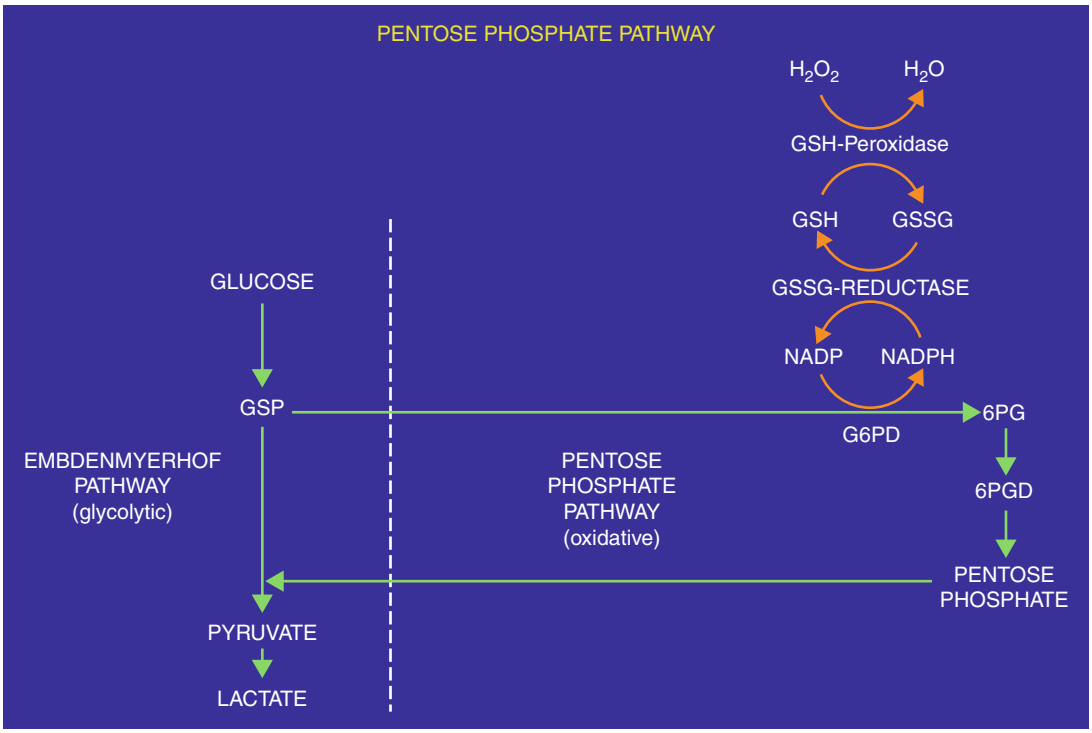

Figure 320.1

Chronic Nonspherocytic Hemolytic Anemia

Small minorities of individuals with G6PD deficiency tend to manifest a variable degree of hemolysis that can be easily detected at all times. Such patients are constantly symptomatic with anemia that ranges from slight to transfusion dependent. Reticulocytosis, jaundice, and splenomegaly are frequent findings. The hemolysis is extravascular, and the picture is that of a chronic hemolytic anemia. Various G6PD mutants are now known to cause congenital nonspherocytic hemolytic anemia (CNSHA), many of which have had their molecular defect and amino acid substitutions elucidated. The reason for the peculiar clinical behavior of this entity remains largely unexplained.

Patients are invariably males and the condition is encountered anywhere in the world especially in Europe and Japan. Symptoms may present at birth with neonatal jaundice (NNJ), which does not clear later on. The condition is caused by special G6PD mutations, commonly clustered in exon 10. Such mutations do not require a triggering exogenous factor to induce hemolytic crisis, hence anemia and hemolysis are always present. Acute exacerbation of hemolysis, however, may occur after exposure to the same oxidative agents that cause acute hemolytic anemia (AHA) in patients with the more common forms of G6PD deficiency. Several mutants of G6PD deficiency are known to manifest CNSHA, which may explain the variation in the severity of the condition.

Red cell morphology is usually normal; anemia, hyperbilirubinemia, low haptoglobin, and elevated LDH are frequently encountered. Lack of hemoglobinuria suggests that the hemolysis is extravascular and splenomegaly is frequently present.

G6PD Deficiency and Malaria

The "malaria hypothesis" was formulated nearly half a century ago based on the observation of the striking correlation between the world distribution of G6PD deficiency and *Plasmodium falciparum* malaria. Several epidemiologic and clinical studies since then have confirmed that G6PD deficiency confers some degree of protection from the potentially lethal malaria parasite. Even though all the clinical studies have agreed that such protection exists, nevertheless there was no agreement on who is

protected. Some studies have shown that the protection involves only the G6PD deficient male, while others concluded that the heterozygous female shows resistance to the parasite. Several factors have been suggested as a potential explanation for such differences. The mechanism of this phenomenon is not fully understood. One of the theories indicates that macrophages are able to recognize the parasite-infected G6PD deficient red blood cells more efficiently, accelerating the removal of the cells (suicidal infection).

Clinical Manifestations of G6PD Deficiency

Symptoms in G6PD-deficient individuals vary significantly in their severity depending on the particular G6PD variant involved. Red cell life span is always somewhat shortened in all types of G6PD deficiency, even though, in most cases, this finding is subclinical and not easily detected. For this reason, it is probably appropriate to describe the clinical manifestations separately for each clinical entity in G6PD-deficient children. Three clinical entities are encountered in patients with G6PD deficiency: acute hemolytic anemia, neonatal jaundice, and chronic nonspherocytic hemolytic anemia. The first two are the most common with AHA usually presenting as an episodic crisis upon exposure to oxidants, or in the neonatal period as jaundice mostly without anemia. The third form however is characterized by chronic life-long hemolytic process.

Acute Hemolytic Anemia

This condition is usually triggered by exposure to certain drugs such as the antimalarials, some sulphonamides, analgesics, and antimicrobials. Of interest, there have been reports of hemolytic reactions due to the use of the cosmetic dye henna applied to different parts of the body in certain populations around the world. Infections such as hepatitis, pneumonia, typhoid fever, and brucellosis were all incriminated in inducing hemolysis in G6PD deficient individuals. Ingestion of fava beans or inhalation of its pollen have caused significant hemolytic crisis in some deficient individuals resulting in the condition known as favism.

Except for the CNSHA mutant, described earlier, children with G6PD deficiency in the steady state are usually asymptomatic and hematologically normal. A hemolytic crisis can begin within a few hours to 3 days after the exposure to the responsible agent. The length of the interval as well as the severity of the reaction is both functions of the offending factor as well as the type of the deficient enzyme. G6PD B− (Mediterranean), for instance, is characterized by a disease that is more severe than G6PD A− (African), with intervals of hours rather than days and the potential of being fatal in rare occasions, rather than self-limited because of the extreme short half-life of the enzyme, even in the newly produced reticulocytes.

Diagnosis

The diagnosis is straight forward if the patient with a history of fava bean ingestion or exposure to its pollen develops hemoglobinuria. Rarely, a hemolytic crisis can occur in breast-feeding infants whose mothers have ingested fava beans. In the absence of such history, however, and in patients with hemoglobinuria, one should consider other forms of hemolytic anemia. A coomb's test is positive in autoimmune hemolytic anemia. Malaria and babesiosis need also to be considered in epidemic regions.

Favism

Ingestion of fava beans by the child with G6PD B− may result in the condition known as favism. This is a term used to describe the harmful effects of fava beans (*Vicia faba*) in certain individuals with G6PD deficiency. The condition has been known for centuries, probably dating from the early Greek and Roman times, as reflected by the observations attributed to Hippocrates and Pythagoras who warned his disciples against dangers of eating fava beans. The etiology of favism remained a mystery, however, until the mid-1950s, when the cause of acute hemolysis in African-American soldiers who were given antimalarial drugs was identified and attributed to the deficient G6PD enzyme. This condition occurs most often in people of Mediterranean, Middle Eastern, or Far Eastern origin. It is described as an episodic intravascular hemolysis associated with hemoglobinuria, described by the parents or the patients as dark urine resembling the color of dark tea or cola. Jaundice, abdominal pain, and vomiting are sometimes described. Laboratory findings reveal anemia with hemoglobins measured as low as 2–3 g/dL, hemoglobinemia, and hemoglobinuria early in the process. The presence of Heinz bodies (Fig. 320.2) on supravital stain or reticulocyte stain preparations supports

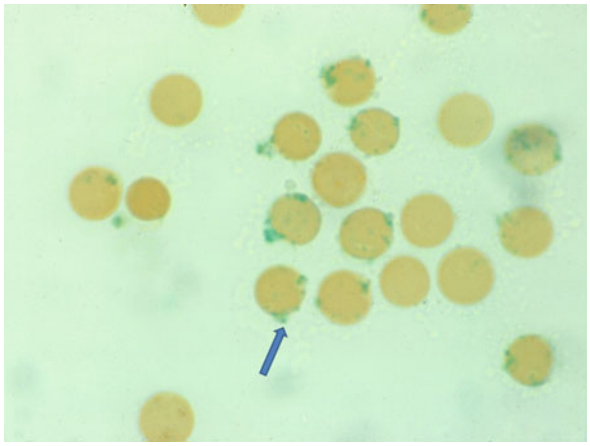

Figure 320.2

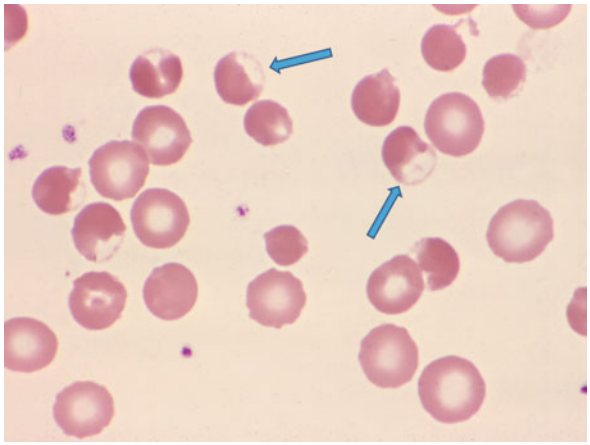

Figure 320.3

the diagnosis. Heinz bodies represent precipitated hemoglobin that is quickly pinched off by the spleen, leaving the characteristic blister or basket-shaped cell (*Fig. 320.3*). The morphology of the red blood cell is striking in that marked anisocytosis, contracted, and spherocytic-like cells are usually seen. Reticulocytes peak may be as high as 30% or more. Even though many patients require red blood cell transfusion, in many others the hemolytic crisis is self-limited and resolves spontaneously.

Not all deficient individuals develop favism upon ingestion of fava beans or inhaling the bean pollen. Furthermore, many individuals have eaten fava beans frequently before and after their first hemolytic crises without any similar episodes. This indicates that other etiologic factors are involved even though they have never been documented.

Neonatal Jaundice

The issue of hyperbilirubinemia in G6PD-deficient neonates of different ethnic groups has been a subject of debate for many years. At the present time, there is enough evidence to suggest that more neonates with G6PD deficiency of any type develop hyperbilirubinemia than do non-deficient ones. Earlier studies have confirmed such findings in newborns with G6PD B− (Mediterranean) and only the premature baby with G6PD A−. A recent report, however, demonstrated that despite the low incidence of hyperbilirubinemia in African-American newborns, 25% of children who develop kernicterus occur in this population of newborns. Sixty percent of the cases were due to G6PD deficiency while 40% were caused by preterm births and ABO hemolytic disease. In almost all such instances, no offending agent was identified and the etiology of the hyperbilirubinemia, which had presented as an exaggerated physiologic jaundice. Once a responsible agent becomes active, however, the potential response is expected to occur in any infant regardless of term or ethnicity. In such circumstances, the clinical picture may present more like hemolytic anemia and hyperbilirubinemia rather than exaggerated jaundice without anemia.

Evidence of cholestasis with significant elevation of conjugated bilirubin without any evidence of hepatobiliary disease was reported in a neonate with novel mutation resulting in CNSHA. A new, previously unrecognized agent has been incriminated as a cause of hemolysis and jaundice in newborns in certain regions of the world, mainly the Middle East, India, and North Africa. Neonatal hyperbilirubinemia of G6PD deficiency is rarely manifested at birth, and it usually peaks between days 3 and 4 of age, which coincides with time of discharge or after being discharged home.

Testing for G6PD Deficiency

All tests for G6PD activity are based on the detection of the presence of NADPH in the red cell by spectrophotometric methods. Leukocytes, which have much higher level of G6PD than erythrocytes, should be removed from the hemolysate for accurate measurements. Two kinds of tests are usually utilized: a screening test designed to identify deficient individuals and a quantitative method that measures the rate of formation of NADPH by spectrophotometric means. Dye decolorization, methemoglobin reduction, and the fluorescence spot test as well are all used for screening purposes. Once a positive test is identified, confirmation by a quantitative method is required.

Samples with less than 30% activity are considered deficient since any level that exceeds 30% is usually asymptomatic. G6PD activity in normal mature red cells is in the range of 7–10 IU/g of hemoglobin. In order to appropriately evaluate the results of G6PD testing, one should be aware of two major causes of false-negative results in deficient individuals at the time of testing. First, because leukocytes and platelets have higher G6PD activity than mature erythrocytes, when these cells contaminate the specimen, artificially elevated G6PD activity will be seen. Secondly, when G6PD is measured in a reticulocyte-rich specimen, levels can be artificially elevated.

Preventive Medicine in G6PD Deficiency

Universal screening for the deficiency is neither feasible nor recommended except in a very few circumstances where the condition is common and the symptomatology is relatively severe. Cord blood screening is currently utilized in several countries of the world where the condition is very common. Once an infant is identified as deficient, oxidant drugs, chemicals, and cosmetics (henna) are to be avoided. In addition, close monitoring for at least the first 4–5 days of life will ensure appropriate and timely management of any otherwise unexplained hyperbilirubinemia. The parents are instructed to avoid certain medications and chemicals in the older child, and to ask the child to give up eating fava beans or any foods that have fava bean as an ingredient (e.g., falafel). The physician should also know that most of the newly introduced drugs, regardless of the indications for its use, are not tested and may carry a potential risk for the deficient child.

It is known that hemolytic anemia and neonatal jaundice are the most common and well-recognized clinical manifestations in G6PD deficient individuals. Many other indirect effects of the deficiency are now being described. High blood sugar in patients with type 2 diabetes have been incriminated in inhibiting G6PD expression causing increased oxidative stress leading to gradual loss of beta cells in patients with diabetes.

The more pronounced effect of the enzyme deficiency on the RBCs is attributed to the fact that the cell is anucleated and unable to produce the enzyme. The eye lens is another example of an organ composed of non-nucleated cells, which might be the site of developing juvenile cataracts in young people with G6PD deficiency. Nucleated cells in the deficient individuals however retain the ability to produce some limited amounts of the enzyme as found in the granulocytes which may maintain a level of 30% of normal compared to only 5% in the RBCs. Despite this fact, some types of G6PD deficiency have been associated with increased incidence of infections, and poor healing after trauma as a result of leukocytes dysfunction.

Treatment

In acute hemolysis that develops after exposure to drugs or chemicals, particularly in patients with the G6PD A− mutant, the course is frequently mild and self-limited. On the other hand, in the G6PD B− (Mediterranean) type of G6PD deficiency, the hemolysis is frequently more severe and intervention is usually required. In many of the Middle Eastern countries, as is true elsewhere, blood transfusion has been used indiscriminately. To avoid such practice and minimize the various risks of blood transfusion, the physician is urged to evaluate the patient's clinical status carefully before blood transfusion is administered. On many occasions, the child presents to the physician toward the end of the course of illness with reticulocytes already rising, urine clearing, and none of the classic morphologic findings (blister cells, Heinz bodies) present. Such patients, even with their hemoglobin at 6–7 g/dL, can be closely observed for 24–48 h. On the other hand, a child with severe anemia and a hemoglobin causing symptoms, or in the face of ongoing hemolysis, should be considered for transfusion. All other acute episodes in between these two extremes should be evaluated carefully and treated accordingly.

Even though renal failure rarely occurs in children, one should always be aware of such a complication. In neonatal jaundice, on should always exclude other causes of hyperbilirubinemia and manage the baby according to the severity of the condition. Phototherapy has decreased the need for exchange transfusion in many neonates with hyperbilirubinemia. In such infants, one is rarely faced with severe anemia similar to the condition observed in hemolytic disease of the newborn. In most cases such infants are usually hyperbilirubinemic rather than anemic, and, unless they were exposed to an oxidant, they do not show any of the classic morphologic findings.

In CNSHA, the treatment depends on the severity of the anemia, which may be very mild, requiring only monitoring of the hemoglobin level and avoiding any oxidant that may exaggerate the existing anemia. Severe transfusion-dependent anemias are also encountered in such patients, and, based on the frequency of the transfusions, iron chelation might be required. Splenectomy was shown to

be effective in some children in either decreasing the frequency of transfusions or to treat a hypersplenic state. Genetic counseling and prenatal diagnosis should be considered in severe cases.

321 Other Red Cell Enzymopathies

Ahmad A. Mallouh

Introduction

Congenital nonspherocytic hemolytic anemia was described for the first time by Dacie in 1952. In addition to a variable degree of hemolytic anemia, these disorders are characterized by the absence of spherocytes in the peripheral blood and normal osmotic fragility of the Red Blood Cells (RBCs). The term "Congenital NonSpherocytic Hemolytic Anemia" (CNSHA) is used to describe a heterogeneous group of congenital hemolytic anemias that results from the inherited deficiency of RBC glycolytic enzymes of the Embden-Meyerhof or pentose phosphate metabolic pathway. As these are anaerobic pathways, in which glucose is catabolized to pyruvate and lactate and thus produce Adenosine TriPhosphate (ATP), deficiency of any enzyme in this pathway results in decreased level or complete absence of ATP in the RBCs. ATP plays a major role in maintaining the red blood cells' membrane integrity. Glucose-6-Phosphate Dehydrogenase (G6PD) deficiency, the most common red blood cells enzyme deficiency, affects around 100 million people around the world. Pyruvate Kinase (PK) deficiency, the second most common red cell enzyme deficiency, affects a few thousand individuals globally. All the other red cell enzyme deficiencies affect a few hundred persons.

Pyruvate Kinase Deficiency

The production of the pyruvate kinase enzyme in human is controlled by two genes. The M gene (located on chromosome 15q22) is responsible for PK production in muscle, brain, white blood cells and platelets, while the L gene (located on chromosome 1q21) is responsible for the enzyme production in the red blood cell and liver. Hemolytic anemia with PK deficiency is limited to the L gene mutation that results in quantitative or qualitative deficiency in the red blood cell and liver with normal enzyme level in other tissues. Several (around 180) mutations of the L gene in association with PK-deficient hemolytic anemia have been identified. Clinically significant hemolytic anemia occurs in patients who are homozygous for the same gene mutation or doubly heterozygous for two different mutations. Heterozygous persons have intermediate level of the enzyme in the red blood cells and they are clinically and hematologically normal without evidence of hemolysis.

Pathophysiology

Pyruvate kinase is involved in the anaerobic glycolytic pathway which results in the production of ATP and lactate. Blockage of this pathway in the pyruvate kinase deficient patients leads to markedly decreased level or absent ATP in the red blood cells. ATP is thought to be essential to maintaining the red blood cell milieu. Reduced or absent levels or activity of PK lead to potassium and water leak from the RBCs resulting in dehydrated, shrunken and spiculated cells (echynocytes) and shortened red cell survival (hemolysis). In vitro, addition of ATP to incubated PK deficient red blood cells corrects this defect, while addition of glucose fails to do so. ATP deficiency, however, is not sufficient to explain the mechanism of hemolysis. It is difficult to demonstrate ATP deficiency in some patients with severe hemolysis, while hemolysis is not found in some disorders with more severe ATP deficiency. PK deficiency results in an increased level of 2,3 diphosphoglycerate (2,3-DPG), which leads to a rightward shift of the oxygen dissociation curve. This shift results in better oxygen delivery to the tissues, which explain the adequate exercise tolerance despite significant anemia in those affected by PK deficiency.

The pyruvate kinase deficiency phenotype is thought to be more common among people of the northern European extraction, with prevalence ranging between 0.14 to more than 1%. Other reports, however, have demonstrated a higher prevalence in other ethnic groups (Indians, Chinese, Saudi Arabs, Turks and Iranians). The prevalence of clinically significant anemia (homozygous or doubly heterozygous) is expected to be higher with high rate of consanguinity.

Clinical Picture

Pyruvate kinase (PK) deficiency is the most common cause of congenital nonspherocytic anemia (CNSHA).

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_321,

It affects males and females equally because it is inherited as a recessive trait. The severity of anemia is highly variable, ranging from a severe transfusion dependent hemolytic anemia beginning at birth to a well-compensated asymptomatic hemolytic process recognized in later life because of the worsening of anemia (aplastic or hemolytic crisis) or because of the development of complications (cholelithiasis). In some extreme conditions, the anemia is severe enough to cause non-immune hydrops fetalis. The degree of severity is typically similar within a family with PK deficiency. The severity is probably related to influence of the L gene and the compensatory effect of the M2 gene, which is widely distributed in various tissues including the red blood cells. Absence of this compensatory mechanism results in severe life threatening anemia. In severe cases, patients present, at birth, with evidence of hemolysis (pallor, jaundice and splenomegaly). Reticulocytes are usually extremely high (40–70%), especially after splenectomy. This interesting phenomenon of increased reticulocytes after splenectomy is thought to be due to the interaction between the PK deficient reticulocytes and some unknown factor in the splenic environment (possibly hypoxia due to hemostasis). The anemia and hyperbilirubinemia might be severe enough to require phototherapy with or without simple or exchange blood transfusion. Patients may present with one or more complications of disease, which include hepatosplenomegaly, gallbladder stones, transient aplastic crisis caused by parvovirus B19, megaloblastic anemia due to folic acid deficiency or a hyper-hemolytic event.

Diagnosis

Diagnosis of PK deficiency is based on clinical and laboratory findings described above and confirmed by the assay of the red blood cells' PK enzyme level. Specific gene mutation can be identified in specialized laboratories.

Treatment

Treatment of PK deficiency consists of supportive care, splenectomy, treatment or prevention of complications, stem cell transplantation and gene therapy. Intra-uterine transfusion is indicated for severe anemia with hydrops. Newborn infants with severe anemia and/or hyperbilirubinemia should be treated with phototherapy, simple transfusion, or exchange transfusion as appropriate. Infants and children who have severe anemia may require repeated transfusions. Transfusion may be sporadically required in patients with mild disease during transient aplastic or hemolytic events. As with all chronic hemolytic anemias, folic acid supplementation is recommended. Splenectomy is recommended for children with severe, transfusion-dependent anemia. Splenectomy results in the amelioration of the hemolytic process leading to either the abolishment or greatly decreasing the need for transfusion. Splenectomy should be delayed until 5–6 years of age to avoid post-splenectomy sepsis, unless otherwise absolutely necessary. Complications which require treatment and/or prevention include cholelithiasis, which often requires surgery. Post splenectomy sepsis by the encapsulated organisms (streptococcus pneumoniae, haemophilus influenzae and neisseria meningitidis) can be prevented by pre splenectomy immunization and post splenectomy antibiotic prophylaxis. Iron overload caused by blood transfusion may require chelation therapy. Hematopoietic stem cell transplantation has been successfully performed in some severe cases. Gene therapy is still experimental.

Deficiencies of Other Glycolytic Enzymes

Congenital nonspherocytic hemolytic anemia had been reported with several other glycolytic erythrocyte enzyme deficiencies, including hexokinase, glucose-6 phosphate isomerase, glyceraldehyde-3-phosphate isomerase, phosphofructokinase, triosephosphate isomerase, aldolase and phosphoglycerate kinase deficiencies. These rare inherited enzymopathies have in common, an autosomal recessive mode of inheritance and a nonspherocytic hemolytic anemia with variable severity, which usually starts in infancy. The anemia in the newborn might be severe enough and may be associated with hyperbilirubinemia that require phototherapy and simple or exchange transfusion. The anemia during infancy and childhood may be compensated and asymptomatic, or severe transfusion dependant. The anemia may be exacerbated with transient bone marrow aplasia or acute hemolytic event in association with infection. Red blood cell morphology is normal and osmotic fragility is normal. However, spiculated red cells and target red blood cells might be seen in some patients. The reticulocyte count is elevated, especially after splenectomy. Clinical manifestations are those of hemolytic anemia and its complications. Pallor, jaundice and splenomegaly are present in patients with severe disease. Gallbladder stones may develop early in childhood. Of interest is the reported association of these disorders with other hematologic, neurologic, metabolic, or glycogen storage diseases. Hexokinase deficiency was reported with Fanconi aplastic anemia, triosephosphate isomerase

deficiency with progressive neurologic disorder, phosphofructokinase deficiency with myopathy, phosphoglycerate kinase deficiency with mental retardation and aldolase deficiency with disorders of glycogen metabolism. Diagnosis of these disorders is confirmed by the enzymatic assay. Treatment is mainly supportive with blood transfusion as needed, phototherapy and/or exchange transfusion for severe neonatal anemia and hyperbilirubinemia, folic acid supplementation and cholecystectomy for symptomatic gallbladder stones. Splenectomy resulted in amelioration, but not complete resolution of hemolysis. After splenectomy, transfusion requirements is decreased or completely abolished.

322 Red Blood Cell Membrane Disorders

Ahmad A. Mallouh

Introduction

The red blood cell (RBC) membrane is a complex structure consisting of approximately 50% proteins, 40% lipids, and 10% carbohydrates, containing 10–12 major proteins and possibly hundreds of minor ones. RBC membrane proteins are divided into those that are integral to the membrane (glycophorins A, B, C, and D that contain membrane receptors and antigens and protein 3 which is responsible for anion exchange) and those that play a role in the cytoskeleton. Spectrin is the major skeletal protein of the RBC membrane; it constitutes 50–70% of the skeletal part of the membrane. The RBC membrane has two major functions: maintenance of the structural integrity of the cell and control of cations, anions, and water permeability. As the membrane is semipermeable, water and some cations and anions can migrate passively through the RBC membrane. However, some cations (Na, K, and Ca) are transported through the membrane both passively and by an active mechanism (Na/K pump and calcium efflux pump) using energy produced by ATP. Changes in the membrane surface area in relation to the red cell volume result in changes in the shape and deformability of the cells. These changes render the abnormal RBCs susceptible to destruction by the reticuloendothelial system. Loss of surface area without loss in volume from either inherited or acquired causes results in formation of spherocytes. Following is discussion of inherited RBCs membrane disorders.

Hereditary Spherocytosis

Around 75% of hereditary spherocytosis (HS) is inherited in an autosomal dominant pattern. The remaining 25% are mostly inherited as an autosomal recessive trait. Some cases (up to 10% in some studies) are thought to be new mutation or mild cases of the dominant type. Homozygous of the dominantly inhireted HS has not been reported and is thought to be incompatible with life. The incidence of HS is about 200–300 per million in the Caucasians, but this figure is likely to an underestimation as mild cases are often not diagnosed. Some studies suggest that the true incidence is probably four to five times greater. The incidence in other ethnic groups is not known but thought to be much lower than that of the Caucasians.

Pathophysiology

The primary problem in HS is loss of the RBC membrane surface area leading to a change of the cell shape from a biconcave disk-like to a spherocyte. This change in the shape makes the cells less deformable and more susceptible to hemolysis in hypotonic solution (increased osmotic fragility). The reticulocytes and the younger red cells are not spherical. As these cell age they become more spherical and their membrane more rigid. The most common defect is spectrin deficiency. However three other abnormalities had been identified as the main causes of HS: combined spectrin and ankyrin, protein 3 deficiency, and protein 4.2 abnormality. The spherical RBCs with a rigid membrane are trapped and hemolyzed in the spleen (extravascular). The severity of anemia depends on this chronic process of intrasplenic hemolysis.

Clinical Picture

The disease is variable in severity ranging from the asymptomatic patient who is diagnosed only because of family history or because they develop cholelithiasis; to the severe patient who may be packed red cell (PRBC) transfusion dependent. Some patients present in the neonatal period with anemia, which may require PRBC transfusion, and/or jaundice, which requires phototherapy, or even exchange transfusion. In such patients, a family history of HS may be the first clue of the diagnosis. Other aspects of the family history that would raise the possibility of HS include "chronic anemia," jaundice in the neonatal period or later, splenomegaly, cholelithiasis, and/or history of HS. A child may present with severe abdominal pain and jaundice with or without fever and chills as a result of the cholelithiasis and/or cholecystitis. The degree of anemia is variable and so its manifestations. Around 5% of patients with HS have severe anemia, reticulocytosis, and significant splenomegaly. Anemia in these patients can be

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_322,

severe enough to cause hydrops fetalis and intrauterine death. Postnatally these patients often require repeated PRBCs transfusion. Up to 75% of patients with HS have moderate anemia with mild to moderate splenomegaly and moderate reticulocytosis, ranging from 5% to 10%. These patients usually, but not always, have the dominantly inherited condition. Patients with mild HS (20–30% of all patients) usually have a dominant type inheritance. As mentioned above these patients are asymptomatic and are diagnosed only on family study or when they develop complications as cholelithiasis or aplastic crisis. The spleen is palpable in 75–95% of people with HS. Splenomegaly in mild cases might be absent. In some patients (usually in the most severe ones who have a recessive type of inheritance), splenomegaly can be massive and may be the main presenting complaint. About 30–50% of adults with HS have history of jaundice. The jaundice in the newborn can be severe and may require exchange transfusion. In older children and adults it is usually mild and intermittent. In addition to the above-mentioned manifestations, patients may present with more acute complication. These include hemolytic events, aplastic events, megaloblastic events, cholelithiasis, cholecystitis, and severe neonatal hyperbilirubinemia. Hemolytic events are usually triggered by a viral infection that stimulates the reticuloendothelial system mainly in the spleen. The patient presents with anemia, jaundice, and reticulocytosis and often increased splenic size. Aplastic events are oftentimes caused by human parvovirus 19 (B19). These patients present with anemia, reticulocytopenia, and no jaundice. Megaloblastic events are due to folic acid deficiency. Therefore, folic acid supplementation is recommended for all patients with HS. Unlike the other types of events, a megaloblastic event usually develops slowly. Cholelithiasis can occur at any early age, having been reported in children as young as 3 years old. The incidence, however, increases with age; upto 75% of all patients with HS after the fifth decade of life. Most patients are diagnosed with gallstones in the second and third decade of life. Many patients with cholelithiasis are asymptomatic. However, several studies suggest that around 50% of patients with pigmented gall bladder stones have or are expected to develop symptoms of cholecystitis and/or biliary colic with jaundice.

Diagnosis

Diagnosis of HS depends on history, physical examination, and appropriately ordered laboratory tests. A family history of chronic anemia, confirmed HS, cholelithiasis at young age, or history of splenectomy is of paramount importance in suggesting the diagnosis. A history of anemia and or jaundice in the neonatal period which is not explained by other causes (blood group incompatibility) may suggest an inherited cause of hemolysis including HS. A history of previous blood transfusions in the patient or other family members might be present. Depending on the severity of anemia, patients may have exercise intolerance. Physical findings may include pallor (depending on level of anemia), jaundice, and splenomegaly. Biliary colic with jaundice may be the first presenting sign. Manifestations of cholecystitis (abdominal pain, fever, chills, and jaundice) may also be the first presenting problem. Growth retardation and delayed sexual maturation may be present in severe cases. Severe cases also may have bone marrow expansion mostly in the facial and other skull bones causing frontal bossing and dental malocclusion.

The degree of anemia is variable, ranging from compensated state with normal hemoglobin to severe, transfusion-dependent anemia. Most cases however have compensated mild to moderate anemia (hemoglobin >10 g/dl). Patients who present early during infancy usually have more severe anemia (hemoglobin 8–9 g/dl). Reticulocytosis is usually present. Its value depends on the severity of the anemia and the appropriateness of the bone marrow response. During aplastic events, reticulocytopenia is present. Unconjugated bilirubin may be high especially in jaundiced patients. Serum haptoglobin is usually low but it is not required for diagnosis. The hallmark of the disease is the presence of microspherocytes on a peripheral blood smear. The blood smear (*Fig. 322.1*) should be inspected by a qualified or experienced observer.

The most commonly used test to confirm the diagnosis of HS is the osmotic fragility. This test detects hemolysis of RBCs from patients affected with HS at higher concentration of saline than those of normal RBC. The unincubated osmotic fragility test, performed on fresh RBCs, may miss up to a third of the cases. Incubation of the blood for 24 h makes the test more sensitive. A newly described flow cytometry assessment can provide a rapid and reliable diagnosis, but is not generally available. Analysis of the cell membrane for determination of the specific protein defect is available only in specialized laboratories and is of no clinical value.

Treatment

As with other chronic hemolytic anemia, daily folic acid supplementation should be given to avoid megaloblastic events. PRBC transfusion might be needed in severe cases of hemolytic events or aplastic events. Phototherapy and/or

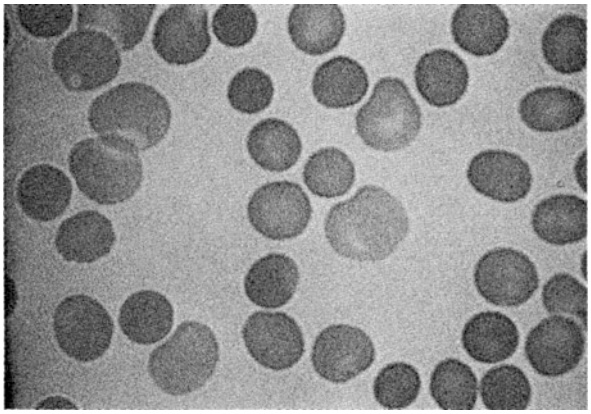

Figure 322.1
Blood smear in hereditary spherocytosis. Note the spherical RBCs without central pallor

exchange transfusion is indicated for newborn infants with severe anemia or hyperbilirubinemia.

Splenectomy usually results in complete or partial correction of the anemia associated with HS. RBCs maintain their spherical shape but their life span increases even though it is usually shorter than normal RBCs. Before proceeding with splenectomy, the following should be considered:

- Indications
- Potential benefits
- Potential risks and their prevention and/or treatment
- Type of the procedure
- Timing
- Potential failure and its causes

In patients with clinically mild HS, the only benefit of splenectomy is prevention of gall stone formation. The risk and cost of the procedure in this setting is higher than the expected benefit. If splenectomy is to be done, some studies suggest doing prophylactic cholecystectomy in the same setting. In patients with clinically severe HS, those who require repeated blood transfusion and those with moderate but symptomatic anemia, splenectomy is recommended. This procedure is expected to correct the anemia to normal values except in some patients with autosomal recessive HS, in which the anemia may be only partially corrected. In those patients with moderate but asymptomatic anemia (hemoglobin concentration from 8 to 10 g/dl), splenectomy may be indicated, even though there is a paucity of studies demonstrating benefit. The expected benefits of splenectomy include correction of anemia, prevention of development of cholelithiasis, prevention of bone marrow expansion and growth failure, decreased serum bilirubin level, and decreased reticulocyte count.

In addition to the risks of anesthesia and the surgical procedure, the most serious risk is post-splenectomy infection caused by encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*). These infections are life threatening. Even though these infections can occur at any age they are more common when splenectomy is performed before 6 years of age. This serious problem can be minimized by:

- Delaying splenectomy until 6 years of age (unless absolutely necessary)
- Giving immunizations against the above-mentioned organism a few weeks before the procedure
- Giving antibiotic prophylaxis (usually penicillin)

The duration of the prophylaxis is not well established. Some authorities recommend a minimum of at least 3 years post splenectomy and probably for life.

Other post-splenectomy complications include an increased incidence of venous and arterial thrombosis and thromboembolism. An increased risk of arteriosclerosis later in life has been reported. Laparoscopic splenectomies are preferred by many centers because they may shorten hospital stay, decrease postoperative pain, and decrease scarring. Partial splenectomy (removing 80–90% of the spleen) results in significant improvement, but not complete resolution of the anemia. It however retains splenic function and decreases or prevents post-splenectomy sepsis. Total splenectomy is often needed later because the spleen regrows in most patients to its original size and hemolysis accordingly increases in severity. In one study near total (98%), splenectomy was found to correct anemia without significant regrowth of the spleen. In some patients, the hemolytic anemia in HS is only partially corrected or recurs after splenectomy, because of:

- The presence of a severe recessive phenotype
- Partial splenectomy
- The presence of accessory spleen which is not removed during surgery
- The presence of splenosis that results from spillage and peritoneal implantation of splenic tissue

Accessory spleens and splenosis should be suspected if Howell–Jolly bodies are not identified postoperatively. Confirmation of this diagnosis can be obtained by radiological means mainly nuclear scan.

Management of asymptomatic cholelithiasis is controversial. Some authorities recommend cholecystectomy with or without splenectomy, while the others suggest expectant observation. Performing the procedure when the patient's condition is stable and the timing is

appropriate for the patient and family is warranted. Management of symptomatic cholelithiasis is urgent.

Hereditary Elliptocytosis

Hereditary elliptocytosis (HE) is a genetically phenotypically and biochemically inherited type of hemolytic anemia characterized by the presence of elliptical, oval, or elongated (rod-like) and sometimes spherical RBCS in the peripheral blood smear (*Fig. 322.2*). The incidence is estimated to be from 250 to 500 per million. The mode of inheritance is autosomal dominant in most cases. However, a recessive inheritance is typical of the subtype called hereditary pyropoikilocytosis (HPP). HE results from a defect in the skeleton of the RBC membrane. Defects in several RBC membrane proteins have been identified, including spectrin, protein 3, protein 4.1, and protein 4.2 alone or in combination.

Clinical Picture

The clinical picture of HE is variable and ranges between a hematologically normal to a severe and occasionally fatal anemia. Most cases, however, are mild. The following subtypes have been described:

- Common HE: This most common type of HE is divided clinically into the following subtypes.
  - Silent carrier: These patients are clinically and hematologically normal. They have normal hemoglobin, normal RBC morphology, a normal reticulocyte count, normal LDH, and normal haptoglobin. Patients who are silent carriers of HE are usually diagnosed on family studies of an affected member.

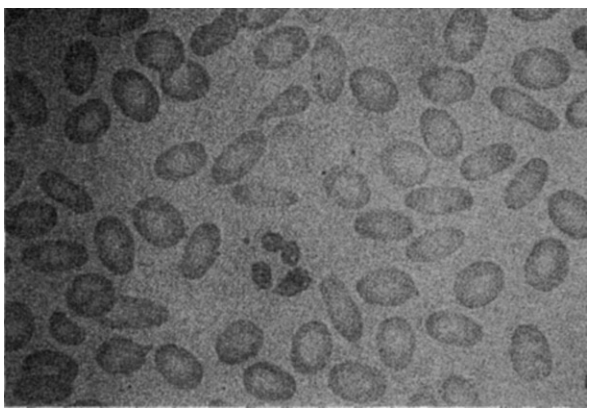

Figure 322.2
Blood smear in hereditary elliptocytosis

- Mild HE: These patients usually have a mild compensated hemolytic anemia with a mild reticulocytosis. They are clinically asymptomatic. They are diagnosed when elliptocytes are seen on a routine CBC. They may develop mild hemolytic events on exposure to certain infections.
- HE with chronic hemolysis: Several families had been reported with moderate hemolytic anemia with reticulocytosis without known trigger. Mild splenomegaly and mild RBC fragmentation can be present in these patients.
- HE with infantile poikilocytosis: In this interesting type of HE, infants have severe hemolytic anemia requiring repeated PRBC transfusions in the first 12–24 months. Their RBC morphologic and laboratory findings are similar to HPP (see below). One of the parents usually has common-type HE. The hemolytic process decreases over time. By 12–24 months of age, the clinical course is similar to those with mild HE. This type seems to be common in certain ethnic groups. The author has seen more than 100 cases in Saudi Arabian infants.
- Severe HE: In this type of HE, patients are often transfusion dependent. The disease can be fatal. Severe HE is thought to be a homozygous or doubly heterozygous form of mild HE.
- Hereditary pyropoikilocytosis (HPP): This type of recessively inherited hemolytic anemia was thought to be a specific entity, however further studies suggest that it a relatively severe subtype of HE. Both parents are often clinically and hematologically normal (silent carriers) but in other families at least one parent may have mild HE. HPP affects mostly people of African descent; however, it has been reported in other ethnic groups including a Saudi Arabian family reported by this author. HPP is characterized by moderately severe hemolytic anemia that usually starts in infancy and is lifelong. Many patients need repeated PRBC transfusions. Patients often have splenomegaly. The hallmark of this condition is the bizarre RBC morphology including spherocytes, microspherocytes, fragmented cells, cell membrane budding, schistocytes, and poikilocytosis. These morphologic changes are exaggerated with in vitro exposure to a relatively low temperature, resulting in increased fragmentation and more budding. Osmotic fragility is increased in patients with HPP. In most patients, the MCV is low, sometimes in the 50 or 60 femtoliter range.

- Spherocytic elliptocytosis: This type of HE is inherited in an autosomal dominant pattern. Spherocytic elliptocytosis has been reported only in Caucasians. The anemia is mild to moderate. Most patients have splenomegaly. Examination of the peripheral blood smear can be confusing as the number of elliptocytes can be lower than the number of spherocytes. Spherocytic elliptocytosis is considered a hybrid of ES an HS.
- Southeast Asian ovalocytosis: As the name implies, this type of HE is preset in the area of the world where malaria is or was endemic. Southeast Asian ovalocytosis is inherited in an autosomal dominant pattern. Heterozygous Southeast Asian ovalocytosis is asymptomatic, does not cause anemia, and is thought to be protective against malaria. The homozygous form is not compatible with life. Review of the peripheral blood smear is characteristic with the presence of "stomatocytic elliptocytes."

Diagnosis

Diagnosis of HE is straightforward, requiring a complete blood count, reticulocyte count, and a peripheral blood smear. Other tests (osmotic fragility, heat stability, and structural study of the RBCS membrane) are often of academic interest and rarely add any significant clinical diagnostic value. When considering the diagnosis of HE, several points should be kept in mind:

- Unaffected people may have up to 5% elliptocytes in their peripheral blood.
- Elliptocytes are increased in some acquired conditions, for example, megaloblastic anemias and iron efficiency anemia.
- Silent carrier HE can be diagnosed only with a RBC member structural study. This is rarely clinically indicated.
- HE with infantile poikilocytosis cannot be differentiated from true HPP except by time.
- Spherocytic HE can be confused with HS.

Treatment

Most patients with HE do not need any treatment except folic acid supplementation (especially when there is evidence of hemolysis) and observation for development of cholelithiasis. Blood transfusion is usually needed for severe episodes of anemia especially in homozygous common HE, HPP, infantile poikilocytosis in the first 12–24 months of life, and occasionally in the common type after a hemolytic event. Splenectomy might be needed in HPP and homozygous common HE if and when anemia is severe and repeated transfusion is required.

Hereditary Stomatocytosis

This rare RBC membrane defect is characterized by the presence of elongated RBCs with a slit-like pallor resembling a mouth (stoma). It is inherited in an autosomal dominant manner. The change in the shape of the RBCs results from a decrease in the ratio between surface area and cell volume, usually due to increased volume. The exact pathogenesis is not well understood. Alteration of the membrane permeability leads to sodium and water movement into the RBC causing increased cell volume. With increased water and sodium, the RBCs become swollen. The clinical and hematologic findings are variable. Approximately one third of the patients are asymptomatic with normal hematological values and no evidence of hemolysis. The remainder of the patients have mild to moderate and occasionally severe transfusion-dependent chronic hemolytic anemia, jaundice, and splenomegaly. Some patients with hereditary stomatocytosis have recurrent vaso-occlusive events (similar to those of sickle cell disease) and an increased incidence of thromboembolic complications especially after splenectomy. These two complications are thought to be due to increased adherence of the elongated RBC to the endothelium. Stomatocytes may be present on the blood smear of several congenital and acquired conditions. Stomatocytosis with thrombocytopenia and large platelets had been reported in people of Mediterranean origin. Stomatocytosis is associated with two hereditary diseases: cryohydrocytosis and familial pseudohyperkalemia. A syndrome of stomatocytosis with mental retardation and cataracts has been reported. Acquired stomatocytosis can occur with acute alcohol intoxication, chronic liver disease, and with administration of vinca alkaloids (vincristine or vinblastine). Stomatocytosis is often an artifact. Diagnosis of hereditary stomatocytosis is supported by the presence of a macrocytic, hypochromic hemolytic anemia with a high number of stomatocytes on the peripheral blood smear (up to 60%). Treatment is usually supportive (folic acid supplementation and blood transfusion in severe cases). Splenectomy for severe cases may be necessary and may improve the anemia. However, splenectomy may increase the risk of serious thrombotic complications.

Acanthocytosis and Echynocytosis

Acanthocytes have a small number (5–10) of irregularly spaced, long spicules that arise from the RBC membrane. Echinocytes, or crenated cells, on the other hand, have 10–30 regularly spaced, short projections that arise from the surface of red cells. Spur cells are remodeled acanthocytes in which spicules become blunt and short. Acanthocytes and echynocytes, separately or in combination, can be associated with several congenital or acquired conditions. They both are often found in end stage renal disease, advanced hepatocellular disease, and vitamin E deficiency. Echynocytes may be seen in association with pyruvate kinase deficiency. Echynocytes are commonly seen as artifact of the preparation of the peripheral blood smear. Acanthocytosis is a typical feature of abetalipoproteinemia, in which progressive ataxia, retinitis pigmentosa, and fat malabsorption are present. Acanthocytosis may be associated with hypothyroidism, myelodysplasia, having no expression of the Lutheran or McLeod blood groups, and infantile pyknocytosis. Acanthocytes are also associated with several neurological diseases including McLeod syndrome, various mitochondrial diseases, choreo-acanthocytosis, familial acanthocytosis with paroxysmal exertion-induced dyskinesias, and epilepsy and Huntington's disease. The significance and pathogenesis of this association is not understood. In most cases, the presence of acanthocytes and/or echynocytes is of no clinical significance except as a diagnostic tool for certain diseases.

Hereditary Xerocytosis

Xerocytosis is a chronic hemolytic anemia inherited as autosomal dominant trait. It is characterized by the presence of densely stained contracted and sometimes spiculated red cells. The hemoglobin may "puddle" in one part of the cell. The pathophysiology is due a defect in RBC membrane permeability, with an increased potassium efflux resulting in low potassium content. These changes lead to decreased deformability, increased rigidity, and increased susceptibility to shear cell damage. The diagnosis is based on the presence of chronic hemolytic anemia and the presence of xerocytes on peripheral smear. The MCV and MCHC are both elevated. Target cells are usually present. The osmotic fragility is decreased. The severity of anemia is variable, particularly during the newborn period, in which anemia may be severe enough to require exchange transfusion. The anemia may be exacerbated by viral infections. Transient aplastic events have been reported. A subtype of xerocytosis (called stomatocytic xerocytosis) is often difficult to differentiate from classic stomatocytosis. Both stomatocytes and dehydrated target cells are present on the peripheral blood smear. Unlike stomatocytosis, the osmotic fragility is reduced in stomatocytic xerocytosis. Like the classic form of hereditary xerocytosis, the MCV and MCHC are elevated. Treatment for xerocytosis is symptomatic. Folic acid supplementation is recommended. Splenectomy has been performed with amelioration of the anemia. However, there have been reports of an increased risk of deep venous thrombosis after this procedure in patients with this diagnosis.

Infantile Pyknocytosis

Infantile pyknocytosis is a transient hemolytic anemia that occurs in the newborn infants, particularly those born preterm. It is characterized by a hemolytic anemia and jaundice without splenomegaly. The severity of anemia is variable and may pass unnoticed. In some infants, however, the anemia is severe enough to require PRBC transfusion. The anemia peaks at 3–4 weeks of age and resolves spontaneously by 4–6 months of age. Pyknocytes are densely stained, spiculated, and irregularly contracted cells. Up to 5% of pyknocytes can be found on the peripheral blood smear in unaffected premature infants. Pyknocytes may be associated with many inherited or acquired disease including severe G6PD deficiency, neonatal hepatitis, hereditary elliptocytosis, vitamin E deficiency, and microangiopathic hemolytic anemia.

Vitamin E Deficiency

Vitamin E deficiency may occur in premature infants and in children with malabsorption disorders such as liver cirrhosis, cholestatic liver disease, cystic fibrosis, celiac disease, Crohn's disease, and pancreatic insufficiency. Hemolytic anemia, thrombocytosis, and the presence of a variable number of spiculated and contracted RBCs are the hallmark of the hematological manifestation of vitamin E deficiency. Generalized or pedal edema may be seen in severely affected infants. When suspected, measuring serum vitamin E levels makes the diagnosis. Oral vitamin E supplementation may be needed especially in premature infants. In patients with chronic malabsorption, the treatment of the original disease together with vitamin E supplementation is required.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disorder characterized by episodes of hemolysis

during sleep as well as early morning hemoglobinuria. Approximately 15% of the reported cases occur in children 6–20 years old. The basic defect is in the glycosylphosphatidylinositol (GPI) anchor. This defect leads to partial or complete absence of all GPI-linked membrane proteins, including CD59 and CD55. Occasionally CD8 expression may be decreased. These changes in the RBC-binding membrane proteins results in increased sensitivity of affected red cells to hemolysis by the activated complement system.

Clinical Presentation

Patients with PNH usually present with episodes of intravascular hemolysis that occur during sleep and lead to early morning hemoglobinuria. The anemia is variable in severity. Some patients have chronic hemolysis. Hemolysis can be induced or exacerbated by infection, whole blood transfusion, vaccine administration, iron therapy, or exercise. The severity of hemolysis is related to the size of the PNH clone, the degree of the abnormality (partial or complete absence of CD59 and CD55), and the degree of complement activation. Patients often present with other hematological or with nonhematological complications. Hematologic complications include venous or arterial thromboembolism, aplastic anemia, leukemia, myelodysplastic syndrome, and iron deficiency anemia. Venous thrombosis is much more common than arterial. Thrombosis may involve any vein, large or small. However, they most often involve the large intra-abdominal veins, particularly the hepatic, portal, and splenic veins, as well as the inferior vena cava. Thrombosis of the cerebral veins, specially the major venous sinuses, occurs less frequently than the intra-abdominal veins. Hepatic venous thrombosis may cause splenomegaly, hepatomegaly, and ascites (Budd–Chiari syndrome). Thrombosis of the small splanchnic veins may cause severe abdominal pain. The prevalence of thrombosis in Japanese patients is lower (6%) than among the American patients (38%). Aplastic anemia may develop after the diagnosis of PNH or it may be the presenting problem. The incidence is not known and it may appear years after the diagnosis of PNH. Leukemia, usually acute myeloid leukemia, develops years after the diagnosis of PNH. The reported incidence ranges from $<1\%$ up to 5%. Myelodysplastic and myeloproliferative disorders have been associated with PNH. Iron deficiency anemia is common in patients with PNH because of the urinary loss of iron caused by hemosiderinuria and/or hemoglobinuria. Nonhematological presentations include acute renal failure (from hemoglobinuria), proximal tubular dysfunction, and chronic renal failure. Esophageal spasm and erectile dysfunction has been reported in patients with PNH, though only in adults.

Diagnosis

Traditionally PNH was diagnosed by inducing in vitro hemolysis using the sucrose lysis test and the Ham acid hemolysis test. Both of these tests depend on activation of the complement system. Recently, flow cytometry using monoclonal antibodies against CD59 and CD55 has largely replaced the sucrose lysis and Ham tests for accurate diagnosis of PNH.

Treatment

The treatment of the anemia associated with PNH is supportive. Iron supplementation for iron deficiency anemia and folic acid supplementation to prevent megaloblastic anemia are indicated. PRBC transfusion should be given if clinically indicated. Caution should be given when iron or blood is given as they may induce acute hemolytic episodes. Whole blood should be avoided and only washed and preferably leukoreduced RBCs are recommended to decrease the possibility of transfusion-induced hemolysis. A humanized monoclonal antibody (eculizumab) that inhibits terminal complement activation by binding to the C5 was found to reduce hemolysis, transfusion requirements, and thromboembolic event rates. Prednisone and androgenic hormones (danazol) have been effective in diminishing anemia in some reports. Their role in PNH, however, is controversial. The thromboembolic complications should be treated in the same therapeutic modality as other patients. Hematopoietic cell transplantation (HCT) from an HLA identical sibling is indicated in the patient with severe aplastic anemia. Immunotherapy with cyclosporine and antithymocyte globulin (ATG) has been successful in some patients with aplastic anemia. Their role remains to be determent by further studies.

323 Microangiopathic Hemolytic Anemias

Ahmad A. Mallouh

Introduction

The hallmark of the microangiopathic hemolytic anemia is the presence of fragmented, distorted red blood cells (schistocytes) on the peripheral blood smear of a patient with hemolytic anemia (*Fig. 323.1*). It does not represent a specific diagnostic entity, but rather a morphologic manifestation of mechanical destruction and fragmentation of the red blood cells by shear stress as they pass through fibrin strands deposited on the vascular endothelium or within small blood vessels. Its clinical value lies in narrowing the differential diagnosis in a patient with hemolytic anemia. It should be remembered that a small number of schistocytes may be present in normal individuals. Mild increase in the number of schistocytes may be seen in some diseases with no evidence of hemolysis, i.e., renal disease, prosthetic heart valve, and preeclampsia. The presence of more than 1% of schistocytes or two schistocytes per high power field on a well prepared blood smear is suggestive of microangiopathic hemolytic anemia. Several disease processes may be associated with microangiopathic hemolytic anemia (*Table 323.1*). The clinical manifestations are those of the hemolytic anemia and the manifestations of the underlying precipitating condition. Following is a discussion of disease entities associated with microangiopathic hemolytic anemia.

Disseminated Intravascular Coagulation (DIC)

Introduction

Human blood remains in a fluid state without bleeding or intravascular thrombosis by a delicate balance between the vascular system and the coagulation, anticoagulation, fibrinolytic and antifibrinolytic pathways. When a blood vessel is injured, it constricts immediately to limit blood loss. This is followed by the formation of a reversible platelet plug. Local activation of the coagulation cascade results in formation of thrombin, which stabilizes the platelet plug and generates fibrin from fibrinogen forming a stable haemostatic plug. The fibrinolytic system is locally activated to remove the unneeded thrombus to keep the injured blood vessel open. As these processes are transient, localized and compensated by production of the consumed factors (platelets and coagulation factors) by the liver and bone marrow, no excessive or prolonged bleeding or harmful thrombosis occur.

Pathogenesis

Uncontrolled and excessive activation of the extrinsic pathway of the coagulation cascade produces large amounts of thrombin. Activation of the coagulation cascade results from exposure of the blood to large amounts of the tissue factor and activated factor VII (FVIIa), which results from tissue injury (by trauma), injury of the vascular endothelium (usually by endotoxin) or increased release or expression in the monocytes. Prothrombin leads to widespread intravascular coagulation and deposition of fibrin in the deferent organs causing tissue ischemia and organ damage. The fibrinolytic system is activated to dissolve the fibrin deposits producing fibrinogen degradation products (FDP) and D-Dimers. Platelets and coagulation factors (fibrinogen, prothrombin, and factors V and VIII) are depleted leading to spontaneous bleeding. Excess FDP enhances bleeding by interfering with platelets aggregation and fibrin polymerization. In addition, excessive amounts of plasmin (which is produced from plasminogen) causes degradation of the clotting factors causing further drop in their level and leading to more bleeding. Destruction of the red blood cells (RBCs) by passing through the fibrin mesh results in the classic finding of Schistocytic hemolytic anemia. Activation of the intrinsic pathway of coagulation is thought to cause hypotension but not DIC.

Etiology

Disseminated intravascular coagulation (DIC) may be triggered by a number of serious disease processes. The

Conditions associated with microangiopathic hemolytic anemia

Disseminated intravascular coagulation (DIC)
Hemolytic-uremic syndrome (HUS)
Thrombotic thrombocytopenic purpura (TTP)
Giant hemangioma (Kasabach–Merritt syndrome)
Extracorporeal circulation (after open heart surgery)
Intracardiac prosthesis
Malignant hypertension
Strenuous exercise

most common causes are infection, trauma (accidental or surgical), and malignancy. However, it may be associated with other disease processes, including, giant hemangioma, acute hemolytic transfusion reaction, paroxysmal nocturnal hemoglobinuria (PNH), snake bites, fulminant hepatic failure, burns, severe hypoxia, shock, heat stroke, and severe metabolic disturbances. In newborn infants, septicemia, severe respiratory distress syndrome, hypoxia, shock, necrotizing enterocolitis and homozygous proteins C or S deficiency are known to cause DIC.

Severe infections, including bacterial, systemic viral (i.e., varicella), parasitic (malaria), fungus (systemic canididemia, aspergillosis) and rickettsial infections are the most common cause of DIC in children. Gram negative sepsis may be present in up to 50% of all children with DIC. Severe trauma (accidental, burn, or major surgery) is the second most common cause of DIC. The possibility of the development of DIC depends on the severity of the trauma and the extent of tissue damage. Head injury is more likely to be associated with DIC, when compared with injuries of similar extent in other organs. The severity of coagulopathy and the development of systemic inflammatory response syndrome (SIRS) are strong determinants of the outcome of trauma associated DIC. DIC develops in most patients with acute promyelocytic leukemia (APL) due to the release of the tissue factor from the blasts. Even though it may be present at presentation, it often develops after starting chemotherapy. DIC also often develops with other types of Hematologic malignancy or disseminated solid tumors.

Clinical Picture

DIC is a secondary syndrome associated with or caused by any of several serious and often clinically obvious causes. Even though the exact incidence is not known, it is estimated that around 1% of the hospitalized patients develop coagulopathy. Clinical picture is that of the triggering disease process together with bleeding tendency, disseminated thrombosis causing organ damage and microangiopathic hemolytic anemia. External (skin, mucous membranes, venipuncture site, or wounds) and/or internal (central nervous system, lungs, gastrointestinal tract, urogenital tract, or adrenal glands) bleeding are usually present. Pallor, jaundice, tachycardia, hypotension, and/or hemoglobinuria are manifestations of hemolysis and may be present depending on the severity of the anemia. Purpura fulminats with skin necrosis and/or gangrene of the fingers and toes may be present. Acute renal, hepatic, pulmonary or CNS injury may occur due to hemorrhage, and microthrombosis of feeding vessels and/or hypoperfusion due to hypotension. It should be remembered that even though activation of the intrinsic coagulation pathway dose not play a role in the pathogenesis of DIC, it may cause or exasperate hypotension and shock, which in turn exasperate tissue hypoxia and organ damage.

Chronic DIC is often associated with solid tumors. It results from release of small amounts of tissue factor and a compensatory response from the liver, which replete the consumed coagulation factors, and the bone marrow, which compensate for the consumed platelets. Patients with chronic DIC have no or minor bleeding tendency. However, they are liable to develop venous or arterial thrombosis.

Diagnosis

DIC should be suspected in any patient with increased bleeding tendency, thrombotic episodes or microangiopathic hemolytic anemia in association with severe disease, especially, the causative entities described above. Diagnosis is confirmed by a combination of laboratory findings which include thrombocytopenia or steadily falling platelets count, prolonged prothrombin (PT) and partial activated thromboplastin times (PTT), low levels of fibrinogen, and elevated levels of fibrinogen degradation product (FDP) and D-dimers. Hemolytic anemia with the characteristic schistocytes is always present. Coagulation factors (especially factors V and VIII) are usually low. Thrombin time and reptilase time are usually prolonged; however they are not usually required for diagnosis or management of DIC. Diagnosis of chronic DIC can be problematic because PT, aPTT, and platelet count may be normal, as the consumed coagulation factors and platelets are compensated for by the liver and bone marrow, respectively. In addition to the clinical picture (usually thrombosis) and the presence of the initiating disease (usually disseminated solid tumor), diagnosis depends on the presence of microangiopathic hemolytic anemia and elevated FDP and D-dimers.

Differential Diagnosis

Even though all causes of bleeding diathesis, hypercoagulable states and hemolytic anemia should be considered in the differential diagnosis, in most case scenarios, the diagnosis is clear based on the clinical findings and simple laboratory tests. Liver disease, hemolytic-uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP) and heparin induced thrombocytopenia (HIT) are sometimes difficult to differentiate from DIC. The clinical picture, however, is often suggestive of the diagnosis. Liver disease in particular can be a difficult diagnostic problem. It should be remembered that severe liver disease may cause DIC and liver damage can be caused by the same triggering disease which causes DIC (i.e. sepsis, trauma, shock). Thrombocytopenia, microangiopathic hemolytic anemia and elevated FDP are usually absent in primary liver disease. Thrombocytopenia, however, may result from congestive splenomegaly and hypersplenism. Hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura (see below) both cause thrombocytopenia and microangiopathic hemolytic anemia. They, however, usually have normal PT, aPTT, fibrinogen, and FDP. Heparin induced thrombocytopenia (HIT) can be differentiated based on the history of heparin administration in the prior few days, the absence of DIC causing diseases (sepsis, trauma, or malignancy), and normal fibrinogen and FDP. PT and aPTT might be prolonged, if the patient is still receiving heparin.

Prognosis

DIC is a serious medical problem with high morbidity and mortality. Multiple organ damage may result from the initiating disease (sepsis, trauma, malignancy, etc.) or from bleeding, thrombosis or hypoxia due to the anemia or shock. Mortality, which can be as high as 80%, depends on the original causative disease (sepsis, trauma, malignance, etc.) and its severity, the severity of the coagulopathy, organs involved and the degree of their damage, the development of systemic inflammatory response syndrome (SIRS) and the appropriateness and promptness of therapy.

Treatment

Other than treating the original initiating disease, which is essential to hope for a good outcome, treatment of DIC is mainly symptomatic. Aggressive treatment of shock is essential part of therapy. Hypo-perfusion and tissue hypoxia furthers tissue damage and mortality. Anemia is treated with packed red blood cells transfusion as required. Platelets and fresh frozen (FFP) transfusion is recommended to stop or prevent anticipated bleeding. They should not be given to correct abnormal laboratory results. Cryoprecipitate should be given if bleeding could not be stopped with platelets and FFP. The transfused elements (red cells, coagulation factors, and platelets) are consumed rapidly; however, their administration helps to stop or decrease bleeding and correct the anemia until the triggering factor is corrected. Anticoagulant therapy, mainly with unfractionated or low-molecular heparin, is often recommended in chronic DIC with major thrombosis. The use of anticoagulant in acute DIC is of questionable value and should be avoided specially in patients with CNS bleeding. Some studies showed that protein C concentrates decreases mortality in adult patients with sepsis and DIC. However further studies are needed before recommending its routine use.

Hemolytic-Uremic Syndrome

Introduction

Hemolytic-uremic syndrome (HUS) is an acquired disease characterized by an acute onset of the triad of

microangiopathic hemolytic anemia, thrombocytopenia, and nephropathy. The disease is classified into two types, the typical type (shiga-like toxin associated, postdiarrheal, D+) and the atypical type (non-shiga associated, non-postdiarrheal, D-). The two types have deferent etiology, epidemiology, clinical picture, clinical course, and prognosis. The typical type constitutes around 90%, while the atypical type constitutes around 10% of the reported cases.

Pathophysiology

Endothelial damage in the capillaries and/or arterioles leading to thrombotic microangiopathy and red blood cells fragmentation is the main lesion in both types of HUS (see section "Nephrology").

Etiology

The typical type (also called classic, epidemic, postdiarrheal, D+ and shiga-like toxin associated) is caused by shiga-like toxin producing organisms. In North America, around 70% of the typical type is caused by enterohemorrhagic *E. coli*, around 80% of which is *E. coli* O157:H7. In contrast, in other countries (Australia, Germany and Austria), the majority of postdiarrheal HUS is caused by non-O157:H7 *E. coli*, while in Asia and Africa, the most common cause is *Shigella dysenteriae* type 1. The atypical type is divided into two types, the genetic and the non-genetic types. The genetic type results from deficiency of complements components (mainly C3, factors H, B, I and the so called membrane factor), Von Willebrand factor cleaving protease (ADAMTS13) or defects of vitamin B12 metabolism. Some cases are inherited, but without known complement deficiency or abnormal metabolic etiology. The atypical non-genetic type is caused by non-enteric infections. *Streptococcus pneumoniae* causes up to 40% of the non-diarrheal type and up to 14% of all HUS in children. HUS has been reported with viral infection (especially HIV), systemic lupus erythematosus, antiphospholipid syndrome, and malignancy.

Epidemiology and Incidence

HUS occurs worldwide. Its incidence, causative agents, and age distribution differ from one area to another. In North America and Western Europe, around 90% of the cases are of the typical and around 10% are of the atypical type. The annual incidence is around 2–3 per 100,000 in children less than 5 years old. The peak incidence is in the summer and fall. However, the atypical type caused by *Streptococcus pneumoniae* occurs more commonly in winter months. The inherited types have no seasonal predilection. Most cases occur sporadically; however, epidemics often occur in day care center either because of exposure to a common source of infection or due to cross infection. Cases may occur in several family members either because they are exposed to the same source of infection or due to inherited type of the disease.

Clinical Picture

Most cases of the typical (shiga-like toxin associated) type occur in children less than 5 years old. Patients usually present with prodromal symptoms of diarrhea (often bloody), abdominal pain, fever, and vomiting. The full blown picture of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure follows in 5–10 days. Diarrhea precedes the development of HUS in over 90% of the cases. However, it is bloody only in 50–60% of the cases. Extra-gastrointestinal infection (urinary tract) with enterohemorrhagic *E. coli* may cause HUS without preceding bloody diarrhea. CNS involvement including irritability, seizures, coma, stroke, or hemiparesis occurs in one fifth to one fourth of the cases of HUS. Renal involvement, which occurs in over 95% of the cases, ranges between simple proteinuria, hematuria and severe acute renal failure. Anuria occurs in around half of the cases. The severity of renal involvement does not correlate with the severity of the prodromal symptoms, anemia, or thrombocytopenia. Hypertension occurs in around 50% of the cases. In addition to the bloody diarrhea, gastrointestinal complications may include intestinal gangrene, perforation, intussusception, or rectal prolapse. Other organs that may be involved include liver and pancreas. The atypical type is heterogeneous in its clinical presentation, severity, complications, and prognosis. It is not preceded by diarrhea. It usually presents in more insidious onset. Patients are at higher risk of severe acute renal failure, chronic renal failure, hypertension, recurrence, and death. It usually occurs at older age. However, recent studies showed that, depending on the etiology, some patients with the atypical type may present at early age and have milder course than the typical type.

Diagnosis and Deferential Diagnosis

With high index of suspicion, diagnosis is usually easily made based on the clinical picture and the presence of

microangiopathic hemolytic anemia, thrombocytopenia, and evidence of renal injury. Isolating *E. coli* or *Shigella* from the stools is helpful but not essential for diagnosis. Serologic detection of the shiga toxin in the stools can be done, but it is neither essential nor available in most settings.

Deferential diagnosis in the prodromal phase includes all causes of infectious (*Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, ameba) and noninfectious (ulcerative colitis, Henoch–Schonlien purpura) bloody diarrhea. All causes of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure should be included in the deferential diagnosis of HUS. Most of these cases, however, can be easily differentiated based on the clinical and laboratory finding. Patients with disseminated intravascular coagulopathy (DIC) have the triad of HUS, but they also have prolonged PT and PTT, low fibrinogen, and high FDP and low coagulation factors (mainly factors V and VIII). The typical type of childhood HUS can be differentiated from thrombotic thrombocytopenic purpura (TTP) by the presence of bloody diarrhea and the isolation of the pathogenic *E. coli*.

Treatment

The need for and modality of treatments depend on the organ/system involved and the severity of involvement. Acute renal failure and its related problems (hypertension, electrolytes disturbance, and fluid imbalance) is managed like other types of acute renal failure (see section "Nephrology"). Indications for dialysis are the same as for other forms of acute failure. It is required in around 50% of the typical type. Early dialysis, as previously suggested, does not improve the final outcome. Anemia might be severe enough to require packed red blood cells transfusion. Blood transfusion is usually recommended, if the hemoglobin drops to <6 g/dl. This indication, however, is not based on solid scientific grounds. The indication for transfusion should be individualized and be based on the clinical picture, the bone marrow activity as evidenced by the reticulocytes count, and the direction in which hemoglobin level is going (upward, downward, or stable). Platelets transfusion should be reserved for patients with uncontrolled active bleeding or those who are at risk of developing bleeding (planned surgical procedures). Careful fluid and electrolytes management is essential, especially in patients with oliguria or Anuria. Treatment of other involved organs (CNS, heart, pancreas, liver, or lungs) is similar to their treatment in other diseases. The role of plasma simple or exchange transfusion is controversial and its efficacy is doubtful in shiga-like toxin associated type. It is, however, recommended by some authorities in cases with severe CNS involvement. Plasma exchange is recommended in the atypical type. The response to this therapy, however, depends on the affected complement. Antibiotic to treat *E. coli* should be avoided, as it was shown to increase the risk of HUS without shortening the course of the gastrointestinal symptoms. Antibiotics may be used in *Shigella* associated HUS, as they do not appear to increase the risk of HUS. Renal transplantation is recommended for the typical type with end stage renal disease. Success rate is similar to other causes of end stage renal disease (ESRD). Recurrence rate is between 0% and 10%. The indication for renal transplant in the atypical type is controversial because of the high rate of recurrence.

Prognosis

Hematologic problems resolve in almost all cases of the typical type. Complete renal function recovery occurs in around 80% of the cases. However, recent long-term follow-up showed that renal dysfunction (clinical or subclinical) persists in much higher percentage (up to 30% of the cases). Around 5% of the patients die from the disease or its complications. Several bad prognostic factors were identified including prolonged oliguria or anuria, leukocytosis, the need for dialysis in the acute stage and the presence of arteriolar microangiopathy, cortical necrosis or microangiopathy involving over 50% of the glomeruli. Prognosis for the atypical type depends on the etiology or the mutated gene. *Streptococcus pneumonia* associated disease has bad early prognosis, caused mainly by death due to the infection itself (sepsis or meningitis), but it has better long-term renal function (inpatients who survive the acute phase) than the typical type. Most patients with HIV associated HUS end with ESRD. The prognosis for the inherited types depends on the mutated gene. Dominantly inherited cases have a better prognosis than the recessive cases. Mutation of factors H, I, C3, and ADAMTS 13 is usually associated with severe and progressive renal disease, while HUS associated with the mutation of membrane cofactor protein (MCP) deficiency rarely leads to ESRD.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is characterized by the sudden onset of microangiopathic hemolytic anemia and consumptive thrombocytopenia, often associated with neurologic dysfunction, impairment of renal function, and fever. It is primarily a disease of the adults. However, both acquired and congenital types are

known to occur in children. In adults, the clinical picture and pathology TTP overlap with hemolytic-uremic syndrome (HUS). The two syndromes are usually considered as one disease (TTP/HUS) and they are managed in the same way. In children, however, the typical type (shiga toxin associated, diarrhea associated) HUS is distinct from TTP in its etiology, clinical picture, therapy, and prognosis. The atypical type (non-shiga toxin associated) can be confused with TTP.

Pathogenesis and Pathology

The hallmark of TTP is the formation of platelets-rich microthrombi in the microcirculation of deferent organs. Obstruction of the blood supply results in ischemic damage of the involved organs. The development of these microthrombi is triggered by the presence of unusually large VWF (ULVWF) multimers in the circulation. In normal individuals, these multimers are cleaved to smaller inactive form by a protease identified as ADAMTS13. Acquired or congenital ADAMTS13 deficiency results in intravascular accumulation of the ULVWF multimers. These multimers promote platelets adhesion and aggregation, causing platelets-rich microthrombi. ADAMTS13 deficiency results from an autoimmune mechanism in the acquired (idiopathic) TTP and from an autosomally inherited gene in the congenital type.

Clinical Picture

The clinical picture and prognosis of TTP depend largely on the organs involved, degree of organ damage, and the type and timing of therapy. The classic required diagnostic criteria are the pentad of microangiopathic hemolytic anemia, thrombocytopenia, neurologic abnormalities, renal dysfunction, and fever. However, because of the efficacy of early plasma exchange in inducing remission and cure in a disease with high mortality, less stringent criteria are presently accepted as a presumptive diagnosis in adult patients and those who (based on family history) are suspected to have congenital ADAMTS13 deficiency. The sudden onset of Coomb's negative microangiopathic hemolytic anemia and thrombocytopenia without an apparent cause is an indication to start therapy. CNS involvement, which is present in most cases, ranges between headache, confusion, transient ischemic attacks and seizures, hemiparesis, coma, or death. Unlike HUS, TTP involves CNS more often than the kidneys. However, both diseases can cause deferent degrees of CNS and/or renal damage.

Diagnosis

For practical purposes, diagnosis depends on the clinical picture. Treatment should be started as soon as the diagnosis is made or highly suspected. Low plasma level of DAMTS13 is important to confirm the diagnosis, but it is not essential to start therapy. ADAMTS13 may be found in normal people and diseases other than TTP, i.e., sepsis and in some cases of HUS. The diagnostic sensitivity and specificity is 89% and 91%, respectively.

Treatment

Plasma exchange is the primary treatment for TTP. It should be started as soon as the diagnosis is highly suspected. Plasma exchange is given once daily (in severe cases twice daily) until complete clinical remission and platelets recovery. In the acquired TTP, plasma exchange removes ULVWF and the auto antibodies against ADAMTS 13 and it increases the level of the deficient ADAMTS 13. In the congenital type, simple rather than exchange plasma transfusion (10–15 ml/k daily) is usually adequate.

Rituximab (an anti-CD20 antibody) is effective in achieving remission and possibly preventing relapse in some refractory or relapsing cases. Steroids, cyclosporine, and cyclophosphamide were used in refractory and relapsing cases with variable results. Splenectomy was effective in some refractory cases. However, nowadays, it is rarely needed and it should be avoided specially in children.

Prognosis

The prognosis used to be dismal with a mortality rate approaching 100. Early plasma exchange decreased mortality rate to around 20%. (It should be remembered that these therapeutic and prognostic data are extrapolated mainly from adult studies because the disease is rare in children.).

Giant Hemangioma and Thrombocytopenia (Kasabach–Merritt Syndrome)

The association of microangiopathic hemolytic anemia, thrombocytopenia with or without evidence of coagulopathy (prolonged PT and PTT, low fibrinogen level and high level of fibrinogen degradation products

and D-dimers) with cutaneous or visceral kaposiform hemangioendothelioma or tufted angioma is referred to as Kasabach–Merritt Syndrome (KMS).

Pathology and Pathogenesis

Recent literature suggests that all cases of KMS are associated with kaposiform hemangioendothelioma or tufted angioma rather than the classic infantile hemangioma. This confusion is thought to be caused by imprecise definition and imprecise histological diagnosis of "hemangioma." However, some other recent literature suggests that it can be associated with other types of vascular tumors (hepatic hemangioma, splenic hemangioma, lymphangioma, and diffuse neonatal hemangioma). Thrombocytopenia results from trapping in vascular spaces of the hemangioma and activation of these platelets by the proliferating endothelium of the tumor. Platelets activation results in thrombin production, which causes local and/or disseminated fragmentation of the red blood cells leading to microangiopathic hemolytic anemia that results from the shear stress (while passing through the small blood vessels) and/or due to the consumptive coagulopathy. Thrombocytopenia and consumption of the plasma coagulation factors may cause localized or generalized bleeding.

Clinical Picture

KMS is a disease of infancy and childhood. Most cases are diagnosed in the first 5 years of age. Cutaneous "hemangioma" may be present at birth or develop or enlarge over few months or occasionally few years. Diagnosis of KMS is usually clear. An infant or a child with cutaneous hemangioma develops thrombocytopenia and microangiopathic hemolytic anemia. In patients with visceral hemangioma, unexplained thrombocytopenia and microangiopathic hemolytic anemia might be the first and the only manifestation of KMS. The clinical picture of KMS depends on the size, location and local complications of the tumor, and the severity of the thrombocytopenia and consumptive coagulopathy. "Hemangiomas" can be of any size, be located in anywhere, and can be single or multiple. The most common site is the skin. Visceral lesion may be located in the liver, spleen, retroperitoneal, mediastinum, or CNS. Clinical manifestations caused by the hemangioma may include (depending on the location, size, and infiltration of adjacent structures) obvious cutaneous lesion, abdominal distention, abnormal live function tests, respiratory compromise, seizures, bony deformity, or obstructive uropathy. High output heart failure may occur. Bleeding due to thrombocytopenia (with or without consumptive coagulopathy) may occur anywhere including skin (petechiae, bruising), mucus membranes (including epistaxis, gastrointestinal, or urogenital), CNS, or within the hemangioma itself. Bleeding in the hemangioma results in sudden increase in size of the visible mass, increased abdominal distention, increased respiratory compromise or CNS complications, i.e., seizure, coma, stroke, etc. Patients may present with complications of the hemangioma, which may include ulceration, infection or infiltration or compression of vital structures, e.g., the eye.

Diagnosis

Diagnosis is usually obvious. Most patients present with a visible subcutaneous mass, with or without evidence of bleeding. Investigations show microangiopathic hemolytic anemia and severe thrombocytopenia. PT and PTT are often high; fibrinogen may be low and FDP may be high depending on the presence and severity of DIC. MRI and/or CT scans of the visible lesion should be done to delineate the extent of the tumor and to decide if surgical removal is feasible. MRA and/or CT scans and Doppler ultrasound may identify large feeding vessels. MRI and/or CT scans of the head, chest, abdomen, and pelvis are indicated in cases of cutaneous lesions to look for multifocal lesions. The same radiological investigations are required when primary visceral hemangioma is suspected. Unexplained thrombocytopenia and microangiopathic hemolytic anemia may be the only manifestation of KMS in which a search for visceral hemangioma is indicated. Biopsy is not routinely indicated.

Deferential Diagnosis

When hemangioma is located in the skin, it is easily identified clinically. MRI or Doppler ultrasonography can differentiate visceral and ambiguous superficial hemangioma from solid tumors. Differentiating hemangioma from vascular malformation is important but often difficult. All causes of consumptive coagulopathy and thrombocytopenia are usually easily differentiated from KMS, except in the case of unrecognized visceral hemangioma in which other causes of DIC should be considered.

Treatment

Supportive treatment is required in symptomatic patients and those who are planned for surgical procedures.

It includes packed red blood cells transfusion as indicated by the severity of the anemia and the clinical picture. Platelets transfusion should be reserved for patients with active and uncontrolled bleeding or those who are planned to have a surgical procedure. Fresh frozen plasma (FFP) is indicated for patients with evidence of consumptive coagulopathy and active bleeding or prior to surgical procedures. Cryoprecipitate is indicated in an actively bleeding patient with severe hypofibrinogenemia. Treatment of the hemangioma depends on its size, site, number, and complications (KMS, bleeding, ulceration, heart failure, or infection). Most hemangiomas run their natural course of proliferative phase followed by involution. Involution usually starts after 1 year of age. Around 75% of them are completely involuted by 5–7 years of age. However, many are left with residual lesions. Asymptomatic patients or those with minimal problems need no active therapy. Surgical removal of a small single lesion or few lesions is recommended if surgically feasible without mutilation. Embolization or ligation of large feeding arteries, if present, can be done in a single or a few lesions. Most lesions are large, infiltrating or visceral and not accessible for surgical removal or embolization. Medical therapy is indicated in such cases. Systemic steroid therapy is the first line of medical therapy. Different dosing regimens were found to be effective (2–3 mg/kg/day for 4 weeks, 5 mg/kg/day for 2 weeks, and megadose of 30 mg/kg/day for 3 days). Response usually starts after few days. Around 90% of cutaneous hemangioma has a good response; however, only 30–50% of KMS patients have a good response because most, if not all, lesions are not true hemangiomas. Alternative therapies which were found to be effective in some cases include alpha interferon, vincristine, cyclophosphamide, and actinomycin-D. Antifibrinolytic, antiplatelet, and anticoagulants should be avoided as their efficacy is controversial and they might increase the chances of bleeding. Even though radiotherapy was effective in many studies, it should be used only in resistant cases with life-threatening situation.

Prognosis

Prognosis depends on the location, extent, infiltration of vital organs, severity of consumptive coagulopathy, and therapeutic intervention. Mortality is more common in visceral lesions and large infiltrating lesions and in those with severe thrombocytopenia with or without DIC. Mortality rate ranges between 10% and 37%. Morbidly includes residual tumor, scar, and residual damage in the involved organs, i.e., CNS, liver.

324 Sickle Cell Disease

Ahmad A. Mallouh

Introduction

Human hemoglobin is composed of two parts: (a) the iron-containing part (heme), which is a porphyrin ring responsible for the reversible combination with and transport of oxygen, and (b) a protein part (globin), which is a tetramer made up of two α and two non-α (β, γ, or δ) polypeptide chains, each formed from a large numbers of amino acids (α = 141, β, γ, and δ = 145 amino acids) attached to each other in a linear sequence. There are three types of normal human hemoglobins:

- Hemoglobin A (α2β2) is the main hemoglobin beyond the neonatal period.
- Hemoglobin F (α2γ2) is the main hemoglobin in the fetus and the newborn. Hemoglobin F is gradually replaced by hemoglobin A after birth reaching an adult level by 9–12 months of age.
- Hemoglobin A2 (α2δ2) constitutes 2.5–3.5% of the total hemoglobin in children and adults.

Hemoglobinopathies result from the substitution of one or more amino acids in the globin chain or by the shortening or elongation of the globin chain by deleting or adding amino acids. To date, more than 800 structurally abnormal hemoglobins have been described. Most structurally abnormal hemoglobins are only of academic interest as they are physiologically normal. Others have abnormal solubility, molecular stability, and/or oxygen affinity, resulting in significant clinical problems. Hemoglobins S, C, E, D, O Arab, unstable hemoglobins, and hemoglobins M are among the clinically important types.

Sickle Cell Disease (SS)

Sickle cell disease usually refers to either homozygous (SS) disease or doubly heterozygous hemoglobin S and other abnormal hemoglobins or β-thalassemia (SC, SD, SE, S O Arab or S β-thal).

Pathophysiology

Sickle hemoglobin (Hb S) results from the substitution of the amino acid valine for glutamic acid (Glutamic acid →Valine) in position number six of the β globin chain of hemoglobin. When deoxygenated, hemoglobin S molecules polymerize, forming an elongated rope-like fiber that aligns with other fibers inside the red blood cells, eventually forming parallel bundles oriented along the axis of sickle-shaped red blood cells (RBCs). This process results in increased RBC membrane rigidity, abnormal membrane function, and deceased RBC deformability. Even though hemoglobin S polymerization is an essential event of the pathogenesis of vaso-occlusion, polymerization does not by itself explain the whole clinical picture. Previously, it was thought that the sickle-shaped cells became entangled in the small capillaries, thus occluding them. In fact, vessel occlusion often occurs in medium sized blood vessels. It is accepted now that vaso-occlusion is a complex process which includes, in addition to Hb S polymerization, increased adhesion of the RBCs to the vascular endothelium, structural and functional RBC membrane abnormalities, increased leukocyte adhesion, platelets and coagulation activation, endothelial damage, and an increased tendency to vasoconstriction. Sickle-promoting factors include hemoglobin S concentration, hypoxia, acidosis, hemoconcentration (increased blood viscosity), hemostasis, hypothermia, and hypotension. Sickling is influenced by the coexistence of hemoglobin S with other hemoglobins. Coexistence of hemoglobins F, A, C, or O Arab increases hemoglobin S solubility which explains the asymptomatic course of sickle cell trait and sickle cell-hereditary persistence of fetal hemoglobin (S-HPF) and the relatively mild course of homozygous Indian–Arabian SS disease (known to have high hemoglobin F levels) and S-C disease, S-D, and A-O Arab. In vivo, hemoglobin S-containing red blood cells undergo sickling and unsickling continuously. They sickle when they pass through the slow capillary circulation and the venous system due to local hypoxia, relative stasis, and acidosis.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_324,

They unsickle as they return to the larger blood vessels with higher blood velocity and better oxygenation. When the process of sickling and unsickling is repeated several times, the RBC membrane becomes stiff, and the RBCs stay in an irreversible sickle form (*Fig. 324.1*). The number of irreversibly sickled cells in a freshly prepared blood smear may be an indication of the severity of the disease.

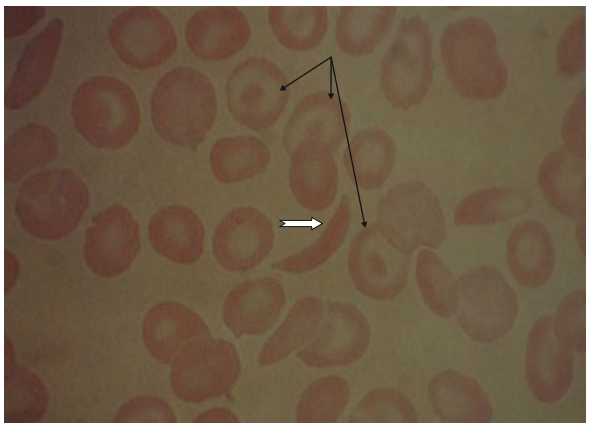

Figure 324.1
Peripheral blood smear in sickle cell disease showing the sickled-shaped irreversibly sickled red blood cell (open arrow). Target cells (solid arrows) are not uncommon in sickle cell disease

Epidemiology

The sickle cell gene is prevalent in parts of the world were falciparum malaria was or is still endemic. The distribution of gene coincides with that of malaria (*Fig. 324.2*). The highest incidence is in sub-Saharan Africa, where the incidence reaches around 30%. It is also common in the Middle East (southern and eastern parts of the Arabian Peninsula) and in other countries around the Persian Gulf (Eastern province of Saudi Arabia, Bahrain, Qatar, southern Iraq, and southern Iran), East and West Africa, Mediterranean countries (southern Italy, Sicily, and certain parts of Greece), and parts of the Indian subcontinent. The incidence in African American is around 8–10%. Sickle cell trait provides protection against severe falciparum infection (up to 90% protection against cerebral malaria and severe malaria-induced hemolytic anemia). Hospitalization and mortality from severe falciparum malaria infection is decreased by around 60% in patients with sickle cell trait as compared with those normal hemoglobin (HbAA). Its protection against mild malaria is controversial.

Diagnosis

The diagnosis of sickle cell disease starts with the clinical suspicion (see below). The diagnosis is then confirmed by:

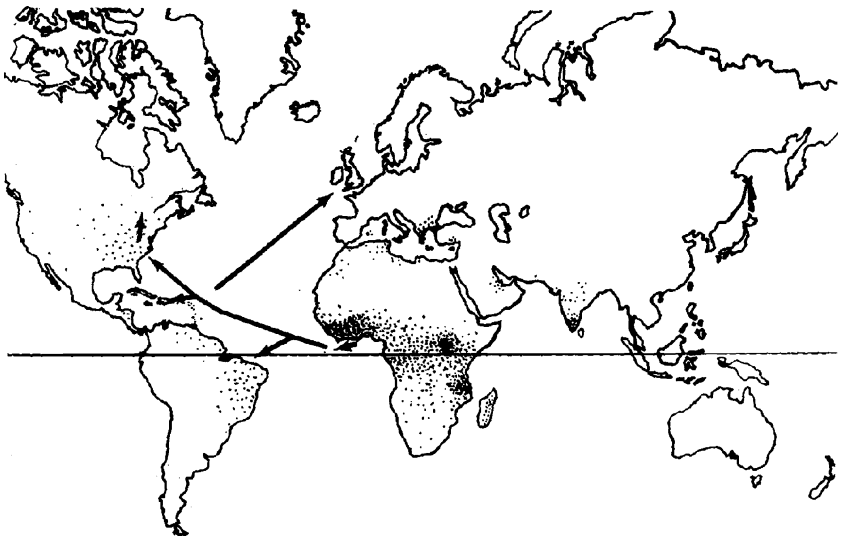

Figure 324.2
Global distribution of sickle hemoglobin gene

- The presence of sickle-shaped cells in a freshly prepared blood smear (irreversibly sickled red blood cells).
- Precipitation tests in which the red blood cells or hemoglobin is exposed to hypoxic environment. The red blood cells take sickle shape in the first, and the hemoglobin precipitates in the second. The above mentioned two methods are not sensitive and do not differentiate homozygous sickle cell disease form sickle cell trait or doubly heterozygous diseases (S-HPFH, S-C, S-D, S-O Arab, or S-E).
- Hemoglobin electrophoresis in cellulose acetate at pH 8.4. It should be kept in mind that hemoglobins S, D, and G have the same mobility in alkaline media. Electrophoresis at acid pH (citrate agar at pH 6.2) separates these hemoglobins.
- High-performance liquid chromatography (HPLC) and isoelectric focusing are sensitive and can be used to diagnose sickle cell disease. Sickle cell disease can be diagnosed in the neonatal periods with some limitation. The presence of hemoglobins S and F with no hemoglobin A is consistent with homozygous sickle cell disease (SS), sickle cell-β° thalassemia, or sickle cell-hereditary persistence of fetal hemoglobin (S-HPFH). Differentiating these diseases is made by family studies. Both parents are expected to have sickle cell trait in SS disease, while one parent has sickle cell trait in the other two entities and the other has β° thalassemia trait or HPFH, respectively. Prenatal diagnosis is technically possible using fetal blood or fetal fibroblasts, or using DNA techniques.

Clinical Manifestations

Infants born with homozygous sickle cell disease are asymptomatic at birth and in the first few months of life because of the protective effect of hemoglobin F. As the production of hemoglobin S increases and replaces hemoglobin F, clinical manifestations start appearing. Vaso-occlusive events may manifest as early as 3 months of age, while chronic hemolytic anemia is usually present by the fourth month of life. Approximately 6% of infants with homozygous sickle cell disease are symptomatic at 6 months, 32% at 1 year, 61% at 2 years, 92% at 6 years, and 96% at 8 years of age. The severity of sickle cell disease is variable. The reason/reasons for this variable clinical expression are not fully understood. However, early onset of dactylitis (hand-foot syndrome), high steady state leukocytes, and low steady state hemoglobin were found to be predictors of a more severe clinical picture. The co-inheritance of α thalassemia with sickle cell disease has been suggested to result in milder anemia; however, its effect on the whole clinical picture is variable. The clinical severity varies among sickle cell genotypes with a milder course in the Arabian-Indian and to a lesser extent in the Singhalese genotypes. This difference is due to persistently high levels of hemoglobin F in these two genotypes.

Sickle cell disease complications can involve any organ. Its clinical manifestations or complications can mimic any disease process involving almost any part of the body. Clinical manifestations can be acute, chronic, acute on top of chronic, or recurrent. They may be divided according to their etiology:

- Manifestations due anemia, whether acute, chronic, or acute on top of chronic.
- Manifestations due the vaso-occlusion phenomenon.
- Manifestations due to infection.

Manifestations due to Anemia

Patients with sickle cell disease usually have moderately severe chronic anemia with appropriate bone marrow response. Hemoglobin concentration levels range between 6 and 10 g/dl (mean 7.9 g/dl). Reticulocyte counts range between 10% and 15%. The major contributing cause of anemia is hemolysis. The mean life span of a hemoglobin S-containing (SS) RBC is approximately 17 days. Folate deficiency due to increased utilization by the hyperactive bone marrow, iron deficiency caused by urinary blood loss due to renal infarction, and erythropoietin deficiency due to renal damage may contribute to the chronic anemia. Iron deficiency was found in up to 20% of patients in some studies. Patients are usually clinically stable. The possible signs and symptoms depend on the severity and acuteness of the anemia.

Acute anemia may develop due to aplastic events, splenic sequestration, hyperhemolytic events, or delayed hemolytic transfusion reaction.

Aplastic Events (Aplastic Crises)

Aplastic events are characterized by a transient drop in the hemoglobin level with bone marrow suppression, as evidenced by reticulocytopenia and decreased erythroid cell precursors in the bone marrow. Most aplastic events are secondary to the human parvovirus B19 which has special affinity to attack the erythroid precursors. Other viruses (EpsteinBarr) or bacterial infections (*Streptococcus pneumoniae*, *Salmonella*) may cause transient aplasia in

patients with sickle cell disease. Human parvovirus B19 is common among all people, especially in children less than 15 years. Because of the short duration of the bone marrow suppression and long red blood cells life span, anemia is not noticed in the population unaffected by hemolytic anemias. Patients with any chronic hemolytic anemia, whose RBC life span is shortened, may develop significant anemia. Erythroid aplasia is usually short lived, lasting a few days. Recovery is often spontaneous without a need for blood transfusion. If the anemia is severe and the patient is symptomatic, packed red blood cells transfusion is indicated. Patients often present at the end of the aplastic episode with high reticulocyte counts and jaundice from the chronic hemolysis. A hemolytic rather than aplastic event might be suggested. Combined aplastic event and splenic sequestration had been reported in association with parvovirus infection. Infection with human parvovirus B19 usually confers a long-lasting immunity. Recurrent aplastic events; however, may be caused by other infectious agents.

Splenic sequestration: Splenic sequestration is defined as a precipitous drop in the steady-state hemoglobin concentration by at least 2 g/dl, sudden enlargement of the spleen (secondary to pooling of the blood in the spleen), and a compensatory bone marrow response as evidenced by reticulocytosis and/or the presence of nucleated red blood cells in the peripheral blood. Splenic sequestration occurs mostly in infants and young children before autosplenectomy due to repeated splenic infarctions occurs. Even though it has been reported in infants as young as a few weeks of age, most cases occur in children between 8 months and 5 years old. Splenic sequestration is not unusual in older children with mild forms of sickle cell syndromes (S-C, S-β thalassemia and in genetically mild homozygous sickle cell diseases, i.e., the Arabian–Indian genotype). The exact etiology of splenic sequestration is not known. It is often associated with viral infection (human parvovirus B19) and/or bacterial infections. Splenic sequestration events often present with sudden onset of severe anemia (pallor, decreased activity, generalized weakness, tachycardia, and tachypnea), hypotension, and abdominal distention due to massive splenomegaly. Splenic sequestration is the initial presenting clinical event in approximately 20% of all infants with homozygous sickle cell disease and 30% in those below 2 years of age. It carries high mortality rates (almost 12% in a Jamaican study). Patients can die prior to presenting for medical care before the diagnosis is made. Association with acute chest syndrome occurs in up to 20% of the splenic sequestration episodes. The recurrence rate can be as high as 50% and carries the same risk of mortality as the first episode. Recurrence is not uncommon even while the patient is on chronic blood transfusion. Subacute splenic sequestration events are characterized by increased splenic size, a modest (up to 25%) drop in the hemoglobin level, and no hypotension.

Splenic sequestration is a medical emergency. Restoration of intravascular volume and improvement of oxygen delivery to various organs are the main goals of treatment. Slow and fractionated PRBC transfusion should be started as soon as possible. Rapid transfusion may lead to congestive heart failure because the sequestered blood returns from the spleen to the vascular system as normal red blood cells are given. Splenectomy is recommended by most authorities after the first episode because of the high recurrence rate and high mortality. Chronic blood transfusion to avoid recurrence and to delay splenectomy has been recommended by some. However recurrence may occur while the patient is on or after chronic transfusion is discontinued and often splenectomy is needed. Some studies showed that the incidence of bacterial infection did not increase after splenectomy in infants with homozygous sickle cell disease because these infants often have functional asplenia. This argument might not apply to the mild forms (SC, SE, SD, and the Arabian–Indian homozygous disease) of sickle cell disease in which the splenic function is maintained for long time. In these cases, splenectomy can be delayed or avoided especially if the sequestration even is of the subacute type.

Hyperhemolytic Events

Hyperhemolytic events are characterized by a sudden drop in the hemoglobin level, unconjugated hyperbilirubinemia, and reticulocytosis. Several authorities doubt its existence and believe that this presentation is due to either aplastic events presenting in the recovery state or a mild splenic sequestration. Sickle cell disease is often associated with G6PD deficiency, which might be the cause of the acute hemolytic episode. Most episodes are self-limiting and require no treatment. If anemia is severe and the patient is symptomatic, blood transfusion may be indicated.

Delayed Hemolytic Transfusion Reactions (DHTR)

Delayed hemolytic transfusion reaction is a posttransfusion hemolytic reaction characterized by hemolytic anemia, reticulocytopenia and posttransfusion hemoglobin levels lower than the pre-transfusion level. Hemolysis

usually occurs 4–10 days (mean 5 days) after transfusion. Even though it has been reported in patients who have received a single transfusions, most cases occur in repeatedly transfused patient with sickle cell disease with a reported incidence of 4–11%. Severe cases can be life threatening and are often associated with other severe complications, including painful events, fever, hemoglobinuria, acute chest syndrome, DIC, pancreatitis, congestive heart failure, acute renal failure, and splenic sequestration. Mild cases can pass unnoticed. The mechanism of the anemia is thought to be due to an immune process. Most patients have a positive direct antiglobulin test (DAT) at presentation. However, 20–30% of the patients never develop detectable antibodies. It is believed that these patients have antibodies below detectable level. Hemolysis of the donor as well as recipient RBCs possibly explains the drop of hemoglobin to a level below that of the pre-transfusion level. Recipient RBC hemolysis is also suggested by the decrease in hemoglobin S percentage. Reticulocytopenia is thought to be secondary transfusion-induced bone marrow suppression. Treatment is mainly by avoiding transfusion as much as possible. Intravenous IgG (IVIg) and steroids were successful in preventing of hemolysis in some cases.

Vaso-Occlusive Events

Vaso-occlusive events are the most common manifestation of sickle cell disease (for pathophysiology see above). It can involve any organ. Repeated attacks of the same organ result in chronic organ damage.

Acute Painful Events

Commonly known as acute vaso-occlusive or thrombotic events, acute painful events are the most common manifestation of sickle cell disease, resulting in the majority of emergency room visits and hospitalizations. The frequency, severity, and anatomic location of the pain differ from one patient to another and from one episode to another in the same patient. Up to 40% of patients with homozygous sickle cell disease (SS) have no painful episodes. In one large study, one third of the patients had three to six episodes per year and one third had more than six episodes per year. Painful events may involve any part of the body. Low back, extremities, or abdomen are common sites. Multiple site involvement is not unusual. The pain may migrate from one site to another during the same episode. The events are usually self-limiting and last for only a few hours in most episodes. However, the pain can last for days and, occasionally, for weeks. Fever, localized tenderness, swelling, warmth, and limitation of joint movement may be present. When local signs are severe, differentiating painful vaso-occlusive event; involving bones; from osteomyelitis may be difficult. Abdominal vaso-occlusive events are of particular concern. Differentiating an abdominal vaso-occlusive event from a surgical abdomen is often difficult, but essential. Appendicitis, cholelithiasis, cholecystitis, and intestinal obstruction can all occur in patients with sickle cell disease and may mimic an acute painful event. Every effort should be made to differentiate vaso-occlusive events from these entities in order to plan proper management and avoid unnecessary high-risk surgical intervention.

Treatment: A first and an important step in the management of painful events is a search for a cause other than vaso-occlusion. Once the diagnosis of vaso-occlusive event is made, every effort should be made to relieve the pain using pharmacologic and/or nonpharmacologic methods. It should always be remembered that the patient is the one who is suffering, not the physician or nurse. Inadequate pain relief results in mistrust between the patient and his or her health care provider. Pain management depends on the severity of the pain and the patient's perception of it. Previous painful events may be used as a general guide to what the patient needs.

The use of pharmacologic agents for adequate pain relief is the mainstay of management of painful events. Acetaminophen, paracetamol, and other nonsteroidal anti-inflammatory drugs together with oral hydration may be tried as a home therapy in mild episodes. Opioids should be used to treat moderate to severe painful episodes. The initial suggested dose of morphine is 0.1–0.15 mg/kg IV, followed by maintenance therapy either by continuous IV infusion or patient-controlled analgesia (PCA). Repeated smaller doses (0.05–0.1 mg/kg) can be given every 15–30 min with close monitoring for respiratory depression until complete pain relieve is obtained. The morphine dosage should be individualized. History of previous painful episodes and their management can be used as a guide. Hydromorphone and fentanyl can be used as an alternative to morphine. Meperidine should be avoided because of its potential CNS toxicity. Adjuvant drugs, which may help in pain relief, include antihistamines, muscle relaxants, and antidepressants. Nonpharmacological therapies which may be helpful include local warm compresses, hypnosis, acupuncture, and behavioral techniques. A short course of steroids was found to shorten the course of the painful episodes. However, severe

rebound pain occurred after discontinuation of steroids. Patients should be continued on oral medication after discharge to avoid pain recurrence. Spinal anesthesia may be required in severe cases. Patients with severe debilitating pain may be treated with chronic RBC transfusions or stem cell transplantation.

Health-care providers often avoid using opioids because of the fear of addiction. It should be stressed that this belief is unfounded. Withholding needed analgesia results in patient suffering, mistrust of health-care providers, and patient's drug-seeking behavior.

Central Nervous System Events

Cerebrovascular accidents (CVAs) are the leading cause of morbidity and mortality in both children and adult patients with sickle cell disease. Cerebrovascular accidents include ischemic stroke, hemorrhagic stroke, transient ischemic accidents (TIAs), and silent infarcts. CVAs occur in 8–15% of children with homozygous sickle cell disease. In the cooperative study of sickle cell disease of 3,647 patients, CVAs occurred in 11% of children (below 20 years of age) with homozygous sickle cell disease. Ischemic stroke (which results from occlusion or stenosis of large intracranial arteries) is most common in children between 2 and 9 years of age, while hemorrhagic stroke occurs most commonly between 20 and 29 years. Hemorrhagic stroke occurs in 3% of children below 20 years of age. Clinical manifestations are similar to those of strokes in people not affected by sickle cell anemia and depend on the location of the lesion, degree of the damage, and etiology (ischemic vs hemorrhagic stroke). Manifestations include seizures, hemiparesis, dysphasia, visual disturbances, abnormal gait, headaches, vomiting, and/or coma. The mortality rate in hemorrhagic stroke is between 25% and 50% and may reach 20% in untreated ischemic stroke. With early and aggressive therapy, mortality is low in the ischemic stroke; however, up to 70% of the survivors are expected to have significant residual neurologic defects or cognitive problems. Computerized tomography (CT) or magnetic resonance imaging (MRI or MRA) are the recommended diagnostic modalities. CT easily detects hemorrhagic lesions, although changes of an ischemic stroke may be delayed for a few hours. MRI is more sensitive in the first few hours (up to 6 h) after an ischemic infarct. MRA has replaced conventional angiography in identifying vascular lesions, e.g., moyamoya, aneurysm, and venous malformations. Conventional angiography may be required in hemorrhagic stroke if MRA is not conclusive. Care should be taken if hypertonic contrast solution is used as this may cause vascular occlusion. Lowering hemoglobin S level before the procedure is recommended.

Treatment: Patients should be managed in the intensive care unit. Treatment of seizures, fever, hypotension, hypoxia, or respiratory compromised (if present) should be managed urgently. A search for and treatment of other causes of the stroke, i.e., trauma, infection, etc. is essential. As the recurrence rate is high (44–67%), chronic blood transfusion to keep hemoglobin S levels below 30% is recommended. This practice results in reduction of recurrence rate to less than 10%. The duration for chronic transfusion is unknown. Stroke recurrence is high after discontinuing transfusion regardless of the duration of the chronic transfusion. Lifelong transfusion with iron-chelation therapy is currently the most reliable method to prevent recurrence. Some authorities recommend stopping chronic transfusion after 5 years or at the age of 18 years. Recurrence can occur while on transfusion in several of these cases hemoglobin S level was found to be higher than the recommended 30%. A recent report showed that progressive cerebral infarcts occurred in 45% (27.5% overt and 17.5% silent) in children with previous overt stroke while receiving transfusion therapy. Hematopoietic stem cell (HSC) transplantation is recommended by several authorities if a donor and resources are available (see bone marrow transplant below). Small studies have demonstrated that hydroxyurea may be effective in preventing stroke recurrence in those patients who are unable to receive blood transfusion (those who have developed alloantibodies, those who are nonadherent with chelation, etc.). However, further studies are needed before recommending its routine use. Treatment of the hemorrhagic stroke depends on the location of the bleeding and if an associated vascular abnormality is present. The benefit of exchange transfusion in the therapy of hemorrhagic stroke is not clear. However, many authorities recommend transfusion, especially if large-vessel disease or abnormal velocity is present.

Transient ischemic attacks are defined as ischemic events in which symptoms resolve in less than 24 h. They are a strong predictor of development of overt stroke. These patients should be evaluated by Transcranial Doppler (TCD) and MRI. Patients who have abnormal velocity on TCD or significant large-vessel disease on MRI/MRA should begin a chronic transfusion regimen.

Silent infarcts were found in up to 30% of children with homozygous sickle cell anemia on screening of asymptomatic patients using MRI. These patients should be evaluated and followed closely if the TCD is normal. Primary prevention using TCD ultrasonography screening

is recommended to identify patients at risk of developing stroke. Screening should start at 2 years of age. Chronic transfusion is recommended for those who had abnormal results (>200 cm/s). The optimal frequency of TCD scanning is not established; however, repeating the study every 3–12 months has been recommended by most authorities.

Acute Chest Syndrome

Acute chest syndrome (ACS) is characterized by the radiographic appearance of new pulmonary infiltrates, fever, respiratory compromise (manifested by cough, tachypnea, wheezing, labored breathing and/or hypoxia), chest pain, and leukocytosis. Radiographic findings may lag behind the clinical picture. Repeat X-ray should be done 24–48 h later if the clinical picture is suggestive of ACS. Many patients (up to 60% in one study) who have fever and chest pain without clinical evidence of pulmonary problems were found to have radiographic evidence of ACS on repeat chest X-ray (*Fig. 324.3*). Over 50% of ACS develops after hospitalization. Triggering factors, which cause local hypoxia and induce local sickling, include splinting in patients with acute pain involving the ribs, abdomen and/or back, respiratory depression as a result of the use of pain medications, postoperative splinting in abdominal or thoracic surgery, or due to under ventilation due to atelectasis and bronchospasm in asthmatic children. ACS is the most common cause of death in children with sickle cell disease (around 2%) and the second cause of hospitalization after acute pain events. Even though ACS occurs at any age and any time of the year, it peaks between 2 and 4 years of age and in the winter.

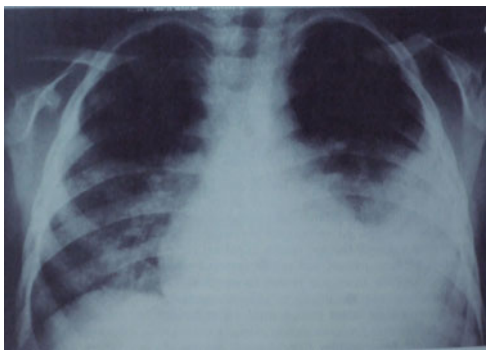

Figure 324.3
Chest X-ray of a child with sickle cell disease and acute chest syndrome (ACS)

The pathogenesis of ACS is complex and includes vasculopathy of SCD and hypoxia induced by pulmonary infection and/or the presence of one or more the sickling-promoting factors mentioned above. Early studies suggested that infection is the main causes of this syndrome in children as opposed to the adults in whom pulmonary infarction is the major mechanism of ACS. Recently, however, it has been shown that pulmonary infarction, caused by fat emboli or local hypoxia due to vaso-occlusion, is a common cause of ACS in children. Whatever the initiating process, the end result is a combination of infection and infarction. Devitalized infarcted lung tissue promotes infection, while infection causes local edema and occlusion of the small blood vessels causing local hypoxia and sickling. An infectious cause is found in 30–40% of ACS in children. Infectious agents include mycoplasma, chlamydia, viral, and bacteria. In over 50% of the cases, no specific etiology was found. Recurrence rate is high, occurring in up to 80% of the cases, especially in those who have been affected before 3 years of age. Hypoxia induced by ACS may lead to worsening of pulmonary involvement, CNS infarction, generalized vaso-occlusion or multisystem failure, and death. Repeated episodes of ACS may lead to lung fibrosis.

Treatment: Acute treatment consists of respiratory support, fluid management, antibiotics, pain management, PRBC transfusion, as well as the possible use of steroids. Long-term, preventative management can include the use of hydroxyurea and hematopoietic stem cell transplantation. Respiratory support includes oxygen supplementation to maintain arterial oxygen saturation ≥92%, incentive spirometry, and nitrous oxide. Mechanical ventilation may be required in severe cases. Dehydration and acidosis should be corrected. Overhydration should be avoided as it may cause pulmonary edema. Third generation cephalosporins and macrolides are a reasonable initial empiric antibiotic combination for coverage of expected pathogens (*Streptococcus pneumoniae*, H influenzae, mycoplasma, and chlamydia). Vancomycin should be added in severe cases or when resistant organisms are suspected or proven by culture. Simple or exchange transfusion should be started early except in the clinically and radiologically mild cases. Simple transfusion is adequate in most cases, particularly in patients with low hemoglobin. Exchange transfusion is indicated in severe cases, progressive cases, hypoxic cases, cases with multiple-lobe involvement, and in those who do not respond to simple transfusion. Hemoglobin levels should not exceed 11–12 g/dl to avoid hyperviscosity, which promotes sickling and thrombosis. With exchange transfusion, the aim is to decrease hemoglobin S level to <30%.

Pain management is important not only because it decreases the suffering and apprehension of the patient but also it controls splinting which may be a factor in increasing hypoxia and worsening the condition. Systemic steroids have been found to be beneficial in mild and moderate cases of ACS. However relapse and readmission was found to be high in patients who received steroid therapy. Further studies are needed before their routine use is recommended. Hydroxyurea is effective in reducing the frequency of recurrence. It is recommended in recurrent cases, especially severe ones (see below). Allogenic hematopoietic cell transplant is curative in 80–90% of cases of SCD. It is recommended for recurrent severe cases of ACS if a matched sibling is available.

Bones and Joints

Cortical bone infarction: Painful vaso-occlusive events are the most common manifestation of sickle cell disease. These events are thought to result from marrow infarction. A less common form of painful event is thought to result from cortical bone infarction. It manifests with local swelling, tenderness redness, hotness, imitation of movement, and fever. Bone destruction and periosteal new bone formation are common. Differentiating this type of event from osteomyelitis is often difficult. A toxic appearance and high-grade fever are suggestive but not diagnostic of osteomyelitis. Even histology can be confusing unless an organism is isolated as both may demonstrate an inflammatory process. Treatment of cortical bone infarction is similar to that of acute painful events.

Osteomyelitis and septic arthritis: Osteomyelitis may involve any bone; however, it most commonly involves the diaphysis of long bones and often involves multiple sites. Technetium bone scan, CT, and MRI are of limited value in differentiating osteomyelitis from cortical bone infarction. Isolating an organism from the local lesion or from blood culture is the only definitive diagnosis of osteomyelitis/septic arthritis. The most common cause of osteomyelitis in children with sickle cell anemia is *Staphylococcus aureus*. However, it is well known that in children with sickle cell disease who develop osteomyelitis, infection is often attributable to *Salmonella*, especially in areas where gastrointestinal infection by salmonella is common. It has been postulated that salmonella egress through microinfarcts of the intestinal wall and settle in the previously infarcted bone. Gram-negative bacilli (*E. coli, Klebsiella*) are relatively common causes of osteomyelitis in the sickle cell population, especially in older children and adults.

Treatment: Surgical drainage and parental antibiotic therapy are the primary therapeutic modality. The initial choice of antibiotic should include coverage for Salmonella species and coagulase-positive staphylococci. The duration of antibiotic coverage is not well established; however, 6–8 weeks are usually recommended. It has been suggested that early surgical drainage is important to assure good and early recovery and avoid chronicity and extensive bone destruction (Fig. 324.4).

Arthritis (non-septic): Arthritis may due synovial infarction or reactive arthritis secondary to adjacent osteonecrosis. Treatment is symptomatic.

Dactylitis (hand–foot syndrome): The vast majority of dactylitis occurs in the first 2 years of life. It is uncommon after 4 years of age. It occurs in over 40% of children with homozygous sickle cell disease. It presents with bilateral swelling of the hands and/or feet. It may involve all four extremities at the same time. It may cause excessive destruction of the affected bones (Fig. 324.5). Dactylitis in the first 2 years of life predicts a more severe clinical course of sickle cell disease. Treatment is similar to that of acute painful events. Most patients recover completely. Some may end with shortening of the involved bones.

Figure 324.4
X-ray of the hand of a child with sickle cell disease with hand-foot syndrome

Figure 324.5
X-ray of the femur of a child with sickle cell disease and salmonella osteomyelitis

Avascular necrosis (AVN): Avascular necrosis of the femoral and humeral head is a common and serious complication of sickle cell disease. The true incidence is not known. In a large study, 10% of the patients were found to have AVN of the femoral head, and 5.6% of patients had AVN of the humeral head. The incidence of AVN is higher in patients with concomitant α-thalassemia. AVN may occur as early as 5 years of age. The prevalence increases with age. AVN of the femoral head is bilateral in over 50% of patients. Clinical manifestations include pain, limp, and limitation of movement. Conservative treatment of AVN in children below 12 years of age usually results in healing and remodeling of the femoral or humeral heads with good function. The natural history in older children and adults is progressive. Permanent damage is the expected result in most patients. Diagnosis can be made by plain x-ray in advanced cases. Expected early or mild lesions should be diagnosed by MRI. Treatment is conservative and includes avoidance of weight bearing (crutches and bed rest), analgesics, and nonsteroidal anti-inflammatory drugs. Surgical intervention in the form of core decompression, osteotomy, or arthroplasty has a low success rate and high rate of complication and failure. These procedures should be reserved for the most severe cases.

Bone marrow hyperplasia: Bone marrow hyperplasia is a consequence of bone marrow hyperactivity in response to the hemolytic anemia, resulting in widening of the marrow space and bone deformities such as frontal bossing, hair on end appearance of the skull x-ray, and protrusion of the incisors with associated overbite. Pathologic bone fracture may result from osteopenia and thinning of the cortex of the long bones. Vertebral collapse due to marrow necrosis and marrow hyperplasia leads to biconcave deformity. Compression fractures may cause a biconcave deformity with or without kyphosis.

Orbital compression syndrome: A rare but serious skeletal complication is the orbital compression syndrome that is caused by bone infarction around the globe. It is associated with pain, periorbital swelling with or without proptosis, ophthalmoplegia, visual impairment, and subperiosteal hematoma. The few reported cases were treated conservatively as other cases of vaso-occlusion.

Hepatobiliary System

Hepatobiliary complications of sickle cell disease include hepatomegaly, hepatic vaso-occlusive events, intrahepatic cholestasis, benign hyperbilirubinemia, hepatic sequestration events, and cholelithiasis with or without cholecystitis. Therapy of other sickle cell complications may also induce hepatobiliary complications. The frequency of hepatomegaly is not known because of different types of reporting (clinical vs radiologic vs autopsy). Hepatomegaly was found in 90% in an autopsy report. Hepatic vaso-occlusive events present with pain and tenderness in the right upper quadrant and jaundice with or without low-grade fever. Liver enzymes and bilirubin are usually modestly elevated (ALT and AST $<$500 IU/l, bilirubin $<$15 mg/dl). Treatment with analgesics and hydration is usually adequate and recovery is the rule. Intrahepatic cholestasis, as evidenced by markedly elevated liver enzymes, may end in hepatic failure. This syndrome is often associated with renal failure. The fatality rate is extremely high. Exchange transfusion and fresh frozen plasma can reverse this process. Liver transplantation is the only option for severe nonresponsive cases.

Benign hyperbilirubinemia is characterized by marked conjugated hyperbilirubinemia, modest elevation of liver enzymes with mild or no symptoms. The patient may look extremely yellow, but feels well. This process usually resolves without any treatment.

Hepatic sequestration events are less common and less severe than splenic sequestration. They present with right upper quadrant pain, a rapid drop in hemoglobin level,

and significant increase in liver size. The frequency of hepatic sequestration events is possibly underestimated as mild episodes might be missed because most patients have steady state hepatomegaly. The treatment depends on the severity of the anemia and the clinical picture. Mild cases resolve spontaneously. In most cases, the liver size decreases and the hemoglobin rises as the sequestered blood returns to the circulation. Treatment of severe, symptomatic cases is similar to that of splenic sequestration and includes restoration of the intravascular volume and simple or exchange transfusion.

Cholelithiasis has been reported in children as young as 2 years old. The incidence increases with age, eventually reaching 70% in adults. Diagnosis is made by ultrasonography that shows stones, sludge, or both. Most patients are asymptomatic. However, cholelithiasis may be complicated with cholecystitis and/or common bile duct obstruction. Cholecystectomy is indicated for the symptomatic patient and for those in whom differentiating hepatic vaso-occlusion from cholelithiasis-related symptoms is not possible. Elective cholecystectomy in patients with asymptomatic cholelithiasis is suggested by some authorities to avoid potential complications at inappropriate times and to alleviate patient and family anxiety. Sludge should be followed by repeated ultrasonography as it may resolve spontaneously. Cholecystectomy is to be done in symptomatic cases. Treatment of cholecystitis is similar to the same problem in other settings and includes antibiotics and cholecystectomy after stabilizing the patient. Common bile duct stones may be removed prior to surgery by ERCP.

Renal System

Renal complications of sickle cell disease include hyposthenuria, hematuria, proteinuria, tubular acidosis, nephrotic syndrome, renal infarction, acute renal failure, urinary tract infection, and end-stage renal disease. Hyposthenuria is almost universal in patients with sickle cell disease. Sickling in the hypertonic environment and slow circulation in the renal medulla leads to poor urinary concentration. Polyuria and enuresis are common manifestation of SCD. No treatment is available or needed. However, patients should be encouraged to drink fluids sufficient to avoid dehydration. Microscopic or gross hematuria is common in both sickle cell trait and sickle cell disease. It is due to papillary necrosis caused by vaso-occlusion in the hypertonic, hypoxic, and acidic environment of the renal tubular system. Bleeding is usually painless and unilateral (most commonly from the left kidney). Hematuria is usually mild and self-limiting. Supportive care in the form of bed rest, hydration, urine alkalization, and diuretics is usually adequate. Occasionally, hematuria may be severe enough to necessitate blood transfusion. Nephrotic syndrome, acute or chronic renal failure, and renal infarction are rare but serious complications in children with sickle cell disease. Treatment is the same as the treatment of similar conditions in patients not affected by sickle cell anemia. Dialysis and renal transplantation is indicated in end-stage renal disease.

Spleen: The presence of a palpable spleen is common in infants with homozygous sickle cell disease (SS) and in young children with compound SC, S β thalassemia, and homozygous sickle cell disease with high hemoglobin F. Splenic infarction (which is more common at high altitude) presents with acute abdominal and pleuritic chest pain. Functional, reversible hyposplenia, or asplenia is found in over 90% of children with homozygous SCD (SS) between 6 months and 3 years of age. Functional hyposplenia/asplenia is due to the slow circulation and local hypoxia in the splenic sinusoids. Functional impairment of the splenic reticuloendothelial system can be demonstrated by an increased number of pocked or pitted red blood cells or by technetium liver/spleen scan. This functional asplenia can be reversed by simple or partial exchange transfusion. Anatomic irreversible asplenia is caused by repeated splenic infarctions which lead to splenic atrophy and shrinkage. The spleen becomes fibrosed or calcified. This anatomic, irreversible asplenia is evident by 5–8 years of age. Hypersplenism, as evidenced by splenomegaly and pancytopenia with evidence of bone marrow hyperplasia, may be present in some infants with homozygous sickle cell disease (SS). Hypersplenism is more common in patients with milder forms of sickle cell disease, i.e., SC, SD, Sβ thalassemia, and homozygous sickle cell disease with high hemoglobin F level. Splenectomy is recommended in patients with significant hypersplenism and massive splenomegaly.

Priapism is defined as sustained painful erection lasting for more than 2 h. Priapism is common in patients with sickle cell disease after puberty. The reported prevalence varies widely from 5% to more than 40%. Priapism in patients with sickle cell disease is a low flow type of priapism. It is due to vaso-occlusion of the venous drainage of the corpus cavernosum. Sickling in the corpus cavernosum is due to stasis, hypoxia, and acidosis. Priapism can be classified as stuttering, an episode which lasts more than few minutes but less than 3 h, and prolonged, which lasts more than 3 h. The peak incidence is 12–15 years of age (some studies showed two peaks; 13–15 and 20–29 years). Up to 90% of the first events occur before 20 years of age. Diagnosis is usually based on

physical exam. The patient presents with unwanted painful erection with a rigid penis and soft glands. Doppler ultrasonography can differentiate low-flow, the usual type in SCD, from high-flow priapism. Prolonged (over 12 h) or repeated attacks may result in necrosis and fibrosis of the corpus cavernosum and erectile dysfunction and impotence in 25–35% of the patients. Conservative management, including hydration, analgesia, and frequent urination, is recommended for cases lasting more than 2 h but less than 6 h. The role of simple or exchange transfusion is controversial because of the lack of evidence of its benefit and the reported high complication rate (headache, seizures, and obtundation). Aspiration of the corpus cavernosa followed by saline irrigation has been demonstrated to be effective for those nonresponsive to conservative management and for episodes lasting more than 2 h. Instillation of α and β adrenergic agonists in the corpus cavernosa together with aspiration was effective in inducing detumescence in 95% of the cases. Surgical shunting is indicated in prolonged nonresponsive cases (over 6–12 h). Creating a shunt from the corpus cavernosa to the corpus spongiosum is the most commonly used procedure.

Skin: Leg ulcers occur mainly over the medial or the lateral malleolus and occasionally on the dorsum of the foot. The ulcers are often painful, indolent, and disfiguring. They occur in 10–20% of patients with homozygous sickle cell disease. The ulcers usually occur between 20 and 50 years of age. Ulcers are caused by skin ischemia due to hypoxic vascular occlusion and may be exaggerated by infection, trauma, or high temperature. The natural course is rapid healing in some cases, recurrent ulcerations in others, and chronic and protracted ulceration in most cases. Secondary local infection is common but systemic infection is unusual. A reasonable approach to the treatment of sickle cell–associated leg ulcers is adequate analgesia, bed rest, elastic compression, leg elevation, good local hygiene, debridement and local antiseptic, and the use of systemic antibiotics if cellulitis, lymphadenitis, or systemic infection is present. Other modalities, which had been used in resistant cases, include local and systemic zinc oxide, hyperbaric oxygen, and skin grafting.

Ophthalmologic manifestations/complications: Vaso-occlusion may involve any blood vessel in the eye or the globe. The clinical significance depends on the involved tissue and the degree of damage. Tortuosity of the conjunctival blood vessels is of diagnostic but not clinically significance. Retinopathy is classified into proliferative and nonproliferative types. Proliferative retinopathy is a serious complication which may lead to vitreous hemorrhage or retinal detachment ending in visual loss. The proliferative process starts with vaso-occlusion of the peripheral retinal arteries which stimulates neovascularization. Proliferative retinopathy is classified in five stages, including:

- Stage 1, peripheral retinal arteries occlusion
- Stage 2, arteriovenous anastomoses
- Stage 3, neovascularization
- Stage 4, vitreous hemorrhage
- Stage 5, retinal detachment

Nonproliferative retinopathy results from retinal infarction and adjacent hemorrhage. It may result in several retinal findings but rarely cause visual problems. Acute loss of vision due to central retinal artery occlusion has been reported. Hyphema may result from trauma. If untreated, it may lead to glaucoma and blindness.

Unlike hyphema in the patient not affected by sickle cell anemia, in which hypemas usually resolve spontaneously, hyphema in sickle cell disease requires immediate evacuation to avoid loss of vision. Treatment is indicated in bilateral disease, rapidly progressive disease, and in case of spontaneous hemorrhage. Laser photocoagulation is the preferred procedure with the least rate of complications. Surgical intervention is required for retinal detachment or unresolving vitreous hemorrhage.

Cardiovascular system: Cardiovascular manifestations are common in patients with sickle cell disease. Systolic heart murmurs are found in most patients and are caused by the anemia. Exercise tolerance is markedly impaired because of the anemia. Cardiomegaly is present in both children and adults and secondary to the anemia and microvascular disease. Detailed studies showed that most patients have dilatation of the ventricles and interventricular septum. However, ventricular contractility is normal in most patients. Heart failure, when it occurs, is usually due to sudden drop in hemoglobin (splenic sequestration) or fluid overload (rapid blood transfusion, especially for splenic sequestration).

Multiorgan failure: Multisystem failure syndrome, defined as failure of two or more systems (hepatic, renal, pulmonary, and cardiac), is a rare and potentially fatal complication in patients with sickle cell disease. It is often associated with severe painful vaso-occlusive event or sepsis. Aggressive exchange transfusion may be life saving.

Hearing: Sensorineural hearing loss occurs in around 10% of patients with sickle cell anemia disease. The frequency increases with age. It is caused by sickling in the cochlear vasculature, which results in destruction of hair cells.

Infection: Bacterial and viral infection is a major cause of morbidity and mortality in patients with sickle cell disease. Hyposplenia/asplenia caused by repeated splenic

infarction is the main reason of increased susceptibility to the encapsulated organisms (*Streptococcus pneumoniae and Haemophilus influenzae*). Impaired opsonization and abnormal alternative complement pathway activation increases the susceptibility to *Salmonella*, *E. coli*, *Staphylococcus aureus*, and *Mycoplasma pneumoniae*. Abnormalities in neutrophil function have been demonstrated in several studies. Devascularized tissue due to vaso-occlusive episodes in the bone, lungs, or skin provides a suitable environment for bacterial invasion and growth. Microinfarcts of the wall of the gastrointestinal tract provide egress of the *Salmonella* to the circulation, causing sepsis and/or osteomyelitis. The incidence of *Streptococcus pneumoniae* and *H. influenzae* infection (sepsis, pneumonia, or meningitis) was 400–600 and 4 times more frequent, respectively, compared with children not affected by sickle cell anemia. The mortality rate is 30% and 10% for sepsis and meningitis, respectively. The incidence of and the mortality/morbidity caused by infection by these two organisms decreased significantly since the universal use of immunization and penicillin prophylaxis. A further drop in the rate of complications from these organisms is expected with the recent approval of the 13-valent pneumococcal vaccine. Infection with the two organisms, however, remains a major cause of morbidity and mortality, especially in children less than 5 years old. Infection by other organisms is less frequent and probably less fulminant than *Streptococcus pneumoniae* and *H. influenzae*. Aggressive antibiotic treatment should be started as soon as bacterial infection is suspected. The choice of the antibiotic depends on the suspected organism. Empiric antibiotics should be started immediately in a febrile child after obtaining the appropriate cultures (blood, urine, local aspirate etc.). Ceftriaxone is recommended as an empiric antibiotic by most authorities. Vancomycin should be reserved for severely sick patients (e.g., those in shock), patients suspected to have meningitis, or in areas where penicillin resistant streptococcus pneumoniae is prevalent. Macrolide antibiotics should be given for febrile patients with pneumonia/acute chest syndrome to cover for mycoplasma and Chlamydia. There is no evidence that children with the sickle cell disease are more susceptible to virus infection than their normal counterparts. The incidence of parvovirus B19 infection is similar to that of general population; however, it may cause transient but severe aplastic anemia.

Prevention: Penicillin prophylaxis was shown to decrease pneumococcal infection by 85%. However, it should be remembered that these results were obtained when almost all isolates of *Streptococcus pneumoniae* were susceptible to penicillin. Oral penicillin or amoxicillin prophylaxis is still recommended for children with SCD as soon as the diagnosis is made. The goal of newborn screening programs is to get penicillin prophylaxis started by 2 weeks of age. The duration of the prophylaxis is not known. At least one study suggested that it should be stopped at 5 years of age. A first generation cephalosporin is a good alternative. Macrolides or trimethroprim-sulfamethoxazole is recommended for patients who are allergic to penicillin. Conjugate *H. influenzae* and conjugate (PCV7) or the most recently approved 13-valent streptococcus pneumoniae are part of routine childhood immunization. Twenty-three-valent pneumococcal vaccine (PCV23) is recommended after 2 years of age and repeated once after 3–5 years. Meningococcal conjugate vaccine is recommended after 2 years of age. Hepatitis B and A vaccination are also recommended.

Psychosocial: The patient with sickle cell anemia as well as their families are under severe psychological, social, and financial stress. Recurrent painful events, frequent hospitalizations, inability to keep up with peer's exercise activities, delayed sexual and physical maturation, school absenteeism, job-related problems, financial and insurance problems, and fear of premature death puts severe pressure on the families. Comprehensive and sympathetic programs for early diagnosis, education, physical and psychological treatment, and financial support are needed. Participation of hematologists, psychologists/psychiatrists, nurses, social workers, self-help groups, and government and nongovernment organizations are essential to assure proper care for patients and their families. Special sickle cell clinics are also important.

Growth and development: The weight and height of infants with sickle cell disease is normal. This is not surprising as the levels of hemoglobin S levels are low intrauterinely as well as in the first few months of life. With increasing age and rising hemoglobin S levels, however, patients become more anemic and fall behind in weight and height. Weight is more affected than height. Growth deficits may be evident as early as 2 years of age and become more pronounced with increasing age. Sexual maturation is delayed in both sexes. Females have delayed onset of menarche. Both males and females have delays in attaining normal Tanner development stages. Development delay is multifactorial. The severe chronic anemia is probably the most important factor. Other implicated factors include, malnutrition, vitamin and mineral deficiency, infection, and the stress of chronic disease. Most patients with sickle cell disease do not require therapy for physical or sexual delays unless they have slow growth velocity.

Cognitive function: For a long time, patients with sickle cell disease were thought to have learning,

neuropsychological, and cognitive problems. Recent evidence suggests that silent CNS infarction may be the major cause of these problems. MRI scans have identified several brain lesions in children without a history of clinical CNS problems.

Neonatal screening: Neonatal screening is recommended in areas where sickle cell gene is prevalent. The interpretation of screening results is shown in Table 324.1. Screening programs, together with close follow-up and parental education programs, have resulted in decreased mortality and morbidity and a better lifestyle in children with sickle cell disease. This improved outcome is the result of:

- Antibiotic prophylaxis
- Appropriate and timely immunization programs
- Aggressive treatment of febrile episodes
- Aggressive management of splenic sequestration events
- Comprehensive multidisciplinary sickle cell programs
- Parental education about the potential complications (splenic sequestration fever, seizures respiratory distress, etc.) and the necessity of urgent medical consultation
- Prenatal diagnosis and counseling of pregnant women
- Premarital counseling of patients with sickle cell trait
- Parental and children guidance on methods of coping with the stress of the condition and its complications

Surgery and General Anesthesia

Children with sickle cell disease are at high risk of developing severe complications with surgery and general or regional anesthesia. Postoperative complications include acute chest syndrome, painful events, infection, fever, CNS events, and death. Sickling-promoting factors that may be induced or exaggerated by surgery and anesthesia include hypoxia, dehydration, acidosis, stasis, hypotension, hypothermia or hyperthermia, hypoperfusion, and pressure on major blood vessels by tourniquets or improper positioning. These factors may be induced by medications, improper preparation, improper positioning (immobility, pressure on major blood vessels), the operating room environment (hypo or hyperthermia), the disease itself (pulmonary or cardiac disease). Generalized sickling leading to serious complications (respiratory failure) and/or death or localized sickling leading to organ damage (loss of a limb) may be the end result. Complications may occur intraoperativly or postoperatively. It is important to remember that complications occur more commonly in the recovery room when patient monitoring may be less intense.

These complications can be avoided by careful monitoring, adequate oxygenation, hydration, avoidance of hypotension, hypovolemia, hypothermia, local or generalized stasis, and acidosis are essential. The use of tourniquets should be avoided, and care should be taken to avoid pressure on major blood vessels due to improper positioning. These measures need to be started prior to general anesthesia and continued during surgery and through postoperative period, until the patient is fully awake. Close monitoring of temperature, blood pressure, oxygen saturation, and blood loss is essential. These measures are more important in patients with compromised pulmonary or cardiac function and in those who require surgery that compromises these organs (i.e., cardiac, CNS, or chest surgery).

The need for preoperative blood transfusion is controversial. Recent evidence suggests that transfusion may not be necessary in all patients. Preoperative blood transfusion to raise the hemoglobin level to 10 g/dl was found to be as effective as exchange transfusion to lower the level of hemoglobin S to less than 30%. Until further studies are completed, preoperative simple blood transfusion is indicated for all patients. Exchange transfusion should be reserved for patients with significant anemia (to avoid CHF), patients with compromised cardiac or pulmonary function, and those undergoing thoracic, cardiac, or CNS surgery.

Table 324.1
Interpretation of hemoglobin electrophones in the newborn

FA	Normal
FAS	Sickle cell trait
FS	1. Homozygous sickle cell disease (SS)
	2. Sickle-β° thalassemia
	3. Sickle hereditary persistent hemoglobin F (HPHF) disease
FS+C,D,E,O Arab, etc.	Double heterozygous of sickle with Hbs C, D, E, or O Arab, etc.
FA+C,D,E, O-Arab	Trait for hemoglobins C, D, E, or O-Arab the present Hb

Any of the above could be associated with alpha gene hemoglobinopathy, mainly α thalassemia.

Pregnancy in Sickle Cell Disease

Fetal and neonatal related issues: Complications associated with maternal sickle cell anemia include spontaneous abortion, intrauterine growth retardation, low birth weight, prematurity, and increased perinatal mortality.

These complications are mainly due to placental compromise caused by decreased uterine blood flow. Other factors which may contribute to fetal problems include maternal anemia, maternal malnutrition, and increased incidence of placenta previa and abruption placenta in mothers with sickle cell disease. Perinatal mortality was as high as 20–50%. However, improvement in obstetric care leads to a significant decrease in the perinatal mortality. Routine prophylactic blood transfusion is not recommended.

Hematopoietic stem cell transplantation (HPSC): Hematopoietic transplantation is the only curative therapy for patients with sickle cell disease. Overall survival and event-free survival range between 91–100% and 73–93%, respectively, with the higher figures in the more recent studies. Transplant early in the course of sickle cell related complications is associated with a better outcome with overall and disease free survival of 100% and 93%, respectively, as compared with 88% and 80% for transplants later in the course of the condition. The majority of the reported cases were from matched siblings. Few cases were from cord blood of matched siblings with overall and disease-free survival of 100% and 90%, respectively. The main limiting factors for HPSC transplant are the variable clinical severity and the lack of known predictors of severity of SCD. Indications for HPSC vary between transplant centers. Accepted indications include a history of stroke, repeated severe acute chest syndrome, and frequent severe and debilitating vaso-occlusive events. It should be remembered that HLA-matched siblings with sickle cell trait can be used as donors.

Augmentation of Hemoglobin F Production

Several pharmacologic agents (5-Azacytidine, 5-Azadeoxycytidine, butyric acid, arginine butyrate, and erythropoietin) have been used in animal model and/or humans to increase hemoglobin F levels. Hydroxyurea is the agent commonly used in clinical practice in patients with sickle cell anemia. Several studies in both adults and children proved its efficacy in decreasing the frequency and severity of painful events, acute chest syndrome, blood transfusion, hospitalization, and mortality. Limited observational studies with small numbers of patients provided evidence that hydroxyurea prevents primary and secondary stroke, reverses splenic function, prevents or reverses chronic organ damage, improves oxygenation, and reduces proteinuria. Currently, hydroxyurea is indicated for patients with recurrent severe painful episodes, recurrent acute chest syndrome, and recurrent hospitalizations. Further studies are needed before recommendation can be made for its use for other indications. It is generally believed that the benefits of hydroxyurea are due to the increase in hemoglobin F level. However, the improvement in many patients was noticed with minimal or no change in hemoglobin F levels. Other possible mechanisms of action include neutropenia (neutrophil count correlates with event rate), reduction of reticulocytes, and young red blood cell which have high tendency to adhere to the vascular wall and induce vaso-occlusion and generation of nitric oxide. The major limiting factor in the routine use of hydroxyurea is neutropenia. However this complication is reversible with reduction of the dose or temporally discontinuing the drug. An unproved but serious concern is the possible carcinogenic effect of hydroxyurea. This concern originated from the observation that hydroxyurea increased the incidence of malignancy in patients with polycythemia vera and myelodysplastic syndromes. These diseases, however, are monoclonal and premalignant. There is no evidence that the hydroxyurea is carcinogenic in patients with sickle cell disease. The recommended starting dose is 15 mg/kg given once daily. The dose is increased every 8 weeks to the maximum tolerated dose.

Blood transfusion in sickle cell disease: Blood transfusion is an integral tool in the treatment of patients with sickle cell disease. When used appropriately, transfusions may treat or prevent complications, prevent organ damage, alleviate suffering, and prevent death. As any patients with SCD are expected to receive repeated blood transfusion, care should be taken to avoid unnecessary transfusion and to avoid or minimize potential complications. In addition to the precaution necessary for transfusion in other patients (donor screening for infectious agents, proper cross matching, etc.), the following steps are essential:

- Donors should be screened for sickle cell disease and trait.
- Antigenic phenotypes of the patient should be known and records well kept for future reference.
- Limited matching for ABO, Rh, E, C, and Kell is essential to minimize the incidence of alloimmunization.
- The use of leukodepleted blood units reduces febrile reactions, platelet refractoriness, infections, and cytokine-induced complications.

The indications for blood transfusion is not precisely defined and most recommendations are based on experience or uncontrolled studies. Most patients with sickle cell disease tolerate their anemia. Indications for packed red blood cell transfusion include:

- Severe symptomatic anemia (splenic sequestration event, aplastic event, hypersplenism, and hyperhemolytic event). The indication of transfusion in these cases depends on the clinical picture (real or pending heart failure, hypotension, tachypnea, tachycardia or pallor hypoactivity, and generalized weakness), degree of the drop in hemoglobin level (2 g/dl) and bone marrow activity as evidenced by reticulocyte count and/or the presence of NRBCS in the peripheral blood. These patients should receive simple transfusion.
- *Acute chest syndrome*: Most patients with ACS present with low hemoglobin. Simple transfusion is usually adequate in mild and moderate case of ACS. Partial or total exchange transfusion is recommended in severe, progressive cases and those patients with high hemoglobin level.
- Preparation for general anesthesia (see "Surgery and General Anesthesia").
- *Stroke*: Immediate exchange transfusion is indicated for ischemic stroke. Chronic transfusions with iron-chelating therapy are recommended for primary and secondary stroke prevention and for patients with recurrent debilitating painful event.
- *Multisystem failure*: Exchange transfusion might be life saving.

Controversial indications include priapism, skin ulcers, preparation for infusion of contrast media, and silent CNS infarction. Some authorities recommend chronic transfusion in infants with ASSC to delay splenectomy. Recent literature, however, suggests that splenectomy does not increase the chances of serious bacterial infection in children with sickle cell disease because these children have functional asplenia. The hematocrit should not exceed 36% in any kind of transfusion. Higher levels result in exponential increase in blood viscosity, leading to painful events. Potential complications of transfusion should be kept in mind when considering such therapy. In addition to the known complications, patients with sickle cell disease have a higher incidence of alloimmunization and delayed hemolytic transfusion reactions. Alloimmunization occurs in 8–35% (mean, 25%) of transfused sickle cell disease patients.

Mild Sickle Cell Disease

An interesting and relatively mild form of homozygous sickle cell disease is known to occur in the Shiite Muslims population of the Arabian Gulf area. These patients have a less severe course, a higher percentage of splenomegaly and normal splenic function in most patients; at least in young children and adolescents, a lower incidence of pneumococcal infection, and a longer life expectancy. The reasons for the relatively mild course are not fully understood. High levels of hemoglobin F, which is common in this population and the common association with the α-thalassemia gene, may be the major contributing factors. This kind of sickle cell disease is not completely benign (as previously reported) as many patients develop serious complications, such as sepsis, meningitis, osteomyelitis, aseptic necrosis of femoral and humeral heads, ACS, and cerebrovascular accidents.

Sickle Cell Trait (AS)

Patients with sickle cell trait are clinically, hematologically, and developmentally normal. Around 40% of their hemoglobin is sickle hemoglobin (hemoglobin S). Hematuria and hyposthenuria are common. Extreme conditions including severe hypoxia may lead to sickling and even death. Flying in an unpressurized plane, strenuous exercise at high altitude, and severe pulmonary or cardiac disease are examples of situations in which complications and death have been reported. During general anesthesia, tourniquets and pressure on major blood vessels should be avoided to prevent severe hypoxia distal to the tourniquet, which may result in sickling and loss of an extremity.

Compound heterozygous sickle cell disease: The term "sickle cell disease" is usually used to describe patients with homozygous sickle cell disease (SS) and compound (doubly) heterozygous disease which results from coinheritance of hemoglobin S and another abnormal hemoglobin or thalassemia. SC, SD, S/O-Arab, and SE diseases are discussed in the chapter on "hemoglobinopathies other than sickle cell disease."

Sickle cell β thalassemia: Compound heterozygous sickle cell-beta thalassemia results from inheritance of a sickle cell gene from one parent and β thalassemia gene from the other. The clinical manifestations are extremely variable ranging from asymptomatic to a clinical picture similar to that of homozygous sickle cell disease. The clinical severity depends on the amount of hemoglobin A produced. Sickle-β+ thalassemia is usually milder than homozygous sickle cell disease and sickle-β° thalassemia. However, both sickle-β° thalassemia and Sickle-β+ thalassemia have a higher incidence of splenomegaly than homozygous sickle cell disease. Retinopathy is more common in sickle-β+ thalassemia than homozygous sickle cell disease and sickle-β° thalassemia. Patients with sickle-β+ thalassemia tends to have a higher hemoglobin

concentration (10–12 g/dl) and lower reticulocyte count than that of sickle-β° thalassemia (8–10 g/dl) who, in turn, have a higher hemoglobin concentration and lower reticulocyte count than those affected by homozygous sickle cell disease. The anemia in sickle-β° thalassemia and sickle-β+ thalassemia is hypochromic and microcytic. Hemoglobin electrophoresis of sickle-β° thalassemia is similar to that of homozygous sickle cell disease with higher hemoglobin A2 level (4–5%) and with no hemoglobin A. Hemoglobin electrophoresis in sickle-β+ thalassemia reveals hemoglobin S, with variable amounts of hemoglobins A, F, and A2. One parent has sickle cell trait while the other has β thalassemia and hypochromic, microcytic red blood cells.

Homozygous Sickle Cell Disease with α Thalassemia

The association of α-thalassemia with homozygous sickle cell disease (SS) results in a hypochromic microcytic anemia. The red blood cells of the newborn infant are usually microcytic (mean corpuscular volume <94 fl). Results of hemoglobin electrophoresis later in life are similar to those of homozygous sickle cell disease (SS). The anemia is usually less severe, and the reticulocyte count is lower than those of sickle cell disease (SS). The clinical effects are variable. Some studies showed that the increased frequency of painful vaso-occlusion is related to the higher hemoglobin level which is usually found in patients with sickle cell/α thalassemia. The incidence of acute chest syndrome was higher in some studies and lower in others. Some studies suggested an increased incidence of avascular necrosis of the femoral head and decreased incidence of leg ulcers.

Sickle cell with hereditary persistence of fetal hemoglobin (HPFH): Two types of HPFH have been described. One type (deletion type) results in higher levels and a pancellular distribution of hemoglobin F. Patients who coinherit this type of HPFH with sickle cell gene (sickle cell trait) are usually asymptomatic and have normal hematologic parameters. The second type (non-deletion) results in a heterogeneous distribution of hemoglobin F. The clinical picture in these patients is variable and depends on hemoglobin F level and the pattern of its distribution. Parents' studies should show that one parent has sickle cell trait, while the other has high hemoglobin F level.

Sickle cell/Hb Lepore disease: Co-inheritance of sickle cell gene with hemoglobin Lepore is rare. The clinical severity is similar to sickle-β+ thalassemia.

325 Hemoglobinopathies-Non-Sickle Cell

Ahmad A. Mallouh

Introduction

The globin part of the normal human hemoglobins (Hb A, F, and A2) consists of two alpha and two non-alpha chains (β in hemoglobin A, γ in hemoglobin F and δ in hemoglobin A2). Hemoglobinopathies result from genetic mutations causing structural changes in one of the globin chains by adding, deleting, or exchange of one or more amino acid. Over 800 mutations have been identified. The majority of these mutant hemoglobins are innocuous. A few of them, however, cause lifelong serious and sometimes fatal health problems. The following hemoglobinopathies will be discussed in this chapter, either because of high prevalence in certain ethnic groups or geographical area and/or their clinical severity either alone or in co-inheritance with sickle cell disease or thalassemia:

- Hemoglobin C
- Hemoglobin E
- Hemoglobin D
- Hemoglobin O Arab
- Unstable hemoglobins
- High oxygen affinity hemoglobins

Hemoglobin C

Pathogenesis and Incidence

Hemoglobin C results from a genetic mutation, resulting in the replacement of glutamic acid with lysine in the β chain subunit at position 6. It is less soluble than hemoglobin A. It precipitates into hexagonal crystals inside the RBCs. The red blood cells (RBCs) become less deformable and are easily removed by the spleen. The prevalence of Hemoglobin C is approximately 40–50% in West Africa, 3.5% in Carribbeans of African descent, 3% in African Americans, and 1–10% in North Africa. It has been also reported in other countries, for example, Italy and Turkey. This geographic distribution is probably due its protective effect against falciparum malaria.

Clinical Picture

Patients with hemoglobin C trait (Hgb AC) are asymptomatic with normal hematological values, except for a mild microcytosis and target red blood cells. Homozygous patients (Hb CC) usually have a mild, compensated hemolytic anemia and splenomegaly. Like other chronic hemolytic anemias, patients affected by homozygous hemoglobin C may develop cholelithiasis. Parvovirus infection may induce a transient aplastic crisis.

Co-inheritance with Thalassemia or Other Hemoglobinopathy

Patients with double heterozygous hemoglobin S/hemoglobin C (Hb SC) disease have a clinical picture similar but usually milder than homozygous hemoglobin S (Hb SS). Approximately 2% of these patients have severe disease. Aseptic necrosis of the femoral head and proliferative retinopathy are, in particular, common in patients with SC disease. Patients with C/β-0 thalassemia usually have a thalassemia intermedia-like picture. Those with C/β+ thalassemia usually have a mild, compensated hemolytic anemia. Patients with C/E, C/Lepore, and C/δ β thalassemia have a moderate hemolytic anemia. Patients with C/O Arab usually have a mild, compensated hemolytic anemia.

Diagnosis

Heterozygous hemoglobin C is usually diagnosed on hemoglobin electrophoresis either as a part of neonatal screening or as part of the investigation of a patient with mild chronic hemolytic anemia. The blood indices typically demonstrate a mild microcytosis. Target cells are seen on the peripheral blood smear of patients with hemoglobin C trait. The peripheral blood smear has a high number of target red blood cells with the presence of xerocytes and hexagonal crystals, inside the red blood cells. Hemoglobin C has the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_325,

same mobility as hemoglobins E, O Arab, and A2 in alkaline media. Hemoglobin electrophoresis in acid citrate agar or high performance liquid chromatography (HPLC) is required for definitive diagnosis. The electrophoresis pattern of C/β-0 thalassemia is similar to that of Hb CC disease. Both demonstrate a high Hb C levels (over 95%) and no hemoglobin A. Hb C/β-0 thalassemia, however, has a marked microcytosis. At least one parent would have β thalassemia trait.

Treatment

No specific therapy is needed for patients with AC or CC. Parvovirus induced aplastic crisis anemia is usually mild and compensated. Folic acid supplementation is recommended in homozygous or doubly heterozygous patients (SC, C/β thalassemia, etc.). Treatment of SC disease is similar to that for SS disease. Treatment for C/β thalassemia depends on the severity of the anemia and may require blood transfusion. Splenectomy is rarely required in CC disease, but might be necessary in SC or Hb C/β thalassemia disease.

Hemoglobin E

Pathophysiology and Incidence

Hemoglobin E results from substitution of glutamic acid by lysine in position 26 of the β globin chain. The β chain of Hb E is synthesized at a slower rate compared with that of Hb A. This leads to imbalance of globin chain synthesis which results in a thalassemia-like morphology of the RBCs. Hemoglobin E is the second most common hemoglobinopathy worldwide. The highest prevalence of Hb E is found in South East Asia (Thailand, Cambodia, and Laos), where the prevalence reaches 20–30%. It is also common in the Indian subcontinent (India, Pakistan, Bangladesh, and Sri Lanka), Vietnam, Nepal, China, Turkey, Malaysia, and the Phillipines. This distribution is probably due to its protective function against falciparum malaria. It has been brought to North America and Europe through immigration.

Clinical Picture

Heterozygous patients (Hb AE) have normal hematologic values except for a mild microcytosis and target cells identified on the peripheral blood smear. Homozygous patients (Hb EE) have a mild compensated hypochromic microcytic anemia. Mild splenomegaly may be present. Co-inheritance of Hb E with β-thalassemia is the major concern for patients with Hb E. Patients with E/β-thalassemia disease have a highly variable clinical and hematologic manifestations ranging from mild thalassemia trait-like hypochromic, microcytic anemia to severe transfusion-dependant hemolytic anemia. Around 50% of the patients are phenotypically similar to β-thalassemia major. The severity seems to be influenced by several factors including the type of the inherited β gene (E/β0 vs E/β+ disease), associated inheritance of α-thalassemia, and possibly environmental factors. Co-inheritance with Hb S (ES) results in a phenotypically mild sickle cell disease. Patients have fewer problems with vaso-occlusive crisis, splenic sequestration crisis, and increased susceptibility to infection than patients with Hb SS.

Diagnosis

Hemoglobin E should be considered in a patient with hypochromic, microcytic anemia, especially if the family history or ethnicity is suggestive of the gene inheritance. It has the same mobility as Hb C and Hb A2 in alkaline medium. It can be differentiated from Hb C by electrophoresis at acid pH, in which its mobility is the same as Hb A and Hb A2. High performance liquid chromatography separates Hb E from hemoglobins A and C.

Treatment

No treatment is needed for Hb E. Treatment for E/β-thalassemia depends on the severity of the anemia and its complications. Mild cases require no therapy except folic acid supplementation. Treatment of severe case is the same as β-thalassemia major. ES disease is managed as patients with SS disease.

Counseling

Patients with heterozygous and homozygous Hb E should be counseled when having children with individuals who have β-thalassemia, Hb SS, β-thalassemia trait, or sickle cell trait.

Hemoglobin D

There are a number of hemoglobins termed "hemoglobin D". Hemoglobin D-Punjab (also called Hb Los

Angeles) and hemoglobin Ibadan are the most common ones. Hemoglobin D-Punjab is a mutant hemoglobin that results from the genetic substitution of glutamic acid by glutamine at position 121 in the β globin chain. It occurs most commonly in the Punjab part of the Indian subcontinent and Iran, where the reported prevalence is around 2%. It is also reported in the Turkish, Algerian, West African, Saudi Arabian, African American, Native American, English, and Irish population. The occurrence of the gene in the United Kingdom and Ireland is mostly a result of immigration from and intermarriage with people from the Indian subcontinent.

Clinical Picture

People with hemoglobin D trait (Hb AD) are asymptomatic and they have normal hemoglobin level and normal red blood cells indices. Homozygous disease (Hb DD) is extremely rare. Patients usually have normal hemoglobin level and normal red blood cells indices. Co-inheritance with hemoglobin S (Hb SD) results in a mild form of sickle cell disease. Patients usually have fewer problems with vaso-occlusive crisis, infection, organ damage or splenic sequestration crisis than Hb SS patients. Some patients, however, develop serious complications including stroke. Co-inheritance with β-thalassemia (Hb D/β-thal) results in mild to moderate hypochromic, microcytic anemia.

Diagnosis

Hemoglobin D has the same mobility as hemoglobin S in alkaline media. It can be differentiated from hemoglobin S by their distinct mobility in acid media, in which hemoglobin D migrates with hemoglobin A and by the fact that hemoglobin D does not sickle. An increased number of target cells is seen on review of the peripheral blood smear. Red blood cells' osmotic fragility is decreased. Differentiating Hb DD from D/β-0thal can be a problem, as both have over 95% hemoglobin D with no hemoglobin A. Red blood cells in patients affected by Hb D/β0-thal are hypochromic and microcytic. At least one parent is expected to have β-thalassemia or β-thalassemia trait.

Treatment

No treatment is needed for Hb AD or Hb DD except for folic acid supplementation, as the patients are clinically and hematologically normal. Patients with Hb SD and Hb D/β-thal are treated as those with Hb SS and β-thalassemia intermedia or thalassemia major, respectively. Therapy depends on the severity and/or complications of the disease.

Counseling

Patients with either heterozygous or homozygous hemoglobin D should be counseled when having children with individuals who have β-thalassemia, Hb SS, β-thalassemia trait, or sickle cell trait.

Hemoglobin O Arab

Hemoglobin O Arab results from genetic substitution of lysine for glutamic acid at position121 in the β globin chain. It is mainly found in the Middle East, the Balkans, Greece, North Africa, West Africa, and in African Americans.

Clinical Picture

Persons with hemoglobin O-Arab trait (Hb A/O Arab) are asymptomatic and have normal hemoglobin levels and normal or mildly microcytic red blood cells. Homozygous disease is extremely rare. Patients are asymptomatic with normal hemoglobin or mild compensated hemolytic anemia. Red blood cells are microcytic with high MCHC. Co-inheritance with hemoglobin S (S/O Arab) results in a moderate sickle cell disease–like clinical picture with variable severity. Patients may have vaso-occlusive events, splenomegaly, jaundice, and reticulocytosis. Hemoglobin level ranges betweem7 and 8 g/dl. Co-inheritance with β-thalassemia results in a thalassemia intermedia picture.

Diagnosis

The red blood cells in patients with heterozygous or homozygous hemoglobin O-Arab are either morphologically normal or mildly microcytic. Hemoglobin O Arab migrates with Hb C in alkaline media and it migrates between hemoglobins A and S in acid media. It can be identified by high performance liquid chromatography.

Treatment

No treatment (except folic acid supplementation) is needed for Hg A/O Arab or Hb O Arab/O Arab, as the

patients are clinically and hematologically normal. Patients with Hb S/O Arab and Hb O Arab/β-thal are treated as those with Hb SS and β-thalassemia intermedia or thalassemia major, respectively. Therapy depends on the severity and/or complications of the disease.

Unstable Hemoglobins

Unstable hemoglobins are inherited structurally abnormal hemoglobins characterized by decreased solubility, resulting in intracellular hemoglobin precipitation forming intracorpuscular Heinz bodies and shortened red blood cells survival.

Pathophysiology

Unstable hemoglobins result from substitution or deletion of amino acids in one of the globin chains. (α, β, or γ). Decreased solubility of the unstable hemoglobins results from the weak binding between globin and heme parts of the hemoglobin and from interference with the tertiary and quaternary structure of the subunits. As a result, hemoglobin is denatured and precipitated inside the red blood cell as Heinz bodies. Heinz bodies attach to the cell membrane and make red blood cells susceptible to destruction by the spleen.

Clinical Picture

Unstable hemoglobins are rare. They are mostly inherited as dominant disorders. Approximately, 250 mutations have been identified so far. Chronic hemolytic anemia of variable severity is the main clinical manifestation. The severity of anemia and the age of its onset depend on the type of the mutation and are modified by extrinsic factors. Mutations involving the γ chain (Hb Poole) are associated with transient hemolytic anemia and jaundice in the newborn, which lasts for the first few months of life. It resolves as hemoglobin A replaces hemoglobin F. Mutations involving the α chain (Hb Hasharon) presents with anemia and jaundice in the neonatal period and persists lifelong. People who inherit an unstable hemoglobin involving the β chain (Hb Koln and Hb Zurich) are hematologically normal at birth. Anemia and dark colored urine (pigmenturia) develop at 2–4 months of age, as hemoglobin F is replaced with hemoglobin A. Patients may develop acute hemolytic episodes triggered by infection or exposure to oxidant drugs and may develop transient aplastic crisis with parvovirus B19 infection. As in other chronic hemolytic anemia, patients may develop cholelithiasis. Patients with the rare types of unstable hemoglobin named "hyperunstable hemoglobin" have a thalassemia intermedia-like clinical and hematologic picture. They have moderately severe hypochromic, microcytic anemia with or without splenomegaly.

Diagnosis

Diagnosis should be suspected in a patient with hemolytic anemia and RBC Heinz bodies found using supravital stains. Diagnosis is confirmed by the heat stability test or isopropanol stability test. Hemoglobin electrophoresis is usually not useful for diagnosis of the unstable or hyperunstable hemoglobins. In these cases, globin chain sequencing using DNA based methods is required to confirm the diagnosis.

Treatment

Treatment is mainly supportive with folic acid and avoidance of oxidant drugs. Blood transfusion is rarely needed as most patients are asymptomatic or have compensated anemia. Splenectomy may be required in the very few severe cases. Splenectomy does not always ameliorate anemia.

High Oxygen Affinity Hemoglobins

Over 200 variants of high oxygen affinity hemoglobins have been described. The oxygen dissociation curve in these patients is shifted to the left. Oxygen delivery to the tissues is poor resulting in tissue hypoxia, increased erythropoietin level and secondary erythrocytosis. Individuals with these hemoglobin variants are usually asymptomatic and require no therapy. However, they should be considered in the differential diagnosis of erythrocytosis.

General Considerations

A red blood cell (RBC) contains approximately 640 million hemoglobin molecules, which allow the red cell to perform its essential function of oxygen delivery in exchange for carbon dioxide. Alteration of the hemoglobin molecule can result in various forms of anemia and their subsequent long-term complications. Hemoglobin abnormalities can be a result of synthesis of abnormal hemoglobin as in Sickle Cell Disease, or abnormalities can result from reduced synthesis of normal hemoglobin, as in thalassemia.

Hemoglobin synthesis, a process that predominantly occurs in the mitochondria of the cells, changes as a fetus develops, is born, and becomes an adult. At any point of hemoglobin development, though, a hemoglobin molecule is made up of four polypeptide chains. In order to accommodate for differences in oxygen delivery requirements as a fetus develops and enters extrauterine life, different polypeptide chains come together to create hemoglobin molecules with oxygen affinity specific for their current environment. The genes for the polypeptide chains are located on chromosomes 11 and 16, and the genes result in the synthesis of six different globin chains: alpha, beta, gamma, delta, epsilon, and zelta. Pairs of these globin chains come together to form tetramers, resulting in functional hemoglobin molecules. In embryonic development, the predominant hemoglobin molecules are $\zeta_2\varepsilon_2$ (Hemoglobin Gower 1), $\zeta_2\gamma_2$ (Hemoglobin Portland), and $\alpha_2\varepsilon_2$ (Hemoglobin Gower 2). Hemoglobin F ($\alpha_2\gamma_2$) is the most prevalent hemoglobin in later fetal development, while the primary hemoglobin in an older infant and an adult is Hemoglobin A1 ($\alpha_2\beta_2$), with small portions of Hemoglobin F as well as Hemoglobin A2 ($\alpha_2\delta_2$) (*Fig. 326.1*). In the first 3–6 months of life, the amount of β chain production increases, and the γ-chain is mostly replaced by β-chain (*Fig. 326.2*). Eventually, the cell synthesizes α-chains in proportion to β-chains in order to match the two together and create adult hemoglobin.

Problems arise when the cells are unable to synthesize the normal amount of α- or β-chain as the two will become mismatched, resulting in decreased synthesis of normal, adult hemoglobin. The general-term thalassemia refers to a group of genetic anemias that are a result of inadequate or absent synthesis of normal globin chains. Thus, in contrast to Sickle Cell Anemia where an abnormal hemoglobin is created, thalassemia is a *quantitative defect* in hemoglobin synthesis. The clinical picture of a patient with thalassemia depends on which chain is affected and how many genes are deleted or mutated.

Epidemiology

The genes producing the different types of thalassemia can be found throughout the world, but they are concentrated in the Mediterranean area, Southeast Asia, India, and Middle East (*Fig. 326.3*). It appears that the heterozygote state provides increased resistance to *falciparum* malaria, much like the genes for Sickle Cell Anemia and Glucose-6-Phosphate Dehydrogenase Deficiency.

Categories of Thalassemia

The thalassemias are a heterogeneous group of anemias resulting from a reduced or absent rate of production of one or more of the globin chains. This quantitative decrease in globin chain synthesis results in the microcytic, hypochromic anemias, called α-thalassemia and β-thalassemia. The classification of thalassemias can be based on which globin chain is decreased or absent.

α-Thalassemia

General Information

The majority of α-thalassemia is a result of deletion of one or more of the α-globin genes. Normal cells have four α-globin genes, and the clinical variability seen in α-thalassemia is in direct relation to the number of genes deleted (*Fig. 326.4*). Deletion of one gene results in a silent carrier state of α-thalassemia. If two genes are deleted (on either chromosome), then the patient has α-thalassemia trait. Hemoglobin H disease refers to the state of three genes being deleted, and results in

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_326,

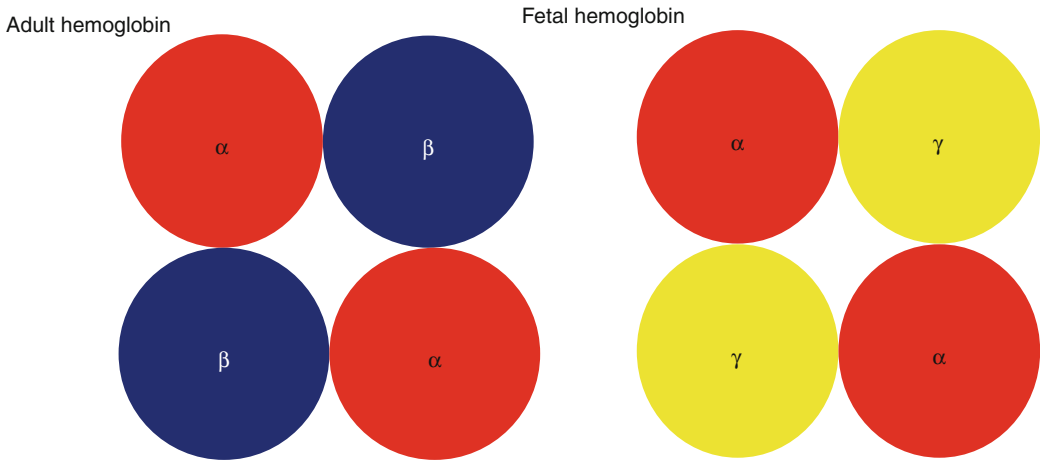

Figure 326.1

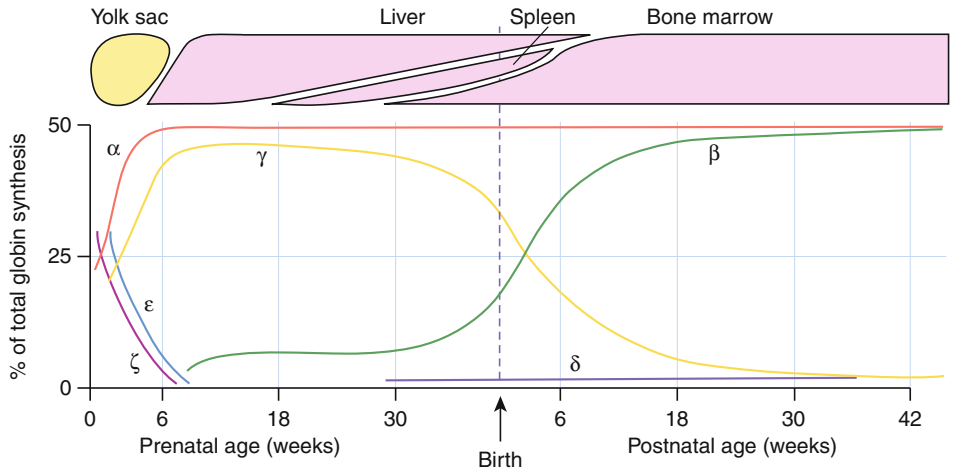

Figure 326.2

a moderately severe anemia. Deletion of all four genes results in hydrops fetalis and is incompatible with extrauterine life.

Clinical Characteristics

As stated previously, the clinical features seen in α-thalassemia are directly related to the number of genes deleted. See *Table 326.1* for a summary of α-thalassemia syndromes, clinical features, and hemoglobin electrophoresis findings.

Individuals who have three α-globin genes present are asymptomatic and have normal hemoglobin levels and mean corpuscular volume (MCV). These silent carriers may come to the pediatrician's attention as a result of a newborn screen report of Hemoglobin Bart's (*Fig. 326.5*). Hemoglobin Bart's is a type of hemoglobin made of four γ-globin chains. Silent carriers show 0–3% hemoglobin Bart's during the newborn period. Eventually, as the γ-chain is replaced by β-chain, the Hemoglobin Bart's disappears. A follow-up hemoglobin electrophoresis at 6 months of age would be normal but is largely unnecessary.

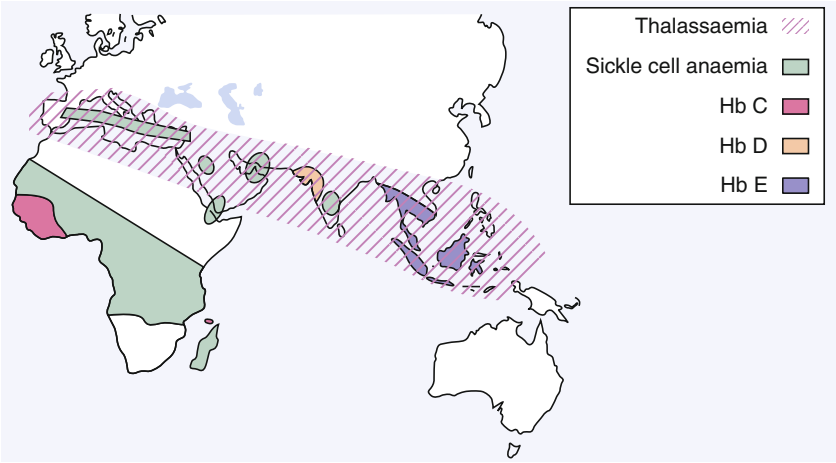

Figure 326.3
Caption missing

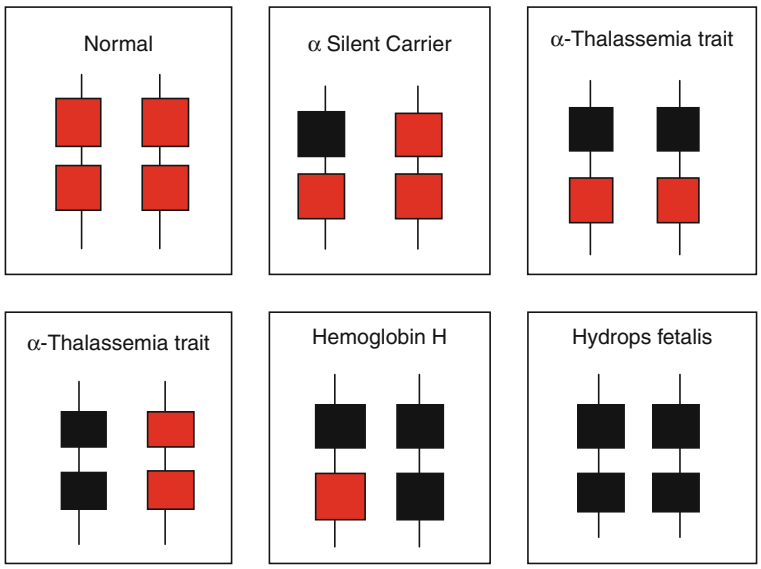

Figure 326.4
The genetics of α-thalassemia. ■ = normal genes ■ = gene deletions

Individuals with only two α-globin genes present are usually asymptomatic as well, and this is termed α-thalassemia trait. As an infant, the MCV will likely be <100, the hemoglobin may be slightly low, and the peripheral smear will appear slightly hypochromic with few target cells. On hemoglobin electrophoresis, α-thalassemia trait patients have 2–10% hemoglobin Bart's at birth, but the electrophoresis is normal after >6 months of age.

When three out of the four α-globin genes are deleted, an individual will have mild to moderately severe microcytic, hypochromic anemia (Hgb 7–11g/dL). This is known as hemoglobin H disease. Hemoglobin H is created when excess β-globins come together to form a tetramer (β_4). Hemoglobin H can aggregate within a red blood cell, forming an inclusion body and resulting in hemolysis. The peripheral blood smear shows

Table 326.1
The α thalassemias

Genotype	# of α genes present	Clinical characteristics	Hgb electrophoresis at birth	Hgb electrophoresis >6 months
αα / αα	4	Normal	Normal	Normal
-α / αα	3	Silent carrier	0–3% Hgb Bart's	Normal
- - / αα or -α/-α	2	α-Thal trait	2–10% Hgb Bart's	Normal
- - / - α	1	Hgb H disease	15–30% Hgb Bart's	β4
- - / - -	0	Fetal hydrops	>75% Hgb Bart's	None

α refers to presence of α globin gene, - indicates deletion of α globin gene, Hgb = hemoglobin, Hgb Bart's = γ4

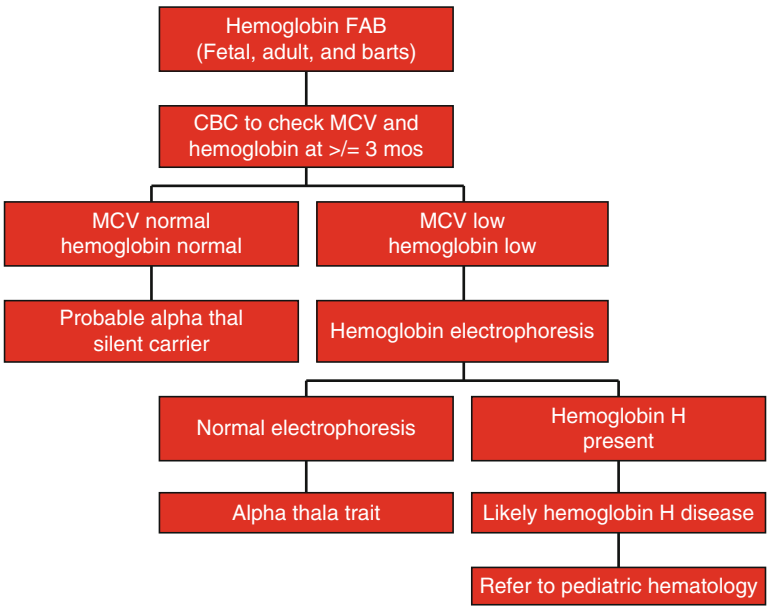

Figure 326.5
α-thalassemia newborn screen results

microcytosis, hypochromia, and poikilocytosis (abnormal cell shape). On hemoglobin electrophoresis, patients with hemoglobin H disease have 15–30% hemoglobin Bart's at birth. As older infants and children, hemoglobin H will continue to be present on electrophoresis. Patients with Hemoglobin H disease generally do well in the first decade of life and do not require many transfusions. However, they will likely show evidence of chronic hemolysis with hepatosplenomegaly, elevated indirect bilirubin, and increased susceptibility to aplastic crisis. In addition, because of ineffective eythropoiesis, patients may have skeletal abnormalities and hepatosplenomegaly, which is less severe than in β-thalassemia (see ❯ "Clinical Characteristics" in β-Thalassemia). As the patient ages, they may require more frequent and eventually chronic transfusions and begin to experience the consequences of iron overload (see ❯ "Complications" in β-Thalassemia). Finally, Hemoglobin H is readily oxidized and makes the patient especially susceptible to oxidative stress as in Glucose-6-Phosphate Dehydrogenase Deficiency, and oxidative stressors should be avoided.

Individuals with deletion of all four α-globin chains have intrauterine anemia and hydrops fetalis, which is incompatible with extrauterine life. This is the most severe form of α-thalassemia. On hemoglobin electrophoresis,

these patients have mostly Hemoglobin Bart's and absent fetal or adult hemoglobin.

Differential Diagnosis

Patient's with α-thalassemia trait will have evidence of microcytosis, and other causes of microcytic anemia should be considered such as iron deficiency, lead exposure, β-thalassemia minor, and other hemoglobinopathies. When compared to children with iron deficiency anemia, patients with α-thalassemia trait have normal or increased ferritin and serum iron. When compared to children with β-thalassemia minor, patients with α-thalassemia trait have normal hemoglobin electrophoresis as older infants and children. Newborns with Hemoglobin Bart's on newborn screen may be a silent carrier of α-thalassemia, may have α-thalassemia trait, or may have α-thalassemia. In an infant with hydrops fetalis, one must also consider other causes of intrauterine anemia such as alloimmunization.

Complications

A common scenario seen in patients with α-thalassemia is unnecessary prescription of oral iron because a child has microcytic anemia thought to be due to iron deficiency. Patients with hemoglobin H disease may require blood transfusions when exposed to oxidant stressors or as they age. Chronic transfusions may result in iron overload and subsequent cardiac, hepatic, endocrine, pulmonary, and renal effects. Mothers of infants with fetal hydrops have complications such as hemorrhage after delivery, and if possible, should be counseled on therapeutic termination of pregnancy.

Treatment and Prognosis

Children with α-thalassemia trait generally do not require treatment and lead a normal life. Similar to patients with G6PD deficiency, individuals with hemoglobin H disease should take folic acid and avoid medications which cause oxidant stress. In addition, hemoglobin H patients may require splenectomy due to the development of hypersplenism. However, the prognosis for most patients with Hemoglobin H disease is excellent, but there are some exceptions that require more extensive treatment and experience more severe complications. Finally, mothers of children with fetal hydrops should have genetic counseling in order to plan for future pregnancies.

β Thalassemia

General Information

In β-thalassemia, the genetic abnormality is most commonly a result of a point mutation. Normal cells, in contrast to the α-globin genes, have only two β-globin genes. Similar to α-thalassemia, though, the phenotypic heterogeneity is a result of the number of normal genes present. If the gene is altered in such a way that no β-globin is produced, then it is termed β^0. If instead the gene is altered in a way that results in a deficit of β-globin, then it is termed β^+. An individual may be heterozygote or homozygote for the altered β gene. Patients that are heterozygotes and produce enough β-globin chain to not develop clinically significant disease typically have β-thalassemia minor. Homozygotes may have β-thalassemia major (also known as Cooley Anemia) or thalassemia intermedia, depending on if they are β^0 or if they are β^+ with a more significant deficiency (*Fig. 326.6*). In addition to the anemia that results from decreased normal adult hemoglobin synthesis, there can be marked hemolysis as the result of precipitation of unpaired α-globin chains.

Clinical Characteristics

Individuals with β-thalassemia minor are asymptomatic, but their complete blood count will be significant for microcytosis with or without a mild anemia. The peripheral blood smear shows hypochromia, target cells, and basophilic stippling (as a result of α-globin chain precipitation). The hemoglobin electrophoresis at birth will be normal, but after 6 months of age, it will show elevated hemoglobin A_2 and hemoglobin F.

Patients with β-thalassemia intermedia fall somewhere between β-thalassemia minor and β-thalassemia major and have varying degrees of anemia. The anemia is typically significant but does not require transfusions as frequently as β-thalassemia major. However, a patient with anemia and a marked microcytosis with splenomegaly and skeletal changes consistent with bone marrow expansion should raise suspicion for β-thalassemia intermedia.

Individuals with β-thalassemia major are normal at birth because β-globin gene production is not necessary for embryonic or fetal hemoglobin. However, it is unlikely for these patients to be missed because the newborn screen will be abnormal as no hemoglobin A will be present. At 3–6 months of life, the infant will become symptomatic as γ-globin production switches to β-globin production.

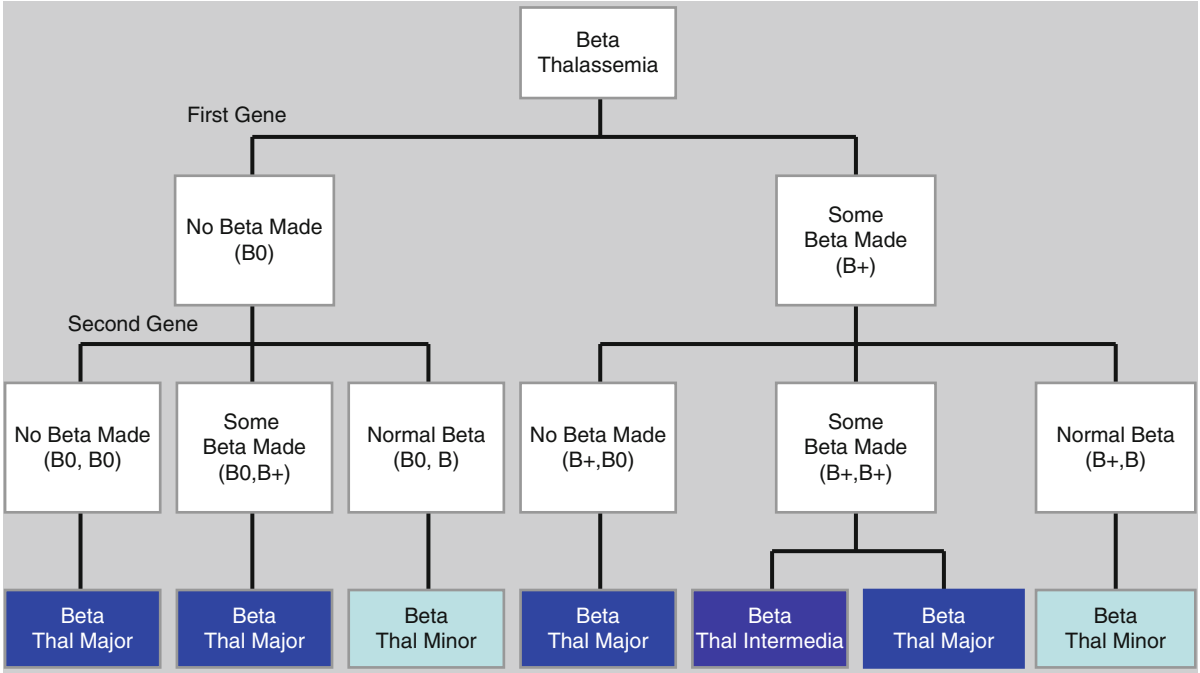

Figure 326.6

Genetics of Beta Thalassemia. The genetic abnormality seen in Beta Thalassemia is a result of a point mutation, which means that the gene is present but altered. The alteration determines, when the gene is expressed, how much Beta globin is made. There can be a variety of Beta globin production when some Beta is expressed as in Beta +. The phenotype of Beta thalassemia can vary for a given genotype

Because little to no β-globin chains will be produced, excess α-globin accumulates. These excess α-globin chains precipitate in red cells at all stages of their development and result in ineffective erythropoiesis and hemolysis. Thus, severe anemia is present because of deceased hemoglobin production as well as destruction of red cells. Similarly, symptoms are present both because of inadequate hemoglobin synthesis as well as hemolysis. The peripheral blood smear of these patients shows severe hypochromic, microcytic anemia with anisocytosis (variety of cell size) and poikilocytosis (abnormal cell shape). A plethora of target cells is a hallmark of the β-thalassemia peripheral blood smear.

The clinical features of β-thalassemia major are many and affect nearly every organ system. As a result of red blood cell destruction, there is extensive extramedullary hematopoiesis within the liver, spleen, kidneys, and entire skeletal system. Hepatomegaly develops and changes in the liver are similar to those seen in viral hepatitis and can result in variable liver dysfunction. Splenomegaly further accentuates the anemia by resulting in increased red cell destruction as well as red cell pooling. Some patients require splenectomy, which places them at increased risk for serious bacterial infection with encapsulated organisms. The expansion of bones for additional hematopoiesis leads to the characteristic thalassemia facies with bossed skull, prominent frontal and parietal bones, and enlarged maxilla. A skull x-ray in β-thalassemia major shows a "hair-on-end" appearance because of extramedullary hematopoiesis. Other bones may be at increased risk of fracture due to thinning of the cortex.

Chronic hemolysis results in elevated indirect bilirubin with subsequent gallstone formation, elevated LDH, increased susceptibility to aplastic crisis (as in Parvovirus B19 infection), and hypersplenism. In addition, patients with β-thalassemia major can experience high-output cardiac failure if frequent transfusions are not administered.

Patients with β-thalassemia major are typically managed with chronic transfusions. The iron overload that results from chronic transfusions is compounded by the fact that patients with β-thalassemia major have increased dietary iron absorption. Iron overload in these patients affects many different organ systems and is further discussed in the "Complications".

Differential Diagnosis

The differential for microcytic, hypochromic anemias includes iron deficiency anemia, α-thalassemia, β-thalassemias, lead poisoning, and other hemoglobinopathies. One way to begin to differentiate iron deficiency and thalassemia is to calculate the Mentzer Index (mean corpuscular volume divided by red blood cell number). Individuals with β-thalassemia minor have a Mentzer Index <13, while iron deficient patients typically have a Mentzer Index >13. An elevated hemoglobin A_2 is diagnostic for β-thalassemia minor, but a normal hemoglobin A_2 level can be misleading since it can be decreased in iron deficiency. In order to differentiate the most common cause of transfusion dependent anemia worldwide, β-thalassemia major, from hemoglobin E/β-thalassemia, one should obtain a hemoglobin electrophoresis.

Treatment

Children with β-thalassemia minor should not receive long-term iron therapy and do not require folic acid supplementation. The two main treatments for β-thalassemia major are chronic transfusions with iron chelation therapy and bone marrow transplantation. Due to the severity of their anemia, children with β-thalassemia intermedia and major need referral to a pediatric hematologist in early childhood to manage issues such as chronic transfusions, prevention of iron overload with chelation therapy, and management of hypersplenism. Children with β-thalassemia major and hemoglobin <6 g/dL should receive chronic transfusions with usual target hemoglobin of 10 g/dL to maintain growth and decrease frequency of infections. Chelation therapy options to avoid iron overload include IV deferoxamine or oral deferasirox (Exjade), which prevents or, at least, limits cardiac, liver, and endocrine complications such as congestive heart failure, hepatic failure, diabetes mellitus, osteoporosis, and delayed puberty. The addition of Vitamin C increases the excretion of iron produced by deferoxamine.

Complications

Like α-thalassemia minor, the most common complication of β-thalassemia minor is the unnecessary prescription of oral iron because a child has microcytic anemia thought to be due to iron deficiency. The most significant complication in β-thalassemia major is iron overload as a result of chronic transfusion and increased iron absorption. Iron overload affects nearly every body system. In the liver, iron accumulates in the Kupffer cells and eventually will result in hepatic fibrosis and potentially end-stage liver disease. Endocrine dysfunctions from chronic iron overload include hyopogonadism, growth failure, diabetes, and hypothyroidism. Iron often infiltrates the cardiac muscle in overload states and can result in a restrictive cardiomyopathy and arrhythmias. Iron deposition can also occur in the skin and result in a gray skin color. However, without blood transfusions, these children will suffer from inadequate growth, increased susceptibility to infections, and high-output cardiac failure. Many patients will develop splenomegaly and hypersplenism, which may necessitate splenectomy. In patients undergoing splenectomy, pneumococcal and *Haemophilus* influenza type B vaccine should be administered prior to surgery. After splenectomy, these children should remain on prophylactic penicillin and seek immediate medical attention for febrile illnesses.

Prognosis

Life expectancy for β-thalassemia depends on the severity of the anemia and requirement for chronic blood transfusions. Specifically, without bone marrow transplantation, children with β-thalassemia major will likely die in their third decade of life as a result of complications from chronic blood transfusions and iron overload symptoms.

Other Thalassemias

In addition to α- and β-thalassemia, there are many other abnormalities of globin chains, which can result in the thalassemia phenotype either alone or in combination with α- or β-thalassemia. Furthermore, a patient can be affected simultaneously by both a qualitative abnormality of hemoglobin synthesis as well as a quantitative defect. Although gene deletions are the most common cause of α-thalassemia, some cases of α-thalassemia are a result of point mutations. Hemoglobin Constant Spring is a result of a mutation that alters termination of translation causing an elongated, unstable α-globin chain. If a patient with two alpha gene deletions also has Hemoglobin Constant Spring, they will have a clinical syndrome similar to Hemoglobin H disease but may require more frequent transfusions. Hemoglobin E is a result of an amino acid substitution on the β-chain, and this mutation results in activation of an mRNA splice site and subsequent

reduced β-chain synthesis. Hemoglobin E/β-thalassemia is common in Southeast Asia and typically results in a β-thalassemia major phenotype, and the patient requires chronic transfusions. In addition, β-thalassemia can combine with Sickle Cell Anemia in a variety of clinical scenarios that largely depend on the extent of β-gene production.

Future Directions

Current treatment for thalassemia involves chronic transfusions and therapy to prevent or treat the complications of iron overload. However, transfusions treat the symptoms of the disease, not the disease itself. If there were more fetal hemoglobin present, then the need for adult hemoglobin would be reduced. In Sickle Cell Disease, Hydroxyurea has become a commonly used agent to increase the proportion of fetal hemoglobin made. Hydroxyurea has been shown in clinical trials to increase hemoglobin and MCV and reduce the need for transfusions in patients with thalassemia intermedia and thalassemia major. However, further work needs to be done prior to Hydroxyurea becoming a mainstay of thalassemia treatment. Bone Marrow Transplant is currently the only known cure for thalassemia, however; bone marrow transplant requires that the patient be healthy enough to undergo the myeloablative pre-transplant conditioning and that there is an available donor source. Extensive work-up must be done prior to transplant in order to assess pre-transplant morbidity, and the family must be well counseled on the possible complications of transplant, including but not limited to graft rejection, graft failure, graft versus host disease, and death. Despite these complications, there have been many successful matched related donor transplants for thalassemia patients. Finally, gene therapy has been proposed as a cure for thalassemia major. The idea of replacing the abnormal β-globin gene with a normal β-globin gene transported via an autologous Hematopoietic stem cell transplant seems plausible, but this therapeutic strategy has met a variety of challenges and has not yet become a part of thalassemia treatment.

In summary, the microcytic, hypochromic anemia that results from the quantitative defects of hemoglobin production seen in thalassemia have a wide range of clinical significance. Disease severity is a function of the number of absent or abnormal genes as well as the aggregation of excess globin chains. Many patients will be brought to the pediatrician's attention as a result of an abnormal newborn screen, but the diagnosis should be included in the differential for any patient who presents with a microcytic anemia. In taking care of patients with more significant disease states, it is important to recognize the signs and symptoms of hemolysis and chronic iron overload.

327 Polycythemia

Hassan M. Yaish

Polycythemia is a condition characterized by an increase in both the total red blood cells mass and blood volume, resulting in hemoglobin and hematocrit levels significantly higher than normal for the patient's age. It is divided into three types: (1) Primary polycythemia, or polycythemia vera (PV), a condition classified as myeloproliferative disease (MPD) and is rarely encountered in children. (2) Secondary polycythemia, resulting from: physiologically appropriate increase in production of erythropoietin in response to hypoxia of various causes or inappropriate secretion of erythropoietin by a tumor, hemoglobinopathy associated with hemoglobin of low oxygen affinity, and decreased level 2–3 DPG in the red blood cells. (3) Relative polycythemia. In the first two types, the red blood cell mass is increased, while in the third type, the plasma volume is decreased, causing relative rather than real increase in red blood cell counts while red blood cell mass is normal.

Primary Polycythemia

Definition: Primary polycythemia, or polycythemia vera (PV), is a myeloproliferative disease resulting from the clonal expansion of an abnormal multipotent stem cell that produces erythroid progenitors which can proliferate without the presence of erythropoietin (EPO), a feature which is frequently utilized as a diagnostic mean for PV. This multipotent stem cell is unlike the normal fetal progenitor stem cells and those cells with a mutation in the EPO receptor in that they still require erythropoietin for clonal expansion.

Incidence and epidemiology: The prevalence of PV has not been well documented in the USA. In 2003, a study from Connecticut demonstrated an incidence of PV of 22 per 100,000 people. Generalized to the population of the USA, this would reflect approximately 65,243 patients with PV in the USA. The median age at presentation of PV is 60 years. Less than 1% of the patients are less than 25 years of age.

Pathology and laboratory findings: The condition is characterized by polycythemia, leukocytosis, thrombocytosis, and a hypercellular bone marrow.

Signs and Symptoms: Patients with erythrocytosis may develop cardiac and CNS related symptoms such as dyspnea, hypertension, paresthesias, and dizziness. Thrombocytosis may result in thrombosis and bleeding. Pruritus and GI symptoms are frequently seen in adults with PV. They are thought to be the result of increased histamine turnover due to granulocytes proliferation. Patients frequently have splenomegaly.

Prognosis: It is common to see long survivors of PV, even though spontaneous remissions are very rare. Disease-related morbidities are mainly the result of vascular occlusion, bleeding, marrow fibrosis, and leukemia transformation.

Diagnosis: In the past, the diagnosis of PV used to be a diagnosis of exclusion. Both secondary as well as relative polycythemias have to be excluded. At the present time, however, a newly described somatically acquired clonal V617F mutation in the Janus 2 kinase (Jak2) as found to be positive in 90% of adults with PV. The incidence of Jak-2 mutation is significantly less in children. A proportion of children with PV were misdiagnosed as a result of relying on the presence of the Jak-2 mutation. This emphasizes the need for separate diagnostic criteria in children (*Table 327.1*). CD 117, polycythemia rubra vera-1 RNA (PRV-1 RNA) over-expression is another myeloproliferative marker found more frequently in children with PV and sporadic ET. In contrast to the acquired nature of the mutation leading to PV, inborn mutations have been described resulting in what is known as primary familial and congenital polycythemia (PFCP). This condition was shown to be a result of erythropoietin receptor mutation as was described in a report on two new such mutations. The condition, also known as familial erythrocytosis, is characterized by elevated red blood cell mass, low serum erythropoietin, normal oxygen affinity, and autosomal dominant inheritance. Other mutations involving exon 12 of the Jak2 were described in patients with PV and negative Jak2 V617F mutation. A variant of the primary familial and congenital polycythemia (PFCP) is known as Chuvash polycythemia. It was first described in an endemic Russian population and was found to be caused by a mutation in the Von Hippel- Landau (VHL) gene. This gene is associated with mutation in oxygen-sensing

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_327,

Table 327.1
Suggested criteria for childhood polycythemia vera (the presence of both major and one minor are required for the diagnosis)

Major criteria: elevated red cell mass
No cause of secondary erythrocytosis, including:
(a) Absence of familial erythrocytosis (e.g., hereditary mutations of erythropoietin (EPO) receptor)
(b) No elevation of EPO caused by
• Hypoxia (arterial po2 < 92%)
• High oxygen affinity hemoglobin
• Truncated EPO receptor
• Inappropriate EPO production by tumor
Minor criteria
(a) Presence of JAK2 V617F mutation
(b) Endogenous erythroid colony formation
(c) Hypercellular bone marrow with trilineage proliferation
(d) Low serum EPO levels

pathway that regulates EPO synthesis. Children with similar conditions outside Russia is referred to as, primary proliferative polycythemia.

Treatment: The goal of PV treatment is to reduce the numbers of the proliferating cells so as to prevent the symptoms associated with high RBCs, platelets, and WBCs. Phlebotomy or isovolemic erythropheresis, are the most commonly used procedures to achieve this goal. Iron replacement is essential to prevent hyperviscosity associated with iron deficiency. Low dose aspirin can also be beneficial. Among agents known to control cell counts, hydroxyurea is thought to be safer and have less side effects than other agents, especially in children. Anagrelide, an agent that targets megakaryocytes differentiation and proliferation, has proven effective in eliminating the thrombocythemia-related symptoms in 80% of patients with PV. Erlotinib, a specific inhibitor of *Jak2* mutation, is currently undergoing clinical trials in PV and other myeloproliferative disorders. Stem cell transplantation has been successfully utilized in some patients.

Secondary Polycythemia

Definition: Secondary polycythemia is defined as a reactive polycythemia as a result of any clinical condition associated with chronic decreased tissue oxygenation, which in turn triggers the physiologic reaction of excess erythropoietin production. Cyanotic congenital heart disease with right-to-left shunts and various chronic pulmonary diseases compromising proper oxygenation are the most common causes of secondary polycythemia. Living at high altitudes, congenital methemoglobinemia, and abnormal hemoglobin with increased oxygen affinity are some of the other common causes of secondary polycythemia. Certain vascular or renal tumors are associated with polycythemia due to erythropoietin secretion by the tumor itself.

Signs and Symptoms: Cyanosis, hyperemia of the sclera and mucous membranes, and clubbing of the fingers are the most frequently encountered clinical manifestations. The oxygen saturation of arterial blood is decreased, and, as the hematocrit rises above 65%, symptoms of hyperviscosity may develop, requiring frequent phlebotomy. To maintain such a high hemoglobin level, and as a result of frequent phlebotomies, iron deficiency develops. In the presence of high viscosity and the rigid iron-deficient red blood cells, the risk of intracranial thrombosis has been reported to be increased. As indicated earlier, iron therapy is recommended despite the high hemoglobin level.

Prognosis: the prognosis of secondary polycythemia is that of the original disease process which have resulted in this condition.

Relative Polycythemia

In contrast to the first two types, relative polycythemia is not associated with true increase in red cell mass, but instead a decrease in plasma volume. Dehydration and burns are classic causes of this type of polycythemia. It is a preventable condition and could be corrected by hydration or treatment of the precipitating cause.

328 Transfusion of Blood and Blood Products

Trisha E. Wong · Meghan Delaney

Our knowledge of blood compatibility and safety has come a long way since the first documented blood transfusion from a sheep to a human in 1667. In developed countries, transfusions are primarily used to support patients undergoing invasive procedures and complex medical treatments for diseases such as cancer and complex surgical procedures. In developing countries, blood is given mostly to children with anemia and women with pregnancy-related complications. Transfusion of blood products can significantly reduce morbidity and mortality, but still carries risks. Children undergoing complicated therapies often depend on transfusions for survival. As the demand for blood component transfusions increase, so must the inventory of safe blood components and the knowledge of transfusion medicine.

Blood Groups

Blood groups are determined by inherited antigenic molecules on the surface of blood cells. These antigens can be proteins, carbohydrates, glycoproteins, or glycolipids depending on the blood group system. A total of 308 blood group antigens are currently recognized, 270 of which are clustered into 30 blood group systems, *Table 328.1*. Once exposed to foreign red blood cells, the immune system can form alloantibodies against blood group antigens that are not present on the recipient's own red blood cells (RBCs). In general, red cell alloantibodies can only be formed following exposure to another person's red blood cells through blood transfusion or pregnancy. Subsequent transfusion of incompatible blood can cause these pre-formed antibodies to trigger hemolysis of transfused cells. Unlike alloantibodies, ABO antibodies are "naturally occurring" and are formed as a result of exposure to A and B-like substances from bacteria, plants, and other exogenous material in the gastrointestinal tract. The most clinically relevant groups will be discussed here.

ABO is the most important blood group for transfusion because nearly all people have naturally occurring ABO antibodies capable of causing hemolysis of incompatible red cells. Each person's RBCs demonstrate A antigens (type A), B antigens (type B), both (type AB), or neither (type O), *Table 328.2*. A person will only make antibodies to ABO antigens that they are lacking; for example, a group A person makes anti-B antibody, *Table 328.2*. ABO antibodies are both IgG and IgM class and can fix complement, which leads to brisk hemolysis. Transfusion of ABO-incompatible RBCs is likely to cause severe morbidity or death. Thus, it is imperative that safety procedures are followed to ensure patient safety. ABO incompatibility is the most common cause of maternal-fetal incompatibility, but it is rarely a cause of severe hemolytic disease of the fetus and newborn (HDFN). ABO antigens are not fully developed in infants <4 months of age and infants do not form natural ABO antibodies until approximately 6 months of age.

The Rh system contains at least 50 antigens of which the major antigens are D, C, E, c, and e coded on two distinct genes. The D antigen (RhD) has greater immunogenicity than any other non-ABO RBC antigen. Antibodies to Rh antigens are mostly IgG and do not bind complement. Therefore, they tend to lead to extravascular hemolysis and can cause mild to severe delayed transfusion reactions. Anti-D antibodies made by multiparous, RhD-negative mothers are able to cross the placenta and are capable of causing HDFN in RhD-positive fetuses.

Hundreds of other blood cell antigen groups have been described. Antibodies to the clinically significant blood groups such as ABO, Rh, Kell, Duffy, Kidd, and Ss are capable of causing HDFN. Antibodies to other blood groups can also cause HDFN if the antibody is IgG and can cross the placenta. In neonates, certain classes of antigens are not fully expressed, including the Lewis system, I, P, Lutheran, and Xg systems. Expression of all blood groups can usually be detected around 1 year of age.

Blood Donation

Blood transfusions would be impossible without a consistent, reliable pool of blood products. Until blood

O	None	Anti-A, Anti-B	O	O, A, B, AB

can be manufactured using synthetic materials, living human donors are the only source. From the time the donor presents for blood collection until the blood is transfused into the recipient, dozens of carefully regulated steps are completed to ensure the safety and efficacy of the blood product.

Donor Screening

Screening donors to identify those at high risk for transfusion-transmitted disease is the first and most cost-effective step in maintaining a safe blood supply. There is a higher frequency of transfusion-transmitted infections when donors are compensated for their donation with monetary or material incentives. As a result, the World Health Organization advocates making all blood donation voluntary. Unfortunately, there are not enough voluntary donors to meet the needs of the blood supply in many developing countries, which still rely on family members and replacement or paid donors. An ideal donor is a healthy adult free of viral disease who does not participate in high-risk behaviors (intravenous drug use, multiple sex partners, etc.) and is willing to donate blood for free. In the United States, donated blood undergoes testing for transfusion-transmitted infectious diseases, including cytomegalovirus (CMV), human immunodeficiency virus (HIV), hepatitis B, hepatitis C, human T-cell lymphotropic virus 1 and 2 (HTLV-1,2), West Nile Virus, *Trypanosoma cruzi*, syphilis, and bacteria (*Table 328.5*).

Autologous Donation

Prior to an elective procedure, a patient may donate blood for their own use during or after surgery. Autologous donations increase the risk of pre-operative anemia and can carry risk if the unit is contaminated ex vivo or if it is transfused to the wrong patient. In addition, autologous donation for a pediatric patient is difficult for ethical and logistical reasons. The child may be unable to consent or assent to phlebotomy and/or the child's size may limit the amount of blood that can be collected. Intraoperative blood salvage, in which blood is removed from the surgical field, washed, and returned to the patient, is another method of transfusing a patient with their own blood.

Directed Donation

Directed blood donation is uncommon in developed countries, but is a common source of blood in developing countries. The strength of directed donation is the ease of identifying a donor. In many places, directed donation is logistically complex. Generally, directed donation is discouraged in places that have access to a safe, volunteer blood supply, as research has shown that directed donation increases blood wastage and carries a higher rate of donor deferral for increased infectious disease risks. Moreover, all red cell and platelet donations from blood relatives must be irradiated to prevent transfusion-associated graft versus host disease (TA-GVHD), a rare but fatal complication of transfusion (see further discussion about TA-GHVD below). If maternal blood is given to her newborn, it should also be washed to prevent antibodies in her serum from reacting to the infant's RBCs. If paternal blood is given to an infant, it may express cognate antigens to clinically significant antibodies which the infant received passively from the mother prior to birth, which could lead to a severe hemolytic reaction.

Collection

In most developed countries, the collection of blood is highly regulated by the government. In other countries, collection processes follow the recommendations of health organizations such as the AABB (formerly known as American Association of Blood Banks), World Health Organization, or American Red Cross or a local government or hospital.

There is a worldwide initiative to use only volunteer blood donors. In the absence of sufficient volunteers, alternate donors are often used. In places where it is expensive to collect a unit of blood and the prevalence of viral disease is high, pre-donation viral testing is done. Once a donor is cleared for donation, whole blood is collected into a sterile storage container containing anticoagulant, buffer, and preservative. To minimize the risk of contamination, the system of needles, tubes, and containers must remain closed, ensuring no contact with the environment. Generally, the maximum amount of blood that can be collected from each donor is 10.5 ml/kg, or around 500 ml. The most common adverse reaction to donating blood is a bruise or hematoma at the site of the venipuncture. A vasovagal event, ranging from lightheadedness to complete loss of consciousness, is seen in 2–3% of donations. Donors experiencing this complication should be kept either supine or in trendelenburg position and provided with electrolyte-containing fluids until they have recovered.

Storage

Preparation and storage of blood components will vary based on the regulations that apply in different countries. In general, whole blood is separated into components to make efficient use of the donor pool and to allow clinicians the flexibility to transfuse only the component(s) needed by the patient. Each unit must be tested for ABO and RhD type and infectious agents prior to release. Once testing is completed and the unit is deemed eligible, it is stored at the proper temperature until it is needed for transfusion or until it expires, ❯ *Table 328.3*. The expiration date of packed red blood cells (PRBCs) varies with the storage solution of the component. The use of additive

Table 328.3
Storage temperature and expiration date for blood components

Product	Storage temperature	Expiration (additive solution)
Whole blood	1–6°C	21 days (CPD)
		35 days (CPD-A)
Packed RBCs	1–6°C	21 days (CPD)
		35 days (CPD-A)
		42 days (AS-1,3,5)
FFP and cryoprecipitate	≤−18°C	24 h after thawing
Platelets	20–24°C	4–7 days
Granulocytes	20–24°C	24 h
RBCs frozen in 40% glycerol	≤−65°C	24 h after deglycerolizing
RBCs frozen in 20% glycerol	≤ −120°C	

solutions lengthens the time for red cell unit storage and has allowed blood banks to maintain larger inventories and minimize the risk of blood shortages. Detailed records of the entire process are maintained for every blood component in order to ensure that each was processed under appropriately controlled conditions. These records are also required so that look-back studies can be done if a unit needs to be recalled or tracked for any reason.

Compatibility

In the United States, tests done routinely to determine donor and recipient compatibility are forward and reverse typing to determine the patient's ABO and RhD type, antibody screen, and crossmatching. To determine the forward ABO-typing (also known as "front type"), reagent antisera is used to test for the presence of A or B antigens on the RBC surface. Reverse ABO-typing ("back type") is done using reagent red cells to test for the presence of ABO antibodies in the serum. The front and back type should always agree. If not, the underlying reason for the discrepancy must be determined prior to transfusion. Red cell antigens other than ABO and RhD are not determined on a routine basis. Exceptions may include chronically transfused patients, such as those with sickle cell disease or women of childbearing age. In the United States, the standard of care for sickle cell disease patients is to provide ABO, RhD, RhCE and Kell blood group antigen matched red cells to prevent alloimmunization.

The antibody screen tests for the presence of red cell alloantibodies in the plasma. The test methodology is an indirect antiglobulin test (IAT), *Fig. 328.1*. The recipient's plasma is incubated separately with at least two reagent RBCs that express a known phenotype of common red cell antigens. Antihuman globulin (AHG or "Coombs reagent") is added to help magnify the agglutination reaction to detect any RBC alloantibody that is present in the recipient's serum. If a clinically significant red cell alloantibody is detected, it is identified by further IAT testing of the serum using more extensive reagent red cell panels. Once identified, antigen negative, crossmatch-compatible RBCs must be transfused.

The direct antiglobulin test (DAT), also called the direct Coombs test, is typically done if autoimmune hemolysis is suspected. The DAT determines if a recipient's RBCs are coated with antibody, *Fig. 328.1*. This evaluation is done by mixing the recipient's red blood cells with Coombs reagent and scoring the reaction for agglutination. If the DAT is positive, follow-up testing requires identification of the antibody using IAT as

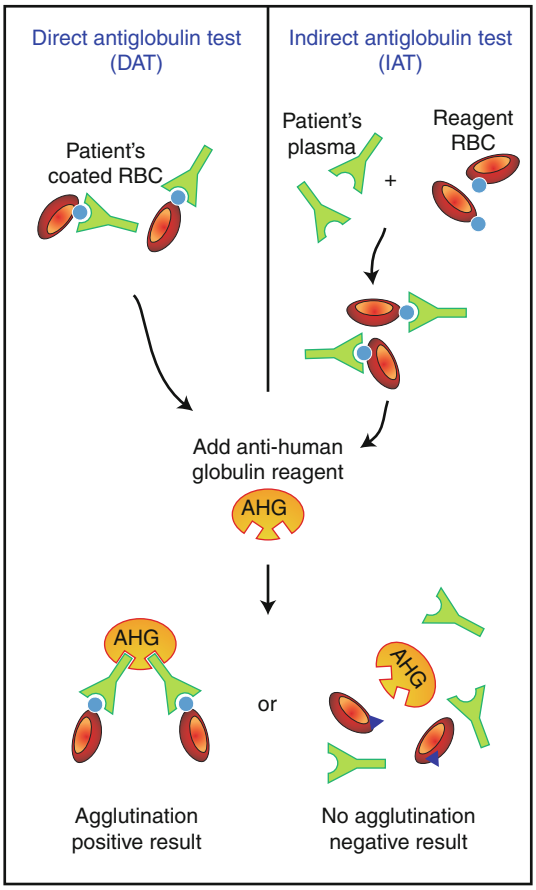

Figure 328.1
Comparison of the direct and indirect antiglobulin tests. The indirect antiglobulin test is also known as an antibody screen. If the antigen and corresponding antibody are present in the reaction, AHG reagent will agglutinate the red cells resulting in visible clumping. If the corresponding antibody or antigen is not present, the antibody cannot bind and agglutination will not occur

described above. In neonates, the DAT is routinely performed using only anti-IgG reagent since any antibody found in the neonate is an IgG antibody that was passively transferred from the mother.

Once a unit of blood is identified for possible transfusion, the patient's plasma is mixed with the donor red cells to ensure that they are compatible; this is called a crossmatch. In emergency situations, the physician may choose to use uncrossmatched group O, RhD-negative blood. Since no compatibility testing is conducted, this should only be done when there is insufficient time to conduct crossmatching. In order of descending preference, the RBC products that should be used during an

emergency are crossmatch compatible RBCs, ABO/RhD-type specific RBCs, and uncrossmatched group O RBCs. Physicians must weigh the risk of a hemolytic transfusion reaction against the need for blood transfusion in a hemorrhaging patient. In these situations, crossmatching can be conducted post-transfusion. Neonates <4 months old typically do not require a crossmatch as long as group O RBCs are given and the antibody screen is negative. If anything other than group O cells are intended, a crossmatch is done to determine if the neonate passively received anti-A or anti-B from the mother.

Causes of incompatibility between donor and patient include red cell alloantibodies, passive maternal immunoglobulin in neonates, recipients of plasma or IVIG, hematopoietic stem cell transplant, laboratory or phlebotomist error, or cold or warm autoantibodies. In most countries, patients require a repeat crossmatch sample every 3 days to detect the development of new red cell alloantibodies. Neonates are unlikely to form alloantibodies, thus only require compatibility testing once per hospitalization when under the age of 4 months. This approach lessens the amount of blood phlebotomized from neonatal patients.

Blood Products

Whole Blood

Whole blood (WB) is rarely used in developed countries because individual component therapy is better tailored to the needs of the patient and more efficiently uses the blood supply. Fresh WB contains RBCs, plasma, clotting factors, platelets, and leukocytes. However, following 24 h of storage at 4°C, the platelets are non-functional. Granulocyte function is also not reliable in WB transfusions. Activity of coagulation proteins will decrease over the duration of the 21 days storage. When large-volume transfusion is necessary, such as in trauma or in exchange transfusion, WB may be used to minimize dilutional coagulopathy. Because WB contains a relatively large amount of plasma containing ABO antibodies, it must be ABO-identical to the recipient to prevent hemolytic reactions.

Packed Red Blood Cells

Packed red blood cell (PRBC) transfusion is indicated to increase the oxygen carrying capacity to vital organs. A unit of PRBCs is made by centrifuging a unit of WB and removing most of the plasma and platelets. PRBCs have a hematocrit of 50–80%, and therefore must be infused slowly due to the high viscosity. In pediatric patients, 10–15 ml/kg is transfused over 2–4 h for routine transfusion. If the patient is not losing blood concurrently, 10 ml/kg should raise the hemoglobin by 1–2 g/dl or the hematocrit by 3–6%. As with every transfusion, the benefit of increased red cell mass must be vigilantly weighed against the risks of exposure.

Platelets

Platelet transfusion is indicated in some patients with thrombocytopenia or platelet function defects, *Table 328.4*. Platelet units can be collected from a single donor during an apheresis procedure or extracted from multiple units of whole blood. The shelf life of platelets is usually limited to 5–7 days because platelets must be kept at room temperature in order to remain viable and efficacious. The risk of bacterial growth is approximately 1 in 5,400 units in the United States and is significantly increased with storage beyond 5 days. This risk has been decreased in some countries by the use of pathogen inactivation protocols.

Typically 10–15 ml/kg of platelets is transfused over 30–60 min. This should increase the platelet count by

Table 328.4
Indications for platelet transfusion in children

Platelet count < 10,000 and decreased platelet production, without other risk factors for bleeding
Platelet count < 20,000 and planned minor procedure, such as lumbar puncture
Platelet count < 50,000 with DIC, active bleeding, or planned major procedure in patient with decreased platelet production
Platelet count < 100,000 with multiple traumas, CNS bleeding, or undergoing surgery in critical sites, such as CNS or eyes

Table 328.5
Estimated prevalence of transfusion-transmitted viruses by country

	Sub-Saharan Africa	United States	Japan
HIV	1:1,000	1 : 2,135,000	1 : 11,000,000
HBV	1:4,300	1 : 205,000	1 : 340,000 – 1 : 450,000
HCV	1:2,500	1 : 1,935,000	1 : 22,000,000

approximately 50,000/μl. However, patients with sepsis, splenomegaly, bleeding, drug-induced thrombocytopenia, disseminated intravascular coagulopathy (DIC), or other illnesses may have lower than expected post-transfusion platelet recovery. Platelets express ABO, but not RhD antigens. Transfusion of ABO-compatible platelets are preferred as they result in improved posttransfusion platelet recovery and reduced rates of alloimmunization. In addition, platelets should be compatible with the patient's RhD type since platelet units contain small amounts of red blood cells. If Rh-positive platelets must be given to a Rh-negative patient, a dose of Rh Immune Globulin (RhIG) may be given to prevent RhD alloimmunization as per the institution's policy. Rather than provide RhIG to all RhD-negative patients who received RhD-positive platelets, some centers choose to give it only to females of child-bearing potential. One 300 ug dose of RhIG neutralizes 15 ml of RBCs, which contains sufficient anti-D to cover several adult-sized transfusions of contemporary platelets derived from whole blood, plateletphersis, or buffy coats.

Platelets express many membrane antigens, including HLA class I antigens. As a result, patients who have been pregnant or exposed to multiple blood donors are at risk of HLA-alloimmunization. Once a patient is HLA alloimmunized, the antibodies may cause the transfused platelets to be destroyed rapidly and the post-transfusion platelet count will not rise as expected. This is called platelet transfusion refractoriness. Three options exist for platelet refractory patients: (a) select HLA-compatible donors from an HLA-typed registry of apheresis donors; (b) identify HLA-antibody specificities and select antigen-compatible apheresis donors; and (c) perform platelet cross-match testing to select compatible platelets.

Plasma Products

Fresh Frozen Plasma

Plasma is the liquid, acellular portion of WB which contains proteins, colloids, nutrients, crystalloids, hormones and vitamins. Plasma can be prepared and stored in several ways resulting in numerous types of plasma products, but fresh frozen plasma (FFP) is most commonly used. FFP is frozen within 8 h of collection to maintain the optimal activity of the coagulation factors. Once thawed, FFP should be given within 24 h. However, plasma used within 5 days of thawing is still considered efficacious for treatment of coagulation factor deficiencies, though there is slightly decreased activity of clotting factors (F) V and VIII. As plasma is rich in clotting factors, the main indication of plasma transfusion is to increase clotting factor levels in a coagulopathic patient. The typical dose of 10–20 ml/kg is expected to increase the coagulation factor concentrations by 30% in a non-bleeding patient. Plasma must be ABO-compatible but does not require Rh-compatibility, crossmatching, or product modifications such as irradiation or leukoreduction because it is acellular.

Cryoprecipitate

When plasma is frozen and subsequently thawed in a refrigerator, an insoluble precipitate forms that is very rich in FVIII, von Willebrand factor (VWF), FXIII, and fibrinogen. Historically, cryoprecipitate was used to treat patients deficient in VWF (von Willebrand disease) or FVIII (hemophilia A). Today, it is primarily used to replete fibrinogen, especially in patients with DIC or dilutional coagulopathy. One pool of cryoprecipitate (six to ten donors) will typically increase the fibrinogen level by 60–100 mg/dl in an adult. The equivalent pediatric dose is one unit of cryoprecipitate for every 10 kg of patient weight.

Albumin

Albumin is the most abundant protein in plasma. Commercially-available human albumin is purified using cold ethanol fractionation, pooled, and sold in either a 5% or 25% solution. The main indication is to increase oncotic pressure in patients with low albumin levels, such as those with liver disease or nephrotic syndrome.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) is a commercial product prepared by purifying and pooling immunoglobulins from human plasma. Indications for IVIG include idiopathic thrombocytopenia purpura, severe combined immunodeficiency, acquired immunodeficiencies, and Kawasaki syndrome. Its mechanism of action in these disease processes is poorly understood. Mild flushing, headache, rash, and allergic reactions are common following infusion of IVIG. More serious side effects, including renal failure, aseptic meningitis, and pulmonary edema, can occur. Because IVIG contains small amounts of all immunoglobulin classes, anaphylaxis has been described in patients with absence of IgA.

Clotting Factors

For patients with a congenital deficiency of a clotting factor, plasma was once the only source of clotting factors. Cryoprecipitate offered a more efficient clotting factor source for those deficient in FVIII and VWF. As technology advanced, various purification techniques allowed for individual clotting factor concentrates to be isolated with minimal contamination by other clotting factors. Recombinant or plasma-derived clotting factor concentrates are the preferred treatment for hemophilia and VWD patients worldwide. With new viral deactivation techniques, plasma-derived products are considered extremely safe but still possess a theoretical risk of transmitting an emerging infectious agent.

Granulocytes

The main indication for infusing granulocytes is a refractory bacterial, yeast, or fungal infection in a severely neutropenic patient. In most cases of granulocyte transfusions, volunteer donors are mobilized with corticosteroids and/or granulocyte colony stimulating factor (G-CSF) to increase their peripheral white blood cell count prior to undergoing donor apheresis. The goal is to maintain the recipient's granulocyte count above 500 granulocytes/ul. Adverse effects are common and include fever, shaking chills, dyspnea, wheezing, and pulmonary infiltrates. Prophylactic granulocyte transfusions are not recommended in patients who are neutropenic without overt signs of serious infection. Granulocytes must be stored at room temperature and given within 24 h of collection in order to preserve granulocyte function. Because granulocytes contain significant amounts of red blood cells, they must be crossmatch-compatible and irradiated in order to decrease the risk of transfusion-associated graft versus host disease (TA-GVHD).

Product Preparation

Upon completion of compatibility testing for cellular components, the most appropriate blood product must be identified for each patient. Factors to consider when selecting a unit for transfusion include using autologous or directed donor cells if available, ABO/RhD typing, antibody screen results, diagnosis, age, transfusion history, volume of blood component needed, and time and date the blood is required. As discussed here, the treating physician may also request specific attributes of cellular blood products depending on the patient's age, diagnosis, and transfusion history.

Leukocyte Reduction

Reducing the number of leukocytes in cellular blood components, such as platelets or red cells, is accomplished by filtration. Indications for leukocyte reduction include prevention of recurrent febrile non-hemolytic transfusion reactions, prevention of primary HLA-alloimunization, and to decrease transfusion-transmitted cytomegalovirus (CMV) infections in immunocompromised patients. As per the standards of the AABB, leukoreduced products must contain fewer than 5×10^6 white blood cells for apheresis platelets and PRBC and fewer than 8.3×10^5 for pooled platelets. Some blood banks universally leukoreduce cellular components while others do so at the discretion of the ordering physician.

CMV-Negative Components

Transfusion-associated cytomegalovirus (CMV) infection is usually of no clinical significance in immunocompetent recipients. However, CMV can result in serious morbidity and even mortality in immunocompromised patients, young children, and fetuses. At-risk people may include fetuses, neonates with immature immune systems, patients with a congenital or acquired immunodeficiency, patients on immunosuppressive medications as part of treatment for cancer or a solid organ or hematopoietic stem cell transplant. Leukocytes are the only hematopoietic reservoir for CMV, thus transfusion of leukoreduced blood products is considered an acceptable substitute to blood products from a CMV-seronegative donor. However, transfusing blood from patients who are CMV-negative may be safer for patients most at risk.

Irradiated

Blood products are irradiated to prevent transfusion-associated graft versus host disease (TA-GVHD), an often fatal transfusion reaction. TA-GVHD occurs when lymphocytes in the blood unit escape detection by the recipient's immune system. The donor lymphocytes then proliferate, detect the recipient's antigens as foreign, and

mount an inflammatory reaction that can cause severe morbidity and mortality. In pediatrics, irradiation is indicated for fetuses receiving intrauterine transfusions, patients with lymphoma or a congenital immunodeficiency, or recipients of granulocyte transfusions or a hematopoietic stem cell transplant. Less evidence supports irradiation of blood products given to premature or term infants, or those receiving immunosuppressants for a hematologic malignancy, solid tumor, or solid organ transplant. In addition, irradiation is indicated for blood products from blood-related donors or in populations with restricted HLA diversity, as their histocompatibility may be similar enough as to go undetected by the competent immune system.

Volume Reduced

Plasma in which red cells or platelets are suspended may be removed from the blood product for several reasons. Volume reduction is accomplished by centrifugation and discarding the plasma from the unit. Plasma may be reduced from RBCs to obtain a concentrated product (hematocrit >90%), which can be used for patients who require tight regulation of volume, such as neonates or patients with congenital cardiac defects. Incompatible plasma can be removed when ABO-incompatible platelets must be transfused. Other indications include reducing the risk of recurrent, moderate allergic transfusion reactions or circulatory overload.

Washed

Washing PRBCs or platelets is done by volume reduction and subsequent suspension of the cells in saline or albumin. There are very few indications for washing cellular blood products. Blood components transfused to patients with congenital absence of IgA should be washed prior to transfusion to avoid anaphylactic reactions triggered by donor IgA. Other indications include removal of residual plasma following recurrent, severe allergic or anaphylactic reactions, reducing potassium accumulated in blood units prior to large-volume transfusions (>25 ml/kg), removing plasma in the case of neonatal alloimmune thrombocytopenia, or removing additive solution prior to transfusion. Routine washing is not recommended because it can lead to loss of cells or functional impairment. When washing cannot be accomplished for potassium or additive solution removal, volume reduction may be an alternative choice. Use of PRBC products without additives (PRBC in CPD solution, *Table 328.2*) can also be used to avoid transfusion of large quantities of additives to small pediatric patients.

Satellite Packs

Sick neonates and small children may require repeated, small-volume units of red cell transfusions. To limit the exposure to different donors, transfer systems that remain closed to the environment can be used to divide a single blood donation into four to eight small aliquots. The aliquots from one donor can be designated for one neonate. By minimizing donor exposure, the risks of transfusion-transmitted infections and alloimmunization are minimized. Satellite packs waste less blood and are proven to be cost-effective. Because these units are given in small doses, the risk of hyperkalemia or other adverse effects of storage are minimal.

Complications

Infectious Complications

The three most clinically significant transfusion-transmitted infectious agents are human immunodeficiency virus (HIV), hepatitis B (HBV), and hepatitis C (HCV). Though the risk of HIV, HBV, or HCV viral transmission via transfusion is low in the United States, such is not the case worldwide, *Table 328.5*. Additionally, many other known or potential pathogens are transmissible by blood, *Table 328.6*. Certain opportunistic infections, such as human parvovirus B19, cytomegalovirus (CMV), and other herpesviruses, may cause serious disease in immunocompromised transfusion recipients. Fortunately, advances in virology, donor screening techniques, and viral detection assays have resulted in a worldwide decrease in the incidences of these and other transfusion-transmitted infections in the last decades. However, vigilance must continue in order to ensure that the blood supply remains free of known and emerging infectious agents.

Non-infectious Complications

Non-infectious complications of transfusion are equally as important as infectious complications and far more common. *Table 328.7* briefly describes the majority of clinically-significant transfusion reactions.

Table 328.6
Categories of transfusion-transmitted infectious agents by AABB

Agents for which donors are routinely screened
Hepatitis B virus
Human immunodeficiency virus
Hepatitis C virus
Human T-cell lymphotropic virus
West Nile virus
Bacteria
Trypanosoma cruzi (Chagas disease)
Cytomegalovirus
Agents with scientific evidence of risk and potential for severe clinical outcome, but not currently screened
Human variant Creutzfeldt-Jakob disease
Dengue viruses
Babesia species
Agents with sufficient scientific evidence of risk that might support elevation to a higher priority in future
Chikungunya virus
St. Louis encephalitis virus
Leishmania species
Plasmodium species
Agents with absent or low scientific evidence of risk but public and/or regulatory concern present
Chronic wasting disease prion
Human herpesvirus 8
HIV variants
Human parvovirus B19
Influenza A virus, subtype H5N1
Simian foamy virus
Borrelia burgdorferi (Lyme disease)
Hepatitis A virus
Agents to monitor but do not currently represent risk or concern
Hepatitis E virus
Anaplasma phagocytophilum (Human granuloyctyic anaplasmosis)
Others – AABB monitoring 51 other low risk prion, viral, rickettsial, and protozoan agents
Agents currently with unclear scientific evidence of risk
Xenotropic Murine Leukemia Virus-Related Virus (XMRV)

Human error in drawing, labeling, and administration of blood is the leading cause of ABO-incompatible hemolytic transfusion reactions, underscoring the importance of maintaining strict and clear procedures during all phases of transfusion. When a transfusion reaction is suspected, the transfusion should be stopped and supportive care instated immediately. The unit label and patient identification should be re-checked to detect possible errors in patient identification. The unit of blood should be sent to the blood bank along with a post-transfusion blood sample from the patient. The blood bank will conduct testing to identify potential causative factors, such as clerical errors, hemolysis, or bacterial contamination.

Transfusion-related acute lung injury (TRALI) is a rapid onset of non-cardiogenic pulmonary edema within 6 h of transfusion and is the leading cause of death from transfusion in the United States. There are three proposed mechanisms for TRALI: (a) donor-derived anti-granulocyte or (b) anti-HLA antibodies, and (c) biologic response modifiers such as cellular membrane fragments of donor cells that stimulate an inflammatory response in the recipient's pulmonary vasculature. These etiologies lead to hypoxic respiratory failure that is not responsive to diuretics. Supportive care is only required for the recipient. TRALI investigations are intended to help the blood center manage their donor pool since a donor with granulocyte or HLA antibodies, most of which are multiparous women, should be deferred from further donations of high plasma-volume components. To this end, the United Kingdom implemented a policy in 2003 to minimize the donations of FFP and platelets from females. This strategy has yielded a significant decrease in the rate of reported cases of probable TRALI.

Some adverse effects are more commonly associated with the pediatric population. Rapid infusion may cause fluid shifts in the intravascular compartment and can cause significant metabolic derangements. As RBCs age during storage, potassium levels increase in the supernatant. Large-volume transfusions of older red cell units to small children can result in hyperkalemic cardiac arrest and death. Hyperkalemia can be avoided by using fresher units, washing the cells, reducing the plasma volume before transfusion, or transfusing red cells slowly. Because blood products contain citrate, a calcium-binding anticoagulant, hypocalcemia may result from rapid infusion of blood products. In order to avoid hypothermia during large volume transfusions, blood can be passed through a blood warmer. Red cell additive solutions contain adenine, which carry a low risk of renal or liver insult when infused at high doses; plasma reduction or washing may decrease the risk. Hyperosmolality, hyperglycemia, hypernatremia, and hyperphosphatemia are theoretical concerns in children based on calculations of these constituents in storage media.

Table 328.7

Non-infectious transfusion reactions

Adverse effect	Etiology	Symptoms	Treatment or prophylaxis
Acute (<24 h) transfusion reactions, immunologic			
Acute hemolytic transfusion reaction	Immune destruction of transfused RBCs by a naturally occurring ABO-antibody or an alloantibody produced following immunization from a previous transfusion or pregnancy	Chills, fever, hemoglobinuria, renal failure, DIC, back pain, pain along infusion catheter, anxiety, shock. Gross hemoglobinemia in vitro	Supportive treatment
Febrile, non-hemolytic transfusion reaction	Accumulated cytokines or antibody to donor white cells	Fever, chills/rigors, headache, vomiting, exacerbation of cardiovascular or respiratory distress	Leukocyte reduction, premedication with acetaminophen
Urticarial transfusion reaction	Antibody to donor plasma proteins	Urticaria, pruritis, flushing	Antihistamine. May restart transfusion if symptoms resolve
Anaphylactic transfusion reaction	Antibody to donor plasma proteins, cytokines	Hypotension, urticaria, bronchospasm, angioedema, anxiety	Fluids, epinephrine, antihistamine, corticosteroids, beta-2-agonists, IgA deficient components
Transfusion Related Acute Lung Injury (TRALI)	Donor-derived antibodies to granulocytes or HLA antigens; or other WBC-activating agent	Hypoxemia, respiratory failure, hypotension, fever, bilateral pulmonary edema	Supportive care until recovery, defer implicated donor(s) if implicated antibody detected
Acute (<24 h) transfusion reactions, non-immunologic			
Sepsis	Bacterial contamination	Fever, chills, hypotension, shock	Supportive care, empiric broad spectrum antibiotics until sensitivity testing completed
Circulatory Overload	Volume overload due to transfused blood products	Dyspnea, orthopnea, cough, tachycardia, hypertension, headache	Upright posture, oxygen, IV diuretics, rarely phlebotomy
Non-immune hemolysis	Physical or chemical destruction of blood (heating, freezing, hemolytic drug or solution)	Hemoglobinuria, hemoglobinemia, jaundice	Identify and eliminate underlying cause
Air embolus	Infusion of air bubble	Sudden dyspnea, acute cyanosis, pain, cough, hypotension, arrhythemia	Place patient on left side with legs elevated above chest and head
Hypocalcemia	Rapid citrate infusion (massive transfusion)	Parasthesia, arrhythmia, tetany	Oral calcium for mild symptoms, slow IV calcium with close monitoring for more severe reactions
Hypothermia	Rapid infusion of cold or room temperature blood	Arrhythmia	Warm patient and use a blood warmer
Hyperkalemia	Leak of potassium into supernatant plasma from RBCs as they age. Pediatric and renal failure patients most at risk	Arrhythmia	Transfuse slowly. Transfuse fresh, washed, or volume reduced units to at-risk patients. Treat same as hyperkalemia from other causes (ie: IV calcium, insulin/glucose)

Table 328.7 (Continued)

Adverse effect	Etiology	Symptoms	Treatment or prophylaxis
Delayed (>24 h) transfusion reactions, immunologic			
Alloimmunization, HLA antigens	Exposure to foreign HLA antigens on WBC or platelet through prior transfusions or pregnancies	Platelet transfusion refractoriness	Avoid unnecessary blood, leukoreduction, transfuse HLA-matched or crossmatched platelet products
Delayed hemolytic transfusion reaction	Anamnestic immune response to RBC antigen; alloantibody titer increases after re-stimulation	Positive antibody screen in vitro following exposure to red cell transfusion, fever, hemolysis, jaundice in vivo 7–14 days after transfusion	Identify antibody, transfuse antigen negative, crossmatch compatible RBCs as needed
Transfusion-assocaiated graft-vs-host disease	Donor lymphocytes engraft in recipient and mount attack on tissues (see section on irradiation of blood components)	Fever, erythroderma, maculopapular rash, anorexia, nausea, vomiting, diarrhea, hepatitis, pancytopenia	Prevent with irradiation of blood components for at-risk patients. Stem cell transplant, corticosteroids, cytotoxic agents
Posttransfusion purpura (PTP)	Recipient-derived antibodies to human platelet antigens (HPA system) destroy donor *and* autologous platelets after re-exposure to platelet fragments (usually through a red cell transfusion)	Thrombocytopia and severe bleeding typically 8–10 days following RBC transfusion	IVIG, plasmapheresis, corticosteroids, antigen-negative platelets preferred
Delayed (>24 h) transfusion reactions, non-immunologic			
Iron overload	Storage of iron in organs and tissues in chronically transfused patients	Diabetes, cirrhosis, cardiomyopathy	Avoid unnecessary transfusions, phlebotomy if possible, iron chelation

Special Considerations

Massive Transfusion

The use of blood products has decreased mortality in hemorrhaging patients. A massive transfusion is defined as replacement of a patient's entire blood volume in 24 h, transfusion of more than ten PRBC units in adults, or replacement of more than 50% of the circulating blood volume within 3 h. In children <1 year, one adult-sized red cell unit can constitute massive transfusion. PRBCs are transfused rapidly to maintain adequate blood pressure and oxygen carrying capacity. For females of childbearing potential, group O, RhD-negative products should be used to protect against sensitization to RhD in cases of emergency, which could later cause HDFN. In the case of life threatening bleeding, however, group O PRBCs of any RhD type are acceptable, and may actually be preferentially used for male patients if medical center policy allows. A blood sample must be drawn early during resuscitation so that the sample reflects the patient's blood type prior to replacement with donated blood products. This is essential if the bleeding patient is to be switched to ABO-type specific products to preserve the inventory of universal donor products (group O RBC and group AB plasma products) in the blood bank.

Many institutions have a massive transfusion protocol that mandates a set ratio of the number of plasma and platelet components transfused per number of PRBC units transfused. This ratio is used to treat active hemorrhage and prevent dilutional coagulopathy. Alternatively, ABO/RhD-specific whole blood can be used if available. Due to a lack of controlled trials, no specific recommendation has been set for the ratio of PRBCs to platelets and plasma, so medical centers must create their own. All patients undergoing massive transfusion should have hematocrit, platelet count, prothrombin time, and fibrinogen checked regularly to assess coagulation status and to guide component therapy. Children undergoing massive transfusion should have electrolytes monitored as they are at higher risk of metabolic derangements including hyperkalemia, hypoglycemia, hypothermia, hypocalcemia, and fluid

overload. Because hypothermia and acidosis can inactivate clotting factors, it is imperative that these be tightly regulated to control bleeding effectively.

Exchange Transfusion

The more common indications for red cell or whole blood exchange transfusion include HDFN with kernicterus, sickle cell crisis, malaria, and hyperleukoctyosis seen in acute leukemia. Exchange transfusions can be accomplished by manual or automated techniques. Warmed, fresh, whole blood or PRBCs reconstituted with compatible plasma should be used to avoid the risks that accompany massive transfusion in whole blood exchange. The reported rate of mortality is 0–3.6% and adverse effects occur in 4–15.3% of patients. Complications includes sepsis, bradycardia, thrombocytopenia, apnea, cyanosis, hypocalcemia, hypoglycemia, and central catheter-related thrombi. Two times the blood volume is usually exchanged, *Table 328.8*. For the treatment of HDFN, this will replace about 75–90% of the recipient's RBCs, and remove 50% of the bilirubin and 75–90% of the causative antibody.

Chronic Transfusions

Some patients require RBC transfusions on a regular basis. The goal of chronic transfusions for patients with hemoglobinopathies (thalassemia or sickle cell disease) is to increase oxygen-carrying capacity, replace the defective red cells with normal RBCs, and to suppress erythropoiesis. Patients with a pure quantitative defect, such as Diamond Blackfan anemia, require transfusions to correct a qualitative defect while patients with myelodyplastic syndrome may have both quantitative and qualitative RBC defects. These patients may require lifelong transfusions if unable to obtain more definitive treatment. The most significant consequence of chronic transfusion is the deposition of iron into organs such as the liver and heart, which can lead to end-organ dysfunction. The effects of iron overload can be ameliorated by conducting exchange transfusion instead of simple transfusions or by starting iron chelation therapy. Neither of these options is without adverse effects, thus the risks and benefits must be heavily considered. Those receiving chronic transfusions also have a higher risk of alloimmunization and of contracting transfusion-transmitted infections based on the number of donors they are exposed to throughout life.

Table 328.8
Estimated blood volume

Age group	Approximate blood volume
Preterm neonate	100 ml/kg
Term neonate	85 ml/kg
>1 month	75 ml/kg

Extracoporeal Circuits Requiring Blood Products

Extracoporeal membrane oxygenation (ECMO), cardiopulmonary bypass (CPB), and automated apheresis are medical therapeutics that require significant blood bank participation. All of these treatment modalities use a circuit with an inline pump which draws blood out, processes it, and infuses it back into the patient. The modalities differ in clinical utility and methodology, as discussed below.

ECMO and CPB both provide artificial oxygenation and cardiac output. CPB is used by pediatric anesthesia during cardiac surgery in order to circulate blood while providing a bloodless, asystolic heart. ECMO is reserved for patients with potentially reversible respiratory and/or cardiac failure who have failed more conventional, less invasive techniques. Automated apheresis is a technique used to separate a cellular component or antibody from the blood and remove it. Apheresis can be used to remove blood cells (cytapheresis) in the case of polycythemia, thrombocythemia, sickle cell disease, or leukocytosis. Plasma can be removed via plasmapheresis and replaced with donor plasma and/or albumin. This is typically used to deplete a pathological IgG immunoglobulin in immune-mediated or malignant disease.

Although these techniques can potentially save lives and improve health, they are invasive, complex procedures that require hospital resources and carry risks. A variety of commercial instruments are available for each technique but each require specialized personnel to operate. Donor blood is usually necessary to prime the circuit in each scenario for small children. An anticoagulant, typically heparin or citrate, is added to the circuit to minimize the risk of a clot forming in the circuit tubing during operation. This can increase the risk of bleeding and/or hypocalcemia in patients. Any of these extracorporeal techniques can cause significant shifts of fluid. In addition, these techniques subsume all the infectious, immunological, and thrombotic risks due to the necessity of an indwelling central line and exposure to multiple blood donors.

Summary

Transfusions of blood and blood products have significantly reduced morbidity and mortality in children worldwide. A readily-available, safe supply of blood is now available to more physicians around the world, although significant disparities in testing and capabilities still exist between regions. Despite the advances, the potential complications of blood transfusion can be significant. The benefits and risks of the transfusion to individual patients must also be weighed against the conservation of the precious community resource. Efficacy and safety will continue to improve as the knowledge of pediatric transfusions increases.

329 Care of the Child Refusing Blood Products

Lynn Boshkov

Background: Jehovah's Witnesses and Prohibitions on Transfusion of Blood

The Watch Tower Bible and Tract Society web site (http://www.watchtower.org/e/statistics/worldwide_report.htm accessed January 29, 2011) indicates that in 2009, there were over 7.3 million Jehovah's Witnesses in 236 countries worldwide. The greatest number of these (over 1.1 million) live in the USA, with numbers in excess of 100,000 being found in other countries in North America (Canada, Mexico), South America (Argentina, Brazil, Columbia, Peru), Eurasia (France, Germany, Great Britain, Poland, Russia, Spain), the Far East (Japan, Philippines), and Africa (Congo, Nigeria, Zambia). Thus, it is likely that the medical practitioner treating children almost anywhere in the world will come into contact with a Jehovah's Witness family.

Jehovah's Witnesses believe that the Bible prohibits ingesting blood and do not accept transfusion of whole blood or any of its four primary components – red cells, platelets, plasma, or white cells. This prohibition applies even in clinical contexts where such refusal may result in serious harm or death. The transfusion prohibition also extends to predonation and storage of a patient's own blood for later transfusion back to the patient. However, it is worth noting that Jehovah's Witnesses are not one of the religious groups who shun medical care generally, and that acceptability of sophisticated medical interventions where their own blood is kept in contact with the body (cardiopulmonary bypass, dialysis), as well as receipt of organ transplants, are considered "matters of conscience" to be decided by each individual Witness. Other "matters of conscience" to Witnesses are intraoperative blood salvage where the blood is kept in contact with the body ("Cell Saver" type devices, perioperative hemodilution) and a range of "minor fractions" of blood (discussed in greater detail below). While most countries legally permit refusal of medical interventions by adults, the desire of Jehovah's Witness parents and guardians to extend refusal of blood therapy to their minor children often results in legal and ethical tensions between the family and health-care providers treating the child, as those providers are most often both legally obligated to provide medical intervention that will save life or prevent serious harm, and also obligated to do so by personal ethical imperatives. This tension may be particularly acute in the case of patients who are "mature minors," and who are themselves also refusing blood.

Faced with such a conflict, what is the best way to proceed? Several general guiding precepts may be helpful:

1. Work in partnership with the patient and family and Jehovah's Witness community; act as the patient's and the family's advocate.
2. Know and explore the acceptability of the full range of "matters of conscience" minor fractions and non-blood therapeutic options with the patient and family and use them prior to resorting to unacceptable interventions.
3. Act preemptively if possible to prevent anemia and coagulopathy and use combined interventions to treat these.
4. Realize physiological tolerance of anemia is generally greater than one might think.
5. Make the family aware of the legal obligation to transfuse a minor to prevent serious harm or death.

If the treating physician truly adheres to these guiding precepts, even though the child ends up receiving a blood product, tensions are minimized to the extent this is possible and the therapeutic relationship is served. Elaborating on these guiding precepts:

Work in partnership with the patient and family and Jehovah's Witness community; act as the patient's and the family's advocate.

In difficult cases, it is especially useful to have access to other physicians who have managed Jehovah's Witness cases (hospitals with Bloodless Medicine and Surgery programs are good places to start), and, if possible, to work in partnership with a local Jehovah's Witness Hospital Liaison Committee Elder. The Hospital Information Services (HIS) branch of the Watch Tower Society, headquartered in Brooklyn, New York, has as its mandate provision of education and facilitation of bloodless medicine and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_329,

surgery. HIS has a web site (http://www.watchtower.org/e/vcnr/article_01.htm, accessed January, 2011) with videos showing transfusion alternatives; it also has a contact phone number for physicians listed on that web site: 1-718-560-4300. When HIS was contacted by this writer regarding a contact number for physicians using this chapter they also suggested their e-mail address: his@jw.org.

HIS services also include Hospital Liaison Committees (HLCs) with specially trained Jehovah's Witness HLC Elders whose function is to support the patient and family and to work in cooperation with treating health-care professionals. There are 131 HLCs in the USA and 1,650 worldwide in over 200 countries. HLC Elders can be contacted through inquiries directed by the Witness family to leaders at their local centers of worship; HLC Elders can also be reached through contact with HIS. HLCs have access to a large database of medical literature on bloodless medicine and surgery and preprinted general information on management of the surgical patient, the critically ill patient, the ob/gyn patient, etc. HLC Elders will often bring such literature to the attention of the treating physician for his or her perusal regarding relevance to the case at hand. More importantly to the treating practitioner, HLC Elders also have access through HIS to a worldwide network of physicians who have extensive experience in treating Jehovah's Witness patients and who are often willing to provide timely telephone and electronic (pertinent papers, etc.) consultation to less-experienced health-care providers. Simply seeing interaction between their treating health-care providers and HLC Elders is often tremendously reassuring to families, and these Elders can also help with support of the family and the child if transfusion is ultimately necessary. Health-care providers are frequently fearful that the transfused child will be ostracized by the Jehovah's Witness community. In this writer's extensive Canadian and US experience, this has not been the case.

Know and explore the acceptability of the full range of "matters of conscience" minor fractions and non-blood therapeutic options with the patient and family and use them prior to resorting to unacceptable blood options, time permitting.

In the Developing World, the only blood product available may be whole blood, and this is unacceptable to Witnesses. Also unacceptable are the four primary components of whole blood (red cells, platelets, plasma, white cells) which are usually prepared by simple centrifugation of whole blood or some modification of this. However, once primary components of whole blood are further subseparated into their constituent parts, receipt of the resulting "fraction" is considered a "matter of conscience." For example, from a 500 ml whole blood donation, a 250–300 ml unit of plasma may be separated. Neither the whole blood nor the plasma is acceptable to Witnesses. However, if that unit of plasma is chilled, and the flocculent white precipitate is centrifuged out to prepare a unit of cryoprecipitate (usually about 10–15 ml), that cryoprecipitate "fraction" is considered to be a matter of conscience – as is the fibrin glue that can be further prepared from a pool of cryoprecipitate activated with bovine thrombin.

The use of cryoprecipitate, if acceptable, can be helpful in avoiding transfusion of unacceptable blood components. As a unit of cryoprecipitate contains, in very concentrated form, about half the Von Willebrand Factor (important in platelet adhesion), half the Factor VIII, and half the fibrinogen in the original unit of plasma, cryoprecipitate given at ~1 unit/5–10 kg can often help improve platelet function and provide at least some crucial coagulation factors necessary for hemostasis.

Large plasma pools (~2,000–20,000 donors) may also be fractionated into a variety of plasma derivatives such as albumin, plasma-derived clotting proteins (FVIII, FIX, fibrinogen, antithrombin, and others), intravenous immune globulins, Rh immune globulin, and many others. Such plasma derivatives may also be used to make local fibrin glue or topical thrombin hemostatic agents. Such plasma "fractions" are all considered to be "matters of conscience" to individual Witnesses and all may be useful in avoiding transfusion of unacceptable primary components in selected situations.

It is worth noting that many adult Witnesses in the USA and elsewhere carry "Advance Directives." These are concise statements of the individual's wishes regarding medical interventions and end-of-life care and include a section dealing with blood and blood fractions. Usually, if one blood fraction is acceptable, all are. However, it is often helpful for the practitioner to be able to explain where the fractions come from in relation to whole blood, as many Advance Directives state the patient might be willing to accept fractions but needs to know more about them.

In explaining fractions to Jehovah's Witness, several things may be helpful. First, the practitioner should make it explicit that the "fraction" discussion is being motivated not by a desire to coerce, but rather to use the full armamentarium of products and interventions available and acceptable to the patient to improve medical outcome and to prevent administration of unacceptable products and interventions. Second, it may be helpful to emphasize plasma's general role as a sort of "carrier river," not only for cellular blood elements made in the bone marrow

(red cells, white cells, and platelets), but also for blood sugar, hormones, waste products, liver and kidney function enzymes, and for clotting proteins made in the liver and linings of the blood vessels (such as Von Willebrand Factor, fibrinogen, and other clotting factors), and for albumin (a protein made in the liver which helps blood stay in vessels and stabilizes many hormones). Third, that use of fractions can truly spare use of unacceptable products at times and even be lifesaving – for example, although neither platelets nor plasma is acceptable to Witnesses, cryoprecipitate can help platelets work better, fibrin glue and topical thrombin hemostatic agents can help make local clots when used during surgery or invasive procedures, and albumin can help blood stay in the vessels. Fourth, it may be helpful to note that while cellular blood elements do not normally traffic across the placenta, the other fractions do. (This was a personal observation made to this writer by a HLC Elder when queried regarding his own "matters of conscience" beliefs, and used with his permission subsequently in explaining fractions to other Jehovah's Witness patients). Lastly, it is also worth noting that HLC Elders can often assist in explaining fractions and transfusion-sparing interventions where the blood is kept in contact with the body (Cell Saver, perioperative hemodilution) to patients and families. They can also help provide the patient and family with information – written, videos – explaining these.

As the whole issue of acceptability of different fractions and interventions can vary greatly according to the individual conscience of a particular Witness family, it can be useful for hospitals and transfusing institutions to have a special "Blood Refusal" Form which concisely summarizes these. As a model, the Oregon Health & Science University "Transfusion Blood Refusal" form is shown in *Fig. 329.1.*

Interestingly, hemoglobin-based oxygen carriers (HBOCs), derived from human or animal red cells, are also considered "fractions" and "matters of conscience" by Witnesses. Only one HBOC (Hemopure by Biopure) was ever licensed worldwide and then only in South Africa, although several have been available on a "Compassionate Release" basis in the past, with the Compassionate Release Programs being made available by the companies and overseen by national regulatory agencies such as the US FDA. Compassionate Release Programs exclude minors, however, and, as of this writing (January 2011), to this writer's knowledge, no Compassionate Release Programs currently exist anywhere worldwide. Also, to this writer's knowledge, manufacture of essentially all HBOCs has currently been terminated or suspended due to unfavorable phase 3 trial outcomes and such products were no longer available anywhere worldwide as of January 2011, apart from residual stores in South Africa.

As mentioned, other "matters of conscience" to Witnesses are intraoperative blood salvage where the blood is kept in contact with the body ("Cell Saver"–type devices, perioperative hemodilution). These interventions are generally not suitable for small children. The "Cell Saver" is most useful in large volume "clean" losses (no infection or malignancy present) such as vascular surgery. Perioperative hemodilution is generally most useful in patients with high starting hematocrits and large volume losses, and may be used in malignancy cases.

Act preemptively if possible to prevent anemia and coagulopathy and use combined interventions to treat these.

Routine supplementation of Witness patients with hematinics, especially in the context of hospitalization and perisurgically is often advisable. This should include consideration of full marrow repletion doses of iron preferably given IV, as oral iron may be poorly tolerated and often cannot be given quickly enough in large enough doses. The iron sucrose preparations and other iron preparations associated with very low reaction rates are recommended. It should be noted that in sick patients, iron studies and ferritin are unreliable and that normal ferritins do not rule out absent bone marrow iron stores. Daily folate either PO or IV should also be given. Vitamin K supplementation PO or IV twice weekly is also often helpful.

The issue of use of erythroid-stimulating agents (ESAs) such as erythropoietin (epo) and darbepoietin (darbe) should be considered. There is more experience with the use of epo in pediatric patients and it alone may be approved for pediatric use. Although neither epo nor darbe is derived from blood, epo is stabilized with traces of albumin and may therefore be unacceptable to certain Witnesses, whereas darbe is albumin free. Iron repletion is essential for ESAs to act most effectively and should be assured prior to ESA administration. ESAs are most effective given preoperatively as there is antagonism to the effect of ESAs mediated by inflammatory cytokines postoperatively and in the context of intercurrent illness. To obtain a reticulocyte rise with ESAs usually takes 3–4 days (rises of five- to tenfold above baseline are usual), and to obtain a meaningful increase in the hemoglobin (>1 g/dl) usually takes 10–14 days. To significantly augment the hemoglobin (Hb) preoperatively with an ESA can therefore take 3–4 weeks. Weekly doses of epo at 300–500 U/kg (or equivalent doses of darbe) are recommended for this purpose, preferably given SQ rather than IV. In the postoperative setting, and in the setting of illness, there is usually inflammatory cytokine-mediated (IL-1, TNF, and

others) resistance to the action of epo. This can often be at least partially overcome by pharmacological doses of epo (300–500 U/kg SQ daily).

ESA use in adults with critical illness and with malignancy is associated with increased thrombogenicity (blood clots, heart failure, myocardial infarction, stroke). It is unclear if this is also the case in pediatrics. In older children requiring sustained high dose epo therapy, consideration should be given to prophylactic doses of antithrombotics. In the case of cancer in adult populations, use of ESAs is also associated with increases in mortality independent of thrombogenicity and possibly mediated by tumor receptors for ESAs and promotion of angiogenesis. The US Food and Drug Administration (FDA) issued a block box warning for ESAs in 2007 prompting a series of revised clinical guidelines and, as of 2010, the FDA is requiring that all ESAs given to patients with malignancy be prescribed under a Risk Evaluation and Mitigation Strategy (REMS) which includes a medication guide to explain risks to patients and caregivers, and the ESA APPRISE (Assisting Providers and cancer Patients with Risk Information for the Safe use of ESAs) Oncology Program (http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm200297.htm, accessed January 29, 2011). Thus, in pediatric patients with cancer, careful weighing of the risk benefit of ESA administration needs to be done.

Regarding management of thrombocytopenia or thrombocytopathy in Witnesses refusing platelet transfusion, cryoprecipitate, if acceptable, at 1 U/5–10 kg is often effective in the treatment of petechaie and minor platelet-type bleeding in patients, and this dose may be administered prophylactically daily if the platelet count is under 10×10^{-9}/l. Adult anecdotal and published experience, and anecdotal pediatric experience, suggests administration of either aminocaproic acid or tranexamic acid may also be helpful in preventing and treating bleeding if the platelet count is $<10^{-30} \times 10^{-9}$/l. Tranexamic acid if available is a more potent antifibrinolytic agent than aminocaproic acid. Consideration may also be given to the use of thrombopoietin (tpo) mimetics if available (romiplostim, eltrombopag).

It should be noted that Witnesses have no issues with the use of a variety of non-blood-derived and non-albumin-stabilized pharmacological hemostatic agents such as ddAVP, antifibrinolytics, and recombinant factor VIIa. As well, as discussed in the section on fractions above, fibrin glues and topical thrombin-based hemostatic agents may be acceptable and transfusion-sparing in the setting of surgery or invasive procedures.

Realize physiological tolerance of anemia is generally greater than one might think.

Tolerance of anemia is determined by multiple factors including chronicity of development, underlying cardiovascular status, age, and oxygen demands. Animal studies suggest the lower limit of tolerance to sustained anemia in animals with a normal cardiovascular system is a Hb of around 3–5 g/dl and in those animals with coronary stenosis is a Hb around 7–10 g/dl. The largest published series of morbidity and mortality in the perioperative setting in adult patients refusing blood transfusion suggests that survival with a Hb < 2 g/dl is very infrequent and that both morbidity and mortality rise substantially when the Hb falls to less than 5–6 g/dl. That said, the Transfusion in Critical Care (TRICC) trial indicates that in adult ICU patients, there is at least an equivalent outcome in patients randomized to a restrictive (target Hb 7–9 g/dl) rather than liberal (target Hb 10–12 g/dl) transfusion strategy. This has recently also been confirmed in the pediatric critical care setting. Thus, as a general rule, concerns regarding adverse effects of anemia should probably begin to rise only when the Hb falls below 7 g/dl, and the decision to intervene subsequently needs to be tempered by the anticipated chronicity of further fall in the Hb, the underlying cardiovascular status of the patient, and the anticipated oxygen demands the patient will face (sepsis, surgery, etc.). In children, it is probably unwise to wait to transfuse until frank florid physiological decompensation as children appear to manifest signs and symptoms of impending decompensation later than adults.

Make the family aware of the legal obligation to transfuse a minor to prevent serious harm or death.

Witnesses generally abide by the law despite strong objection at times to its dictates (transfusion of minor children). In the USA, in the case of impending serious irreversible harm or death, traditionally "court orders" have been obtained mandating transfusion of minor children whose Jehovah's Witness parents or guardians have refused to sign permission for blood transfusion. Court orders are often traumatic to Witness families not only because of the transfusion itself, but because court orders are usually subsets of child abuse laws, and when a court order is obtained the child is made a ward of the court, and a court-appointed representative thereafter legally signs permission for surgeries, dialysis, etc. If a court order is obtained therefore it is advisable to ask that it be limited only to blood. At the author's institution, Oregon Health & Science University (OHSU), the Transfusion Blood Refusal Form (*Fig. 329.1.*) tries to avoid court orders by incorporating specific language indicating that the parent or guardian, while not giving permission for the transfusion, nonetheless recognizes the legal obligation of

the treating physician to transfuse to save life or prevent irreversible harm. If the parent or guardian signs this form, it is the opinion of both OHSU Legal and Risk Management that a court order is not necessary, and very few have been obtained subsequent to this form's adoption.

330 Disorders of Heme Biosynthesis

Thomas G. DeLoughery

Porphyria

The porphyrias are a group of rare diseases of heme metabolism (*Table 330.1*). They have a protean array of symptoms and can represent a diagnostic challenge. Although rare, diagnosis is important as a mainstay of therapy for most porphyria is avoidance of precipitating factors.

Symptoms

One fundamental principle is that the pathogenesis of symptoms of porphyria is due to accumulations of the metabolites of heme synthesis (*Fig. 330.1*). These metabolites can be neurotoxic (ALA, PGB), acutely toxic to the skin (protoporphyrins), or chronically toxic to the skin (uropophyrinogen and coproporphyrinogen) (*Table 330.2*). Thus, there are three basic ways porphyria can present:

1. Neurovisceral – The neurovisceral symptoms consist of autonomic neuropathies (constipation, colicky abdominal pain, vomiting, hypertension), peripheral neuropathy (most often motor), seizures, delirium, coma, and depression. The abdominal pain is severe and lasts for several days. Severe abdomen pain of short (less than one day) duration or chronic abdominal pain is unusual. The sequence of events in attacks is usually: first abdominal pain, then psychiatric symptoms such as hysteria, and then the peripheral neuropathies. Most patients are completely free of symptoms between attacks. Hyponatremia due to SIADH can be seen in severe cases. These symptoms can be seen with AIP, HCP, and VP.
2. Acute cutaneous – Symptoms occur quickly (minutes) of being exposed to the sun – redness, edema, and itching and is seen with EP, CEP, and HP.
3. Chronic cutaneous – The cutaneous manifestations are characterized by bullae formation in sun exposed areas, fragile skin, and hypertrichosis and is seen with PCT, HCP, VP, CEP, and HP.

Most porphyrias present at puberty or older. The exceptions are the rare ALA dehydratase porphyria, congenital erythropoietic porphyria, or hepateoerythropoietic porphyria which present soon after birth. Also, symptoms of EP can start in childhood.

Diagnosis

The diagnosis of any porphyria is based on both the clinical presentation and the demonstration of excessive porphyrin excretion in relation to these symptoms. The essential procedure in ascribing any neurovisceral symptoms to porphyria is to establish that there is an increase in porphyrin precursors at the time of these problems. These precursors are PorphoBilinoGen (PBG) and AminoLevulinic Acid (ALA). A common mistake in diagnosing porphyria is to observe just an elevated level of porphyrins (not precursors) in the urine or stool and label the patient as having porphyria. Neurovisceral attacks are only associated with over-excretion of PGB and ALA. This is most common in AIP, but can be seen in VP and HCP. Another difficulty in diagnosing porphyria is many patients have minor (less than 3–5 times) elevation of urine and/or stool porphyrins. This can be a normal variant or seen in fasting, iron deficiency, ingestion of meat, or any illness. The chronic cutaneous porphyrias – PCT, HCP, and VP – have classic dermatological manifestations. The key testing is urine and stool for the formed porphyrins such as uropophyrinogen. There is an entity known as "Pseudoporphyria" where patients have the skin manifestations of porphyria but urine and stools demonstrate normal porphyrin excretion. This can be seen as a complication of certain medications such as naproxen or in dialysis patients. The acute cutaneous porphyrias are diagnosed by finding increased erythrocyte porphyrins.

A very simple bedside assay for acute porphyrias is examination of a fresh urine sample. It is clear at first, but will darken with exposure to the sun. If available, the presence of PBG can be confirmed by adding Ehrlich's aldehyde reagent in a 1:1 ratio to the urine; the presence of a pink color confirms the presence of PBG. Definitive

diagnosis of the different porphyrias requires analysis of urine, stool, and blood samples for the specific porphyrins and their precursors. In theory, since most porphyrias are due to mutations in the genes encoding the enzymes for heme synthesis, DNA analysis or assays of enzymes active would be useful. But given the low penetrance of the porphyria, this testing is useful only in selected cases.

Acute (Neurovisceral) Porphyrias

Acute intermittent porphyria has onset in puberty with only neurovisceral symptoms. Many more patients have the genetic defect than express clinical disease. Most patients will only have one attack. Attacks are provoked by anything that leads to increase in the heme synthesis pathway. The classics are starvation (glucose suppresses heme synthesis) and a multitude of drugs. The classic drugs are estrogen, barbiturates, and ethanol. There are lists of "safe" and "unsafe," easily found on the Internet. http://www.drugs-porphyria.org and http://www.porphyriafoundation.com are the two most researched and complete websites.

Diagnosis is by a demonstrated increase – greater than tenfold – in urine porphobilinogen. Levels can remain raised for years after the attack. One can verify by checking the activity level of PBG deaminase, but this will be normal in 10% of patients as only the hepatic form is affected and not the form measured in the circulating red cells.

The therapy of the neurovisceral symptoms of AIP is based on shutting down the heme synthesis pathway to prevent accumulation of the toxic precursors. High doses of glucose (300 g/day) can mildly inhibit the pathway and is used for mild attacks. Hematin, which is intravenous preparation of heme, is used for severe attacks to stop the heme synthesis pathway. Either heme-arginine (250 mg × 5 days) or hematin (4 mg/kg × 4 days) can be used to suppress the heme synthetic pathway and is effective for severe acute attacks or attacks associated with neurological defects. These agents are well tolerated but can lead to

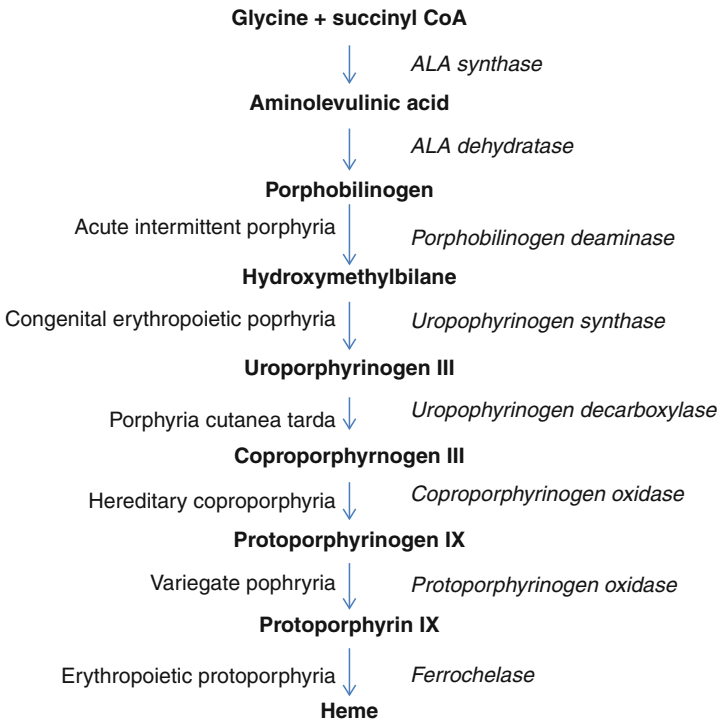

Figure 330.1
Heme synthesis

Table 330.2
The porphyrias: symptoms and therapy

	Therapy
Neurovisceral	Acute: increase glucose, hematin Chronic: avoid fasting and precipitating drugs
Acute intermittent porphyria (AIP)	
Coproporphyria (HCP)	
Variegate porphyria (VP)	
Cutaneous	Phlebotomized to reduce ferritin, avoid sun exposure, avoid precipitating medications
Porphyria cutanea tarda (PCT)	
Photosensitivity	Avoid sun exposure, beta-carotene
Erythropoietic protoporphyria (EP)	
X-linked protoporphyria	
Recessive	
ALA dehydratase porphyria	Hematin
Congenital erythropoietic porphyria (CEP)	Stem cell transplant
Hepateoerythropoietic porphyria (HP)	Avoid sun exposure

thrombophlebitis and often need to be given via central venous access. Rarely, there can be a severe sympathetic crisis manifesting with severe hypertension and seizures. Patients with repeated attacks can be treated with weekly heme infusions. In patients with severe intractable symptoms, liver transplantation can be considered. Prevention of future attacks is by avoiding precipitating factors such as fasting, medications, and alcohol.

Hereditary coproporphyria has both neurovisceral and skin manifestations (described under PCT). Patients are rarely symptomatic. Diagnosis is by demonstrating markedly increased urine and stool coproporphyrinogens. As noted above, mild elevations of coproporphyrinogens is common and not pathogenic. Treatment is the same as AIP.

Variegate porphyria has both neurovisceral and skin manifestations (described under PCT). Patients are sporadically symptomatic. Diagnosis is by demonstrating markedly increased urine and stool coproporphyrinogen and protoporphyrinogen. Treatment is the same as AIP.

Chronic Cutaneous (Blistering) Porphyrias

Porphyria cutanea tarda presents with skin disease in sun exposed areas. The first signs are fragile skin with, then, the formation of blisters and bulla that can take weeks to heal. This over time leads to chronic skin damage with increased pigmentation and hair growth. Given the relationship with sun exposure, the skin involved is on the upper hands, face, and neck. Most patients have an acquired inhibitor of uropophyrinogen decarboxylase, with only a minority (∼25%) having a mutation in the gene encoding for this enzyme; but even, patients with the mutation will only manifest symptoms with acquitted risk factors. The risk factors for PCT are liver damage – from alcohol – iron overload and hepatitis, estrogens, and HIV. Iron overload appears to be crucial given the relationship of the hemochromatosis genotype and iron overload with PCT.

Diagnosis is the combination of the classic skin findings and demonstration of excess urine uropophyrinogen and stool isocoproporphyrinogen. Therapy is by reduction of iron stores. Phlebotomy with a goal ferritin of under 50 mg/L is very effective. Patients must be cautious that their skin disease resolution can lag by months, as the porphyrin laden skin must be shed for symptoms to abate. Chloroquine (100–200 mg two times weekly) can also be effective especially in the rare patient who cannot be phlebotomized. Also helpful is avoidance of risk factors such as excess sun exposure, estrogen, or alcohol.

Acute Cutaneous (Photosensitive) Porphyrias

Erythropoietic protoporphyria has early onset of acute photosensitive. Patients noticed with sun exposure will have a burning, stinging sensation in their skin. This can be accompanied by swelling and redness. Cold water or compression can bring symptom-relief. Over time, there can be chronic skin damage with skin thickening, crusting, and waxy-changes. In ∼10% of patients, there can be liver disease due to accumulation of protoporphyrins that, over time, can lead to liver failure. Diagnosis is established by showing increased levels of stool and red cell protoporphyrins. The vast majority of patients have mutations in the ferrochelase gene, but about 2% have an X-linked mutation in the ALA synthase gene.

Therapy is by protecting the skin from sunlight. Clothing, large hats, and sun screen can be used. Beta-carotene (75–200 mg/day) can help symptoms in some patients. Patients need to be screened yearly for liver disease, for which liver transplantation may sometimes be required.

Neonatal Porphyrias

ALA dehydratase porphyria is extremely rare but can cause neurovisceral attacks in children. Diagnosis is made by demonstrating marked over-excretion of ALA in the urine. Therapy is with hematin, but some patients have had a progressive course despite therapy.

Congenital erythropoietic porphyria is marked by severe photosensitivity starting at an early age that can lead to mutilating changes and disfigurement with loss of appendages. Teeth can be pink to red due to accumulation of porphyrins. Patient can have bone disease leading to fractures. Many patients have a hemolytic anemia that can be severe with associated large spleen.

Diagnosis can be suggested by the clinical findings and red urine in the diapers. Diagnosis is established by finding excess isomer I of uropophyrinogen and coproporphyrin in urine, stool, and red cells.

Curative therapy is with stem cell transplantation. If this cannot be done, then supportive care can be tried with avoidance of sun exposure and splenectomy if hypersplenism is present.

Hepateoerythropoietic porphyria can lead to a severe PCT syndrome in childhood. The main differential diagnosis is CEP, but the skin disease tends to be more scarring than mutilating. The defect is a homozygous mutation in the uropophyrinogen decarboxylase gene and diagnosis is made by demonstrating excess urine uropophyrinogen and stool isocoproporphyrinogen. Therapy is supportive with avoiding sun exposure. Unlike PCT, reduction of iron stores and chloroquine are not effective.

331 Platelet Structure, Function, and Disorders

Daniel Greenberg

Introduction

Platelets are anucleate cells that circulate in the bloodstream. They are essential for normal hemostasis, and patients with a very low concentration of circulating platelets or disorders that result in severe platelet dysfunction have serious bleeding disorders. They are also essential for normal clot retraction and wound healing. Conversely, platelet adhesions to vascular atherosclerotic lesions are a major cause of myocardial infarction and ischemic stroke. Over the past several years, numerous elegant experimental observations suggest platelets also play a key role in angiogenesis and in pathological processes such as infection and cancer metastasis.

Platelets are derived from bone marrow progenitor stem cells in a process known as thrombopoiesis. During this process, the pluripotent marrow stem cell first undergoes a transformation into a giant cell with a large cytoplasm and a polyploid nucleus, called a megakaryocyte. Platelets are created when the cytoplasm of the megakaryocyte divides into thousands of individual platelets that are released into the circulation through the bone marrow sinusoids (see *Fig. 331.1*). Accordingly, platelets can be thought of little packages of the megakaryocyte cytoplasm wrapped up in a specialized membrane. Thrombopoiesis is regulated, in large part, by the hepatic production of the cytokine thrombopoietin (TPO). TPO is homologous with erythropoietin (EPO); however, the TPO receptor (Mpl) is primarily expressed by stem cells and megakaryocytes in the bone marrow, whereas the EPO receptor is primarily expressed by erythroblasts and developing erythroid cells. Although TPO is not known to have a direct biological effect on mature platelets, TPO is cleared from the plasma by platelets through the process of receptor-induced endocytosis. The concentration of TPO in the plasma and its biological effect of inducing thrombopoiesis are largely regulated by the platelet count through this negative feedback pathway: Because of the clearance of TPO by platelets, a high platelet count has the effect of decreasing the concentration of biologically active TPO. Conversely, a low concentration of platelets results in an increased concentration of free TPO in the plasma. For almost all normal individuals, this feedback mechanism results in circulating a platelet concentration between 150,000 and 350,000/μl of whole blood.

During normal hemostasis, platelets are recruited to a site of vascular injury where they become activated to form a plug over the disrupted vessel(s). This process of platelet activation is mediated by complex array of membrane receptors and other integral membrane and cytoskeleton proteins which are essential for normal platelet activation and hemostasis. The receptors present on the platelet plasma membrane range from specialized adhesive receptors that recognize complex polymeric proteins such as fibrinogen, collagen, and Von Willebrand Factor to specific single molecule receptors (e.g., ADP, thrombin, and collagen) that mediate platelet activation through intracellular signal transduction pathways. *Figure 331.2* shows a schematic representation of platelets adhering to the sub-endothelium by VWF and aggregating in the presence of fibrinogen. The aggregated platelet plug provides a surface for the coagulation proteins to form fibrin (secondary phase of hemostasis).

Most clinical laboratory testing of platelet activation relies on the ability of platelets to aggregate in the presence of fibrinogen after the platelets are stimulated with a platelet agonist such as thrombin, collagen, or ADP. These agonists act on specific platelet receptors (see below) all of which end up causing the activation of the platelet fibrinogen receptor to recognize and bind fibrinogen. Fibrinogen is a large hetero-heximeric protein that forms bridges between activated platelets piled one on top of another to form a stable aggregate. In the commonly practiced platelet aggregation test, a solution containing the patient's platelets (either platelet rich plasma or whole blood) is treated with the appropriate agonists in the presence of fibrinogen. The solution is then analyzed to determine the extent to which the platelets have aggregated into clumps relative to a standard, positive control. Full activation of platelet function requires, but is not limited to, platelet aggregation. As discussed below, platelet activation involves much more than the ability to

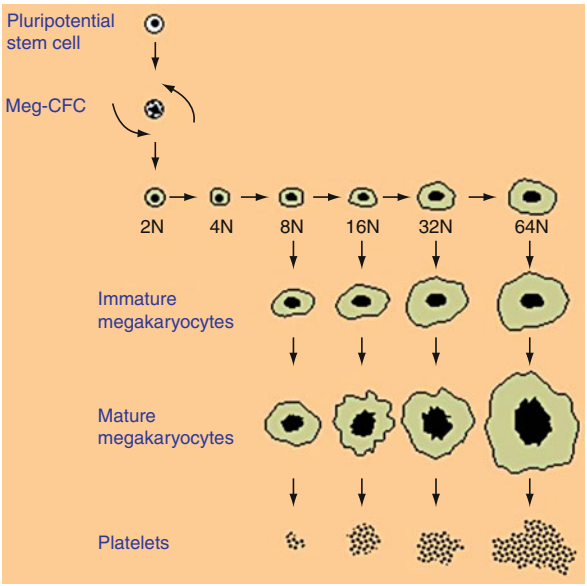

Figure 331.1
Thrombopoiesis. Illustration of the process of megakaryocytic differentiation and thrombopoiesis from the pluripotent bone marrow stem cell. The megakaryocyte first reaches a state of nuclear multiploidy and increases the size of the cytoplasm. Platelets are formed when hundreds of small cytoplasmic fragments are packaged in specialized phopholipid membranes surrounded by a central microtubular ring. Megakarocytic differentiation and thrombopoiesis are controlled by the hepatic production of the cytokine thrombopoietin

aggregate in the presence of fibrinogen. Like other coagulation assays, platelet aggregation and other tests of platelet function require careful interpretation and a firm grasp of their limitations.

Platelet Structure

Cytoskeleton

Normal circulating platelets are about 10 μm in diameter, and appear discoid in shape. The platelet plasma membrane consists of a complex arrangement of constituents including cholesterol, phospholipids, and integral membrane proteins. Many integral membrane proteins, including the adhesive receptors to fibrinogen and Von Willebrand factor, are anchored to an extensive platelet cytoskeleton composed chiefly of actin filaments. These actin filaments are arranged in a fine meshwork just below the plasma membrane and become less dense and more orthogonal in configuration deeper into the platelet cytoplasm. Just under the plasma membrane and surrounding the diameter of the platelet is a thick microtubule filament composed alpha and beta tubulin. *Figure 331.3* shows a circulating discoid platelet with the membrane peeled back and the cytoskeleton exposed. When platelets are activated to cover a vascular defect, the sub-plasma membrane microtubule ring contracts toward the center of the platelet as the actin cytoskeleton undergoes extensive rearrangement. This results in a dramatic shape change from the inactive, discoid platelet to a flattened platelet that looks somewhat like a "fried egg" spread out over an adhesive surface such a Von Willebrand factor, fibrinogen, or collagen.

The Plasma Membrane

Coincidental with the cytoskeletal changes that occur when platelets are activated to spread over a vascular defect, dramatic changes in structure of the activated platelet plasma membrane also occur and are critical to maintaining normal hemostasis. These events are summarized in *Fig. 331.4*. The overall effect of these plasma membrane changes is to form a phospholipid surface for the assembly of coagulation cascade components, particularly the *tenase* (FVIIIa/FIXa) and *prothrombinase* (FVa/FXa) complexes. These complexes require the "clottable" phospholipids (phophatidylserine and phosphatidylethanolamine) to achieve their maximal activity. In the resting or inactive state, circulating discoid platelets have an asymmetrical distribution of the phopholipid bilayer of the plasma membrane: Phophatidylcholine and phophatidylinositol, which do not support clotting ("non-clottable" phospholipids) are present predominantly on the outer plasma membrane. Phosphatidylserine and phosphatidylethanolamine, which efficiently support clotting, are present predominantly on the inner plasma membrane. This phopholipid membrane asymmetry is an energy-dependent process mediated, in part, by the integral membrane protein complex *aminophospholipid translocase*. Once platelets are activated to participate in hemostasis, the distribution of the membrane phospholipids is "scrambled" by another integral membrane protein called *scramblase*. The favorable clotting surface provided by phosphatidylserine and phosphatidylethanolamine translocates from the inner leaflet to the outer leaflet of the plasma membrane. In this activated phopholipid membrane configuration, the phospholipid-dependent

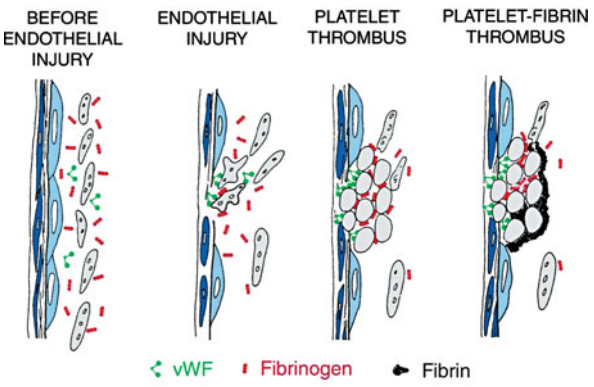

Figure 331.2

Primary and secondary phases of hemostasis. Formation of the platelet plug over a vascular defect is illustrated when Von Willebrand factor (*green*) binds to exposed sub-endothelial collagen and the platelet gpIB receptor. Once a layer of platelets cover the vascular defect, fibrinogen (*red*) further aggregates platelets on top of one another (through activation of platelet gpIIB-IIIA) to form a platelet plug. At the same time, tissue factor generated by injured endothelial cells associates with factor VIIa to start the extrinsic pathway of coagulation. With the platelet plug in place, the coagulation factors assemble on the activated platelet membrane surface to form a strong fibrin (*black*) covering that stabilizes and secures the platelet plug. The formation of the platelet plug by Von Willebrand factor and fibrinogen is referred to as the primary phase of hemostasis, and the production of fibrin by the plasma coagulation factors is referred to as the secondary phase of hemostasis

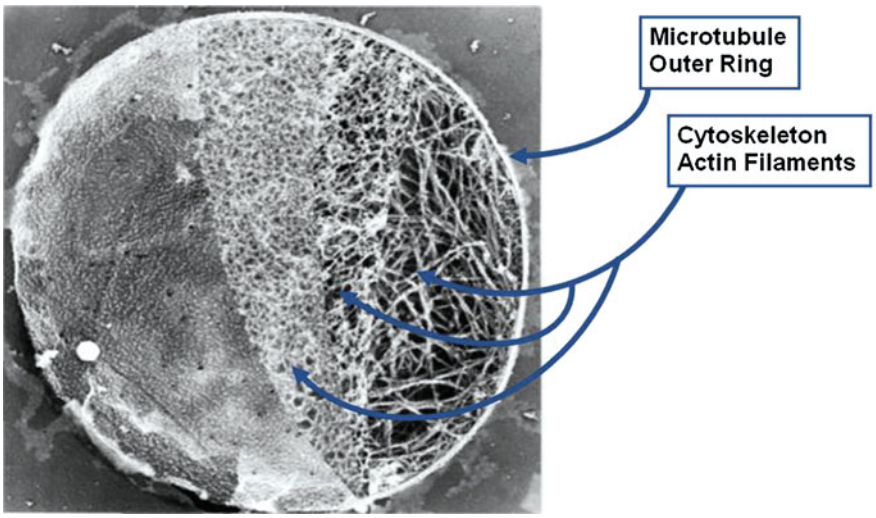

Figure 331.3

Platelet cytoskeleton. The cytoskeleton of the circulating discoid platelet is shown by electron micrograph. Immediately beneath the plasma membrane is a fine meshwork of filamentous actin which becomes more orthogonal and less dense deeper into the cytoplasm. An outer microtubule ring composed of a tubulin filament surrounds the platelet and contracts toward the center upon platelet activation and granular secretion

steps of the coagulation cascade are able to assemble on the platelet surface to generate a fibrin covering that anchors and protects the platelet plug. Accordingly, hemostasis is often divided into two phases: the primary phase in which platelets are localized to the wound by VWF and aggregated on top of the wound by fibrinogen, and a secondary phase in which the coagulation cascade (which is dependent on a "clottable"

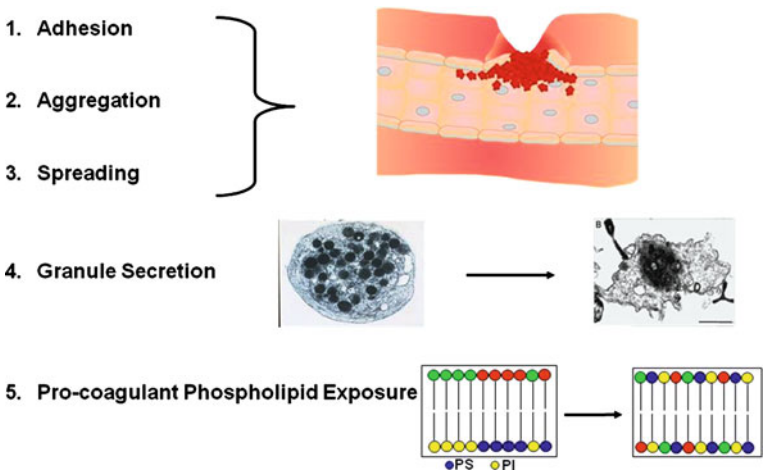

Figure 331.4

Multistep process of platelet activation. The process of platelet activation starts with platelet adhesion, aggregation, and spreading (Steps 1–3). Simultaneous central contraction of the microtubule ring with granule secretion as well as translocation of phophatidylserine [(PS) ''clottable'' phospholipid (Steps 4 and 5)] and ''non-clottable'' phosphatidylinositol (PI) are also illustrated

phospholipid surface provided by the localized, activated platelets) results in the activation of thrombin and the conversion of fibrinogen to fibrin.

Cytoplasmic Granules

Platelets also contain unique granules within their cytoplasm. These granules are of two distinct types: dense (or delta) granules and alpha granules. Dense granules are smaller than alpha granules and are composed mainly of calcium and magnesium ions, non-metabolic ATP and ADP, and the vasoconstrictive agent 5-hydroxytryptamine. Dense granules are composed chiefly of fibrinogen, Von Willebrand factor, P-selectin (an adhesion protein that is thought to play an important role in atherosclerosis), and platelet factor 4 (a homo-tetramer of uncertain function that is associated with heparin-induced thrombocytopenia). Both alpha and dense granules release their contents from the platelet cytosplasm after the platelet undergoes activation. During platelet activation, these granules merge with a specialized membranous system called the open canalicular system (OCS). The OCS is a complex membranous structure that is contiguous with the plasma membrane and serves as the pathway for transport of substances into the platelet and as conduits for the discharge of granule products secreted during the platelet release reaction (activation). Inherited deficiencies in platelet granule structure or function often result in mild to moderate bleeding disorders.

Adhesion Receptors: Von Willebrand Factor Receptor and Fibrinogen Receptor

Platelets express a number of important receptors on the plasma membrane surface that is essential for normal platelet function. These receptors can be grouped as adhesive, such as the fibrinogen and Von Willebrand factor receptors, or activating, such as the thrombin and collagen receptors. First the adhesive receptors will be discussed followed by the activating and other receptors. *Figure 331.5* shows a diagram of the major platelet receptors discussed below.

The Von Willebrand receptor is also known as platelet glycoprotein IB complex (gpIB). The complex is composed of two Ib-alpha, two Ib-beta, two gpV, and one gpIX polypeptides. This receptor complex is essential for localization of the platelet to the vascular defect and exposed sub-endothelium. Deficiencies of gpIB complex, known as Bernard–Soulier syndrome, have a severe lifelong bleeding disorder. A normal human platelet expresses about 25,000 gpIB receptor complexes. While gpIB is essential to localizing the platelet to the site of injury, it does not appear to have a major role in platelet activation. Accordingly, the gpIB-Von Willebrand factor interaction is critical but not sufficient for normal platelet function.

The other major adhesion receptor present on platelets is the glycoprotein IIB-IIIA complex (gpIIB-IIIA), also known as the fibrinogen receptor. This receptor complex, numbering about 50,000 copies per cell, is also

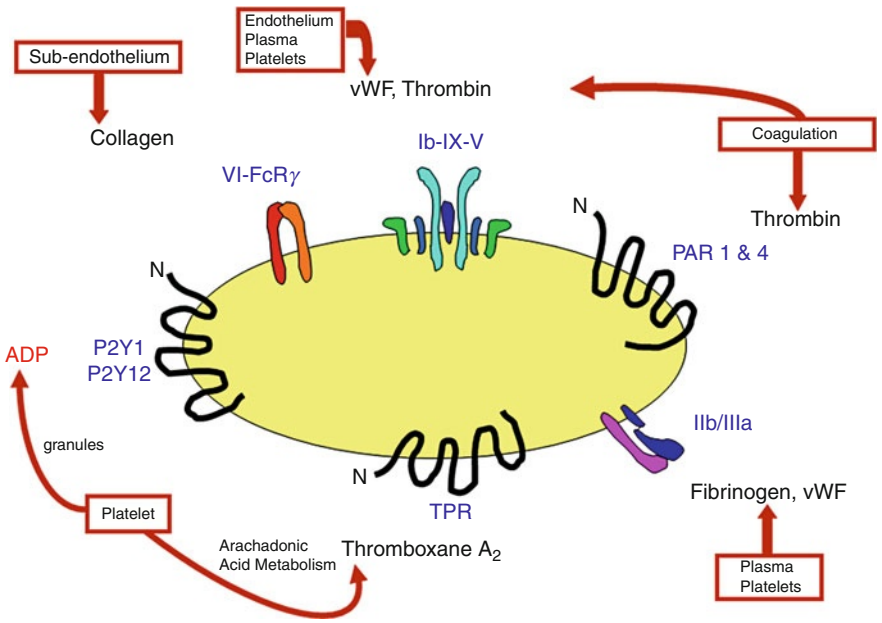

Figure 331.5

Platelet receptors. Representational view of platelet receptors is shown with their corresponding activating ligands. The most abundant receptors on the platelet surface are the adhesive receptors gpIIB-IIIA (50,000 copies/cell) and the gpIB complex (25,000 copies/cell). The other platelet receptors shown activate platelets by "priming" the gpIIB-IIIA receptor to bind fibrinogen

essential for normal platelet function. Accordingly, inherited deficiencies of gpIIB-IIIA, known as Glanzman's thrombasthenia, confers a lifelong bleeding disorder. The gpIIB-IIIA complex is a heterodimer, composed of one gpIIB and one gpIIIA polypeptide. The function of the gpIIB-IIIA complex is to aggregate platelets on top of the initial platelet plug. Once a thin layer of platelets is localized to the wound by the gpIB receptor complex and Von Willebrand factor, circulating fibrinogen binds to the platelet gpIIB-IIIA receptors, acting as a bridge between platelets. This aggregating step localizes more platelets to the site of injury and greatly strengthens the integrity of the platelet plug. Platelets that have not been sufficiently activated will not aggregate in the presence of fibrinogen. Accordingly, platelets must be "primed" by other platelet receptor agonists before they will aggregate. This platelet priming is sometimes referred to as inside-out signaling because it involves the release of intracellular calcium within the platelet cytoplasm in response to the priming step. The increase in intracellular calcium concentration causes a conformational change in the structure of the gpIIB-IIIA complex which allows tight binding with circulating fibrinogen. Thus, fibrinogen has two functions in normal hemostasis: It forms fibrin when digested by thrombin and it mediates platelet aggregation at the site of injury.

Nonadhesive Activating Receptors

There are several important activating receptors present on the platelet plasma membrane. These receptors "prime" the platelet by activating the gpIIB-IIIA receptor complex to bind fibrinogen, as discussed above. There are two major classes of receptor-activating agonists: weak and strong. For example, the thrombin receptor is a strong platelet agonist, while the epinephrine receptor is a relatively weak one. By weak or strong agonist, we mean the extent to which the agonist in question supports platelet aggregation through activation of the gpIIB-IIIA complex. What follows is a brief discussion about the major platelet-activating receptors and their corresponding agonists.

Thrombin is the most powerful physiologic platelet agonist known. Resting platelets exposed to physiologic concentrations of thrombin rapidly form aggregates in the presence of fibrinogen. Three distinct thrombin receptors have been characterized, two of which are present in human platelets. Thrombin receptors have thrombin recognition sequences and specific thrombin cleavage sites. When thrombin is present, the extracellular amino terminus of the receptor is cleaved by limited proteolysis. Cleavage of this amino terminus exposes a series of critical amino acid residues that results in activation of the

receptor and intracellular signaling which activates the receptor. Thrombin receptors are also known as protease-activated receptors (PAR). PAR1 is the most numerous and potent thrombin receptor and is the major pathway by which platelets respond to thrombin. Human platelets also express PAR4, a relatively weak platelet agonist with unclear physiologic significance. Treatment with thrombin inhibitors (e.g., argatroban, hirudin, and heparin) inhibits platelet activation because thrombin is such a potent platelet agonist. Thus, in addition to the decreased generation of fibrin afforded by heparin and the direct thrombin inhibitors, platelet activation by thrombin is also diminished. This may account, in part, for the success of heparin in the treatment of acute arterial thromboembolic settings such as an evolving myocardial or cerebral infarction. Heparin's antiplatelet properties also contribute to its usefulness in an adjuvant therapy with thrombolytics (tPA and *urokinase*) and angioplasty procedures in similar clinical settings.

Platelets also contain two types of adenosine diphosphate (ADP) receptors: the P2Y1 and P2Y12 receptors. ADP is considered a relatively weak platelet agonist relative to thrombin in that treatment of platelets in solution with varying concentrations of ADP results in about 50% the amount of platelet aggregation than with thrombin. ADP is present in the platelet dense granules and is also secreted by endothelium and other cell types. After a layer of platelets is localized by VWF to the site of vascular injury, more platelets must aggregate on top of the base layer for normal hemostasis to proceed. Accordingly, the platelet must be "primed" by an agonist in order for the gpIIB-IIIA complex to recognize and bind fibrinogen (as discussed above). Thrombin plays such a role since it is a very strong platelet agonist and is being generated simultaneously through tissue factor exposure and the coagulation cascade. However, circulating thrombin inhibitors and binding of thrombin to the endothelium and other cell types limit the ability for thrombin to completely sustain platelet aggregation in the absence of ADP. Clinical evidence of the importance of the ADP pathway is demonstrated by the fact that rare inherited abnormalities of the P2Y12 receptor confer a moderate bleeding disorder similar to that of moderate type I or II Von Willebrand disease. The drug clopidogrel, currently used to treat coronary and peripheral artery diseases, is a P2Y12 inhibitor. The P2Y1 receptor is a much weaker agonist than even the P2Y12 receptor, and has not been shown to directly result in the activation of the gpIIIB-IIIA receptor.

The thromboxane receptor is also considered a moderately weak platelet agonist. Thromboxane (TX2) is a prostaglandin that is produced from membrane-derived arachadonic acid after platelet activation. The production of TX2, like many other prostaglandins, is dependent on the activity of the membrane-bound enzyme *cycloxegenase 1* (COX1). Inherited deficiencies in TX2 synthesis or the thromboxane receptor are rare. These patients have mild to moderate lifelong bleeding disorders. Interestingly, analysis of their platelet function shows a deficiency in dense granule secretion, an observation that has been confirmed experimentally by inhibiting TXA2 receptor signaling.

The use of aspirin (salicylic acid) for the prevention and treatment of heart disease and stroke is based on its ability to irreversibly inhibit platelet COX1 by covalent modification of a key serine residue (Ser 529) that blocks entry of the eicosanoid substrate to the active site of the enzyme. Non-aspirin anti-inflammatory drugs (such as ibuprofen and the majority of other NSAID class members) also inhibit platelet COX1, but unlike aspirin these drugs do not covalently modify the enzyme. Accordingly, the antiplatelet effect of the NSAID group is reversible and dependent on the half-life of the particular drug.

The major collagen receptor present on the platelet plasma membrane surface is glycoprotein VI or gpVI. Compared to thrombin, collagen is considered a moderately weak platelet activator. Accordingly, treatment of platelets with collagen in solution results in an aggregation response similar to that of ADP. Inherited defects of gpVI are rare and confer a mild to moderate bleeding disorder. The function of the collagen receptor is to activate the platelets to aggregate after they have been localized to the vascular sub-endothelium by VWF and the gpIB receptor complex. It is important to keep in mind that the platelet gpVI is not an adhesion receptor, although it does bind collagen. Adhesion of the platelets to collagen is primarily mediated by VWF and gpIB. Once localized to the collagen surface, the interaction between collagen and gpVI results in the activation of gpIIB-IIIA and aggregation to form a stable primary platelet plug over the vascular defect.

Platelets undergo a relatively weak aggregation response when exposed to epinephrine through activation of the alpha-2 adrenergic receptor. The activation of gpIIB-IIIA, and hence platelet aggregation in response to alpha-2-andrenergic receptor activation, is heavily dependent on the synthesis of TXA2 (thromboxane) and signaling through the TXA2 receptor. TXA2 is synthesized from arachadonic acid present in the plasma membrane as a result of intracellular signaling by the alpha-2-andrenergic receptor through the COX1 pathway. As a result of this TXA2-dependent aggregation in response to epinephrine, platelets that have been exposed to aspirin (or other NSAIDs that inhibit COX1 activity) do not aggregate

normally in response to epinephrine. For this reason, epinephrine is often used as an agonist in clinical platelet aggregation studies.

Another weak platelet agonist is 5-hydroxytryptamine (serotonin), a constituent of the platelet dense granules. The corresponding receptor present on platelets is the 5HT2A isoform. Platelets do not synthesize serotonin but actively transport it into the dense granules by endocytosis in a process that is inhibited by selective serotonin uptake inhibitor drugs (SSRIs). With the widespread use of SSRI, there was concern that diminished activation of platelets by the decreased concentration of serotonin in the dense granules might cause bleeding due to platelet dysfunction. However, there does not appear to be an increased risk of bleeding or thrombosis associated with the use of SSRI medications.

Platelet Function

As mentioned in the introduction, platelet localization to site of a vascular injury is essential for normal hemostasis. Patients with platelet disorders or defects in the localization of platelets to the site of injury have mild to severe bleeding. On the other hand, activation of platelets near or on the site of a vascular atherosclerotic plaque (such as might occur in the setting of an acute myocardial infarction or stroke) is the leading cause of death in the modern industrialized world. Platelets are also important for normal wound healing and have been associated with the infectivity of malaria and other infections as well as the process of cancer metastasis. As a result of these observations, there is a great deal of interest in the physiology of platelet function. What follows is primarily a description of the role platelets play in normal hemostasis.

When a vessel is disrupted to cause bleeding, there is an almost instantaneous constriction of the lumen of the vessel near the injury site by reflex neurological pathways and the local release of vasoconstrictive substances. This vasoconstriction and the mechanical damage to the vessel wall and surrounding tissues results in a disruption of laminar blood flow and produces high shear forces at the site of injury. At the same time, the injured tissue exposes collagen, which is a main constituent of the basement membranes of almost every imaginable blood vessel. The high shear forces result in a conformational change in the structure of VWF from a globular to a linear configuration. In the linear configuration, the VWF is able to recognize and bind collagen and tether the platelet to the site via binding to gpIB, the VWF receptor complex. The exposed collagen also results in the activation of gpVI, the platelet collagen receptor. Signaling via gpVI results in the activation of the fibrinogen receptor, gpIIB-IIIA and platelets aggregate on top of the VWF bound platelets. Signaling through gpVI also results in the synthesis of TXA2 and release of ADP, epinephrine, and 5-hydroxytryptamine by the platelet dense granules. The effect of this "second wave" of platelet activation after localization by VWF and activation by collagen is to further strengthen the aggregation response. In fact, the activation of platelets to aggregate is a very redundant system such that defects in one component or another are unlikely to cause major bleeding [with the notable exception of disorders involving gpIIB-IIIA (Glanzman's thrombasthenia), gpIB (Bernard–Soulier disease), or the absence of VWF (type III Von Willebrand's disease)]. Tissue factor, which initiates the extrinsic pathway of coagulation when it binds factor VIIa, is also expressed by the injured endothelial cells and circulating monocytes which are localized to the site of the vascular injury. Tissue factor binding to circulating factor VIIa results in an initial burst of thrombin generation. Since thrombin is the most powerful physiologic activator of platelets to undergo aggregation, its production at the site of injury is critical to insure the adequate recruitment of platelets to form a platelet plug. Thrombin also activates fibrinogen to form a tough fibrin layer over the surface of the aggregated platelets. Accordingly, thrombin provides a key link between the primary phase of hemostasis, in which the platelets are localized and aggregated to the site of vascular injury, and the secondary phase of hemostasis, in which the coagulation proteins form fibrin.

Platelet function, as indicated in the preceding sections, involves more than plugging up a defect. The platelet membrane and cytoskeleton also undergo dramatic changes upon adhesion and activation. The platelet membrane changes its phopholipid distribution so that the high levels of "clottable" phophatidylserine and phosphatidylethanolamine appear on the outer leaflet of the plasma membrane. These membrane changes are essential to the localization of the clotting cascade protein complexes (*tenase* and *prothrombinase,* see above) and the efficient formation of thrombin and fibrin. The circulating discoid platelet also spreads and flattens over the vascular defect as a result of intracellular signaling pathways which rearrange the actin cytoskeleton filaments in an orthogonal configuration, with bundles of fibers composed of filamentous actin and myosin (stress fibers) arranged in a pattern connecting adjacent gpIIB-IIIA adhesion points (focal adhesions). The result is a firmly attached platelet plug covered by a thick fibrin meshwork.

Once the platelet forms a plug over the vascular defect that is anchored and covered with fibrin, clot retraction

must then occur for normal wound healing to take place. The platelet-dependent process of clot retraction is poorly understood, but is an energy-dependent process in which the actin–myosin stress fibers contract in a manner similar to striated muscle. This filamentous contraction by the platelet brings the margins of the wound together and facilitates tissue repair with the recruitment of epithelium, fibroblast, and other cells. This process of clot retraction is distinct from thrombolysis, which involves the digestion of fibrin, though both processes overlap with respect to timing and their importance in normal wound healing.

Platelet Disorders

Platelet disorders are broadly grouped according to whether they are acquired or hereditary. Acquired platelet disorders will be covered first, followed by a brief discussion of selected hereditary disorders. *Table 331.1* summarizes the acquired and hereditary platelet disorders discussed below.

Acquired Platelet Disorders

Platelet function deficiencies can be acquired or hereditary. Most are acquired and due to drugs such as aspirin, which inhibits platelet function by interfering with COX1 activity (see above). Other mechanisms of drug-induced platelet dysfunction result from thrombocytopenia. Drug-induced thrombocytopenia is difficult to diagnose as many drugs are rare causes of thrombocytopenia that must be excluded by the largely empirical process of elimination of other causes. Severe thrombocytopenia soon after the start of a medication is the most straightforward presentation of drug-induced thrombocytopenia. For example, drugs such as the antibiotic vancomycin result in rapid immunologic clearance of platelets in some individuals. The mechanism of vancomycin-induced thrombocytopenia is due to antibody formation to the complex of vancomycin associated with the adhesive platelet receptor gpIIB-IIIA. Quinine may also cause an immune-mediated severe thrombocytopenia. In general, drug-induced immune thrombocytopenia resolves within a week or two of stopping the drug but may recur when the drug is reintroduced. Other drugs such as thiazide diuretics and some of the earlier NSAIDs which are not commonly used such as phenylbutazone and antineoplastic agents can cause amegakaryocytic thrombocytopenia. Treatment involves stopping the offending medication and supporting the patient with platelet transfusion as necessary to prevent or treat bleeding. In the setting of acute myocardial infarction or after revascularization procedures, gpIIB-IIIA antagonists have proved very effective at reducing the rate of post-revascularization thrombosis. These antagonists are powerful antiplatelet agents that directly interfere with the binding of fibrinogen to gpIIB-IIIA, and hence stop platelet aggregation. These drugs are never administered outside the intensive care setting with close monitoring because of the high risk of bleeding. The gpIIB-IIIA antagonists are usually stopped within 24 h after the revascularization procedure. These drugs are available as an antibody (abciximab) or as small molecules (tirofiban, eptifibatide). The major side effect is thrombocytopenia and bleeding. The thrombocytopenia is characterized by the appearance of clumps of aggregated platelets on the peripheral smear together with a falling

Table 331.1
Acquired and hereditary platelet disorders. Selected examples of common acquired and hereditary platelet disorders are shown with the primary mechanisms of platelet malfunction. See text for details

	Disorder	Mechanism of platelet dysfunction
Acquired	Drugs	Decrease production
		Immune clearance
	Liver disease	Decreased production
		Increased sequestration
		Membrane defects
	Vitamin B12 and folate	
	Deficiencies	Decreased production
	Marrow stem cell disorders	Decreased production
		Structural defects
	ITP	Immune clearance
	Microangiopathic anemias	Platelet activation and consumption
Inherited	Membrane defects	Bernard–Soulier (gpIB)
		Glanzman's (gpIIB-IIIA)
	Storage pool disease	Alpha granule and dense granule
	Macrothrombocytopenia	May–Hegglin anomaly

platelet count. The treatment is to stop the drug as soon as possible and consider administering platelet transfusions if there is bleeding or the platelet count is less than 50,000/μl.

Most drug-induced platelet disorders involve the occurrence of thrombocytopenia and bleeding with the notable exception being heparin-induced thrombocytopenia (HIT) or type II heparin-induced thrombocytopenia. In this case, the offending drug, unfractionated heparin, causes a platelet activation syndrome with a high risk of intravascular clotting. HIT usually develops within 4 days to 2 weeks of initiating unfractionated heparin with the onset of mild to moderate thrombocytopenia and often life-threatening venous and/or arterial thrombosis. The mechanism appears to be the formation of endogenous IgG antibodies to standard heparin in complex with platelet factor 4 (PF4). This antibody-heparin-PF4 complex activates platelets by associating with the FCR-gamma receptor present on the surface of the platelet plasma membrane. The FCR-gamma receptor is normally paired with the collagen receptor gpVI, where it functions as a moderately weak platelet agonist. However, when the FCR-gamma receptor is activated by the antibody-heparin-PF4 complex, the platelet aggregation response is similar to thrombin – the strongest physiological platelet agonist. Patients who develop thrombocytopenia within 2 weeks of starting unfractionated heparin demonstrate anti-PF4 antibodies in their serum and whose plasma confers brisk platelet aggregation in the presence of heparin are considered to have HIT. The treatment for HIT is to stop all heparin infusions of any kind. Furthermore, due to the risk of thrombosis in the setting of HIT, patients are treated with a non-heparin anticoagulant such as the direct thrombin inhibitors argatroban or hirudin until the platelet count returns to normal. If the patient with HIT has a thrombosis, heparin-free anticoagulation is maintained for at least 3 months.

There are many other causes of acquired thrombocytopenia which are often grouped according to whether the mechanism is due to decreased production, increased destruction, or sequestration. The most common cause of decreased platelet production (after drug toxicity) is liver disease. Hepatic dysfunction results in thrombocytopenia because of diminished thrombopoietin production by hepatocytes and synthetic membrane defects which shorten the circulating life of the platelet. Hypersplenism with increased platelet sequestration is also commonly associated with liver disease. Vitamin B12 and folate deficiencies are also important causes of thrombocytopenia due to poor platelet production. Finally, bone marrow stem cell disorders such as myelodysplasia, aplastic anemia, and acute and chronic leukemia adversely affect the production of megakaryocytes and the process of thrombopoiesis. Thrombocytopenia due to increased peripheral destruction is most commonly seen in immune disorders such as idiopathic thrombocytopenic purpura (ITP) and rheumatologic disorders.

ITP is an immune disorder that results in the clearance of platelets from the circulation by antibodies formed against platelet surface antigens. The most common target of the platelet autoantibodies is the gpIB receptor complexes; however, other platelet surface proteins and receptors have also been reported as targets. The mechanism behind the formation of these platelet autoantibodies is unclear. However, ITP is associated with low-grade lymphoproliferative disorders such as CLL as well as other immunological disorders such as AIDS. Interestingly, in children, ITP is almost always a self-limited disease, while in adults, the disease is almost always chronic or relapsing. While ITP can result in very low platelet counts, life-threatening spontaneous bleeding such as intracranial hemorrhage occurs in less than 1% of patients. Treatment of acute episodes of ITP in the adult or child usually includes immunosuppression agents. The first line of therapy is usually corticosteroids, which increases the platelet count to normal levels in about two thirds of patients. A favorable response to corticosteroids is associated with an increased chance of cure with splenectomy in adult patients. Patients who do not respond to corticosteroids are sometimes treated with the anti-CD20 monoclonal antibody rituximab. High-dose intravenous immune globulin and anti-Rh antibodies (Rho-D) can be used successfully to rapidly increase the platelet count within a day or two, but these medications usually result in short-lived remissions and are expensive. Because of the relatively low incidence of spontaneous bleeding in patients with ITP and the relatively high toxicity of the immunosuppressive drugs used to treat the disorder, patients are often left untreated if they maintain a platelet count of at least 30,000/μl. For patients with lower platelet counts or bleeding who have chronic ITP, thrombopoietin (TPO) is now available. There are two TPO preparations currently manufactured: one is taken orally on a daily basis and the other is given as a weekly subcutaneous injection. These TPO preparations have about a 90% response rate and are generally well tolerated. However, the thrombocytopenia returns when TPO is discontinued and long-term studies regarding the safety of these drugs is ongoing.

Other important platelet destructive or consumptive disorders are the microangiopathic hemolytic anemias, thrombocytopenic thrombotic purpura (TTP), disseminated intravascular coagulation (DIC), and the hemolytic-uremic

syndrome (HUS). These disorders are characterized by microvascular thrombosis and thrombocytopenia due to systemic activation of platelets by ultra-large VWF (TTP and HUS) or by thrombin (DIC). These are life-threatening disorders with high mortality rates. Treatment of DIC and HUS involves addressing the underlying cause, which is often infection or malignancy. Successful treatment of TTP involves daily plasma exchange until the platelet count reaches normal levels. DIC and HUS do not respond to plasma exchange. About one third of patients diagnosed with TTP have a chronic relapsing form of the disease and must be treated with immunosuppression and plasma exchange at regular intervals. TTP treatment is best done at a major medical facility with the resources to perform plasma exchange and physicians with expertise in plasma exchange and blood banking.

Inherited Platelet Disorders

There are many rare familial platelet disorders that occur in isolated families. While these disorders are of scientific interest, they are rarely encountered by most physicians. Inherited disorders are grouped according to whether they involve membrane defects, disorders of granules, or macrothrombocytopenia.

The most important membrane defects are those which involve the adhesion receptors gpIB and gpIIB-IIIA, known as Bernard–Soulier syndrome and Glanzman's thrombasthenia. These disorders, like almost all inherited platelet disorders, are autosomal recessive in their inheritance pattern. Multiple genetic mutations in the genes coding for these disorders have been reported. Homozygous mutations result in severe, lifelong bleeding disorders. In the heterozygous state, these patients usually have mild bleeding disorders characterized by excessive post-traumatic bleeding. The diagnosis is usually suspected when the patient's platelets fail to aggregate in response to weak or strong agonists and confirmed by platelet flow cytometry using antibodies which recognize the corresponding surface receptors. Treatment for these disorders with platelet transfusions usually results in the development of allo-immunization or antibodies against the receptor. Recombinant factor VIIa has been used successfully to prevent perioperative and post-traumatic bleeding. Bone marrow stem cell transplantation would provide definitive treatment, but the mortality rate is unacceptably high with this therapy.

Platelet granule disorders, also known as platelet storage pool disease, encompass a range of disorders with variable reduction in the concentration and structure of dense granules, alpha granules, or both. These disorders are generally inherited in an autosomal-recessive pattern. The most common of these disorders is dense granule deficiency. These patients all have a mild to moderate bleeding disorder, characterized by bleeding when challenged by trauma or surgery. The formation and secretion of granules is a complex process involving many genes. Accordingly, the specific genetic mutations that cause platelet storage pool disease are largely undetermined. The diagnosis is made by analysis of platelet structure with electron microscopy or by flow cytometry using chemical probes that specifically recognize platelet granules. Treatment involves the appropriate use of DDAVP, antifibrinolytics such as epsilon aminocarproic acid or tranexamic acid, and platelet transfusions.

The macrothrobocytopenias are rare disorders that usually involve multiple inherited birth defects together with large platelets and thrombocytopenia. These patients generally have mild bleeding disorders, with most episodes of bleeding occurring after trauma or surgical procedures. The most common macrothrombocytopnenia is the May–Hegglin anomaly, a disorder that affects only leukocytes and platelets. The peripheral blood smear is often suggestive of this disorder because of the prevalent appearance of leukocyte cytoplasmic inclusion bodies and large platelets with mild thrombocytopenia.

Some specific genetic mutations have been found which account for a subset of May–Hegglin patients. These tests are available through specialized genetic laboratories.

Summary

Blood platelets have several important functions. They adhere to sites of vascular injury and spread over the defect, secrete their procoagulant granular contents, and serve as a "clottable" surface upon which coagulation can occur. Accordingly, platelets are essential for normal hemostasis, and patients with acquired or inherited defects in platelet function have mild to severe bleeding. The diagnosis and classification of platelet disorders is complex and often requires the assistance of specialized regional laboratories capable of ultrastructural analysis, DNA sequencing, and platelet function testing. Treatment for bleeding disorders in patients with platelet defects is variable, and may involve platelet transfusion, antifibrinolytic medications, recombinant factor VIIa, DDAVP, and cryoprecipitate.

332 The Phagocytic System

Hassan El Solh · Abdallah Al-Nasser · Saleh Al-Muhsen

Function and Morphology of the Phagocytic System

Phagocytes play a critical role in the initial response to infections with bacteria and fungi. They follow certain immune responses in order to combat and clear the infection. They adhere to the endothelial wall and subsequently migrate to the site of infection (chemotaxis). Once they ingest the pathogen (phagocytosis), they kill via different mechanisms including oxidative burst, proteases, and other toxic peptides. The phagocytes are also involved in the production of cytokines and other cellular mediators that participate in the inflammatory response. In addition, they contribute to the recognition of certain pathogens (opsonization or coating objects with certain proteins). Phagocytes originate within the bone marrow and move into the circulation (mobilization), and then exit to sites of inflammation (chemotaxis).

The phagocytic system consists of monocytes (mononuclear), neutrophils (polymorphonuclear), and eosinophils. Neutrophils and monocytes share many morphologic and functional characteristics. They originate from the same stem cell progenitors in the bone marrow. The proliferation and differentiation into mature leukocytes require stimulation by a variety of cytokines: interleukins and lineage-specific cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (GCSF), and macrophage colony-stimulating factor (M-CSF). The neutrophils have nuclei with three to five segments and constitute the predominant type of phagocytes. Monocytes are characterized by their large size with lobulated nuclei and azurophilic granules. The eosinophils are distinguished by large red granules and are involved in the inflammatory and parasitic reactions.

Disorders of the Phagocytic System

The phagocytic disorders can be classified to abnormality in number, function, or both. Affected patients typically present with recurrent and severe bacterial and fungal infections in early childhood. Respiratory tract and skin dominate the affected organs. However, deep-seated abscesses and oral stomatitis are commonly encountered. In the last few decades, our knowledge of the phagocytic disorders has clearly been revolutionized by the discovery of the underlying molecular defects in many clinical phenotypes, largely through international collaborations. However, many remain to be identified. Nevertheless, addressing the details of all known phagocytic disorders is beyond the scope of this chapter and the most common disorders of the phagocytic system will only be discussed.

Abnormality in the Number of Phagocytes

Neutropenia

Neutropenia is defined as an absolute decrease in the number of circulating neutrophils in the peripheral blood. Neutropenia is considered severe if the absolute neutrophil count (ANC) is less than 0.5×10^9 cells/L, moderate if the ANC is $0.5–1.0\times10^9$ cells/L, and mild if the ANC is $1.0–1.5\times10^9$ cells/L. Neutropenia can be classified based on pathophysiology (disorders of production, maturation, or peripheral utilization) or on intrinsic defects in the myeloid progenitors as compared to extrinsic factors to the bone marrow, causing acquired neutropenia (*Table 332.1*).

Congenital Neutropenia (CN)

Severe congenital Neutropenia (SCN) is a heterogeneous group of primary immune deficiency diseases conferring susceptibility to infections due to lack of neutrophils. It follows different mendelian inheritance, including autosomal dominant (AD), autosomal recessive (AR), and X-linked. There are some sporadic cases. Moreover, many syndromes are associated with severe neutropenia. SCN classically presents with persistent low neutrophil counts with typical myeloid maturation arrest at the level of promyelocytes in bone marrow studies. Recent discoveries have elucidated the underlying molecular defect of many SCN phenotypes.

Drug-induced neutropenia
Autoimmune neutropenia
Isoimmune neutropenia

Non-syndromic SCN

AD and Sporadic ELA2 Defect The most common form of SCN is caused by mutation in *ELA2*, the gene encoding neutrophil elastase. This disease presents as autosomal dominant or in a sporadic pattern. A subgroup of patients with the ELA2 mutation presents in an oscillatory cyclic pattern with a nadir every 3 weeks, giving rise to what is known as "Cyclic Neutropenia" with subsequent periodicity of clinical manifestations, including bacterial infections and stomatitis. Patients with cyclic neutropenia usually have a mild phenotype; however, death occurs in 10% due to overwhelming infections during the neutropenic nadir. Patients harboring the ELA2 mutation have a higher risk of myloid dysplasia and leukemia associated with somatic mutation in the granulocyte colony-stimulating factor receptor (GCSFR) gene.

AR: Kostmann Syndrome Although this is the classical autosomal recessive SCN that was described more than 50 years ago by Kostmann, the underlying molecular defect was only recently identified with a deficiency in HAX1, leading to increased apoptosis of myeloid cells. Patients might present with neurological abnormalities.

Other Rare Non-syndromic SCN These include X-linked neutropenia caused by mutation in *WAS*, the gene encoding Wiskott–Aldrich Syndrome protein and *GFI1*, a transcriptional repressor and splice control factor of the zinc-finger family of transcription factors with similar clinical presentation to common SCN.

Congenital Neutropenia Associated with Syndromic Features

Reticular Dysgenesis This is an autosomal recessive disease characterized by severe neutropenia and lymphopenia, resembling severe combined immune deficiency. The underlying molecular defect has been recently identified by mutations in the gene-encoding mitochondrial adenylate kinase 2. Patients usually die soon after birth with overwhelming infection in the early neonatal period unless offered hematopoietic stem cell transplantation. Bone marrow studies typically reveal arrest in myeloid differentiation at the promyelocytic stage, whereas erythrocytic and megakaryocytic maturation is generally normal.

Congenital Neutropenia with Hyperpigmentation Chediak–Higashi Syndrome (CHS) and Griscelli syndrome type 2 are associated with transient neutropenia and abnormal skin pigmentation. Hermansky–Pudlak syndrome type 2 (HPS2) and p14 deficiency are two other syndromes associated with abnormal pigmentation and neutropenia that is persistent. HPS2 consists primarily of hypopigmentation and prolonged bleeding times due to defective platelet granules. Patients with P14 deficiency may present with other features, including short stature, hypogammaglobulinemia and reduced numbers of B-cell subsets, and defective function of cytotoxic T cells. In contrast to the SCN, the bone marrow studies in all these four syndromes show normal maturation of the neutrophils. In CHS, GS2, and P14 deficiency, the abnormality is due to low levels of neutrophils and their impaired killing ability.

Congenital Neutropenia Associated with Glycogen-Storage Disease (GSD) Patents with GSD1b are not only characterized by abnormal glycogen storage, hypoglycemia, and lactic acidosis, but also demonstrate congenital neutropenia. This disease is caused by mutations in the

glucose-6-phosphate translocase (G6PT, encoded by the gene SLC37A4), a transporter mediating translocation of G6P into the endoplasmic reticulum.

Another glucose metabolic disease was recently described, where, in addition to congenital neutropenia, patients may present with various congenital defects of the cardiovascular and/or urogenital system and increased visibility of superficial veins. It is caused by a defect in G6PC3.

WHIM Syndrome (Warts, Hypogammaglobulinemia, Immunodeficiency, Myelokathexis) WHIM is a rare autosomal dominant disease caused by mutation in the chemokine receptor gene *CXCR4*. It is characterized by multiple warts and hypogammaglobulinemia. Myelokathexis indicates dysregulated granulopoiesis which includes hypersegmentation and increased apoptosis. Severe infections are not typical because of the adequacy of neutrophils in the circulation during infection.

Shwachman–Diamond Syndrome This is a rare autosomal recessive disorder, characterized by exocrine pancreatic insufficiency, skeletal abnormalities, bone marrow dysfunction, and recurrent infections. Almost all patients suffer intermittent or cyclic neutropenia. Pancytopenia occurs in 25% of patients. Patients are at higher risk of bone marrow aplasia, myelodysplasia, and leukemia.

Dyskeratosis Congenita This is an X-linked recessive disorder characterized by nail dystrophy and skin hyperpigmentation. Some patients have marrow hypoplasia, and others (one third) have neutropenia.

Neutropenia Associated with T- and B-Lymphocyte Abnormalities Neutropenia has been described in severe combined immunodeficiency diseases, common variable immunodeficiency, agammaglobulinemia, and typically with hyper IgM syndrome, especially CD40 deficiency

Acquired Neutropenia

Bone Marrow Replacement

Neoplasms infiltrating the bone marrow induce neutropenia. Leukemia and lymphoma are the most common neoplasms that can cause neutropenia. Other disorders, such as osteopetrosis, myelofibrosis, and myelodysplastic syndrome, can result in severe neutropenia and pancytopenia.

Infection

Viral infection is the most common cause of transient neutropenia in children. Epstein–Barr virus, influenza A and B, measles, hepatitis A and B, respiratory syncytial virus, rubella, and varicella are noted to induce neutropenia. Other infections, such as typhoid, paratyphoid, tuberculosis, brucellosis, malaria, and rickettsial infections, can induce neutropenia through different mechanisms.

Ineffective Granulopoiesis due to Nutritional Deficiencies

Megalobalstic anemia secondary to nutritional deficiencies of folic acid or vitamin B12 has been associated with neutropenia.

Neutropenia Associated with Metabolic Diseases

Neutropenia can occur in children with metabolic disorders due to impairment of proliferation and differentiation of myeloid cells. These disorders include hyperglycinemia, propionic acidemia, methylmalonic acidemia, glycogen-storage disease type IB, and isovaleric acidemia.

Drug-Induced Neutropenia

The underlying cause of neutropenia associated with certain drugs is unclear. However, damage to the microenvironment of the bone marrow and/or immune-mediated destruction of neutrophils are the most likely mechanisms. The list of drugs reported to cause neutropenia includes antibiotics such as sulfonamides and penicillins; phenothiazines; antipyretics such as aspirin, acetaminophen, phenybutazone; anti-inflammatory agents such as penicillamine, levamisole, gold; and sedatives such as benzodiazepines and barbiturates.

Autoimmune Neutropenia

Patients may develop antineutrophil antibodies, causing rapid removal of neutrophils by the reticuloendothelial system. These patients may have recurrent infections and frequent hospitalizations. Therapy with corticosteroids has been shown to improve the neutrophil count in 50% of patients. High-dose intravenous immunoglobulin or splenectomy has been tried, but their efficacy is still unproven.

Isoimmune Neutropenia

Neutropenia occurring in the neonatal period can be due to neutrophil antibodies crossing the placenta from the mother after sensitization to the fetal neutrophil antigens. Usually, by the age of 7 weeks, the neutrophil count becomes normal.

Approach to Diagnosis and Therapy of Neutropenia

The diagnostic approach to neutropenia should focus through the history and physical examination on the

following: duration, frequency, site, and severity of infection; family history; recent viral infection; medications; dysmorphic features; lymphadenopathy; and hepatosplenomegaly. Patients should have white blood cell counts and differentials twice per week for 6 weeks to evaluate the possibility of cyclic neutropenia. Patients with persistent neutropenia should undergo a bone marrow aspiration and biopsy for detecting malignant disorders and congenital etiologies. Antineutrophil antibody may be helpful to detect immune-mediated neutropenia. The Rebuck skin window test can assess neutrophil mobilization. The steroid mobilization test evaluates the storage pool size. Immunologic evaluation can detect immune deficiency disorders. Plasma and urine amino acid screening can be helpful in the diagnosis of metabolic diseases associated with neutropenia. Chromosomal studies can establish the diagnosis of Fanconi anemia. Exocrine pancreatic function tests can detect Shwachman syndrome.

In spite of improvement in antibiotic therapy and supportive care, infections and septicemia are still a major cause of morbidity and mortality. A patient with severe neutropenia presenting with a febrile illness has at least a 60% chance of having a bacterial infection. Accordingly, broad-spectrum antibiotics to cover gram-positive (especially Staphylococcus) and gram-negative organisms should be started immediately. Blood, urine, and, if indicated, throat and sputum cultures should be done, and the appropriate radiologic imaging should he performed. Patients should receive antibiotics for a few days (duration to be determined by the clinical course, results of cultures, and neutrophil levels). If the patient continues to be febrile for more than 5–7 days in spite of adequate antibiotic coverage, then antifungal therapy should be initiated empirically. Patients with proven bacterial or fungal sepsis may benefit from granulocyte transfusions if they are still neutropenic, especially for critically ill patients, although this still has not been studied in a randomized trial. Caution should be taken regarding transmission of infections such as hepatitis, toxoplasma, and cytomegalovirus. Also, there is a potential risk for pulmonary toxicity and transfusion-associated graft-versus-host disease. Patients with immune-mediated neutropenia may respond to steroid therapy. Cytokines, such as granulocyte colony stimulating factor (GCSF), have been instrumental in improving the outcome of many congenital neutropenia. In fact, before the GCSF era, most patients affected by the SCNs succumbed to severe sepsis. Since its introduction into the clinical practice, the morbidity and mortality of infection have decreased significantly. In spite of all this supportive therapy, the definite cure is only possible by hematopoietic stem cell transplantation in most SCNs.

Neutrophilia

When the ANC exceeds 7.5×10^9 cells/L, patients can be considered to have neutrophilia. Neutrophilia can occur as a result of any one or a combination of the following: increased production, enhanced release from marrow storage pool, decreased exit from the circulation, and reduced margination. *Table 332.2* lists possible etiologies of neutrophilia.

Eosinophilia

Allergic disorders are the most common cause of eosinophilia in the developed countries, and parasitic infections account for a large proportion of patients with esoinophilia in the developing countries. Other causes include tumors such as Hodgkin disease, and hypereosinophilic syndromes (eosinophilic leukemia and Löffler syndrome).

Basophilia

Hypersensitivity reactions are the most common cause of basophilia. Other disorders that are associated

Steroids
Decreased exit from circulation
Splenectomy

with basophilia include ulcerative colitis, rheumatoid arthritis, chronic renal failure, tuberculosis, and myeloproliferative disorders.

Monocytosis

In malignant hematologic disorders such as preleukemia, juvenile chronic myeloid leukemia, and lymphoma are associated with monocytosis. Other causes include infections such as tuberculosis, bacterial endocarditis, and granulomatous diseases.

Disorders of the Phagocyte Morphology

Morphologic Variations in Neutrophils

These disorders affecting the morphology of neutrophils include nuclear as well as cytoplasmic abnormalities.

1. *Pelger–Huet Anomaly.* Neutrophils of patients with this anomaly have a limitation of segmentation of the nucleus to two lobes. The disorder is inherited as an autosomal dominant trait; however, it can he acquired in infections such as mycoplasma and malaria or in malignant diseases such as leukemia or lymphoma.
2. *Hereditary Hypersegmentation of Neurophils.* This is a benign condition characterized by hypersegmentation of the nucleus in the neutrophil into four to five lobes.
3. *Prevalence of Nuclear Appendages.* In women, nuclear appendages (female specific) are present in about 2–10% of neutrophils. An excessive number of appendages may be present in trisomy 13–15.
4. *Vacuolization.* Cytoplasmic vacuolization has been noted in neutrophils in association with infections and burns.
5. *Alder-Reilly Anomaly.* Prominent granules in neutrophils are present in Hurler syndrome. Other cells, such as monocytes and lymphocytes, may have similar granules.
6. *Chédiak–Higashi Syndrome.* The neutrophils and other leukocytes of patients with Chédiak–Higashi syndrome contain giant granules.
7. *Hermansky–Pudlak Syndrome.* This is an autosomal recessive disorder characterized by albinism and increased bleeding tendency due to platelet dysfunction. The macrophages in the bone marrow have ceroid-like pigment.
8. *May–Hegglin Anomaly.* This disorder is characterized by thrombocytopenia with giant platelets. There are pale blue inclusions present in neutrophils, eosinophils, monocytes, and basophils. It has an autosomal dominant inheritance.

Abnormality in the Function of Phagocytes

Abnormal function of phagocytes may occur at any step involved in the process of engulfment and destruction of foreign particles described at the beginning of this chapter (*Fig. 332.1*).

Disorders of Adhesion

Leukocyte Adhesion Deficiency (LAD)

LAD is a heterogeneous group of disorders characterized by impairment of adhesion or chemotaxis of leukocytes to the site of infection. It is inherited as an autosomal recessive disorder. LAD-I is the most common and is caused by lack of glycoprotein molecules, the α subunits of the β2 integrin (CD18) shared by LFA-1 (CD11a), MAC-1 (CD11b), and P 150, 95 (CD11c).

Patients present with severe infections early in infancy without pus formation. They also have impaired wound healing manifesting early as delayed separation of the umbilical cord and omphalitis. Severe periodontitis, cellulitis, ulcerative skin lesions, and pneumonia are typical manifestation. Due to impaired trafficking of leukocytes, patients have an elevated peripheral neutrophil count. Flow cytometry using monoclonal antibodies to detect expression of the subunits of the β2 integrin can provide the diagnosis. The treatment of LAD should focus on the management of infections using appropriate antimicrobial therapy. Trimethoprim-sulfamethoxazole can be used for prophylaxis, and adequate oral hygiene is very important to prevent recurrent infections. Hematopoietic stem cell transplantation is the only modality which may provide definite cure in LAD.

LAD-II is caused by mutations in a GDP-fucose transporter. It was initially reported in two boys of Arab origin causing lack of expression of Sialyl Lewis^X, the ligand for E-selectin with subsequent impaired rolling of the leukocyte along the endothelium. In addition to the clinical manifestations of LAD-I, patients with this defect have short stature, facial dysmorphism, mental retardation, and Bombay blood-type phenotype due to generalized defect of fucose metabolism.

LAD-III is caused by a mutation of kindlin-3, which is involved in integrin signaling. Patients may have bleeding tendency due to impaired platelets adhesion.

A very rare clinical phenotype resembling LAD-I has been described with a mutation in Rac2 GTPase. It is

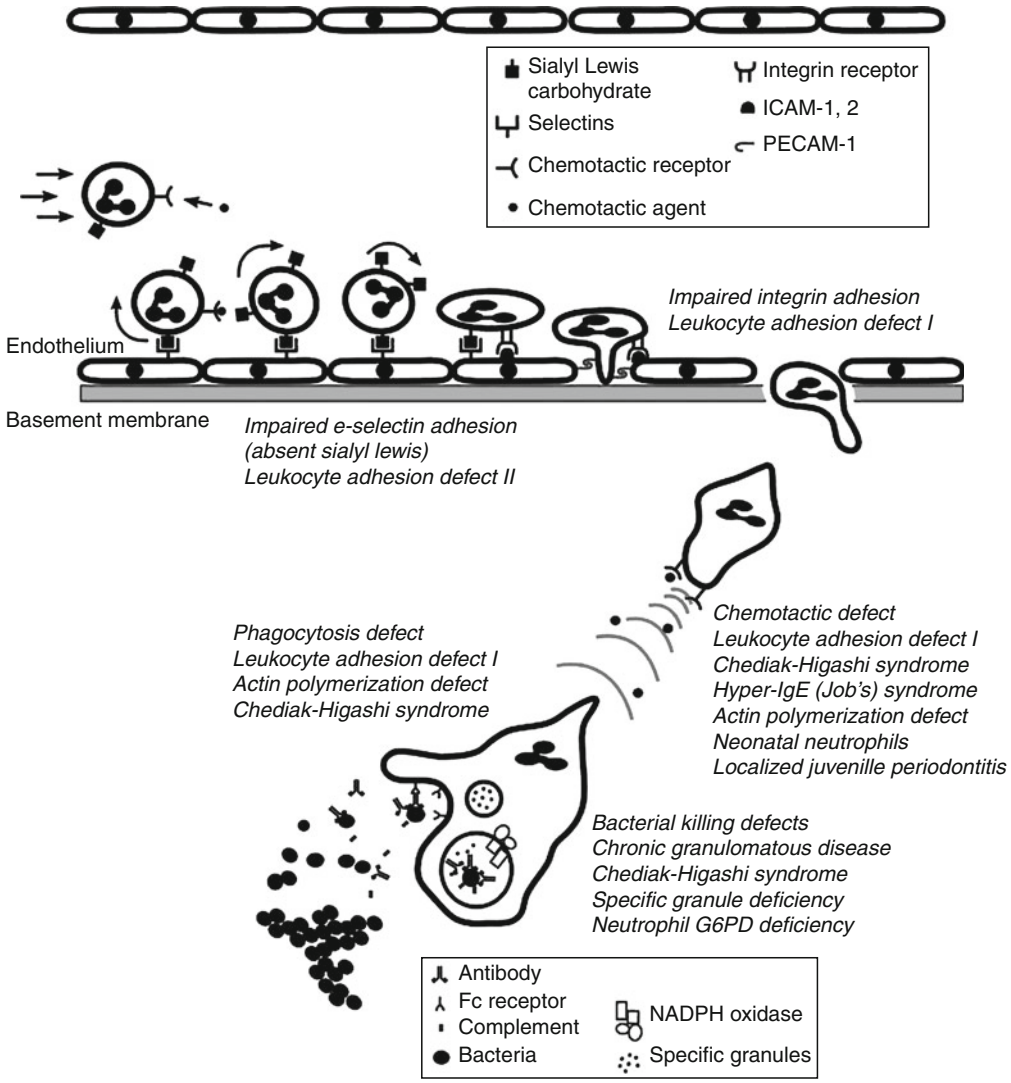

Figure 332.1

Steps in the response of circulating neutrophils to infection or inflammation (Reprinted with permission from Dinauer MC, Coates TD (2005) Disorders of phagocyte function and number. In Hoffman R, Benz J, Shattil S et al. (eds) Hematology: basic principles and practices. Elsevier Churchill Livingstone, Philadelphia, pp 787–830)

characterized by impaired neutrophil adhesion and motility, along with decreased neutrophil glucose-6-phosphate dehydrogenase (NADPH) oxidase activation and degranulation in response to chemoattractants.

Disorders of Chemotaxis

Patients with chemotactic disorders have recurrent bacterial (gram-positive and gram-negative) and fungal infections. The most common microorganism is Staphylococcus aureus. Several conditions are associated with defective chemotaxis, including inactivation of chemotactic factors (Hodgkin disease and cirrhosis of the liver); inhibitors of neutrophil responses (hyperimmunoglobulin E syndrome, localized juvenile periodontitis, rheumatoid arthritis, bone marrow transplantation, and drugs); deactivation of increased levels of chemotactic factors (Wiskott–Aldrich syndrome and bacterial sepsis); and phagocytic defects (neonatal neutrophilia, LAD,

Chédiak–Higashi syndrome, specific granule deficiency, and "lazy leukocyte" syndrome).

Hyperimmunoglobulin E (Job) Syndrome (HIGE)

HIGE a heterogeneous group of inherited disorders characterized by recurrent staphylococcal infections of the skin (cold abscesses) and lungs with subsequent formation of pneumatoceles. Candida infection is commonly encountered among HIGE patients. On the other hand, aspergillous frequently causes secondary pneumatocele infection. Chronic eczema and high levels of immunoglobulin E are consistent features of HIGE. AD and AR forms have been recently identified. The AD HIGE is caused by mutation in STAT-3 and is characterized by additional features, including defective shedding of primary teeth with double rows, scoliosis, easily bone fractures, joint hyperextensibility, coarse facial features, and aneurysms. In AR HIGE, patients might suffer viral infections but unlikely to present with skeletal or dental abnormalities. Vasculitis and autoimmunity are common in this phenotype. Mutations of the tyrosine kinase 2 gene (TYK2) have been identified as one of the causes of AR HIGE. Recently, a mutation in DOCK8 has been identified as a genetic cause of many AR HIGE patients. It is characterized by severe viral infection with HSV, extensive molluscum contagiosum, and several patients develop squamous-cell carcinomas. This phenotype is described as combined immunodeficiency with dysregulated IgE production. Patients with HIGE have variable defects in neutrophil chemotaxis. Treatment includes antibiotics for *S. aureus* infections and surgical drainage if indicated. Trimethoprim-sulfamethoxazole prophylaxis helps in decreasing the incidence of serious infections and improving the outcome. There is no definite treatment available for HIGE syndrome to date.

Neonatal Neutrophils

Neonatal neutrophils have defects in adhesion, chemotaxis, phagocytosis, and bactericidal activity, particularly in premature infants. The chemotactic deficiency is the most important one and has been attributed to abnormal regulation of cell adhesion molecules and decreased polymerization of F-actin in neutrophils after stimulation.

Disorders of Recognition

Complement (C3) deficiency is inherited as an autosomal recessive disorder, leading to recurrent infections due to absence of two major opsonins, C3b and C3bi.

Disorders of Ingestion

Neutrophilia in patients with LAD involves deficiency in ingestion of opsonized particles. Also, patients with deficiency of cytoskeleton-related 89-kDa protein or neutrophil actin polymerization have abnormal phagocytic function. Patients with paroxysmal nocturnal hemoglobinuria have deficiency of receptors (FcR III) that are important in the process of ingestion.

Disorders of Degranulation

Two main disorders belong to this category: Chédiak–Higashi syndrome and specific granule deficiency. Both are rare and inherited as autosomal recessive traits.

Chediak–Higashi Syndrome

CHS is a rare AR inherited disorder caused by mutation in *CHS1*, which encodes a large protein thought to regulate lysosomal and granule trafficking. It is characterized by partial oculocutaneous albinism, frequent and severe bacterial infections (*Staphylocuccs aureus*), and neuropathies (cranial and peripheral). Those who survive the recurrent infections develop diffuse lymphohistiocytic infiltration and pancytopenia "accelerated phase" and succumb to its complications. In addition to ineffective granulopoiesis, neutrophils have deficiency in chemotaxis and degranulation. Neutrophils from patients with Chédiak–Higashi syndrome have giant granules that appear to be a coalescence of azurophilic and specific granules. BM studies are often indicated as they are often more prominent in bone marrow neutrophils than in peripheral blood neutrophils. Management includes treatment of infections, such as prophylaxis with trimethoprim-sulfamethoxazole. If a suitable donor is available, hematopoietic stem cell transplantation can offer cure for this fatal disease.

Specific Granule Deficiency

Specific granule deficiency (SGD) is a rare disorder characterized by the absence of specific or secondary granules in developing neutrophils. It is caused by molecular defect involving the myeloid transcription factor C/EBPå. SGD neutrophils also demonstrate relatively severe chemotactic defect. Therefore, they present with severe infections of the skin, ears, lungs, and lymph nodes (*S. aureus*, *Proteus*, *Pseudomonas aeruginosa*, and *Candida*). The neutrophils lack or have empty specific granule vesicles (by electron microscopy) due to deficiency of certain proteins

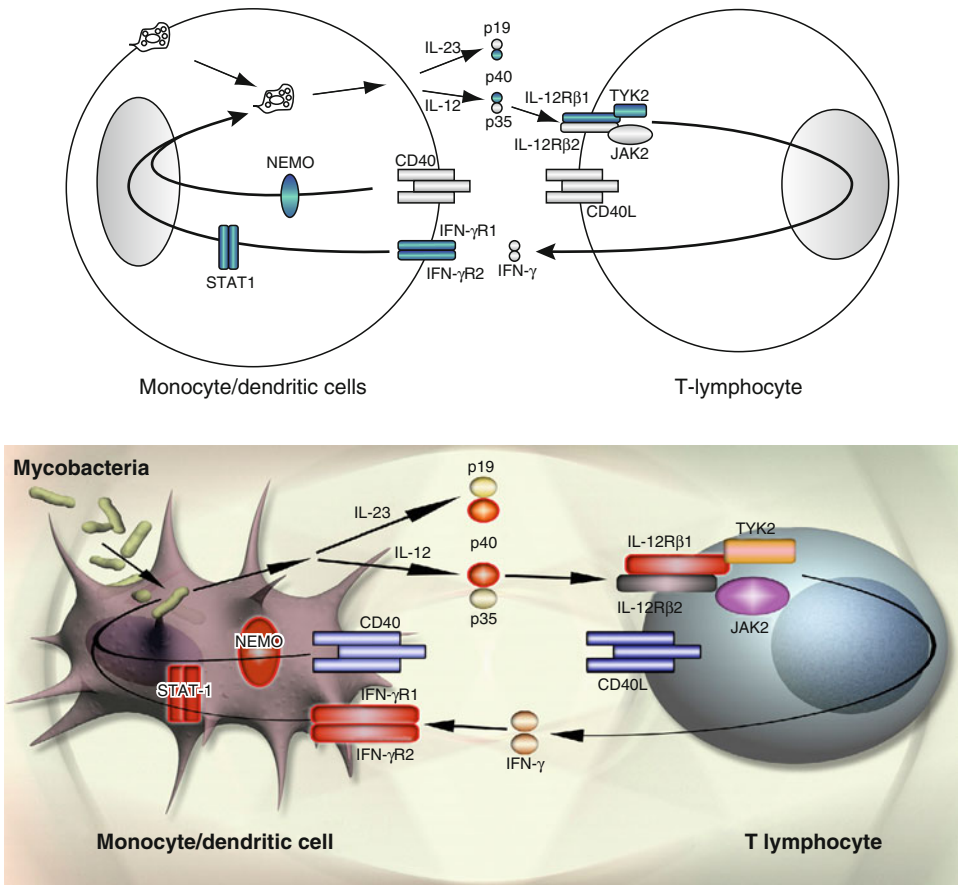
(defensins and lactoferrin). Treatment of SGD is supportive with prophylactic antibiotics, and prompt and prolonged treatment of infections.

Disorder of Signaling (Defect in IL-12/IFN-γ Axis)

The mononuclear phagocyte interaction with lymphocytes and monocytes through IL-12/IFN-γ axis is critical for the immune response against intracellular microorganisms, such as mycobacteria, salmonella, and listeria. The presence of pathogens as Mycobacterium triggers macrophages to produce IL-12. It binds to a specific receptor expressed by T and NK lymphocytes and induces secretion of IFN-γ that triggers macrophage microbicide on binding to the IFN-γ receptor. Defects of this crucial signaling pathway account for mendelian susceptibility to mycobacterial disease (MSMD). There are six MSMD-causing genes, including one X-linked gene (nuclear factor-kB–essential modulator [NEMO]) and five autosomal genes (IFN- γ receptor 1 [IFNGR1], IFN- γ receptor 2 [IFNGR2], signal transducer and activator of transcription 1 [STAT1], IL-12 p40 subunit [IL12P40], and IL-12 receptor b-subunit [IL12RB1]), producing heterogeneous clinical phenotypes of MSMD (◉ *Fig. 332.2*).

All forms of MSMD are characterized by increased susceptibility to environmental mycobacteria and to BCG vaccine strain. Salmonella, Listeria, and Histoplasma species infections can also be observed, especially in patients with IL12RB1 mutations.

Management of MSMD relies on aggressive therapy of infections, long-term prophylaxis. IFN-γ might be useful in patients with AD IFN- γ R1 deficiency, IL-12 p40 deficiency,



◘ Figure 332.2

MSMD-causing genes in the IL-12/23-IFN-g pathway. Schematic representation of host immune response against mycobacterial infection(Reprinted with permission from Al-Muhsen S, Casanova JL (2008). The genetic heterogeneity of mendelian susceptibility to mycobacterial diseases. J Allergy Clin Immunol 122(6):1043–1051)

or IL-12R defects. Bone marrow transplantation may provide cure for severe cases. However, the high mortality associated with graft rejection has limited this curative option.

Disorders of Intracellular Killing (Oxidative Metabolism)

Chronic Granulomatous Disease (CGD)

CGD is a heterogeneous group of inherited disorders caused by genetic defects in the components of the phagocyte's NADPH oxidase complex. Hence, the phagocytes are unable to generate the microbicidal reactive oxidant superoxide anion and its metabolites. As a result of the defect in this key host defense pathway, CGD patients suffer from recurrent life-threatening bacterial and fungal infections. Five genetic mutations involving the phagocytic oxidase system have been identified so far. The most common is an X-linked recessive defect in gP91phox, while three other AR defects were reported in P22phox, P47phox, and P67phox components of the NADPH oxidase system. A novel mutation in *NCF4*, the gene encoding P40phox, has also recently been reported in a boy who presented with granulomatous colitis, delineating the fourth AR form of CGD. International data indicate that X-linked is more common (65%); however, in highly inbred populations, the AR forms of the condition seem to be more frequent. Clinically, patients with CGD present with recurrent bacterial (*Staphylococcus aureus, Serratia marcescens, Salmonella*, and *Burkholdaria cepacia*) and fungal (*Aspergillus*) infections. In addition to susceptibility to infections, CGD patients are prone to develop noninfectious complications characterized by unregulated inflammation such as granulomatous colitis, chorioretinal lesions, and lupus-like disease. The diagnosis of CGD is based on a compatible clinical presentation and demonstration of a defective respiratory burst by nitroblue tetrazolium test which relies on the intracellular reduction of NBT by superoxide anion to a blue formozan precipitate that can be seen microscopically. More recently, a sensitive tool using flow cytometry to detect dihydrorhodamine 123 oxidative burst assay has been widely used in clinical practice. Genetic confirmation is the gold standard diagnostic test. Prenatal diagnosis can be done by percutaneous umbilical sampling or by puncture of placental vessels using fetoscopy. Treatment of patients with CGD includes appropriate management of infections (antibiotics and antifungal). Prophylaxis with trimethoprim-sulfamethoxazole and itraconazole antifungal prophylaxis have reduced the rate of serious infections substantially and hence improved the outcome. Introducing Interferon-γ prophylaxis was shown to be beneficial in reducing the frequency of serious infections. Hematopietic stem cell transplantation may provide definite cure for severe cases. CGD was formerly associated with a high mortality, but the current practice of prophylaxis with antimicrobials and IFN-γ, aggressive surgery, and early hematopoietic stem cell transplantation or gene therapy have improved the outcome substantially.

Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

G6PD is an X-linked inherited disorder leading to a low concentration of NADPH. Patients have recurrent bacterial infections and hemolytic anemia. Diagnosis is made by testing neutrophil G6PD activity (<5% of normal) and erythrocyte G6PD levels. Treatment focuses mainly on appropriate management of infections.

Myeloperoxidase Deficiency (MPO)

MPO is the most common disorder of phagocyte function. It is inherited as autosomal recessive with variable expression. The defect results in diminished production of hydrochlorous acid (HOCI) required for killing of microorganisms (especially *Candida*). Usually patients are clinically asymptomatic but rarely may present with disseminated candidiasis. The deficiency may be acquired in acute myeloid leukemia. Diagnosis is made by testing neutrophils and monocytes for peroxidase (by histochemical analysis). Patients with MPO deficiency and diabetes are usually treated aggressively to prevent fungal infections. Otherwise, MPO does not require prophylactic antibiotics. Prognosis is usually excellent.

Glutathione Metabolism Disorders

Glutathione reductase deficiency and glutathione synthetase deficiency are uncommon and inherited as autosomal recessive traits. Diminished levels of these enzymes lead to toxic accumulation of hydrogen peroxidase due to decreased catabolism by glutathione. Patients may have hemolysis with oxidant stress and usually have a benign course (patients with glutathione synthetase deficiency may have metabolic acidosis, recurrent otitis media, and intermittent neutropenia).

333 Bone Marrow Failure Disorders

Hassan El Solh · Abdallah Al-Nasser · Peter Kurre

The term "bone marrow failure syndromes" (BMF) captures a heterogeneous group of disorders that result in an effective mismatch between blood and immune cell production in the bone marrow and peripheral demand. Most often clinical symptoms of cytopenia bring children to medical attention and prompt laboratory evaluation. However, in children, given the compensatory capacity of their cardiovascular system, relatively greater baseline incidence of infections and their general propensity for minor trauma, they often present relatively late in the process. The clinical presentation is further compounded by the frequently insidious nature of onset and can be masked by disease specific symptoms in other organs. For example, children with cytopenia following infection may undergo evaluation for predominant fevers and skin findings. Indeed, with some regularity the diagnosis is unsuspected and even incidental during evaluation for more common childhood problems, especially infections, recurrent bleeding, or failure to thrive. On rare occasions, patients will be referred because siblings or family members have been diagnosed with a specific BMF disorder. Notwithstanding specific symptoms, the hemogram often reveals a variable degree and combination of multi- or single lineage count decrements.

Etiologic considerations are broad, covering specific acquired and multi-system heritable genetic disorders. Medical history and physical evaluation can provide critical clues to guide differential diagnosis and tailor choice of ancillary studies. However, in the absence of acute blood loss or evidence of immune mediated destruction, further evaluation will almost always require a bone marrow evaluation and, where available, more specialized biochemical and genetic testing. Setting appropriate expectations with patient, family, and other providers, the often extensive evaluation may not always establish a definitive diagnosis, but is crucial in making appropriate treatment recommendations and excluding heritable etiologies that require family counseling.

General Considerations

Definitive hematopoiesis during human development follows a carefully orchestrated series of in utero developmental phases. Beginning in the aorta-gonadomesonephros region of the early fetus, production of blood and immune cells passes through a placental phase with subsequent expansion in the fetal liver before ultimately moving to the bone marrow at 22 weeks of gestation. Trabecular bone provides the scaffold structure that supports the stromal, hematopoietic, osteoblastic, as well as endothelial cellular components and extracellular matrix that comprise the hematopoietic microenvironment. It is widely believed that hematopoiesis and immunopoiesis are hierarchically organized in a system of successive steps of differentiation and progressive restriction with functional specializations of cells. All mature cells in the blood stream are derived from rare hematopoietic stem cells residing in the bone marrow microenvironment and capable of asymmetric division. Cell fate decisions determine self-renewal and differentiation activity and match blood and immune cell production to physiologic needs. Driving the process of amplification and specification is a network of endocrine and paracrine signaling molecules and their cognate cellular receptors. Hematopoietically active cytokines, interleukins, adhesion molecules, and growth factors are responsible for maintaining cells in quiescence and providing hierarchically specific cues to initiate proliferation and cell type specific coordinated expansion. For example, during adjustment to lower partial oxygen pressures at high elevations, hypoxia signaling in the kidney will result in erythropoietin secretion and selective activation of red blood cell progenitors in the bone marrow to increase production of oxygen carrier capacity. Similarly, pathophysiologic events such as infection or bleeding can trigger massive increases in production and mobilization of leukocytes or platelets. Expansion of virus specific T-cells on the other hand provides an instructive model for interleukin-2 and its role during induced clonal proliferation of immune cells in response to a very specific viral agent. The often remarkably advanced and tightly controlled signaling effects reflect the combined diversity of ligands and receptors.

Differential Diagnosis

Children presenting with signs of single or multilineage cytopenias offer a broad differential diagnosis. Patient age,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_333,

physical findings, and specific circumstances can help guide the work up and narrow relevant diagnoses. Principally, infections, environmental exposures, nutritional deficiencies, immune dysregulation, malignant, or benign infiltrative bone marrow processes must be considered.

Evaluation

Physical examination and thorough patient and family history are cornerstones in the diagnosis of BMF, often providing critical clues to tailor additional investigations. The relatively greater proportion of children in whom marrow aplasia is merely the presenting manifestation of an underlying heritable condition emphasizes their critical importance. The distinction between acquired and inherited etiologies in children is crucial, not only for proper treatment and to avoid unnecessary toxicities, but also to initiate family counseling. In some conditions, such as Fanconi Anemia, characteristic physical stigmata are obvious in only a minority of patients and their absence should never lead the clinician to dismiss the diagnosis. In other instances, such as thrombocytopenia with absent radii, abnormalities on physical exam are obvious and the diagnosis more straightforward. Several ancillary studies are useful to ascertain the diagnosis and begin to delineate more specific etiologies:

Quantitative cytopenic abnormalities of individual or all hematopoietic lineages in the peripheral blood often lead to symptomatic presentation, prompt further work up and lead to specialty referral. The complete hemogram provides a wealth of information about the patient's hematological status and may help narrow the differential diagnoses to be pursued. Normal range values for blood cell counts and indices should be interpreted with consideration of age, gender, and laboratory reference standards. Separately, a blood smear for microscopic evaluation and reticulocyte stains should be included to assess cell morphology and bone marrow red cell compensatory activity, respectively.

The bone marrow evaluation is a key for the classification of cytopenias and provides an opportunity for several separate tests. Ideally, the decalcified Giemsa stained bone marrow biopsy captures the architecture, cellular composition, and extracellular matrix of hematopoietic tissue. Additional, more specific histochemical stains can help answer questions of iron stores, infection, malignant (e.g., leukemia) or nonmalignant (e.g., glycogen storage disease) displacement of hematopoietic cells. However, the hallmark finding in bone marrow failure is the adipose replacement and proportional decrease of hematopoietic elements inappropriate for age. Reduced cellularity (defined as $<30\%$ averaged for multiple fields of view) and variable peripheral cytopenias are defining diagnostic features of bone marrow failure, regardless of etiology. A bone marrow aspirate is usually obtained to evaluate size and morphology (dysplasia, nuclear bridging), but also cytogenetic analysis for karyotype abnormalities. Depending on circumstance, immunophenotyping, or fluorescence in situ hybridization (FISH) studies may be desired to delineate aplastic anemia (AA) from hypoplastic myelodysplastic syndrome (MDS) or lymphomatous invasion. Incidental diagnosis of fatty marrow replacement has been reported in patients who underwent magnetic resonance imaging for unrelated causes, but radiologic evaluation, other than for specific symptoms, has no routine role in the diagnostic algorithm. Additionally indicated diagnostic tests are discussed in the context of specific diagnoses below.

Acquired Aplastic Anemia (AAA)

Pathophysiologically AA is widely considered to reflect immune destruction of stem cells with the resulting progressive depletion of mature blood and immune cells. The degree of peripheral blood neutropenia, reticulocytopenia, thrombocytopenia, and the proportion of hematopoietic elements in the bone marrow are usually used to grade severity. Values of $<500 \times 10^9$/l for neutrophils, $<1\%$ reticulocytes, $<20{,}000 \times 10^9$ platelets, and $<30\%$ cellularity define severe disease, often associated with a transfusion requirement for red blood cells and platelets. Most practitioners will consider therapeutic intervention only in such cases, whereas moderately severe disease may progress or resolve in up to 30% of cases without intervention. The incidence ranges from two to six cases per million without ethnic or gender predilections, but with notable regional differences between western and eastern hemisphere.

Etiology

Paul Ehrlich's initial description associated with pregnancy in a young woman is now considered exceedingly rare. But, notwithstanding its shared pathophysiology, the most common finding will be idiopathic bone marrow failure without a known cause even though several specific etiologies and common associations that alter treatment decision making must be considered in children.

Infections

A wide range of infections has been associated with prolonged cytopenias. Especially in children, these can be asymptomatic and are often transient. However, congenital or postnatal infection with parvovirus (*B19* strain), human immunodeficiency virus (HIV-1, or rarely -2), Epstein Barr Virus (EBV), or Cytomegalovirus (CMV) may result in sustained low blood counts. Failure to eradicate these infections may also provide clues to underlying immunodeficiencies. Hypocellular cytopenias have long been appreciated as sequelae of, or rarely concurrent with, A, B, or C viral hepatitis. Regionally different incidences for AA range from 2% to 5% of children with hepatitis and a slightly higher percentage in patients who received orthotopic liver grafts. Clinically heterogeneous, even patients with substantial and life-threatening liver failure, organ function recovers and does not necessarily affect treatment, complications, response to therapy, or ultimate prognosis. Serological or pathogen-specific nucleic acid based laboratory evidence will help distinguish past from active infection and can be helpful guiding successful treatment.

Drugs

When it was in more widespread medical use, chloramphenicol was linked to aplastic anemia. Case reports also implicate more commonly used drugs, including sulfonamides, carbamazepines, cimetidine and quinacrine, and others. Mechanistic insight into this etiology is missing and no specific test will be helpful in ascertaining this etiology.

Chemicals and Toxins

Environmental exposure to aerosolized benzene in particular is an established cause of marrow dysfunction and occasionally myelodysplasia. But, while patients and caregivers often focus on this etiology, it is in fact very rare in industrialized western society. A particularly informative recent study suggests that environmental exposure to pesticides and other agents including organophosphates may be a problem in other parts of the world. An extensive exposure and occupational history is important in making the diagnosis.

Etiologies such as ionizing radiation or graft versus host disease (GVHD) are well-established causes of marrow aplasia and pancytopenia, but the context dependence makes their diagnosis more straightforward.

Paroxysmal Nocturnal Hemoglobinuria (PNH)

PNH is a clonal stem cell disorder resulting from somatic mutations in PIG-A gene and the production of blood cells defective for glycosylphosphatidyl-inositol (GPI) anchorage of several cell surface proteins. Clinically PNH is characterized by periodic lysis of red blood cells with resulting intravascular hemolysis. However, considerable overlap exists in the clinical presentation and diagnostic findings of patients with idiopathic AA and those with PNH. Indeed, commonalities between the two entities have been interpreted to indicate an immune pathophysiology for PNH, as well. Care should be exercised to distinguish the two from each other, and the existence of coagulation abnormalities and symptoms of thrombosis may be considered defining features of classic PNH. Accordingly, the demonstration of clonal deficiencies of select cell surface proteins in red blood cell or leukocyte lineages should not be automatically considered diagnostic of PNH since positive tests have been found in many patients with marrow failure. Historically, testing relied on sucrose lysis, with more recent flow-cytometry based assays greatly increasing sensitivity and quantitation. A prognostic role for PNH clones and the value of sequential analyses in guiding treatment has been suggested.

Complicating matters further, PNH has been well documented as a potential late complication after treatment with immunosuppressive agents.

Myelodysplasia (MDS)

Primary, non-treatment related myelodysplasia is a rare form of bone marrow dysfunction in childhood that may progress to acute myeloid leukemia. Cytopenias bringing the patients to medical attention and the diagnosis of a hypocellular bone marrow overlap with those of AA. Importantly, many patients present evidence not only of morphologic dysplasia on examination of smears, but also hallmark chromosomal aberrations. Accordingly, all patients with bone marrow failure undergoing a marrow aspiration procedure should have a cytogenetic analysis for karyotypic abnormalities. Numeric and gross structural abnormalities will be readily apparent. Depending on availabilities of laboratory facilities for further testing, additional studies for characteristic abnormalities such as loss of chromosome 7 or gains in chromosome 8 using FISH are indicated. Myelodysplasia and leukemia can be the initial presenting sign of cancer prone genetic disorders, including Fanconi Anemia and Shwachman–Diamond Syndrome. This, along with the generally infrequent

occurrence of myelodysplasia in children, implies the need to test these children for genetic disorders, especially in the very young.

Laboratory Findings

The backbone of the diagnostic work up is a complete peripheral blood count with indices, reticulocyte count and leukocyte differential. A blood film may hold additional valuable information on cell shape, morphology, and size. The bone marrow aspirate and biopsy should be evaluated for morphology and cellular composition and cellularity. Cytogenetic testing to exclude cases of myelodysplasia is important. When available, flowcytometric immunophenotyping to exclude leukemic involvement is helpful. Additional studies helpful in confirming the diagnoses and considering differential etiology include peripheral blood chromosome breakage testing to exclude Fanconi Anemia. Immunologic evaluation may include determination of immunoglobulin subclasses, lymphocyte subsets, the presence, and compositions of PI negative clones. Underlying viral infections should be excluded, especially HIV, hepatitis, and parvovirus. Radiological imaging has no routine role in the diagnostic work up of AA.

Therapy

Supportive Care is the backbone of treatment of patients with AA. Because most will present with cytopenias, diagnosis and treatment of infections as well as the need for transfusions are principal concerns in newly presenting patients. Neutropenic patients frequently come to medical attention with recurrent febrile episodes, oral mucosal ulcers, and fevers of unexplained origin. Symptom-guided diagnostics are indicated, although frequently unrevealing, and appropriate broad-spectrum antibiotics should be considered under these circumstances, especially in patients with indwelling central venous catheters. The role of empiric antibiotic coverage in patients is more controversial, although many practitioners consider antifungal coverage and prophylaxis against *pneumocystis carini* important. Children have profound cardiovascular reserve and the signs and symptoms of anemia routinely occur late with hemoglobin values often <6 g/dl. The transfusion of chronically adjusted patients requires judicious and slow correction, often over the course of several days. Normal hemoglobin values are not the goal, rather, improving oxygen delivery to tissues to relieve immediate symptoms of fatigue and exertion with post-transfusion target range between 8 and 10 g/dl. Because, patients are often neutropenic and lymphopenic, they should be considered immunocompromised even before receiving treatment. Therefore, to avoid transfusion associated immune reactions and minimize transmission of pathogens, transfusions of whole blood, red blood cells, or platelets should be prepared to eliminate viable lymphocytes (γ-irradiation) and filtered to remove trace leukocyte carriers of cytomegalovirus whenever possible. Long-term complications of transfusions include blood group and human leukocyte antigen (HLA) sensitization. They may accelerate transfusion requirements and sensitize the patient to transfusion associated immune reactions. HLA matching of platelets or family directed donation is often technically feasible, but should be strenuously avoided so as to not increase the risk of subsequent rejection in any patient who is considered for a stem cell transplant procedure in the future. The hemoglobin contained in red blood cells is complexed with iron, and transfusion of blood in patients unable to mobilize stores during red blood cell production in the bone marrow can lead to iron deposition and end organ dysfunction in liver, heart, and pancreas. Therefore, transfusion of blood products should always be judicious to minimize side effects. White blood cells and especially granulocytes are rarely transfused in cases of severe invasive infections.

Hematopoietic growth factors in the treatment of AA produce no sustained responses by themselves, but may have a role in the context of immunosuppressive therapy. Whether long-term use of G-CSF contributes to clonal evolution of myelodysplasia or acute myeloblastic leukemia is controversial. Androgenic steroids can temporarily improve hematopoietic output and are widely used in some parts of the world, but their side effects make long-term use problematic.

The treatment algorithm for idiopathic severe AA is subject to patient specific considerations and available resources and can therefore be regionally different. However, because the pathophysiology of AA is widely agreed to be an immune elimination of bone marrow stem cells, suppression or replacement of immune function are the principal considerations. Based on risk-benefit ratio and local resources, stem cell transplantation from an HLA matched sibling is the primary modality, followed by a variety of immunosuppressive strategies. Transplantation of stem cells from an unrelated donor is a potentially curative option for patients who fail immune suppression.

Immunosuppression Therapy (IST)

The incidental observation of sustained endogenous recovery following graft failure in AA patients undergoing transplantation provides powerful evidence for the immunological basis of AA. Based on a landmark randomized trial, the modern backbone of AA treatment is a course of rabbit or horse derived anti-lymphocyte or anti-thymocyte globulin (ATG). The combination with calcineurin inhibitor cyclosporine in particular has proved effective in inducing partial or complete remission in a majority of patients. Response to treatment is notoriously slow, but white blood cell count recovery can be hastened by addition of granulocyte colony stimulating factor. Responses may be drug dependent and the disease may recur, but immunosuppression can present a viable functional cure allowing independence from transfusions and high survival rates in children. Re-treatment with a second course of ATG will provide remission in about half the patients, without gains after switching between globulin preparations. Survival after IST is improved for younger patients with less severe disease who respond to treatment early, whereas clonal evolution to myelodysplasia or leukemia is frequently fatal. In aggregate, between 15% and 20% of long-term survivors develop late clonal disease (MDS, AML, and PNH).

Corticosteroids have not been effective in producing sustained remissions whereas cyclopshophamide can be successful, but immunosuppression is profound and complications can be severe.

Bone Marrow Transplantation

Transplantation of bone marrow stem cells is the only curative treatment of AA. Resources and donor availability permitting, transplantation of hematopoietic stem cells from an HLA matched related sibling donor is the treatment of choice. Improvements in supportive care and transfusion practices result in long-term survival rates in children exceeding 90%. Conditioning with ATG and high dose cyclopshophamide combined with adequate stem cell dose leads to stable donor chimerism with acceptable toxicities and effective prophylaxis against graft versus host disease. Unlike patients with malignancy, those with AA do not benefit from GVHD and the use of peripheral blood stem cell grafts worsens outcomes. Endocrine late effects on growth, thyroid, and gonadal functions are less frequent than following high dose radiation conditioning, but secondary malignancies have been seen.

Inherited Bone Marrow Failure Disorders

Fanconi Anemia (FA, OMIM: 227650)

A heritable multi-system disorder with great phenotypic diversity, Fanconi Anemia comprises a combination of physical anomalies, progressive bone marrow failure, and propensity to develop cancer. Mutations in at least 12 genes are the basis for predominantly autosomal inheritance, except for one rare form inherited in autosomal dominant fashion. Remarkably, most of the affected proteins functionally cooperate in a molecular pathway involved in genome damage repair. The phenotypic presentation of these subgroups, referred to as complementation groups, show considerable overlap, although some groups seem to follow a more severe and rapidly progressive course. Historically, radii and thenar abnormalities, microcephaly, as well as short stature have been considered characteristic physical findings, prompting a diagnostic work up. However, more recent studies of presymptomatic siblings and routine screening for excessive chromosomal breakage of children with any form of marrow failure reveal that over one third of patients ultimately diagnosed with FA do not have obvious findings on physical exam. Therefore, specific screening for chromosome breakage must be considered in any child with marrow failure, whether single or multilineage. FA is a multi-system disorder and many patients suffer from endocrine dysfunction with thyroid and growth hormone imbalance, glucose homeostasis, and reproductive function. Patients should be followed at routine intervals.

Bone marrow failure in FA is characteristically progressive and slow. Children commonly present with symptoms of cytopenias and are often followed for years before definitive intervention. Guidelines for transfusion and infection apply as in any form of aplastic anemia. Temporary responses to androgenic steroids and use of granulocyte colony stimulating factor have been described. The only curative treatment remains transplantation of hematopoietic stem cells from and unaffected HLA matched individual, preferably a matched family member who has tested negative for FA. However, caution must be exercised in selecting conditioning regimens, as patients will suffer excessive mucosal toxicities from chemotherapeutic regimen and especially higher doses of radiation used in AA. Low doses of cyclopshophamide combined with ATG produce rapid and reliable engraftment of unmanipulated marrow grafts. An alternative approach intended to reduce rates of GVHD has been to deplete the graft of T-cells. Especially in the unrelated donor setting, where

graft failure, frequently severe GVHD, and invasive infections compromise outcomes, this can be of benefit. The risk of FA patients developing myelodysplasia or leukemia is several hundred folds in excess of those in the general population. While the successful replacement of blood and immune system in FA presents a cure for the bone marrow manifestations of the disease, other organ systems remain at risk. Most notably, the risk for epithelial cancers of the head/neck region and the female genital tract is high. As follows from observations on conditioning regimen toxicity, selecting chemotherapeutic agents, or radiation doses, effective at eradicating cancer cells, while limiting toxicity is a challenge that applies to treatment of any cancer in children with FA. Early detection is of key importance and screening for head-neck and gynecological cancers are recommended where available. The lifespan for children with FA has greatly improved with an improved understanding of disease biology, supportive care, and advances in modifying conventional treatment regimens. However, genetic counseling remains important.

Dyskeratosis Congenita (DC, OMIM: 127550)

Children with congenital dyskeratosis show characteristic reticular skin changes, dysplastic nails, oral leukoplakia, and progressive bone marrow failure. Presentation and severity are heterogeneous and can vary among individuals within affected families. Longitudinal studies reveal an increased risk of solid tumors, MDS, leukemias, and pulmonary fibrosis. Classic dyskeratosis is thought to be a severe form in a spectrum of disorders of telomere biology. Rare forms of DC can present with significant neurologic and cognitive dysfunction. Most patients come to medical attention with macrocytic anemia. Evaluation of bone marrow and peripheral blood smear in conjunction with clinical findings is the key to establishing the diagnosis. More recently the diagnosis of shortened telomeres in multiple leukocyte subsets has been proposed as a sensitive and specific assay, though limited in availability. This test can be useful for screening children fulfilling clinical criteria. Subsequent mutation sequencing can be confirmatory for patients and helpful for family carrier screening. Depending on which genes harbor mutations, inheritance mode can be autosomal dominant, recessive (*TERC, TERT, TINF, NHP2 NOP10*) or even x-linked (*DKC1*). Treatment is symptomatic as in other BMF syndromes, relying on transfusion support and aggressive treatment of infections. Androgens, growth factors, erythropoietin, and G-CSF have been used with variable success, but the risk of complications including virilization and rare reports of splenic rupture, respectively, should be carefully weighed. In patients with symptomatic bone marrow failure who have an available HLA matched and non-affected sibling donor, transplantation of hematopoietic stem cells is the recommended treatment. Pulmonary and hepatic cirrhosis can complicate transplantation suggesting that non-myeloablative conditioning strategies result in improved long-term outcomes.

Shwachman–Diamond Syndrome (SDS, OMIM 260400)

The combination of exocrine pancreatic insufficiency, marrow failure and metaphyseal dysostoses comprise the principal findings in Shwachman–Diamond Syndrome. The overwhelming majority of cases reflect mutations in the Shwachman–Bodian–Diamond gene on chromosome 7. The gene product has prominent functions in mitotic spindle formation and ribosome biogenesis. Patients most commonly present with chronic or intermittent neutropenia, but other cell lines are also frequently affected, reflecting the underlying quantitative and qualitative stem cell abnormalities. Additionally, immune function can be abnormal in SDS patients with variable cellular defects of neutrophil polarization and migration, B, T, and NK cell number. Like patients with other bone marrow failure syndromes, SDS patients are at greatly increased risk for developing MDS and myeloid leukemia. These often go hand in hand with cytogenetic abnormalities, such as loss of chromosome 7. Notwithstanding, cytogenetic abnormalities also occur without over signs of dysplasia and can wax and wane, putting their clinical significance in question. Compromised exocrine pancreatic function results in steatorrhea and reduced absorption of fat-soluble vitamins. Failure to thrive and growth failure are frequent presenting signs. Imaging studies will reveal a small pancreas. Liver abnormalities are also common. Pathologic correlates in liver and pancreas are fatty replacements. Remarkably, symptoms may vary over time with many patients recovering sufficient pancreatic function in later years. Specific testing for fecal elastase or serum pancreatic trypsinogen with a negative sweat chloride test to exclude cystic fibrosis will help establish the diagnosis. Metaphyseal dysostosis of the long bones are found in roughly half the patients, although they are frequently asymptomatic. Rarely, rib cage anomalies can result in respiratory compromise. Structural cardiac anomalies have been described in several patients and cardiovascular complications can manifest after high dose therapy in the context of transplantation.

Treatment is predominantly symptom based and should include supplemental vitamins, antibiotics to treat infections, and transfusions when needed. Routine follow up by hematologist, gastroenterologist, endocrinologist, and genetic counselor are recommended. Stem cell transplantation can be curative for hematological manifestations and has been performed successfully using matched related and non-affected, as well as unrelated donors. Different conditioning strategies have been used depending in part on donor availability and whether patients progressed to MDS and AML. The ideal timing in patients with asymptomatic cytopenias is a matter of discussion and institutional preference.

Reticular Dysgenesis (OMIM 267500)

This is a severe form of inherited immunodeficiency and an exceedingly rare disorder of leukocyte and immune function manifesting in infancy. Patients will present with agranulocytosis, lymphopenia, thymic hypoplasia and absent immune function. Recent evidence suggests that a defect in mitochondrial metabolism may be causative. Overwhelming infections are frequent causes of death, but stem cell transplantation is potentially curative.

Congenital Amegakaryocytic Thrombocytopenia (CAMT, OMIM: 604498)

CAMT is a hypomegakaryocytopenic thrombocytopenia commonly diagnosed during infancy with an inherent propensity to progress to AA. Thrombocytopenia in these patients can be severe, with potentially life-threatening bleeding requiring transfusion of platelets. Additional congenital anomalies can be seen, mostly involving heart, kidney, or neuromotor function. The differential diagnosis should include TAR (below) and the Wiskott–Aldrich Syndrome as well as neonatal alloimmune thrombocytopenia. The diagnosis is often established on clinical grounds with bone marrow confirmation and where available genetic testing. The molecular defect rests on mutations in the thrombopoietin (TPO) receptor, c-MPL, coinciding with high levels of the cytokine in patients. The role of TPO in stem cell pool maintenance and differentiation is consistent with the frequent evolution to AA in patients. Cytokine and steroid treatment can have transient benefit, but transfusion is the main therapeutic recourse to treat symptoms. The definitive treatment and only known cure is the transplantation of stem cells from unaffected HLA matched donors. It is unclear if patients with CAMT suffer an increased risk of malignancy.

Pure Red Cell Aplasia

Diamond Blackfan Anemia (DBA, OMIM;105650)

DBA is the principal cause of inherited erythroid specific bone marrow failure. Care should be taken to distinguish it from acquired causes of red cell aplasia, namely Pearson Syndrome; transient erythroblastopenia of childhood (TEC); and secondary immune or malignancy associated forms. The incidence in the population is 5–7 cases per million without gender or ethnic predilection. DBA is inherited in autosomal dominant mode in 45%, but de novo mutations are frequent. More than 90% of patients are diagnosed within the first year of life based on anemia, either related to symptoms or in the work up of the cephalic, thumb, cardiac or urogenital malformations seen in up to 50% of DBA patients. Short stature is diagnosed in 30%. At the extremes of the spectrum, some carriers are clinically silent while other patients present with nonclassical DBA picture indistinguishable from AA. There is no significant correlation between patient presentation, disease severity, clinical response to treatment and genotype. A macrocytic normochromic anemia with reticulocytopenia is found most often in the context of a normal bone marrow cellularity with dramatically reduced (<5%) erythroid precursors resulting from increased apoptosis in the erythroid precursors. In distinction to TEC, the anemia tends to be macrocytic and red cell adenosine deaminase (ADA) is elevated in 85% of individuals. Haploinsufficiency in one of at least seven responsible genes identified to date results in ribosomal dysfunction. But, while mutation sequencing in patients can therefore be useful, where available, for confirmation, family or prenatal screening, these genes account for only 43% of DBA patients. Erythropoietic failure in DBA is characteristically responsive to steroids, the mainstay of treatment. Up to 80% of patients respond to steroids, with about half each experiencing sustained responses and drug-dependent erythropoiesis versus relapse to transfusion dependence, respectively. Up to 20% will remit over time. However, related to potentially severe and debilitating effects steroids can have on immune function, neuromotor and musculoskeletal development, many practitioners favor transfusion for infants. In general, hemoglobin levels between 8 and 9 g/dl permit

musculoskeletal growth without undue suppression of hematopoiesis and excessive transfusional iron loading. Surveillance bone densitometry measurements may be indicated where available to detect developing osteoporosis early. As in cases of multilineage bone marrow failure, or hemoglobinopathies, the only curative treatment for DBA is transplantation. The indication for transplantation is often predicated on development of side effects of steroids treatment and transfusion associated iron overload. Outcomes for patients less than 10 years of age with available HLA matched sibling donors is up to 90% survival, while results in older patients and following unrelated donor transplantation are significantly worse. Anecdotal reports indicate occasional response to cyclosporine, metoclopramide and leucine in steroid resistant patients. Finally, it must be noted that patients with DBA, as with other BMF syndromes suffer an excessive risk for cancer at a generally earlier onset than the general population. Reports show predominant leukemia, MDS, lymphoma, and sporadic breast cancer or melanoma.

Transient Erythroblastopenia of Childhood (TEC)

Often the principal competing diagnostic consideration, TEC is an acquired, self-limiting disorder of erythropoiesis in children 1–4 years old and rarely in infants younger than 6 months. A normochromic and normocytic anemia with reticulocytopenia can last up to several months. A bone marrow evaluation is usually not indicated, only revealing erythroblastopenia while mostly normal red cell ADA levels are potentially useful in distinguishing DBA in the acute setting. A viral etiology has been suggested and there may be overlap with herpes, or parvovirus B19 infections. Close follow up and supportive care including transfusions for symptomatic patients may be required. The prognosis for complete recovery is excellent and treatment is not usually indicated, although empiric use of IVIG has been proposed for persistence.

Congenital Dyserythropoetic Anemia (CDA, type I–III)

CDA comprises a group of rare inherited disorders defined by ineffective erythropoiesis. CDA I (OMIM: 224120) presents with congenital macrocytic anemia and occasionally intrauterine hydrops. Infants tend to show signs of hepatomegaly and jaundice. However, some patients are not diagnosed until well into child and even adulthood. A moderate anemia is lifelong with jaundice and splenomegaly that may be delayed in onset. Additionally, some patients come to attention with dyskeratotic skin pigment changes and limb anomalies, specifically syndactily and metatarsal bone duplication. Autosomal recessive inheritance based on mutations in *CDAN1* has been reported in Bedouin populations. CDA is diagnosed based on evidence of ineffective erythropoiesis with high reticulocyte counts and low serum haptoglobin. Elevated indirect bilirubin is evidence of intramedullary and extramedullary hemolysis. The bone marrow exam shows characteristic erythroid hyperplasia with double nucleated erythroblasts and prominent ultrastructural abnormalities. Chromatin bridging occurs in over 50% and occasionally increased non-ringed sideroblasts and peripheral elliptocytosis are seen. It is important to exclude megaloblastic anemias, MDS, and myeloid leukemia, subtype M6. The administration of interferon alpha 2a can increase hemoglobin values.

Hemochromatosis is a frequent long-term complication, secondary to transfusion and increased intestinal absorptions. Patients requiring transfusions need to be monitored for iron load and end organ functions. Surveillance evaluation of hemoglobin, bilirubin, and ferritin is recommended. Similarly, where available, gall bladder ultrasound to evaluate for cholelithiasis and T2 MRI to determine cardiac as well as hepatic iron load is helpful. Chelation therapy may be indicated.

CDA type II (OMIM: 224100) is a more frequent and potentially more severe anemia characteristically associated with expression of an antigen that reacts with a naturally occurring cold reacting IgM antibody and abnormal glycoprotein band 3. Bone marrow evaluation shows multinuclearity in $>$50% of erythroblasts. Splenectomy has been found to be helpful in reducing bilirubin and improve anemia. Those benefits are sustained, but do not alter iron absorption. Malformations are less common.

CDA type III (OMIM: 105600) is a very rare form running a mild course with autosomal dominant inheritance. Diagnostically, it is distinguished by giant multinucleated erythroblasts and occasional monoclonal gammopathy.

Thrombocytopenia with Absent Radii (TAR, OMIM: 274000)

The characteristic association of an absent radial bone and isolated thrombocytopenia makes this rare syndrome straightforward to diagnose. The majority of patients are diagnosed with associated bleeding during the neonatal

period and many have additional orthopedic anomalies of other long bones. Bleeding can be severe, frequently gastrointestinal and occasionally intracranial. Thrombocytopenia typically resolves with time, but transfusions may be required. Not all patients recover normal platelet counts and resolution often takes until school age. No specific genetic test is indicated and a bone marrow is not required. The inheritance pattern is unknown.

Neutropenia Syndromes

Bone marrow failure with predominant neutropenia, including *ELANE* related congenital and cyclic neutropenia, is discussed elsewhere in this book.

Unclassified Bone Marrow Dysfunction

Not all bone marrow failure syndromes can be classified. This often causes considerable anguish and uncertainty among patients, parents, and practitioners. While symptomatic treatment is unaffected and should follow the standard of care for transfusions and in treating infections, clinical judgment has to be exercised to determine appropriate surveillance of blood counts and bone marrow status. As research into bone marrow failure has seen a recent resurgence, new genetic abnormalities and testing will become available.

334 Developmental Hemostasis

Rowena C. Punzalan · Veronica H. Flood

The Hemostatic System in the Neonate

In neonates, the coagulation system is dynamic and its development continues after birth. This phenomenon is more evident in premature neonates. *Figure 334.1* shows the prenatal development of components of the hemostatic system. Establishing reference ranges is complicated, as multiple reference ranges are needed, blood samples are difficult to obtain, and the amount of blood obtained is limited. In addition, more subjects are needed because of greater variability. Therefore, interpretation of coagulation test results in infants should take into account the age-dependent normal values.

Overall, in newborns, there is enhanced primary hemostasis, but decreased thrombin generation; in turn, there is reduced ability for anticoagulation and a hypofibrinolytic state. In the healthy newborn, all of these factors balance out and, therefore, do not lead to increased bleeding or thrombosis. In sick and preterm neonates, there are many acquired disturbances that can predispose to either bleeding or thrombosis.

Primary Hemostasis

Platelets can be found in the peripheral circulation at 11 weeks of gestation and have generally reached adult levels by 18 weeks of gestation (*Fig. 334.1*). Platelet function in neonates is slightly different than that seen in adults, with most studies indicating decreased responsiveness to the agonists ADP, collagen, epinephrine, and thrombin. Ristocetin-induced platelet aggregation is increased, likely secondary to higher von Willebrand factor levels in the neonate. Activation of platelets may occur in the neonate during childbirth. Neonates are not, however, at high risk of bleeding from platelet dysfunction despite these physiologic changes.

Coagulation

Neonates have overall decreased thrombin generation. Levels of the vitamin K–dependent factors (II, VII, IX, and X) and factor XI are significantly decreased compared to values in adults; the levels of fibrinogen and factors V and VIII are similar to adult values (*Table 334.1*). In healthy neonates, the prothrombin time (PT) is prolonged up to 2s above the adult reference ranges, while the activated partial thromboplastin time (aPTT) is $\geq$20 s or more above adult values. Von Willebrand factor is increased and ultra large molecular weight multimers are present at birth, which may explain the shorter bleeding time. Progressive maturation of the coagulation system occurs unless a coincident problem is present, with adult levels achieved by 6 months of age for some clotting factors but not until adolescence for others. Premature neonates are somewhat more likely than term neonates to have achieved adult levels by age 6 months. In otherwise well infants, the decreased coagulant factor levels are not associated with clinical bleeding.

Anticoagulation and Fibrinolysis

Both anticoagulation and fibrinolysis are thought to be downregulated in newborns. Plasma concentrations of naturally occurring anticoagulant proteins (antithrombin, protein C, and protein S) are significantly lower at birth than during later childhood and adulthood. Plasminogen and plasmin generation are reduced and plasmin inhibitors are increased. These observed decreases in anticoagulant and fibrinolytic factors usually do not cause thrombosis in otherwise healthy newborns. Being a sick neonate is a known risk factor for thrombosis, but the contribution of these decreased levels to this risk is unknown. All these differences need to be taken into account when interpreting lab values and managing anticoagulation in neonates.

Hemorrhagic Disorders in the Neonate

Most hemorrhagic disorders in the neonate are acquired. Thrombocytopenia likely contributes to most of these, but often coexists with other coagulation disturbances. Several inherited coagulation problems can also manifest in this age group.

In: Orkin SA, Fisher DE, Look AT, Lux SE, Ginsburg D, Nathan DG (eds) Nathan and Oski's hematology of infancy and childhood. Saunders Elsevier, Philadelphia)

Evaluation of the Bleeding Neonate

The most important consideration in the initial evaluation of the bleeding neonate is the clinical setting in which the bleeding occurs. Bleeding in an otherwise healthy neonate is more suggestive of an inherited coagulation disorder or immune-mediated thrombocytopenia. In a sick or premature neonate, abnormal bleeding is usually from acquired causes and often is multifactorial, including medications. Sepsis or surgery can cause a consumptive coagulopathy or disseminated intravascular coagulation (DIC). Protein loss (from chest or peritoneal drainage) can involve coagulation factors, but this is usually balanced by loss of anticoagulant factors as well. Maternal factors, including drugs (anticoagulants, antiepileptics, and antituberculosis drugs) and illness (preeclampsia) should always be considered. Complications during delivery can cause activation of the coagulation system and DIC. As discussed below, vitamin K deficiency may cause significant bleeding in the neonatal period. Finally, family history should be investigated, although not all affected infants will have a family history of bleeding disorders.

The bleeding manifestation is another very important consideration, especially in the presentation of an inherited bleeding disorder. Congenital coagulation disorders may present with oozing from the umbilical cord stump, scalp bleeding, cephalohematomas, bleeding from IV puncture sites, bleeding with circumcision, mucocutaneous bleeding, and bleeding with invasive procedures (*Table 334.2*). Sometimes, anemia may be the only manifestation of increased bleeding, so for unexplained anemia a source of bleeding should always be sought. Although not uncommon in premature infants, intracranial hemorrhage (ICH) in a term or late preterm infant without significant trauma should prompt an investigation for a bleeding disorder. In 349 newborns with hemophilia, bleeding consisted of ICH, more commonly subdural (27%) and increased bleeding with circumcision (30%) and heel stick (16%).

Laboratory Testing in Neonates

In the laboratory evaluation of a neonate with abnormal bleeding, it is important to consider sampling problems.

Table 334.1

Reference values for coagulation tests in healthy infants [mean (range of 95% of the population)][a]

Test or level	30–36 Weeks gestation infant	Term infant	1 Month–1 year	Children 1–5 years	Adults
Screening tests					
PT (s)	13 (10.6–16.2)	15.6 (14.4–16.4)	13.1 (12.1–14.6)	13.3 (12.1–14.5)	13 (11.5–14.5)
aPTT (s)	53.6 (27.5–79.4)	38.7 (34.3–44.8)	39.3 (35.1–46.3)	37.7 (33.6–43.8)	33.2 (28.6–38.2)
Platelet function screen					
Collagen/epinephrine closure time (s)		81 (61–108)		109 (92–126)	106 (82–142)
Collagen/ADP closure time (s)		56 (48–65)		89 (69–109)	85 (67–111)
Bleeding time (min)	3.4 (1.7–5.2)	1.8 (1.2–2.4)		6 (2.5–10)	4 (1–7)
Coagulant factors					
Fibrinogen (g/L)	243 (150–373)	2.8 (1.92–3.74)	2.42 (0.82–3.83)	2.82 (1.62–4.01)	3.1 (1.9–4.3)
Factor II (%)	45 (20–77)	54 (41–69)	90 (62–103)	89 (70–109)	110 (78–138)

[b]Value at 180 days

In newborns, there is often a volume limit to the amount of blood that can be collected, so the appropriate tubes that will yield the correct anticoagulant-to-blood sample ratio should be used. This is particularly important in neonates with polycythemia, which can cause spurious prolongation of the PT and aPTT. Activation of coagulation of the blood sample may occur more often in neonates because of the often difficult blood draws. Sample contamination, for instance, with heparin from central line sites of blood draw, may be more common in neonates

Table 334.2
Clinical presentation and treatment of rare congenital coagulation disorders

Factor deficiency	Clinical presentation	Treatment
Fibrinogen[a]	Umbilical stump bleeding, circumcision bleeding, soft tissue bleeding; infrequent ICH	Cryoprecipitate, FFP, fibrinogen concentrate
Factor II	Mucosal bleeding; surgical or trauma bleeding; rare joint bleed, ICH	FFP, PCC Aminocaproic acid
Factor V	Factor level does not predict severity of bleed, but homozygotes usually have spontaneous bleeding; mucous membrane bleed; ICH, subdural bleed; umbilical stump bleed; GI bleed; surgery/trauma bleed	FFP rFVIIa, FEIBA, platelets for those with inhibitors
Factor VII[a]	ICH, GI bleeding, soft tissue bleeding in very young; epistaxis, bruising, gum bleeding, postoperative bleeding; menorrhagia	rFVIIa PCC, FFP
Factor X[a]	ICH, umbilical stump bleed, GI bleed, bleed from needle punctures; menorrhagia, easy bruising, epistaxis, hematoma, hemarthrosis	PCC, FFP Factor X concentrate (Switzerland)
Factor XI	Circumcision bleeding, subdural hemorrhage; surgical (especially mucosal surgery) bleeding	FFP Factor XI concentrate
Factor XIII[a]	Umbilical stump bleed (80%); ICH (20–25%); delayed wound healing, abnormal scar, mucosal bleed, recurrent soft tissue bleed	Cryoprecipitate, FFP Factor XIII concentrate
Alpha2 antiplasmin-1	Umbilical stump bleed	Tranexamic acid Aminocaproic acid (no data in neonates)

[a]Disorders most likely to present in the neonatal period

because of the smaller blood volumes. As above, age-appropriate reference ranges should always be used when interpreting results (*Table 334.1*). However, even those values should be interpreted with care, as there can be overlap of the abnormal and normal values. A striking example of this is the values for aPTT, which can be physiologically prolonged in neonates, but may be "normal" in the presence of hemophilia.

Evaluation of hemostasis in neonates is similar to that performed in older children. A complete blood count is essential to determine platelet number. Review of the peripheral blood smear is useful to evaluate platelet size and granularity. PT and aPTT provide a general screen of clotting factors. Fibrinogen levels may also be useful to detect consumption or decreased fibrinogen production. The platelet function analyzer (PFA), although intended to provide an assessment of platelet function, has suboptimal sensitivity and specificity for diagnosis of both von Willebrand disease and platelet function defects. Some studies have shown shorter PFA closure times in term infants, but no data exists for premature infants and a normal range is not well established for neonates. Platelet aggregation studies will demonstrate platelet function, but the amount of blood required and need for a specialty laboratory restrict the general application of this test. *Table 334.3* details the laboratory studies useful in workup of neonatal hemostasis.

Congenital Deficiency of Coagulant Factors

The most common congenital disorders of coagulation are deficiencies of factors VIII and IX (hemophilia A and B, respectively). These, along with congenital disorders of primary hemostasis (von Willebrand disease, platelet function defects), are discussed in a previous chapter.

Clinically significant congenital deficiencies of fibrinogen, prothrombin, and factors V, combined V/VIII, VII, X, XI, and XIII, combined vitamin K–dependent factors (prothrombin and factors VII, IX, X), and the contact

Table 334.3
Evaluation of neonatal hemostasis

Screening tests	Diagnostic tests
CBC	Factor VIII
PT	Factor IX
aPTT	Factor XIII
Fibrinogen	Von Willebrand factor (antigen, activity)
d-Dimer	Platelet glycoprotein expression
Platelet function analysis	Platelet aggregation

factors are rare and usually inherited as autosomal-recessive traits. Those most likely to present in the neonatal period include deficiencies of factors VII, X, and XIII, and deficiency or dysfunction of fibrinogen (*Table 334.2*). Of note, recent studies show that deficiencies in factor XII, prekallikrein, and high-molecular-weight kininogen may prolong the aPTT but do not cause abnormal bleeding. Patients with congenital coagulant factor deficiencies are usually treated episodically for acute bleeding or surgery. The mainstay of treatment is coagulation factor replacement. Generally, neonates with single-factor deficiencies are treated with either recombinant or plasma-derived concentrates for the specific factor whenever available, which allows the administration of adequate and precise doses in relatively small volumes. These products have also been treated to minimize the risk of viral disease transmission. Recombinant factor VIIa (rFVIIa) is used both as bypassing agent in the treatment of hemophilia with inhibitors and replacement therapy for bleeding or surgery for patients with factor VII deficiency. Cryoprecipitated antihemophilic factor is used as a source most frequently of fibrinogen and rarely of factor XIII. However, purified factor XIII concentrate and a virus-inactivated fibrinogen concentrate are available. A factor XI concentrate is available in Europe. Prothrombin complex concentrates or plasma may be used for the treatment and prophylaxis of bleeding in patients with deficiency of prothrombin, factor VII and X, and the vitamin K–dependent factors. There is no factor V concentrate available.

Acquired Coagulant Factor Deficiency

Common acquired disorders include liver disease, DIC, and hemorrhagic disease of the newborn.

Liver Disease in the Neonate

Liver disease in neonates may lead to disorders of coagulation. Since the liver is the site of synthesis for the majority of coagulation factors, hepatic dysfunction will lead to a decrease in procoagulant factors as well as some anticoagulant factors. The PT and PTT will be prolonged, and fibrinogen should be low. Bleeding, particularly mucosal bleeding, is common. Treatment consists of coagulation factor replacement via plasma infusions and cryoprecipitate. Fresh frozen plasma at a dose of 10–20 mL/kg should increase clotting factors by approximately 1% per mL given per kilogram of body weight. Evaluation and treatment for the underlying cause of liver disease will be required.

Disseminated Intravascular Coagulation

Prolonged PT and PTT may also represent consumption of coagulation factors due to DIC. Sepsis is the most common cause in neonates, particularly those in intensive care units. Infants with DIC may present with either bleeding or thrombosis. Congenital protein C or protein S deficiency should be suspected in the setting of purpura fulminans, although infection may also cause this presentation. D-dimers are usually elevated in DIC, but these elevations are usually non-specific. Treatment is aimed at eradicating the underlying cause. Administration of plasma, cryoprecipitate, or platelets may be required, but should be reserved for those infants who are actually symptomatic. Heparin anticoagulation in DIC is occasionally used in patients with evidence of thrombosis, but there is a paucity of evidence to support its effectiveness.

Previously, treatment of patients with coagulopathy due to synthetic or consumptive processes was restricted to replacement with fresh frozen plasma to replete all coagulation factors, and/or cryoprecipitate to replete fibrinogen, factor VIII, and von Willebrand factor. Recently, rFVIIa has become available and has been widely used in this setting, although it is not generally recommended due to the potential risk of thrombosis.

Hemorrhagic Disease of the Newborn

Vitamin K is a cofactor in γ-carboxylation of procoagulant factors II, VII, IX, and X, as well as anticoagulant factors such as protein C and S. Vitamin K levels are decreased in the newborn as compared to adults. Therefore, those

clotting factors that depend on vitamin K–mediated posttranslational modification will be decreased in the newborn period. Deficiency of vitamin K leads to a relative decrease in procoagulant factors, which may lead to clinically significant bleeding. Such bleeding, originally termed hemorrhagic disease of the newborn, is now referred to as vitamin K–dependent bleeding, or VKDB.

Early VKDB presents within the first day of life with severe bleeding, often intracranial hemorrhage or GI bleeds. Early VKDB may be due to maternal medications such as anticonvulsants leading to chronically low vitamin K levels throughout pregnancy. Classic VKDB presents in the first week of life in infants with inadequate intake. The incidence is approximately 1 in 10,000 births without prophylaxis. Late VKDB presents within 6 months of birth in breast-fed infants or infants with malabsorption disorders such as cystic fibrosis or celiac disease. Usual sites of bleeding include the skin and GI tract, although intracranial hemorrhage is unfortunately not an uncommon presenting feature.
