Case History. A 2-year-old girl experienced a ketolactic acidotic hypoglycemia with hypocalcemia in the third month of life, and she had five further episodes with severe ketolactic acidosis, peripheral shock, and hypoglycemia during the first 2 years of life. The parents were not particularly attentive and did not note any relationship between acidotic episodes and consumption of sweet substances. She was admitted electively to prove the presumed clinical diagnosis of FDPase deficiency. Despite the short stature of the parents, her height on admission was 92 cm and weight 14.8 kg, which were in the 75th percentile. On examination she had 2-cm hepatomegaly below the right costal margin, with a smooth and round liver edge. The fasting blood glucose was 4.3 mM, lactate was 2.4 mM, and there was no BE; her other liver function tests were within normal limits and blood insulin was appropriate for glycemia. She was given a challenge of 250 mg/kg fructose. Blood glucose decreased gradually from 4.3 to 3 mM and blood lactate gradually increased to 5.7 mM at 90 min after

fructose loading. The test was discontinued in 3 h, at which time the blood glucose was 3.8 mM and lactate 4.2 mM. The BE at 90 min as well as at 3 h was −5.7 mEq/L. Thus the clinically presumed diagnosis of FDPase deficiency was proven and she was sent home on a strictly fructose-restricted diet. She came to the ER four times over the next 2 months with the same findings: peripheral shock, coma, acidosis, and hypoglycemia. It was learned that there were five normal children in the family, and that they were giving her candy behind the parents' backs, which was triggering the episodes. Since venous excess gradually became a problem and since she always reached the ER in shock, she was admitted and an indwelling catheter was placed. The parents became more attentive and during the next year she did not experience another episode, and the indwelling catheter was removed. At present, she is 8 years old, and her growth parameters are in the tenth percentile.

Glycogen Storage Disease Type 1 (von Gierke Disease)

This is a disease with a highly variable phenotype and etiologies. In its classic form, the infant starts experiencing early-morning hypoglycemia and lactic acidosis that usually are associated with grand mal seizures. History reveals a bleeding tendency, particularly from the nose, and failure to thrive, and the parents note the protuberant abdomen as early as 2–3 months of age. Physical examination will reveal impressive hepatomegaly in a child with abnormal fat distribution. The face will accumulate fat in the cheeks, looking like that of a trombone player (*Fig. 38.29*), while the extremities are thin. The skin may reveal ecchymoses or petechiae. The presence of almost continuous hyperlactic acidemia and low blood glucose alerts the pediatrician to the disease. The blood uric acid, triglyceride, and cholesterol levels are usually very high. Significant renal involvement may lead to a Fanconi syndrome–like urinary excretion pattern with significant aminoaciduria. Despite the bleeding tendency, both the number of platelets and bleeding and coagulation studies are normal. The metabolic crisis may be extremely severe, with pronounced hypoglycemia, hypokalemia, metabolic acidosis due to the accumulation of lactic acid, some degree of ketosis, and a serum that looks like milk, indicating fat mobilization from the adipose tissue. Such a crisis should be managed vigorously with glucose, potassium, and alkaline administration.

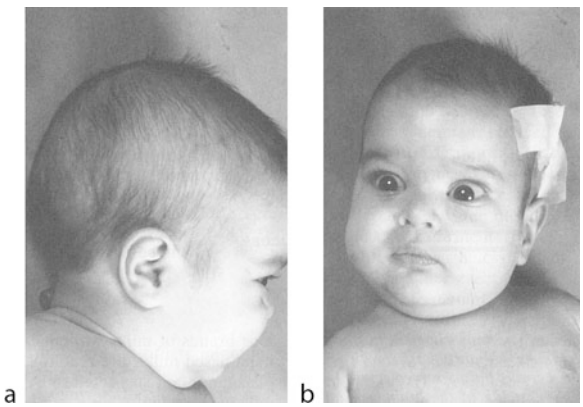

Figure 38.29
(a) Trombone player face of a patient with glycogen storage disease type 1A (von Gierke disease), lateral view. (b) Frontal view of the face in the same patient

The deficiency or abnormal structure of the microsomally located glucose-6-phosphatase (*Fig. 38.9*) causes GSD type 1A disease. The liver is unable to convert the lactic acid and alanine arriving from peripheral organs into blood glucose; therefore, continuous fat mobilization leads to fat infiltration in the liver. The liver biopsy will reveal large amounts of fat in addition to glycogen. Despite the severe liver involvement, liver enzymes in the circulation are elevated only slightly, certainly less than that observed in GSD type 3. Since this situation can be best described as "overfed liver and starving periphery," the treatment is aimed at reversing this cycle. In severe cases, the patient must be given a solution with glucose and high nitrogen (e.g., Vivonex) through a NG tube if he or she can tolerate it (e.g., if he or she does not develop difficult-to-control nosebleed). This feeding is done during the night by continuous administration of the solution through a pump; the child must be fed breakfast in the morning as soon as the pump feeding stops, otherwise he or she will develop a reactive hypoglycemia. When noctural feeding through a pump is not feasible, late-night feeding with a pudding prepared with uncooked starch and artificial sweeteners will prevent early-morning hypoglycemia. Successful management will lead to diminished liver size, improved growth, and improvement in the aforementioned biochemical parameters. The long-term complications of the disease are stunted growth, hepatomas, and uric acid nephropathy.

A distinct variety is GSD type 1B, in which the translocase for glucose 6-phosphate that carries the sugar phosphate to the compartment of glucose-6-phosphatase is deficient. This phenotype includes defective neutrophil leukocyte function and neutropenia, in addition to the features of GSD type 1A. The patient suffers from frequent infections. Treatment with granulocyte colony-stimulating factor may control these infections. The determination of glucose-6-phosphatase in liver biopsies, fresh

and frozenthawed, establishes the diagnosis. When the enzyme activity is absent both in fresh and frozen-thawed samples, it is type 1a; when it is absent in fresh but present in frozen-thawed samples, it is type 1B.

Case History. A 4-month-old boy at the time of admission was the product of a normal pregnancy and delivery, the second child of second-degree-cousin parents who were of Lebanese origin. The referral diagnosis was type 1 GSD, since he had a greatly enlarged liver. He experienced a devastating metabolic acidosis with a pH of 7.16, BE of −23 mEq/L, and blood glucose of 1 mM. At that time, he was found to have a hepatomegaly 3 cm below the right costal margin. He was treated with IV fluids and discharged home without a diagnosis. The mother noticed a distended abdomen at 3 months, with chubby cheeks. He was admitted to another hospital, where he was found to have a right liver edge at 7 cm and possibly a left lobe of the liver 3 cm below the costal margin. An abdominal ultrasound confirmed the enlarged organ on the left to be the liver and not the spleen. He did not have hypoglycemic seizures.

On admission his height, weight, and head circumference were at the 25th percentile. The liver on the right was 14 cm and on the left was 4 cm below the costal margin. He had evidence of nosebleed, but the platelet count was 440,000/mm^3. He had mild hypochromic, microcytic anemia. Hepatic profile indicated triglycerides of 20.3 mM (normal upper limit: 1.82 mM), cholesterol of 7.28 mM (normal upper limit: 4.7 mM), uric acid of 560 µM (normal upper limit: 240 µM), and alkaline phosphatase, ALT, and AST of 306, 173, and 199 U/L, respectively (normal upper limits: 240, 25, and 40 U/L, respectively). The abdominal ultrasound confirmed the enlarged liver and detected enlarged kidneys. An EEG was normal; MRI of the brain indicated mild delayed myelination and somewhat dilated ventricles, but there was no brain atrophy. A liver biopsy was done that indicated the presence of type 1A GSD. The glucose-6-phosphatase was 0.5 µmol/mg/h in both fresh and frozen-thawed samples (normal: 3.3 ± 1 µmol/mg/h); liver glycogen content was 5.3 µmol/g protein (normal upper limit: 1.2 µmol/g protein). The liver brancher enzyme, phosphorylase, phosphorylase b kinase, and debrancher enzyme activities were normal. He was placed on a fructose-restricted diet with frequent feedings. His growth and liver profile did not improve during the next year. He was then placed on Vivonex high-protein nocturnal feedings through a NG tube nightly for 10 h for 6 months at 33% of his daily caloric need. He suffered from frequent nosebleeds, at times copious, and had to have nasal septum cautery twice. The nocturnal feedings therefore had to be abandoned.

During the next 3 years his growth remained parallel to normal growth lines, but the height remained 4 standard deviations (SD) below the normal lower limit and weight at the fifth percentile. At present he is 5.5 years old. His liver size has decreased to 6 cm below the right costal margin; the left lobe of the liver is not palpable. The abdominal ultrasound indicates a normal echogenic liver with no focal lesions. Both kidneys remain enlarged, with increased echogenicity of the cortex but preserved echogenicity of the medulla. His last CT of the brain and EEG were normal. He never experienced hypoglycemic seizures, but continues to have bleeding diathesis and nasal bleeds. His chubby appearance has become less prominent. His disturbed liver profile with mildly increased liver enzymes, cholesterol, hypertriglyceridemia, lactate, and urate remain as before.

Galactosemia

Although the disease may manifest early during the neonatal period, its appearance may be delayed a few weeks to a few months after birth. In severe galactosemia the initial symptom might be sepsis, and, in all infants/neonates who have sepsis, galactosemia must be ruled out. There are several types of galactosemia with different enzyme defects in the pathway of galactose utilization (*Fig. 38.30*). Only classic galactosemia, that is, phosphogalactose (PGal) transferase deficiency, will be presented here. In most infants with classic galactosemia, the first symptoms are hepatomegaly, cataracts, and renal Fanconi syndrome. In many instances, it is the ophthalmologist who refers a child whose cataracts are surgically removed to the

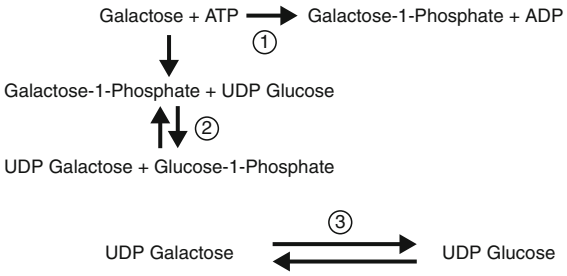

Figure 38.30
Pathway of galactose metabolism. Enzymes involved: (1) galactokinase, (2) galactose-1-phosphate uridyltransferase (PGal transferase), and (3) uridine diphosphate galactose 4-epimerase. Diseases related to deficiency of the aforementioned enzymes: (1) galactokinase deficiency, (2) classic galactosemia, and (3) epimerase-deficient galactosemia

pediatrician for evaluation, at which time the disease is diagnosed. A patient with PGal transferase deficiency whose cataracts have been removed is shown in *Fig. 38.31*. The patient will have hypoglycemia but no acidosis. The most important pathognomonic finding is positive reducing substance in the urine that tests negative with glucose oxidase-dipped paper. It must be remembered that any patient with severe primary or secondary liver disease will have tyrosinuria, which will react as a positive reducing substance. The identity of galactose in such urine samples must be proven by special biochemical tests. An alternative approach will be to determine the putative enzyme deficiency (i.e., PGal transferase) by directly testing in the red blood cells. A word of caution is that, in order to prevent false-positive and false-negative results, the patient must not have been transfused within 4 months, and the blood sample must be processed fresh, since the enzyme is labile and will lose its activity, even in the cold. The disease is best controlled by strictly restricting the galactose- or lactose-containing food substances in the diet. Various brands of milks without lactose, or soybean- or banana-based milks, are readily available. It is advisable to place an infant suspected to have galactosemia on such a milk product while waiting for the results of enzyme analysis. Long-term complications of the disease include sterility in female patients. The intelligence will be usually, but not always, normal in well-controlled patients. The mother of such a child must be placed on a galactose-restricted diet during subsequent pregnancies in order to prevent the emergence of cataracts in a galactosemic fetus.

Case History. A 14-month-old boy was noted to have poor development since birth. He was found to have cataracts at 1 year of age, and was referred for workup. His height and weight were 3 SD below the normal limit, and head circumference was at the fifth percentile. He could not sit without support and had no speech. The liver was enlarged 4 cm below the right costal margin. He had central hypotonia with head lag. His liver enzymes were mildly elevated but he had normal fasting glycemia. The uridine diphosophoglucose galactose-1-phosphate transferase (PGal transferase) in red blood cells was 2 U (normal: 20–40 U). The enzyme levels in the father and mother were 22 and 22 U, respectively. The EEG was normal; MRI of the brain revealed delayed myelination, particularly prominent at the frontal cortex. His cataracts were removed. He was placed on a galactose-free diet and was discharged home. He did well, and, when assessed at 43 months of age, his mental age was 16 months with pronounced linguistic delay, and he showed hyperactive behavior. At the age of 72 months, his mental age was 60 months, but he still showed hyperactive behavior. Retinal examination at that time indicated a prominent nerve fiber layer around the macula and optic disc. A recent MRI of the brain indicates improved myelination and no brain atrophy.

Figure 38.31

Amino Acidemias

Although most amino acid disorders are of late infantile/childhood onset, only those five disorders listed in *Table 38.9* will be presented. Their diagnosis will often be missed in the absence of a neonatal screening program.

Hyperphenylalaninemia

This disease is due to a deficiency of phenylalanine hydroxylase, which catalyzes the conversion of phenylalanine to tyrosine (*Fig. 38.32*). Its deficiency leads to hyperphenylalaninemia, decreased tyrosinemia, and an increased phenylalanine/tyrosine ratio (>2). The hyperphenylalaninemia leads to an increased excretion of its catabolic product, phenylpyruvic acid, which reacts with ferric chloride at acid pH to give a dark green color, which was used in the past to diagnose the presence of the disease. The name PKU (phenylketonuria) was used to indicate

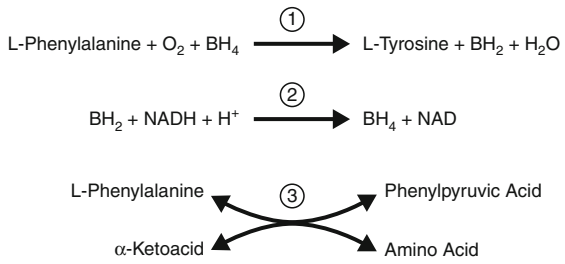

Figure 38.32
Metabolism of phenylalanine. Enzymes involved: (1) phenylalanine hydroxylase, (2) dihydropterin reductase (DHPR), and (3) transaminase. Diseases due to deficiency of the aforementioned enzymes: (1) classic PKU, and (2) biopterin-dependent PKU due to DHPR deficiency. (3) The transaminase pathway under normal conditions is a minor one; when phenylalanine hydroxylase is deficient, large amounts of phenylpyruvic acid are formed and excreted in the urine, which can be detected by the ferric chloride test

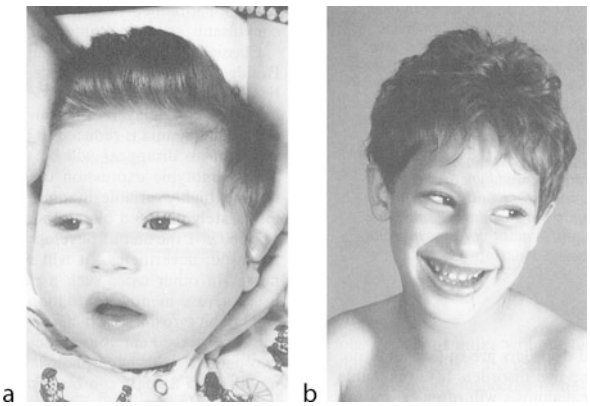

Figure 38.33
(a) A blond, 8-month-old infant who was referred for his myoclonic seizures and was found to have PKU. (b) An 8-year-old boy with PKU, whose disease was diagnosed at 1 year of age. He had mild disease that responded to dietary treatment. His school photo indicates his persistent light complexion

the excretion of phenylpyruvic acid in the urine. Hyperphenylalaninemia in infants is an insidious disease, which may show no symptoms until after 1 year of age. The initial rationale for many neonatal screening programs was this late presentation. Since the safety window for its diagnosis is only 6 weeks after birth, by the time the first symptoms appear the child will be microcephalic and moderately retarded, in which case the neurologic damage cannot be reversed. Occasionally the disease might manifest with myoclonic seizures as early as 4 months of life; such a child will be treated in vain with adrenocorticotropic hormone (ACTH) and anticonvulsants as having "infantile hypsarrhythmia."

Classic hyperphenylalaninemia is a panethnic disease. Besides seizures, the symptoms in an untreated older patient include severe attention-deficit disorder, hyperactive behavior, and delayed or absent speech. When the hyperphenylalaninemia is reduced to less than 800 μM, the first symptom to disappear will be the hyperactive behavior. The phenotypic expression of classic hyperphenylalaninemia is highly variable; in some patients, despite persistent moderately elevated blood phenylalanine values of 1,200–1,600 μM, the mental development might not be severely impaired; nevertheless, it will remain below the normal range. In other cases such a persistently high level will cause severe mental retardation. Hyperphenylalaninemia will inhibit tyrosinase, which causes light pigmentation that can be observed early in infancy. The light complexion of two patients with hyperphenylalaninemia at the age of 4 months and 8 years can be appreciated from the photos in *Fig. 38.33*. At times, an eczematous lesion will be apparent on the face or various parts of the body. Successful management leads to gradual darkening of the hair and skin color.

The infant with hyperphenylalaninemia must immediately be placed on phenylalanine-restricted formulas or food, with frequent monitoring of blood phenylalanine values, to assure a blood level of 300–800 μM. Well-managed patients will have normal mentality, and the diet may be relaxed after the teenage years. More recently, it has been shown that the supplementation of the diet with BCAAs and tryptophan will decrease the entry of phenylalanine into the CNS and ameliorate the deleterious effects of hyperphenylalaninemia. At a later age, a patient with hyperphenylalaninemia will have aversion to protein, since increased phenylalaninemia will cause cerebellar signs, in addition to speech difficulties and dull behavior. In female patients with hyperphenylalaninemia, if the blood phenylalanine level is not strictly controlled during pregnancy, the baby will be born with severe congenital defects, such as congenital heart disease, microcephaly, and severe brain damage (maternal PKU).

Case History. A 1-year-old boy was normal until 3 months of age, at which time he developed tonic seizures following a febrile episode. He had two to three seizures daily and was considered to have hypsarrhythmia, for which he was treated with ACTH. His seizures did not

improve; later he was given phenobarbital, which did not control the seizures either. He developed strabismus and nystagmus at 6 months of age. At the referral hospital his urine tested positive with a ferric chloride test and he was referred for detailed workup. He had started to sit with support at 6 months of age but lost all his milestones after 7 months. The parents noticed his visual loss at 8 months of age. At the time of the initial encounter at 1 year of age, he was an irritable child, continuously fussing, and he had no visual pursuit. He was blond and had fair features, while his parents and their other children were of darker complexion. He had severe nystagmus. He showed choreoballismus with occasional myoclonic twitching of the face and extremities. The height and weight were at the 50th percentile, while the head circumference was below 2 SD. His face had a cushingoid appearance, the result of the ACTH treatment. His eyegrounds showed bilateral moderately severe optic atrophy. He lay in the pithed-frog position, with severe central hypotonia. He did not have any parachute or magnetic response and had not developed primitive bipedal reflexes. He could not sit with support. He made cooing sounds but had no syllabic speech. He was assessed at a 2- to 3-month functional level at 12 months of age. His blood phenylalanine was 1,810 μM (normal: <120 μM). The early onset of severe encephalopathy and myoclonic activity suggested a biopterin-dependent PKU; however, his blood phenylalanine was not normalized when he was given tetrahydrobiopterin. The MRI of the brain indicated severe generalized white matter disease; a fibroblast culture was tested for metachromatic leukodystrophy as well as for Krabbe disease, both of which were negative. Carboxylase activities, blood very-long-chain fatty acids, and phytanic acid were also normal. The EEG showed poor background organization with discharges from the posterior quadrant. Visual evoked potentials indicated absent response. BAERs were also abnormal, with small peaks 3 and 5. The peripheral nerve conduction was normal. The CSF analysis indicated normal pterins and normal protein. He was diagnosed as having classic PKU of unusual severity and was placed on a phenylalanine-restricted diet. At present he is 9 years old and his mental age is 30 months; his motor skills are less impaired than his cognitive ability and speech. He is showing hyperactive behavior. The parents were not very compliant with the diet, and his blood phenylalanine level could be maintained only in the range of 700–1,600 μM. His nystagmus has disappeared, with only moderate left optic atrophy and alternating strabismus. Meanwhile, the parents had another male child who was diagnosed to have classic PKU at birth. He was placed on a phenylalanine-restricted diet. At present he is 5 years old and is totally normal, with no neurologic signs and with normal development.

Biopterin-Dependent Hyperphenylalaninemia (PKU)

Reduced biopterin (tetrahydrobiopterin or BH_4) is the cofactor of phenylalanine hydroxylase (◉ *Fig. 38.32*). BH_4 is synthesized from guanosine triphosphate (GTP) in several steps, the lack of any of which will cause its deficiency (◉ *Fig. 38.34*). The disease is known as malignant PKU. BH_4 is also a cofactor for other hydroxylases, namely, tyrosine hydroxylase and tryptophan hydroxylase, as well as for nitric oxide (NO) synthetase. This enzyme initiates pathways that lead to the synthesis of norepinephrine, epinephrine, and serotonin, and NO, a general neurotransmitter. Therefore, when BH_4 is deficient, in addition to the symptoms of hyperphenylalaninemia, serious autonomic and CNS dysfunction occurs. The CNS manifestations of the autonomic dysfunction include disturbed respiratory and cardiac rhythm. Immune function in these patients might also be disturbed. The presentation of this type of PKU is usually early, at 2–4 months of age, with infantile parkinsonian symptoms such as bradykinesia and cogwheel rigidity, indicating dihydroxyphenylalanine (DOPA) deficiency, in association with myoclonic seizures caused by the serotonin deficiency. A typical story is a consultation from the intensive care unit for an infant who developed bronchopneumonia and who has arrested with respiratory and cardiac irregularities, and who was found to have the aforementioned neurologic signs. The blood phenylalanine may not be as high as that in classic PKU, since some biopterin supplied through the milk or diet might be adequate to replenish the requirement of the liver phenylalanine hydroxylase. Since high doses of biopterin are required for its transport into the CNS, the neurologic symptoms will be severe in the face of mild hyperphenylalaninemia. The diagnosis can be easily verified by following the blood phenylalanine before, during, and after the administration of BH_4. Its values will be normalized within hours of administration of BH_4.

The determination of types of pterins excreted in the urine will establish an exact location of the enzyme defect. In GTP cyclohydrolase deficiency there will be no pterins in the urine. The clinical picture of this deficiency might be transient and may vary in its severity. In 6-pyruvoyltetrahydropterin synthetase (6PTS) deficiency, urine neopterin will be very high and biopterin will be very low. The clinical presentation of this disease is also variable, ranging from severe to mild. The fair features and rigidity of a patient with 6PTS deficiency are shown in ◉ *Fig. 38.35*. The prognosis of the mild variant of

Other reactions catalyzed by BH_4

Enzymes involved: (1) tyrosine hydroxylase; (2) tryptophan hydroxylase; (3) nitric oxide synthetase

Tetrahydrobiopterin Synthetic Pathway

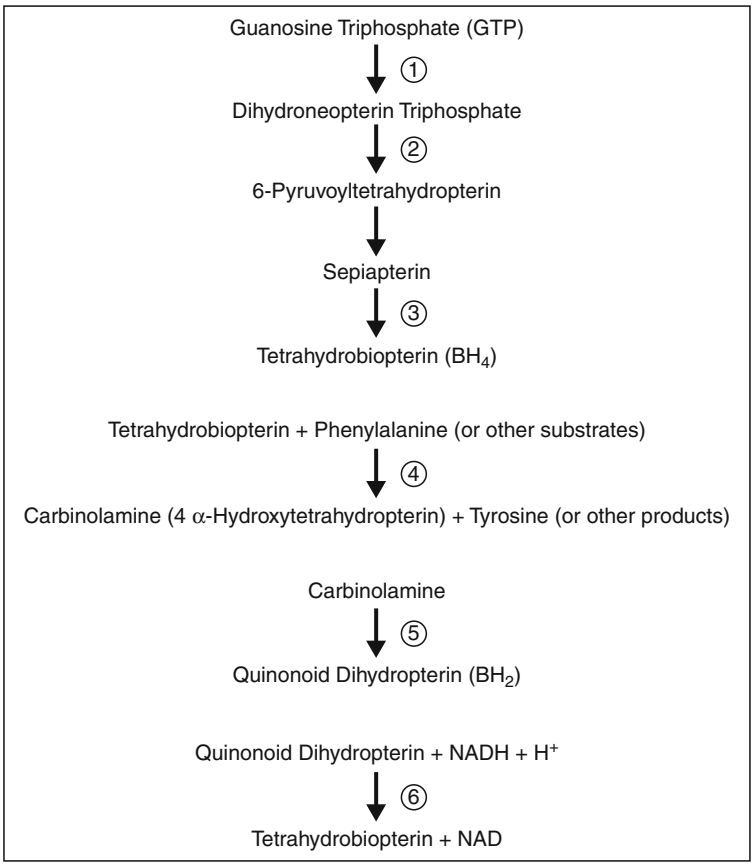

Figure 38.34

Reactions catalyzed by tetrahydrobiopterin and the tetrahydrobiopterin biosynthetic pathway. Deficiencies of several enzymes cause biopterin-dependent PKU. (1) GTP cyclohydrolase; in its deficiency there are no pterins in the urine. (2) 6-Pyruvoyltetrahydropterin synthase (6PTS); in its deficiency urine neopterin is high and urine biopterin is low. (3) Sepiapterin reductase; its deficiency-related condition is not known. (4) Hydroxylating enzymes such as phenylalanine, tyrosine, or tryptophan hydroxylases. (5) Carbinolamine dehydratase; when it is deficient, primapterinuria occurs. (6) Dihydropterin reductase; in its deficiency, increased urinary excretion of biopterin occurs. Folic acid deficiency also is observed since the enzyme also catalyzes the reduction of dehydrofolic acid

a 6PTS-deficient patient is excellent, as evidenced by the photo of the same patient together with another affected brother of school age (*Fig. 38.35*). In dihydropteridine reductase deficiency, there is excessive urinary excretion of biopterin. The clinical picture of this deficiency is very severe, and the clinical course might not be altered by the treatment procedures outlined later.

Once the diagnosis is established, the patient must be immediately provided the precursors of the aforementioned neurotransmitters, that is, the compounds subsequent to

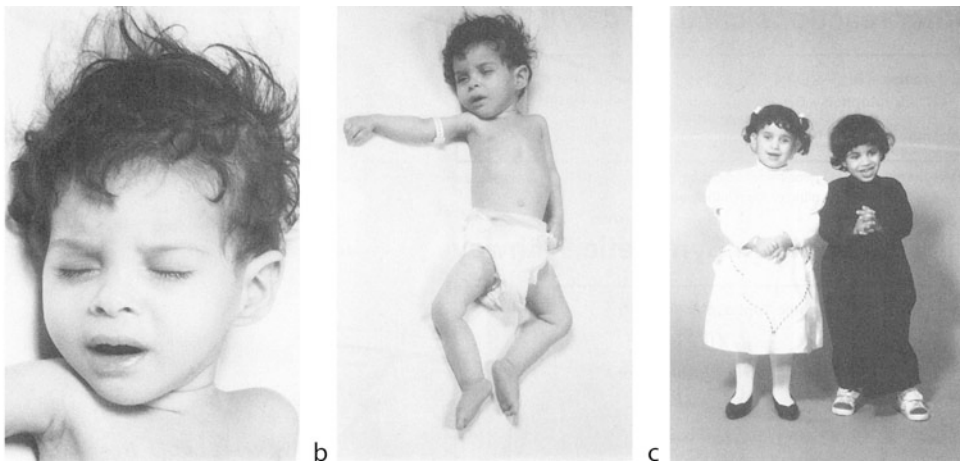

Figure 38.35
(a) Light complexion of a 1-year-old girl who was referred for rigidity, myoclonus, frequent chest infections, and cardiac arrest. She was found to have biopterin-dependent PKU due to 6-pyruvoyltetrahydropterin synthase (6PTS) deficiency. (b) Her rigid posture. (c) At the age of 7 years, she is attending normal school after rewarding response to the treatment. Her brother, at her side, was diagnosed very early to have 6PTS deficiency, and is a normal boy after the treatment

the step of hydroxylation reaction. These are DOPA and L-5-hydroxytryptophan, together with carbidopa to prevent their uptake by the peripheral tissues as well as assure adequate CNS uptake. The symptoms will resolve immediately except in late-diagnosed cases, in which, due to supersensitivity of the CNS autonomic neurons to the neurotransmitters, some symptoms suggestive of tardive dyskinesia, choreoathetosis, and at times high blood pressure might appear. In most instances tachyphylaxis will be established within a week, and the patient will tolerate the medication without side effects. A costly but effective treatment is to provide the patient with oral BH_4.

Case History. A 6-month-old boy who was an IUGR infant with 1.4-kg birth weight failed to thrive after birth, suffering from numerous chest infections requiring intensive care hospitalization three times. The parents were first cousins and the father had married twice. Previously he had a son from each wife, both of whom expired with a similar disease that led to sudden cardiorespiratory arrest. At the age of 5 months the patient suffered a cardiorespiratory arrest and the pediatric intensive care unit physician noticed truncal hypotonia, bradykinesia, and periods of "eye rolling." The patient was observed to have facial eczematous lesions and fair eye color with fair features. A metabolic disease was suspected and a blood test revealed hyperphenylalaninemia, at 1,632 μM (normal upper limit: 120 μM). At the time of initial encounter at 8 months of age, his weight was 2.76 kg and height 50 cm. He had a draining right otitis media and mild hepatomegaly. He was lying in a rigid posture with clenched hands and did not move, with eyes rolling upward periodically, increased reflexes, and severe head lag. A chest x-ray revealed minor infiltrates bilaterally. CT of the brain showed delayed myelination, and the EEG did not confirm the clinically observed myoclonus. Repeat sweat chloride tests were normal, and immunoglobulins G, A, D, and E were normal, although M was nine times elevated. Subclasses of immunoglobulin G were also normal. The clinical presentation strongly suggested a biopterin-dependent PKU. A urine study revealed ten times the elevated neopterin with barely detectable biopterin. When he was given BH_4 20 mg/kg/day, blood phenylalanine reduced to less than 120 μM within 24 h, with normalization of urinary neopterin and biopterin within 36 h. Initially the CSF neopterin was five times that of normal with no biopterin. Upon treatment with BH_4, the CSF neopterin decreased to normal levels and biopterin became detectable. He was kept on BH_4 treatment at the dose mentioned, and was also given DOPA (15 mg/kg/day), carbidopa (3.75 mg/kg/day), and L-5-hydroxytryptophan (4 mg/kg/day). During the initial month of this therapy he developed transient high blood pressure and mild choreoathetosis with mild symptoms of tardive dyskinesia. These symptoms eventually disappeared, and his further development has been normal and uneventful. His only problem has been a persistently draining right otitis media, which

unfortunately led to loss of function on that side. At present he is 12 years old and is attending grade school, where he is an average student. His height and weight remained 4 SD below the lower limit, but his growth velocity is normal. The father later had another daughter with the same disease. She was diagnosed soon after birth, was given appropriate treatment, and is growing normally.

Dihydrolipoyl Dehydrogenase (E_3) Deficiency

Dihydrolipoyl dehydrogenase, or E_3, is the common subunit of three dehydrogenases: pyruvic, α-ketoglutaric, and branched-chain α-keto acid dehydrogenases (*Fig. 38.36*). When defective, it leads to a clinical picture with periodic metabolic crisis, reminiscent of MSUD. Such a patient will be normal in between attacks, which are precipitated by heavy protein intake or infections. During the metabolic crisis, the patient will show cerebellar signs and, besides lactic acidosis, there will be significantly high α-ketoglutaric aciduria and branched-chain α-keto aciduria. The blood levels of BCAAs will be elevated four to eight times. These findings will establish the diagnosis, since the enzyme determination might not be always available. The disease is self-limiting, and the child should be managed by avoidance of fasting and frequent feeding of low-protein meals.

Case History. An 8-year-old boy had experienced two devastating metabolic episodes with severe ketolactic acidosis. Heavy meals or a minor respiratory infection triggered these episodes, and he vomited continuously for 1–2 days before becoming obtunded and sick and showing acidotic breathing. Intravenous fluids, glucose, and bicarbonate easily managed his symptoms, and he would recover without any neurologic deficits. These episodes took place at another hospital, and urine and blood samples from the time of the acute attacks were not available. During the next 3 years, he was followed up on an outpatient basis with extensive workup. Clinically he was normal, with no organomegaly or neurologic signs. He remained an excellent student in grade school, participating in all school activities. While he had no clinical complaints, numerous studies for urine, blood organic and amino acids, and blood acylcarnitines all remained within normal limits, except for lactic acid, which ranged from 2.4 to 2.8 mM. Finally, during one of these acidotic episodes, he was found to have five to six times elevated leucine, isoleucine, and valine in blood, with significant lactic acidosis of 5 mM and ketonuria. Urine GC/MS showed elevated 2-ketoisocaproic acid, 2-keto-3-methylisovaleric acid, and 2-ketoisovaleric acid (i.e., intermediates of MSUD). He was placed on a low-protein diet and frequent feedings. Over the next 2 years he did not have any further episodes. Dihydrolipoyl dehydrogenase activity in his fibroblasts could not be determined, and the diagnosis of E_3 deficiency was based on blood and urine biochemical findings observed during the acute attack.

Homocystinuria

This disease truly poses a challenge to the pediatrician, since its presentation is highly variable. The usual presentation is with cataracts in an otherwise mildly delayed, shy young child. The slender, marfanoid appearance might not be noticeable early in life. At the later stage of the disease, the presentation is usually that of a neurologic catastrophe, such as seizures, dystonia, hemidystonia, or acute hemiplegia. These complications are caused by CNS infarcts due to a high level of blood homocystine caused by a deficiency of cystathionine β-synthase (◉ *Fig. 38.37*). Homocystine is highly toxic and at high blood levels will cause thrombosis. Homocystine also binds and destroys fibrillin, an important connective tissue component. The gradual destruction of fibrillin is responsible for lens subluxation and dolichostenomelia. These changes require several years, and the marfanoid features might be better appreciated after 4 or 5 years of age. The typical patient with homocystinuria has aphakia (thick cylindrical lenses), slender marfanoid appearance, and moderate arachnodactyly (◉ *Fig. 38.38*). The neurologic manifestations might be attributed to an entirely different etiology, and the missed diagnosis will cause further neurologic damage. Since a number of homocystinuria patients are pyridoxine responsive, early diagnosis and a high index of suspicion in a neurologically impaired child is of utmost importance. A simple special type of nitroprusside test of the urine, or detection of high methionine in the blood, will rapidly establish the diagnosis. High blood methionine levels might not always indicate homocystinuria, as summarized in ◉ *Table 38.10*. Its detection, however, should prompt a detailed diagnostic workup, including the measurement of cystathionine β-synthase activity in various cells. Determination of homocystine in the blood is cumbersome and, although a desirable adjunct, is not a readily available technique. At later stages the untreated disease will cause bone changes due to infarcts, and might be crippling. The treatment of the disease might be as simple as providing large doses of pyridoxine in pyridoxine-responsive patients. In pyridoxine-unresponsive cases, betaine and folic acid should be given, the reasons for which are illustrated in ◉ *Fig. 38.37*. In young infants, special formulas that restrict homocystine precursors, and in older children restricted protein diets, are used. In all cases, low doses of acetylsalicylic acid should be provided daily, to prevent clotting and infarcts.

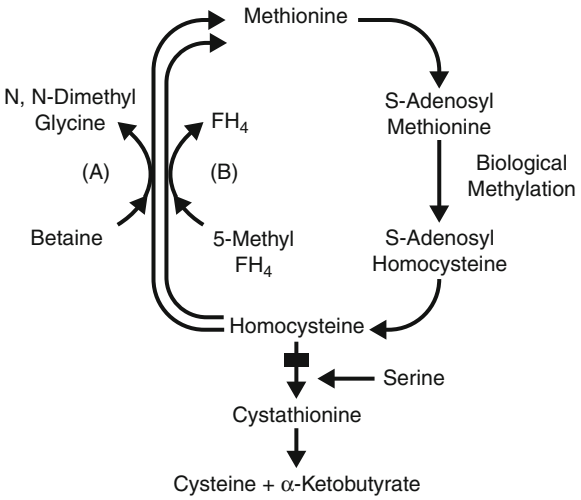

Figure 38.37
Metabolic pathways related to homocysteine. (1) Cystathionine β-synthase, the enzyme deficient in homocystinuria. (a) The mechanism of action of betaine used for treatment. (2) Methionine synthetase. (b) The mechanism of action of folic acid used in treatment. Methylcobalamin also participates in this methylation reaction. Therefore, the deficiency of this step is the etiology of homocystinuria and hypomethioninemia in the methylcobalamin-deficient type of methylmalonic acidemia

Case History. A 9-year-old girl was referred from an eye hospital with suspected homocystinuria. The teacher at school noticed her to have visual difficulties, and at the referral hospital she was found to have angle-closure glaucoma with inferiorly subluxated lenses bilaterally. Her school performance was average, and she did not have any neurologic complaints or findings. Her past history and development were normal. The parents were first cousins and had three normal children. On examination she had marfanoid features with arachnodactyly. A urine screening test for homocystinuria was positive, and blood amino acids indicated greatly elevated methionine, at 1,142 μM (normal upper limit: 50 μM). She was placed on a low-protein diet, betaine (100 mg/kg/day), folic acid (5 mg/day), pyridoxine (25 mg/kg/day), and aspirin (325 mg/day). The x-ray of the knees, obtained because of knee pain, and of the vertebral column revealed osteopenia, with mild compression of T-7 through T-12 vertebrae. A cardiac examination, echocardiogram, and electrocardiogram were normal. At 13 years of age she is attending a normal school but at fourth-grade level. Her participation in normal school activities is somewhat lower than average for the grade. She has chronic lung problems, and CT of the chest revealed widespread bronchiectasis with extensive bronchocentric infiltration

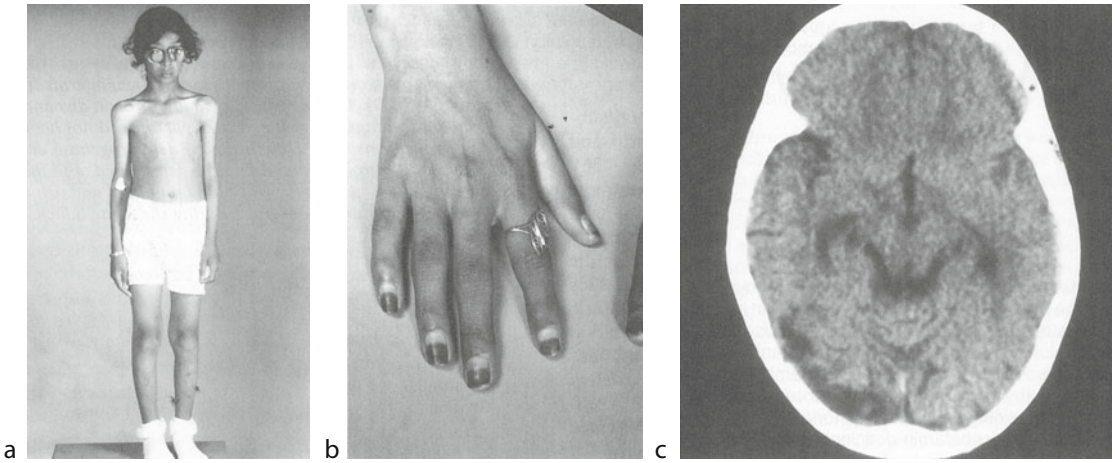

Figure 38.38

Hypermethioninemia due to underutilization
Genetic deficiency of *S*-adenosylmethionine synthetase
Severe generalized liver disease
Tyrosinemia type 1
Hypermethioninemia due to overproduction
Cystathionine β-synthase deficiency (homocystinuria)
6-Azauridine administration
Hypermethioninemia due to uncertain causes
Transient hypermethioninemia of infants
Hypermethioninemia with elevated serum folate
Persistent hypermethioninemia with normal serum folate

scattered throughout both lungs. The lung problems were not caused by tuberculosis.

Tyrosinemia Type 1

This disease is caused by a deficiency of the enzyme in the last step of tyrosine breakdown (*Fig. 38.39*). The enzyme defect leads to the accumulation of fumarylacetoacetate, which is in isomeric equilibrium with the toxic compound maleylacetoacetate, which accounts for most of the clinical symptoms. Fumarylacetoacetate, through succinylacetoacetate, is further decarboxylated into succinylacetone, which is an inhibitor of porphyrin synthesis, leading to the accumulation of Δ-aminolevulinic acid. The disease may have mild to severe manifestations. In the severe form it manifests as early as 2 months of age, with liver derangement associated with normal liver enzymes but greatly increased α-fetoprotein and decreased prothrombin. The bone marrow involvement will cause thrombocytopenia, and the initial symptom might be bleeding. At times the disease is associated with cardiac valvular defects. The kidneys are affected and a renal Fanconi syndrome will be observed. When untreated, these symptoms will progress to rickets and terminal liver failure, and the patient will eventually expire due to liver failure or an acute porphyria crisis and brain edema caused by the accumulation of Δ-aminolevulinic acid. A patient with tyrosinemia type 1, her rickets in the wrist, and the rachitic rosary are shown in *Fig. 38.40*. In milder forms, the age of onset is usually 12–18 months and the initial symptoms might reflect the kidney involvement, such as renal diabetes insipidus and/or liver disease. The clinical course will end with the emergence of hepatomas, leading to death from malignancy.

The definitive mode of treatment is liver transplantation. However, a recent discovery permits a highly rewarding treatment. This is the use of a compound that inhibits the tyrosine breakdown pathway at the stage of *p*-hydroxyphenylpyruvic acid oxidase level. The compound, 2-(4-trifluoromethyl-2-nitrobenzoyl)-1,3-cyclohexanedione (NTBC), has been a life-saving drug, preventing galloping liver damage, reducing the accumulation of Δ-aminolevulinic acid, and preventing the formation of

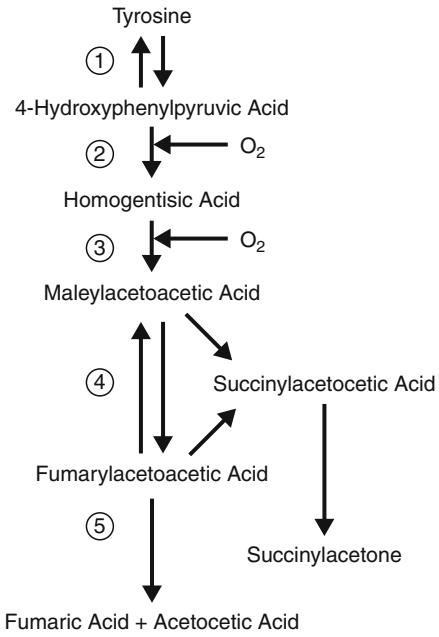

Figure 38.39
Catabolism of tyrosine. Enzymes involved: (1) tyrosine transaminase, (2) 4-hydroxyphenylpyruvic acid dioxygenase, (3) homogentisic acid oxidase, (4) maleylacetoacetic acid isomerase, and (5) fumarylacetoacetic acid hydrolase. Diseases due to deficiencies of the aforementioned enzymes: (1) tyrosinemia type 2 (Richner-Hahnhart syndrome), (3) alkaptonuria, and (5) tyrosinemia type 1. The deficiency of 4-hydroxyphenylpyruvic acid dioxygenase (2) is largely innocuous; this enzyme functions at the site of inhibition of the pathway by NTBC. Causes of hypertyrosinemia include inborn errors of metabolism (Tyrosinemia type 1, tyrosinemia type 2, 4-hydroxyphenylpyruvic acid dioxygenase deficiency), transient tyrosinemia of the newborn, severe hepatocelluar dysfunction, scurvy, hyperthyroidism, and postprandial effect

maleylacetoacetate. The circulating α-fetoprotein levels are reduced within months of its use, indicating prevention of liver damage. The drug is used in conjunction with a tyrosine-restricted diet. Tyrosinemia must be diligently searched for in any infant with any type of liver disease, since NTBC is life saving. Tyrosine and methionine are usually elevated in all types of liver disease (*Table 38.10*); therefore, the diagnosis of tyrosinemia type 1 can be firmly established only be detecting the elevated succinylacetone in the urine or Δ-aminolevulinic acid in blood.

Case History. A 10-month-old girl was referred for the workup of liver cirrhosis and Fanconi syndrome. She developed normally until 3 months of age, at which time she started to develop frequent chest infections and failed to develop in motor areas, although she continued to have normal social skills. The parents noted her failure to thrive, her poor feeding, and her constant ill health. She could never sit with support, but had developed syllabic speech. The parents were distantly related. They had eight normal children, but lost two girls and a boy to the same disease at 5, 7, and 9 months of age. A liver biopsy done at the referring hospital indicated prominent degenerative/regenerative changes in hepatocytes, with bile duct proliferation, cholestasis, and fibrosis indicating liver cirrhosis. On admission at 10 months, her height was 61 cm (corresponding to median age of 4 months) and her weight 4.8 kg (corresponding to median age of 2 months), with a head circumference of 41 cm (at lower limit of normal). Sclerae were mildly icteric. She had a rachitic rosary and enlarged epiphyses at the wrists. Her abdominal girth was 48 cm, enlarged with the liver 4 cm and spleen 5 cm below the costal margin. She showed muscle wasting, peripheral hypotonia, and no pyramidal or extrapyramidal tract signs. Her laboratory examinations indicated alkaline phosphatase of 1,530 U/L (normal upper limit: 350 U/L), but her ALT and AST were only borderline deranged. Bilirubin was 57 μM (normal upper limit: 21 μM). Her PT and PTT were elevated at 30.3 and 60.4 s, respectively (normal upper limits: 14.4 and 39 s, respectively). Her parathyroid hormone level was 430 pg/mL (normal upper limit: 65 pg/mL), her 25-hydroxy vitamin D was 66 nM (normal lower limit: 52 nM), and her 1,25 dihydroxy vitamin D was 360 pM (normal upper limit: 160 pM). The α-fetoprotein level was 240,000 U (normal upper limit: 15 U). Her urine tested positive for glucose at a blood glucose level of 4 mM. There was increased generalized aminoaciduria and phosphaturia; the urine pH was 7.5 and specific gravity 1.015. Her blood tyrosine and methionine were 310 and 210 μM, respectively (normal upper limits: 150 and 50 μM, respectively). The urine was tested three times for succinylacetone and was found to contain high amounts. Therefore, a conclusive diagnosis of tyrosinemia type 1 was reached. The abdominal ultrasound revealed abnormal echogenicity of the liver, with multiple nodular areas, the largest measuring 3 cm. The spleen was enlarged but had no focal lesions. There was a small amount of ascitic fluid. The enlarged kidneys were abnormal, with increased cortical echogenicity and prominent medulla. Chest x-ray revealed a consolidated right upper lobe. The child had had bacille Calmette-Guérin at birth. The sweat chloride test and α_1-antitrypsin activity

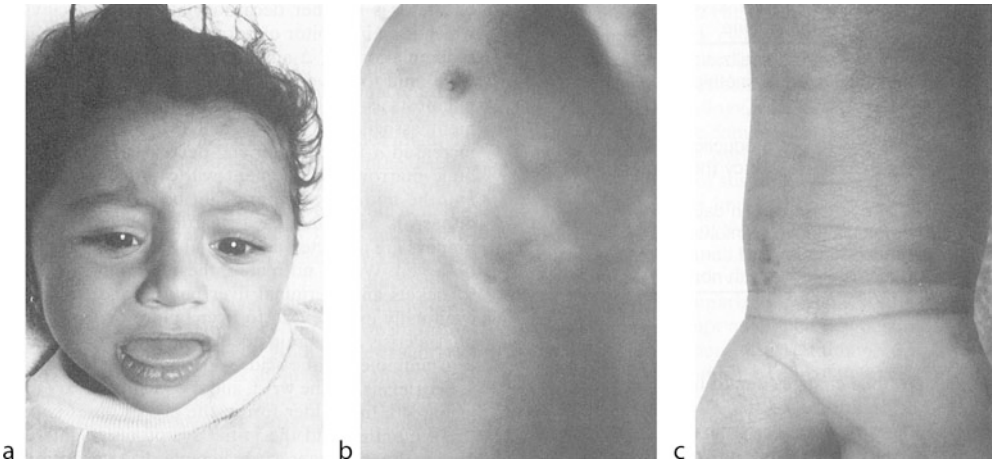

Figure 38.40
(a) A patient with tyrosinemia type 1. (b) Rachitic rosary in the same patient. (c) Changes of rickets evidenced by the enlarged wrist

were normal. The skeletal survey showed osteopenia and evidence of severe rickets. A cardiac workup was normal. CT of the brain and the EEG were normal. The child was placed on vitamin K_1 (5 mg), 1-Alpha (alpha-calcidiol) 0.3 μg (three drops), vitamin A (370 μg), and vitamin K (6 IU orally) daily. At the time, the hospital did not have NTBC for treatment. She was discharged to the referring hospital pending liver transplant. She developed sudden brain edema there and expired at the age of 14 months.

Diagnosis

Clinical and Biochemical Differential Diagnosis

In contrast to the devastating metabolic diseases of the newborn, the diseases listed in this section have more specific symptoms. A summary of the pertinent clinical and biochemical findings, as well as patients with a particular symptom that need to be investigated, are listed in *Table 38.11*.

Patients with the milder phenotypes of methylmalonic acidemia, isovaleric acidemia, HMG-CoA lyase deficiency, and oxidative phosphorylation diseases may experience their first metabolic attack later during the infancy or early childhood. Their clinical and biochemical presentations remain the same. Propionic acidemia that manifests in this age group usually has unusual symptomatology as presented; it may appear as an immune deficiency syndrome, as a basal ganglia disease, or as a seizure disorder.

The phenotype of 3-methylglutaconic aciduria in this age group is usually that of an extrapyramidal disease with prominent dystonia and choreoathetosis. It may be easily confused with glutaric aciduria type 1; however, a simple CT of the brain will reveal mainly putaminal lesions in the former and the "wide operculum sign" in the latter. Both diseases are "silent," "neurologic," or "cerebral" organic acidurias, since they are not associated with significant changes in acid-base balance, hyperammonemia, or hypoglycemia. It is important to reach an accurate diagnosis since both may be manageable but they require different treatments.

Besides those already listed in the section on devastating metabolic diseases of the newborn, the disorders that appear with periodic acidotic attacks that are particular to this age group are 3-ketothiolase deficiency, MCD, FDPase deficiency, GSD type 1, and E_3 deficiency.

In 3-ketothiolase deficiency the ketonuria is massive and blood glucose is normal; lactic acidemia is either normal or mildly elevated. The normoglycemia rules out FDPase deficiency and GSD type 1. Normal or near-normal lactic acidemia rules out MCD. The presentation of E_3 deficiency might be very similar to that of 3-ketothiolase deficiency (i.e., periodic acidotic attacks). However, E_3 deficiency usually occurs at a later age and is associated with acute cerebellar signs, and the biochemical findings suggest MSUD, with lactic and α-ketoglutaric aciduria.

Total biotinidase deficiency rarely manifests with acidotic crisis; its presentations may include pyramidal tract signs, dermatitis, hair loss, and seizures, which are easy to identify. Partial biotinidase deficiency is a progressive

Table 38.11

Brief synopsis of clinical and laboratory findings in organic acidemias of early infancy and childhood

Disease	Brief summary of clinical and laboratory findings	In which patient it should be investigated
3-Methylglutaconic aciduria	Progressive encephalopathy with dystonia, choreoathetosis, but with normal routine chemistries	Any infant or child who develops extrapyramidal signs with loss of milestones
3-Ketothiolase deficiency	Periodic metabolic crisis with acidosis following a prodrome of lethargy and vomiting	Any child who develops metabolic crisis with massive ketonuria but with normoglycemia (nonspecific symptomatology)
Glutaric aciduria type 1	Sudden extrapyramidal tract signs such as rigidity, dystonia, and choreoathetosis following a metabolic stress or infection. Macrocephaly, normal routine blood chemistries	Any child who develops extrapyramidal tract signs and has wide operculum sign on neuroradiologic studies
Medium-chain acyl-CoA dehydrogenase deficiency (MCAD)	Periodic metabolic crises with severe hypoglycemia and moderate lactic acidosis, with no neurologic or systemic findings	Any child who has a hypoglycemic episode with no systemic or neurologic findings
Very-long-chain acyl-CoA dehydrogenase deficiency (VLCAD)	Acute hepatic failure, myopathy, cardiomyopathy, hepatomegaly and, during metabolic attacks with hypoglycemia, disturbed liver function and lactic acidosis	Any child with acute liver failure, hypertrophic cardiomyopathy, unexplained hepatomegaly, metabolic crisis with hypoglycemia and lactic acidosis
Biotinidase deficiency	Hair loss, deafness, visual difficulties, pyramidal tract signs, seizures, dermatitis; occasionally metabolic crisis with acidosis	Any child with etiology-unclear seizures, hair loss, deafness, or dermatitis with or without metabolic crises or long tract signs
Holocarboxylase sythetase deficiency	Severe early metabolic crisis with acidosis	Any infant who has severe metabolic crisis with ketolactic acidosis (nonspecific symptomatology)
4-Hydroxybutyric aciduria	Profound hypotonia with seizures, at times with extrapyramidal signs, or cerebellar signs or profound mental retardation; normal routine laboratory chemistries	Any infant or child with profound hypotonia, seizures, and cerebellar or extrapyramidal tract symptoms (nonspecific symptomatology)
Fructose sensitivity (fructose-1, 6-bisphosphatase or FDPase) deficiency	A big infant with mild hepatomegaly who develops profound lactic and ketoacidosis with severe hypoglycemia following ingestion of sweet substances, infections, or fasting	Any infant large in size who is always hungry, with mildly disturbed liver enzymes, mild lactic acidosis between attacks, and severe precipitous hypoglycemia and acidosis
Glycogen storage disease type 1A (von Gierke disease)	Massive hepatomegaly, history of hypoglycemia in the morning with prominent cheeks (trombone player's face) with episodes of hypoglycemia and profound lactic acidosis	Any infant with prominent hepatomegaly, with suggestive facial features, who has early morning hypoglycemia and metabolic crisis with hypoglycemia and lactic acidosis
Glycogen storage disease type 1B	Same as type 1A, but immune deficiency as a result of defective neutrophil function; frequent infections	Same as type 1A, neutropenia; enzyme activity appears after freeze-thawing the sample
Galactosemia due to UDPglucose galactose-1-phosphate transferase (PGal transferase) deficiency	Massive hepatomegaly with cataracts, history of hypoglycemia without acidosis, and amino aciduria with deeply disturbed live function tests, positive urine reducing substance	Any infant with cataracts, hepatomegaly, and reducing substance in the urine

Table 38.11 (Continued)

Disease	Brief summary of clinical and laboratory findings	In which patient it should be investigated
Hyperphenylalaninemia (classic PKU)	Early seizures, developmental delay mostly after 1 year; loss of 50% of the IQ by 1 year of age; fair features, eczematoid lesions	Neonatal screening must be performed since the clinical features before 1 year of life are not striking; child with mental retardation and/or seizures
Biopterin-dependent or malignant PKU	Early infantile myoclonic seizures, repeated early chest infections requiring hospitalization and PICU care due to cardiopulmonary arrest	Any infant with fair features and repeated chest infections or cardiopulmonary arrest without a good reason, with hypotonia and myoclonic seizures
E_3 deficiency	Infantile/childhood devastating metabolic disease with ketolactic acidosis and hypoglycemia; quick recovery upon appropriate treatment; the patient is normal between attacks	Any child who has periodic attacks of hypoglycemia and acidosis but is normal between attacks
Homocystinuria (cystathionine β-synthase deficiency)	Shy infant, with tall slender features, arachnodactyly and long toes; early visual difficulties with lens dislocation downward and early cataract; in late-diagnosed case, repeated thromboembolic attacks, with cerebrovascular accidents, extrapyramidal signs, and internal capsular lesions	Any child who had a cerebrovascular accident, unexplained hemidystonia, deep vein thrombosis of legs, long slender fingers and toes with slender body; any patient with cataracts
Tyrosinemia type 1	Several phenotypes exist: early presentation includes bleeding tendency with hepatomegaly and rickets; later during infancy it presents with diabetes insipidus (i.e., with reanal manifestations) and renal rickets, hepatomegaly, thrombocytopenia, disturbed liver functions; later in early childhood, it presents with chronic liver failure	Any infant with elevated PT and PTT, enlarged liver, elevated α-fetoprotein, thrombocytopenia but with other liver functions preserved, particularly if aortic or pulmonary valve disease is present; any older infant with renal rickets, diabetes insipidus and above-listed findings; any child with acute or chronic liver failure with any of the above-mentioned findings

PICU pediatric intensive care unit, *PT* prothrombin time, *PTT* partial thromboplastin time

encephalopathy primarily with seizures and pyramidal tract signs; its symptoms are nonspecific; therefore, biotinidase must be measured in all infants with a seizure disorder or with long tract signs. The assay of biotinidase does not require a sophisticated laboratory setting and can be accomplished anywhere.

In GSD type 1, the hepatomegaly is impressive, while in FDPase deficiency it is mild/moderate and is apparent only during crisis. A 4- to 12-month-old child who develops a precipitous hypoglycemic acidosis with peripheral shock either has HMG-CoA lyase or FDPase deficiency. Urine contains ketones in FDPase deficiency, but there is no ketonuria in HMG-CoA lyase deficiency.

Both MCAD and VLCAD are primarily hypoglycemic diseases; acidosis when present is due to increased lactic acid. An infant with MCAD with the milder phenotype does not have systemic symptoms. An infant with VLCAD will either have prominent cardiac symptoms, such as hypertrophic cardiomyopathy and myopathy, or liver findings such as increased enzymes, hepatomegaly, or impending liver failure. Again the acidosis is caused by the accumulation of lactic acid, and ketonuria is absent.

The presentation of 4-hydroxybutyric aciduria depends on the severity of the phenotype and is different at different age groups. The phenotype that appears early in infancy will manifest with severe central hypotonia and myoclonic seizures that are resistant to treatment, which are all non-specific symptoms. At a later age group, the past history usually includes infantile hypotonia and seizures, but the child shows profound mental retardation. 4-Hydroxybutyric aciduria is also a "silent" or "cerebral" organic aciduria (i.e., not associated with disturbed glucose, acid–base, or ammonia metabolism). The majority of the reported patients are of Middle Eastern origin.

The phenotype of galactosemia may vary from one country to another. In its classic form, the disease appears early during the neonatal period with sepsis; in the late-onset forms, the first symptoms occur at 2–12 months of life, and the presenting symptoms are cataracts and hepatomegaly. In fact, most such patients are referred from an eye hospital, where the infant is taken for cataracts. The hypoglycemia may be detected only in the laboratory, and sepsis may be uncommon. The presence of a renal Fanconi syndrome, in association with previously listed symptoms, will prompt a rapid diagnosis. Cataracts are a part of mitochondrial and peroxisomal diseases. In these latter diseases the child will show severe neurologic symptoms, while in galactosemia the CNS symptoms are milder. Homocystinuria will also show cataracts. Its presentation does not include hepatomegaly or the symptoms seen in mitochondrial or peroxisomal diseases.

Most amino acid disorders of this age group are associated primarily with severe neurologic symptoms and mental retardation. Noteworthy is classic PKU. The phenotype of classic PKU in the Middle East is highly variable. In some patients, despite very high phenylalaninemia, there may be only mild/moderate mental retardation, while in others hyperphenylalaninemia might not be impressive ($<$1,200 μM), but the infant will show early and severe myoclonus, myoclonic seizures, and early and severe regression of milestones with eventual severe mental retardation. Fair features are common but not always detected. The disease is easily identified through available neonatal screening programs. When neonatal screening is not performed, blood phenylalanine must be measured immediately in any young infant or child with the slightest suspicion of a neurologic finding. For this purpose various biochemical tests are available and can be applied in any setting. A ferric chloride test is useful if the urine is tested when fresh. It will yield false-negative results when the urine is stored cold more than a few hours. The treatment of classic PKU is very rewarding, particularly if identified early (i.e., less than 6 weeks of life).

A variant of PKU is "malignant PKU" or "biopterin-dependent PKU." Although four different types are known, the most common type in the world is 6PTS deficiency, a deficiency of the enzyme responsible for the second step of biopterin synthesis, namely, 6-pyruvoyltetrahy-dropterin synthase. An alert pediatrician may easily identify the 6PTS deficiency since it causes severe early parkinsonian signs such as bradykinesia and cogwheel rigidity, in addition to myoclonic seizures, cardiorespiratory rhythm abnormalities, and intrauterine and early infantile failure to thrive. Again, the skin and hair color are usually fair. The requirements of the liver phenylalanine hydroxylase for biopterin might be partially met by the small amounts of biopterin present in milk and other foods; therefore, hyperphenylalaninemia in this disease is not usually impressive. It may be easily missed in the neonatal screening programs. Its presence must be tested for in any small infant who experiences an unusually severe chest infection at 2–4 months of age. The treatment is most rewarding, and, if the infant survives the cardiorespiratory problems, and if the disorder is diagnosed before 6–12 months of age, minimal or no residual damage will be left upon appropriate treatment. All infants who test positive for PKU at any age should be tested for biopterin-dependent PKU. This is performed either by serially measuring blood phenylalanine level before, during, and after tetrahydrobiopterin administration, or by identifying and estimating the urine pterins.

In the absence of a neonatal screening program, most patients with homocystinuria will unfortunately be missed for a long period. The mental retardation and regression of milestones might not be very noticeable, and the child will arrive with a neurologic catastrophe. A lucky child will have his or her iridodonesis or cataracts noticed by an ophthalmologist who encounters the patient because of the complaint of visual difficulty, and the workup initiated will reveal the homocystinuria. The marfanoid features and arachnodactyly are usually noticed later during childhood. Any child with unusual CNS symptoms, particularly with hemiplegia, must be checked for homocystinuria. Hemiplegia is commonly caused in this age group by sickle cell disease, protein S deficiency, or anticardiolipin antibodies. Approximately 20% of the patients will have the "pyridoxine-responsive" phenotype of homocystinuria, which readily responds to treatment by large doses of pyridoxine, since cystathionine β-synthase in these cases carries a mutation that will be functional in the presence of a high concentration of pyridoxal-5′-phosphate. Early diagnosis of homocystinuria is a highly desirable goal, since the treatment of a neonate with homocystinuria with either phenotype, or of infants with the "pyridoxine-responsive" variant, is most rewarding, leading to an eventual normal lifestyle.

The presentation of tyrosinemia type 1 is essentially different from the diseases thus far presented. It can present with early derangement of certain liver functions, such as prothrombin synthesis in association with thrombocytopenia, presenting as a bleeding diathesis in an infant with mild hepatomegaly. Later presentations include renal Fanconi syndrome, diabetes insipidus, rickets, and the same liver symptoms as listed above. A simple determination of α-fetoprotein will reveal its very high

value, and will prompt the workup. In tyrosinemia type 1, besides elevated tyrosine and methionine, urine might contain large amounts of *N*-acetyltyrosine and 4-hydroxyphenylpyruvic and 4-hydroxyphenyllactic acids. These biochemical observations are also noted in patients with liver derangement due to other causes. The definitive diagnosis of tyrosinemia type 1 can only be reached by measuring urinary excretion of succinylacetone or the level of Δ-aminolevulinic acid in the blood. The ultrasound examination of the liver is also pathognomonic, with hepatomas and nonhomogeneous appearance. A patient with tyrosinemia type 1 is susceptible to intercurrent neurologic crisis with coma and death as a result of the brain edema caused by the porphyria, due to the inhibition of porphyrin synthesis by Δ-aminolevulinic acid. This compound is fat soluble and, if the patient fasts or is subjected to increased fat mobilization, it will be liberated from the adipose tissue, causing the neurologic crisis. Therefore, such patients should not be permitted to fast, and glucose should be administered when they develop an intercurrent infection. The disease is invariably fatal unless the patient receives a liver transplant, which is not always readily available. However, the recent discovery of a drug, NTBC, that inhibits the pathway before the formation of maleylacetoacetate, is life saving and probably permits the child to reach adolescence, when a liver transplant might be more feasible.

Conclusive Biochemical Diagnosis

The presumed diagnosis, based upon clinical and clinical biochemical findings, must then be confirmed by special biochemical tests that are available only in certain health care settings. These tests are listed in ❯ *Table 38.12*. The available tools include GC/MS analysis for organic acids, HPLC analysis for amino acids, tandem MS analysis for organic and amino acids, and special enzyme tests.

The pathognomonic organic acids will be identified during crisis in 3-ketothiolase deficiency, glutaric aciduria type 1, MCAD, VLCAD, MCD, FDPase deficiency, GSD type 1, and E_3 deficiency; however, they might not be readily detectable between crises. The elevated organic and amino acids are always detected in patients with 4-hydroxybutyric aciduria, classic PKU, biopterin-dependent PKU, homocystinuria, and tyrosinemia type 1. In this regard, tandem MS is a much superior tool, since it detects the carnitine esters of organic acids, as well as minor elevations of amino acids, at all times. So far, tandem MS has not been used to identify the diseases involving carbohydrate metabolism, and it will not detect 4-hydroxybutyric aciduria.

The disorders of fatty acid metabolism can be diagnosed accurately only through the use of tandem MS, since in these diseases the GC/MS findings are rarely conclusive. In most settings, E_3 deficiency is identified based only on amino acid and GC/MS findings, since the determination of enzyme activity is not readily available.

The definitive diagnosis of the disorders in this section must rely on confirmation by at least two different techniques. In certain cases, such as biotinidase deficiency or galactosemia, one of these is based on the determination of defective enzyme activity. Enzyme analysis is also recommended for 3-ketothiolase deficiency, galactosemia, and GSD type 1, since they have more than one phenotype.

Genetics and Incidence

The incidence for most of these disorders cannot be stated in the absence of neonatal screening programs. Glutaric aciduria type 1, 4-hydroxybutyric aciduria, FDPase deficiency, GSD type 1, homocystinuria, classic PKU, biopterin-dependent PKU, MCAD, VLCAD, biotinidase deficiency, galactosemia, E_3 deficiency, and tyrosinemia type 1 are not rare diseases.

The gene locations of most of these disorders have been identified (❯ *Table 38.13*), and the cDNAs of relevant enzymes are becoming increasingly available. Once the particular mutations of an enzyme in a population are identified, it will become increasingly possible to conduct screening procedures for the carriers.

Prevention Through Neonatal Screening

Most of these disorders are readily identifiable in a neonate, as listed in ❯ *Table 38.6*. The early identification, in most instances, will lead to rewarding treatment and normal or near-normal lifestyle in the child. Even glutaric aciduria type 1, a hitherto severly neurologically crippling disease, may be managed vigorously with medication and by early intervention at times of catabolic events such as infections, to an extent that is nearly compatible with a normal lifestyle, Delayed diagnosis in most instances, such as classic PKU, homocystinuria, and tyrosinemia type 1, will lead to severe crippling, mental retardation, or death, while the reverse is true when they are identified early.

In the absence of neonatal screening, it is the responsibility of the pediatrician to test all other children in the

Table 38.12

Specialized biochemical tests required to confirm diagnosis in patients with metabolic diseases primarily of late infantile or childhood onset[a]

Disease	GC/MS studies	HPLC studies for amino acids	Tandem MS studies	Enzyme studies or special tests[b]
β-Ketothiolase deficiency	2-Methylacetoacetic, 2-methyl-3-OH-butyric, tiglylglycine, 3-OH-butyric, acetoacetic	Glycine may be elevated	2-Methyl-3-OH-butyrylcarnitine, tiglylcarnitine	Mitochondrial β-ketothiolase (F)
Glutaric aciduria type 1	Glutaric, glutaconic, 3-OH-glutaric	N.P.	Glutarylcarnitine	Glutaryl-CoA dehydrogenase (F)
MCAD deficiency	Adipic, sebacic, 5-OH-hexanoic, 7-OH-octanoic, hexanoylglycine, suberylglycine	N.P.	Carnitine esters of C6, C8, and C10 fatty acids	MCAD assay (F) or gene mutation assay by PCR in blood spots or cells
VLCAD deficiency	Suberic, sebacic, dicarboxylic acids of C10 and C12 in urine	N.P.	Carnitine esters of C12, C14, C16, C18, and C20 and their mono-and diunsaturated forms	Mutations in the VLCAD gene must be assayed to confirm the clinical diagnosis (F)
Biotinidase deficiency	3-OH-Propionic, 3-methylcrotonyl, and 3-OH-propionylglycine, lactic, methylcitric (elevated only during acidotic crisis)	N.P.	Propionylcarnitine and methylcrotonylcarnitine (elevated only during acidotic crisis)	Biotinidase (serum)
4-Hydroxybutyric aciduria	4-Hydroxybutyric and its lactone, intermediates of MADD (GAT 2)	N.P.	N.P.	Succinic semialdehyde dehydrogenase (L)
Fructose-1,6-bisphosphatase deficiency	Lactic, pyruvic, acetoacetic, 3-OH-butyric	N.P.	N.P.	FDPase assay and fructose-1-phosphate aldolase assay in liver biopsy
Glycogen storage disease types 1A and 1B	Lactic, pyruvic, some ketone bodies	N.P.	N.P.	Glucose-6-phosphatase in liver; fresh and frozenthawed
Galactosemia	N.P.	N.P.	N.P.	PGal transferase and galactokinase (R)
Classic PKU	N.P.	⇑ Phenylalanine, ⇓ tyrosine	⇑ Phenylalanine, ⇓ tyrosine	N.P.
Biopterin-dependent PKU (6PTS deficiency)	N.P.	⇑ Phenylalanine, ⇓ tyrosine, ⇑ neopterin, and ⇓ biopterin in urine and CSF	⇑ Phnylalanine, ⇓ tyrosine, ⇑ neopterin, and ⇓ biopterin in urine and CSF	6PTS (R) Dihydrobiopterin reductase (R) GTP cyclohydrolase (L)
E_3 deficiency	Branched-chain α-keto acids, lactic acid, α-ketoglutaric	⇑ Branched-chain amino acids during the acute episode	⇑ Valine, leucine, isoleucine, alanine during the acute episode	N.A.

Tyrosinemia type 1	Succinylacetone	Tyrosine, methionine	Tyrosine, methionine	Δ-Aminolevulinic acid (serum) (R)

Table 38.13

The gene information contains consecutively: name of the deficient gene, number of the protein, symbol of the gene, chromosome location of the gene; the size of the gene; the number of introns and number of mRNA's. The annotation denotes (http://www.hgmd.cf.ac.uk/ac/index.php) consecutively the number of mutations, insertions, deletions, splicing errors, and other errors

Name of the disease	Gene information	Annotation
β-ketothiolase deficiency	Acetoacetyl coenzyme A transferase – EC 2.3.1.9 -ACAT 1; 11q22.3-q23.1; 31.56 kb; 19 different introns; 13 different mRNA	25/4/7/7/0
Glutaric aciduria type 1	Glutaryl Coenzyme A dehydrogenase; – EC 1.3.99.7 – GCDH; 19p13.13; 23.61 kb; 23 different introns, 20 different mRNA	92/0/7/9/0
MCAD deficiency	Acyl-Coenzyme A dehydrogenase, C-4 to C-12 straight chain; EC 1.3.99.3, 2.5.1; ACADM; 1p33.1; 76.8 kb; 49 introns, 26 different spliced mRNA	46/4/10/7/0
VLCAD deficiency	Acyl-Coenzyme A dehydrogenase, very long chain; EC 1.3.99.13; VLCAD; 17p13-p11; 8.14 kb; 33 different introns, 26 different mRNA	60/4/23/11/0
Biotinidase deficiency	Biotinidase, EC 3.5.1.12; BTD; 44.29 kb; 3p25; 13 different introns 14 alternatively spliced mRNA	85/3/12/2/1
4-Hydroxybutyric aciduria	Succinic semialdehyde deficiency; EC 1.2.1.24; ALDH5A1; 6p22.2-p22.3; 42.45 kb; 12 different introns, 5 alternatively spliced mRNA	19/4/9/7/0
Fructose bisphosphatase deficiency	Fructose 1, 6 bisphosphatase 1; EC 3.1.3.11; FBP1; 9q22.3; 37.35 kb; 11 introns, 8 different mRNA's	8/3/4/0/0
Fructose bisphosphate aldolase deficiency	Fructose 1, 6 bisphosphatase aldolase B; EC 4.1.2.13; ALDOB; 9q21.3-22.2; 16.84 kb; 11 different introns, 5 different mRNA's	23/3/10/7/0
Glycogen storage disease type 1 A	Glucose 6-phosphatase; EC 3.1.3.9; G6PC; 12.57 kb; 17 q21; 4 different introns, 2 alternatively spliced mRNAS;	63/7/11/4/1
Glycogen storage disease type 1 B	Glucose 6-phosphate transporter; SLC37A4; 11q23.3	62/7/16/7/0
Glycogen storage disease type 1 C&D	Glucose 6-phosphate transporter; SLC37A4; 11q23.3	6/0/0/0/0 and 1/0/0/0/0
Galactosemia, P-Gal transferase deficiency	Galactose-1-phosphate uridylyltransferase; EC 2.7.7.12; GALT; 9p13; 12.54 kb; 22 introns, 24 alternatively spliced mRNA's	146/4/23/11/0
Galactosemia; galactokinase deficiency	Galactokinase 1; EC 2.7.1.6; GALK; 17q24; 12.03 kb; 13 different introns; 8 alternatively spliced mRNA	18/4/4/0/0
Galactosemia; epimerase deficiency	UDP-galactose-4-epimerase; EC 5.1.3.2; GALE; 1p36-p-35; 38.27 kb; 11 exons;	20/0/0/0/0
Classic PKU	Phenylalanine hydroxylase deficiency; EC 1.14.16.1; PAH 12q22-q24.2; 120.68 kb; 26 different introns, 18 different mRNA	371/15/75/72/1
PKU; dihydropteridine reductase deficiency	Quinoid dihydropteridine reductase; EC 1.6.99.7; QDPR; 4p15.31; 29.21 kb; 19 different introns; 20 different mRNA's	20/4/2/6/0
PKU; 6-PTS deficiency	6-pyruvoyltetrahydropterin synthase. EC 4.6.1.10; PTS; 11q22.3-q23.3; 11.12 kb; 10 different introns; 8 different mRNA	34/1/5/5/0
PKU; cyclohydrolase deficiency (DOPA responsive dystonia)	GTP cyclohydrolase 1; EC 3.5.416; GCH1; 14q22.1-q22.2; 61.84 kb; 12 different introns; 11 different mRNA	80/8/18/15/2
E_3 deficiency	Dihydrolipoamide deficiency; EC 1.8.1.4; DLD; 7q.31-q32; 48.51 kb; 23 different introns; 13 different mRNA	10/1/1/1/1
Classic homocystinuria	Cystathionine beta-synthase; EC 4.2.1.22; CBS; 21q22.3; 23.93 kb; 26 introns, 29 different mRNA	105/8/22/11/1
Tyrosine type 1	Fumarylacetoacetate hydrolase; EC 3.7.1.2; FAH; 15q23-q25; 34.45 kb; 23 different introns, 16 different mRNA	26/1/3/13/0

Table 38.14

Formulas and medications used for long-term management of late infantile/childhood-onset metabolic diseases[a]

Disease	Formulas	Cofactors and medications
3-Ketothiolase deficiency	Low-protein or L-isoleucine-restricted formulas and diets	L-Carnitine, 200 mg/kg/day; bicarbonate or citrate 4–6 mEq/kg/day
Glutaric aciduria type 1	L-Lysine– and L-tryptophan–restricted or low-protein diet; IV dextrose during febrile disease	L-Carnitine, 200 mg/kg/day; riboflavin, 50–100 mg/kg/day; baclofen, 5–10 mg t.i.d.; vigabatrin 35–50 mg/kg/day; valproic acid, 25–35 mg/kg/day
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency	Frequent feeding with high- and slowly digested carbohydrate diets; avoidance of fasting	L-Carnitine, 200 mg/kg/day; Polycose in soft drinks upon vomiting
Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency	Low-fat/high-carbohydrate diet; avoidance of fasting	Medium-chain triglycerides (MCT oil), 1–2 g/kg/day; L-carnitine, 200 mg/kg/day
Biotinidase and biotin-responsive holocarboxylase (HCS) deficiencies	N.R.	*Biotinidase deficiency*: Biotin, 5–10 mg/kg/day
		HCS deficiency: Biotin, 10 mg/kg/day; L-carnitine, 200 mg/kg/day; citrate, 4 mEq/kg/day
4-Hydroxybutyric aciduria	N.R.	Vigabatrin, 35–50 mg/kg/day; dextromethorpham 20–30 mg/kg/day[b]
Fructose sensitivity (FDPase deficiency)	Strict restriction of fructose- and sucrose-containing food substances	Bicarbonate or citrate 4–6 mEq/kg/day; Polycose in diet drinks upon vomiting or diarrhea
Glycogen storage disease (GSD) type 1	Frequent feeding with fructose restriction; late-night feeding with slowly digested glucose polymers; if and when possible, high-protein vivonex through NG tube by pump (33% of daily calories) nocturnally	N.R.
Galactosemia (PGal transferase deficiency)	Galactose- and lactose-restricted formulas and diets	N.R.
Hyperphenylalaninemia (classic PKU)	Galactose- and lactose-restricted formulas and diets	N.R.
	Phenylalanine-restricted milk formulas and food substances to assure blood phenylalanine between 300 and 800 μM	N.R.
Biopterin-dependent PKU	No phenylalanine restriction if the patient is given BH_4; otherwise same restrictions as in classic PKU	L-DOPA, 15–20 mg/kg/day; L-5-hydroxytryptophan, 4–5 mg/kg/day; carbidopa, 4–5 mg/kg/day; and if possible BH_4, 20 mg/kg/day[c], with folic acid, 5–10 mg/day
E_3 deficiency	High-carbohydrate diet; avoid fasting; during metabolic crisis, IV dextrose and alkalinizing agents	The use of lipoic acid or its amide its experimental but can be tried at 25 mg/day

Table 38.14 (Continued)

Disease	Formulas	Cofactors and medications
Homocystinuria (pyridoxine-responsive, -nonresponsive variants and in neonates)	*Neonates*: methionine-restricted formula	*Pyridoxine-responsive type*: pyridoxine, 10–20 mg/kg/day
	Pyridoxine-nonresponsive type: methionin-restricted or low-protein diet, whichever is possible	*Others*: Betaine, 100–200 mg/kg/day; folinic acid, 15 mg/day; aspirin, 65–325 mg/day
Tyrosinemia type 1	Tyrosine restriction will assure adequate growth and prevention of renal complications but will not prevent the liver disease	2-(2-Nitro, 4-trifluoromethyl benzoyl)-2,3-cyclohexanedione (NTBC), 0.1–0.6 mg/kg/day[d]; IV glucose in case of neurologic crisis. Hematin (experimental)

[a]N.R., not relevant
[b]The results are not always rewarding; however, the use of vigabatrin will improve the seizures
[c]Available only from Schirks Laboratories, Jona, Switzerland
[d]Although available commercially, it is advisable to use this compound according to a standard protocol, available from Dr. S. Lindstedt, Department of Clinical Chemistry, Sahlgrenska Hospital, Göteborg University, Göteborg, Sweden

extended family, as well as the future newborns, for the existence of the disease detected in the index case. Such an effort is mandatory for early diagnosis, treatment, prevention of crippling, mental retardation, and death.

Medications and Formulas Used in Acute and Long-Term Management

Acute Crisis

The management of acute events is pertinent to organic acidemias, and the same procedures and considerations cited for the management of devastating metabolic diseases of the newborn are also valid for the disorders encountered at this age group. Acute metabolic events in patients with 3-ketothiolase deficiency should be managed by vigorous use of IV sodium bicarbonate and L-carnitine. In glutaric aciduria type 1, even minor infections require hospitalization, IV administration of L-carnitine, and prevention of protein catabolism by IV glucose. The acute attacks of fatty acid oxidation disorders and HCS deficiency also require intravenous L-carnitine, large amounts of glucose, and bicarbonate treatment. The acute crises of FDPase deficiency, GSD type 1, and E_3 deficiency are managed by administration of bicarbonate and glucose. The neurologic crisis of tyrosinemia type 1 is managed by IV glucose administration.

Chronic Management

The diseases listed in this section, except for 4-hydroxybutyric aciduria and the cardiomyopathic phenotype of VLCAD, are all treatable disorders with eventual normal or near-normal lifestyle of the child. The formulas and medications used are shown in *Table 38.14*. The formulas are based on restricting the offending compound from the diet (e.g., fructose in FDPase deficiency and GSD type 1, galactose in galactosemia, and phenylalanine in classic PKU). Use of MCT oil in VLCAD deficiency and nocturnal feeding by Vivonex in GSD type 1 prevents the serious consequences of these diseases.

In some disorders, dietary intervention might be enough, but in most others, large doses of cofactors and specific medications must be used as adjuncts to achieve the best results (e.g., baclofen, vigabatrin, and valproic acid in glutaric aciduria type 1 and pyridoxine in homocystinuria). Although pyridoxine is essential for the "pyridoxine-responsive" phenotype, most pediatricians currently add this compound to the treatment of all patients with homocystinuria. This is permissible, as long as it is used in prescribed amounts that will not lead to peripheral neuropathy. The excess homocystine that is responsible for the thromboembolic phenomena in homocystinuria may be removed by its chemical methylation through betaine. In this disorder, aspirin is used also to delay clotting.

In certain diseases, only cofactors or medications without dietary therapy will prove effective. For example, in biopterin-dependent PKU, the precursors of neurotransmitters such as L-dopa, L-5-hydroxytryptophan, and BH_4 are used without any diet. In tyrosinemia type 1, strict dietary restriction of tyrosine is not required if NTBC is used. Biotinidase deficiency will be successfully treated by large doses of biotin. In other diseases, detoxification will be achieved by L-carnitine,

Table 38.15
Outcome of metabolic diseases of late infantile/early childhood onset, if treated early and appropriately

Disease	Outcome
3-Ketothiolase deficiency	Excellent, if metabolic crises are managed vigorously
Glutaric aciduria type 1	Minimal neurologic damage if it is diagnosed before the first neurologic crisis, and when all subsequent febrile episodes are treated vigorously through preventing protein catabolism
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency	Excellent if the disease is not of severe variety and if therapeutic precautions listed are followed
Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency	*Cardiomyopathic phenotype*: poor prognosis
	Phenotype with acute liver failure: good if the disease is diagnosed before the liver failure occurs and if it is treated vigorously
Biotinidase deficiency	Excellent; deafness if diagnosed late
Holocarboxylase synthetase deficiency	Good if the patient is biotin responsive and is closely followed and if metabolic crises are managed vigorously
4-Hydroxybutyric aciduria	Poor, with eventual severe mental retardation
Fructose sensitivity (FDPase deficiency)	Excellent
Glycogen storage disease types 1A and 1B	*Type 1A*
	Mild phenotype: very good, with adequate growth
	Severe phenotype: difficult to manage and establish adequate growth; late complications
	Type 1B: poor due to neutropenia and immune deficiency; infections may be treated by using granulocyte colony-stimulating factor
Hyperphenylalaninemia (classic PKU)	Normal intelligence if diagnosed and treated early, with minimal speech and behavioral deficits, in pregnant mother with PKU, teratogenic effect in fetus if her PKU is not controlled during pregnancy
Biopterin-dependent PKU	*Mild and transient phenotypes*: good, with minimal residual damage, speech and behavioral deficits
E_3 deficiency	*Severe phenotype*: microcephaly and spastic quadriplegia
	Excellent
Homocystinuria	*Neonate diagnosed early*: good, normal to near normal intelligence
	Pyridoxine-responsive phenotype: good if diagnosed early
	Pyridoxine-unresponsive phenotype: intelligence will not improve but thromboembolic phenomena will be controlled with the outlined therapies in late-diagnosed cases
Tyrosinemia type 1	Always fatal if the patient is not treated by liver transplantation; early trial results using NTBC are very rewarding, indicating it to be a life-saving medication

the use of which is necessary in glutaric aciduria type 1, biotin-responsive HCS deficiency, MCAD, and VLCAD.

Outcome

The outcomes of these disorders, when identified and treated early, are listed in *Table 38.15*. These are highly treatable disorders, except for 4-hydroxybutyric aciduria, the cardiomyopathic phenotype of VLCAD, GSD type 1B, and the severe phenotype of 6PTS-deficient PKU. When the diagnosis is late, the resultant CNS damage in glutaric aciduria type 1, VLCAD deficiency, classic PKU, and homocystinuria will be irreversible. This is the reason for a neonatal screening program to identify these diseases. If tyrosinemia type 1 is recognized late, the patient will expire before NTBC treatment can be initiated.

Acknowledgments

Excellent and detailed reviews of the diseases discussed in this chapter can be found in *The Metabolic and Molecular Bases of Inherited Disease* edited by C. R. Scriver, A. L. Beaudet, W. S. Sly, and D. Valle (New York, McGraw-Hill, 7th edition 1995). Suggested reading material for important aspects of each disease presented is listed in the sections below.

39 Lysosomal Storage Diseases

Pinar T. Ozand · Mohammed Al-Essa

Many inborn errors of metabolism manifest with clinical evidence of a storage disease in the central nervous system (CNS) and/or peripheral organs. Since this storage occurs within the lysosomes, these inborn errors of metabolism are known as lysosomal storage diseases. In most types, the clinical presentation usually is similar, and there are only a few clinical hints that guide the pediatrician to the correct diagnosis. For example, only an experienced clinician can differentiate Hurler syndrome from Maroteaux–Lamy syndrome at the bedside early in infancy.

The diagnostic efforts are further complicated by the fact that the phenotypic expression of the disease varies according to its age of onset. For example, while G_{M2} gangliosidosis, either Sandhoff or Tay–Sachs variety, manifests first in early infancy with a severe dementing disease, the same disorder with a lesser degree of enzyme deficiency will manifest in late childhood or early adolescence with motor clumsiness or ataxia.

As the name implies, lysosomal storage diseases are usually associated with the enlargement of visceral organs. However, visceromegaly is also observed in other storage diseases that do not involve lysosomes. For example, glycogen storage disease (GSD) types 1, 3, and 4 cause significant hepatomegaly with or without splenomegaly and can easily be confused clinically with a lysosomal storage disease. The GSDs usually, but not always, lead to significant impairment of glucose and lipid metabolism, which are not seen in lysosomal storage diseases, and may be diagnosed through simple clinical laboratory tests. Some types of GSD, such as GSD type 3, cause early hepatosplenomegaly but no significant hypoglycemia or lactic acidosis. At early stages of the disease, it is nearly impossible to differentiate clinically GSD type 3 from Niemann–Pick disease type B, except that biochemical studies are helpful (e.g., GSD type 3, in contrast to Niemann–Pick disease, causes elevated creatine kinase [CK]).

A common misconception is that all lysosomal storage diseases cause clinically visible organomegaly or skeletal changes. A large group of them affect primarily the CNS, with little or no involvement of the peripheral organs. For example, Krabbe disease is associated with the storage of galactocerebrosides in the CNS, with no visceromegaly. Unless the pediatrician is aware that some storage diseases primarily affect the CNS, appropriate laboratory tests might not be ordered to reach the diagnosis.

This chapter is intended to provide a bedside guideline to the pediatrician for the diagnosis of lysosomal storage diseases. This is important since experimental therapies are available, such as enzyme replacement therapy. However, such therapeutic attempts require early diagnosis; for example, a bone marrow transplant (BMT) is rewarding only if the diagnosis is reached early. Newly available in utero BMT as well as the recent availability of gene therapy (e.g., for Hurler syndrome) make mandatory an accurate diagnosis of the disease in the index case, in order to provide intervention in future siblings or fetuses. The list of lysosomal storage diseases that are reviewed in this chapter is presented in *Table 39.1*.

Major Phenotypic Expressions and Alerting Signs of Lysosomal Storage Diseases

All lysosomal storage diseases are inherited as autosomal recessive traits except for Hunter syndrome (mucopolysaccharidosis type II) and Fabry disease, which are X-linked. In the following presentation, each disease is summarized with regard to its major phenotypic expression as well as the signs that should alert the pediatrician. An example case history with relevant physical or laboratory findings is also given when possible.

Mucopolysaccharidoses

Most patients with mucopolysaccharidosis (MPS) show similar physical features, such as coarse facies and physical appearance, macroglossia, stunted growth, corneal cloudiness, visceromegaly, umbilical and inguinal hernias, CNS involvement with mental retardation (MR), and skeletal changes known as dysostosis multiplex. The latter includes broadened metacarpal and metatarsal bones and ribs, severe deformities of the vertebral bodies, skull abnormalities with a "J-shaped" sella turcica and bony

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_39,

Table 39.1
List of lysosomal storage diseases

Mucopolysaccharidoses
Hurler, Hurler–Scheie, and Scheie syndromes (type, IH, IH/IS, and HS)
Hunter syndrome (type II)
Sanfilippo syndromes A, B, C, and D (type III)
Morquio syndrome (type IV A and B)
Maroteaux–Lamy syndrome (type VI)
Sly syndrome (type VII)
Glycogen storage disease type II (Pompe disease)
Wolman disease (Acid lipase deficiency)
Farber disease (Acid ceramidase deficiency)
Neuronal ceroid lipofuscinosis
Disorders of lysosomal enzyme phosphorylation
Mucolipidosis II (I-cell disease)
Mucolipidosis III (pseudo-Hurler polydystrophy)
Disorders of glycoprotein degradation
α-Mannosidosis
β-Mannosidosis
Fucosidosis
Sialidosis
Aspartylglucosaminuria
Disorders of glycolipid metabolism
Niemann–Pick disease types A and B
Niemann–Pick disease type C
Gaucher disease types I, II, and III
Galactosylceramide lipidosis (globoid cell leukodystrophy; Krabbe disease)
Metachromatic leukodystrophy
Multiple sulfatase deficiency
Fabry disease
Schindler disease
Gangliosidoses
G_{M1} gangliosidosis (infantile, late infantile, and chronic-on-set types)
Galactosialidosis (infantile–juvenile types)
G_{M2} gangliosidosis I (classic Tay–Sachs disease)
G_{M2} gangliosidosis II (Sandhoff disease)
G_{M2} gangliosidosis (activator protein deficiency)
G_{M2} gangliosidosis III (juvenile Tay–Sachs disease)
Cystinosis
Lysosomal transport disorders
Sialic acid storage disorder (infantile free sialic acid storage and Salla disease)
Chediak–Higashi syndrome

abnormalities of the basis cranii, and abnormalities of the hip joints, elbows, wrists, knees, and ankles. Both ligaments and joints are involved. This physical appearance of this symptom complex is referred to as "features of MPS."

Hurler Syndrome (Mucopolysaccharidosis Type IH)

The age of onset is usually between 6 and 24 months. Coarse facial features (gargoylism), macroglossia, stertorous breathing, persistent copious nasal discharge, cloudy cornea, glaucoma, hearing loss (conductive + neurosensory), cardiomyopathy, obstructive airway disease, umbilical and/or inguinal hernia, hepatosplenomegaly, dysostosis multiplex, joint stiffness, stunted growth, hydrocephalus, early developmental delay, and MR are present (*Fig. 39.1*). Death occurs in the first or second decade.

Alerting Signs. Hurler syndrome is marked by severe features of MPS such as coarse physical appearance, macroglossia, cloudy cornea, visceromegaly, hernias, dysostosis multiplex, and MR.

Case History. An 8-year-old boy was referred for the evaluation of coarse features, with a referral diagnosis of a dysmorphic syndrome. The parents noticed his features becoming coarse after 1 year of age. He developed stertorous breathing and continuous nasal discharge at approximately the same time. An umbilical hernia was noticed to grow in size before referral. Family history indicated the death of a previous sister at the age of 10 years. She was diagnosed to have Hurler syndrome. There were no normal children. The presence of a second affected child disrupted the family; they were divorced with acrimonious feelings and remarriage of the father. He had three normal children from the second marriage. On physical examination, the patient's growth parameters indicated severe dwarfism, corresponding to the development level of 3–4 years of age. He had coarse features suggestive of MPS. He had a large dolichocephalic head, severely clouded corneas, persistent nasal discharge with noisy breathing, macroglossia, shortened thick fingers and toes, narrowed intercostal spaces, kyphosis, a large umbilical hernia, and impressive hepatosplenomegaly. Cardiac examination indicated mitral and pulmonary valve regurgitation and he was placed on captopril and furosemide (Lasix). The skeletal survey showed dysostosis multiplex. The peripheral blood film showed leukocytes with metachromatic granules. An MPS screen of the urine indicated 4+ mucopolysaccharidiuria. Both leukocytes and cultured fibroblasts showed normal lysosomal enzymes, except for

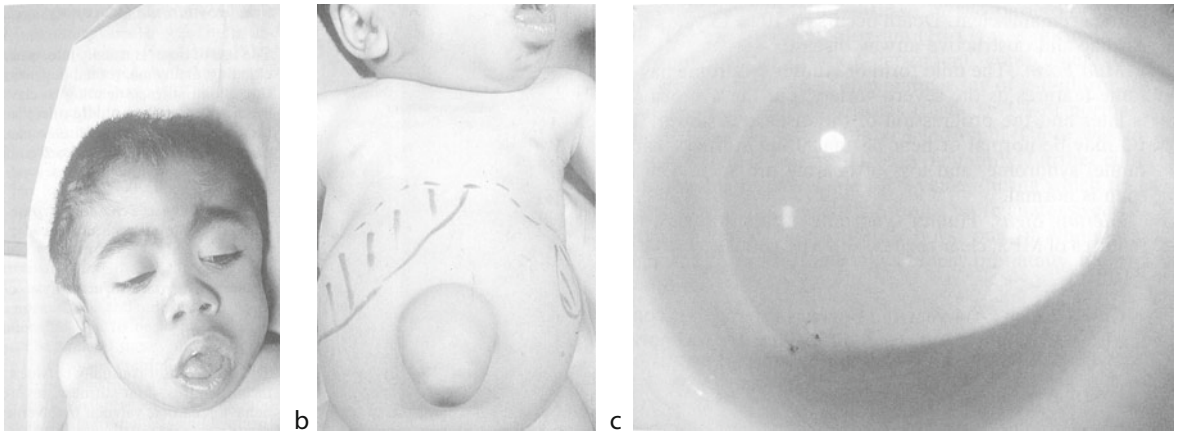

Figure 39.1
Hurler syndrome. (a) The coarse face and macroglossia. (b) The umbilical hernia. (c) The corneal cloudiness

α-L-iduronidase activity, which was less than 1% of normal. He suffered strangulation of his hernia and had to be operated on, following which he developed respiratory insufficiency due to upper airway obstruction and a tracheostomy had to be performed. At present he is at home under respiratory care.

Hurler–Scheie Syndrome (Mucopolysaccharidosis Type IH/IS)

The age of onset is around 1 year. Physical features are intermediate between Hurler and Scheie syndromes. Progressive dysostosis multiplex, coarse facial features, corneal clouding, severe joint stiffness, cervical cord compression, cardiac valvular involvement, and normal intelligence are observed. Death occurs usually late, in the teens and twenties, due to cardiac involvement and obstructive airway disease (◉ *Fig. 39.2*).

Alerting Signs. The physical features are like Hurler syndrome, but IQ is usually normal.

Case History. A 13-year-old boy, at the time of initial encounter, had chief complaints of coarsening of features, dwarfism, joint contractures, and lower back pain since 4 years of age. There was another sibling affected more severely with the same condition who died at the age of 20 years with cardiac complications of the disease. The parents were first-degree cousins. The patient's height and weight corresponded to median ages of 5 and 8 years, respectively, at the age of 13. He had a coarse face, widened fingers and toes with joint contractures, mild macroglossia, narrowed intercostal spaces, very cloudy corneas, mild hepatosplenomegaly, and an umbilical hernia. The psychometric examination indicated normal intelligence for age. He was attending school despite handicaps and was a good student. Neurologic examination

Figure 39.2
Hurler–Scheie syndrome in a 25-year-old male whose disease was first noticed at 6 years of age. He had severe pyramidal tract signs and upper airway obstruction due to the impressive macroglossia. He died despite intensive supportive measures

was normal; although they could not be visualized fully, the eyegrounds appeared normal. The level of α-L-iduronidase was 0.1% and 4% of normal in leukocytes and fibroblasts, respectively. An abdominal ultrasound indicated mild hepatosplenomegaly and no renomegaly. A skeletal survey indicated moderate dysostosis multiplex, with prominent involvement of pelvic bones and a "J-shaped" sella turcica. Magnetic resonance imaging (MRI) of the neck at 13 years of age indicated narrowing of the spinal canal at the C-1 to C-2 level with no compression.

He remained under clinical follow-up for over 12 years, during which time the disease progressed only mildly. Despite a large kinship, there was no human leukocyte antigen (HLA) match in the family for a possible BMT. During this time a cardiac workup indicated thickened mitral and tricuspid valves with no significant stenosis; heart function otherwise was normal. A dental workup indicated malocclusion. His large umbilical hernia required surgery. An ear, nose, and throat (ENT) examination indicated hearing loss of 30% at low frequencies at the age of 20 years. A chest x-ray at the age of 20 years indicated mild bronchiectasis despite no history of smoking. His joint contractures advanced to a stage at which he could not use his hands, and therefore could not be employed because of this handicap despite normal intelligence. He had bilateral corneal transplantation at the age of 18 years, with gain of some visual acuity. He suffered from gastroesophageal reflux and chronic hypertrophic gastritis that required treatment with antacid medication. A stomach biopsy did not show infiltration by MPS-loaded cells. He is now 25 years old and is maintaining a relatively normal lifestyle despite no occupation. He is married and has two normal children.

Scheie Syndrome (Mucopolysaccharidosis Type IS)

The age of onset is usually late, during childhood. Corneal clouding, glaucoma, retinal degeneration, mild coarse features, joint stiffness leading to claw hands, carpal tunnel syndrome, pes cavus, late-onset aortic regurgitation, at times obstructive airway disease causing sleep apnea, normal intelligence, and spinal cord compression and resultant signs of myelopathy are observed. Life span is usually normal.

Alerting Signs. Scheie syndrome is marked by cloudy cornea, stiff joints, and normal IQ.

Hunter Syndrome (Mucopolysaccharidosis Type II)

Severe Form. The age of onset is usually between 2 and 4 years. Coarse facial features, joint stiffness, severe MR with aggressive behavior, cardiac valvular involvement, obstructive airway disease, myocardial disease, mild hepatosplenomegaly, and subcutaneous "Hunter nodules" are observed (*Fig. 39.3*). The cornea remains clear. Death occurs by 10–15 years from cardiac and obstructive airway disease.

Mild Form. The mild form of Hunter syndrome has the same features as the severe variety, but the age of onset is later and the progression of the disease is slower. The IQ may be normal or near normal. Joint stiffness, carpal tunnel syndrome, and loss of hearing are seen. The life span is normal.

Alerting Signs. Hunter syndrome occurs in males, with features of MPS, clear cornea, and MR with aggressive behavior.

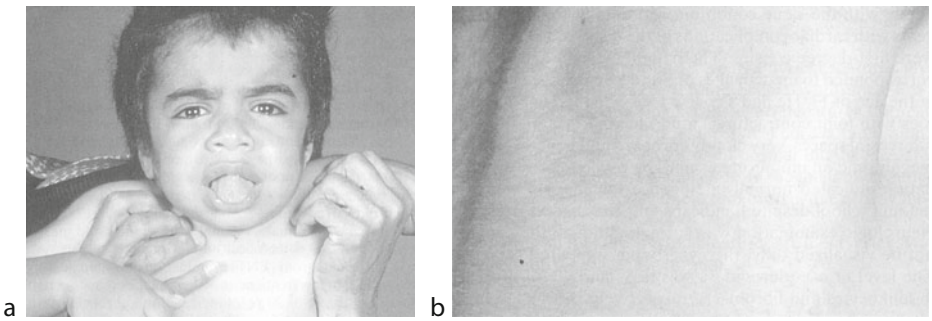

Figure 39.3
A boy with Hunter syndrome. (a) Coarse face but the corneas were clear. (b) Hunter nodules on pressure surface on the back (*See Color Fig.* 5–3*B*)

Case History. A 4-year-old boy was referred for coarse features, irritability, and social difficulties. He was normal until 1 year of age, when his parents noted him to show coarse features and irritable behavior. He was late in acquiring speech, but motor milestones were normal. He could not be toilet trained. He showed shy behavior and would cry if there were strangers around. The parents noticed him to have noisy breathing and persistent nasal discharge. The physical examination indicated a child at the 90th percentile of height and weight with macrocephaly (head circumference corresponding to 12 years of age at the age of 4 years). He had markedly coarse features, clear corneas, pectus carinatum, scoliosis, thoracolumbar kyphosis, and valgus deformity of the lower limbs. The eyegrounds examination was normal. The liver edge was 3 cm below the right costal margin and the spleen tip was palpable. He had a large umbilical hernia. Neurologic examination indicated normal tone and reflexes. A psychometric examination indicated him to be at a 24-months level at 4 years of age. The skeletal survey showed right-sided maxillary sinusitis, dysostosis multiplex with markedly enlarged and thickened calvarium, "J-shaped" sella turcica, markedly hypoplastic vertebrae, enlarged ribs, and enlarged metacarpals in addition to scoliosis and kyphosis of the thoracolumbar vertebrae. MRI of the brain showed subcortical white matter disease in the parieto-occipital area. The electroencephalogram (EEG) was normal. The radioactive sulfur fixation-dependent complementation analysis, and later direct enzymatic assay of α-L-iduronate sulfatase in cultured fibroblasts (result: <1% of normal), indicated him to have Hunter syndrome. There was no HLA-matched donor available in the family. Further clinical follow-up was available for 2 years, during which time he lost most of his speech, showing a more aggressive MR. Two subsequent siblings, both boys, one of whom was diagnosed from chorionic villus biopsy prenatally, had the same disease.

Sanfilippo Syndrome (Mucopolysaccharidosis Types IIIA, B, C, and D)

There are four forms of this disease, each with a different deficient enzyme. The most severe form is type A; type B is less severe, and the severity of type C is between A and B. Type D may have milder features.

Severe Forms. The age of onset is usually between 2 and 3 years, with previous normal development. Severe progressive CNS disease, little or no systemic involvement, severe MR and aggressive behavior, hirsutism and synophrys, sleep disorder with nocturnal insomnia, seizures, late onset of mild joint stiffness with minimal or absent dysostosis multiplex, and minimal or absent hepatosplenomegaly are seen (Fig. 39.4). No corneal cloudiness is observed. Death occurs by 10–30 years of age.

Mild Forms. Age of onset is usually late in childhood, with developmental regression and seizures.

Alerting Signs. Sanfilippo syndrome manifests with only mild features of MPS, extreme hirsutism with synophrys, and aggressive behavior with MR.

Case History (*Sanfilippo Syndrome Type B*). A 15-month-old boy was referred with a presumptive diagnosis of fetal Dilantin syndrome. The mother had a seizure disorder and was under therapy with heavy dose of phenytoin (Dilantin) during pregnancy. Mild coarse features, bilateral epicanthic folds, blepharophimosis, and mild central hypotonia were noticed at 1 year of age that were attributed to the teratogenic affect of phenytoin. The physical, social, mental, verbal, and psychological development remained normal. At the time of examination, coarse features, hirsutism particularly prominent on the forehead, and borderline hepatomegaly were found. He had no neurologic signs and was a happy, cooperative infant with severe atopic dermatitis on the cheeks.

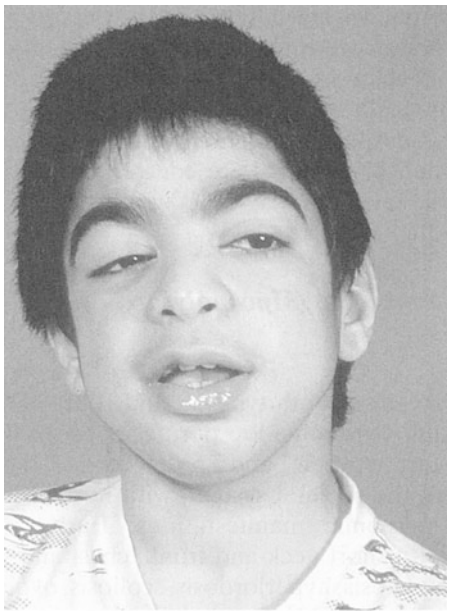

Figure 39.4
An 11-year-old boy with Sanfilippo syndrome type B, whose features coarsened in time, developing hirsutism and synophrys

A skeletal survey, computerized tomography (CT) of the brain, and the EEG were normal. There was no mucopolysaccharidiuria or metachromatic granulation of leukocytes. Since his coarse features suggested an MPS, a lysosomal battery was determined in lymphocytes and in cultured fibroblasts, which indicated absent α-*N*-acetylglucosaminidase, confirming the diagnosis of Sanfilippo syndrome type B.

The further clinical course is available until 11 years of age. Sequentially he started to show progressive encephalopathy with loss of mental, social, and verbal skills starting at 3 years of age but with preserved gross and fine motor function. Psychometric evaluations indicated the following developmental levels: 17 months at 3 years, 13 months at 5 years, 10 months at 7 years, and 6 months at 10 years of age. He developed an aggressive attitude at 5 years. CT of the brain showed mild/moderate atrophy until 5 years of age, at which time MRI of the brain indicated white matter disease, most prominent in the parietal area. The EEG remained normal until 6 years of age, at which time the background was found to be disturbed. He started to have frequent grand mal seizures at 9 years of age. Facial features started to become coarse, with hair on the forehead and synophrys. Bilateral contractures of the fifth fingers of the hand were noticed at 10 years of age. Ovoid vertebral bodies were first noticed at 6 years of age. He started to develop insomnia at 6 years of age. Eventually he had to be institutionalized at 10 years of age. At the age of 11 years, he is severely mentally retarded with aggressive behavior, and his seizures are controlled with phenobarbital.

Morquio Syndrome (Mucopolysaccharidosis Types IVA and B)

The phenotypes of both types A and B are alike. Infants with Morquio syndrome are normal at birth; skeletal deformities start between 1 and 3.5 years of age. It is primarily a disease of the skeletal system, with normal intelligence and mild systemic manifestations. Early and severe dwarfism with short neck and trunk, chest and sternal deformities, kyphosis, hyperlordosis, scoliosis, ovoid deformities of vertebrae with platyspondyly, ulnar deviation of the wrist, delayed ossification of carpal and metacarpal bones, hypermobile wrist joint due to ligament laxity and valgus deformity of the elbow, and odontoid hypoplasia leading to atlantoaxial instability, subsequent subluxation, and spinal cord compression occur (*Fig. 39.5*). All children with Morquio syndrome should have periodic examination of the neck by CT or MRI to detect impending cervical cord compression. Rare and mild systemic manifestations include mild corneal cloudiness, mild cardiac valvular lesions, and mild hepatomegaly. Patients with type A disease have enamel hypoplasia. The life span is normal.

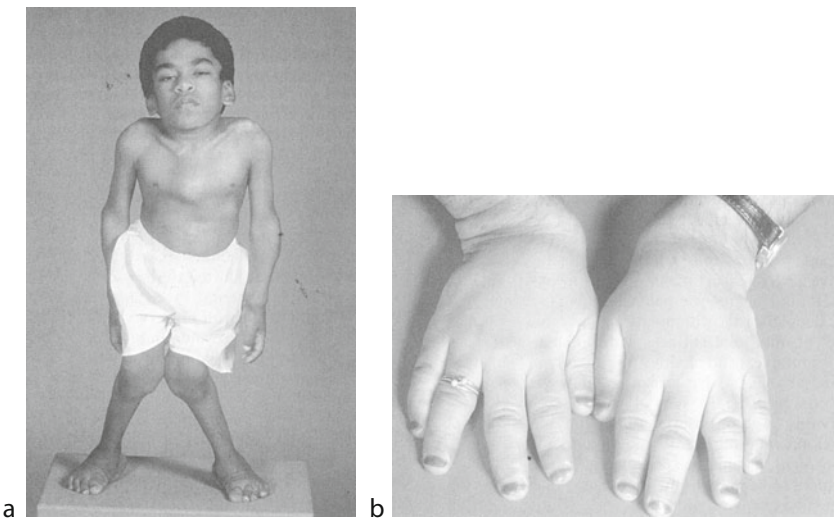

Figure 39.5
Morquio syndrome. (a) General appearance of a boy 16 years of age. (b) Wrists of a boy with deviation due to hypermobile joints

Alerting Signs. Morquio syndrome shows no features of MPS, but dwarfism, short neck, hypermobile joints, vertebral column and chest wall deformities are present, with normal IQ. *Type A* has enamel hypoplasia; *type B* has no enamel abnormalities.

Case History. A boy was diagnosed to have Morquio syndrome at birth by enzyme analysis (galactose-6-sulfatase < 2% of normal) and because of the family history (the presence of a previous sister who had already been diagnosed to have Morquio syndrome). During the first year of life he started to develop gradually the features of the disease, with stunted growth, shortened neck, and eventually kyphoscoliosis. His weight and head circumference remained normal; he did not develop hepatomegaly, and the corneas remained clear. At the age of 18 months a skeletal survey revealed platyspondyly with kyphoscoliosis, coxa valga with hypoplasia of the lateral aspect of the acetabular roof, and instability of the upper cervical spine, with displacement of C-1 in relation to C-2. Blood studies were normal and no metachromatic granules were found. At the age of 3 years, after a trivial pull of his head, the patient developed quadriparesis with increased deep tendon reflexes, bilateral ankle clonus, and Babinski sign. He lost sphincter control for urine and stool. Urgent MRI of the neck showed forward displacement of the C-1 in relation to the C-2 vertebra and hypoplastic odontoid process. He underwent emergency surgery for posterior fusion of the cervical spine. The patient improved gradually and started to walk again 4 months later. The abnormal deep tendon reflexes, Babinski sign, and ankle clonus disappeared 6 months after the surgery. He resumed control of his sphincters in 1 year. He had to wear a neck collar for more than a year. There was no HLA-matched donor in the family. At present he is 6 years old and has a normal IQ, and is leading a normal lifestyle despite worsening of his skeletal deformities.

Maroteaux–Lamy Syndrome (Mucopolysaccharidosis Type VI)

The symptoms are very similar to those of Hurler–Scheie syndrome. The development is normal for first few years of life, with the disease appearing after 2–4 years. The intelligence remains normal. The skeletal findings of dysostosis multiplex are severe; cervical cord compression from thickened dura might be seen. Death occurs in the late 20s to the 40s.

Alerting Signs. Maroteaux–Lamy syndrome is marked by severe features of MPS but normal IQ.

Sly Syndrome (Mucopolysaccharidosis Type VII)

The symptoms are similar to those of Hurler–Scheie syndrome. Severe forms may cause hydrops fetalis and abortions. The usual age of onset is after 4–5 years. Corneal clouding is variable; moderate MR or normal intelligence is seen.

Alerting Signs. Sly syndrome is marked by mild features of MPS, late age of onset, and normal or retarded IQ.

Glycogen Storage Disease Type II (Pompe Disease)

Severe Form

The age of onset is shortly after birth. Massive cardiomegaly with hypertrophic myocardium, macroglossia, hepatosplenomegaly, early feeding difficulties with poor sucking, marked peripheral hypotonia, and progressive muscle weakness including respiratory muscles, with usually firm muscles to palpation, are observed (*Fig. 39.6*). Rapid death occurs, usually before 1 year of age, with cardiorespiratory failure. The intelligence is normal.

Milder, Later Onset Forms. Those forms that present before 2 years show cardiomegaly and muscle weakness.

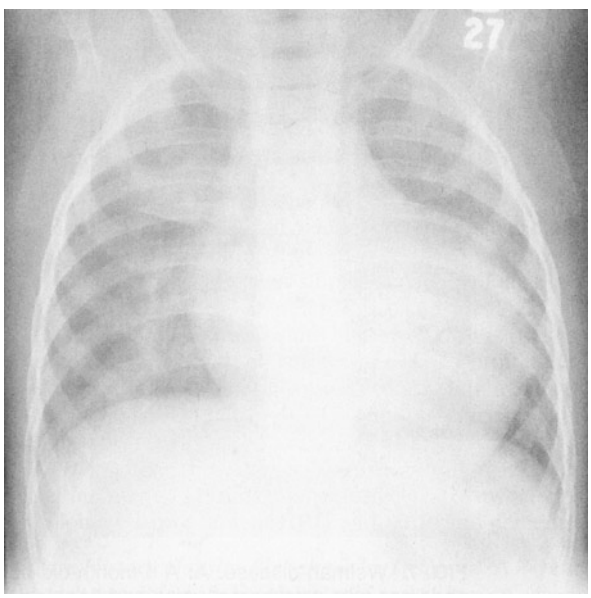

Figure 39.6
Pompe disease. Gross cardiomegaly due to hypertrophic cardiomyopathy

Those that manifest after 2 years of age show only muscle weakness. Muscle weakness is proximal, with involvement of respiratory muscles. Death is late, depending upon the severity of enzyme deficiency. Both severe and mild types show pseudomyotonic discharges on electromyography (EMG), namely, myotonic discharges without myotonia.

Alerting Signs. The *infantile-onset form* of Pompe disease shows massive hypertrophic cardiomyopathy, visceromegaly, and hypotonia. The *late-onset form* shows pseudomyotonic bursts in the EMG.

Case History (*Pompe Disease, Early Infantile Type*). An 8-month-old boy was referred for severe hypotonia. He was the product of a normal pregnancy and delivery. The parents noted him to be hypotonic since 2 weeks of age. The parents were first-degree relatives, with several normal children and no family history of a similar disease. Physical examination indicated height and weight below the fifth percentile. There was a grade 4 systolic murmur generalized over the pericardium with no heave. The liver was enlarged 6 cm below the costal margin; the spleen tip was palpable. There were severe peripheral hypotonia and diminished deep tendon reflexes. Primitive bipedal reflexes were absent. The muscles were very firm to palpation. The x-ray of the chest indicated gross cardiomegaly. Blood glucose and lactic and uric acid were normal. Pompe disease was suspected. Analysis of acid maltase (acidic α-glucosidase) in lymphocytes and, later, in cultured fibroblasts indicated acid maltase to be less than 2% of normal, confirming the clinical diagnosis. The general condition deteriorated rapidly, and the baby died because of heart failure.

Case History (*Pompe Disease, Late Infantile Onset*). The chief complaint of a 3-year-old girl was bilateral facial and diaphragmatic paralysis. She was normal until 30 months of age, at which time, after a chest infection, she could not maintain breathing and had to be placed on ventilatory support. At that time she was found to have severe peripheral hypotonia. She came off the respirator after 1 month and started to walk again with support. She had normal IQ for age. Three months later, she had to be admitted again with inability to support breathing, received a tracheostomy, and was referred for a diagnostic workup. At the time of admission she was alert but had respiratory distress. She had difficulty in swallowing. She had normal heart sounds and normal pulses. There was no visceromegaly.

Her muscle tone and deep tendon reflexes were greatly decreased. Blood chemistries indicated greatly increased CK, at 1,340 U/L (normal: <195 U/L); blood lactic acid and cerebrospinal fluid (CSF) protein were normal. Shortly after admission she developed atelectasis of the left lower lobe, requiring ventilatory support, and this time she could not be weaned off the ventilator. An EMG showed pseudomyotonic discharges without clinical myotonia. The electrocardiogram and echocardiogram revealed normal heart function. Peripheral nerve conduction was normal. Light microscopy of her muscle biopsy showed glycogen accumulation, and electron microscopy (EM) indicated widespread presence of glycogen both within and outside the lysosomes. The acid maltase (α-glucosidase) activity in her cultured fibroblasts was 6% of normal. She was placed on a high-protein (26%) diet, but her clinical status did not improve. She is alive after 3 years on a ventilator.

Wolman Disease (Acid Lipase Deficiency)

The age of onset is early during infancy, with failure to thrive (FTT), steatorrhea, massive hepatomegaly, occasionally splenomegaly, abdominal distention, markedly enlarged adrenals compressing the superior poles of the kidneys, and adrenal calcifications (Fig. 39.7). Mental development is normal. Eventually hepatic fibrosis occurs. Anemia, occasionally acanthocytosis, and vacuolated lymphocytes are seen.

Alerting Signs. Wolman disease is marked by massive hepatomegaly with FTT and adrenal calcifications.

Case History. A 3-month-old boy was referred for abdominal distention and FTT. He was small for gestational age, and abdominal distention had been noticed since birth. The family history revealed the presence of seven infant deaths due to Wolman disease as diagnosed enzymically. Four maternal and two paternal cousins also died of the same disease. On physical examination, he was an alert baby with height, weight, and head circumference corresponding to median ages of 1, 0.5, and 2.5 months, respectively. He had good visual following. There was no subcutaneous fat tissue; the marasmus was most apparent in the face. Protuberant veins were visible on the distended abdominal wall. Hepatomegaly filled the entire right half of the abdomen; the spleen was not enlarged. Neurologic examination was normal with mild hypotonia. The eyegrounds examination was normal. Blood chemistries were normal except for mildly elevated aspartate transaminase (AST) (139 U/L). Dihydroxycholecalciferol was low, at 11 ng/L (normal: >18 ng/L). Chest x-ray, skeletal survey, and CT of the brain were normal. Abdominal ultrasound and x-ray indicated focal areas of calcification in the suprarenal glands. There were acanthocytes in peripheral red blood cells. Bone marrow biopsy revealed histiocytes with hypervacuolization. Liver biopsy indicated small

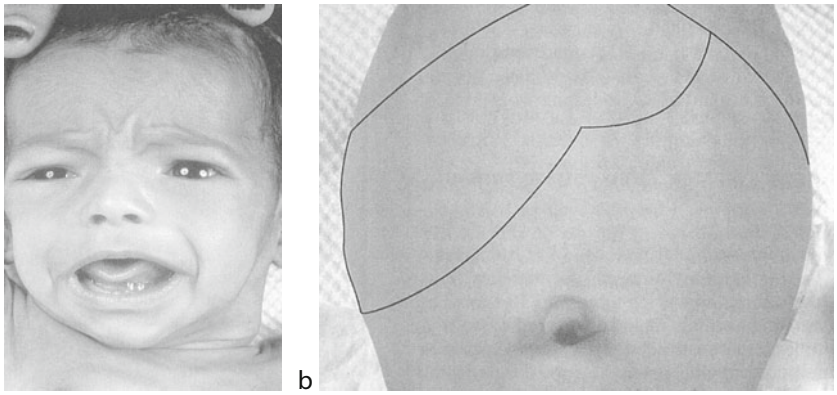

Figure 39.7
Wolman disease. (a) A 6-month-old boy with facial cachexia due to marasmus. (b) Distended abdomen with protuberant veins and hepatomegaly

and large fat vacuoles in hepatocytes, elliptical empty clefts in Kupffer cells, focal fibrosis, and thickened blood vessels. The acid lipase in leukocytes and cultured fibroblasts were 5% and 9% of normal, respectively, confirming the diagnosis of Wolman disease. The parents had previous experience with the fatal outcome of the disease and refused further intervention. He was discharged home, where he died 1 month later.

Farber Disease (Acid Ceramidase Deficiency)

Classic Variety (Severe, Intermediate, and Mild Phenotypes)

The age of onset is between 2 weeks and 2 months in the severe, birth to 9 months of age in the intermediate, and 2–20 months in the mild phenotype. Painful and progressively deformed joints suggest rheumatoid arthritis. Subcutaneous nodules are encountered near joints and at pressure points. Progressive hoarseness due to formation of nodules in the vocal cords; nodules on the external ear, nostrils, conjunctiva, and buccal mucosa; and cardiac valvular involvement due to granulomatous lesions are seen. Corneal opacities and cherry-red macula occur in 10% of the patients. Lung infiltrates, hepatomegaly, mild to moderate MR, and peripheral neuropathy with myopathy are usual. Mean age at the time of death is 1 year in the severe, 5 years in the intermediate, and 16–18 years in the mild phenotype.

Progressive Neurologic Variety. The age of onset is 1–2 years. Joint and nodule involvements are the same as in the classic type. However, the CNS disease predominates, with ataxia, polymyoclonia, rigidity, tremors, dementia, and cherry-red macula. No lung involvement and no corneal opacities are seen. Death usually occurs by 3 years of age.

Alerting Signs. Farber disease is marked by painful joints, subcutaneous nodules on joints and pressure surfaces, and hoarse voice. The neurologic variant also has progressive encephalopathy.

Neuronal Ceroid Lipofuscinosis

All forms of neuronal ceroid lipofuscinosis (NCL) are inherited as autosomal recessive disorders. This group of diseases is classified according to age of appearance.

Infantile Form (Santavuori Type)

The age of onset is 6–12 months, with motor regression, visual failure, and macular degeneration. These symptoms progress to truncal ataxia, dystonia, choreoathetosis, and stereotypic hand movements like those of Rett syndrome. Severe myoclonus and myoclonic seizures and eventually dementia are seen by 6–18 months. CT of the brain indicates dense thalami. The EEG flattens by 12 months, then becomes isoelectric. The visual evoked potentials (VEP) and electroretinogram (ERG) are absent by 12 months. Rectal biopsy shows ganglion cells with granular EM inclusions. Death occurs before 14 years. Subunit *c* of ATP synthetase does not accumulate in lysosomes.

Alerting Signs. Santavuori-type NCL manifests with myoclonus, myoclonic seizures, macular degeneration, dense thalami, and absent ERG or VEP.

Late Infantile Form (Jansky–Bielschowsky Disease)

The age of onset is 2–4 years. The neurologic findings and progressive encephalopathy are very similar to those of Santavuori disease, except stereotypic hand movements are absent and pigmented retinopathy is present. The EEG shows large polyspikes. The VEP and ERG show increased wave height. No dense thalami are seen in CT of the brain. MRI of the brain shows periventricular white matter disease. Death occurs by 10–15 years. Subunit *c* of ATP synthetase accumulates in lysosomes.

Alerting Signs. Jansky–Bielschowsky disease manifests with myoclonus, myoclonic seizures, pigmented retinopathy, periventricular white matter disease, and abnormal waves in the ERG and VEP.

Juvenile Form (Spielmeyer–Vogt Disease)

The age of onset is between 5 and 9 years. The neurologic findings and progression of the disease are similar to the late infantile variety, except slurred speech and echolalia are present. The EEG is not helpful, and the VEP and ERG are absent. Central white matter disease is present. The storage in the form of curvilinear or fingerprint bodies can be shown in peripheral lymphocytes. Death occurs by 20–40 years. Subunit *c* of ATP synthetase accumulates in lysosomes.

Alerting Signs. Spielmeyer–Vogt disease is marked by visual failure and retinitis pigmentosa (*Fig. 39.8*), myoclonus, myoclonic seizures, absent ERG and VEP, and dementia.

Case History (*Jansky–Bielschowsky Disease*). A 7-year-old girl was referred for myoclonic jerks, loss of vision, and spastic quadriplegia. She was doing well, acquiring milestones normally, until 4 years of age. She then started to have frequent, and later on continuous, jitters and lost her motor function gradually, becoming bedridden. Subsequently she lost her vision, speech, and sphincter control. She was immunized and had not had measles in the past. The parents were consanguineous, and other children in the family were normal with no familial history of a neurodegenerative disease. On physical examination, she showed continuous polymyoclonic jerks of the extremities and face. She was blind and deaf. There were no neurocutaneous lesions. The head was microcephalic. The eyegrounds examination revealed bilateral optic atrophy, retinal degeneration with pale retina, and very narrowed blood vessels. She had spastic quadriplegia, somewhat increased deep tendon reflexes, and Babinski sign. Blood chemistries, ammonia, lactate, tandem mass spectrometry studies, and urine organic acids were normal. MRI of the brain showed mild brain atrophy. The EEG showed diffuse background slowing and dysfunction at this late stage of the disease. The ERG indicated absent waves bilaterally. The nerve conduction studies were normal. These results suggested the diagnosis of NCL of the Jansky–Bielschowsky type. The EM analysis of lymphocytes of the buffy coat and a conjunctival biopsy revealed the curvilinear (fingerprint) bodies typical of NCL. The disease since then has progressed relentlessly, and she has become vegetative.

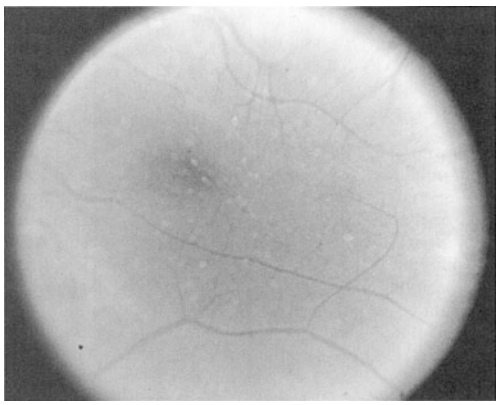

Figure 39.8
Neuronal ceroid lipofuscinosis (Spielmeyer–Vogt disease): retinitis pigmentosa in a 25-year-old girl whose disease started at 7 years of age (*See Color Fig.* 5–8)

Disorders of Lysosomal Enzyme Phosphorylation

Mucolipidosis II (I-Cell Disease)

The disease is always apparent at birth with somatic features and x-ray findings of dysostosis multiplex of Hurler syndrome. Its severe form causes hydrops fetalis. Birth weight and length are lower than normal. Coarse face, corneal cloudiness, aortic valvular disease, inguinal and umbilical hernias, bilateral talipes equinovarus, and congenital hip dislocation are seen. Striking gingival hyperplasia and absent mucopolysaccharidiuria as well as the features of MPS at birth differentiate I-cell disease from Hurler syndrome. Death usually occurs by 5–8 years of age. Those surviving show severe delay of motor function and moderate MR. The deficiency of a specific

phosphotransferase that phosphorylates a mannose residue on newly synthesized lysosomal enzymes leads to impaired uptake of all lysosomal enzymes by lysosomes and their excretion into medium, blood, or urine.

Alerting Signs. Mucolipidosis II shows severe features of MPS at birth and gingival hyperplasia (◉ *Fig. 39.9*).

Case History. A patient who was severely cyanotic and had respiratory distress was first seen at the age of 5 months in the company of her 2-year-old sister, who was already diagnosed to have I-cell disease. Her growth had completely stopped after birth; she had not grown an inch, had not gained 0.5 kg of weight, and had not increased her head circumference more than 1 cm. Physical examination indicated an infant with a weak cry, microcephaly, closed fontanel, significant gingival hyperplasia, odd coarse-looking features, an abnormal chest cage with flaring of the lower ribs, mild hepatosplenomegaly, increased muscle tone, and cortical fisting. The EEG showed mildly abnormal background. CT of the brain was normal. Skeletal survey indicated reduction of the sagittal diameter of vertebrae with bilateral convexity and bilateral dislocation of the hips with extreme acetabular dysplasia. Cardiac workup indicated pulmonary stenosis, severe dilation of the right atrium and right ventricle, severe tricuspid regurgitation with malaligned septum, ventricular septal defect, overriding aorta, and hypoplasia of the descending aorta. The lysosomal battery in lymphocytes and cultured fibroblasts revealed 3–8% of normal activity for all lysosomal enzymes tested, confirming the diagnosis of I-cell disease. The psychometric assessment at the age of 14 months showed her motor skills to be at less than 6 months of age, but her verbal and social skills at 10 months of age. By then the repeat EEG indicated markedly slow background. She survived until the age of 18 months, when she died of heart failure.

Figure 39.9
Mucolipidosis II (I-cell disease). A 1-year-old infant who had coarse features since birth; her hypertrophic gingiva are shown

Mucolipidosis III (Pseudo-Hurler Polydystrophy)

The age of onset is 2–4 years, with mild features of MPS. Prominent joint stiffness confuses the disease with rheumatoid arthritis. The characteristic ophthalmologic triad of corneal clouding, mild retinopathy, and hyperopic astigmatism appears by 7 years of age. Mild dysostosis multiplex evolves slowly. Mild to moderate MR is seen. Survival is until the 30s or 40s. The enzyme deficiency is the same as in mucolipidosis II, but it is milder.

Alerting Signs. Mucolipidosis III shows mild features of MPS with severe joint involvement.

Disorders of Glycoprotein Degradation

α-Mannosidosis (Severe and Mild Forms)

In the severe form, the age of onset is 3–12 months, and death occurs by 3–10 years. In the mild form, the age of onset is 1–4 years, and death occurs after 10 years of life. The phenotype includes coarse facial features, mild dysostosis multiplex, hernias, and hepatosplenomegaly. Corneal opacities are encountered mainly in the lower pole, and cataracts occur in a characteristic spoke-like pattern in the posterior lens. Severe to moderate MR is present. Recurrent bacterial infections due to impaired chemotaxis are frequent.

Alerting Signs. α-Mannosidosis shows features of MPS, opacities at the lower pole of the cornea, cataract, and frequent infections.

Case History (*α-Mannosidosis, Mild Form*). An 18-month-old boy was referred for hepatosplenomegaly, repeated chest infections, diarrhea, jaundice, and MR. He was a premature infant who sat at 6 months but could not walk at 18 months of age. He had no verbal skills. He had been hospitalized for chest and upper respiratory

infections three times previously, and had prolonged jaundice of unknown etiology for 3 months at the age of 14 months. The family history indicated five premature births who were now normal and a 6-year-old moderately mentally retarded sister with hepatosplenomegaly. According to the parents, the sister developed hazy corneas at 4 years of age and also had frequent chest infections. The patient's growth parameters were at the fifth percentile and the head circumference at the 50th percentile. He had the mildly coarse features of a patient with MPS. There was no corneal cloudiness. The cardiac workup was normal. The liver was 8 cm and spleen 4 cm below costal margins. Psychometric assessment placed him at 50% developmental level. Detailed ophthalmologic examination showed no cherry-red macula or corneal cloudiness. Neurologic examination showed normal muscle tone and reflexes. The peripheral blood and bone marrow examination indicated vacuolated lymphocytes. He had mild neutropenia. Liver enzymes were elevated (alanine transaminase [ALT] 354 U/L and AST 214 U/L). Skeletal survey indicated mild dysostosis multiplex, more prominent in the metacarpal bones, which showed proximal tapering. The lysosomal battery indicated α-mannosidase to be 6% of normal in leukocytes and 10% of normal in fibroblasts, indicating the presence of mannosidosis. There was no HLA-matched donor in the family. The patient was lost to follow-up.

β-Mannosidosis

The presentation is nonspecific, with MR, seizures, and, in the severe phenotype, spastic quadriplegia.

Alerting Signs. In β-mannosidosis there are none, except that it is a progressive encephalopathy.

Fucosidosis

Severe Form. The age of onset is around 1 year. Coarse facies, dysostosis multiplex, kyphoscoliosis, ovoid formation of vertebrae with beaking, joint contractures, hearing loss, tortuous conjunctival vessels, recurrent infections, cardiomegaly, hepatosplenomegaly, severe MR with aggressive behavior, seizures, and rapidly progressive encephalopathy are present. There is no corneal opacity. Sweat sodium chloride is elevated. Death occurs by 4–5 years of age.

Mild Form. The age of onset is around 2 years, with the same features as in the severe form, except they are milder. Angiokeratoma is seen only in this type (*Fig. 39.10*); sweat chloride is normal, but anhidrosis is present. Death occurs by 10–40 years of age.

Figure 39.10
Fucosidosis. Angiokeratoma on abdominal wall (*See Color Fig.* 5–10)

Alerting Signs. Fucosidosis is similar to Sanfilippo syndrome but with prominent features of MPS and angiokeratoma.

Case History (*Fucosidosis, Mild Form*). A 5-year-old girl was referred for aggressive behavior and mildly coarse features. She developed normally until 18 months of age, at which time the parents noticed her to lose speech and show hyperactive behavior. The parents were first cousins, and they had one normal and two affected daughters. The physical examination indicated a girl with normal physical growth. Her lips were thick; she had mild hirsutism on her forehead, no corneal cloudiness, but mildly increased vascularity of conjunctiva. Her liver was 3 cm below the costal margin and the spleen tip was palpable. She showed aggressive behavior with mild spastic diparesis, increased deep tendon reflexes, and unsustained ankle clonus. Cardiac workup was normal. Skeletal survey indicated ovoid lumbar vertebrae with beaking. MRI of the brain revealed mild white matter disease in the centrum ovale. The EEG indicated slow background. Blood chemistries were normal. The clinical impression was a case of Sanfilippo syndrome. All four heparan sulfatase activities were tested

and were found to be normal. The α-fucosidase in her leukocytes and cultured fibroblasts indicated activity less than 1% of normal, indicating the diagnosis of fucosidosis. The younger, 3-year-old sister showed similar physical features; the 6-month-old sister physically appeared normal. Both children had absent α-fucosidase activity in their leukocytes. The youngest sister with the disease started to lose milestones at 2 years of age, with coarsening features and borderline hepatosplenomegaly. Sweat chloride test repeated twice was normal. During subsequent visits a peculiar rash was observed on the anterior and posterior wall of the abdomen; biopsy indicated it to be angiokeratoma. There was no HLA-matched donor in the family. She was lost to follow-up.

Sialidosis

Type I (*Cherry-Red Macula-Myoclonus Syndrome*). The age of onset is usually around the second decade, with cherry-red macula appearing later during the disease. Loss of visual acuity, night blindness, spontaneous or stimulus-induced myoclonus, ataxia, and nystagmus are seen.

Type II (*Severe, Infantile Form*). The more severe form causes hydrops fetalis, stippled epiphyses, and periosteal cloaking. The onset is usually at birth, with features of MPS such as coarse facies, visceromegaly, hernia, corneal clouding and cherry-red macula, seizures, and dysostosis multiplex. Death occurs by 2 years of age.

Alerting Signs. Type 1 sialidosis is marked by late-appearing cherry-red macula with myoclonus in an adolescent. *Type 2* sialidosis is marked by features of MPS at birth, with cherry-red macula but no gingival hyperplasia; it is easily confused with G_{M1} gangliosidosis.

Case History (*Sialidosis Type I*). A 14-year-old girl, at the time of initial encounter, had a chief complaint of action-induced myoclonus, with myoclonic jerks of the extremities that first appeared at 9 years of age and progressed to a stage such that she had stopped walking for the last 2 years. She had several grand mal seizures that were controlled by clonazepam. The parents were first cousins, and two of her cousins had the same disease. At the time of first visit her height, weight, and head circumference were normal, with no organomegaly or cherry-red macula. (The cherry-red macula appeared later, at the age of 22 years.) The deep tendon reflexes were normal. She had tremors of the hands throughout an intentional movement. She frequently showed exaggerated "startle response" followed by seizure and postictal sleep. She had severe action-induced myoclonus, bouncing up and down when standing. A psychometric assessment indicated normal intelligence and no dementia but depression. The level of neuraminidase (sialidase) in fibroblasts was 10% of control and was absent in leukocytes. Other lysosomal enzymes were normal. The 5-hydroxyindole acetic acid (in CSF) and homovanillic acid (in CSF and urine) were normal. CT of the brain was normal, and the EEG indicated poorly organized background. The VEP, brain stem auditory evoked potentials (BAEPs), and somatosensory evoked potentials were normal at the age of 16 years. She was placed on 5-hydroxy-tryptophan, which did not improve her myoclonus. Although her seizures could be controlled by valproic acid and clonazepam, the action myoclonus worsened to a degree that she eventually became totally wheelchair bound at the age of 24 years.

Aspartylglucosaminuria

The age of onset is few months after birth, with recurrent infections, diarrhea, and hernias. Subtle coarse features, macroglossia, hoarse voice, mild dysostosis multiplex, joint laxity, sagging skin folds, occasional hepatomegaly, and crystal-like lens opacities occur after 5–10 years; neutropenia, abnormal prothrombin time, and aspartylglucosaminuria also occur. Mental deterioration is seen between 6 and 10 years. Death occurs in the late 30s or 40s.

Alerting Signs. Aspartylglucosaminuria is marked by mild features of MPS with FTT and chronic diarrhea, neutropenia, and abnormal coagulation studies.

Disorders of Glycolipid Metabolism

Niemann–Pick Disease

Type A. The age of onset is usually 4–6 months after birth, with feeding difficulties, severe hypotonia, and distended abdomen due to hepatosplenomegaly. A cherry-red macula appears, and has a gray granular appearance (macular halo syndrome). Loss of motor function, dementia, striking emaciation with yellowish brown color of the skin, and at times xanthomas are seen. The pulmonary involvement is not prominent. The age of death is 2–3 years.

Type B. The age of onset is any time between early childhood and adolescence. Hepatosplenomegaly is impressive; the hepatomegaly is usually bigger than the splenomegaly and occurs earlier (Fig. 39.11). Neurologic findings and intelligence are normal. Cherry-red macula is usually present. Elevated ALT and AST are common. It is primarily a pulmonary disease, with lung

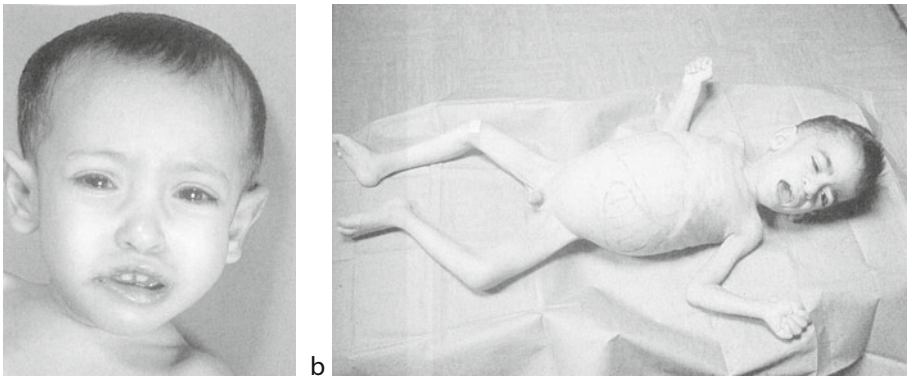

Figure 39.11
Niemann–Pick disease type B. (a) Typical marasmic face with loss of orbital fat tissue and prominent fat pad on nasal bridge. (b) A terminal patient with impressive hepatosplenomegaly and severe cachexia

infiltrates and eventually significant pulmonary compromise and death by 10–20 years of age. The Saudi and Middle Eastern variety appears as in type A, but with no neurologic involvement, very early pulmonary disease, emaciation, and death by 2–3 years of age.

Alerting Signs. Type A Niemann–Pick disease shows hepatosplenomegaly, cherry-red macula, and early emaciation with progressive encephalopathy; *type B* is similar to type A but with slow progression, elevated ALT and AST, and no neurologic involvement, and death is due to pulmonary infiltration.

Case History (*Niemann–Pick Disease, Type B, Middle Eastern Variety*). A 28-month-old boy was referred for hepatosplenomegaly. Birth and subsequent development were normal, and he acquiring the expected milestones. The parents noticed the abdominal distention at 9 months of age, and he started to lose weight and developed frequent chest infections that required repeated hospitalization. The abdominal distention progressed, and a biopsy of the liver at the referring hospital indicated cirrhotic changes and abundant foamy cells, typical of Niemann–Pick disease. The parents were first cousins and this was their first living child (the mother had had five miscarriages). The family history otherwise was not significant. The physical examination showed a cachectic child, with height, weight, and head circumference corresponding to median ages of 10, 6, and 18 months, respectively, at the age of 28 months. There was no subcutaneous fat tissue; he had sunken eyes and a marasmic face, except for a preserved fat pad on the nasal bridge (i.e., the typical face of a patient with Niemann–Pick disease). He responded poorly to visual stimuli and had a cherry-red macula. The hepatosplenomegaly was impressive, filling up the entire abdomen. He had mild central hypotonia. Blood chemistries indicated elevated ALT of 220 U/L, AST of 250 U/L, cholesterol of 6.5 mM (normal: <4.2 mM), and partial thromboplastin time of 45s (normal: < 35s). The sphingomyelinase in both leukocytes and cultured fibroblasts was less than 1% of normal, confirming the clinical diagnosis of Niemann–Pick disease. MRI of the brain revealed mild central white matter disease; the EEG revealed mild disturbance of the background. His clinical course progressed rapidly downhill. He eventually developed severe pulmonary disease with diffuse infiltrates and died as a result of his lung disease.

Type C. Severe forms of the disease may start neonatally, but the age of onset is usually after 4–5 years of age. Prolonged neonatal jaundice is always seen. The severe form of the disease manifests with terminal hepatic failure and pulmonary infiltrates in infancy. In its classic form, a slow dementia starts at school age with clumsiness, ataxia, dysarthria, dysphagia, and extrapyramidal signs such as dystonia, drooling, and seizures. Mild hepatosplenomegaly is usually first noticed at school age. Death occurs by puberty. The pathognomonic sign of the disease is vertical supranuclear ophthalmoplegia. Defective intracellular trafficking of exogenous cholesterol is shown by cholesterol accumulation in perinuclear lysosomes by a fluorescent stain, filipin.

Alerting Signs. Niemann–Pick disease type C shows progressive encephalopathy with splenomegaly and vertical supranuclear ophthalmoplegia.

Gaucher Disease

Type I. The age of onset varies between infancy and 33 years. Death occurs early in severe variants. Life span

is normal in late-onset variants. Early hepatosplenomegaly is observed, and the spleen is usually bigger than the liver. The skeletal involvement occurs early (Fig. 39.12). In a severe variant, hepatosplenomegaly may fill the abdomen. The abdominal protuberance is more marked than in Niemann–Pick disease type A or B. The early sign of bleeding is due to thrombocytopenia, which is not present in Niemann–Pick disease type A or B. The bone storage is debilitating, leading to an "Erlenmeyer flask" appearance of the distal femur, fractures in long bones and vertebrae, and painful "bone crisis." In severe cases, patient will be crippled due to multiple fractures. Lung infiltrates are common among Saudi and Middle Eastern patients. There is no CNS involvement, and the intelligence is normal.

Type II. The more severe form may occur at birth with hydrops fetalis and ichthyosis. The age of onset is usually early infancy, with death by 2 years of life. Extensive hepatosplenomegaly, severe early neurologic involvement with oculomotor apraxia, and the Gaucher triad of bilateral fixed strabismus, opisthotonus, and trismus are seen (Fig. 39.13).

Type III. The severity of this phenotype is between those of types I and II, with early hepatosplenomegaly that occurs at a median age of 1 year, and late neurologic manifestations that are seen at a median age of 2 years.

Alerting Signs. Type I Gaucher disease shows hepatosplenomegaly (spleen bigger), thrombocytopenia, normal ALT and AST, severe lytic bone changes, and normal neurologic findings. *Type II* Gaucher disease manifests as in type I but with severe CNS involvement (*Gaucher triad*: trismus, opisthotonus, strabismus); *type III* is milder than type II and more severe than type I.

Case History (*Gaucher Disease Type II*). A 3.5-year-old girl, at the time of initial encounter, had a chief complaint of abdominal distention, first noticed at the age of 12 months, which progressed to a size over the years that prevented her from achieving a sitting position. She had one chest infection before her first visit. Early developmental milestones were normal; she had developed good speech skills. The trismus and fixed strabismus were first noticed at 24 months. She was the second child born to a first cousin marriage, with one normal sibling. At the time of admission her height, weight, and head circumference corresponded to median ages of 18, 24, and 6 months, respectively, at the age of 42 months. The abdominal girth was 60 cm. She had marked rigidity of her neck, trismus, and strabismus (Gaucher triad). The liver span was 20 cm and the spleen span was 17 cm. She had severe anemia (61 g/L) and marked thrombocytopenia ($< 25{,}000/mm^3$) requiring repeated platelet transfusions. The β-glucosidase level in her cultured fibroblasts was 5% of normal value, with normal sphingomyelinase and other lysosomal enzymes. A bone marrow biopsy indicated the presence of Gaucher cells. A skeletal survey indicated collapsed L-4 vertebra and multiple cyst-like structures

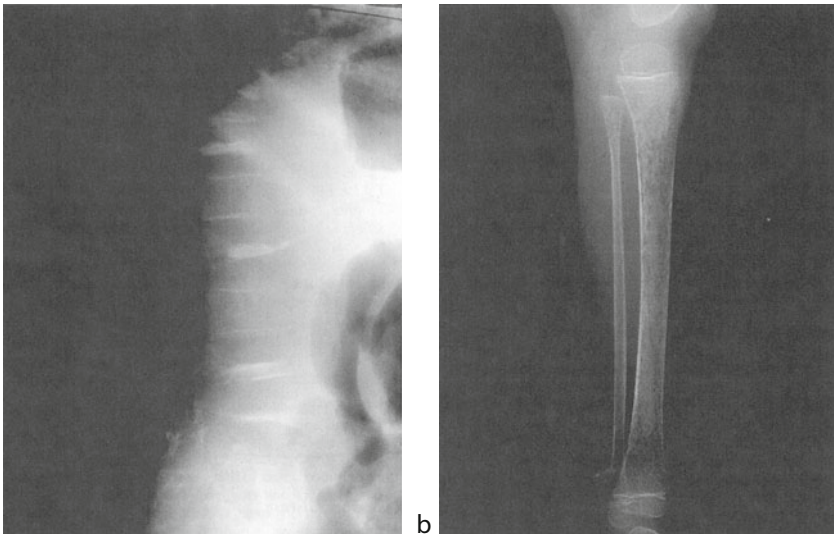

Figure 39.12
Skeletal changes in Gaucher disease. (a) Wasted vertebral body fractures and kyphosis in a patient with type I Gaucher disease. (b) "Moth-eaten" appearance of tibia in a patient with type II disease

Gaucher disease type II. (a) The lateral view of a distended abdomen due to impressive hepatosplenomegaly. (b) Trismus in a patient with Gaucher triad

scattered through the long bones. Chest x-ray did not indicate lung infiltrates. There was mild white matter disease on CT of the brain with atrophy, and the EEG showed mildly slowed background activity. She underwent splenectomy, and the weight of the spleen removed was 2.5 kg (30% of her body weight). There was no HLA-matched donor in the family, and, given the CNS involvement, no effort was made to secure a BMT; the patient was discharged home and died later.

Galactosylceramide Lipidosis (Globoid Cell Leukodystrophy; Krabbe Disease)

The age of onset is usually 2–3 months in the early infantile and 6 months to 3 years in the late infantile form. Rare juvenile–adult types can start at 3–35 years of age. The infantile variety is characterized by extreme irritability (an unsoothable infant), with severe spasticity, blindness, optic atrophy, and rapidly progressive encephalopathy with dementia. Severe central white matter disease is seen in neuroradiologic studies. Pathognomonic findings are peripheral neuropathy, diminished to absent deep tendon reflexes in the presence of spasticity, prolonged nerve conduction time, and increased CSF protein. Death occurs by 1–3 years of age. The juvenile–adult forms start with psychomotor deterioration, ataxia, loss of vision, and pyramidal tract signs but occur usually without peripheral neuropathy.

Alerting Signs. Galactosylceramide lipidosis is marked by extreme irritability, spasticity with absent deep tendon reflexes due to peripheral neuropathy, and increased CSF protein.

Case History (*Krabbe Disease, Late Infantile Form*). A child was first encountered at 7 months of age with the chief complaint of developmental regression and extreme irritability. His early development was normal until 5–6 months of age, when he first started to show irritability, then losing the ability to smile at his mother and to sit with support. The growth parameters were normal. He was an unsoothable infant, whining continuously. He had midline hypotonia with hypertonic extremities. Deep tendon reflexes were normal. Primitive bipedal responses were absent. The eyegrounds examination indicated pale optic discs. A peripheral nerve conduction study indicated prolonged nerve conduction in the median and ulnar nerves and absent potential in the sural nerves bilaterally, with decreased amplitude in several motor nerves (i.e., evidence of peripheral neuropathy). The BAEP and ERG were normal; however, VEP were absent. MRI of the brain indicated areas of increased signal intensity in the centrum ovale, within the dentate nucleus of the cerebellum, and in the anterior limb of the internal and the posterior limb of the external capsule, indicating widespread white matter

disease. Brain positron emission tomography indicated markedly decreased glucose uptake widespread in the cortex, absent uptake in the caudate, and normal uptake in the thalamus and putamina bilaterally. The CSF protein was elevated, at 900 mg/L (normal: <450 mg/L). Lysosomal enzyme tests for arylsulfatase A and B, hexosaminidase, and β-mannosidase were normal, but the galactosylceramide-β-galactosidase activity was 3% of normal, confirming Krabbe disease. The further clinical course was that of a progressive encephalopathy at 2 years of age, with severe spastic quadriplegia developing and deep tendon reflexes disappearing. He had to be placed on gavage feeding since he could not swallow.

Metachromatic Leukodystrophy

The age of onset is different from that of classic forms of Krabbe disease, and the earliest age is about 2–3 years. The juvenile-onset (4–12 years) and adult-onset (mid-teens to seventh decade) forms are rare. The initial symptom is mental regression with gait disturbance and incontinence in a previously toilet-trained infant. This is followed by dementia, blindness, optic atrophy, quadriplegia, hypotonia, loss of verbal skills, and evidence of peripheral neuropathy with diminished deep tendon reflexes and prolonged nerve conduction time. The CSF protein is increased. Severe central white matter disease is seen in neuroradiologic studies. Eventually decerebrate posture with pseudobulbar signs and vegetative state emerge, leading to death by 5–8 years of age.

Alerting Signs. Metachromatic leukodystrophy shows progressive pyramidal tract disease with loss of milestones at 2–3 years of age, hypotonia, diminished deep tendon reflexes due to peripheral neuropathy, and increased CSF protein.

Multiple Sulfatase Deficiency (Austin Disease)

This disease combines features of MPS, particularly those of Maroteaux–Lamy syndrome and Morquio syndrome, with metachromatic leukodystrophy and features of deficiency of cholesterol sulfate sulfatase (i.e., ichthyosis). The age of onset of the disease is 1–2 years in the Middle East and Saudi Arabia. Psychomotor retardation in a shy child and some degree of hirsutism might initially suggest a Sanfilippo syndrome. Short neck and trunk, with odontoid hypoplasia and compression of the cervical cord, appear by 2–3 years of age. Hepatosplenomegaly, failure of growth, pyramidal tract signs, and progressive encephalopathy lead to death by 4–5 years of age. The IQ remains normal or near normal until late in the progression of the disease. In Japan and the United States, features of metachromatic leukodystrophy predominate, with lesser features of MPS. Pathognomonic features of the severe, early form of the disease are a poorly developed orbital cavity leading to proptosis in almost all patients and subtle to marked ichthyosis, which make rapid clinical diagnosis possible (Fig. 39.14).

Alerting Signs. Multiple sulfatase deficiency shows combined skeletal features of Morquio syndrome, hirsutism of Sanfilippo syndrome, and coarse features of Maroteaux–Lamy syndrome, with metachromatic leukodystrophy, ichthyosis, and proptosis.

Case History. A 2-year-old girl was referred for mildly coarse features and proptosis. She was slow in acquiring milestones, sitting at 1 year and able to take a few steps with help at 2 years of age. She had only two words, and had just started to transfer objects from one hand to the other and to hold her bottle. Her features became coarse at 1 year, and proptosis was observed shortly before referral. The parents were first cousins and were aware of the nature of her disease, since they previously had had a son who was diagnosed to have multiple sulfatase deficiency. They had refused clinical follow-up for him. He developed spastic quadriplegia after a sudden movement of the head, due to cervical cord compression by the dislocated C-1 vertebra, at 3 years of age. As a result, he was severely disabled and lived only another 3 years, to die at 6 years of age at home. The parents knew that this was a lethal disease, but wanted to prevent a cervical dislocation in this girl. On physical examination, her height was below the fifth percentile but her weight and head circumference were normal. The skin showed mild ichthyosis on the lower limbs. Her facial features were coarse and she had marked proptosis. Her nasal bridge was depressed and wide; there was some hirsutism on the forehead; and she had thick lips, broad, short, and stubby fingers, thoracolumbar kyphosis, and an umbilical hernia. Her corneas were cloudy; there was no cherry-red macula. There was a grade 3 systolic murmur over the precordium. The liver and spleen both were 4 cm below the costal margin. Neurologic examination revealed no pyramidal tract signs. An echocardiogram revealed a thickened mitral valve and mitral, tricuspid, and aortic valvular regurgitation with dilated left atrium and ventricle. The skeletal survey showed severe dysostosis multiplex. MRI of the brain showed mild white matter disease in the centrum ovale, and MRI of the neck showed instability of cervical vertebrae 1 and 2. The EEG was normal; however, VEP and BAEP indicated delayed responses. The following sulfatase

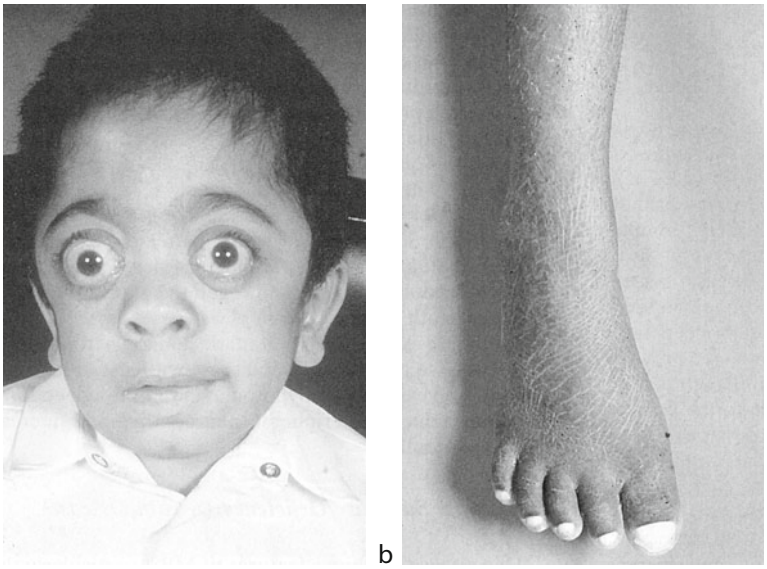

Figure 39.14
Multiple sulfatase deficiency. (a) The pathognomonic proptosis of the disease due to a shallow orbital cavity. (b) Ichthyosis on the leg

activities were below 10–15% in her cultured fibroblasts: arylsulfatase A and B, heparan sulfatase, keratan sulfatase, and steroid sulfate sulfatase, confirming the diagnosis of multiple sulfatase deficiency. She was operated on by a neurosurgeon, who immobilized her cervical vertebrae. There was no HLA-matched donor in the family. At present she is 5 years old, and the changes in her physical features and proptosis have become more pronounced. The mother subsequently gave birth to a normal child.

Fabry Disease

In the hemizygous male, the disease is of adult-age onset; the earliest age observed is late childhood or adolescence. The initial symptom is periodic severe excruciating pain in the extremities (acroparesthesia), hipohidrosis, angiokeratoma, and characteristic eye findings. These are whorl-like, cream-colored inferior corneal opacities; propeller-like inferior lenticular opacities; or spoke-like deposits of fine granular material in the posterior lens capsule. Later, during adult age, cardiac, renal, and cerebral disease due to vascular storage of globotriaosylceramide results in cardiac and brain ischemia, infarctions, and renal failure.

Alerting Signs. Fabry disease manifests with excruciating pain, corneal opacities, angiokeratomas, hipohidrosis, and, later, renal failure.

Schindler Disease (Neuroaxonal Dystrophy Types I and II)

Type 1 is a childhood and type 2 is an adult disease. Type 1 remains normal until 9–12 months of age. The early sign is developmental delay followed by progressive encephalopathy during the second year of life. This is followed by myoclonus, spasticity, hyperreflexia, reduced muscle mass, profound mental retardation, blindness, optic atrophy, and vegetative state with decorticate posturing.

Alerting Signs. Schindler disease is marked by nonspecific progressive encephalopathy with spinal cord disease and myoclonus.

Gangliosidoses

There is accumulation of various classes of gangliosides in this group of diseases. This accumulation occurs mainly in the CNS and, in severe forms, in other organs as well.

G_{M1} Gangliosidosis (Infantile, Late Infantile or Cerebral, and Chronic Late Onset)

Infantile Type. The infantile type presents with features of MPS at birth. Rapid dementia with pyramidal tract signs, hepatosplenomegaly, generalized dysostosis multiplex, and cherry-red macula with vegetative state are seen, and

occasionally dense thalami are observed in CT of the brain. Death occurs by 2 years of age.

Late Infantile Type (*Cerebral Type*). The age of onset is between 7 months and 3 years, with myoclonic or generalized tonic-clonic seizures and developmental regression developing into spastic quadriplegia, blindness, and optic atrophy. Cherry-red macula, visceromegaly, dysmorphic features of MPS, and dysostosis multiplex are absent.

Chronic Late Onset. The age of onset is 3–30 years, with mild symptoms. The disease is usually not suspected and remains undiagnosed before early adult age. The initial signs are gait and speech disturbances, usually with extrapyramidal signs. The only skeletal manifestation is flattening of vertebral bodies.

Alerting Signs. Infantile G_{M1} gangliosidosis shows features of MPS at birth and cherry-red macula; the *cerebral* type shows nonspecific progressive encephalopathy and no cherry-red macula; and the *chronic late-onset* type shows gait and speech disturbances.

Case History (*G_{M1} Gangliosidosis, Early Infantile Onset*). A 4-month-old boy was referred for the evaluation of coarse features, macrosomia, hepatosplenomegaly, and dementia. His coarse features and hepatosplenomegaly were noticed at birth. He also had nonimmune hydrops fetalis, albeit mild. He achieved no milestones. The parents were first-degree cousins and had two previous babies who died of a similar disease at 1–1.5 years of age. At the time of admission his height and weight were at the 90th percentile. The fontanel was 3 × 3 cm. He had mild macroglossia, some gingival hypertrophy, mildly coarse facial features, thickened fingers and toes, large umbilical and inguinal hernias, and hepatosplenomegaly, with liver span of 8 cm and spleen span of 7 cm. He had an increased amount of subcutaneous tissue. His eyegrounds examination revealed a cherry-red macula. Initially, the corneas were clear. He had severe central hypotonia with mild spasticity of the extremities; the deep tendon reflexes were mildly exaggerated. An acoustic myoclonus could be elicited but was not followed by myoclonic seizures. The blood chemistries indicated elevated AST (253 U/L) and ALT (298 U/L) and normal thyroxine and thyroid-stimulating hormone. CT of the brain indicated dense thalami. The EEG revealed disturbed background. The skeletal survey indicated dysostosis multiplex with involvement of vertebral bodies and a "J-shaped" sella turcica. The lysosomal enzymes in his cultured skin fibroblasts indicated normal levels except for β-galactosidase, which was less than 1% of normal. Neuraminidase was 35% of normal and carboxypeptidase Y 40% of normal. The diagnosis of G_{M1} gangliosidosis was reached. In further clinical follow-up, his height and weight deviated from established percentiles at 7 months of age, and he was eventually below the fifth percentile at the age of 15 months. Corneal cloudiness appeared at 1 year of age. He developed a difficult-to-control seizure disorder at 10 months of age. He died at home at 18 months of age.

Galactosialidosis (Infantile and Late Infantile/Juvenile Types)

The more severe form of the disease causes hydrops fetalis.

Infantile Type. The age of onset is birth to 3 months, with features of MPS such as coarse face, hepatosplenomegaly, hernias, cardiac valvular involvement, dysostosis multiplex, vertebral abnormalities, corneal clouding, cherry-red macula, blindness and hearing loss, dementia, and progressive encephalopathy. Occasionally dense thalami are seen in CT of the brain, and abnormal mottled dark pigmentation of the skin may be present (*Fig. 39.15*). Death occurs before 8 months with cardiac and renal failure.

Late Infantile/Juvenile Type. The age of onset is 12–36 months, with similar features as described for the infantile phenotype. The only difference is the benign neurologic course with no eventual MR. Cardiac valvular involvement is more prominent in this type. The life span is normal.

Alerting Signs. Early infantile galactosialidosis is similar to G_{M1} gangliosidosis; in the *late infantile* form, there are less apparent features of MPS and a benign clinical course with normal IQ.

Case History (*Galactosialidosis, Early Infantile Variety*). An 11-month-old boy was referred for abdominal distention, failure to thrive, repeated chest infections, and chronic diarrhea since 1–2 months of age. He never gained any milestones, never smiled, never had visual fixation, and needed nasogastric tube feeding because of his inability to suck since birth. He started to experience seizures at 5 months of age. The parents were first-degree cousins, with ten normal children and two children who died of the same disease at 1 year of age. On examination, his height, weight, and head circumference corresponded to the median ages of 6, 4, and 5 months, respectively, at 11 months. He had coarse features, long eyelashes, and hazy corneas. There was cherry-red macula. The skin showed spots of hyperpigmentation. The liver was 9 cm below the costal margin; the spleen tip was palpable. He had large bilateral hydroceles. Blood examination showed vacuolated lymphocytes that contained granular material. CT of the brain showed brain atrophy. The skeletal survey showed loss of modeling of long bones. Chest x-ray

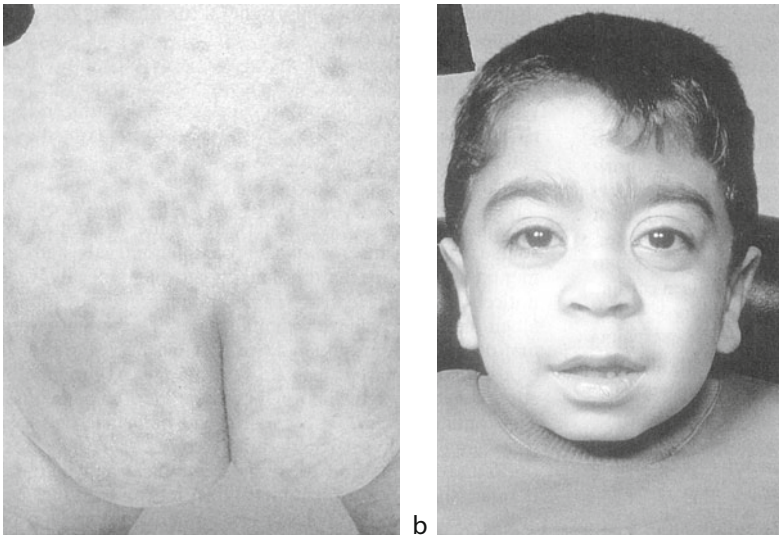

Figure 39.15
Galactosialidosis. (a) Skin marked with spots of pigmentation, a feature that is almost always associated with the severe infantile form of the disease in Saudi Arabia. (b) Mild coarse facial features of a 5-year-old boy with the late infantile form of the disease (*See Color Fig.* 5–15*A*)

indicated patchy lung infiltrates. Cardiac workup showed mild left ventricular hypertrophy with mitral regurgitation. The EEG was abnormal, with poor background activity and multifocal spikes at frontal areas bilaterally. The β-galactosidase, neuraminidase, and carboxypeptidase Y activities were 1%, 7%, and 5% of normal, respectively, in leukocytes and cultured fibroblasts. He was discharged home, where he died several months later.

Case History (*Galactosialidosis, Late Infantile Variety*). An 18-month-old boy was referred for evaluation of his coarse features, hepatosplenomegaly, bilateral inguinal hernia, and repeated chest infections. The parents noticed him to breathe noisily since first week of life. He had to be hospitalized numerous times for chest infections. His development has been relatively normal, sitting at 6 and walking at 16 months of age. He developed adequate verbal and social skills. At the age of 6 months he was found to have hepatosplenomegaly. His urine, sent by referring hospital to metabolic laboratory, indicated normal MPS excretion but increased intensity of oligosaccharides on thin-layer chromatography (TLC). The parents were first cousins with three normal children. The physical examination indicated height at the median of 10 months at 18 months and weight at the 25th and head circumference at the 50th percentiles. He had the coarse features of a patient with MPS, with broad hands and feet. The firm liver edge was 6 cm and the spleen 4 cm below the costal margin. He had macroglossia, kyphosis, bilateral inguinal hernias, and hydrocele. Neurologic examination indicated mildly increased muscle tone and increased reflexes with Babinski sign. The ophthalmologic examination indicated punctate densities in the stroma of the corneas and cherry-red macula. A cardiac workup was normal, with mild left ventricular hypertrophy. The chest x-ray showed patchy lung infiltrates. The skeletal survey indicated a "J-shaped" sella turcica, broadened metacarpals and fingers, broad ribs, and kyphosis. MRI of the brain indicated patchy leukodystrophy in the centrum ovale. The EEG was normal. The psychometric assessment indicated normal verbal and social skills. The lysosomal enzyme determination in serum indicated normal values, ruling out mucolipidosis. The β-galactosidase, neuraminidase, and carboxypeptidase Y activities in cultured fibroblasts were all less than 10% of normal, indicating the disease to be galactosialidosis of the late infantile variety. He was followed up until 5 years of age. His height at 5 years of age corresponded to the median age of 2 years; his weight and head circumference remained normal. At the age of 4 years he developed unusual capillary lesions on the lower part of the abdomen and scrotum. A biopsy revealed them to be angiokeratomas. His last psychometric assessment was borderline normal. Since they dropped out of the clinic, his fate is unknown. Molecular genetic analysis of carboxypeptidase Y revealed an unusual mutation, confirming the clinical and biochemical diagnosis of galactosialidosis.

G_{M2} Gangliosidosis

Infantile Tay–Sachs Disease (Type I) and Sandhoff Disease (Type II)

Both types I and II disease manifest similar symptoms. They differ only in the deficiency of the subunit of hexosaminidase: the α subunit is deficient in Tay–Sachs and the β subunit is deficient in Sandhoff disease. Most patients in the Arab world have Sandhoff disease, while Tay–Sachs is the disease of Ashkenazic Jews. The usual onset is at about 3–5 months with gelastic fits, followed by myoclonus, myoclonic seizures, hyperacusis (acoustic myoclonus), rapidly progressive pyramidal tract signs, early hypotonia and later spasticity, hyperreflexia, blindness, and dementia. They are usually beautiful babies. There is usually no systemic involvement, such as visceromegaly (can be observed rarely in type II) or dysostosis multiplex. The pathognomonic features of both type I and II diseases are the cherry-red macula in the presence of acoustic myoclonus. As a rule, dense thalami are observed in CT of the brain (*Fig. 39.16*). At later stages, macrocephaly due to increased CNS storage, vegetative state, and inability to swallow occur. Death usually occurs by 2–4 years of age and is due to aspiration pneumonia and inanition due to inability to feed.

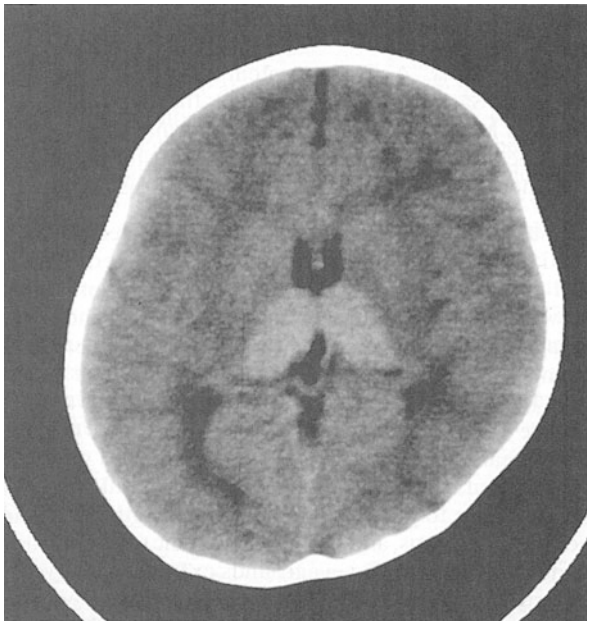

Figure 39.16
G_{M2} gangliosidosis. Dense thalami observed on CT of the brain are characteristic of gangliosidoses and early infantile neuronal ceroid lipofuscinosis

Alerting Signs. In Tay–Sachs/Sandhoff disease, a beautiful baby manifests gelastic fits, acoustic myoclonus, pyramidal tract signs, cherry-red macula, and late macrocephaly.

Case History (*Sandhoff Disease*). A 10-month-old boy was referred for myoclonic seizures and blindness after an ophthalmologic examination in another hospital had shown the presence of cherry-red macula. According to the parents, he was a slow infant from the beginning, never smiled, never reacted to maternal cues, never vocalized, and never could sit with support. They noticed the "acoustic startle" at the age of 4 months; he developed myoclonic seizures at 6 months of age. He began to have difficulty in swallowing at 9 months of age, and, by the time of referral, he was totally demented. The parents were first cousins who previously had had three children all of whom had the same disease and died; one of them was diagnosed to have Sandhoff disease. The unfortunate parents had no normal children and were aware of the grave prognosis of his disease. The physical examination indicated a beautiful baby boy lying motionless, but showing exaggerated startle upon acoustic stimuli; he also had action-induced myoclonus. His height and weight were at the fifth percentile, but his head circumference was at the 95th percentile. The anterior fontanel was open and measured 2 × 3 cm. He had searching nystagmus. The eyegrounds examination showed a cherry-red macula. The liver was enlarged 3 cm below the right costal margin; there was no splenomegaly. He had spastic quadriplegia with greatly increased deep tendon reflexes. CT of the brain revealed the characteristic dense thalami bilaterally. The hexosaminidase A and B activities in both leukocytes and cultured fibroblasts revealed both activities to be absent. Other lysosomal enzyme activities were normal. The diagnosis of Sandhoff disease was thus confirmed. He lived two more years, during which period he had to be given high-caloric nutrients by gavage feeding. He died at home of aspiration pneumonia. A chorionic villus biopsy sampling from the mother at the next pregnancy indicated another fetus with Sandhoff disease.

Activator Protein Deficiency

The presentation is similar to Tay–Sachs or Sandhoff disease, except the onset is somewhat delayed until 1–1.5 years of age. The diagnosis is reached by finding normal hexosaminidase activity when tested using an artificial substrate in a patient with typical symptoms of G_{M2} gangliosidosis, such as cherry-red macula, acoustic myoclonus, and dense thalami in CT of the brain. However, the hexosaminidase activity is absent when tested with the

natural substrate since this requires the activator protein for its hydrolysis.

Alerting Signs. Activator protein deficiency is similar to Tay–Sachs/Sandhoff disease, except the age of onset is later and hexosaminidase activity is normal with artificial substrate, while cherry-red macula, acoustic myoclonus, and other typical signs of a G_{M2} gangliosidosis are present.

Case History. An 18-month-old girl was referred for dementia. The history indicated she had developed normally until 1 year of age, at which time she had several words and was walking. Suddenly she stopped walking and started to have myoclonic jerks. The family history indicated the parents to be first-degree cousins; they had one normal child. Later on, a second sister was delivered and was found to have the same disease; she also developed normally until 1 year of age and then became demented gradually. The physical examination revealed a beautiful baby with little response to painful stimuli. She had an easily elicited acoustic myoclonus, and showed myoclonic seizures following acoustic startle. The eyegrounds examination revealed a cherry-red macula. There was no visceromegaly or dysostosis multiplex. Both the muscle tone and reflexes were increased. CT of the brain indicated bilateral thalamic densities. The clinical diagnosis was Sandhoff or Tay–Sachs disease. However, the enzyme assay for hexosaminidase activity as tested with artificial substrate was found normal on numerous occasions. As a result, hexosaminidase activity was assayed with labeled G_{M2} ganglioside and was found to be less than 1% of normal. Later on, molecular genetic analysis performed elsewhere confirmed the diagnosis by detecting the mutation. She lived until 5 years of age.

Juvenile Tay–Sachs Disease (G_{M2} Gangliosidosis Type III)

The age of onset is usually by 4–5 years. The initial symptoms of motor clumsiness, dystonia, choreoathetosis, and ataxia are followed by dementia. The clinical presentation resembles Niemann–Pick disease type C, except there is neither vertical gaze paralysis nor splenomegaly. There is no cherry-red macula. In some variants the predominant presentation is that of a spinocerebellar degeneration with ataxia, dysarthria, spasticity, and normal or increased deep tendon reflexes. The intelligence is preserved until late in the disease. Another subgroup manifests with a motor neuron disease as progressive muscle wasting and fasciculations resembling late-onset spinal muscular atrophy (Kugelberg–Wielander disease). The EMG shows chronic active denervation-reinnervation with fibrillation potentials, suggesting an anterior horn disease with normal nerve conduction. Eventually dementia and death occur late in the 20s.

Alerting Signs. Juvenile Tay–Sachs disease manifests with nonspecific progressive encephalopathy with symptoms of pyramidal, cerebellar, or anterior horn disease of the spinal cord, usually mistaken for Kugelberg–Wielander disease. Absence of vertical gaze paralysis and splenomegaly differentiate it from Niemann–Pick disease type C.

Case History. A 6-year-old boy presented with the chief complaint of loss of milestones (i.e., progressive encephalopathy). He was normal until 3 years of age, at which time he first lost his ability to walk, tripping and falling frequently. Then he lost comprehension of even simple commands, his speech, and eventually his vision. There was no precipitating illness. The parents were first-degree cousins and there was one normal sibling. On examination he showed pseudobulbar affect with bouts of crying and laughter for no reason or out of proportion to stimuli. There were no neurocutaneous stigmata. There was no cutaneous or buccal pigmentation suggesting Addison disease. There was no visceromegaly. Cranial nerve examination indicated bilateral optic atrophy and searching nystagmus. There was spasticity particularly of the lower extremities, with exaggerated deep tendon reflexes, ankle clonus, and Babinski sign. A presumptive diagnosis of X-linked adrenoleukodystrophy (X-ALD) was made, since MRI of the brain showed periventricular white matter disease, particularly prominent around the occipital horns. The CT scan did not show thalamic density. The abdominal ultrasound showed a nonhomogeneous appearance of the right lobe of the liver; otherwise, spleen and liver size were normal. AVEP showed prolonged P100 latency with atypical shape and characteristics. The plasma very-long-chain fatty acids and phytanic acid were found to be normal, ruling out X-ALD or a peroxisomal disease. A lysosomal battery in leukocytes revealed normal enzymes except for hexosaminidase A, which was not detectable, indicating the disease to be juvenile Tay–Sachs. The patient was lost to follow-up.

Lysosomal Transport Disorders

Cystinosis

The patient with cystinosis is normal at birth, developing renal Fanconi syndrome by 6–12 months of age. Growth fails, and severe dwarfism and hypophosphatemic rickets appear. Photophobia due to crystalline cystine storage in the corneas, hipohidrosis, and hypothyroidism are seen. The disease progresses to renal failure, causing death by 6–12 years of age.

Alerting Signs. Cystinosis, a common cause of renal Fanconi syndrome, presents as a blond and dwarfed baby with rickets and signs of corneal irritation (◉ *Fig. 39.17*).

Case History. A girl was first seen at 2 years of age for polyuria, polydipsia, poor growth, and weight gain. These complaints were noticed during early infancy, and the parents were particularly worried about her failure to gain height. The parents were first cousins and they had a normal child. The physical examination revealed a child whose height and weight were at the median ages of 10 and 16 months, respectively, at 24 months of age. Her head circumference was at the fifth percentile. She had very fair features, with blond hair, eyebrows, and eyelashes, while the other child in the family and the parents had dark complexions. Her wrists were enlarged and she had rachitic rosary. The x-ray of the wrist confirmed the rickets. Slitlamp examination of the cornea revealed extensive deposition of a crystalline material. The laboratory workup indicated proximal renal tubular disease and renal Fanconi syndrome, with renal tubular acidosis, proteinuria, phosphaturia, glucosuria, hypoisosthenuria, and generalized aminoaciduria. The amino acid pattern in blood was normal. Her hemoglobin was 85 g/L. A skin biopsy indicated the presence of many small, elongated crystals under light microscope by polarized light. The leukocyte cystine content was five times higher than normal. A diagnosis of cystinosis was reached. The patient was placed on oral supplement of phosphate, sodium bicarbonate, potassium chloride, and indomethacin, and treatment with phosphocysteamine was initiated. She has now been followed up for 5 years. Her growth in height and weight improved, with slow catch-up. She was given human growth hormone treatment to augment the growth. She was also started on treatment with erythropoietin and her hemoglobin values improved. The corneal crystals became less during this period. At the age of 7 years, abdominal ultrasound indicates both kidneys to be borderline small without any evidence of calculus or nephrocalcinosis.

Figure 39.17
Cystinosis. Obvious fair features and short stature in a 6-year-old Arab girl

Sialic Acid Storage Disease

Infantile Sialic Acid Storage Disease

This disease presents at birth with severe FTT, severe developmental delay, coarse facial appearance, hepatosplenomegaly, and dysostosis multiplex; death usually occurs by 1 year of age. The urinary excretion of sialic acid is increased 2- to 200-fold.

Salla Disease

Salla disease starts at 6–9 months of age with axial hypotonia and horizontal nystagmus. After 1 year of age, ataxia, spasticity in the lower limbs with hyperreflexia, seizures, delayed speech, general developmental delay, and moderate to severe MR occur. Death is by 4–7 years of age. Sialic acid excretion in the urine is increased 10- to 100-fold.

Alerting Signs. The *infantile* form of sialic acid storage disease is marked by features of MPS with severe FTT and developmental delay; *Salla disease* is marked by spastic diplegia with ataxia, developmental delay, and MR. Both forms are associated with increased sialic acid excretion in the urine.

Chediak–Higashi Disease

This disease has been reviewed in detail elsewhere; only features pertinent to a lysosomal storage disease are summarized here. It is a disease of childhood onset, with susceptibility to bacterial infections, partial albinism,

photophobia, nystagmus, metallic silver-gray tint in the light brown hair, reduced and unevenly pigmented irises, giant peroxidase-positive lysosomal granules in the peripheral blood granulocytes, and bleeding (abnormal platelet aggregation). Death occurs by the accelerated phase of a lymphoma-like picture.

Alerting Signs. Chediak–Higashi disease is marked by frequent infections, albinism, abnormal distribution of pigment in the irises, and giant granules in leukocytes.

Differential Diagnosis

As this review indicates, a large number of systemic, visceral, skeletal, joint, skin, eye, ENT, and CNS findings are almost always associated with the lysosomal storage diseases. The clinical findings are not always pathognomonic for any particular disease. However, the alerting signs will raise a strong suspicion through the spectrum of clinical symptoms emphasized. The differential diagnosis should include consideration of many symptoms. In order to facilitate a bedside diagnosis, two diagnostic tables are presented. In *Table 39.2*, the prominent systemic, visceral, skeletal, and skin symptoms associated with major lysosomal storage diseases are tabulated. In *Table 39.3*, the prominent neurologic, eye, and ENT findings of the same diseases are presented.

Some specific features of lysosomal storage diseases deserve emphasis. For example, severe forms of these diseases present with hydrops fetalis at birth (*Table 39.4*). Hydrops fetalis may be caused by so many different etiologies that a neonatologist might neglect considering the presence of lysosomal storage disease, although such disorders are encountered rather frequently in consanguineous families. A detailed workup, including bone marrow biopsy to demonstrate storage cells, study of lymphocytes for vacuolization, enzyme measurements, and skeletal survey, should always be obtained in a neonate with hydrops fetalis, particularly when visceromegaly, coarse facial appearance, joint contractures, ichthyosis, and skeletal abnormalities are observed (*Fig. 39.18*).

A most important part of physical examination is the eyegrounds. So many times, in a baby with rapidly progressive encephalopathy, early dementia, and myoclonus, a rapid diagnosis of gangliosidosis may be reached simply by detecting a cherry-red macula. A number of lysosomal storage diseases lead to the accumulation of a storage substance within the ganglion cells around the retinal fovea, an area particularly rich in ganglion cells, while the fovea is poor in these cells. This accumulation causes a white halo around the fovea, the so-called cherry-red macula. This is most prominent in G_{M2} gangliosidosis (*Fig. 39.19a*) and can be seen in somewhat different form in galactosialidosis (*Fig. 39.19b*), while in Niemann–Pick disease the storage may just appear as a grayish and interrupted halo (*Fig. 39.19c*). Not only gangliosidoses, but also a variety of other lysosomal storage diseases, cause cherry-red macula; a comprehensive list is presented in *Table 39.5*.

Some lysosomal storage diseases primarily manifest as a progressive encephalopathy, with no or minimal evidence of peripheral tissue involvement. This may confuse the pediatrician accustomed to thinking in terms of visceromegaly, dysostosis, and skin findings in association with a lysosomal storage disease. A list of lysosomal storage diseases that manifest mainly, or only, with CNS symptomatology is presented in *Table 39.6*.

Since major forms of lysosomal storage diseases cause progressive encephalopathy and/or eventual MR, it is often forgotten that a number of them do not lead to MR, even in the presence of florid systemic symptomatology. A list of diseases that do not cause significant MR is presented in *Table 39.7*.

The aforementioned considerations will usually suffice to reach a presumptive diagnosis. Nevertheless, in all instances a definitive final diagnosis should be reached by specific enzyme or cellular morphologic studies.

Pathogenesis of Lysosomal Storage Diseases

It is important to know the pathophysiology of lysosomal storage diseases in order to understand their phenotypic manifestations and to order appropriate laboratory tests for diagnosis. For example, heparan sulfate is an integral part of plasma membranes, particularly in the CNS, and when heparan sulfate-catabolizing activities are absent (i.e., Sanfilippo syndrome types A through D), the phenotypic manifestation involves mostly the CNS. Iduronate sulfate is not present in significant quantities in the cornea; therefore, when iduronate sulfatase is deficient (i.e., Hunter syndrome), the cornea remains clear. Keratan sulfate is an important component of the skeletal system, joints, and ligaments, and, when keratan sulfatase is deficient (i.e., Morquio syndrome), the major phenotypic expression is in the skeleton and joints. Arylsulfatase A and galactosylceramide galactosidase are involved in the catabolism of components of myelin; in their absence (i.e., metachromatic leukodystrophy and Krabbe disease, respectively), white matter disease in the

CNS and peripheral nerves emerges. When enzymes are involved in the breakdown of cellular components that are particularly rich in ganglion cells, cherry-red macula is seen (e.g., gangliosidoses, sialidoses, sphingomyelinase deficiency).

A lysosomal disease might be due to the deficiency of a single protein; most lysosomal diseases fall in this category. In another group of lysosomal diseases, the defect is in the processing of the proenzyme of the lysosomal activity in endoplasmic reticulum (ER). All lysosomal enzymes are synthesized on ER-bound ribosomes and all have a signaling sequence that enables them to dock onto a transport protein that carries them into the lumen of the ER. There, polymannose-containing oligosaccharides are attached. Then these oligosaccharides are trimmed to size back in the ER, and the proenzyme is transferred to the Golgi apparatus, where the mannose residues are phosphorylated into mannose 6-phosphate. The presence of mannose 6-phosphate is a prerequisite for the entry of all lysosomal enzymes into the lysosomes. The phosphorylation of the mannose residue is achieved by a specific phosphotransferase. The deficiency of this enzyme is responsible for mucolipidoses II and III. Although the lysosomal enzyme is now ready to enter the lysosomes, it must first travel across the cytosol. During this process a protective protein is needed, for example, for the cytosolic crossing of neuraminidase and β-galactosidase. When this protective protein is missing, both of these enzymes remain in the cytosol and are destroyed, leading to the combined deficiency of neuraminidase and galactosidase (i.e., galactosialidosis). In other instances, the active center of the lysosomal enzyme must be modified in order to create a functional protein, for example, all sulfatases share a common structure at their active center, and, when the enzyme responsible for the modification of their active center is lacking, multiple deficiencies of sulfatases occur (i.e., Austin disease).

Most enzymes of glycoprotein degradation are exoglycosidases, that is, they break down the mucopolysaccharide from the terminal end, removing one modified sugar residue at a time. For example, in the degradation of heparan sulfate, a key component of plasma membranes in neurons, the important first step is the removal of an N-terminal sulfate residue from heparan sulfate by an N-terminal heparan sulfatase. It is only after this step that the remainder of the glycoside residues in the molecule can be hydrolyzed sequentially. The more severe form of heparan sulfate-degrading diseases (i.e., Sanfilippo syndrome A) is due to the deficiency of this initial activity, since the sequential hydrolysis of heparan sulfate cannot be initiated. At times an inconsequential alternate pathway resumes importance due to a deficient enzyme activity. For example, in Krabbe disease a specific galactosidase, galactosylceramide galactosidase, is missing. Psychosine/sphingosine-galactose is a minor metabolite but requires galactosylceramide galactosidase for its breakdown. In the absence of this enzyme, psychosine accumulates in the oligodendroglia and, since it is extremely neurotoxic, it destroys the oligodendroglia, leading to the formation of "globoid cells."

This brief review indicates participation of multiple biochemical mechanisms in the pathogenesis of

lysosomal storage diseases. The defective enzymes in various lysosomal storage diseases are summarized in *Table 39.8*.

Specific Laboratory Studies Used in the Diagnosis of Lysosomal Storage Diseases

The diagnosis is based on the aforementioned pathogenic mechanisms. The strategies employed are (a) to measure directly or indirectly the putative defective enzyme activity, (b) to demonstrate the storage substance, (c) to seek additional evidence of the derangement in target organs of the disease or displacement of a lysosomal enzyme, and (d) prenatal diagnosis.

Measurement of Enzymes

Analytical procedures are available for the measurement of most of the enzymes listed in *Table 39.8*. A large number of these tests depend on the use of artificial substrates, and fluorometric procedures are available that are sensitive enough to detect the deficiency in either leukocytes or cultured cells, such as fibroblasts or lymphoblasts. Although no distinctions are made between the use of leukocytes, lymphocytes, and fibroblasts, the latter source is more reliable for diagnostic purposes. In some instances this should be the preferred tissue (e.g., Pompe disease), since results with peripheral blood cells might be equivocal. Artificial substrates that can be used by colorimetric methods are also available, but their sensitivity is less. In some instances, no artificial substrates are available, and natural substrates must be used. Examples are radioactively labeled substrates for Hunter syndrome, sphingomyelin for Niemann–Pick disease type A or B, and ceramide for Farber disease. Some of these radioactively tagged substrates are not commercially available, and only the few laboratories that have access to them can perform these diagnostic tests. It is always preferable to use a reliable laboratory for enzyme measurements, since some lysosomal enzymes, such as neuraminidase, are very thermolabile and will quickly deteriorate, giving false-positive results. When multiple enzymes are deficient (e.g., Austin disease), the activity of as many enzymes as possible must be determined to rule out possible false-positive results. In patients with galactosialidosis, not only galactosidase and neuraminidase but also protective protein (carboxypeptidase Y) activity should be measured.

In other instances (e.g., activator protein deficiency), the hexosaminidase deficiency cannot be demonstrated by using the artificial substrates of hexosaminidase, but require the natural G_{M2} ganglioside. The presence of a pseudodeficiency gene for arylsulfatase A complicates the interpretation of results; therefore, the diagnosis of metachromatic leukodystrophy should also be performed with natural substrate, when possible, to rule out a disease in the unusual normal subject with a very low arylsulfatase A activity. Since various saposins participate in the action of arylsulfatases, they must be measured in clinically suspect cases of metachromatic leukodystrophy when arylsulfatase activity is found to be normal. The deficiency of β-galactosidase causes three different diseases: G_{M1} gangliosidosis with visceral and brain involvement, G_{M1} gangliosidosis with only cerebral involvement, and Morquio syndrome type B. This enzyme has two catalytic functions, one for the breakdown of keratan sulfate, an essential component of bone, and another one for the hydrolysis of G_{M1} gangliosides in the CNS. Most mutations of β-galactosidase lead to the loss of function of the enzyme for both compounds (i.e., the classic infantile variety of G_{M1} gangliosidosis). However, in rare instances, the mutation will affect only one function and not the other, leading to the emergence of either Morquio syndrome (catabolism of keratan by the enzyme is defective), or the cerebral variety of G_{M1} gangliosidosis (hydrolysis of ganglioside by the enzyme is defective). These two variants can only be diagnosed by the use of natural substrates.

An alternative indirect technique is complementation analysis. The cultured fibroblasts of an unknown case are grown together with fibroblasts from different patients with an already established diagnosis. Lysosomal enzymes released into the culture medium have the mannose 6-phosphate residue, and they are easily exchanged between cells. When radioactive sulfate is added into the culture medium, it is incorporated into the sulfated ground substance secreted by fibroblasts. In the absence of breakdown, this accumulation is much greater in the growth medium (e.g., of MPS cells) than in normal fibroblasts. When fibroblasts from two different types of MPS are grown together, both types of cells eventually end up containing a normal spectrum of enzyme activities, and the sulfate fixation into the ground substance decreases to normal limits. However, if both cell types have an identical enzyme deficiency, radioactive sulfate fixation remains high, establishing the diagnosis.

Demonstration of the Storage Substance

The original description of most of these disorders was based on the histological demonstration of the stored substance in tissues, peripheral blood cells, and cultured cells. At present, the ready availability of the substrates makes diagnosis possible through rapid enzyme measurements, which are universally preferred over the histologic procedures. It is still customary in many institutions that do not have access to enzyme measurements to use a bone marrow biopsy to show, for example, the Gaucher cell with its "creased silk" appearance (*Fig. 39.20*) or the Niemann–Pick type A or B cell with its "soap bubble" appearance (*Fig. 39.21*). A peripheral blood film will demonstrate vacuolated lymphocytes in most storage diseases or the presence of metachromatic granules in MPS (*Fig. 39.22*). The brain biopsy will indicate the typical "globoid cells" in Krabbe disease. Myelin degeneration can be shown in the biopsy of peripheral nerves in metachromatic leukodystrophy, appearing as "zebra bodies." Staining for glycogen or EM studies in muscle, for example, will show the presence of glycogen accumulation in the lysosomes in type II GSD.

Table 39.8

Deficient enzymes in lysosomal storage diseases

Disease	Deficient enzyme
Hurler, Hurler–Scheie, Scheie syndromes	α-L-Iduronidase deficiency is most severe in Hurler. There are several alleles for the enzyme; all are deficient in Hurler.
Hunter syndrome	α-L-Iduronate sulfate sulfatase
Sanfilippo syndromes	Four different enzymes for each phenotype (A, B, C, and D), all of which are involved in the breakdown of heparan sulfate.
Morquio syndrome	Galactose 6-sulfatase in type A; specific defect in β-galactosidase in type B
Maroteaux–Lamy syndrome	Arylsulfatase B
Sly syndrome	β-Glucuronidase
Glycogen storage disease type 2	Acid maltase (acid α-glucosidase); deficiency is less in late-onset type
Wolman disease	Acid lipase
Farber disease	Acid ceramidase
Santavuori disease	Unknown; subunit *c* of ATP synthetase does not accumulate in lysosomes
Jansky–Bielschowsky and Spielmeyer–Vogt diseases	Accumulation of subunit *c* of ATP synthetase
Mucolipidosis II and III	Defective mannose phosphorylating activity for newly synthesized lysosomal enzymes, deficiency of a specific phosphotransferase. The same enzyme defect in both diseases, except it is milder in mucolipidosis type III
α-Mannosidosis	α-Mannosidase
β-Mannosidosis	β-Mannosidase
Fucosidosis	α-Fucosidase
Sialidosis	Neuraminidase
Aspartylglucosaminuria	Aspartylglucosaminidase
Niemann–Pick disease types A and B	Sphingomyelinase; in type A: $<$5%; in type B: 5–10%.
Niemann–Pick disease type C	Intracellular trafficking defect of exogenous cholesterol
Gaucher disease type I–III	β-Glucosidase (glucocerebrosidase)
Krabbe disease	Galactosylceramide-β-galactosidase
Metachromatic leukodystrophy	Arysulfatase A
Multiple sulfatase deficiency	All lysosomal sulfatases are deficient; the enzyme that activates the active center of sulfatases is lacking
Fabry disease	α-Galactosidase
Schindler disease	α-*N*-acetylgalactosaminidase
G_{M1} gangliosidosis (infantile variety)	β-Galactosidase
G_{M1} gangliosidosis (cerebral variety)	A specific mutation in β-galactosidase
Galactosialidosis	Carboxypeptidase "Y" or protective protein that binds, carries, and modifies both β-galactosidase and neuraminidase before they enter into lysosomes
G_{M2} gangliosidosis, types I–III, and activator protein deficiency	Hexosaminidase in all, but α-chain defective in classic and juvenile Tay–Sachs disease, β-chain is defective in Sandhoff disease, and activator protein is deficient in activator protein deficiency
Cystinosis	Defect in carrier-mediated cystine transport from lysosomes
Sialic acid storage diseases	Defect in carrier-mediated sialic acid transport from lysosomes
Chediak–Higashi disease	Unknown

In only four instances is the only available diagnostic tool a histologic examination:

1. In Niemann–Pick disease type C, the storage of cholesterol in perinuclear lysosomes can only be demonstrated specifically by a special fluorescent staining technique, filipin.
2. NCL requires the EM demonstration of curvilinear "fingerprint" bodies or "beeswax" bodies.
3. Immunochemical techniques are used to show the accumulation of the subunit *c* of ATP synthetase in the Jansky–Bielschowsky and Spielmeyer–Vogt types of NCL.
4. Demonstration of giant lysosomes is accomplished by routine staining of leukocytes in the peripheral blood in Chediak–Higashi disease.

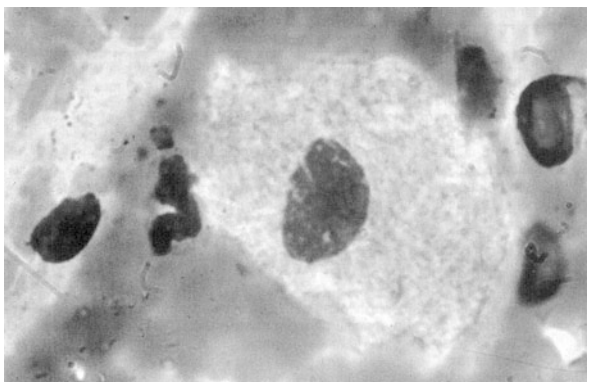

Figure 39.20
The light microscopic appearance of a typical Gaucher cell (*See Color Fig. 5–20*)

Seeking Additional Evidence of Storage

The accumulation of sphingomyelin in Niemann–Pick disease type A or B in the liver deranges the liver function, and both ALT and AST are increased in the circulation, while this is not true for Gaucher disease, which is clinically similar to Niemann–Pick disease. The only other visceral storage disease that causes elevated liver enzymes is deficiency of amylo-1,6-glucosidase (debrancher) (i.e., GSD type III).

Although there are methods to measure the phosphotransferase the deficiency of which is responsible for mucolipidosis II and III, they are difficult procedures, and these diseases can readily be detected by the increased levels of lysosomal enzymes (e.g., hexosaminidase) in blood and urine.

In cystinosis, the determination of increased accumulation of cystine can be shown in many tissues, but leukocytes are preferred. In sialic acid transport disorders the measurement of sialic acid, and in aspartylglucosaminuria the chromatographic measurement of aspartylglucosamine, in the urine will establish the

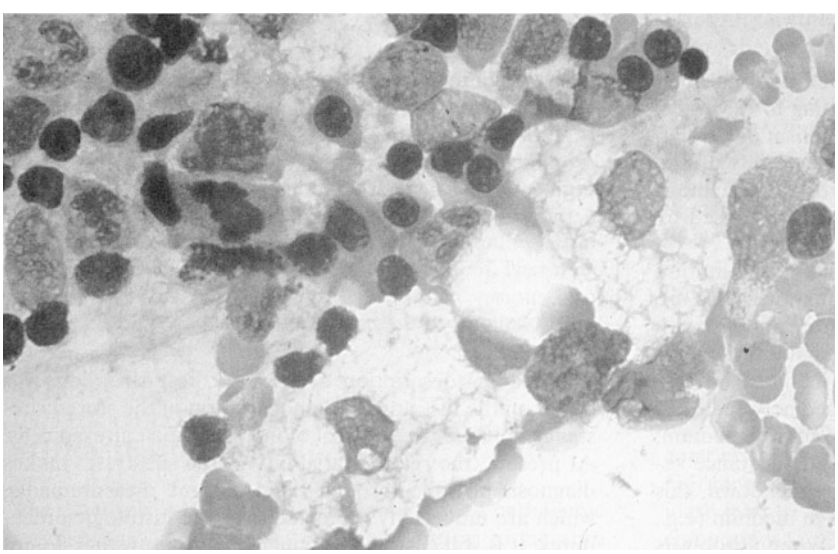

Figure 39.21
The light microscopic appearance of a typical Niemann–Pick cell (*See Color Fig. 5–21*)

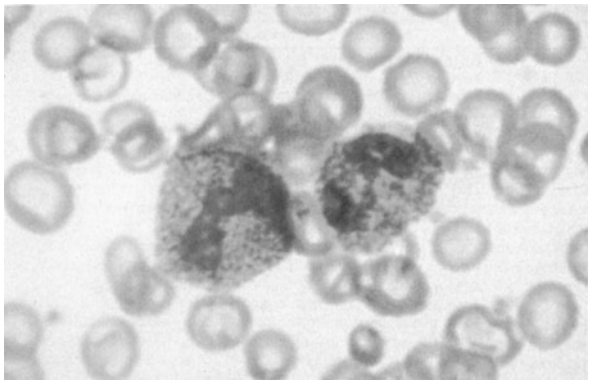

Figure 39.22
Increased metachromatic granulation in leukocytes in a patient with mucopolysaccharidosis (Hurler syndrome) (*See Color Fig. 5–22*)

diagnosis. A large number of institutions use a simple spot test or "screening test" to detect the increased mucopolysaccharide excretion in the urine to diagnose MPS. This test in inexperienced hands might give false-negative or false-positive results. A more sophisticated technique is the use of TLC or capillary electrophoresis in the urine to demonstrate the increased excretion of oligosaccharides or sialo-oligosaccharides that accompanies most of the lysosomal storage diseases. Although these latter tests lack specificity, they provide an excellent screening technique to show the presence of a lysosomal storage disease. In all instances it is advisable to measure the specific enzymes if the TLC or capillary electrophoresis test is positive.

Prenatal Diagnosis

Both chorionic villus biopsy and amniotic cell cultures have been used to show defective enzyme activity in the fetus. The main problem with this approach is the usually normal low expression of enzyme activity in a heterozygous fetus. In the prenatal testing for Hunter syndrome, the sex of the fetus should also be determined; a female hemizygous fetus might test deficient due to mosaicism. If a prenatal diagnosis is considered, particularly for intrauterine BMT, it is best to use molecular genetic methods. Although this technique is more complicated than is usually appreciated, requiring a specialized laboratory experienced in such diagnostic efforts, it is most reliable and will not provide false-positive or false-negative results. The gene locations and cDNA are available for most of the lysosomal storage diseases (*Table 39.9*).

Treatment of Lysosomal Storage Diseases

In most instances, the long-term management of a lysosomal storage disease is difficult. Most efforts involve supportive measures. In certain cases, the stored substance can be cleared through the administration of specific compounds or the synthesis of the storage substance can be inhibited. Some experimental therapies, such as administration of the enzyme that is deficient by BMT, either in utero or after birth, and gene therapies have been employed. Such experimental therapies are justified, since these are desperate diseases, and in so many instances show a protracted course causing intolerable pain and suffering to the patient and parents, and eventually death. A graphic summary of therapeutic interventions is shown in *Fig. 39.23*.

Supportive Measures

Lysosomal storage diseases cause significant CNS and systemic involvement, although, as the list in *Table 39.3* indicates, not all lysosomal storage diseases have CNS involvement. A dementing disease is a challenge to the pediatrician. Nutrition in a child who is unable to feed must be maintained by nasogastric tube feeding or by gastrostomy, using special formulas rich in calories. Such dementing diseases cause repeated aspirations and pneumonia, and the child usually expires due to inanition or pulmonary complications. The painful "bone crises" of Gaucher disease will often require use of narcotics. The patient with Gaucher disease will usually undergo splenectomy to manage the severe thrombocytopenia associated with the disease. When splenectomy is performed, it should be partial in order to prevent accumulation of glucocerebrosides in the lung. Such a patient should receive pneumococcal, meningococcal, and *Haemophilus influenzae* vaccinations and prophylactic antibiotics to prevent intervening life threatening bacterial sepsis. In patients with late-onset G_{M1} gangliosidosis, trihexyphenidy1 has been used to combat dystonia, since in such cases dopaminergic neurons are hypofunctional, while cholinergic neurons are hyperactive in basal ganglia. Several other aspects of lysosomal storage diseases deserve emphasis.

Patients with milder forms of MPS that have minimal CNS involvement, such as Hurler–Scheie and Scheie syndromes, Morquio syndrome, milder forms of Austin disease, and late-onset forms of galactosialidosis, have near-normal life spans, and the progressive skeletal

Table 39.9

Salla disease	6q.14-q15

[a] Different mutations are known and reported in the literature that can be used for molecular genetics studies.
[b] Prenatal diagnosis has been achieved either by conventional enzyme measurement techniques or by molecular genetics studies.

deformities pose significant problems to the patient. They become orthopedic problems, and the skeletal deformities need to be corrected surgically. Atlanto-occipital joint, odontoid luxation, or C-1 vertebral abnormalities, as frequently observed in Hurler–Scheie and Scheie, Morquio, and Maroteaux–Lamy syndromes and Austin disease, lead to compression of the cervical cord and might transect the cord, causing paralysis. Such patients must have frequent and careful clinical follow-up to detect early signs of cord compression. When pyramidal tract signs such as bilateral ankle clonus or hyperreflexia are observed, the patient must receive CT or MRI of the cervical vertebrae, with

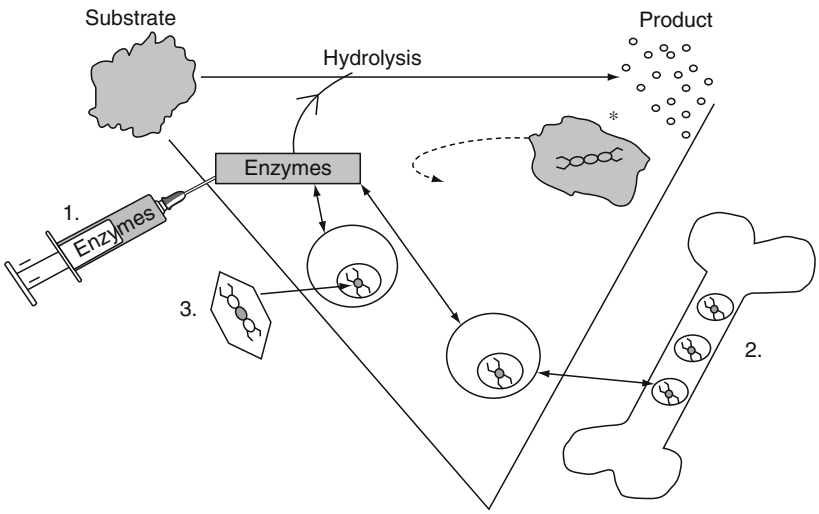

Fig. 39.23
A cartoon illustrating the principles of therapy in lysosomal diseases. The supply of exogenous enzyme (1), normal cells (2), and retrovirus-linked normal gene (3) are shown; the patient's defective cell is unable to produce the enzyme (*See Color Fig. 5–23*)

neurosurgical intervention when necessary to stabilize the atlanto-occipital joint.

Laryngeal obstruction in Hurler–Scheie syndrome and Farber disease might require tracheostomy. Large umbilical hernias of MPS, G_{M1} gangliosidosis, and galactosialidosis might require surgical intervention. Macroglossia in a teenage patient with Hurler–Scheie syndrome might require plastic surgery to keep the patient alive for a few more years. Craniofacial deformities in a patient with Hurler–Scheie syndrome can be debilitating, requiring surgery to alleviate the obstructive airway disease.

A patient with cystinosis or Fabry disease might develop chronic renal failure and will require hemodialysis for survival. Renal allografts have been attempted in cystinosis and fetal liver transplantation in Fabry disease, both of which have prolonged the survival of the patients. Corneal cloudiness in a patient with Hurler–Scheie syndrome will cause severe visual impairment in a mentally normal individual, requiring corneal transplantation from a healthy donor.

Clearing the Storage Substance and Enzyme Therapy

At present one of the preferred treatment procedures for Gaucher disease is periodic injection of a specially modified β-glucocerebrosidase. This commercially available enzyme, Ceredase or Cerezyme, is a biochemically modified human placental β-glucocerebrosidase in which the terminal mannose residues are exposed to assure its uptake by macrophages (*Fig. 39.23*). More than 600 patients with Gaucher disease at present are under treatment with Ceredase or Cerezyme. Most of these patients showed benefits such as decreased liver or spleen size, improved anemia and platelet counts, normalized pulmonary function, and normalized physical growth. This is a noninvasive method of treating Gaucher disease, but the cost involved is prohibitive, particularly when it is considered that the patient must receive this treatment lifelong. It is advisable to use Ceredase or Cerezyme until a suitably matched donor can be secured for BMT.

Case History (*Gaucher Disease Type I – Ceredase Treatment*). A child was admitted at the age of 6 years for fever of unknown origin, at which time he was discovered to have hepatosplenomegaly. The presumptive diagnosis of brucellosis was ruled out; a bone marrow biopsy done to rule out an early malignancy revealed the presence of Gaucher cells, and he was referred to the metabolic service. He was the only child of nonconsanguineous parents. At initial encounter his growth parameters were normal, but the liver span was 8 cm and the spleen span was 10 cm. Investigations revealed mild thrombocytopenia (90,000/mm^3) and prolonged bleeding time. There was no HLA-matched donor available, and he was followed without any therapeutic intervention for 3 years, during which period he suffered a linear fracture of his right femur neck after

jumping down from a height of 80 cm. He started to suffer from chronic anemia, with the hemoglobin dropping from 12 to 10 g/L in 3 years, and from chronic bone pain. His general well-being deteriorated and he was exhausted all the time. At the age of 9 years, the blood angiotensin-converting enzyme level was 72 U/L (normal: <42 U/L); the skeletal survey indicated mild/moderate involvement of long bones with Gaucher disease. The chest x-ray was clear. Eventually, he was started on Ceredase (90 U/kg every 2 weeks). His general health returned to normal, bone pain disappeared within a year, and liver and spleen size regressed to 2 cm below the costal margin in 2 years. His hemoglobin increased to 12 g/L and platelet count returned to normal within 1 year. At present he is a normal child for all purposes; he is an excellent student and a good football player, without suffering from fractures when he gets kicked accidentally.

More recently, purified α-L-iduronidase became available and was found to be useful in the canine model of Hurler syndrome; however, it has not been tested extensively yet in the human disease. As an experimental therapy, splenic α-galactosidase A has been found to be effective in clearing the globotriaosylceramide from the circulation and kidneys of two patients with Fabry disease. This enzyme is also not commercially available. An alternative approach is plasmapheresis to deplete the accumulated substrate in Fabry disease, which has been employed with some success.

An alternative therapeutic approach has been to reduce the production of the stored substance. For example, inhibitors of cholesterol synthesis, such as lovastatin, have been of some value in the management of Wolman disease. Furosimin, an inhibitor of sphingolipid synthesis, has been advised in the treatment of Farber disease. Dimethylsulfoxide, which reverses cholesterol trafficking, might be tried in patients with Niemann–Pick disease type C.

Maybe the most impressive use of a compound to clear the stored substance has been the use of cysteamine in cystinosis. The oral use of this compound has improved physical growth, particularly when used in conjunction with human growth hormone. Cysteamine has an unpleasant smell and taste, but a modified form of the drug, phosphocysteamine, is better tolerated by the patient and is equally, if not more, effective. The use of cysteamine/phosphocysteamine prevents the long-term renal complications of cystinosis; however, it is ineffective in clearing the corneal deposits, which is usually achieved by frequent and prolonged use of eyedrops containing these medications.

Bone Marrow Transplantation (BMT)

This therapeutic approach has been extensively used in the treatment of various types of lysosomal storage diseases (*Fig. 39.23*). The principle is to supply normal hematopoietic stem cells to the recipient. Adjacent cells will pick up the lysosomal enzymes released by a normal cell since they carry the mannose marker. One cell thus provides cure to many neighboring cells. Many reports indicate a dramatic improvement in the somatic features of MPS in Hurler disease after BMT. Over 140 patients with Hurler syndrome have received allogeneic BMT. Improvement and leukocyte enzyme levels maintain as long as the graft lasts. The problems with BMT are its cost, its invasive nature frequently leading to death in the hands of who are not experienced in BMT, rejection of the graft, graft-versus-host reaction, and finally loss of the chimera in the long term in many instances. BMT also is less effective in patients with advanced disease. In Hurler syndrome, although BMT has been curative, it does not prevent the long-term severe skeletal involvement, and such patients still require orthopedic interventions and correction of facial deformities that lead to obstructive airway disease.

BMT has been less effective in MPS II and III and metachromatic leukodystrophy. It has been ineffective in MPS IV, Krabbe disease, and G_{M1} and G_{M2} gangliosidosis. However, good results have been obtained in patients with MPS VI, Niemann–Pick disease type B, and Gaucher disease, and in these disorders the use of BMT is definitely advisable. Successful BMT in a patient with Niemann–Pick disease and in a patient with Gaucher disease are summarized in the case studies presented below.

Case History (*Niemann–Pick Disease – BMT*). A 1-year-old boy who had Niemann–Pick disease (sphingomyelinase <1%) had recurrent chronic chest infection, and his liver and spleen edges were 8–10 cm below the costal margin. He underwent splenectomy at 14 months of age and an allogeneic BMT from his sister at 16 months of age. He was followed for 5 years after BMT with the following clinical and biochemical changes:

1. Hepatomegaly decreased to normal in 4 years after BMT; the initial values of ALT (342 U/L) and AST (782 U/L) decreased to within normal range after 5 years, but cholesterol, which initially was 13.35 mM (normal: <4.2 mM), normalized only after 5 years.
2. The abnormal reticular granular pattern of the lung returned to normal in 1 year.
3. The height and weight at the time when he had BMT, at the age of 16 months, corresponded to 7 and

5 months, respectively; they increased to the fifth percentile at the age of 7 years.
4. The patient developed morphea (scleroderma) in the legs and around the laparotomy site for splenectomy 2 years after BMT, which prevented him from motion. This was due to chronic graft-versus-host reaction. These lesions became less indurated in the next 4 years after treatment with cyclosporin and prednisone.
5. He developed peripheral neuropathy 2 years after BMT, with nerve conduction times reverting to normal only after 4 years of therapy.
6. Initially he had mild demyelination of the central white matter, which became normal in 2 years after BMT.
7. A successful chimera was established as evidenced by repeat sphingomyelinase determination in leukocytes (10% of normal) and in fibroblasts (6% of normal) 4 years after BMT.

At the age of 7 years, he was in excellent health despite the handicaps caused by scleroderma. He had gained most of his motor function and was walking with crutches. He had started to attend school.

Case History (*Gaucher Type I – BMT*). A 1-year-old boy was referred for repeated chest infections, abdominal distention, and failure to grow. Biochemical studies revealed him to have Gaucher disease with a β-glucosidase of 5% of normal in his fibroblasts. During the next 6 months, he started to lose weight and the liver enlarged from 5 to 15 cm and the spleen from 8 to 18 cm below the costal margin. The chest x-ray revealed diffuse granular infiltrates. He developed severe thrombocytopenia, with the platelet count dropping to 10,000/mm^3, and a partial splenectomy had to be performed. Both the bone marrow biopsy and histology of the spleen removed showed numerous Gaucher cells. He received a BMT from an HLA-matched sibling at the age of 20 months. The further clinical course was complicated by chronic lung disease, with further loss of weight for 3 months. He was placed on cyclosporin, folic acid, and prophylactic penicillin. His general condition started to improve slowly, and the liver regressed to 4 cm below the costal margin in 2 and 2 cm below the costal margin in 3 years. Clinical and x-ray findings in the lungs disappeared in 2 years. The hemoglobin increased from the preoperative value of 60 g/L to 120 g/L in 2 years. The platelet count during the same period increased to 500,000/mm^3. The bone changes of Gaucher disease regressed only moderately, but he never suffered from bone pain or fractures. His general health improved so much that he could participate in games with other children. He started school at 6 years of age; at 8 years of age, he is an excellent student participating in all school activities at present. He is now a normal child.

Another experimental therapy, in utero BMT, has been advised for the treatment of lysosomal storage diseases that do not have prominent CNS involvement. The method employs intraperitoneal injection of hematopoietic cells isolated from the fetal liver of an electively aborted healthy fetus. This is best done before 13 weeks of gestation, before the fetus becomes immunocompetent. A patient with Niemann–Pick disease type B has already been treated with some success through this procedure. An alternative approach is the use of maternal stem cells, injected into the fetal circulation several times during the pregnancy in order to establish an immune tolerance. The neonate then receives a BMT from the mother after delivery. Although in utero BMT has proved to be most effective in the management of such hematologic diseases as thalassemia, and in various types of severe combined immunodeficiency, its efficacy in the treatment of lysosomal storage diseases has not been tested widely yet.

Gene Therapy

This mode of therapy is certainly more advantageous than BMT (*Fig. 39.23*). However, the difficulties in maintaining the gene introduced into the stem cell, as well as assuring that the gene is transferred with its regulator to a location where it can function appropriately, and the risks involved by the use of transfecting crippled virus vectors require adequate solutions before the widespread adoption of this technique. Recently, a multicenter effort has been initiated for the therapy of Hurler syndrome with the α-L-iduronidase gene.

40 Osteopetrosis

Soud A. Al-Rasheed

Osteopetrosis (marble bone disease) is a rare condition characterized by marked radiodensity of bones throughout the skeleton and failure of remodeling of the metaphysis due to impaired lysosomal function of osteoclasts and their precursor cells, monocytes. The overall prevalence varies from 1:500,000 to 5.5:100,000. It is not a single disease but a syndrome with several variants defined on clinical criteria. These variants can be categorized as (a) infantile-malignant autosomal recessive, (b) intermediate autosomal recessive, and (c) autosomal dominant.

Infantile-Malignant Osteopetrosis

This form usually presents in infancy with failure to thrive, anemia with thrombocytopenia, severe, overwhelming infections, or fractures. The inheritance is usually autosomal recessive. Hyperostosis crowds the bone marrow cavity, leading to anemia, thrombocytopenia, and hepatosplenomegaly. The macrophage killing is defective, which may account for recurrent infections.

Other manifestations include growth and psychomotor retardation, optic atrophy, squint, deafness, and rickets. Radiologic features include generalized sclerosis of bone with metaphyseal widening, transverse striations, and bone-in-bone appearance that is most marked in the vertebral bodies. The base of the skull is dense.

Treatment is usually symptomatic, correcting anemia and thrombocytopenia, with aggressive treatment of infections. Other therapeutic measures include a low-calcium diet, prednisone, calcitriol, and more recently bone marrow transplantation. Neurosurgical unroofing of the optic foramina is necessary in some patients.

The prognosis for survival is poor, and death is usually from complications of anemia, thrombocytopenia, or infections.

Osteopetrosis with Renal Tubular Acidosis

This entity is the best example of the intermediate autosomal recessive group. The condition is caused by carbonic anhydrase (CA) II deficiency. It is the only type of human osteopetrosis that is understood at the biochemical/molecular level. The majority of patients with CA II deficiency have been reported from Saudi Arabia, Kuwait, and North Africa. In North America, the disorder has not been reported among ethnic groups of Western European descent. To date, the condition has not been described in blacks or Asians. It is discovered late in infancy or early childhood through developmental delay, short stature, fractures, weakness, cranial nerve compression, dental caries or malocclusion, and/or mental retardation.

The clinical expression is heterogeneous among different ethnic groups and is due to different mutations in the CA II candidate gene. Several mutations have been identified; a mildly affected Belgian patient homozygous for the HIO7Y mutation had frequent skeletal fractures and no mental retardation. Three American kindreds included three patients who were compound heterozygotes for the HIO7 mutation and for a splice junction mutation in intron 5. They had many skeletal fractures but were not mentally retarded. Many Arab patients were found to be homozygous for a splice junction mutation in intron 2. They had osteopetrosis, severe renal tubular acidosis, moderate to severe mental retardation, and infrequent fractures. Other mutations have also been reported.

Typical radiographic features of osteopetrosis are present (*Fig. 40.1*) and resemble those of other forms with two exemptions: the osteopetrosis and defective skeletal modeling can diminish spontaneously over decades, and there is cerebral calcification that usually appears at approximately 2–5 years of age. Deposits occur in the basal ganglia and affect cortical gray matter of all lobes of the brain. Bone scintigraphy shows characteristic features of widened metaphyses of all long bones that show increased tracer uptake, particularly in the distal femur and proximal tibia (*Fig. 40.2*). Dual x-ray absorptiometry shows increased bone density. Bone densitometry is a safe and noninvasive method of observing the natural history and therapeutic response.

The biochemical diagnosis of CA II deficiency can be achieved by demonstrating severe, selective reduction of CA II in erythrocyte lysates. Patients are usually not

anemic. A hyperchloremic metabolic acidosis, sometimes with hypokalemia, is caused by proximal, distal, or combined renal tubular acidosis. Serum levels of calcium, inorganic phosphate, magnesium, and parathyroid hormone are normal. Alkaline phosphatase and acid phosphatase activity in serum are usually normal but occasionally increased.

There is no established medical treatment for CA II deficiency. Some therapeutic trials with a low-calcium diet, alkali therapy, and high doses of 1,25 dihydroxy vitamin D3 have been tried in some patients.

The identification of the locus of the CA II gene on the long arm of chromosome 8 and the identification of its mutations provide a means for prenatal diagnosis. Carriers can be detected by the assay of erythrocyte CA II levels.

Autosomal Dominant Osteopetrosis

This is the most prevalent form of osteopetrosis and is often asymptomatic, and the diagnosis may be reached by chance. Autosomal dominant osteopetrosis is radiographically characterized by universal osteosclerosis involving the axial skeleton and symmetric involvement of the long bones without modeling defects. Based on radiographs, it is possible to describe two different subtypes. Type I is characterized by pronounced osteosclerosis of the cranial vault, whereas type II involves the endplate of the vertebrae (Rugger-Jersey spine) and pelvic bones. In the skull, the osteosclerosis is most pronounced at the base. In both types, the general physique, mentality, and life span are normal, and anemia is uncommon. Other clinical manifestations include bone pain, cranial nerve compression, recurrent fractures with delayed healing, and increased susceptibility to infections. The treatment is usually symptomatic.

41 The Porphyrias

Hisham M. Nazer

The porphyrias are predominantly a group of inherited metabolic disorders which result from a specific deficiency of one of the eight enzymes along the pathway of heme biosynthesis and characterized by an excessive production of porphyrins or their precursors. Eight enzymatic steps (❯ *Fig. 41.1*) are involved in this pathway. There are eight clinical disorders of porphyrias associated with deficiencies of appropriate enzymes involved in the relevant steps in the heme biosynthetic pathway. In general, those disorders are characterized by photodermatitis, visceral and neuropsychiatric complaints of variable severity. The diagnosis of porphyria is usually triggered by a high index of suspicion that might save affected patients unnecessary investigations and ensure early management. Females are more commonly affected than males. Early intervention is important in porphyria, because most attacks can be prevented by avoidance of certain drugs with some dietary manipulation. The porphyrias are classified into acute porphyrias which present as intermittent attacks of neurogenic dysfunction and the non-acute porphyrias which are characterized by photosensitive skin eruptions. Acute porphyria is a life-threatening condition associated with a significant mortality of up to 10%. The porphyrias are also classified into hepatic and erythropoietic forms according to whether excessive production of porphyrins is predominantly in liver or the erythropoietic system. The estimated incidence is around 1 in 30,000 population; however porphyrias remain underdiagnosed. Increased awareness of the varied spectrum of clinical presentation in porphyrias contributes to early diagnosis and institution of appropriate therapeutic measures which will improve the overall outcome in this condition.

Precipitating factors can be identified in the majority of cases with drugs or alcohol most commonly implicated. Attacks of acute porphyria may also be precipitated by acute infection or fasting. Drugs that precipitate an attack of acute porphyria include barbiturates, sulphonamides, chloramphenicol, chloroquine, imipramine, pentazocine, oral contraceptives, phenytoin, and theophylline.

Classification of various disorders of heme biosynthesis related to porphyrias depends on the major site of overproduction of heme precursors as hepatic or erythropoietic porphyrias.

Porphyrias may also be classified into cutaneous and non-cutaneous forms or acute and non-acute forms. A definite diagnosis may not be always possible due to the varied spectrum of presentation in porphyries which could mimic several disease entities. However the diagnostic accuracy has improved recently with the advent of molecular biological techniques. Mutation screening of family members is recommended to identify presymptomatic carriers.

Diagnosis, especially in the acute form of the disease, is essential to avoid precipitating factors and the use of triggering drugs. In spite of the well-recognized role of genetics in confirming clinical suspicion, and in family screening, the diagnosis is still based mainly on clinical suspicion, course of the disease, as well as biochemical and clinical studies.

Hepatic Porphyrias

The clinical types of the different forms of hepatic porphyria have many features in common, e.g., neurovisceral, neuropsychiatric, and mental abnormalities. Hepatic porphyrias are mostly inherited in an autosomal dominant mode of inheritance associated with specific enzymatic deficiencies. The group of hepatic porphyria includes the following conditions:

1. 5-aminolevulinic acid dehydratase deficiency porphyria (ALAD porphyria)
2. Acute intermittent porphyria (AIP) due to porphobilinogen deaminase deficiency
3. Porphyria cutanea tarda (PCT) due to urogen decarboxylase deficiency
4. Hereditary coproporphyria (HCP) due to coproporphyrinogen oxidase deficiency
5. Variegate porphyria (VP) due to protoporphyrinogen oxidase deficiency

ALAD Deficiency Porphyria

This rare type of porphyria is due to deficiency of the enzyme 5-aminolevulinic acid dehydratase required for

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_41,

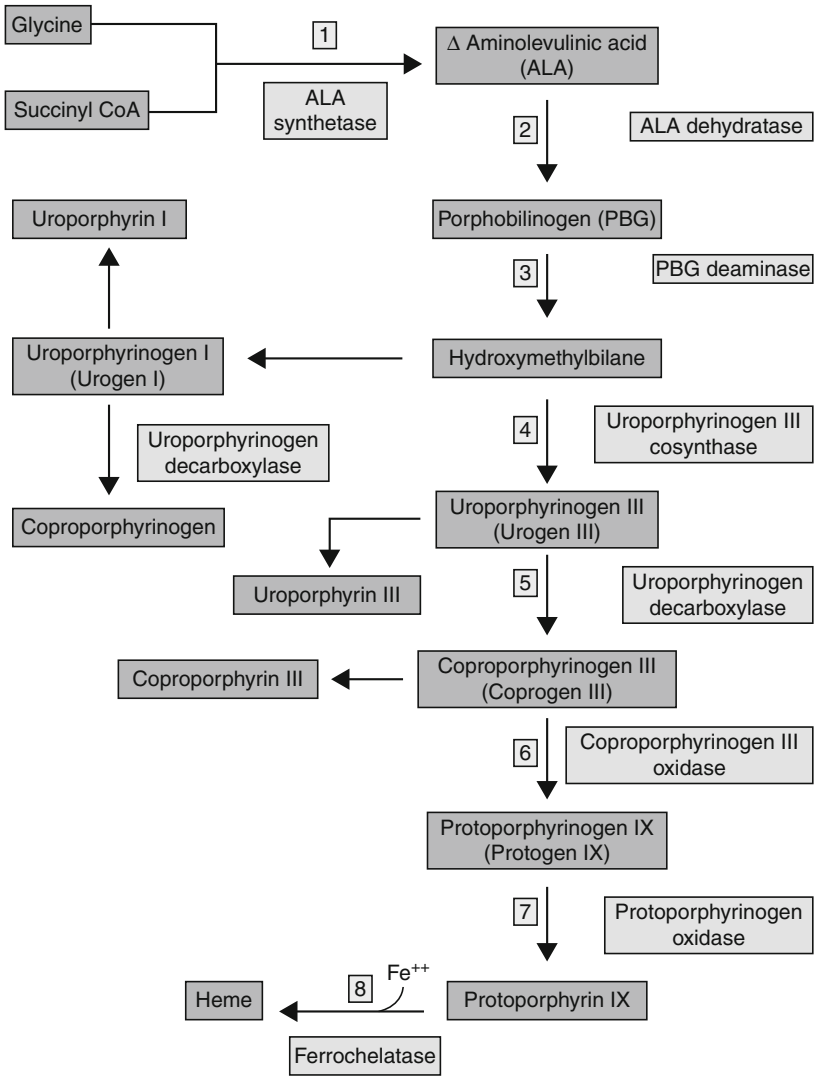

Figure 41.1
The heme biosynthesis pathway

the transformation of aminolevulinic acid (ALA) into porphobilinogen in the heme biosynthesis pathway. It is inherited in an autosomal recessive fashion. The onset is in the teenage years with acute clinical attacks similar to AIP.

Affected child suffers from systemic involvement in the form of abdominal pain, joints pain, hypotonia, and even paralysis. Laboratory investigations confirm the diagnosis by the presence of severe deficiency of the enzyme ALAD in the erythrocytes. Plweinska et al. reported the identification of the molecular lesions in severely affected homozygote. The mutation was confirmed in genomic DNA from family members by the competitive PCR technique. Treatment requires the administration of intravenous glucose during the acute episodes.

Acute Intermittent Porphyria (AIP)

Acute intermittent porphyria (AIP) is considered as the most common type of porphyria affecting pediatric age group. It results from the half-normal activity of the third enzyme in the heme biosynthetic pathway, porphobilinogen deaminase (PBGD), required for the transformation of porphobilinogen (PBG) into hydroxymethylbilane (HMB). The mode of inheritance is

an autosomal dominant. The defect has been located on the long arm of chromosome 11. AIP is due to mutation in the gene encoding for PBGD. Approximately only 10% of patients who inherit the gene have clinical symptoms. This type of porphyria has varied clinical presentations ranging from mild or even asymptomatic to those with severe abdominal pain, abdominal distension, vomiting, and constipation, a picture consistent with acute abdomen requiring surgical consultation. The vomiting may lead to malnutrition, dehydration, and renal failure. The urine has a port wine color. Other clinical features may include fever, diarrhea, and urinary retention. Hyponatremia due to the release of antidiuretic hormone from the hypothalamus may cause delirium, seizures, and coma. The gastrointestinal symptoms may be attributed to disturbances of the autonomic nervous system. Signs of sympathetic overload such as tachycardia and hypertension may occur. The patient may also have some psychiatric manifestations in the form of hallucination, anxiety, paranoia, and depression. Neuropathy, both motor and sensory, may develop with potential complication of bulbar paralysis and respiratory insufficiency. Episodes of neurovisceral disturbances typically begin in early adult life and are exceptional in childhood. The episodes vary in duration from days to weeks and may be intermittent. Life-threatening acute attacks may be precipitated by various factors, including drugs as steroids, sulfonamides, valproic acid, oral contraceptives, barbiturates, etc. Other predisposing factors to initiate acute attacks include fasting, stress, menstruation, and infections.

It is important to mention that symptoms of AIP may also be experienced by patients with tyrosinemia type 1. This may be attributed to the inhibition of δ-ALA dehydratase (Porphobilinogen synthetase) by succinylacetone which is known to accumulate in such patients due to fumarylacetoacetate deficiency.

Treatment includes removal of the causative agents, administration of carbohydrates, and may also include intravenous glucose and hemin to reduce the production of heme precursors.

Diagnosis is supported by the findings of high levels of porphobilinogen and aminolevulinic acid in the urine together with a variable level of reduction in the level of PBGD activity in the erythrocytes. In borderline case, cultured fibroblasts may have to be studied for the deficiency of PBGD activity.

Some individuals with decreased enzymatic activity do not have clinical features of the disease. Prenatal diagnosis has been reported by demonstrating the deficiency of the enzyme in cultured amniotic cells. Biochemical diagnosis is problematic, and the identification of mutations in the HMB-synthase gene could contribute to the accurate diagnosis of presymptomatic heterozygotes. The diagnosis of presymptomatic patients with AIP is recognized to be difficult in some cases due to the significant overlap between low, normal, and high heterozygote value for the enzyme.

Recently, accurate presymptomatic diagnosis was made possible by the identification of genetic mutations causing AIP. Lee et al. reported the identification of two mutations causing AIP: an adenine deletion at position 629 in exon 11 (629delA) and a nonsense mutation in exon 12 (R225X). Many different methods have been developed for mutation screening in AIP. Heteroduplex analysis method was recognized as an efficient mutation screening method.

Affected patients should not be exposed to the predisposing factors stated above including drugs, hormones, alcohol consumption, starvation, and other forms of stress. Should an episode develop in spite of all precautions, oral or even intravenous carbohydrates should be administered without delay. Beta-adrenergic blockers may be needed for control of tachycardia or hypertension. Analgesic as strong as morphine may be required to relieve associated pain. If the attack is severe enough and lasts for more than 48 h, with associated neurological involvement, intravenous hematin should be considered to facilitate resolution of neurological symptoms.

Porphyria Cutanea Tarda (PCT)

The disease is due to deficiency of the enzyme urogen decarboxylase which has been mapped on the short arm of chromosome 1. Mode of inheritance is in an autosomal recessive pattern. The enzyme catalyzes the decarboxylation of four acetic acid side chains of urogen III to yield coprogen III. The relevance of iron in the pathogenesis of PCT is well established. The clinical manifestation of the disease is often triggered by iron overload so that iron depletion remains the cornerstone of therapy in PCT. Specific treatment is accomplished by a series of phlebotomies and/or low-dose chloroquine administration. Two types of PCT have been recognized:

- *Type 1*: Sporadic PCT which usually affects adults
- *Type 2*: Familial PCT which usually affects children

PCT is probably the commonest type of porphyrias and is particularly prevalent in South Africa. It has been described in children in conjunction with either liver disease or prolonged iron therapy. Hift et al. reported

that viral hepatitis may precipitate overt PCT in the genetically predisposed child. The severity of the PCT declined as the hepatitis improved. PCT is rarely manifested in infancy or childhood. Most cases of childhood PCT are familial and some severe cases have been shown to have a hepatoerythropoietic porphyria or homozygous uroporphyrinogen decarboxylase deficiency.

Clinical manifestations are focused on the skin in the form of vesicles, bullae, scarring, crusting, and hyperpigmentation. Hepatic involvement may result in cirrhosis or even hepatocellular carcinoma. Diagnosis is confirmed by demonstration low level of the enzyme urogen decarboxylase in the liver or erythrocytes. Hepatic uroporphyrinogen decarboxylase activity is usually deficient but may be normal or increased in patients with PCT. Decarboxylase activity may return to normal after treatment, suggesting that the enzyme deficiency may be reversible. The characteristic pathological findings are alcoholic cirrhosis and excessive hepatic deposition of iron. The urine contains an excess of uroporphyrin. Acidified urine exhibits a pink fluorescence under UV light. Fecal porphyrin concentration may be normal or considerably increased. Serum concentration of iron and ferritin are increased in PCT.

Treatment includes avoidance of precipitating exposures as drugs (e.g., iron) or sunlight. Phlebotomy has been resorted to in some cases to decrease total body iron.

Hereditary Coproporphyria (HCP)

This type of hepatic porphyria with deficiency of the enzyme coprogen oxidase is also inherited in an autosomal dominant fashion with high penetrance and variable expressivity. HCP is considered to be the least common of the acute porphyrias. Affected patients present with neurovisceral, neurological, and mental manifestations usually indistinguishable from those of AIP. Clinical features also include gastrointestinal, neuropsychiatric, and respiratory manifestations together with sun intolerance. HCP is recognized by rather atypical clinical features and laboratory findings which could well attribute to the possible underdiagnosis of the condition.

Downey reported that a large number of patients with oral conditions and unknown pathophysiology had the clinical symptomatology and porphyrin abnormalities classically found in hereditary coproporphyria. Diagnosis is confirmed by the presence of low enzymatic activity of coprogen oxidase in the fibroblasts and leukocytes. Urine examination reveals excessive excretion of coproporphyrin, ALA, and porphobilinogen. The activity of hepatic δ-ALA synthetase is increased as in AIP.

Treatment is similar to AIP together with avoidance of exposure to predisposing factors as sunlight and drugs especially barbiturates.

Variegate Porphyria (VP)

The name "variegate" refers to the varied clinical features which may be exclusively predominantly cutaneous or neurovisceral. Variegate porphyria (VP) is also a type of hepatic porphyria with similar clinical features to other types of hepatic porphyrias especially AIP and HCP. VP has also been called South African genetic porphyria in reference to the studies of Dean who traced 236 cases of VP in 13 families which had descended from a Dutch couple who had settled in South Africa in 1688. The incidence among South African whites is about 1:333. The disease is inherited in an autosomal dominant pattern and characterized by the deficiency of the enzyme protoporphyrinogen (protogen) oxidase which is required for the transformation of protoporphyrinogen 1X (Protogen 1X) to protoporphyrin 1X in the heme biosynthesis pathway.

Clinical features usually involve the skin and nervous system. Over 80% of patients have skin involvement characterized by excessive fragility on mild trauma. Photosensitivity is usually mild but can be severe when there is concurrent liver damage.

The diagnosis is confirmed by the deficiency of the protogen oxidase enzyme in the lymphocytes and fibroblasts. There is excessive fecal excretion of protoporphyrin and coproporphyrin. During the acute neurovisceral attacks, there is considerable excretion in the urine of the porphyrin precursors δ-ALA and PBG, and of porphyrins.

Management of this disorder is similar to that of AIP.

Erythropoietic Porphyrias

These disorders are classified into two types of porphyrias.

Congenital Erythropoietic Porphyria (Gunther's Disease; CEP)

Congenital erythropoietic porphyria (CEP) is a rare metabolic disorder caused by deficiency of the enzyme uroporphyrinogen (urogen) III cosynthetase, the fourth enzyme of the heme biosynthetic pathway, which is required for the transfer of hydoxymethylbilane into uroporphyrinogen III. It is inherited in an autosomal

recessive pattern. This type has sometime been referred to as erythrohepatic protoporphyria in view of the evidence that liver may be also affected. There is a marked increase of porphyrins in the bone marrow, erythrocytes, spleen, urine, and feces.

The main clinical features of CEP are severe photosensitive dermatosis and hemolytic anemia. In the majority of reported cases, photosensitive skin lesions have occurred in the first few years of age. The disorder manifests clinically usually in the neonatal period with reddish brown staining of the diaper. Skin manifestations are prominent with the presence of photosensitive lesions in the exposed areas: vesicles, scarring, hyperpigmentation, and subsequent deformities of the phalanges, nose, and ears. There is blistering and bullous formation in the epidermis. Friable skin and hypertrichosis are present. Infections may cause extensive scarring and tissue loss, including loss of the eyelids and parts of the pinnae and fingers. The teeth may show reddish brown discoloration due to porphyrin deposits.

The disease may also manifest with other clinical features as pathological fractures, splenomegaly, and hemolytic anemia. Oguz et al. reported the presence of ocular involvement in two patients with congenital erythropoietic porphyria.

The prognosis is reported to be poor in severely affected patients. Death often occurs in early childhood. Diagnosis is confirmed by the deficient enzymatic activity of urogen III cosynthetase in the erythrocytes and fibroblasts. Erythrocyte protoporphyrin content is usually normal but exceptionally increased. There is excretion of large amounts of uroporphyrin I and coproporphyrin I in the urine and coproporphyrin I in the feces. The urobilinogen content of the feces is usually increased. In addition to the variable anemia, there is usually a reticulocytosis with normoblasts in the peripheral blood. The bone marrow shows erythroid hyperplasia.

Determination of the complementary DNA nucleotide sequence encoding the uroporphyrinogen III synthetase has helped to elucidate the molecular mechanisms underlying CEP.

Treatment includes avoidance of predisposing factors as sunlight, screening window light, protective clothing, barrier creams containing zinc or titanium oxide to improve light tolerance, together with hyper-transfusion regimen, and the administration of β-carotene. Splenectomy is indicated in the presence of hypersplenism. Oral administration of charcoal and hematin infusion have been used with good results. Cholestyramine may be used to bind and retard absorption of endogenous enteral porphyrins from the gut.

Bone Marrow Transplantation

Bone marrow transplantation (BMT) has significantly improved the outcome of severely affected patients with CEP. The role of BMT in many hematological and immunological disorders is well established. BMT in patients with CEP was first performed on a 10-year-old girl by Kauffman et al. The patient died of cytomegalovirus infection in spite of initial normalization of erythrocyte uroporphyrinogen synthetase activity. Thomas et al. reported the success of BMT performed on a 2-year-old girl with severe form of CEP. The authors recommended that HLA-identical allogeneic BMT should be proposed to severely affected patients with CEP as it might very well cure them.

Erythropoietic Protoporphyria (EPP)

Erythropoietic protoporphyria is a rare autosomal dominant disorder of erythropoietic porphyria, with variable penetrance, due to deficiency of the enzyme ferrochelatase, the final enzymatic step (step 8) in the heme biosynthetic pathway involved in the transfer of protoporphyrin IX to heme through the addition of iron. In children, it is recognized as the most common form of porphyria especially erythropoietic porphyria.

The disease is associated with excessive accumulation and excretion of protoporphyrin. EPP is also associated with mild cutaneous photosensitivity. Symptoms usually start in the first decade. Typically, within minutes or hours following exposure to sunlight, there is severe pain, pricking, itching, edema, and erythema of the skin. Blisters, cutaneous hemorrhages, and scarring are less common. EPP is the most common type of erythropoietic porphyrias. However hepatocellular disease, though rare, may be present and progress to cirrhosis. Cholelithiasis commonly occurs and often presents at an early age. The excess of protoporphyrin in protoporphyria is excreted exclusively by hepatic biliary secretion into the intestine for ultimate elimination in the feces. A significant proportion of protoporphyrin is reabsorbed in the intestine and may circulate through the enterohepatic circulation. The use of nonabsorbable binding agents as cholestyramine has been recommended for this reason. Rademakers et al. reported the presence of ultrastructural changes in the hepatic parenchymal cells even in early stages of the disease. The presence of changes in the bile canalicular ultrastructure suggests a defective hepatic excretory function, probably caused by the toxic effect of protoporphyrin. Liver damage is a significant complication in a small percentage of patients (5%) with protoporphyria.

Once jaundice develops, there is nearly always a rapid decline in liver function leading to death, unless liver transplantation is performed. It is not certain why some patients with EPP die of hepatic failure while most show no signs of liver disease. Rank et al. reported evidence of neurological dysfunction in end-stage protoporphyric liver disease due to protoporphyrin access to neural tissue when serum levels are markedly increased resulting in neurotoxicity. There is increasing evidence in the literature to suggest that protoporphyrin itself is a neurotoxin.

Diagnosis is confirmed by the low enzymatic assay of ferrochelatase in both erythrocytes and fibroblasts. Elevated free protoporphyrin IX is noted in the liver, erythrocytes, plasma, and bile. It is important not to miss the diagnosis of EPP because a number of patients may develop fatal liver disease. There is evidence that early detection can improve the outcome. The diagnosis of EPP is based on the presence of photocutaneous lesions, appropriate clinical and family histories, elevated levels of free erythrocyte protoporphyrin, and the absence of porphyrin in urine.

Treatment is focused mainly on prevention of exposure to sunlight and application of some sun protection measures. Sunscreens, particularly those blocking rays in the UV range, may offer some protection from the photodermatitis and other symptoms associated with sun exposure. Ross and Moss reported a reduction in the degree of photosensitivity with the use of oral pyridoxine. β-carotene has also been recommended but the dose required may be high enough to cause some side-effects as skin discoloration. Light-protective β-carotene is prescribed Cholestyramine and vitamin E have also been prescribed for patients with evidence of hepatocellular involvement. Cholestyramine helps to interrupt the enterohepatic circulation of protoporphyrin and lessen the level of hepatic protoporphyrin accumulation in patients with hepatic disorders.

Hepatoerythropoietic Porphyria (HEP)

This is a rare disorder due to the deficiency of the enzyme uroporphyrinogen decarboxylase (UROD), the fifth enzyme in the heme biosynthetic pathway. Decreased activity of UROD is responsible for three diseases:

1. Sporadic porphyria cutanea tarda
2. Familial porphyria cutanea tarda
3. Hepatoerythropoietic porphyria

HEP is inherited in an autosomal recessive fashion. The disease is a severe form of cutaneous porphyria that is usually manifest in early childhood.

The clinical entity is often difficult to distinguish from congenital erythropoietic porphyria. Clinical features include cutaneous photosensitivity, bullae, cutaneous erosions, discoloration of urine and teeth, hepatosplenomegaly, and hemolytic anemia.

Mutations of the UROD were identified. The first mutation in HEP, the substitution mutant G281E, was initially detected in a Tunisian family. Many other mutations were subsequently identified. Moran-Jimenez et al. reported two new missense mutations at the homoallelic state: P62L (proline-to-leucine substitution at codon 62) and Y311C (tyrosine-to-cysteine substitution at codon 311).

The identification of the molecular defects in UROD gene does allow*genetic counseling* and may hopefully lead to an effective*gene therapy* in the future.

Treatment is, at present, similar to that of CEP and EPP. It includes prevention of exposure to direct sunlight together with depletion of iron by repeated removal of blood to reduce urine porphyrin concentration to normal levels.

Screening for Porphyria

The porphyrias are group of inherited metabolic disorders in the pathway of heme biosynthesis. Relatives and siblings of index patients should be screened for latent porphyria. The finding of normal levels of porphyrin in the blood, feces, and urine does not rule out latent porphyria as these may only be raised during acute attacks. It is now possible to diagnose patients even with latent porphyria through the application of enzymatic assay.

It should also be possible that with the identification of the gene locus, a more reliable technique will be adopted to diagnose index cases and potentially affected relatives.

Secondary Porphyrinurias

Increased urinary excretion of porphyrin has been observed in many conditions as hemolytic anemia, pernicious anemia, liver diseases as chronic hepatitis, cirrhosis, Dubin–Johnson syndrome, diabetes mellitus, and heavy metal poisoning. These conditions must be differentiated from HCP and VP in remission by assessment of fecal porphyrins.

Differential Diagnosis

As porphyrias are recognized to have varied clinical manifestations with cutaneous, visceral, and neuropsychiatric

presentations, they should be included in the differential diagnosis of many disorders:

- Essential hypertension
- Hysteria and psychosis
- Acute surgical abdomen
- Hyperthyroidism
- Lead poisoning
- Tyrosinemia type 1

Safety of General Anesthesia and Surgery

It has long been recognized that patients with acute hepatic porphyria should be denied essential surgery because of the concern that general anesthesia, stress of surgery, operative medications, and surgery could well precipitate a life-threatening porphyric crisis. Dover et al. have reported following a major review of such an issue that major surgery can be undertaken safely in patients with porphyrias.

Postoperative complications have been reported mainly in patients prior to the diagnosis of porphyria. It is also important to ensure that patients with acute hepatic porphyrias undergoing surgery are kept on intravenous glucose infusion perioperatively until they are able to resume an adequate diet. It is also as important to choose the correct anesthetic agents and perioperative drugs and also to avoid starvation which could trigger an acute crisis.

Pseudoporphyria

Pseudoporphyria is defined as a cutaneous disorder characterized by skin fragility, vesiculation, and scarring in light-exposed areas affecting patients in the presence of normal porphyrin metabolism. This condition has been recognized recently associated with varied clinical conditions and medications. It has been reported in particular with naproxen therapy. Pseaudoporphyria has been induced not only by naproxen but also by other nonsteroidal anti-inflammatory drugs. Howard et al. were the first to report pseudoporphyria similar to porphyria cutanea tarda in patients with normal porphyrin metabolism but receiving naproxen therapy. Lang et al. reported that up to 12% of children with juvenile rheumatoid arthritis (JRA) receiving naproxen developed pseudoporphyria even without high sun exposure. Pseudoporphyria of the erythropoietic protoporphyria type has also been reported with naproxen therapy. The mechanisms of EPP-like-drug-induced pseudoporphyria remain unknown. Children with JRA should be protected from severe exposure to sunlight and should use broad-spectrum sunscreen and protective clothing including wearing a wide-brimmed hat while receiving naproxen therapy. Being aware of such complication, naproxen therapy should be discontinued in patients with JRA if they develop skin fragility or blistering.

Phototoxic reactions in patients taking nonsteroidal anti-inflammatory drugs should be well recognized. Moreover, since the recognition of pseudoporphyria-like eruptions in patients taking naproxen, other drugs such as ketoprofen, nabumetone, diflunisal, benoxaprofen, and tiaprofenic acid have also been recognized to induce pseudoporphyria.

Pseudoporphyria cutanea tarda has also been reported in patients undergoing peritoneal dialysis and receiving erythropoietin therapy. The clinical picture is similar to porphyria cutanea tarda but with a normal porphyrin profile. The mechanism of photosensitization due to erythropoietin therapy remains unknown.

Liver Transplantation

The recent adoption of liver transplantation in porphyria with end-stage liver disease has transformed the life of affected patients. Sarkany and Cox described a family in which two siblings with protoporphyria suffered from severe photosensitivity and developed hepatic failure requiring liver transplantation. It is not clear why some patients with EPP die of hepatic failure, while most show no signs of liver disease. Liver transplantation has been a life-saving procedure for patients who present with advanced liver failure where other available therapeutic modalities have proved ineffective. However, there are some operative hazards of liver transplantation in patients with protoporphyria. Exposure to bright surgical light during the operation may provoke a generalized motor neuropathy, hemolytic crises, or abdominal wall burns.

Polson et al. reported a successful outcome of liver transplantation in the treatment of EPP of a 13-year-old boy with end-stage cirrhosis and marked cholestatic jaundice. However, continued extrahepatic production of protoporphyrin was reported to result in recurrent allograft injury in patients with EPP. More recently, Meerman et al. reported two patients with EPP who were followed-up for 7 years after liver transplantation. Both patients have shown fibrosis with hepatocellular protoporphyrin accumulation 8 and 6 months, respectively, after liver transplantation. Reichheld et al. recommended the use of preoperative intravenous heme-albumin and plasmapheresis to reduce

the postoperative complications of orthotopic liver transplantation in patients with erythropoietic porphyria.

Developmental, Learning and Behavioral Disorders

Pamela High and Yvette E. Yatchmink

42 Normal Child Development

Linda S. Grossman

Introduction

Over the past centuries, there have been times when children were considered to be fully formed at birth and just needed feeding and education to prepare them for adulthood – such as during Victorian times. Caregivers and theorists assumed that the qualities of the child were already determined at birth. Child rearing was largely devoted to feeding, clothing, and providing formal education. Unfortunately this theory, in many cases, led to a failure to provide the caregiving environments that would foster child development and often led to children being punished for misbehavior that did not have the conscious intent that was assumed. Other times, experts postulated that parenting was the sole factor, or at least the main factor, which determined how a child matured into adulthood (such as during the period post World War II). Unfortunately, this led parents to be blamed (or to blame themselves) for developmental outcomes that they did not cause, such as when parents were thought to be responsible for autism in their child.

Current research has confirmed that development is partially determined by genetic and prenatal factors with the corresponding steps in neuromaturation that occur at each age. However, these steps are heavily influenced by other factors such as the interactions between the child and his environment, nutritional status, health, stresses, and, most importantly, interactions with key others.

Theories of Development

Several core theories of child development have influenced our understanding of children and how they develop. Each of these theories is based on extended observations of children and an effort to make sense of the developmental changes observed. These theories provide clinicians with insight about different components that likely play a role in child development. The patterns that theorists describe provide some insight into what is going on with the child, even if the theory eventually is "discredited." Some of the key theories that have helped shape our understanding of child development are described below.

Maturational Theory

This theory first emerged in the eighteenth century but subsequently most extensively developed by *Arnold Gesell* and his followers. It views the child as an immature organism who follows a predictable pattern and rate of maturation in the various developmental domains determined largely by internal factors controlled by genes. Maturational theory focuses on *fixed milestones* that the child achieves and a usual age range for acquiring those milestones. While maturational theory does acknowledge that environment can have an impact on development, this is largely seen in terms of environmental factors that might impede development rather than considering that environmental factors could enhance development. According to this theory, children must have an inner readiness to perform a task before they will be able to learn that task. The idea that development is linked to neuromaturational changes and proceeds in a predictable sequence is one that has stood up over time. The systematic look at developmental steps described by Gesell continues to be a useful way of thinking about the young child's development, although the model he proposed is more applicable to motor development and possibly early language development, and is weakest when applied to cognitive and emotional development.

Psychosexual Theories

These theories focus on the impact of early childhood experiences in shaping personality and emotional development. *Sigmund Freud* drew on his in-depth discussions with adult patients about their memories of their childhood experiences to develop a theory that proposes three parts of personality, the id, the ego, and the superego. In this theory, *the id* reflects basic drives or instincts and is the dominant force during early infancy. *The ego* is the aware or rational self and develops during late infancy and early toddlerhood. *The superego*, or the conscience, emerges during the preschool period between ages 3 and 6. He hypothesized that the way these components develop and are integrated during early childhood determines the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_42,

individual's functioning into adulthood. He asserted that each stage has sexual meaning focused on a particular body part. Infancy is the *oral stage* (with sucking, feeding, biting as central). The *anal stage* follows during which the child masters control over his bowel functions with toilet training. The third phase is called the *phallic or the oedipal stage* and focuses on interest in genitals and resolving the competition with the same gender parent for the attention and love of the opposite gender parent. Freud believed that the successful resolution of the sexual conflicts of each of these stages results in a new level of emotional and social maturity.

Margaret Mahler proposed that a child's mental and physical relationship with his mother moves from one of *symbiosis to independence* through the first 3 years of life to allow the child to see himself as an independent person. According to this theory, the close relationship of a mother and infant was a crucial first step. *Erik Erikson*, in the mid 1960s, further expanded this to include psychosexual stages throughout the whole life cycle. He described each stage as tension between competing factors. Moving on to the next stage is only possible with resolution of the conflict. He also hypothesized that society and culture, in addition to family, play major roles in how successfully the individual is able to resolve the conflicts at each stage. The stages he describes for children include *trust versus mistrust* (birth to age 18 months), *autonomy versus shame and doubt* (18 months–3 years), *initiative versus guilt* (3–6 years), *industry versus inferiority* (6–11 years), and *identity versus role confusion* (adolescence).

Behavioral and Social Learning Theories

Behavioral theorists (*Ivan Pavlov, J. B. Watson, and B. F. Skinner)* believe that the environment is the primary source of change based on *patterns of reinforcement* of the child's behavior. They postulate that behaviors that are rewarded continue while those that are ignored or punished disappear. However, according to this theory, the child's own emotions, motivations, and styles of adapting play little role in shaping the child's development. As a result, this theory is limited in its contribution to the current understanding of child development, although it does provide important foundations for some of the interventions commonly used for problem behaviors.

Social learning theorists expanded on the work of the behaviorists by elucidating the role of *social models* in development. *Albert Bandura* one of the founders of social learning theory, describes children as mentally constructing models and developing behavior patterns on their own, learning from the models they see in their environment. This concept of the influence of the child's environment on his development and behavior is an important addition to current understanding of child development, although clearly only one factor in development.

Piaget

Jean Piaget published extensive theories of development of young children based on his detailed observations of the language and cognitive development of his own children. He is especially known for his observations that children think differently about things at different ages. He proposed that there were "stages of development" based on the way in which the child interacted with and interpreted the world around him. Piaget postulated that the sequence was fixed although the exact times of the shifts between stages vary from child to child.

He divided the child's approach to the world into four stages: the sensorimotor stage, preoperational stage, the stage of concrete operational thinking, and the stage of formal operations. In his *sensorimotor stage*, which usually occurs when babies are between birth and age 2, the child understands the world through direct sensations and motor actions. The child needs to master the concepts of *object permanence* (objects continue to exist, even when you can't see them), causality, spatial relationships, and the use of instruments (for instance using a rake to reach something beyond your reach) before moving on to the next stage. In the stage of *preoperational thinking*, usually occurring between ages 2 and 6, the child's thinking is egocentric. The child in this stage believes that the world is organized around him and his wishes. He needs to master his sense of animism (understanding that objects don't actually have a life although it is sometimes useful to describe them as doing so), egocentrism (the child is not the center of the world), idiosyncratic associations, and transductive reasoning (things are not necessarily linked just because they occurred at the same time) in order to move on to the next stage. In the stage of *concrete operational thinking* (usually ages 6–11), the child can reason through real and mental actions on real objects and can reverse changes in the world in his head in order to understand things. He can reason with a stable rule system and enjoys working with others to establish a set of rules. However, children in this stage continue to think about things in very concrete terms and have trouble imagining hypothetical situations. In order to move on to the next stage, the child must master the concepts of number, mass, volume, and linear time, deductive reasoning, and objective

causality. The final stage is called *formal operations* and occurs in youth sometime after the age of 12. In this stage, the youngster develops abstract thought, can reason about ideas, and can deal with broad abstract concepts. Steps for this stage include mastery of abstract thinking including inductive reasoning and complex deductive reasoning.

Moral Development

Lawrence *Kohlberg* builds on the basic Piagetian framework to describe children's moral problem solving. He proposes that children and adults solve moral dilemmas along a continuum but that the cultural context and values influence the stage in which the person thinks. *Carol Gilligan*, among others, objects to this schema, asserting that it is biased toward the male perspective and too much influenced by Western thinking. She points out that males and females tend to think about moral issues quite differently and that Kohlberg's concepts do not apply as well to children in non-Western cultures. However, there has been some evidence to support Kohlberg's theories that young children see rules as rigid and absolute while late school age children shift to understand that rules are things that a group of people agrees upon. Similarly, young children tend to view the damage done as determining their guilt while older children understand that intention to do wrong is a better determinant of degree of guilt.

Developmental and Behavioral Milestones

The developmental theorists described above tend to concentrate only on one or two realms of development at any given time. However, both parents and primary care providers are well aware that children develop in multiple areas simultaneously and that the child's development in one area impacts on the other areas of development. Observing and anticipating developmental milestones allows both parents and clinicians to provide and support experiences for the child that will enhance the development in each area. By convention, development is thought of as occurring in five areas: gross motor, fine motor, language, cognition, and social/emotional domains.

Infancy and Toddlerhood

During the first year and a half of life, the infant makes dramatic gains in gross motor skills. In general, gross motor development proceeds *centrally to distally* and *pronation precedes supination*. Typically, at birth, the child has little control over his motor state although should be able to move all of his extremities in a random fashion. Three developing processes allow him to acquire the skills to maintain upright posture and to move limbs across the midline of the body. These processes include the *balance between extensor and flexor tone*, *decline of the primitive reflexes* that the baby has at birth, and the *evolution/maturation of protective and equilibrium responses*. Evolution of these allow the infant to be able to hold up his head and later his chest when prone, roll over, sit with support, and get to sitting, and then develop the skills to be able to stand and then walk, such that the average youngster is walking by 12 months or soon afterward and running by 18 months of age. Fine motor skills move from being able to unfist hands, to reaching, transferring objects between hands, raking in objects, and then to developing a mature pincher grasp, all before 12 months of age (see *Table 42.1* for motor skills by age). Motor skills are less dramatic during the toddler years although there continue to be sizeable gains. Between 18 and 36 months of age, the youngster will become skillful in running, walking up and down stairs, jumping, and pedaling a tricycle. Similarly, the child will be skillful in scribbling and should be able to draw a vertical and horizontal line as well as a circle by age 3.

The rapid development in *sensory abilities* parallels and facilitates these changes. At birth babies already respond differentially to music they heard in utero. They quickly learn the sounds of their caregivers' voices and respond to them as well. At birth, a child can see clearly objects that are approximately a foot from his eyes, about the distance that the mother's face is from the baby when she is breast feeding her child. Objects that are closer than a foot or further away are seen much less clearly until around 2–3 months of age. This change at age 2–3 months, facilitates the development of motor skills with the child's hands. Vision further develops so that acuity and scope of visual fields is similar to adults later in the first year although full maturation does not occur until the preschool years. Sense of smell is also fairly well developed at birth. Soon after birth, babies can distinguish the smell of their mother's milk from the smell of other mother's milk. These rapidly evolving sensory skills contribute to and facilitate the attachment that is crucial for babies and their key caretakers. This attachment is key in social/emotional development.

Language development also has regular milestones related to maturational changes but seems to be more sensitive to environmental input than some other areas

Table 42.1
Motor and language development in infants and toddlers

Age	Gross motor skill	Fine motor skill	Receptive language skill	Expressive language skill
1 month	Head up when prone	Hold rattle	Responds to sound with startle or turns to look for source of sound	Crying
2 months	Chest up when prone	Grasps toy briefly	Turns to familiar voices	Smiles responsively, differentiated cry
3 months		Hands unfisted	Makes differentiated responses to familiar voices	Babbling vowels and few consonants
4 months	Rolls front to back	Hands to midline	Turns head to localize sounds	Laughs, squeals, says "ooh" and "ahh"
5 months	Sits with support	Transfers objects	Localizes sounds	Labial consonants (ba, ma, ga)
6–7 months	Sits without support	Rakes in toy, Bangs blocks together (7–8 months), transfers objects from hand to hand	Knows own name and familiar words (e.g., bath, doggy)	Repeats sounds
8–9 months	Pulls to stand	Immature pincher, feeds self pieces of food	Can do at least one simple "game" – peek-a-boo, so big, clap your hands, etc.	Jargon with the phonetic and intonation features of the child's native language
				Mama, dada nonspecific
10 months	Cruises holding onto furniture, Crawls or "cover territory"	Mature pincher – picks up small objects with thumb and fingers	Responds to simple commands – "say bye-bye"	Two syllable repetitions (baba, dada)
12 months	Cruises, beginning to walk alone	Releases – put down a small toy without dropping it	Points to objects – to share interest	Points to objects with vocalization; first words
15 months	Can bend over to pick up a toy on floor and then stand up without support	Scribbles on paper, uses a spoon to feed self but messy	Follows single step commands	Common to add and then lose words during this period
18 months	Walks up stairs, one stair at a time holding on	Tower of three cubes, Takes off shoes, socks	Points to body parts	10–50 words
24 months	Jumps with two feet, jumps down a step from last step	Uses a spoon without spilling much, uses turning motion with doorknobs or jars	Follows two step commands; Points at pictures in book	Two word sentences
30 months	Walks down stairs, both feet on each step, runs well, kicks a ball	Builds bridge from three blocks; copies vertical and horizontal lines	Can follow a simple story with pictures	Adjectives, possessives beginning to be used correctly
36 months	Walks up stairs alternating feet	Can string beads on shoestring; copies a circle, feeds self well with fork and spoon	Understands prepositions	Understood about three fourth of the time, beginning to use pronouns and plurals

of development and is closely linked with cognitive development. Although even deaf infants will develop initial sounds, if the sounds the infant makes are not reinforced by the responses of important people around them, these vocalizations will disappear. Hearing the sounds alone is not sufficient. For instance, hearing the sounds on TV or on audiotape does not result in the same mimicking of sounds after 8 or 9 months of age. By age 3–4 months, infants develop babbling repetition of all vowel sounds and some consonants. By 10 months, they start to produce two syllable repetitions such as dada, mama, and baba. Initially these are nonspecific, but as people surrounding them respond selectively to some and not to others, they begin to have a symbolic reference for the infant. The ability to attach a name for something requires a sense of object permanence. That is, they need to be able to hold an image of the object or person in their minds. Usually between 10 and 15 months, infants speak their first real words where there is a clear effort to name a person or object. They also begin to use symbolic gestures during this period, such as lifting their arms to indicate that they want to be picked up, pointing to objects that they want, and shaking their head to mean "no." Consistently, receptive language slightly precedes the same skill in expressive language. Children can point to pictures of animals or point to their body parts before they can name them directly. By age 2, they are putting words together and beginning to add adjectives as modifiers. By age 3 they are using prepositions correctly in sentences although they still may mix up pronouns. Their speech should be understandable by someone who does not know them about half of the time. Between 2 and 4, the clarity of their speech improves dramatically so that almost all of what they say should be understandable by age 4. They also will increase the complexity of their language by adding prepositions, correctly using pronouns, and beginning to use clauses.

Human understanding of children's cognitive development during infancy continues to evolve – partially because the ways of measuring and assessing cognitive development tend to be linked so closely to language and fine motor skills. Piaget vastly underestimated the cognitive skills of children because he was relying so heavily on language as a measure of their thinking skills. Even very young infants demonstrate signs of memory of auditory experiences, and appear to remember experiences that happened prior to birth. At birth infants already respond selectively to parent voices and maternal smells. They can learn simple patterns of behavior at quite a young age, even before they seem to understand the concept of object permanence, which does not appear until toward the end of the first year. By the end of the first year, they pay more attention to real words in the language of those around them as compared to nonsense sounds. By 18 months they are making categories of things, although these may not be the same categories adults might make. For instance, it is common for an 18 month old to call all animals "doggy." *Table 42.2* summarizes the major cognitive milestones of childhood.

For infants and toddlers, cognitive development, language development, and social/emotional development are completely intertwined. From very soon after birth, the infant fixes her eyes on key adults who are holding her and clearly pays attention more closely to those with whom she is attached. Very early on, the infant learns to engage in reciprocal interactions with those key adults, smiling at things they do and then laughing out loud when they do those things even more. The reciprocal interaction is key to development of both the cognitive connections in the brain and for the development of language skills. For the first few months, the infant's major goals are to learn how to regulate his systems, learn some self soothing, learn how to get assistance when he needs attention or tending to, and how to get comfort when he needs comfort. Once this self-regulation is in place, the infant turns her attention to interactions with those key adults, clearly responds differently to those important adults, and takes pleasure in those interactions. These interpersonal interactions are key for building the cognitive connections in the brain and for developing the initial components of language.

By 18 months, the toddler has developed a clear understanding that things continue to exist even when he can't see them, that his actions result in responses from both toys and people, and that he can manipulate the world around him, both literally and figuratively. After being closely linked to those key adults, the child now needs to exert his independence, to be able to function separately from those key people. This results in efforts on his part to begin to care for himself – feeding himself and beginning to use the toilet. He also is interested in the skill of removing his clothes and then later learning how to put them on himself. The toddler further exerts her independence by making liberal use of the word "no" just to stake out a position opposite that of the adult, even when she has conflicted feelings about it. Mastering that separation from those key adults is an important first step in growing to be an independent person.

Preschool Development

Gradually between the ages of 1 and 3, youngsters acquire the capacity to imagine things beyond what they can

Table 42.2
Childhood cognitive milestones

Milestone	Description	Approximate age of attainment
Early object permanence	Follows an object falling out of sight, search for a partially hidden object	4–8 months
Object permanence	Searches for an object completely hidden from view	9–12 months
Cause and effect	Realizes his/her action causes another action or is linked to a response	9 months
Functional use of objects	Realizes what objects are used for	12–15 months
Representational play	Pretends to use objects functionally on others, on dolls	18 months
Symbolic play	Uses an object to symbolize something else during pretend play	2–3 years
Pre-academic skills	Knows letters, numbers, shapes, colors, and counts	3–5 years
Logical thinking	Understands conservation of matter, multi-step problem solving; realizes there can be different perspectives	6–12 years
Abstract thinking	Able to hypothesize, think abstractly, draw conclusions	>13 years

directly see and, eventually, to imagine things beyond their experience. An 18-month-old child will pretend to drink from an empty cup while a 3 year old may pretend that that cup is a toy car on a trip to visit grandma. Throughout the preschool period, this imaginary play becomes increasingly complex and prolonged in duration so that, by the time the child is five, he may play an imaginary game all afternoon. This new imagination is both wonderful and very scary for these youngsters since they don't yet have a firm grip on what is real and what they just dreamed up in their heads. As a result, preschoolers tell wonderful tales but also can easily scare themselves with worries about monsters under the bed, or fears about all kinds of things from bugs to dogs. For many youngsters, the skill to be able to do a reality check and sort out real from imaginary doesn't fully mature until age 7 or 8. Even adults need to think hard about whether something is real or just imaginary sometimes.

At the same time, preschoolers become increasingly interested in interactive play with their peers. Prior to the preschool period, most enjoyed playing side by side with age mates and sometimes even stopped to watch what their peers were doing and then copied it. However, it is not until the preschool period that the play becomes truly interactive with multiple "turns" in the interactions. Preschoolers also develop a clear identity of themselves as a boy or a girl. This may involve excessive focus on activities that the child relates to his or her gender – such as always wanting to wear a dress – or it may involve "playing doctor" to check out the differences in anatomy between boys and girls. Often this exploration of gender includes being in competition with the same gender parent for the love and affection of the opposite gender parent (oedipal period). By the end of the preschool period, most youngsters resolve this by identifying more firmly with the same gender parent although the closeness with the opposite gender parent continues. Both motor skills and language skills also become more refined during this period. Preschoolers become adept at climbing and can convey their ideas in increasingly complex sentences.

School Age Development

The school age period is unique in that it is the one time during a child's life when the growth of his trunk and limbs proceeds at the same rate. This facilitates development of skills of coordination such as eye-hand coordination as well as kicking, batting, and throwing skills. The neurologic changes also facilitate development of fine motor skills such as writing and playing an instrument. At the same time, youngsters have acquired cognitive skills that facilitate learning to read and do math. The association between letters in certain patterns on the paper translating into words and sentences becomes something that early school age children find comes easily to them, especially if they acquired the building blocks for this during the toddler and preschool period. Key to learning to read is having had the experiences with books and being read to so that the youngster understands that print is a set of letters, which make up words and a story. Equally important is to have skills in "hearing" and appreciating that certain words begin and/or end with the same sound. Being able to come up with rhyming words and words that start with the same sound are important building blocks for reading. Similarly, in math, understanding the

concept of numbers and that number stays the same no matter how the items are arranged is a key concept to be able to understand the basic principles of addition and subtraction.

Later in elementary school, children become interested in classifying things and in learning about sets of things. In play this translates into interest in collections. In school, it translates into interest in learning about how things are similar and different and about categories of things – for instance learning about the differences between reptiles and mammals and which animals belong in each category.

Further developing skills in social interactions with peers is an important component of development for elementary school age children, both for the friendship skills that are acquired and because it gives the youngster perspectives about the world beyond those of his immediate family. Involvement in many activities for school age youngsters is motivated by two things – are there skills that will improve by participating in this activity and will she get to spend time with the kids she likes while doing this. Most commonly youngsters seek peer groups of the same gender during the early school age period although some youngsters seem to cross gender activities (such as the tomboy girl who loves sports) as part of the normal developmental process.

Adolescent Development

The teen years are a time of multiple physical and neurologic changes that have an impact on development and behavior. The hormonal changes, the rapid growth associated with puberty and the physical changes of puberty, and continuing evolution of brain development all have an impact on the adolescent's overall development. Recent studies suggest that the myelination of the areas that process motor and sensory information, as well as the areas connecting brain regions specialized for language and understanding spatial relationships is largely complete by the start of adolescence. However, the regions that deal with more advanced functions, including integrating information from the senses, reasoning, and other "executive functions" such as planning, organizing, and managing emotions, myelinate last and are not completely mature until the early to mid 20s. As a result, teens often misread emotional cues, especially in stressful situations, and are more likely to be risk takers because of the stage of their brain development.

In general, adolescent development is described as occurring in three phases: early, middle, and late adolescence. During adolescence, the teen needs to accomplish four goals. He needs to become independent from his parents, both psychologically and such that he is eventually capable of living on his own. She needs to establish her own identity, including a sexual identity. He needs to develop a career and a plan for his future. And she needs to develop a set of values congruent with society.

In *early adolescence*, the youngster is struggling to handle all of the changes of puberty – or struggling with why he or she has not yet started to have those pubertal changes. As a result, the teen often feels that his body is "out of control" with the rapid changes and may focus on the few things he or she does have control over such as hairstyle. Clothing choices often are made either to accent the changes or cover them up – thus the extremes of too revealing or very loose, baggy clothes that are often prevalent in early teen's attire. Early teens also focus on establishing their independence from parents as a first step in figuring out identity. In many ways it resembles the "terrible twos" in that early adolescents make every effort to be as different from their parents as possible in order to establish a separation. They may argue with their parents about trivial things, deliberately make choices that they know their parents would not approve of, and push the limits of whatever rules are set for them. The conflict of wanting to be independent but not truly able to be independent results in temper tantrums not dissimilar to those of the "terrible twos" although they usually involve more door slamming than kicking and screaming on the floor.

Middle teens' main focus is on establishing their identity including their sexual identity. They often take idealistic stances on things, reflecting some of their newfound ability to think in more abstract terms. For instance, it is common for a middle teen to become a vegetarian or be passionate about environmental causes. However, becoming independent is also a scary concept, so youngsters in early to mid adolescence typically are closely bound to their peer group and opt to dress and talk just like their peers. This often confuses parents because the parents correctly see this as not being independent at all, but just changing the dependent links. Early to mid teens may try out different persona, trying to find a role and style they are comfortable with. These efforts to sort out identity also apply to sexual identity. Early adolescents are coming to grips with their new sense of sexuality and will also experiment to figure out who they are in this arena. This is especially challenging for youths who come to sense that they may be gay or lesbian since both their school community and society as a whole may be very unsupportive of this identity.

While efforts to determine a career path may begin earlier, this is the main focus of late middle to *late*

adolescence. Prior to this time, most teens have trouble thinking ahead to next week much less thinking about long-term goals. However, by middle adolescence, the combination of a better sense of identity and more capacity to think long-term logically leads to efforts to set a career path. In addition, their increasing capacity for more complex and abstract thought leads them to establish a value system for themselves that allows them to function in society. These values may be very idealistic or very pragmatic depending on their experiences, both in their families and in their community, as well as their personal goals.

Screening and Assessment

Screening to determine children with early signs of developmental delay, followed by appropriate assessment and early intervention targeted at the specific documented problems, is crucial to enhancing child development. According to the guidelines set in the American Academy of Pediatrics 2006 Policy Statement, primary care providers should engage in *surveillance* for delays at each visit and *formal screening* for delays at the 9, 18, and 30 month (or 24 month if there is no planned 30 month) visits as well as formal screening when the question of delays occurs at other visits. This policy statement describes surveillance as consisting of five components: eliciting and attending to the parents' concerns, maintaining a developmental history, making accurate and informed observations of the child, identifying the presence of risk and protective factors, and documenting the process and the findings. Probably the most crucial of these is asking the parents about their concerns and taking their concerns seriously. Repeated studies have demonstrated that parents' identification of concerns has the highest correlation with a developmental disorder actually being diagnosed. However, for parents to feel comfortable voicing their concerns to their medical care provider, they must feel that the care provider is interested in their observations and plans to take their concerns seriously.

For the recommended *screening* at ages 9, 18, and 24 or 30 months as well as when parents have voiced concerns or when the other measures of surveillance suggest that there may be a concern, it is appropriate to complete a formal screening using a standardized test with a measure that has appropriate sensitivity and specificity. The goal is to identify which children need a full evaluation, missing as few as possible of those with a developmental disorder while not over identifying children. Over-identifying children can be a problem both because of the anxiety it provokes in parents and for the substantial costs of an appropriate evaluation.

The screening measure can be a parent questionnaire or a screening completed by staff in the office. Several are described in detail in the policy statement although most providers in the USA are choosing either the Ages and Stages Questionnaires (ASQ), which is available in English, Spanish, French, and Korean, or the Parents' Evaluation of Developmental Status (PEDS) (available in 14 languages). Both of these instruments are parent completed questionnaires that parents can complete while waiting for the visit and are easily scored in a matter of a few minutes. ASQ consists of a series of 19 age-specific questionnaires for children from 4 to 60 months of age. Each questionnaire asks questions pertaining to the domains of communication, gross motor, fine motor, problem-solving, and personal adaptive skills for that particular age child. It provides an option for the clinician to offer materials for parents to test if their child can do an item when they don't know the answer. Sensitivity is 0.70–0.90 and specificity is 0.76–0.9. PEDS is a parent-interview questionnaire with a single form used for any age of child (birth to age 8 years). Sensitivity is 0.74–0.79 and specificity is 0.70–0.80. The clinician or a member of the office staff can read the questions to the parent to obtain their observations of the child's development if parent literacy is limited for both of these parent report instruments.

The same guidelines note that using a general screen is best except in the case of autism since the symptoms of autism are quite different from other developmental disabilities. An autism-specific screening test should be used if there are parental concerns about autism, the clinician has concerns on surveillance, and routinely at a visit when the youngster is around 18–24 months of age. Unfortunately, there is not an excellent autism screening test at present. Currently most popular is the Modified Checklist of Autism in Toddlers (M-CHAT) (available in English, Spanish, Turkish, Chinese, and Japanese), a 23-item questionnaire that is intended for children ages 16–48 months. While the published sensitivity of this is 0.85–0.87 and the specificity is 0.93–0.99, subsequent studies have suggested that it has a strong tendency to over-identify children – in some studies only a third of the children identified by this screen were diagnosed with an autism spectrum disorder on further evaluation. Efforts are underway to add a second stage that may help address this problem with over-identification. Other social-emotional problems in children prior to school age can be identified via the Ages and Stages Social Emotional, the Brief Infant-Toddler Social and Emotional Assessment

(BITSEA), the Devereaux Early Childhood Assessment, or the Eyberg Child Behavior Inventory. Because of the complex interactions between environment and social-emotional status in young children, positive findings on any of these need to be investigated in depth before any diagnosis is given to the child. More typically, the sources of social/emotional problems in young children involve a complex interaction among many factors.

Older children's developmental delays usually are best identified by questions about their functioning in school since school performance relies on cognitive, language, and fine motor skills. However, screening for social/emotional delay and for behavior problems may require alternative measures. Asking about functioning within the family, with peers, and at school or daycare does give useful information. Probably the best accepted behavioral screen for school age children is Jellinek's Pediatric Symptoms Checklist. More in-depth questionnaires are available to use when questions have been raised and include the Behavior Assessment Scale Parent Rating Scale (BASC-P), the Conners' Rating Scale Revised (CRS-R), and Achenbach's Child Behavior Checklist (CBCL). Each of these has a parent form, a youth form, and a teacher form, is available in English and Spanish, and may help document the concerns in a systematic way, although none are diagnostic.

When children have a positive finding on a screen such as those described above, or when the parents or the clinician have sufficient concerns, even if the screen is not positive, a more extensive *evaluation* should occur. The primary care physician often completes at least part of this, reviewing the child's medical history, obtaining hearing evaluations if that is relevant to the concerns, and coordinating any further evaluation. The further evaluation could be done by a developmental-behavioral pediatrician in concert with appropriate other specialists such as speech and language clinicians, audiologists, and psychologists or could be done initially by an Early Intervention Team so that timely intervention can occur even if the medical component is delayed by long wait times for evaluation. In the USA these early intervention teams are linked to services available under Part C of the Individuals with Disability Act (IDEA), where services can be provided to the child and his family once developmental delay or certain specified risk factors for delay are documented. This more extensive evaluation should look in detail at the child's and family's medical history, and include the specific details about the child and his developmental skills, a physical exam, an assessment of his sensory capabilities (especially hearing and vision), an assessment of the child's strengths. Appropriate additional testing will be determined by the specific details about the findings.

Influences on Development

While developmental steps are determined by neuro-maturation, exactly how development proceeds for the child is influenced heavily by the child's experiences as well as by the child's nutritional status and exposure to toxins, the environmental stimulation and the quality of caregiving the child has had, stresses both for the child and his caregivers, and the child's health. Research has shown that the particular experiences the child has, especially during critical periods, lead to the creation of connections within the brain and the preservation of cells in the brain. Connections not made during certain critical periods and areas not used are pruned out. While there is some opportunity to establish new connections at later points, it often is accomplished in ways that are less efficient or less useful than if the connections had been established during the usual critical period. One example of this is the development of binocular vision. If the input from the eyes is such that a double image is created, as with children with ambylopia, the brain stops processing the image from one eye so that the input makes sense. Correction is possible up to a certain age but beyond that age (sometime in early elementary school), the brain will no longer process information from that one eye, even if the muscle imbalance between the eyes is fixed.

However, the impact of experience is not unidirectional. The child's behaviors and responsiveness have a profound effect on those around him and, in turn, influence the behaviors of people toward the developing child. This is referred to as the *transactional model* of development. When a child has a challenging temperament or when his style clashes with that of the parent, less than optimal interactions may result. Parents are less likely to interact with a child who is irritable or who is slow to respond to their efforts at interacting. So, the challenge is to foster optimal interactions and especially to identify situations which may interfere with optimal interactions, whether they are problems with the child or with the adults in the child's life.

Environmental Influences on Development

Many environmental factors influence development, including nutritional factors, presence or absence of toxins, and factors such as noise, light, and availability of appropriate toys, etc. Adequate nutrition including adequate protein, vitamins and essential minerals can have a profound effect on the child's development. For instance, Betsy Lozoff's studies of Costa Rican children

with iron deficiency anemia have documented that children with severe iron deficiency, even when the iron deficiency is promptly corrected once discovered, have lower cognitive skills and more behavior problems than their peers who never experienced iron deficiency. Clearly iron deficiency during critical periods of brain development has long lasting effects on the child's brain. Similarly, multiple studies document that children who experience failure to thrive, no matter what the cause, will have lower cognitive functioning, even when their growth rates return to normal.

Equally, it is known that toxins have long lasting impacts on growth and development. Children with elevated lead levels continue to have higher rates of behavior problems and lower cognitive scores than similar peers without lead exposure. Other toxins, such as mercury, have also been documented to have long lasting effects on brain functioning. Likely there are other substances that similarly interfere with optimal growth and development.

The physical environment also has an impact on youngsters. Studies have demonstrated that children respond differently to the sounds that they heard while in utero. Similarly, premature babies grow better when the noise level of the intensive care nursery can be kept down. Higher levels of ambient noise, caused by the elaborate machines used in caring for premature infants, inhibit growth in these small children. Equally, the availability of appropriate toys for a given age has an impact on development. For instance, multiple studies document that the presence of books in a household is correlated with the child's language development. While the key component of this language development is the adult–child interaction related to books, having books readily available is an important component to foster both language development and early literacy skills. The toys need not be elaborate or expensive, but can play a major role in facilitating development at a given age. For instance, for a toddler, access to a plastic cup and plate, as well as couple of pots and pans and a big wooden spoon will help foster imitation and early pretend play.

Familial Influences on Development

As mentioned above, families have a profound impact on their children's development, especially in the areas of cognition and language, although other areas of development can also be influenced by family environment. The time and attention given to the child by family members and the qualities of that attention play a major role in infant and toddler development. However, families continue to have a major impact on development in older children as well. For example, the academic success of high school age youngsters is highly correlated with whether or not the family eats meals together routinely as a family.

Children today are raised in families with a wide variety of family composition. Western countries are unique in having nuclear households be the norm. For most societies, extended families live in the same household or are frequent household visitors and all play a major role in child rearing. When the nuclear family assumes the major or sole responsibility, features about the family potentially can have more impact on the child. The idealized American two-parent household is only advantageous if the parents agree about basic childrearing and both are actively involved. Single parent households are more challenging, not because a single parent cannot do a good job of rearing his or her child, but because the stresses of earning a living, managing the day to day responsibilities and childrearing are falling on one person alone. This is complicated by the fact that many single parent households struggle much more financially, thus diverting time and energy from the tasks of child rearing. There are now multiple studies that also confirm that having gay or lesbian parents does not impact child development. Children reared by same sex couples do as well on average both developmentally and behaviorally as children reared in more traditional households.

Similarly, family composition in terms of number of children and the spacing of children has minimal effect on child development, if all other things are held constant. When family composition seems to be related to child development, the key factor is usually other stressors, such as the stress of more mouths to feed, challenges posed by a particular child in the household, or parental over-commitment to careers at the expense of time and energy devoted to child rearing.

Parental mental health has a clear impact on children's development. Young children with depressed mothers demonstrate substantial delays in cognition and language. They are likely to have a higher incidence of internalizing mental health problems as they get older as well. This impact can be moderated if there are other adults in the household who can take over the role of providing responsive, caring interactions with the young child on a regular basis. Similarly, there are several studies now that have shown an association between having a parent in the household who has aggressive behaviors or problems controlling his or her temper and a child's risk for demonstrating aggressive behaviors. Children in abusive households have long-term consequences for development,

their mental health, and their adult physical health at least partially related to the impact of stress on the developing brain.

Societal Influences on Development

Most children are influenced not just by their families but also by other social institutions in their communities. Multiple studies demonstrate that the quality of childcare has a clear impact on children's development. Children who are enrolled in high quality childcare with low child to caregiver ratios and with caregivers who are nurturing and provide a stimulating environment do well. For children from households where there is limited nurturing possibly due to financial hardships or exhausted parents, this quality childcare or preschool can make a dramatic difference in the child's success in language development and acquisition of academic skills. The long-term studies from the original Head Start Programs in the USA indicate that such a comprehensive preschool program can also have an impact on the children's ability to graduate from high school and avoid involvement in illegal behavior in adolescence.

Similarly several studies look at qualities of schools and the impact these qualities have on the academic and social success of their students. While class size does make a difference, it takes a dramatic decrease in class size to have a substantial impact on the children's academic success. On the other hand, schools with high expectations for their students' ability to be successful, who display and celebrate students' good work, and who encourage active involvement by students and faculty in decision making at the school level have students who perform better.

Extensive research has examined the impact of media on child development. Clearly there is a role for media in enhancing development, when media is used constructively, in moderation, and at the correct age. The American Academy of Pediatrics has strongly stated that children under age 2 should not watch television or videos, saying that it does not enhance development and detracts from time and energy that should be spent in interactive activities with the child. For older children, the impact of television watching is less clear, although children with high levels of television viewing are likely to have lower grades in school, more symptoms of depression, and more problems with obesity. Additional concerns center on the effects of violent programs for children and the impact these have on children's emotions and the strategies they use to address interpersonal conflicts.

The impact of institutional care can be profound on the children who need the help of institutions outside the family for their rearing. Research on children in orphanages in the former USSR countries by numerous authors has clearly demonstrated that those children from orphanages have long-term impairment in physical growth, cognition, and behavior, despite having their basic needs met. The staff members are too busy to have meaningful interpersonal interaction with their charges which leads to the deficits seen. Children who were removed and put into foster care in the same country had substantially better outcomes although the differences in outcome depended on what age they went to the orphanage, staffing at the particular orphanage, and how long the child stayed at the orphanage.

For children for whom home is not a safe or healthy place to remain, foster care remains a viable option. However, the stability of the placement and the quality of care have substantial impact on the development and mental health of the child. Long-term foster care, especially if it involves replacement in different households, clearly has negative consequences for the youngster. Children have better outcomes when foster placement is a short-term solution and the child is either reunited with their family who is now able to care for the child or who is adopted by a family committed to the development of the young child.

Chronic Illness and its Influence on Child Development

The impact of chronic illness on child development is dependent on multiple, complex factors. Development usually draws on input from all senses resulting in special challenges for children with sensory impairment. A child who cannot see will have difficulties in learning to name objects. A child who cannot hear will not be able to develop spoken language until the hearing problem is corrected. Children with cyanotic heart disease, chronic renal failure, or other disorders that affect their energy levels will be influenced by their lack of energy as well as by the altered focus of parent attention. However, in most chronic illnesses, the child's development can proceed normally. Some children may, in fact, have advanced understanding of some complex concepts such as illness causation.

Stress and Child Development

Stress is an inherent component of life. Research on stress suggests that some "stress" promotes child development by motivating the child to seek and master challenges. The steps to mastering those challenges may well be "stressful"

but the cognitive processes by which the child seeks to solve the problem to master the new skill enhances, not detracts, from his development.

However many stresses are beyond those of typical life. These can include illness or death of a family member, loss of family income, parental promotion at work, a household move, addition of a new sibling, parental separation or divorce, national or local disaster, etc. Refer to Chap. 50, "Children in Disasters", for a more extensive discussion of the effects of stress on the developing child.

Summary

Children's development is a complex process, partially determined by genetic factors but heavily influenced by the key people in the child's life and the events that happen throughout the developmental stages. Parents, and others caring for children, can play a central role in fostering development by being sensitive to the developmental stage of the child, his unique personality and temperament, and the kinds of stimulation and opportunities which will best foster development for the individual child. Helping the child build on his individual strengths and helping him find ways to master the developmental tasks of each stage and work around the challenges of his individual situation will help produce a mature, resilient young adult.

43 Behavior Management of Medical Problems

Yamini Jagannath Howe · Robyn Mehlenbeck · Jack H. Nassau · Pamela High

Introduction

In pediatric practice, it is common to encounter medical conditions that are complicated by the complex relationship between parent and child, as well as by the child's own temperament and beliefs about his or her own illness. For a number of common problems such as colic, encopresis, poor feeding, and insomnia, a combination of medical and behavioral interventions is often needed for optimal management. Furthermore, chronic medical illnesses in childhood often have behavioral comorbidities that complicate their treatment. As a result, pediatricians are often called upon to design behavior plans to complement medical treatments. The goal of this chapter is to help physicians understand and be able to develop and implement behavior plans with their patients.

In developing an effective behavioral program, the following components should be taken into consideration: (1) developing and maintaining positive parent–child interactions; (2) defining the behavior to be changed; (3) measuring and monitoring the target behavior; (4) setting a behavior change goal; (5) developing specific strategies to change the behavior; (6) implementing and evaluating the behavior program; and (7) maintaining behavior change (*Table 43.1*). Each of these steps will be discussed in detail, utilizing several case examples.

A basic knowledge of types of learning and common behavioral management techniques is also useful in designing a behavior plan, and these are summarized in *Tables 43.2* and *43.3* for your reference. These will be helpful to refer back to as three clinical cases are presented, each highlighting a different developmental stage, and addressing specific behavioral considerations and interventions.

Case 1: Infant with Colic and Feeding Problems

Ming is a 5-month-old infant, who was born to 29-year-old Suyin. Suyin has a history of depression and migraines. Ming was born full-term via C-section due to breech presentation. His father is away, fulfilling a military obligation. Because of long-standing fussiness around feeding, Suyin gave up nursing Ming. It now takes up to one hour to feed Ming with a bottle because he gags, spits up, and hiccups during and after his feedings. Physical examination is normal, weight gain has been appropriate, and he is developing well. His mother has tried three different formulas and many different nipples trying to get Ming to eat. She reports that he wakes every hour in the night to feed, and "catnaps" in the day in his mother's arms. She reports a total sleep time of 6–8 hours out of 24. Ming cries especially hard in the evenings and does not have a consistent bedtime. He has a hard time falling asleep at night. His mother sometimes resorts to running the vacuum close to him or taking him on a late-night car ride to get him to fall asleep. Suyin also reports that Ming wakes every hour at night requiring her help to return to sleep. Suyin admits that she is exhausted and near the end of her rope. She questions her adequacy as a mother.

Although crying is a common complaint among parents of infants, prolonged crying can negatively affect the parent–child relationship and can lead to increased parental symptoms of anxiety and depression. Infants with colic may also have difficulty with feeding, and the relationship between this infant's crying and feeding difficulties can be examined and addressed using the Seven Steps to Behavior Management model (*Table 43.1*).

1. *Developing and maintaining positive parent–child interactions*: Before implementing any behavior strategy, it is important to establish a foundation of trust and to nurture the bond between parent and child. In general, increasing the number of positive interactions parents have with their children leads to a decrease in the number of negative interactions between them. Enriched or enjoyable environments provide a basis for the use of time-out or ignoring as an effective deterrent of negative behaviors. Finding ways of rewarding a child, even an infant, for desired behaviors, rather than punishing him for undesired behaviors, tends to be a more effective way of changing behavior.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_43,

Table 43.1
Seven steps to behavior management model

1. Develop and maintain positive parent–child interactions • Conflict related to medical and behavioral issues is common. Increasing positive interactions is essential to successful behavior management. A positive, soothing regular bedtime routine and a media-free family mealtime where parents and children share their daily experiences are two examples of ways to implement this.
2. Define the behavior to be changed • What behavior do parents want to change? Define a behavior that can be measured and tracked so that progress can be determined.
3. Measure and monitor the target behavior • Set up a recording chart, diary, or journal for baseline data collection of the target behavior.
4. Set a behavior change goal • Set a measurable, specific, obtainable goal
5. Develop specific strategies to change the behavior • Review all strategies to be implemented, have a recording system (sticker chart, diary) to monitor progress
6. Implement and evaluate the behavior program • Emphasize consistency, monitoring, and reinforcement as appropriate.
7. Maintain behavior change • Often involves gradually fading the external reinforcement

There may be many barriers that make it difficult to establish positive interactions between parents and their children. For example, parents may feel overwhelmed with the responsibilities of parenting; or other jobs or relationships may impact parents' abilities to enjoy their time with their children. In addition to teaching parents to attend to even small instances of positive child behavior, specific behavioral techniques such as *special time* (see *Table 43.3*) can be implemented to increase positive interactions between children and parents.

In this case, positive interactions between Suyin and Ming may be limited due to the stress of single parenting while Suyin's husband is completing military service, along with Ming's sleep difficulties and Suyin's resulting exhaustion from her own disrupted sleep. Screening for maternal depressive symptoms is important, given her history, and its potential influence on her parenting behaviors. Review of Ming's growth and development can provide reassurance to Suyin that her son is doing well despite his feeding and sleep issues. The clinician should help Suyin identify times when she can enjoy her time with Ming. Often early in the day is preferable, because both she and Ming may feel the most rested at that time. The provider/pediatrician could discuss simple activities such as singing, looking at books, cuddling together, "tummy-time," "peek-a-boo" and other play activities. When providers point out how well a child is growing and developing and compliment parents for their hard work and for being responsible for these gains, this enhances the provider–parent relationship and can also model how praise can also enhance the parent–child relationship.

2. *Defining the behavior to be changed*: It is important to be specific when determining what the goals are in behavior management. At the outset, it is often helpful to work collaboratively with parents to "break down" complex goals or behaviors into simpler component behaviors that can be measured and observed for improvement. Although the temptation may be to tackle the most bothersome behavior first, it is often helpful to choose a small and simple behavior to address initially, even if the family has many concerns. Success with changing the initial behavior will empower parents to have more confidence and become more invested in addressing additional, more difficult, behaviors.

In Case 1, Suyin is clear that she wants Ming to cry less and sleep more. During infancy, sleeping, crying, and feeding are very closely associated with one another. Before attempting to change these behaviors, it would be most helpful to understand Ming's crying, sleeping, and eating behaviors. Tracking when, how long, and where Ming is crying and sleeping, as well as how these interact with his feeding schedule is a logical first step.

3. *Measuring and monitoring the target behavior*: The effectiveness of any treatment is difficult to assess without a measurable outcome. As such, if a behavior cannot be measured and monitored, then it would be difficult to develop an intervention to change it, because any objective change would be very difficult to discern. Measuring and monitoring involves counting the frequency, the intensity, and the duration of a behavior. The "ABCs" – that is, the *Antecedents* to the *Behavior*, and its *Consequences* – should also be noted. These should all be documented in written form. Parents often learn about the behavior they are interested in changing during this step, for example, realizing that it happens more or less often than they thought or that it has a pattern of antecedents or consequences associated with it. Just by monitoring Ming's crying, feeding, and sleep, Suyin is likely to feel more in control of what is happening, and more likely to identify times where she can implement positive time or other helpful strategies. *Figure 43.1* (Infant Behavior, Cry and Sleep Diary) illustrates one tool that can be used to measure and monitor infant behaviors.

Table 43.2
Types of learning and their clinical application

Types of learning	Examples	Application
1) Classical Conditioning (also called *Pavlovian Conditioning*) is a type of learning related to an automatic or *reflexive response* to a specific stimulus	A child comes to associate the pediatrician's office with painful immunizations. When he goes to the office for any cause, the child becomes anxious, fearing getting a shot. A child with leukemia becomes nauseated while dressing to go to her chemotherapy appointment.	This type of learning plays a role in the development of phobias, food aversions, and school refusal. Interventions often include gradual exposure to the *conditioned stimulus* (pediatrician's office) paired with a more desirable stimulus (children's book or sticker rather than immunization) to decrease the response (fear). This is called *counter conditioning*. Classical conditioning can also teach desired behaviors: e.g., a bedwetting alarm wakes a child when she begins to wet.
2) Operant Conditioning (also called *Stimulant-Response Learning*) is a type of learning that occurs in response to environmental consequences. Operant behaviors are influenced either by *antecedents* to the behavior, or *consequences* of the behavior. Consequences may either increase the behavior (*positive and negative reinforcement*) or decrease the behaviors (*punishments or deterrents*).	A preschooler swears when he becomes frustrated. His older brother laughs when he hears it. The preschooler interprets his brother's laughter as approval and swears more because he enjoys his brother's attention.	This type of learning often plays a role in the development of 3 types of behavioral concerns: 1. *Behavioral excess* (e.g., aggression or tantrums) 2. *Behavioral deficiency* (e.g., toileting or food refusal) 3. *Inappropriate behaviors* (e.g., inappropriate dress, language, or touching). Interventions to increase or decrease the frequency of these behaviors focus on consequences following the behavior. Interventions aimed at changing the time or place of the behavior focus more on antecedent events.
3) Social or Observational Learning is a third type of learning that occurs through *modeling* or *imitation*. This learning may be either purposeful or incidental.	Parents may inadvertently promote undesired behaviors such as smoking by modeling them, even while talking about the dangers of this habit. Actions often speak louder than words.	Children learn most commonly by watching those most important in their world (family, friends, celebrities) and then by emulating them. The influence of the model on the child's behavior increases with the child's perceived similarity to the model and the status and success of the model in the child's view.

This Infant Behavior, Cry and Sleep Diary is used to monitor patterns of infant sleep, feeding, and crying behaviors. Number of hours spent fussing, crying, sleeping, awake, and eating should be totaled at the bottom as measurable data to be used for comparison. Diaries can be color-coded with highlighting markers to ease interpretation and to facilitate comparisons across 2–3 days and from week to week.

In this Case, a diary approach is useful, because the behaviors Suyin is trying to address are highly interrelated. This diary records feeding, crying, sleeping, and awake behaviors in 15 min intervals, as illustrated in ❯ *Fig. 43.1*, and should be kept for 2–3 days. Although monitoring behavior every 15 minutes for even a day or two is labor intensive, in clinical settings, in developed countries, more than 80% of parents can collect these data

Table 43.3

Behavior management techniques and their applications

Behavior management technique	Examples	Application
1) Time-in: Parents are encouraged to have frequent and brief positive physical, verbal, and visual contact with their child throughout the day, whenever the child is engaged in non-problematic behaviors. *When a child's behavior is praiseworthy, it should be praised consistently*. There are many variations of Time-In that are commonly advocated to teach children desired behaviors. These include advice to find moments to praise children in order to "*catch them being good*" and to have regular "*Special Time*" or "*Me Time*"	With "*Special Time*," parents plan an opportunity to observe their child's positive behaviors, perhaps during a creative activity and make sure that they praise the child for her effort and accomplishments. "*Me Time*" is time in which the child generally chooses what she wants to do within reason. The child is given choices from an array of desirable activities that usually include parental involvement. This should occur frequently, optimally daily. Naming the time "Me Time" or "Andrew Time" often elevates it in stature in the child's view.	"*Time-in*" *is an essential prerequisite for any behavioral management program*. *Special time* should not be removed as a punishment. *Time-in* and *special time* are conducive to a child's learning appropriate behaviors and her motivation to cooperate. They are more helpful when they occur often and regularly (but are not necessarily longer than 10–20 min), than when they are much longer but occur only rarely.
2) Time-out: The child is given time away from *positive reinforcers* such as desired activities or family attention. This is one of the most common forms of punishment used in most behavior management programs. In order to be effective, *time-out* should happen immediately and consistently after the targeted misbehavior. The duration of a *time-out* is generally short (approximately 1 min per year of child age) but may need to be extended if the child continues to misbehave or protest when the "time-out" would be expected to conclude (using a timer is recommended). *Time-out* is most effective with *time-in* and when applied to infrequent dangerous, or destructive behaviors.	1. Make a short and clear command or request of the child ("Please stop. . .") 2. Give a clear warning if the child does not respond to the request ("if you don't do what is asked, then you will have to sit in *time-out*"). 3. If the child does not complete the command or request, administer *time-out*. Select a location with as few pleasurable distractions as possible (i.e., the bottom step of a staircase, or a chair in a boring part of the room) and do not reason or talk with the child. *The child should be completely ignored during time-out*	*Time-out* is most effective in 2–6 year olds, but can be effective in older children as well. Be prepared in case the child refuses to go to time-out. Effective alternatives are adding additional time or, if the child still refuses, giving the child a choice of either going to *time-out* or losing a privilege. Following a *time-out*, the original command or request should be repeated. If the child does not comply, repeat the procedure. Once the child has complied with the request and the *time-out* is over, it should be forgotten, rather than dwelled upon.
3) Stimulus control: Controlling behavior by limiting access to antecedents that served to increase that behavior.	An overweight boy who drinks many sugar-filled sodas each day can be aided in decreasing this habit when his family decides that the whole family will only drink sodas on Sundays. Sodas are only available in the house on that day.	As in any technique, collaboration is key. Making sure the child is aware of the rule/expectation prior to implementing the strategy will be necessary in order to minimize protests from the child.
4) Differential reinforcement of incompatible behavior (DRI): Reinforcing a behavior that is not compatible with the behavior that is targeted for extinction.	A child with dermatitis exacerbates her condition by scratching in her sleep. *DRI* might include praise and a desired outing after a specified number of successes in wearing cotton gloves at night to limit scratching.	There are several types of differential reinforcement; however, the overarching principles include reinforcing wanted behaviors and withholding reinforcement for unwanted behavior.

Table 43.3 (Continued)

Behavior management technique	Examples	Application
5) Shaping: Gradually increasing a behavior by giving positive reinforcement to small increments (*successive approximations*) of the target behavior. Most commonly used to develop a new behavior pattern.	A preschooler who is refusing to eat vegetables is rewarded with a sticker first for allowing the vegetable to sit on her plate, then for touching the vegetable, then for smelling it, then for licking it, then for tasting it, then for eating a bite. A row of stickers earns a trip to the ice cream store.	*Steps* (*successive approximations*) should be identified before attempting to shape a behavior. Carefully outlining small increments of the behavior will facilitate success for the child and minimize frustration in the process.
6) Systematic desensitization: Gradually increasing a child's exposure to an anxiety-producing stimulus in order to enable him to gradually overcome his anxiety.	A child with school avoidance based on fear of bullying may be gradually exposed to school by attending one class on the first day, two classes on the second day, etc. while other supports like counseling are in place. This is also very effective with children who fear medical procedures.	*Systematic desensitization* is most commonly used in children who exhibit difficulties with anxiety. This technique usually includes careful instruction in relaxation training.
7) Fading: Gradually decreasing a *positive reinforcer* as a desired behavior becomes integrated into routine. This is the natural response once a new behavior is learned. Fading also refers to changing something gradually.	Once a toddler learns not to jump on the couch, he may not need to get hugs for each time period that he refrains from jumping. Gradually moving bedtime earlier by 15 min every 3 days is another use of fading.	*Fading* can often be used to reduce the level of protests displayed by a child. Gradually changing a behavior instead of abruptly changing it commonly results in less confrontation.
8) Planned ignoring (*extinction*): Withdrawal of all attention when a child is engaging in an unwanted behavior. Ignoring should only be used in situations that are nondangerous and nondestructive.	A toddler who often throws tantrums when wanting an unhealthy snack can be *ignored* by the parent who continues to perform another act (e.g., reading book, cleaning up, etc.) until the child's escalation ceases. Most useful for behaviors such as whining, tantrums, pouting, and arguing	*Ignoring* should include no physical contact, no verbal contact, and no communication non-verbally (i.e., no making faces, eye contact, etc.). Expect an *extinction burst* or an initial sharp increase in the child's unwanted behavior; however, with continued use, the unwanted behavior will decrease.
9) Redirecting: Changing the child's attention from one interest to another.	A toddler sees a child eating an apple and whines for an apple herself. Her mother does not have an apple to give and so she redirects her daughter's attention to the dogs across the street playing in the yard.	Redirection is most effective in younger children.
10) Corporal Punishment: Application of *physical pain* as a *punishment* with the goal of discouraging unwanted behavior.	Spanking and other physical punishments are commonly used for discipline. However, with recurring use, increasing intensity may be required to attain desired decrease in problem behavior, which can lead to significant injury. It can also result in other discipline methods losing their effectiveness. Parents should be assisted in learning other techniques to deal with problem behavior in children.	Research suggests that corporal punishment teaches children that hitting is acceptable, negatively alters parent–child relationships, and results in aggression in children. In addition, corporal punishment is not more effective than other discipline approaches.

Infant Behavior, Cry and Sleep Diary

During each 15 min period of the day you are to indicate the main activity of your baby.

The baby behaviors you will record are: **F** = Fussing **C** = Crying **S** = Sleeping **E** = Eating **A** = Awake

_____ _____ _____ _____
Day of the Week Month Day Year

12MN 1AM 2AM 3AM 4AM 5AM 6AM 7AM

8AM 9AM 10AM 11AM 12noon 1PM 2PM 3PM

4PM 5PM 6PM 7PM 8PM 9PM 10PM 11PM

Where baby falls asleep (**S** = swing, **A** = arms, **B** = parents' bed, **Ba** = bassinette, **C** = crib, **CS** = car seat)
Place above the block designating onset of a sleep episode. If baby is bottle feeding, put volume that is taken above times he/she is eating.

Best 5 min of the day _____

_____

Figure 43.1
Infant Behavior, Cry and Sleep Diary

dependably and find the results informative and helpful. Diaries can also be used to prompt parents to note the "best 5 minutes of the day," which practitioners can use to help build on existing positive interactions between parent and child (as discussed in Step 1).

In review of her behavior diaries, Suyin noticed that Ming only woke up every 3 hours at night, not every hour. Ming slept only 10–11 hours out of 24; although this was more than his mother's perception, her concern was validated because it was less than what would be expected for his age. Furthermore, his sleep phase was noted to be shifted with a bedtime after midnight and late morning waking. Evenings were especially difficult with 3–4 hours of crying after 7 PM. His feeding times were prolonged, and she was feeding him only 1½–2 ounces every 1½–2 hours.

4. *Setting a behavior change goal*: After a period of monitoring, the clinician should help the parents identify patterns in the occurrence of the observed behavior, and help them develop a desired goal. It is important to set realistic goals so that the patient and family can experience success early in the course of treatment. Success encourages the family – and child – to continue the program. Over the course of an intervention, the patient and family should be encouraged to set a number of intermediate goals on the way to achieving the goal that is ultimately desired.

Because of Suyin's current level of stress, it will be especially important to set an initial behavior change goal that she thinks is attainable, even if it is only a relatively small step toward her ultimate goal for Ming. Going to bed earlier is a common goal for parents of infants, as is having their child learn to fall asleep without needing to be held, rocked, or otherwise loved to sleep. Decreasing the length of Ming's feedings may be another goal in this case. Based on review of the diaries, Suyin decided that she wanted Ming to fall asleep earlier in the evening, perhaps between 7 and 9 PM rather than after midnight, and to learn to fall asleep on his own.

5. *Developing specific strategies to change the behavior*: Once a goal has been established based on initial measuring and monitoring, specific strategies may be incorporated into a behavior plan aimed at changing the behavior in order to reach the goal. Selection of specific strategies should be based on what appears to maintain the unwanted behavior. The main components of the plan will be to alter the antecedents and the consequences of the behavior. In deciding what changes to make, it is

helpful to have the parent write down the specific changes/goals decided upon. This will help them remember what they plan to do after leaving the clinician's office.

With her behavior goals in mind, Suyin develops a plan with her clinician that utilizes many behavioral management elements. Moving Ming's crib out of her room will allow Suyin to sleep through normal sleep activity, such as Ming's sighs in his sleep, and attend only to clear signals requiring her help. Slowly shifting his bedtime earlier by about 30 min every few nights, while simultaneously moving his wake time earlier in the morning, will gradually *shape* his sleep cycle. Developing a soothing bedtime ritual such as giving him a bottle in his room with low lighting, then a quiet activity such as soothing music and reading together, ending with placing Ming in his crib drowsy, but awake, will help to develop pleasant sleep-onset associations. Keeping any night-wakings "business only" by feeding Ming and putting him back into his crib as quickly as possible will limit positive reinforcement for his waking in the night.

After waking him in the morning, she plans to keep him active for several hours, and space the amount of time between his feedings to every 3 hours. During the day, she will put him into his crib for naps at regular times after a shorter version of his bedtime routine, not letting naps exceed 2 hours. In addition, observation of Ming's feeding in clinic, in conjunction with his mother's diaries and reports, is suggestive for painful gastroesophageal reflux, and a trial of medication is simultaneously initiated.

6. *Implementing and evaluating the behavior program*: Following the development of specific behavioral strategies, parents are faced with the challenge of implementing the plan and evaluating their child's behavior change. It is okay to emphasize how difficult it is to start and maintain a program. Consistency is critical, however, and it is important to brainstorm things that might get in the way of consistency. For example, letting a child cry at night is very difficult for parents. If the plan includes leaving their baby in his crib after the nighttime routine, discussing what a family will do when the baby cries is important. It may be decided that the parent will check on the baby briefly to ensure that there is no immediate concern, say a soothing word or two, and then leave without picking the baby up. Working together with parents on how this will help them achieve their goal will likely increase the consistency in which parents are able to implement the plan set at home. A monitoring form should be part of this plan for parents and the clinician to see what changes are occurring. Often adjustments to the plan need to be made, and that is hard to do if ongoing monitoring is not done.

Once a program has been implemented for a specified period of time, usually a minimum of 1–2 weeks, behavioral change should be observable. The clinician should have the family carefully track targeted behaviors and should regularly meet with them to assess the quality and effectiveness of the strategies being implemented. Comparisons to monitoring from before the plan was implemented will help determine whether the behavioral goal is being met and when additional behavioral goals may be set. If behavioral goals are not being met, the clinician must discuss this with the family, explore possible reasons, and modify the behavioral program, usually by modifying antecedents and/or consequences.

Suyin will need to continue to keep diaries of Ming's behaviors and bring them to her next follow-up appointment. Based on progress, new intermediate goals and new strategies can be developed. At follow-up 2 weeks after implementing the plan, Ming is falling asleep by 9:30 PM in his crib with only a little whimpering and waking three times at night to feed. Naps are more problematic and sporadic. Ming continues to fall asleep in his mother's arms or in his swing for afternoon naps, but is sometimes placed in his crib once asleep. He is feeding a larger quantity of food, less often in the day. On medication, he continues to have occasional spitting up, but no longer cries during or after feeds, and the feeding duration has decreased to less than 30 min per feeding.

7. *Maintaining behavior change*: The ultimate goal of a behavioral program is to maintain behavior change. It is very easy for parents and children to fall back into old habits, as well as stop positively reinforcing the new habits. It is also important to predict that there will be setbacks, and discuss how to address them. In situations where parents and other parents are attempting to decrease an undesired behavior, clinicians should provide education about the likelihood of an *extinction burst*, a period when the frequency of the undesired behavior increases before decreasing. For example, it is important to remind the parents of infants that it will be difficult to ignore their baby's cries at night, because this will involve ignoring their own instincts to comfort their child. Once they have made the decision to do so, the baby will likely cry louder and harder in the attempt to gain his parents' attention. If the parents remain steadfast in their resolve to ignore his cries, their baby will quickly learn to go back to sleep again if extended crying does not get their parent's attention.

Suyin's ability to recognize improvement in Ming's sleep, and its association with her own improved sleep and mood, will encourage her to set additional goals, for example, providing a consistent routine for afternoon

naps in Ming's crib. She decides to wait for stronger signals from Ming at night before feeding him, thereby stretching out times between feedings in the night, *fading* (gradually eliminating) the reinforcement of prompt feeding in the night. Suyin does not interpret putting Ming down drowsy but awake and letting him settle and possibly fuss as a *time-out* or punishment, which would have been unacceptable to her. Instead she sees this strategy as teaching him an important skill, that he can put himself to sleep with supports (his regular bedtime and routine), and no longer need to listen to the vacuum to fall asleep. Of course, she may need to modify her responses in the night if Ming gets sick or if the family travels. Nonetheless, having successfully modified sleep behavior once, Suyin has a good chance of revising her strategies to help Ming get his sleep back on track after a disruption in schedule.

Case Summary

In this case of a 5-month-old infant with prolonged crying, decreased sleep, and symptomatic gastroesophageal reflux, a combination of medication and behavioral management has resulted in improved feeding, sleeping, and crying behavior patterns. Ming's bedtime routine and his mother's plan to encourage him to learn to fall asleep on his own in his crib utilizes both *classical* and *operant conditioning learning* techniques as described in Table 43.2 as well as many of the common behavior management techniques described in Table 43.3. Ming begins to associate his sleepiness, his bath, his full tummy, the low lights, the music, the room, and his crib with sleep onset. When he wakes in the morning, or after a sufficient nap, the positive attention he receives from his mother when they spend time playing together reinforces his appropriate sleep behavior.

Case 2: Child with Encopresis

Varesh is a 10-year-old boy who has been otherwise healthy, but who has 1–2 fecal soiling accidents per day. His parents report that he is very bright and is doing well in second grade. He has two older siblings, both of whom are toilet trained on time and had no problems. Varesh has soiling accidents occasionally at school, but mostly at home. He has never gone more than 2 days without a soiling accident, but has not had any eneuretic accidents since being fully toilet trained for urine by age 3. Varesh's parents do not understand why he continues to have accidents. They have tried everything, including yelling, pleading, bribing, and punishing him, and this has become a daily struggle. His medical history is otherwise benign, and his physical examination reveals fullness of the abdomen and a large amount of stool in his rectum.

Functional fecal incontinence with chronic constipation is a common problem among children which is often *silent* – that is, a family secret. What often begins as toilet avoidance, leads to chronic constipation. Retained stool in the distal colon becomes dehydrated and may become hard, forming a fecolith. Nerve endings become habituated to chronic distension of the colon, and become insensitive. The colonic wall musculature is distended around the fecolith, and becomes ineffective in contracting to propel it forward. Newly formed, softer stool leaks around the fecolith, resulting in incontinence. The child usually has no sensation that they are "leaking", and often have also become desensitized to the foul smell. Treatment requires a bowel "clean-out" that softens the impacted stool and empties the colon. Remission requires a long-term maintenance plan aimed at medication and dietary modifications to maintain softened stool, and ongoing monitoring to ensure that the child's stools are soft and that elimination occurs at least every 1–2 days.

1. *Developing and maintaining positive interactions*: In many cases of encopresis, parents and their children report increased negative interactions, largely around the incontinence, and a decrease in any positive interactions. In fact, almost all parent–child interactions may end up being about incontinence. It is important to find out what positive interactions are occurring with both parents and siblings. It is also important to assess the parent's beliefs about the cause of encopresis. For example, do they believe the child is doing it willfully? Such a belief will likely contribute to negative interactions and attributions, neither of which is helpful in resolving the encopresis. Prior to starting the intervention, parents should be educated about the pathophysiology of encopresis, have an open discussion about the shame the child and family may be feeling, and should find ways to enjoy some time together.

For Varesh, his incontinence is a source of embarrassment for him and his parents, and has become a source for contention in the household. His parents do not understand how a bright, social, second grader can have soiling accidents. All they talk about is how to make him stop soiling. Thus, the first step will be redefining some of their interactions, learning what they enjoy doing together, and what they would enjoy talking about if they were not spending time talking about his toileting behaviors.

2. *Defining the behavior to be changed*: With encopresis, the target behaviors are fairly easy to define – stop soiling and start having regular bowel movements in the toilet.

Everyone is in agreement with the goal, but they need guidance on how to achieve it. This is true for Varesh's family. Varesh has expressed interest in learning how to control his encopresis, but he feels hopeless. He also does not want to disappoint his parents again.

3. *Measuring and monitoring the target behavior*: The next step is to get an accurate assessment of the antecedents, behaviors, and consequences. This involves monitoring what happens prior to soiling incidents, including the time of day, location, and who the child is with; what happens during the soiling incident, including describing the incident itself and quality of stools; and what consequences follow the incident, such as whether he leaves his class, is punished, or loses some privileges. An example of an encopresis monitoring chart is seen in *Fig. 43.2*.

This monitoring sheet can be used for a child with toileting problems. This type of table is a useful tool which focuses on improving both quantitative (number of minutes spent sitting) and qualitative (attitude) measures.

Patterns may emerge that are helpful in both setting behavior change goals and identifying strategies that will be most helpful. Varesh's monitoring showed he consistently has two soiling accidents per day, typically on the way home from school and after dinner. He has mostly smearing and leakage, but occasionally a larger amount of watery stool. His current consequence included changing and washing his own clothes, as well as his parent's frustration and disappointment.

4. *Setting a behavior change goal*: A behavior change goal should be specific and measurable. Behavior change also targets the *behavior*, not the outcome. A certain outcome is expected when behavior changes, but if the outcome alone is targeted, it is likely to fail. Based on the patterns and behaviors that emerge from monitoring, a specific, measureable goal can be set. For encopresis, a typical goal is "sitting on the toilet" after meals, after school, and before bed each day. Clearly, it is expected that the child will start stooling in the toilet, and it will be tracked continuously, but the initial behavior goal is to comply with the toilet-sitting plan.

Varesh was not happy about starting a toilet-sitting plan and was worried about doing this at school. It was agreed to start on a long weekend, so that he could get used to the plan. His family also contacted the school nurse and a plan was set up for Varesh to use the private bathroom in her office after lunch and immediately prior

Varesh's daily monitoring sheet
Day of week:_____ **Date:**_____

Time/Activity	Time	Number of minutes	Amount of stool produced if any	Played videogame- Yes or NO	Attitude – scale 0 (problem) to 3 (pleasant)
Sat on toilet first thing in morning					
Took morning medication:____					
Sat on toilet after breakfast					
Sat on toilet after lunch					
Sat on toilet after dinner					
Sat on toilet at bedtime					
	Time	Amount	Attitude		
Soiled pants					
Soiled pants					
Wet pants

Sample encopresis monitoring chart

to leaving school. A bowel cleanout was scheduled with his pediatrician for a Friday afternoon after school. His behavior change goal of sitting on the toilet at regularly scheduled intervals started immediately afterward, in conjunction with a plan for medications aimed at maintaining soft stools.

5. *Developing specific strategies to change the behavior*: A combination of *special time*, *stimulus control*, and *positive reinforcement* is used to address encopresis. Highlighting that parents need to have some *special time* with their child each day that does not revolve around the problem is a key strategy. Setting up a scheduled toilet-sitting plan provides *stimulus control* – increasing the opportunity for the desired behavior of stooling in the toilet and decreasing the opportunity for soiling accidents. *Positive reinforcement* is key to engaging the child in the plan. Given that no one enjoys spending extra time on the toilet, it is important to make this a time that is acceptable. For example, many children enjoy playing a handheld electronic game that is only available at this time. This can be designated as time to play for 10 minutes while trying to go to the bathroom. The child could also read a preferred book. The goal is to engage the child in making an attempt to stool in the toilet. In addition, a reward can be set up for consistent compliance with the behavior expected. For example, if a child complies with the toilet-sitting plan 85% of the time over a two day period they will earn a special reward. This reward is also an opportunity to reinforce special time with a parent, rather than an expensive, material reward.

Varesh and his family agreed to set up a chart to track his toilet-sitting time, taking of his medication, and his *special time* of playing one game of chess with his father each night. In addition, if he completes 90% of his sitting times without complaint, he will earn a movie out with a friend the following weekend. Note that a goal of 100% completion should not be set, because if the child cannot achieve perfection, motivation for continuing the behavior will plummet. Because Varesh was motivated to increase his time with his father and go out to the movie, he was less likely to resist sitting on the toilet at home and at school.

6. *Implementing and evaluating the behavior program*: In implementing a behavior strategy, all involved parents must be in agreement and demonstrate a clear understanding of the plan and be prepared to give rewards or punishments appropriately. The consistency, immediacy, and saliency of each reward or consequence should be emphasized to the parent. That is, rewards or consequences should be given each time the behavior occurs, should be given at the time it happens, and should be meaningful to the child. The clinician should model appropriate use of the techniques, and allow parents to practice in the office. Parents and older children might also work together to develop a behavioral "contract" that outlines the behavioral goals as well as the specific rewards and consequences that will be used; such contracts can be signed by parents and children to indicate their agreement with the plan.

Varesh's parents, although skeptical about a chart being effective when they had already "tried" everything, agreed to the plan and the rewards discussed. They did not want to involve the school at first, but agreed, given the frequent soiling accidents on the way home from school. In the first week, Varesh's accidents decreased by 50%. He was both surprised and proud, as were his parents. This helped increase his motivation for the second week. Over several weeks, his monitoring charts showed that he was more likely to have an accident in the early evening, and had only one all week on the way home from school. Thus, the plan was slowly modified to eliminate the "after lunch" sitting, and give him an additional sitting in the evening.

7. *Maintaining behavior change*: Once the behavior goal has been achieved, the clinician can help the parents begin the process of *fading* reinforcement in order to gradually decrease reliance on immediate reinforcement to maintain the behavior. For example, parents could offer reinforcement every two or three times a behavioral goal is met rather than every time; *fading* reinforcement would continue until the behavior is reinforced at a much lower rate. Other ways of decreasing reinforcement include reinforcing groups of behaviors, rather than single behaviors, or reinforcing with desired privileges rather than material rewards.

Varesh was able to decrease his soiling accidents to 1–2 per week within the first month. During this time, Varesh slowly trained his body to recognize the signs of having to go to the bathroom and became more aware of his own body's signals. With consistency maintained on his toilet-sitting plan, medication regimen, and increased positive time with his parents, he continued to experience increased success in staying continent. Varesh and his family agreed to maintain the toilet-sitting plan for several months after he was totally continent to maintain his success. At that time, they decreased the toilet-sitting plan slowly, first eliminating the morning sitting and the before bed sitting because these rarely produced stools.

Parents should be made aware of three challenges to maintaining behavior change: (a) reinforcers losing their saliency, (b) parents not naturally maintaining new behavioral methods once adequate behavior change is established, and (c) children not maintaining behaviors

as reinforcement is faded. Practitioners should talk with parents about these challenges in the context of follow-up appointments, the frequency of which will depend on how well the plan is working. For encopresis, maintenance must be attended to for at least 6 months, as the colon continues to heal. Setbacks should be expected, and a rescue plan to increase medication if stools harden should be an element of this plan. Ideally, just as parents fade reinforcement of established behaviors over time, practitioners will titrate the schedule of follow-up appointments such that families are seen less frequently over time.

Case Summary

In this case of a 10-year-old boy with primary encopresis, continence was achieved by establishing a medical bowel regimen, and implementing a behavior plan to increase compliance with appropriate toileting behaviors after a full bowel cleanout procedure. The plan was reinforced by positive time with his father and weekly rewards for adherence with the behavioral expectations. As a result, he achieved bowel continence for the first time and maintained his success.

Case 3: Adolescent with Difficulty Adhering to her Medical Regimen

Maria is a 16-year-old girl with insulin-dependent diabetes who had been controlled relatively well through close monitoring by her parents. Like most teenagers, Maria now spends more and more time with her friends, and her parents no longer provide the supervision that they once did. Her parents also think that because she is older, it is her responsibility to take charge of her own care. Unfortunately, Maria has not been testing her blood sugar or giving herself insulin as scheduled, nor has she been keeping to her diet, particularly when she is out with her friends. As her diabetic control has deteriorated, arguments in the home have increased.

Adherence to medical regimens among children and adolescents with chronic medical conditions is a common problem, and a combination of educational and behavioral approaches can be effective. Adolescence, in particular, can be a time of increased parent–child conflict as teenagers struggle to achieve independence from their parents. For the adolescent with a chronic disease, adherence to treatment can become another context in which parent–child conflict arises. From the parental perspective, the difficulty of altering adolescent adherence behaviors may be increased because of decreased supervision and a desire for the adolescent to take on more responsibility for their own health. But from the adolescent perspective, adherence is made difficult because of immature judgment and decision-making skills as well as the increasingly social context in which adherence behaviors must occur.

1. *Developing and maintaining positive interactions*: As in other cases, developing and maintaining positive parent–child interactions is important to provide the base from which to enact a behavioral plan to improve adolescent treatment adherence. Given the increased conflict that naturally occurs during adolescence, many parents step back too much and do not realize how important ongoing positive time with their teenager can be. Highlighting some positive time that is not related to any medical issue is critical. Another option is helping parents take advantage of the adolescent's natural drive for independence. The clinician can encourage parents to identify areas in which the adolescent can exercise independence without jeopardizing her health, such as how the adolescent dresses or keeps her room. Parents can also be encouraged to provide positive reinforcement for particular ways that the adolescent has asserted independence or responsibility in an appropriate way. For example, they should praise and reward her for helping to care for a younger sibling, or for working hard in school.

In the case of Maria and her parents, almost all of their interactions have become around medical care (or lack thereof), and being "grounded" from going out with her friends unless she takes better care of herself. Maria and her mother agreed to go get coffee together once a week and not discuss anything related to her diabetes during this time.

2. *Defining the behavior to be changed*: Ultimately, Maria's parents want her to take more responsibility for her own diabetes management. The clinician should help the family break down this goal into smaller parts by having the family outline the steps needed for diabetes management. They should then identify steps that she is already achieved, as well as areas with which she has difficulty. Outlining details in this way can have the effect of helping members of the family realize that adherence is difficult, because of everything it entails, and also aid in identifying areas of adherence that are more or less problematic. The clinician can then help Maria's family pick a specific aspect of adherence to be addressed initially. Research with adolescents with Type I Diabetes also shows that if parents collaborate with the teen on picking a specific goal, they are more likely to be successful.

Maria and her family decide to address the behavior of blood glucose testing and insulin administration when she is out with friends. Note that this assumes that Maria has the knowledge and technical skills necessary to perform these tasks; if this is not the case, then further diabetes education will be necessary before she can be expected to carry out these tasks with her peers.

3. *Measuring and monitoring the target behavior*: A behavior chart that lists the adherence behaviors to be monitored and allows for record-keeping each day as to whether the behavior was performed would be a useful way for Maria and her parents to monitor the chosen target behaviors. If possible, an electronic glucometer that records and reports time and results of blood glucose testing could be used to verify her records. *Figure 43.3* provides an example that can be modified depending on the age and specific behaviors targeted for increased medical adherence.

This type of chart is a variation of the standard "Sticker chart" used for encouraging typical childhood activities, such as chores and homework completion. In this case, it has been applied to diabetes care, but can be applied to any situation to empower children to take control of their own behavior. The level of detail and reward amount can be varied according to the developmental level of the child.

Maria and her family agree that she will monitor her blood glucose several times a day, and record when she administers her insulin. Each evening her mother will sit down with her to review the glucometer and write the blood sugar readings in her log.

4. *Setting a behavior change goal*: Although the ultimate goal is for Maria to fully perform her diabetic care when with peers, the clinician can help the family agree on some intermediate goals. For example, an initial goal could be for Maria to demonstrate increased independence in adherence behaviors at home. In addition, the family might agree to set a goal in which only a portion of adherence behaviors need to be done independently at the outset. Once this has been achieved, the family could then set goals for independent blood sugar testing in certain peer situations where success may be more likely, such as when Maria is with a small group of friends who know about her diabetes, before setting the goal for this to occur in all peer situations. For example, initially Maria needs to test her blood glucose 75% of the time while at home and

Maria's diabetes plan

	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
Test blood sugar 4x/day	★						
Give myself shots and write down on log	★						
Keep room clean							
Do homework before calling friends							
Eat Healthy							
Sit with mom to review glucometer							

35 Stars = Special activity with friends

Figure 43.3
Sample diabetes sticker plan

50% of the time while out with friends. Once she achieves this goal, she will earn an outing with her friends paid for by her parents. She will then be ready to increase the adherence necessary to earn the next reward.

5. *Developing specific strategies to change the behavior*: Identifying strategies for adolescents can be more complicated than with younger children. The keys are determining what motivates the adolescent, what stimulus control strategies would be effective for this family, and reinforcing the family collaboration. In Maria's case, her strong desire to spend time with her friends can be used as a motivator and to *positively reinforce* success with behavioral goals. A consequence for lack of diabetic care when with friends could be less time with friends. *Stimulus control* techniques, such as setting up times with friends to specifically include circumscribed needs for adherence behaviors (for example, meeting a friend for lunch for 1 hour) might also be employed, or having friends come to the house when it involves an extended period of time, so that parents are around to ensure adherence. Maria's family decided to use increased *time-in* with friends as a reward. They also agreed that parents could send Maria a text message when it was time to test her blood glucose if she was out.

6. *Implementing and evaluating the behavior program*: With respect to implementation, Maria and her family could consider what role Maria's friends might play. Her peers may be in a position to encourage and support her in meeting her adherence goals. Other issues to consider are that Maria's parents may be setting increased limits about the amount of time she is allowed to spend with peers, and this could increase conflict between them and Maria. One strategy to reduce this conflict may be for Maria's parents to help her identify times she can be with friends when diabetic adherence behaviors are not routinely required. If Maria's glucometer can provide electronic recording, there are ample data to evaluate whether adherence behaviors are being conducted and in what contexts. With such information, Maria and her parents will know whether the goals are being met and when additional goals, either with respect to achieving the same behaviors more often or in new contexts, or becoming more independent in other adherence behaviors (e.g., accurate carbohydrate counting) can be introduced.

7. *Maintaining behavior change*: One specific issue to maintaining behavior change in this case is Maria's ability to generalize the skills of independent adherence behaviors to new contexts such as summer jobs or after-school activities. Similar strategies of having Maria gradually increase her involvement in such activities as she demonstrates appropriate adherence could be considered. Another issue, that is similar to maintaining behavior change in other cases, is Maria's parents' ability to continue to monitor her success despite their desire for her to function independently. The clinician should provide praise and encouragement to the family, using the data of Maria's success as evidence of the importance of their efforts and to reinforce their continued involvement. Over time, the family can be guided to gradually reduce their involvement and assess the effect of that change on Maria's adherence.

Case Summary

Maria, a 16-year-old with Type I Diabetes, presented with her family due to non-adherence to her diabetic regimen. By helping the family reengage with positive interactions, identify all the aspects of Maria's regimen, and then target two specific behavioral goals, Maria was able to improve her self-care and continue to work collaboratively with her family to improve her diabetic control.

When to Refer

Given the constraints of the primary care clinician and the complexity of some cases, there are times when it advisable to refer the family to a behavioral specialist. In particular, this course of action is recommended in cases where the behavioral concerns are complicated by significant family dysfunction, child psychopathology, or when the practitioner does not have adequate time to provide such treatment.

Conclusions and Further Applications

A behavior management approach, involving the seven basic steps outlined in *Table 43.1*, can be effective in treating common medical problems in childhood. In this chapter, cases of colic, functional encopresis with constipation, and poor medication adherence have been presented, but these principles apply to numerous medical and behavioral concerns. This is also true in the case of children with autism and other developmental disabilities, where an applied behavioral approach has been used in helping children to work toward functional independence. For example, a behavioral program for parents of children with autism can be accessed at http://media.mindinstitute.org/education/ADEPT/Module1Menu.html. Resources have been included below for further reading and to direct practice.

44 Sensory Disorders

Heidi M. Feldman · Maria A. Salinas · Brian G. Tang

Vignette

Jose was diagnosed in the newborn period with congenital cytomegalovirus infection because of a distinctive rash and liver enlargement. As part of the initial work-up, he had a full audiological assessment and was found to have mild to moderate sensorineural hearing loss. He was appropriately fitted with hearing aids by 6 months of age and tolerated the aids well. His first words emerged when he was 16 months old and he progressed steadily in language development for 2–3 years. However, repeat audiological testing at age 36 months revealed a moderate to moderately severe hearing loss. At that point, his parents began learning sign language and he became bilingual in spoken and signed language. By the time he was 5 years old, he was enrolled in a special education program for children with hearing impairment and deafness because his hearing continued to deteriorate. Though he was able to speak, he easily became fatigued in verbal environments when he had no interpreter for sign language. At age 9 years old, audiological assessment revealed a profound hearing loss and he became a candidate for cochlear implantation.

Introduction

Sensory impairments are a diverse set of problems in either sensing environmental stimuli using one of the five major senses, converting the information into nervous signals, passing the signals through the nervous system and brain, and/or using the information to accurately interpret objects and events in the world. Definitions, classifications, and causes of sensory impairments vary for the five sensory systems. This chapter focuses on impairments of vision and hearing. These senses are the best studied and most likely to have profound significance on the overall functioning of infants, children, and adolescents, as evidenced in the vignette described. The chapter will briefly discuss disorders of olfaction and gustation together because they are interrelated. It will also include a brief description of disorders of touch, including pain, though refer to Chap. XX for a more extensive discussion of pain.

Visual Impairment

Definitions/Classification

Visual acuity is typically assessed in terms of the ability to read fonts of specific sizes from specific distances. If normal vision is considered 20/20 in feet in the USA, visual impairment is defined as vision of 20/70 or worse after treatment or refractive correction. This fraction means that the person sees at 20 ft what individuals with normal vision see at 70 ft. Blindness is defined for legal purposes in the USA as visual acuity less than or equal to 20/200 in the better eye or a visual field of less than 20° diameter. The World Health Organization, using the metric system, defines low vision as the visual acuity after best correction of less than 6/18 m and equal to or better than 3/60 in the better eye. Blindness is defined as less than 3/60 or a visual field less than 10° from the point of fixation. The World Health Organization also has a functional definition of blindness that is the inability to use vision for the planning and/or execution of a task for which vision is essential.

Epidemiology

Approximately 1.4 million children in the world are blind. In low-income developing countries with high rates of mortality for children under age 5 years, the prevalence of visual impairment is 1.5 per 1,000 children. In high-income countries with low child mortality rates, the prevalence drops to 0.3 per 1,000 children. Approximately 87% of visually impaired people live in developing countries. More than 12 million children ages 5–15 are visually impaired because of uncorrected refractive errors (nearsightedness, farsightedness, or astigmatism); these are conditions that could be easily diagnosed and corrected with glasses, contact lenses or refractive surgery.

In the USA, in 2000, the Metropolitan Atlanta Developmental Disabilities Surveillance Program found 1.2 per 1,000 8-year-olds had vision impairment, or a rate of 1 in 833. Between 50% and 66% of these children had other impairments. The same survey found that 7/10,000 children were legally blind.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_44,

Etiology and Pathogenesis

Abnormal vision may be categorized as myopia (near sightedness or limited ability to see distant objects), mydriasis (farsightedness or limited ability to see near objects), reduced visual fields, or imbalanced use or acuity of the two eyes (strabismus and amblyopia). Visual impairment in children can be acquired or congenital. In developed countries, genetic diseases of the optic nerve and higher visual pathways predominate. Retinopathy of prematurity is another important cause. In developing countries, acquired problems predominate. These include corneal scarring from measles; inadequate light sensitive pigments from vitamin A deficiency; trauma from the use of harmful traditional eye remedies; ophthalmia neonatorum and other eye infections from *Neisseria gonorrhoeae*, *Staphylococcus*, *Streptococcus pneumoniae*, and *Chlamydia trachomatis*; and cataracts from rubella. In all countries, congenital abnormalities such as cataracts, glaucoma, and hereditary retinal dystrophies are significant causes of visual impairment. The National Library of Medicine maintains a comprehensive list of genetic causes of visual impairment at (http://ghr.nlm.nih.gov/conditionCategory=eyesandvision).

The pathogenesis of visual impairment may be conceptualized as a disruption of one or more structures or functions of the eye and visual pathways. *Table 44.1* reviews some of the many causes of visual impairment as a function of the affected anatomical structure. For example, corneal opacities and blindness caused by *Chlamydia trachomatis* are highly prevalent in poor rural areas of Africa, Asia, Central and South America, Australia, and the Middle East. Onchocerciasis, an insect-borne disease caused by a parasite *Onchocerca volvulus*, is the world's second-leading infectious cause of blindness and is most prominent in African countries. Trauma, intraocular hemorrhage, ocular inflammatory disease, and intraocular tumor are important causes of glaucoma in the pediatric population. Infectious diseases are a frequent cause of cataracts in childhood and corticosteroids are the most important pharmacological agents that produce cataracts in the pediatric age group. Cataracts may be a sequela of eye trauma from child abuse.

Retinopathy of prematurity (ROP) is a pathologic process of immature retinal tissue that can progress to retinal detachment and functional or complete blindness. Children born prematurely should receive examinations by an experienced ophthalmologist to detect and treat ROP, following the guidelines and recommendations for management of ROP promulgated by professional organizations. Retinoblastoma is the most common primary malignant intraocular tumor of childhood. The initial sign in the majority of patients is often a white pupillary reflex (leukokororia), a reflection of light off the white tumor rather than the red retina.

Optic nerve hypoplasia is associated with defects of vision and of visual fields of varying severity, ranging from blindness to normal or near-normal vision.

Clinical Manifestations

The impact of visual impairment on an infant or child is highly variable, related to the age of onset, severity of and type of visual loss, the presence of other conditions, and psychosocial factors. Important signs of visual impairment in infancy may be poor tracking and following, nystagmus, and limited interest in brightly colored objects. Smiling may look unusual or may diminish over time. Parents may notice abnormalities in eye movements, including wandering eye movements or a gaze fixed in one direction. Infants may not blink or cry in response to a looming or threatening gesture. As children age, they may have complaints of poor vision. Mobile children tend to fall or bump into objects. School-aged children may be unable to read.

Even with typical intelligence, a child who is blind from birth or early childhood may experience delays in fine and gross motor development. Language development may also be delayed since speech is aided by imitating mouth movements as well as by listening to sounds. Clinical manifestations also relate to accompanying disabilities.

Diagnosis

Examination of the eyes should be performed beginning in the newborn period and at all well-child visits. Newborns should be examined for ocular structural abnormalities, such as cataract, corneal opacity, and ptosis. Vision assessment beginning at birth has been endorsed by US professional organizations. All children who are found to have an ocular abnormality or who fail vision assessment should be referred to a pediatric ophthalmologist or an eye care specialist trained to treat children.

The eye evaluation in the physician's office should include ocular history, vision assessment, external inspection of the eyes and lids, ocular motility assessment, pupil examination, and red reflex examination in infants birth to 3 years of age and older. In children 3 years and older, age-appropriate visual acuity measurement is important.

Table 44.1

Causes of visual impairment by type of condition and anatomic structure

Type of condition	Anatomical structures							
	Lid	Cornea	Anterior chamber	Iris	Lens	Retina	Optic nerve and visual pathway	Cortex

Neoplasm	Capillary hemangiomas Lid tumors			Wilm's tumor with aniridia		Retinoblastoma	Pituitary adenoma	

Tests of visual acuity vary by age. Vision assessment in children younger than 3 years or any nonverbal child is usually limited to the child's ability to fixate on an object, maintain fixation, and then follow the object throughout various gaze positions. Failure of the child to perform these maneuvers may indicate significant visual impairment. If poor fixation and following is noted for both eyes after 3 months of age, a significant bilateral eye or brain abnormality should be suspected. Vision assessments in children older than 3 years can usually be accomplished in the pediatrician's office. *Table 44.2* summarizes methods for assessing vision in the pediatric office.

Photoscreening is an innovative adjunct to vision screening for children who are difficult to screen, including infants, toddlers, and children with developmental delays. A photograph is produced by a camera under specific lighting conditions, which shows a red reflex with both pupils. A trained observer can identify ocular abnormalities by identifying changes in the photographed pupillary reflex. This method does not substitute for testing visual acuity but it can identify strabismus, refractive errors, media opacities, and retinal abnormalities.

Tests of visual fields vary by patient cooperation. External examination of the eyes includes penlight examination of the lids, conjunctiva, sclera, cornea, and iris. Persistent discharge or tearing may be attributable to ocular infection, allergy, or glaucoma.

The assessment of ocular alignment in preschool children is important since the development of strabismus may occur. Slow or poorly reactive pupils may indicate significant retinal or optic nerve dysfunction. The red reflex test can be used to detect opacities along the visual axis, such as cataract or corneal abnormality, and abnormalities of the back of the eye, such as retinoblastoma or retinal detachment.

Treatment

The first step is treating the underlying condition causing visual impairment, such as using surgery to relieve hydrocephalus or antibiotics to cure infections. Treatment of clinically significant cataracts often requires surgical removal of the lens and subsequent correction of the resultant refractive error with glasses, contact lenses, or a lens implantation. Infantile glaucoma often requires surgical treatment. Treatment of ROP includes cryotherapy or laser photocoagulation of the retina to stop the progression of the disease. Advances in vitreoretinal surgical techniques have led to limited success in reattaching the retina in infants with total retinal detachment (ROP stage 5).

Glasses may correct refractive errors, disorders of eye movement and alignment. According to the World Health Organization, Vision 2020 partners have been actively involved in addressing the causes of childhood blindness and developing pediatric eye care services where interventions are amenable to prevention and treatment. Rehabilitation for individuals with visual impairment includes optimizing functional capabilities and quality of life. The multifaceted process involves the assessment of visual capabilities and the evaluation of functional performance (e.g., reading, writing, and mobility) within the context of employment, family activities, attitudes, and psychological well-being. Most vision rehabilitation strategies involve prescribing assistive devices (magnifiers and other optical devices) or providing training. Environmental interventions may help individuals to function well at home, in the workplace, and/or out in public places. For the child with low vision or blindness, reading readiness for Braille begins in kindergarten. Braille uses raised dots on a page to allow individuals who are blind to access written language. Research is focusing on the development of new devices and application of advanced technologies to develop visual and/or sensory substitution aids.

Prognosis

The prognosis for the child with severe visual impairment depends on the amount of residual vision, the child's intellectual functioning, the motivation of the child and the family, and the quality of education and training the child receives. Some eye conditions such as cataracts, glaucoma, diabetic retinopathy, and retinitis pigmentosa are progressive, worsening over time.

Prevention

Worldwide approximately 85% of visual impairment and 75% of blindness can be prevented or cured. Many strategies are available. Early detection and prompt treatment of ocular disorders in children is important to avoid lifelong visual impairment. Correction of refractive errors with glasses could restore normal vision to more than 12 million children ages 5–15 years old. Vitamin A supplements not only improve vision but also reduce child mortality in areas where Vitamin A deficiency is a public health problem. National vaccination programs have reduced the prevalence of eye complications of infectious diseases. Testing for and treating prenatal infections prior to delivery may prevent congenital infections. The use of silver nitrate or erythromycin prevents neonatal

Table 44.2
Eye examination guidelines

Function	Recommended tests	Stimuli	Response	Referral criteria ages 3–5 years	Referral criteria ages 6 years and older
Distance visual acuity	Snellen	Different letters and numbers on a wall chart 10 ft from child	Verbal identification	*For all tests*: <4 of 6 correct on 20-ft line with either eye tested at 10 ft monocularly (i.e., less than 10/20 or 20/40) Or Two-line difference between eyes, even within the passing range (i.e., 10/12.5 and 10/20 or 20/25 and 20/40)	*For all tests*: <4 of 6 correct on 15-ft line with either eye tested at 10 ft monocularly (i.e., less than 10/15 or 20/30) Or Two-line difference between eyes, even within the passing range (i.e., 10/10 and 10/15 or 20/20 and 20/30)
	Tumbling E	The capital letter "E" in different spatial orientation on a wall chart 10 ft from child	Manually showing the direction the E are pointing:		
	HOTV	Large H O T V letters on a wall chart 10 ft from child	Pointing to matching letter on the testing board		
	Allen figures	Seven schematic figures on wall chart 10 ft from child	Verbal identification		
	LEA symbols	Spiral flash cards with four figures	Verbal identification		
Ocular alignment	Cross-cover test	Distant object	Movement of the uncovered eye	Any eye movement in or out when shifting the cover indicates strabismus	Same referral criteria as ages 3–5 years
	Random dot E stereo test	Stereo blank card and the raised and recessed "E" card simultaneously	Manually showing the direction the "fingers" of the E are pointing	Fewer than 4 of 6 correct	Same referral criteria as ages 3–5 years
	Simultaneous red reflex test (Bruckner test)	Direct ophthalmoscope examination	Red reflexes seen from each eye	Any asymmetry of pupil color, size, or brightness	Same referral criteria as ages 3–5 years
Ocular media clarity (cataracts, tumors, etc.)	Red reflex	Direct ophthalmoscope examination of eyes separately	Red reflexes seen from each eye	White pupil, dark spots, absent reflex	Same referral criteria as ages 3–5 years

infectious eye disease. Prevention of ROP ultimately depends on prevention of premature births and its attendant problems. However, appropriate management of ROP can reduce visual impairment.

Over the life span, reducing exposure to UV-B with sun glasses reduces cataracts. Cataracts can also be prevented by reducing cigarette smoke and alcohol consumption. Protective eye wear is important for preventing eye injuries in certain sports.

Hearing Impairment

Definitions/Classification

Hearing acuity is assessed in terms of the amount of energy, measured in decibels (dB) that is required to detect sounds across a range of frequencies between 250 and 8,000 Hertz (Hz). Normal hearing in children is defined as a hearing threshold better than 20 dB,

depending on the reference. Hearing loss is defined as an inability to hear specific frequencies at the appropriate intensity. Hearing loss in childhood is classified as mild (20–40 dB threshold), moderate (41–54 dB threshold), moderate-severe (55–70 dB threshold), severe (71–90 dB threshold), and profound (>90 dB threshold). Thresholds can vary as a function of frequency. When differences in the threshold occur, higher frequencies are typically more severely affected than lower frequencies. Deafness is defined functionally as a hearing impairment that is sufficiently severe that the individual is impaired in processing linguistic information through hearing, even with amplification.

Epidemiology

The World Health Organization estimates that worldwide over 65 million people have hearing impairment that originated in childhood. Childhood hearing impairment affects 2–4 per 1,000 live births in developed countries and upwards of 6 per 1,000 in developing countries.

In 2000, The Metropolitan Atlanta Developmental Disabilities Surveillance Program reported that hearing loss was estimated at 1.2 per 1,000, or about 1 in 833, 8-year-olds. The same survey found that nearly 25–33% of children had one or more other developmental disabilities.

Etiology and Pathogenesis

Hearing loss generally falls into three categories – conductive, sensorineural, and mixed – related to the anatomic section of the ear in which an abnormality occurs. The external ear (pinna and ear canal) collects and focuses sound waves on the tympanic membrane, which converts acoustic energy into mechanical energy that pass through the ossicular chain of the middle ear. Conductive hearing loss occurs when transmission of sound information is mechanically disrupted through the external and/or middle ear. The cochlea of the inner ear converts these vibrations into hydraulic energy that move hair cells along the organ of Corti, causing neural impulses to be transmitted into the midbrain and higher cortical structures. Sensorineural hearing loss (SNHL) occurs when hair cells in the inner ear fail to transmit neural impulses normally within the cochlea or when problems disrupt nerve transmission down the acoustic division of the eighth cranial nerve (vestibulocochlear nerve). Mixed hearing loss involves both conductive hearing loss and SNHL, and typically represents damage to both middle and inner ear structures. A less common type of hearing loss in children is central hearing loss, in which the functional or structural lesion affects the auditory pathways from the brainstem to cerebral cortex.

Hearing loss can be acquired or congenital. *Table 44.3* reviews causes as a function of the anatomic structure affected. The most common form of hearing loss is genetic. Approximately 50% of SNHL cases are inherited, either with hearing loss isolated or associated with other abnormalities as one feature of a clinical syndrome. Over 500 syndromes with hearing loss have been characterized. Approximately 70% of inherited causes of SNHL are labeled nonsyndromic because they have no accompanying impairments. In this group, 80% have an autosomal-recessive mode of transmission. Mutations of the gene encoding the protein connexin 26 (Cx26) on chromosome 13 account for almost half of all nonsyndromic autosomal-recessive hearing loss representing the most common genetic cause of hearing loss. The National Library of Medicine maintains a comprehensive list of genetic causes of hearing loss at (http://ghr.nlm.nih.gov/conditionCategory=earnoseandthroat).

Cytomegalovirus (CMV) is the most common infectious cause of congenital SNHL. Congenital SNHL caused by maternal rubella, mumps, and measles have become uncommon in the developed world due to the advent of vaccination programs. These infectious diseases, however, continue to be significant risk factors for children born in developing countries where large segments of the population are unimmunized.

Extracorporeal membrane oxygenation (ECMO) is a significant risk factor for congenital SNHL that is progressive in nature. Hyperbilirubinemia and kernicterus are causes of damage to the auditory nerve that are more prevalent in the developing world than in the developed world.

Acquired causes of SNHL (e.g., high intensity noise, ototoxic medications, meningitis, and trauma) are progressive and permanent in most cases. Therefore, careful and close monitoring by an audiologist after one of these exposures is recommended, even when hearing tests are initially normal.

Most conductive hearing loss is acquired. The most frequent cause of conductive hearing loss is otitis media with effusion in which the hearing loss is transient and typically minimal to mild in severity. Structural anomalies of the external ear, canal, or middle ear are rare congenital causes of permanent conductive hearing loss.

Table 44.3
Causes of hearing impairment by type of condition and anatomic structure

Type of condition	Anatomical structure			
	Associated with conductive hearing loss		Associated with sensorineural hearing loss	
	Outer ear (e.g., external auditory meatus)	Middle ear (e.g., tympanic membrane, ossicular chain)	Inner ear (e.g., cochlea) and/or Auditory pathway	Cortex
Structural abnormality	Microtia Atresia of the ear canal	Congenital anomalies of the tympanic membrane Ossicular chain malformations	Anatomical abnormalities of the cochlea and temporal bone Auditory dysynchrony	Central hearing impairment
Genetic conditions and systemic disorders	Treacher–Collins syndrome Goldenhar hemifacial microsomia Branchio-oto-facial syndrome (BOF) Stickler syndrome Deletion 18 Q syndrome	Treacher–Collins syndrome Goldenhar hemifacial microsomia	Connexin 26 disorders Mitochondrial disorders Hyperbilirubinemia Waardenburg Syndrome Neurofibromatosis 2 Usher syndrome (problems of vision) Complications of Rh incompatibility	Neurodegenerative disorders Demyelinating disorders Alport syndrome (renal failure) Perinatal anoxia ECMO
Infection or inflammation	Otitis media externa Foreign body with inflammation	Tympanic membrane perforation Otitis media Cholesteatoma Mastoiditis	TORCHS infections Meningitis Lyme disease Measles HIV	Congenital rubella Encephalitis
Toxicity and metabolic conditions			Ototoxic drugs in pregnancy (e.g., isoretinoin) Aminoglycosides Loop diuretics (e.g., furosemide) Chemotherapy regimens (e.g., cisplatin)	
Trauma	Physical damage Cauliflower ear	Penetrating injury Scarring	Hypothyroidism Diabetes Noise-induced hearing loss Head trauma	Head trauma
Neoplasm			Acoustic neuroma	

Clinical Manifestations

The impact of hearing impairment on an infant or child is highly variable, related to the age of onset, severity of and type of hearing loss, the presence of other conditions, and psychosocial factors. Hearing loss in neonates and young infants may be associated with minimal clinical signs. For this reason, universal screening programs are important for early detection of hearing loss. Infants with hearing impairment may show diminished response to sounds and excessive vigilance toward visual stimuli. Delayed language milestones and age-inappropriate unintelligible speech are common associated findings of hearing loss in toddlers and young children. Other findings include behavioral difficulties or academic failure. Unilateral hearing loss may be detected when children show a unilateral preference for using a phone or appear disoriented when trying to indentify sources of sounds, such as turning toward people calling their names.

Older children, adolescents and adults with hearing loss may complain of decreased or muffled hearing or difficulty understanding what people say, particularly in the presence of competing auditory stimuli. Difficulties understanding language make it difficult to participate in social interactions. For this reason, affected individuals may complain of fatigue after a long social interaction. Some individuals experience tinnitus as the first symptom of hearing loss.

Screening and Diagnosis

Universal newborn hearing screening (UNHS) programs have been successfully implemented in several developed countries. Unfortunately, most developing nations lack such programs, contributing to a high rate of children and adults with undiagnosed hearing impairment. The Joint Committee on Infant Hearing recommends UNHS before 1 month of age. A behavioral or clinical assessment does not accurately detect hearing loss in children less than 6 months of age. Typically, screening occurs after birth in the hospital nursery using either evoked otoacoustic emission (OAE) or an automated auditory brainstem response (ABR). OAE detects emitted sounds generated by the cochlea in response to auditory bursts of clicks or tones. ABR detects and measures electroencephalographic waveforms in the auditory and brainstem nerve pathways via skin electrodes. OAE and ABR are both rapid and inexpensive screening tools that do not require voluntary responses from the child. Infants who fail this initial screen should be referred for a comprehensive audiology evaluation by 3 months of age and receive appropriate interventions by 6 months of age if diagnosed with a hearing loss. The full ABR, which includes frequency specific information, is the gold standard for determining hearing thresholds in infants younger than 6 months and in children who cannot be tested behaviorally. These recommendations were based on seminal studies showing that hearing impaired children developed language at the same rate as normal hearing peers if they were identified and treated by 6 months of age.

Some types of congenital hearing loss are late-onset or progressive and not evident until late childhood or even adolescence. Acquired hearing loss due to infections, trauma, or other genetic risk factors may present after infancy. Children with risk factors for hearing loss (*Table 44.4*) should be referred for a minimum of one diagnostic audiology assessment between 24 and 30 months of age, even if they passed newborn screening. One important risk factor is caregiver concern that a child might have hearing loss. In one study, caregiver concern was found to be a better predictor of hearing loss than an informal behavioral examination by the physician.

All children with possible hearing loss warrant a thorough physical examination as part of the evaluation and assessment. Careful examination of the ear canal and tympanic membrane may reveal causes of conductive hearing loss, including impacted cerumen, otitis media with effusion, foreign bodies, or a perforated tympanic membrane. Examination of the head and neck may reveal findings associated with several syndromic forms of hearing loss. Important physical findings include ear pits, microtia, cleft lip and palate, malformation of the external ear structures, and atypical pigmentation of the skin and eyes.

Any child who fails a hearing screen or shows signs or symptoms of hearing loss requires a referral to an audiologist for a comprehensive evaluation to confirm and define the nature of the hearing loss. Audiometry quantifies a child's hearing sensitivity, assists in qualifying the site of the lesion, and provides a clinical impression of the child's auditory functioning. Conventional behavioral audiometry is typically used to assess cooperative children 3–4 years or older. Tones of various frequencies (typically from 250 to 4,000 Hz) are delivered through headphones and various transducers (e.g., bone conduction oscillators). The child is instructed to respond when the tone is heard. For younger children, the use of play or visual reinforcements can condition and motivate a child to respond when auditory stimuli are presented. Often, these procedures are done in a sound field and the results represent the hearing of the better ear if a difference exists.

Tympanometry is a standard part of all audiology evaluations and can be performed in a general pediatrician's office. It measures the mobility of the tympanic membrane, providing a reliable assessment of middle ear pressure and function. Tympanometry is used to help diagnose middle ear disorders including otitis media with effusion and perforated tympanic membranes. It does not, however, directly assess hearing.

Treatment

Amplification through hearing aids is the most common treatment for children with SNHL. Hearing aids can be fitted on children as soon as the loss is identified. Regular audiology follow-up is necessary to monitor the child's hearing sensitivity and to make adjustments to the hearing aids. Children with hearing impairment, even with appropriate and early amplification, should be assessed

Table 44.4
Risk factors associated with hearing loss in childhood

Risk factors for early-onset hearing loss	Risk factors for delayed-onset or progressive hearing loss
Neonatal intensive care hospitalization >5 days	Caregiver concerns regarding hearing, speech, language, or developmental delay
Mechanical ventilation	Family history of progressive childhood hearing loss
Family history of permanent childhood hearing loss	Extracorporeal Membrane Oxygenation (ECMO)
Exposure to ototoxic medications (e.g., gentamicin, furosemide)	Head trauma, especially those requiring hospitalization or affecting the temporal/basilar region
Hyperbilirubinemia requiring exchange transfusion	Postnatal infections associated with sensorineural hearing loss, including confirmed bacterial and viral (herpes viruses and varicella) meningitis
In utero infections, such as herpes, rubella, syphilis, and toxoplasmosis	Cytomegalovirus in utero infection
Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies	Chemotherapy (e.g., cisplatin)
Physical findings, associated with a syndrome known to include a sensorineural or conductive hearing loss	Syndromes associated with hearing loss or progressive or late-onset hearing loss (e.g., neurofibromatosis, Pendred syndrome, Usher syndrome)
Recurrent or persistent otitis media for at least 3 months	Neurodegenerative disorders (e.g., Hunter syndrome) or sensory motor neuropathies (e.g., Friedreich ataxia)
	Excessive noise exposure

Adopted from Joint Committee on Infant Hearing (2007) Year 2007 position statement: principles and guidelines for early hearing detection and intervention programs. Pediatrics 120(4):898–921

by a speech and language therapist and enrolled in treatment if necessary to improve their communication skills. Children with SNHL should also be followed by an audiologist for management of the hearing loss.

Cochlear implants are prosthetics that have been successful in improving outcomes for children with profound hearing loss, even if the loss is congenital or prelingual. These implants work by transforming sound that is picked up by an external microphone into digital neural impulses that are sent directly to the auditory nerve, bypassing the Organ of Corti. Hearing through a cochlear implant is qualitatively different than normal hearing. However, coupled with intensive postimplantation therapy, children can often acquire speech and language. Many children treated with cochlear implantation are able to participate in mainstream education. Early implantation during infancy has the advantage of exposing children to sounds during the period of development when children with normal hearing are acquiring speech and language skills.

Children with some types of conductive hearing loss are medically or surgically treatable and can restore normal hearing. Guidelines have been developed for the judicious use of antibiotics in acute otitis media and chronic otitis media. In some cases, surgical procedures are appropriate. Tympanostomy tube placement has not improved outcomes for otherwise healthy and typically developing children with persistent chronic otitis media with effusion. However, they may be important for children with preexisting hearing loss or other conditions. For children with severe to profound hearing loss, with or without cochlear implantation, education in sign language may provide the child with a useful primary or supplemental communication system. Sign language has all of the features of verbal language and uses hands, body postures, and facial expressions to convey meaning.

As molecular genetic testing becomes more refined and inexpensive, genetic testing will play a greater role in assisting clinicians in the treatment and management of children with hearing loss. Genetic testing and counseling is recommended for families of children with SNHL or a syndrome associated with hearing loss.

Hearing loss in children may result in significant impairment in function and developmental delay. These children depend on other senses to communicate. Therefore, an evaluation of the child's overall development and functioning, including vision, should be included in the work-up of all children with a hearing impairment.

In addition to the technologies used to treat children with hearing impairments, an interdisciplinary and family-centered approach is needed to ensure that these children have the educational and emotional supports to be successful in schools and their communities.

Prognosis

The early identification of children with hearing impairment provides opportunities for effective early treatments to prevent or minimize lifelong deficits in linguistic, cognitive, academic, and socio-emotional functioning. Successful treatment of hearing loss in children depends on several factors. The most important factor is the age at which the hearing loss was diagnosed and treatment initiated. When compared to delayed or no treatment, early treatment of hearing loss leads to early interventions and more favorable outcomes with regards to the child's language development, cognitive functioning, and future academic performance.

Prevention

The World Health Organization estimates that half of all cases of deafness and hearing impairment are avoidable through prevention, early diagnosis and appropriate management. Healthy People 2010 identifies several objectives for reducing the prevalence of functional problems caused by hearing loss. They include (1) increasing the number of newborns who get their first hearing test before they are 1 month old; children found to have a hearing loss should get additional testing before they are 3 months old, and should be enrolled in rehabilitative services by the time they are 6 months old, (2) decreasing the number of ear infections in children, and (3) increasing the number of individuals who are deaf or hard-of-hearing who use habilitation services and adaptive devices, such as hearing aids or cochlear implants. Immunizations have led to prevention of congenital hearing loss from rubella. Immunizations for *Haemophilus influenzae* and *Streptococcus pneumoniae* have led to reductions in rates of otitis media and meningitis with resulting prevention of hearing loss.

Another major initiative is to decrease noise-induced hearing loss. About 30 million Americans are exposed to dangerous levels of noise every day and 10 million Americans already have hearing loss from noise. Sounds that can cause damage include a chainsaw (110 decibels, or dB), ambulance siren (120 dB), 12-gauge shotgun (165 dB), hair dryer or gas-powered lawn mower (90 dB), and a rock concert or firecracker (140 dB). A common risk factor for hearing loss in children and adolescents today is the use of earbuds to listen to music on portable audio players. Regular exposure to 110 dB for more than 1 min risks permanent hearing loss. More than 15 min of unprotected exposure to 100 dB also is damaging. Prolonged exposure to any noise above 85 dB can cause gradual hearing loss. Prevention includes increasing the use of ear protection devices and equipment, such as earplugs or earmuffs as well as limiting exposure (National Institute of Deafness and Other Communication Disorders).

Olfaction and Gustation

Definitions/Classification

Olfaction (smell) and gustation (taste) are classified as the chemical senses. Together they allow full appreciation of the flavor and palatability of foods; serve as an early warning system given their ability to detect toxins, smoke, gas, and spoiled food; and aid in normal digestion by triggering gastrointestinal secretions. Humans can distinguish among hundreds of substances by smell, even in minute quantities. Disorders of olfaction represent a continuum from partial (hyposmia) to total impairment (anosmia). Humans can distinguish five distinct qualities of taste–salty, sweet, sour, bitter, and umami (a taste generated by the monosodium glutamate). However, because many nerves are responsible for transmitting taste information to the brain, total loss of taste (ageusia) is rare.

Epidemiology

A 1994 survey revealed that 2.7 million American adults have an olfactory problem, and 1.1 million report a gustatory problem. Many people are aware of a period in their life in which they had decreased smell or alterations in taste.

Etiology and Pathogenesis

As with the senses of vision and hearing, one method of classification of disorders of olfaction and taste relate to the anatomical structure that is abnormal. *Table 44.5* lists causes by anatomical structure affected. When individuals complain of problems with smell and taste, careful testing frequently reveals that the impairment is primarily

Table 44.5

Causes of disorders of smell and taste by type of condition and anatomic structure

Type of condition	Anatomical structure			
	Nose	Orbital cortex	Mouth and oral structures	Neural pathways and cortex
Structural abnormality	Chloanal atresia Nasal polyps Adenoidal hypertrophy	Nasal obstruction from chloanal atresia, polyps, deviated septum		
Genetic conditions and systemic disorders	Holoprosencephaly Encephalocele Dermoid cysts	Kallmann syndrome Congenital anosmia	Individual variation (non-tasters)	Malnutrition Chronic renal failure Liver disease (including cirrhosis) Cancer Acquired immunodeficiency syndrome
Infection or inflammation	Sinusitis Viral upper respiratory infection	Tympanic membrane perforation Systemic Lupus erythematosus	Oral and perioral infections (candidiasis, gingivitis, herpes simplex, periodontitis, sialadenitis) Sjögren's syndrome	Bell's palsy
Toxicity, metabolic and endocrine conditions	Cigarette smoking Cocaine abuse	Nutritional factors (e.g., vitamin deficiency [A, B_6, B_{12}], trace metal deficiency [zinc, copper]) Malnutrition Chronic renal failure Liver disease [including cirrhosis], cancer Endocrine disorders (adrenocortical insufficiency, Cushing's syndrome, diabetes mellitus, hypothyroidism, primary amenorrhea, pseudohypoparathyro, idism, Kallmann's syndrome, Turner's syndrome, pregnancy)	Toxic chemical exposure (benzene, benzol, butyl acetate, carbon disulfide, chlorine, ethyl acetate, formaldehyde, hydrogen selenide, paint solvents, sulfuric acid, thrichloro-ethylene) Industrial agent exposure (e.g., chromium, lead, copper) Radiation treatment of head and neck Anti-neoplastic, medications	Anti-neoplastic medications Nutritional factors (e.g., vitamin deficiency [B_3, B_{12}], trace metal deficiency [zinc, copper]) Endocrine disorders (e.g., adrenocortical insufficiency, Cushing's syndrome, diabetes mellitus, hypothyroidism, panhypopituitarism, pseudohypoparathyroidism) Kallmann's syndrome Turner's syndrome
Trauma	Physical damage to nasal structures	Frontal skull fracture Nasal fracture Disruption of cribiform plate Cerebrovascular accident	Burn to tongue or oral structures Dental surgery	Head trauma
Neoplasm		Brain tumor (osteoma, olfactory groove or cribiform plate meningioma, frontal lobe tumor, temporal lobe tumor, pituitary tumor Radiation treatment of head and neck		Tumor or lesions associated with taste pathways (oral cavity cancer, neoplasm of skull base

olfactory. Volatile airborne molecules pass through the nose and contact olfactory receptor cells. Flavors depend on stimulation of the smell receptors. Nasal blockage from any cause – polyps, upper respiratory infections, or sinusitis – may affect olfaction and result in the changes in the flavor of foods.

Impairments of olfaction can result from disruptions of the olfactory nerve fibers. Impairments of olfaction are prevalent after head trauma because of shearing injuries to the olfactory nerve fibers at the level of the cribiform plate. Central neural factors, such as tumor or epilepsy, particularly if injury is in the frontal or temporal lobes, may result in disruption of smell and taste.

Taste can be affected by changes in the oral cavity such as destruction of the taste buds from excessive dryness or burns. Gingivitis and sialadenitis or inflammation of the salivary glands may also disturb taste by creating products in the mouth that have bad tastes. Taste is affected by damage to one or more of the neural pathways innervating the taste buds from diverse causes, including Bell's palsy or dental surgical procedures.

Acquired causes of smell and taste disturbance are more common than congenital causes. Underlying basal cells generate olfactory neurons approximately every 30–60 days throughout life. Individual taste buds are modified epithelial cells with a short life span of approximately 10 days. Underlying basal cells replace them continuously in a process similar to olfactory receptor cells. For these reasons, most disturbances of smell and taste are transient. However, chronic use of nasal sprays that cause vasoconstriction of nasal circulation may ultimately lead to damage to olfactory receptor neurons and permanent damage.

Congenital causes of anosmia or hyposmia include Kallman syndrome, also known as hypothalamic hypogonadism or hypogonadotropic hypogonadism, a genetic disorder. Holoprosencephaly, a condition in which the forebrain fails to develop into two hemispheres from either genetic or nongenetic causes typically includes anosmia. *Table 44.5* includes additional conditions.

Congenital causes of taste disturbance includes an autosomal dominant inability to taste phenylthiourea (bitter) and other compounds with an –N-C= group. Type I familial dysautonomia (Riley–Day syndrome) causes severe hypogeusia or ageusia because of the absence of taste bud development.

Clinical Manifestations

Disorders of olfaction and gustation may be entirely silent, particularly in individuals with congenital conditions. Individuals with acquired and especially sudden onset anosmia may find food unappetizing and appetite diminished. Memories of smells are often intimately associated with emotional memories because of the connection of the olfactory bulb and the limbic system. Loss of smell has been associated with the onset of depression. Loss of olfaction in individuals with a previous intact sense may also lead to the loss of libido.

Diagnosis

Disorders of taste and smell generally have been difficult to diagnose. The process begins with a comprehensive history of infections, inflammation, diet, and medication use. A comprehensive physical examination focuses on the head and neck.

It is possible to make simple tests for olfaction, such as samples to sniff or taste. Commercial tests of olfactory function that evaluate threshold of odor detection and odor identification have been developed to provide a reliable measure of olfaction. The Cross-Cultural Smell Identification Test includes banana, chocolate, cinnamon, rose, and smoke because representatives of many different countries were able to identify these odors.

Evaluation of taste disorders is not as well developed as that of olfaction. No comparable approach to odor identification tests is available. Only four of the five basic tastes are typically tested (sweet, salty, bitter, and sour).

Treatment and Prognosis

Treatment of olfactory and gustatory disorders relies primarily on treatment of the specific underlying cause of the disturbance. Since many of the causes are transient, restoration of the senses is possible. Where cures are difficult to achieve or take time to accomplish, then acknowledgement of the disorder, reassurance, and treatment of secondary effects may be necessary.

Disorders of Touch

Definitions/Classification

Tactile sensations are received by nerve endings in the epidermis and sent to the brain via the spinal cord. The number and distribution of receptors vary across different body parts. Large sensory fibers sheathed in myelin register light touch, vibration, and position. Small sensory

fibers without myelin sheaths transmit pain and temperature. All of the sensory information flows along sensory or afferent tracts to the spinal cord, to the thalamus, and then usually into somatosensory areas of the parietal lobe of the cortex. Disorders of touch may involve reduced sensitivity, also known as hypoesthesia or increased sensitivity, also known as hyperesthesia. Hypersensitivity to touch may be sufficiently severe to be classified as pain. Allodynia is the term for painful sensations from stimuli that do not cause pain in other individuals.

Epidemiology

The prevalence of disorders of touch is not well established.

Etiology and Pathogenesis

Disorders of touch may arise from any anatomical structures involved in the pathway. Damage to the skin from trauma, burns, and surgery may affect touch sensation in that body part. Injury to peripheral sensory nerves may cause a neuropathy with resulting sensory changes. When other types of nerves are also involved, these problems may be accompanied by weakness and/or autonomic changes. Neuropathy is a feature of many conditions: metabolic and endocrine disorders, such as diabetes mellitus; toxic exposures, including alcoholism, heavy metals, and antineoplastic drugs; vitamin deficiencies, including B12, A, E, and B1; and infections, such as herpes varicella zoster. The dorsal root of the spinal cord may be affected in conditions such as Sjorgen syndrome. Central pain syndrome is caused by damage to the brain, brainstem, or spinal cord from any cause, including tumor or epilepsy.

Disorders of sensation may be part of a systemic condition. Riley–Day syndrome is an autosomal-recessive disorder that affects the development and function of nerves. The inability to feel pain and temperature in this condition can lead to significant injuries. Congenital insensitivity to pain and anhidrosis is one of a family of disorders known collectively as hereditary sensory and autonomic neuropathies. Children with these disorders do not respond to pain while they do respond appropriately to touch, pressure, heat, and vibration.

Clinical Manifestations

In the absence of disease or injury, children have highly variable responses to touch. Some children appear to be extremely insensitive. These children may bang their head on the corner of a table without crying or even slowing down. Such children may be oblivious to other sensory input as well. This pattern may affect children with certain specific neurodevelopmental diagnoses, including autism spectrum disorders, attention-deficit/hyperactivity disorder, and other mental health disorders. Other children appear to be overly sensitive to touch and related somatosensory input. These children complain about labels in their clothing, refuse to play with clay and sticky materials, and dislike hugs. They may be highly sensitive to other sensory input as well, refusing to try new foods or holding their ears when sirens go off. This pattern may affect some children with neurodevelopmental diagnoses, including autism spectrum disorders, attention-deficit/hyperactivity disorder, anxiety disorders, or intellectual disability.

Damage to large sensory fibers reduces the ability of the individual to sense vibration and touch, resulting in numbness, particularly in the hands and feet. Affected individuals may loose graphesthesia and may have a loss of position sense, compromising their motor skills. Damage to small sensory fibers may reduce sensitivity to touch and temperature. Affected individuals may not realize they have been injured. Pain receptors in the skin can become oversensitive so that individuals sense pain from stimuli that do not usually cause pain (allodynia). Disturbances of touch may also be associated with anorexia, poor appetite, sleep disturbance, and psychological symptoms.

Diagnosis

Establishing the diagnosis of disturbances of touch is very difficult because of the inherent subjectivity in testing. In addition, many factors besides the conditions of the sensory pathway may influence the response to touch, including the psychological state of the individual. More than 100 types of peripheral neuropathy have been identified, each with their own symptoms.

The medical work-up begins with a good history and physical examination. The pattern of involvement leads to specific testing. Nerve conduction studies and electromyelogram are used primarily for multifocal symptoms. Nerve biopsies can also assist in diagnosis.

Treatment and Prognosis

Treatment of disorders of pain is highly dependent on the nature of the disorder, its cause, and its functional implications. Analgesia may be appropriate for hyeralgesia and pain.

Prevention

Touch plays a prominent role in establishing the affectionate bond between parents and children. Touch and massage remain highly useful throughout the life span in reducing pain, anxiety, depression, and aggression.

Summary

Examination of the sensory systems is often challenging in infants and young children who cannot cooperate fully with testing. However, disorders in these systems may have profound functional consequences, particularly in learning, mobility, communication, and social interactions. Therefore, assessment of the sensory systems is a fundamental component of the neurological examination. Visual and hearing screening tests are appropriate at different times throughout childhood. It is particularly important to assess these senses in children with developmental disorders because sensory impairment frequently accompanies other conditions. Similarly, it is important to assess overall development in children with vision or hearing impairment because these might be part of a larger syndrome. Responses to smells and taste should be assessed in children with problems in anorexia, growth disturbance, or specific complaints. Response to touch is often assessed implicitly throughout a physical examination. Appropriate diagnosis and management of sensory disorders, as described above, may restore sensation with corresponding improvements in function. Prevention of sensory disorders, and in particular visual and hearing impairment, is a major focus of national and international public health efforts.

45 Disorders of Cognition, Attention, Language, and Learning

Lynn M. Wegner · Jennifer K. Poon · Michelle M. Macias

Across all cultures, some children impress observers with their quick acquisition of developmental milestones and proficiency in understanding and mastery of information taught to them. If they live in societies with extensive formal systems of education, these children often do well in their classes, show strong performance on examinations, and are perceived as successful adults in their chosen vocational or professional fields. There are other children who do not show any notable delays in early developmental attainment, but struggle when the learning environment changes to formal instruction of reading, math, and written instruction. Sometimes children demonstrate uneven acquisition of academic skills. They may be advanced in math, but are slow and uncertain readers. Adults who endeavor to teach children face a quandary: What is hampering the child's progress in learning?

Educational attainment is multifactorial and very culture-dependent. The biology of the individual reflects genetics of the populace and the inheritance of their parents, nutrition, and environmental contaminants affecting the central nervous system. The social environment affects the teaching resources and the emphasis on academic success. There are individuals in all cultures, however, who are relatively not successful in academic endeavors. This chapter first will examine three domains affecting the ability to learn: cognitive profiles, selective attention (and executive functions), and language abilities. Specific disabilities in reading, math, and written expression will be presented. Most of the published literature in these topics is based on industrialized cultures; therefore, some bias may be noted. It is recognized that, despite the additional effort and expense required to educate special needs school-age children and adolescents, society as a whole benefits from helping them enter adulthood as capably as possible.

Cognition

Maria is 6 years old and her parents are upset that she is not interested in learning to read. Her teacher also has told them Maria's math abilities are not progressing like the other students. Maria had always needed more demonstration to learn games and home routines, but she has such a happy disposition that her parents and siblings did not mind giving her the extra help. When she is outside playing with other children, she seeks children 2–3 years younger than her for playmates. Her mother asks: "Isn't she as smart as my other children?"

Definition/Classification

Intelligence reflects the skills of logical reasoning, problem solving, critical thinking, and adaptation. Language, memory, processing speed, attention and executive function, and fluid intelligence are all components of most formal theories of intelligence. For example, memory is very important in learning and occurs in auditory, motor, perceptual, and visual domains. More recent conceptualizations of cognition include emotional, motor, and social intelligence.

In the USA, the terms "mental retardation (MR)" and "intellectual disability (ID)" are used synonymously, and current federal and state laws continue to contain the term "mental retardation." However, in 2007, the American Association on Mental Retardation (AAMR) changed its name to the American Association on Intellectual and Developmental Disabilities (AAIDD), and released its updated classification manual in 2010 in which "mental retardation" was universally replaced with "intellectual disability." The AAIDD defines ID as a disability characterized by significant limitations in both intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills. The AAIDD does not base their identification of an individual as "intellectually disabled" on cognitive testing standard scores alone, but rather the degree of external support the individual needs for life functioning. *Table 45.1* describes different levels of intellectual disability based on intelligence testing performance and level of external support needed by the individual.

Intellectual ability is presumed to occur in a population in a normally distributed manner. This is true for all societies. Children should be compared with

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_45,

children who live in similar cultures and communities. A normal distribution curve is symmetric around a mean value of 100 (50 percentile) and has a standard deviation of 15 points (Fig. 45.1). When percentages are examined on the normal curve, 2.14% of the population earns standard scores less than 70. The 2.14% of the population with intellectual abilities scores and adaptive functioning scores falling in this range fall within the category of ID. Not all countries use the terms "intellectual disability" or "mental retardation" to describe the individuals with intellectual testing and adaptive functioning in the lower 1–3% of the normally distributed population. The UK, for example, uses the term "learning disabilities" to describe individuals with ID as well as those with cognitive ability in the average range, but significantly weaker standardized academic achievement test scores. Regardless of the term used, common agreement is that the disordered cognition must be apparent before the age of 18 years.

Table 45.1
Intellectual disability: cognitive test level and external support needed

Descriptor	IQ	External support needed
Mild	55–70	Variable, situation dependent
Moderate	40–55	Minimal
Severe	25–40	Extended
Profound	<25	Complete in all situations

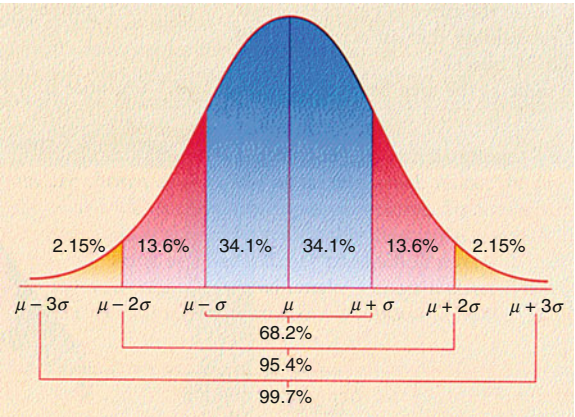

Figure 45.1
Normal distribution curve

Etiology/Pathogenesis

Identifying the etiology of ID may have more significance to the family than the medical provider unless there are associated conditions requiring ongoing medical monitoring and management. Prognosis for functioning as an older child and adult is a significant question and families may want to know the recurrence risk if additional children are planned. An important element of identifying the cause of the ID is dispelling myths and correcting any erroneous preconceived ideas of outcome the family may have.

The etiology of mild ID is identified in only 40% of patients. In children with moderate to more severe levels of ID, the etiology can be discerned more frequently, but specific identification still is unknown in 20% of these patients. Chromosome anomalies, metabolic disorders, extensive pre- and perinatal adverse events all have shown characteristic morphological and/or behavioral phenotypes. Some of the more well-recognized patterns are listed in Table 45.2.

Trisomy 21 is the most common genetic cause of ID; Fragile X is the most common inherited cause of ID; and fetal alcohol syndrome is the most preventable cause of ID.

Some children's ID is attributable to an identified pre- or postnatal event or condition. These include extreme prematurity (<30 weeks), congenital hypothyroidism, maternal untreated phenylketonuria, congenital hydrocephalus and other severe neural tube defects, severe intrauterine growth retardation or low birth weight, extensive intracranial bleeding, meningitis/encephalitis, and epilepsy. There also are external causes: head trauma; central nervous system infections and bleeding; heavy metal exposure (lead, manganese, methylmercury, and other forms of mercury, arsenic); exposure to polychlorinated biphenyls, organophosphates, chlorinated hydrocarbons; chronic hypoxemia; prenatal maternal medication and substances (antiepileptics, alcohol). Often, the end result of CNS dysfunction, whether prenatal, perinatal, or postnatal, results in ID. However, in the majority of individuals with ID, there may not be a specific structural abnormality identified.

Epidemiology

The prevalence of ID has slight variability due to the variations in diagnostic criteria. Although the prevalence was once thought to be as high as 3% it is now estimated to be between 0.78% and 1.27% of the US population. This discrepancy is due to the elimination of ID being diagnosed based solely on IQ scores, and now takes into

Table 45.2
Chromosomal and prenatal causes of intellectual disability

Disorder	Abnormality	Signs
Down syndrome	Trisomy 21	Hypotonia, small brachycephalic head, epicanthal folds, upslanting palpebral fissures, Brushfield spots in iris, single transverse palmar crease, flat nasal bridge, hypothyroidism, hearing loss, heart defects
Williams syndrome	(del) 7, 7q11	Periorbital fullness, short nose with bulbous nasal tip, long philtrum, wide mouth, and full lips; hypocalcemia, supravalvular aortic stenosis; "cocktail chatter"
Angelman syndrome	Four mechanisms: maternal (del) 15q11.2-q13; parental uniparental disomy; imprinting defects; mutation on UBE3A	Microcephaly, seizures, characteristic electroencephalogram; movement/gait disorder, happy demeanor
Smith–Magenis syndrome	(del) short arm 17, 17 p.11.2	Brachycephaly, broad face, midface hypoplasia, prognathism, short stature; hearing impairment
Fragile X syndrome	Trinucleotide repeat expansion (CGG; $\geq$200) in FMR1 gene	Mild-severe ID, autism
Prader–Willi syndrome	(del) 15q11.2-q13	Infancy: failure to thrive, hypotonia; obesity, hyperphagia, hypogonadism, short stature; almond-shaped eyes, hypopigmented hair; obsessive-compulsive disorder
Fetal alcohol syndrome	Not specified; associated with confirmed history of prenatal maternal ETOH use	Head circumference $\leq$10%; postnatal height or weight $\leq$10%; and at least two of these: short palpebral fissures, thin upper lip, smooth philtrum

account adaptive behavior. For example, in 1981, Swedish studies reported unequivocal ID in the school-aged Swedish population to be $<$1%.

Clinical Manifestations

Clinical presentation relies primarily on the degree of cognitive impairment. Initial presenting signs may include delayed language acquisition, cognitive skills, and adaptive skills. Children with severe to profound ID present at a very young age with globally delayed developmental skills. However, individuals with mild ID may be identified later, when they have difficulty with preacademic skills or multiple step instructions. Social skills may also be impacted, where a child may have more naive interests than his or her age-matched peers.

Diagnosis

The comprehensive evaluation of a child with ID can be coordinated by a primary pediatric health provider, but other professionals will have important roles. The focus of assessment is identifying etiology and extent of the intellectual disability. Family counseling should include discussion of prognosis and recurrence risk. The medical provider should be aware of any published guidelines for ongoing management. The child and family benefit from a comprehensive assessment as identifying the cause can lead to genetic counseling for future pregnancies and more accurate monitoring of the child for relevant physical conditions emerging in later years. Parents may be given a more accurate estimation of future developmental attainment and the frequent unspoken worry, "did I do anything to cause this?" may be answered.

A careful physical examination with measurements of: weight, height, frontal-occipital-head circumference, right auricle length, right palpebral length, philtrum length, testes volume (in postpubertal males) is needed. Hair patterns (including eyebrows), texture, density; skin texture and pigmentary changes (including nevus formation); examination of palmer creases and a careful neurological examination are essential parts the primary medical provider can do. Visual acuity and hearing thresholds should be documented as part of the examination.

The physical signs of Fragile X may not be obvious in very young children therefore all children with cognitive

delays should have specific DNA testing for Fragile X. Whole genome microarray testing can more precisely identify subtle chromosome abnormalities. Metabolic testing (plasma amino acids and urine organic acids) is indicated in the context of historical factors (parental consanguinity, family history, developmental regression, episodic decompensation) or physical examination findings suggestive of a specific etiology (coarse facial features, organomegaly). If the child shows abnormalities of head shape, microcephaly, or macrocephaly, neuroimaging (most often MRI) should be considered, but this is not a universal recommendation.

Formal psychometric testing is essential to establish the extent of ID. Psychologists customarily do this standardized testing, with instruments such as the *The Wechsler Intelligence Scale for Children*-Fourth Edition or the *Stanford Binet Intelligence Scale*-Fifth Edition and they often have adaptive functioning questionnaires, such as the Vineland Adaptive Behavior Scales for the parents (and sometimes teachers) with which the cognitive results are compared. Finally, it is very important to take into consideration the current functioning of the child and the "established" cognitive description. Children who entered high-quality daycare and preschools may perform at a transiently elevated cognitive level if their intelligence is tested as a young child. Their weaker cognitive level may be masked by this early intense stimulation. If an older child struggles in academics and adaptive functioning, yet has a record of "passing" early cognitive testing, an updated evaluation (with new cognitive testing and assessment of adaptive functioning) should be strongly considered.

Differential Diagnosis

If a child is labeled "mildly" ID but shows a variable profile of academic attainment (especially if math is strong) and age-appropriate adaptive skills (with the exception of weak communication), reassessment should be done with a comprehensive evaluation of expressive and receptive language abilities. If there is any question of the child's ability to understand what is said or to express herself/himself in an age-appropriate manner, a full language evaluation should be sought by a speech pathologist trained in evaluating children and adolescents. Weak language performance mandates the use of a cognitive test minimizing language during the testing and word use to solve the problems on the test in order to distinguish between a language disorder and ID. ● *Table 45.3* lists cognitive measures with minimal word knowledge required in the problem solving.

Children with impaired verbal IQ but normal nonverbal performance are likely to have a language-based learning disability rather than ID. Similarly, the opposite profile (below average nonverbal IQ but normal verbal scores) is more likely to represent a nonverbal learning disability. Children with autism often score in the impaired range on standardized assessments because of their language disorders or unwillingness to perform, but may not truly have ID.

Treatment

Supports for individuals with intellectual disability and their families are important. Much of the management for individuals with ID involves the educational setting, providing interventions and accommodations, while maintaining the least restrictive learning environment. Services such as physical, occupational and speech therapies, behavioral interventions, and/or specialized classrooms may be incorporated into the academic settings. It is also important to find extracurricular activities and social opportunities, which promote self-esteem. Transition planning should begin by early adolescence and focus

Table 45.3

on future medical care, work environment, and living environment. Furthermore, the development of a skill set for daily living is critical to foster maximum independence. Behavioral therapies should be utilized for maladaptive behaviors (e.g., aggression, self-injurious behaviors), including a functional behavior analysis. Pharmacologic management of impairing behaviors should be employed judiciously, and as an adjunct to behavior management strategies.

Prognosis

Long-term prognosis is difficult to predict in early childhood, as there may be variability in testing scores. However, in school-aged children, test scores become more consistent and more predictive. Individuals who have mild ID are commonly employed, and may support themselves and have a family of their own. Those who have moderate ID also may be able to work, but need more supervision. They may transition to a group home setting where they have higher levels of support. In individuals with severe and profound ID, more focus is placed on life skills and activities of daily living. Living arrangements will require constant supervision and assistance.

Attention Deficit Hyperactivity Disorder

Kashif is a 7-year-old boy who presents to your office with his mother for concerns of poor school performance. His mother complains that he has been doing poorly in his classes from a behavior and academic standpoint. You review notes from his teacher: "Kashif's behavior keeps him from learning. He leaves his seat during class and cannot keep his hands to himself. He talks while I am teaching. During reading, he stares off into the window and rarely completes his assignment. He forgets to bring home his assignment book."

When asked about how he is doing in the home, Kashif's mother has no major complaints. She says, "He is a typical boy and does not do anything around the house and at times, is impatient with his sisters, but otherwise there are no major problems." Upon further questioning, with simple chores like watering the plants, Kashif usually gets into something else before he finishes. He often fights with his younger siblings in playing games, as he does not have the patience to let them take a turn. Kashif's mother confides that his father does not believe that there is a problem at all. He says, "I was just like Kashif when I was his age. He is just a boy and he will be fine."

Attention deficit hyperactivity disorder (ADHD) is one of the most prevalent neurodevelopmental disorders of childhood. It can persist through adolescence and adulthood. While typically perceived as a pattern of overactivity, easy distractibility and impulsivity, there are other symptoms of poor planning, self-monitoring, organization, and task completion.

Definition/Classification

Attention Deficit/Hyperactivity Disorder (ADHD) is characterized by symptoms of hyperactivity, inattention, and impulsivity. The American Psychiatric Association's Diagnostic and Statistical Manual (DSM-IV) criteria for the disorder are: 6 out of 9 symptoms of inattention and/or 6 out of 9 symptoms of hyperactivity/impulsivity with noted impairment prior to 7 years of age, in two or more settings, and with clinically significant impairment in social, academic, or occupational functioning. Furthermore, the symptoms cannot occur with a pervasive developmental disorder, schizophrenia, or other psychotic disorder, nor can they be better accounted for by another mental disorder. DSM-IV categorizes ADHD into subtypes: (1) predominantly hyperactive/impulsive subtype, (2) predominantly inattentive subtype, and (3) combined hyperactive/impulsive and inattentive subtype. The proposed updated DSM-V changes the age of symptom onset. It proposes that in the evaluation of those over 17 years of age, 4 of 9 symptoms of inattention and/or 4 of 13 symptoms of hyperactivity/impulsivity are present. Furthermore, it raises the age of symptom presentation from 7 to 12 years. Similarly, the World Health Organization (WHO) classification under ICD-10 refers to hyperkinetic disorder and disturbance of activity and attention. These diagnostic criteria differ from DSM-IV in number of symptoms meeting threshold criteria, and differentiation of home vs. school as follows: Home: 3 of 5 symptoms of inattention, 3 of 5 activity problems, and 1 of 3 impulsivity problems; School: 2 out of 4 attention problems, 3 of 5 activity problems.

Etiology

ADHD is thought to be a genetically based neurobiological disorder, with multifactorial etiology. Genetic studies, neuroimaging studies, and environmental risk factor studies have provided evidence for this reasoning. Hereditability of the disorder is high, between 70% and 80% in studies involving families in the USA, Australia,

Scandinavia, and the European Union. A family history of ADHD has been shown to be higher in individuals with ADHD than their control counterparts. Twin studies have shown greater concordance for the disorder in monozygotic twins versus dizygotic twins.

Furthermore, genetic studies in families have found several genes that may be related to the disorder. Examples of genes related to ADHD include those related to dopamine (DRD4, DRD5, DAT1, DBH, and SNAP-25) and with serotonin (5-HTT, HTR1B). The International Multisite ADHD Gene identified 18 genes associated with ADHD.

The role of various environmental factors in the etiology of ADHD has been researched as well. However, as it is hard to control for confounding variables, the studies do not establish causality, but rather highlight attention to possible risk factors. Studies examining early risk factors for ADHD have identified prenatal exposure to maternal cigarette smoking as a consistent predictor of child ADHD, even when other factors are controlled. These findings are consistent internationally, including in the Netherlands, Finland, the UK, New Zealand, Australia, the USA, Canada, and Brazil and in animal models. Other prenatal and perinatal exposures that may be associated with ADHD are polysubstance abuse and alcohol exposure. The impact of these environmental exposures appears to function as part of a gene × environment interaction. For example, children exposed to prenatal nicotine and who have a polymorphism in the DRD4 are at the highest risk of developing ADHD. Similarly, children with the 10–10 allele for DAT who experience psychosocial adversity are more likely to develop ADHD.

Neuroimaging studies also suggest an association between structural abnormalities and ADHD. These associations may correspond to an underlying etiology of ADHD or may represent developmental adaptations to the disorder. A number of studies have demonstrated decreased volumes particularly in the caudate, globus pallidum, cerebellar vermis, anterior cerebrum, and white matter tracks. One study noted a correlation between cortical thinning in children with ADHD and the course of the disorder – children with persistent symptoms had persistently thin cortex, whereas those whose symptoms improved had normalized cortical thickness.

Epidemiology

World prevalence of ADHD ranges from 1% to 20%. The wide variability may be due to methodological differences among studies such as inclusion criteria, informants, instruments used, and the population studied. Studies within the USA alone have ranged between 4% and 12%. Studies in other countries' prevalence of ADHD include Canada 6%, Iceland 6%, Brazil 18%, Colombia 16%, the UK 17%, Germany 11%, India 11%, Israel 4%, Iran 6%, China 6%, and New Zealand 3%.

ADHD is diagnosed more frequently in males, with the ratio ranging from 2:1 to 4:1. Boys are more likely to be referred for evaluation as they tend to demonstrate disruptive behavior. There have been studies showing a higher prevalence of ADHD reported in urban versus rural children, although this may reflect more on disparities in health care.

Clinical Manifestations

ADHD is the most common childhood neurobehavioral disorder in primary care pediatrics. The core clinical features of ADHD are hyperactivity, inattention, and impulsivity. Not all of these symptoms manifest uniformly, and the clinician must remain vigilant to detect these problems.

Children with ADHD may first come to attention because they have symptoms of hyperactivity and trouble with impulse control. These symptoms may be seen early in the preschool years and at that time they may or may not be impairing. Trouble in the school setting often highlights symptoms. In school, the hyperactive–impulsive subtype of ADHD may manifest as a child who squirms in his or her seat, leaving it at inappropriate times. They may blurt out answers in the classroom or even talk to others while the teacher is teaching. In play and other peer interactions, they may have difficulty waiting their turn in games or conversation, often interrupting others. They can also have a higher rate of accidental injuries such as lacerations or fractures related to climbing or impulsive behaviors.

Children with the inattentive subtype of ADHD may be identified at a later time, as they are struggling with their academic work. Unfortunately, many are unidentified, as they may not be disruptive. However, these symptoms can be equally impairing as the hyperactive–impulsive subtype of ADHD. Inattention can present in a number of ways. For instance a child may appear to be staring at nothing, not listening, or not paying attention. They may forget easily about chores and assignments. Social skills may be impaired as they may not be able to pick up on others' social cues if they are distracted. Furthermore, inattention can result in poor planning, mistakes, and difficulty completing assignments.

Up to 75% of children with ADHD may also have existing comorbid conditions. Some of these conditions include oppositional defiant disorder, conduct

disorder, depression, anxiety, tic disorder, mania, and learning/academic problems. More than half of children with ADHD have sleep disorders as well. Learning problems and substance abuse disorders, including nicotine, also co-occur with ADHD. Similar patterns of comorbidity are present in children from eastern Asia and central Europe. In light of the high rate of comorbidities, it is important for the clinician to consider symptoms of these in the diagnosis and treatment plan of ADHD.

Diagnosis

There is no single test diagnostic for ADHD. Instead, it is a diagnosis based on clinical impressions and established criteria. Utilization of these criteria is important for a uniform standard of care and accurate diagnosis. Any school-aged child who presents with concerns about academic underachievement and/or behavioral concerns, including hyperactivity, inattention, and impulsivity should be evaluated for the disorder.

The clinician must gather information about the symptoms in multiple settings, the impairment from the symptoms, and any symptoms that may be related to comorbid diagnoses. It is important to discuss the age of onset, the frequency, duration, and level of impairment. As symptoms of ADHD manifest in differing environments, it is crucial to obtain information from both the home environment and an alternate setting, which is most often the school. Furthermore, the importance of the psychosocial history and family history should not be underestimated. A psychosocial history allows the clinician to look at other contributing factors to the behaviors at hand. Information such as the home environment, school setting, potential violence and/or trauma, and other stressors should be elicited. Family history can be valuable as ADHD is highly heritable.

Several ADHD-specific questionnaires and rating scales are available for both parents and teachers to complete in order to ascertain information from different environments. These questionnaires are valuable tools for the diagnosis of ADHD; however, they should not be viewed as the sole diagnostic tool, but instead, a supporting piece of evidence.

Vision and hearing should be screened to make sure there is no impairment causing the presenting symptoms. However, laboratory tests, such as lead levels or thyroid hormone levels are not advised, unless clinically indicated. Furthermore, brain imaging studies and electroencephalography have not consistently demonstrated differences between children with and without ADHD, and should not be relied upon to assist or confirm a diagnosis.

Differential Diagnosis

Hyperactivity is a nonspecific symptom that can occur in a range of other disorders. Hyperactivity that is situational or relationship specific may reflect anxiety or distress. Mania shares the hypermotoric patterns of ADHD, but can usually be differentiated by a decreased need for sleep (not simply sleep problems), euphoria or irritability, and grandiosity. Misbehavior only in classes may suggest a learning difficulty that must be assessed. Children with obstructive sleep apnea can also present with behaviors that are similar to ADHD and sleep patterns should be assessed as part of the assessment. Inattentive type ADHD symptoms must be distinguished from anxiety, including dissociative symptoms, from partial complex seizures, and either boredom in school or learning disabilities.

Treatment

Treatment should be based on the principles that ADHD is chronic, and often transcends into adulthood. Both the family and patient should be educated on the nature of the neurobiological basis of ADHD, the course of the disorder, and the treatment plan itself. In order to invest the family, including the child, in the treatment, they should have input in setting their goals for improvements in home life, academic settings, and interpersonal relationships. Treatment consists of both behavioral modifications and medication.

The Multimodal Treatment Study of ADHD provided significant knowledge to the understanding of treatments available for ADHD. The study was a multisite clinical trial to evaluate four treatment arms: (1) pharmacotherapy alone, (2) behavior-based treatment alone, (3) a combination of pharmacotherapy and behavioral treatment, and (4) community-based treatment. Results demonstrated that pharmacotherapy alone or a combination of pharmacotherapy with behavioral treatment resulted in the most significant improvement in ADHD symptoms. To date, there have been no studies supporting the efficacy of psychotherapy for ADHD.

Behavioral therapies should avoid focusing on negative behaviors and instead on promoting positive behaviors. Classroom modifications may improve academic performance. For instance, assignments may be broken into shorter segments, and timers may be used to encourage task completion. Children with ADHD may require lessons on note taking and organization, as these may not be intuitive. Furthermore, children with more prominent features of hyperactivity may require planned opportunities

for controlled movements. This may be in the form of helping with classroom housekeeping, passing out classroom materials, or even standing beside their desk periodically while doing classwork. The teacher may utilize positive reinforcement, token economy, and time-out.

While studies have shown the short-term effectiveness of behavioral modifications, often children with ADHD have trouble generalizing the modified behaviors to other situations. Furthermore, behavioral interventions are unable to ameliorate the neurobiological component of ADHD. Therefore, successful treatment involves a long-term combination approach and includes pharmacologic management.

Psychostimulants are considered first-line pharmacotherapy in the treatment of ADHD. They are the most studied of any medications and have a proven record of efficacy in over 70% of children with ADHD. The mechanism of action involves increasing the intersynaptic availability of the neurotransmitters, dopamine, and norepinephrine. The primary classes of stimulants include methylphenidate and the amphetamines. There are multiple formulations, from short to intermediate to long acting (see *Table 45.4*). The stimulants' onset of action is typically around 30 min. The most common side effects tend to be appetite suppression, insomnia, headaches, stomachaches, and irritability. These side effects may mostly be avoided and/or alleviated by adjusting the time or strength of the dose or to a different method of delivery. Unlike other medications, stimulants are not dosed according to weight, as each individual possesses a different dose-response curve. Patients should be started at a low dose and titrated up to maximum effect, with minimal to no side effects.

Stimulants do not induce seizures, and they may be used in children with tic disorders. While studies have shown that there may be some reduction in stature over the first year of treatment, this was not true for the long term and there was no overall affect on the ultimate height outcome. Teenagers who take stimulants for ADHD have been associated with better outcomes in the avoidance of substance abuse. While stimulants have been shown to have a statistically significant affect on blood pressure and heart rate this has not been clinically significant. The American Academy of Pediatrics recommends careful screening of children for whom stimulant medications may be indicated. This should include a good medical history and physical examination, including a cardiac history and examination, as well as a review of the family history, including a family history of unexplained sudden death in children and young adults, long Q-T syndrome, or hypertrophic obstructive cardiomyopathy. Any concerns from the history or physical examination should prompt further evaluation by a cardiologist prior to the initiation of a stimulant. Electrocardiograms and echocardiograms are not a necessary part of the screening, unless prompted by history or examination.

Table 45.4
Stimulant medications used in ADHD

Generic name	Trade name(s)	Doses	Dosing intervals
Amphetamine	Dexedrine	5,10,15 mg ER	Daily
	DextroStat	5,10 mg	Daily to three times daily
Dexmethylphenidate	Focalin	2.5,5,10 mg	Twice daily
	Focalin XR	5,10,15,20,30 mg ER	Daily
Lisdexamfetamine	Vyvanse	20,30,40,50,60,70 mg	Daily
Methylphenidate	Concerta	18,27,36,54 mg ER	Daily
	Daytrana	10,15,20,30 mg patch	Daily (9 h)
	Metadate CD	10,20,30,40,50,60 mg ER	Daily
	Metadate ER	10,20 mg ER	Daily to twice daily
	Methylin	5,10,20 mg; 2.5,5,10 mg chewable; 5,10 mg/5 mL	Twice to three times daily
	Ritalin	5,10,20 mg	Twice to three times daily
	Ritalin LA	10,20,30,40 mg ER	Daily
	Ritalin SR	20 mg ER	Daily to twice daily
Mixed amphetamine salts	Adderall	5,7.5,10,12.5,15,20,30 mg	Daily to twice daily
	Adderall XR	5,10,15,20,25,30 mg ER	Daily

Stimulant medications are typically titrated to effect, monitoring carefully for side effects, over the first month from initiation. Weight, height, blood pressure, and heart rate should be monitored at each visit. During this time, it is also important to obtain feedback from parents and teachers about how the child is responding to the medication. Objective measures in the form of brief follow-up rating scales can provide valuable information for the clinician to determine the optimal dosage for the medication. If a child is not responding favorably to one class of stimulants, despite proper administration, or if side effects cannot be avoided, the clinician should switch to the other class of stimulants. If the alternate class of stimulants is not effective, the clinician should consider one of the second-line medications, reevaluating for unrecognized coexisting disorders, and referral to a subspecialist.

Other medications that are also used include noradrenergic reuptake inhibitors, tricyclic antidepressants, and alpha-agonists (see *Table 45.5*). These are considered to be second-line agents in the treatment of ADHD. They may also be considered for patients who have had a history of substance abuse, as an alternative with less abuse potential than the stimulants.

Atomoxetine, a norepinephrine reuptake inhibitor, was developed as a nonstimulant treatment for ADHD. It is typically dosed once to twice daily and unlike stimulants, has a longer onset to action. Common side effects include gastrointestinal upset and sedation. There have been rare reports of liver dysfunction and failure, which were found to normalize after the cessation of the medication. Therefore, routine blood monitoring of liver function tests has not been recommended, unless there are signs and symptoms of liver dysfunction (e.g., right upper quadrant abdominal discomfort, jaundice). There is a black box warning regarding suicidal ideation; however, there have been no reported cases of suicide.

Tricyclic antidepressants have been used with success in the treatment of ADHD in children. They also inhibit the reuptake of norepinephrine. Because the tricyclic antidepressants present a cardiovascular risk, baseline electrocardiography should be obtained and monitored. Bupropion is another antidepressant that has been used for symptoms of ADHD. It is an aminoketone antidepressant that has noradrenergic effects.

Originally, clonidine and guanfacine, alpha 2 agonists, were developed to treat hypertension. Because these medications also have noradrenergic effects on the prefrontal cortex, they also help with hyperactivity and impulsivity. Improvements may not be seen for several weeks. Clonidine and guanfacine are typically dosed between two and four times a day, although recently, extended release versions of both medications have been introduced, reducing dosing to twice daily for clonidine and once daily for guanfacine. Side effects include sedation, fatigue, dry mouth, and hypotension. Furthermore, there is risk for rebound hypertension if the medication is stopped immediately.

Regular follow-up is important in the successful treatment of ADHD. Follow-up every 3–4 months allows reassessment of medication efficacy and provides the clinician time to help problem solve any issues that may

Table 45.5
Nonstimulant medications used in ADHD

Generic name	Trade name	Doses	Dosing intervals	Mechanism of action
Atomoxetine	Strattera	10,18,25,40,60,80,100 mg	Daily	Selective norepinephrine reuptake inhibitor
Buproprion	Wellbutrin	75,100 mg	Daily to three times daily	Norepinephrine dopamine reuptake inhibitor
Clonidine	Catapres	0.1 mg	Daily to four times daily	Nonselective alpha-2
Hydrochloride	Kapvay (extended release)	0.1,0.2 mg	Twice daily	Adrenergic agonist
Guanfacine	Tenex	1 mg	Daily to three times daily	Selective alpha-2a
	Intuniv (extended release)	0.1,0.2 mg	Twice daily	Adrenergic agonist
Impipramine, Desipramine	Tofranil	10,25,50 mg	Daily	Tricyclic antidepressant;
	Norpramin	10,25,50,75,100,150 mg	Daily	norepinephrine reuptake inhibitor
Modafinil	Provigil	100,200 mg	Daily	Unknown-CNS stimulant

be deterrents in the successful treatment of the disorder. Feedback, including objective measures, is important to obtain at these regular visits to track improvement, or lack thereof. Again, feedback should include both home and school settings.

Prognosis

ADHD often persists into adulthood. Up to 85% of children with ADHD continue to have impairment in adolescence and up to 60% in adulthood. Often the hyperactivity component of the disorder decreases with age, but the other symptoms of inattention and impulsivity persist. Studies have found that adults with a history of ADHD as a child are more likely to have criminal behavior, injuries, marital difficulties, job problems, and teen pregnancies. Outcomes have been found to be dependent on the quality of the symptoms, existing comorbidities, socioeconomic status, and history of treatment. Individuals who receive appropriate management and treatment tend to have improved outcomes. Some adults are able to accommodate the symptoms or choose careers in which the symptoms are less impairing.

Speech and Language Disorders

Levi is in your office for a routine health maintenance examination. He is 30 months old. His mother has no concerns about his health or development. In review of his developmental milestones, he runs well and he demonstrates that he can stand on one foot for 1 s, while smiling at you and his mother. He cooperates with your request to copy a horizontal and vertical line and as soon as you get out blocks, he stacks a tower of 10. He has five words that he uses consistently. He identifies his eyes, ears, and nose when you ask him; however, he looks away when you ask him to point to specific pictures. You ask his mother more about his language, and she says, "I am not concerned, Levi is a smart boy. Boys talk later than girls and he never has a chance to talk because his 5-year-old sister does all the talking for him."

Language acquisition is an extremely important component of a child's development. Language represents objects or actions in symbolic form and communicates ideas, intentions, and emotions. Speech and language disorders are the most common developmentally disabling disorders of childhood. Pediatric health-care providers are responsible for promoting language development, alleviating concerns about language development, and/or detecting language development problems. Early recognition and intervention are necessary to provide children with speech and/or language disorders with the best possible outcome. The reader is referred to ❯ Chap. 42, Normal Child Development, ❯ *Table 1*, for a detailed review of language milestones:

Speech produces complex acoustic signals that communicate meaning and is the result of interactions between the respiratory, laryngeal, and oral structures. This acoustic signal varies with regard to vocal pitch, intonation, and voice quality. The symbols need to conform to the language code so they can be decoded as meaningful communication.

Language involves both expressive and receptive components. Expressive language involves the communication of ideas, intentions, and emotions. Receptive language involves understanding what is said by someone else. Receptive language includes auditory comprehension (listening), literate decoding (reading), and mastery of visual signing.

Language has several components, as outlined in ❯ *Table 45.6*. The simplest "units" of language are *phonemes*, or individual sounds. Phonemes are combined to produce *morphemes*, which are the meaningful units of sound combined to produce a word. The *lexicon* (vocabulary) is the collection of all of the meaningful words in a language. *Syntax* (grammar) is the order of words in phrases and sentences. *Semantics* are the individual word and sentence meanings. The literal interpretation of words can be modified by *prosody* or vocal intonation. The social use of language is known as *pragmatics*.

Definition/Classification

A speech-language or communication disorder is defined as impairment in the ability to receive, send, process, and/or comprehend verbal, nonverbal, or graphic symbol systems. The most common variation in language development is language *delay*. The word *delay* inherently implies that catch-up will occur. Of children with early language delays, approximately 60% will catch up by 4 years of age with no persistent problems. Another variation is language *dissociation*. This can occur either within the domain, as seen when developmental rates differ between expressive and receptive language, or between different domains (e.g., language and motor skills). *Deviancy* of language development occurs when language development deviates from the norm, for example when children learn more advanced language-based concepts before they have mastered early language milestones. An example of

Table 45.6
Components of speech and language

Term	Definition
Speech	
Intelligibility	Ability of speech to be understood by others
Fluency	Flow of speech
Voice and resonance	Sound of speech, incorporating passage of air through larynx, mouth, and nose
Language	
Receptive language	Ability to understand language
Expressive language	Ability to produce language
Phoneme	Smallest units of sound that change the meaning of a word, e.g., "map" and "mop"
Morpheme	Smallest unit of meaning in language, e.g., adding –s to the end of a word to make it plural
Syntax	Set of rules for combining morphemes and words into sentences (grammar)
Semantics	The meaning of words and sentences
Pragmatics	The social use of language, including conversational skills, discourse, volume of speech, and body language

this is a child who is able to recite the alphabet or TV jingles but is not yet able to communicate needs using words and phrases. Deviant language development can often be a sign of autism spectrum disorders.

Etiology and Epidemiology

Language development occurs in an orderly and predictable manner for most children. However, virtually any disruption in brain function can affect language acquisition; therefore, a variety of conditions affecting the brain are associated with language problems. Delays in comprehension and/or expression not associated with other developmental or neurologic problems are found in 7.5–10% of North American preschool children with a significantly higher proportion of boys being affected.

The pediatric practitioner should not attribute cultural or gender differences as reasons for delayed language development. Children who learn two languages simultaneously follow the same pattern of speech and language development as monolingual language learners. The child may have a period when he or she mixes the two languages, but this should gradually disappear as language skills develop. Studies have shown that girls are more talkative (have more total words) than boys at all ages, with significant gender differences found between 1 and 2½ years of age. Although some boys may develop expressive language more slowly than girls, it is generally only by a few months and still within the accepted time frame. Language development is almost never delayed because the child "doesn't need to speak" (e.g., "her big sister always talks for her"). There is a tremendous motivation to improve communication, as the use of verbal labels allows the child to meet needs more efficiently than pointing.

The term *language delay* implies the delay will resolve and the child will catch up at some point. However, more than 40% of children whose early language delays show improvement have later reading or cognitive difficulties. Preschoolers with language disorders are at higher risk for language-based learning disorders, social, and behavioral problems. Speech and/or language concerns should not be dismissed with reassurance that the child will "catch up," given the possibility of future difficulties and better outcomes with earlier detection of these problems.

Pathogenesis and Genetics

The general location of basic language centers was determined in the nineteenth century by Paul Broca and Carl Wernicke, which then led to the theory of cerebral dominance. For virtually all right-handed people and two-thirds of left-handed people, speech and language are processed in the left cerebral hemisphere. Lesions bordering the sylvian fissure of the dominant hemisphere usually cause disturbances in speech and language. A functional anatomic loop connects the eyes and ears to the visual and auditory system, an intrahemispheral section through white matter connects the temporal with the frontal lobes, and the frontal lobes connect to the mouth and hand.

Meaning is provided to sounds and shapes through intrahemispheral and transcallosal pathways to the rest of the brain from the sylvian region. Recent advances in functional neuroimaging studies have suggested specific cortical areas associated with individual language skills. Positron emission tomography scans have shown increased metabolic activity across the left and right temporal and frontal cortex areas of the brain during speech and nonspeech acoustic processing. Functional magnetic resonance imaging studies show differences between the

sexes, with activation in the left inferior frontal gyrus for males and activation in both right and left inferior frontal areas for females during phonologic tasks. Word analysis and articulation has been mapped to Broca's area of the inferior frontal gyrus, whereas skilled word form discrimination involves the occipitotemporal region.

A substantial heritable component exists in speech and language disorders, but the underlying genetic basis is complex and involves different risk factors. Close examination of families with persistent signs of disordered language skills have suggested a genetic basis; however, exclusive of recognized genetic disorders with strong, specific language differences (e.g., velocardiofacial syndrome, Williams syndrome, or fragile X syndrome), no genetic markers for "developmental language disorder" have been clearly identified. Recent genome scanning techniques have identified chromosomes 2, 13, 16, and 19 as having potential candidate genes involved with more common forms of language impairment. Molecular genetic techniques are currently being utilized to investigate speech and language disorders.

Clinical Manifestations

Speech Disorders

Speech disorders reflect problems with creating the appropriate sounds representing the language symbols (the words). These problems include phonologic (*articulation*) disorders, speech fluency disorders (*stuttering*), and voice disorders. Speech disorders may or may not also include impairments in expressive language.

A phonologic or articulation disorder is characterized by the substitution, omission, addition, or distortion of phonemes and represents most speech therapy referrals. Children master sounds at different ages depending on the difficulty in producing the sound. In the first 2 years, children master simple sounds, including all vowels and the consonants /b/, /c/, /d/, /p/, and /m/. More difficult sounds, such as the consonants /j/, /r/, /l/, and /v/ and blends (i.e., sh, ch, th, st) may not be mastered until 5 or 6 years of age.

Dysarthrias are motor speech disorders that involve problems of articulation, respiration, phonation, or prosody as a result of paralysis, muscle weakness, or poor coordination. Dysarthric speech is characterized by weakness in specific speech sound production and is frequently associated with cerebral palsy. Dysarthric speech may also encompass problems in coordinated breath control and head posture.

Apraxia of speech or *dyspraxia* is a speech disorder involving problems in articulation, phonation, respiration, and resonance arising from difficulties in complex motor planning and movement. The child with apraxia/dyspraxia has problems putting syllables together to form words, and has more difficulty with longer words rather than shorter, simpler words. It is not due to weakness of the oromotor musculature as seen with dysarthria. Therefore, apraxia/dyspraxia can be differentiated from dysarthria by the lack of association with other oral-motor skills, such as chewing, swallowing, or spitting. Other neurologic "soft signs," such as generalized hypotonia, may be present on examination. Acquired apraxia/dyspraxia commonly results from head injury, tumor, stroke, or other problems affecting the parts of the brain involved with speaking and involves loss of previously acquired speech. It may co-occur with dysarthria or aphasia, a communication disorder impacting understanding or use of words caused by damage to the language centers of the brain. Developmental apraxia of speech is present from birth. Individuals with apraxia or aphasia might both have difficulty with verbal expression; however, apraxia on its own does not present a problem with language comprehension. Apraxia of speech is differentiated from an expressive language delay, in that children with expressive language delay typically follow a normal language trajectory but at a slower pace. Because individuals with apraxia of speech demonstrate similar language concerns as individuals with expressive language disorders, it is necessary for examiners to administer an oral-motor examination to help differentiate the two conditions.

Variations in pitch, volume, resonance, and voice quality can be seen in isolation or in combination with a language delay. Impaired modulation of pitch and volume can be seen in children with autism spectrum disorders, nonverbal learning disorders, and some genetic syndromes. Hyper- or hyponasal voice quality suggests anatomic differences or sometimes neurologic dysfunction, with hypernasal speech occurring secondary to velopharyngeal palatal incompetence and hyponasal speech arising from air impeded by large adenoids. Velopharyngeal palatine incompetence (insufficiency) can be a marker of velocardiofacial syndrome.

A fluency disorder involves the interruption in the flow of speaking. Examples of dysfluent speech include pauses, hesitations, interjections, prolongations, and interruptions. This is common in early childhood (age 2½–4 years) and at that time is categorized as *normal dysfluency of childhood*. Persistent or progressive dysfluency is more likely *stuttering*, which arises in the preschool years for most affected children. Red flags indicative of pathological dysfluency requiring speech therapy include repetitions associated with sound prolongations (e.g., "ca-caaaaa-caaaaat"), multiple part-word repetitions

(e.g., "ca-ca-ca-cat"), hurried and jerky repetitions with associated self-awareness and frustration, associated articulation problems, or a home environment with a low tolerance for stuttering or high pressure for verbal communication. Normal dysfluency usually improves over time.

Language Disorders

A language disorder, or specific language impairment (SLI), is an impairment in the ability to understand and/or use words in context, both verbally and nonverbally. The disorder may involve the form of language (phonology, morphology, and syntax), the content of language (semantics), and/or the function of language (pragmatics). Language disorders are also classified as receptive disorders (trouble understanding others), expressive disorders (trouble sharing thoughts, ideas, and feelings), or mixed receptive and expressive disorders.

Deficits in receptive language almost always occur in conjunction with expressive delays. There are situations where a child may appear to have an isolated receptive delay, but on careful evaluation, deficits in both areas are present. For example, a child with an autism spectrum disorder may appear to have normal or advanced expressive language skills due to extensive use of echolalia, but their functional communication delays are similar to their impaired receptive skills. Children with hydrocephalus (congenital or acquired) may have superficially appropriate or advanced expressive language skills but exhibit poor content of expression known as "cocktail party syndrome." In this case, receptive language lags behind expressive language and is felt to be secondary to hydrocephalus and related effects on the language centers of the brain.

Expressive language disorders represent a broad spectrum of delays, including developmentally inappropriate short length of utterances, word-finding weakness, semantic substitutions, and difficulty mastering grammatical morphemes that contribute to plurals or tense. Signs of weakness in expressive language include circumlocutions (using many words to explain a word instead of using the specific term), excessive use of place holders ("um," "uh"), nonspecific words ("stuff" or "like"), using gestures excessively, or difficulty generating an ordered narrative. Isolated expressive language delays are generally less indicative of organic pathology if not also associated with anatomic abnormalities.

Unless formal language testing using standardized instruments supports the presence solely of an isolated articulation disorder or specific receptive or expressive weakness, a child with a history of "language delays" should be presumed to have had some combination of language understanding and expression weaknesses. Impairment in both the receptive and expressive language domains raises the possibility of a more serious pathologic process, including intellectual disability (mental retardation), autism and other communication disorders, and deafness.

Deficits in pragmatic skills involve the inability to use language appropriately for social communication. A child may be unable to regulate social interactions or reciprocal body language or appropriately modulate their voice. They may stand too close or too far away from people or have improper voice pitch or volume. They commonly have difficulty initiating, maintaining, or terminating a conversation; modifying a topic for an audience; or including others in conversation. Pragmatic language disorders are often found in children with autism spectrum disorders and nonverbal learning disorders.

Diagnosis

The ICD-10 diagnostic criteria for speech and language disorders are outlined in *Table 45.7*.

Screening all children for delays in any of the developmental domains should be conducted at periodic intervals and whenever parents voice concerns about their child's development. This includes eliciting and attending to parental concerns, updating attainment of speech and language developmental milestones, determining risk and protective factors, and making accurate observations of the child. It is important to take parental concerns about speech or language development seriously, as these concerns are valid up to 75% of the time. A 25% delay in milestone attainment is cause for concern and indicates the need for more detailed screening and/or assessment of speech and language skills. Red flags for delayed language skills are outlined in *Table 45.8*.

The evaluation of a child suspected of having a speech or language delay should involve a thorough history and physical examination to determine the nature and extent of the problem but also uncover the etiology whenever possible. The clinician needs to determine whether the delay involves expression alone or both expressive and receptive language abilities. Parental concerns are often focused on a child's inability to express herself/himself and they may not be aware of associated delays in comprehension. Asking parents about any articulation or intelligibility difficulties is important. Inquiry about prenatal and delivery history, hearing loss, multiple ear infections, excessive drooling or difficulty feeding, and delays in other developmental domains will further

Table 45.7
ICD-10 criteria for specific developmental disorders of speech and language

F80.0 Specific speech articulation disorder
Note: Also referred to as Specific speech phonological disorder
A. Articulation (phonological) skills, as assessed on standardized tests, below the 2 standard deviations limit for the child's age
B. Articulation (phonological) skills at least 1 standard deviation below nonverbal IQ as assessed on a standardized test
C. Language expression and comprehension, as assessed on a standardized test, within the 2 standard deviation limit for the child's age
D. Absence of neurological, sensory, or physical impairments that directly affect speech sound production, or a pervasive developmental disorder (F84.-)
E. Most commonly used exclusion criterion: Nonverbal IQ below 70 on a standardized test
F80.1 Expressive language disorder
A. Expressive language skills, as assessed on standardized tests, below the 2 standard deviation limit for the child's age
B. Expressive language skills at least 1 standard deviation below nonverbal IQ as assessed on a standardized test
C. Receptive language skills, as assessed on standardized tests, within the 2 standard deviation limit for the child's age
D. Use and understanding of nonverbal communication and imaginative language functions within the normal range
E. Absence of neurological, sensory, or physical impairments that directly affect use of spoken language, or of a pervasive developmental disorder
F. *Most commonly used exclusion criterion*: Nonverbal IQ below 70 on a standardized test
F80.2 Receptive language disorder
Note: Also referred to as mixed receptive/expressive disorder
A. Language comprehension, as assessed on standardized tests, below the 2 standard deviations limit for the child's age
B. Receptive language skills at least 1 standard deviation below nonverbal IQ as assessed on a standardized test
C. Absence of neurological, sensory, or physical impairments that directly affect receptive language, or of a pervasive developmental disorder
D. *Most commonly used exclusion criterion*: Nonverbal IQ below 70 on a standardized test

Table 45.8
Red flags for delayed language development

Age	Milestone
6 months	No cooing responsively
10 months	No babbling
12 months	No basic gesturing (waving bye-bye, holding arms out to be picked up)
18 months	No words other than mama, dada
	No understanding of simple commands
	No pointing to what she/he wants
24 months	<50 words
	No two-word phrases
	<50% intelligibility
36 months	No three-word sentences
	<75% intelligibility
4–5 years	Not able to tell a simple story

elucidate an underlying cause. A detailed social history may uncover environmental causes of mild speech delay, including regression after a stressful event (e.g., divorce, birth of a sibling), lack of stimulation, or the over-anticipation of needs by older siblings and parents. Twin and family aggregation studies have demonstrated high heritability of language disorders therefore a detailed family history inquiring about speech and language or learning difficulties is important.

A simple conversation with the child may be all that is needed to determine the extent of their comprehension, expression, and deficits in speech delivery. This includes all attempts to communicate, whether it is verbal (e.g., babbling, jargoning, words) or nonverbal (e.g., facial expressions, gesturing or pointing, presence of joint attention, eye contact, and body posture). A neurologic examination focused on oromotor skills should be completed. The oromotor examination should include imitation of tongue movements in all directions, observance of palatal elevation on phonation, and evaluation of structural integrity of the oral cavity.

Evaluation of articulation disorders begins with good surveillance. A formula for the expected conversational intelligibility levels of preschoolers talking to unfamiliar listeners is: AGE IN YEARS/4 × 100 = % understood by strangers:

Child aged 1.0 = 1/4 or 25% intelligible to strangers
Child aged 2.0 = 2/4 or 50% intelligible to strangers
Child aged 3.0 = 3/4 or 75% intelligible to strangers
Child aged 4.0 = 4/4 or 100% intelligible to strangers

Any child older than 4 years with a speech intelligibility score of less than 66% (i.e., less than two-thirds of utterances understood by unfamiliar listeners) should be considered a candidate for intervention.

If a child is suspected of having a language disorder, evaluation by a speech-language pathologist is recommended. Referral to a developmental pediatric specialist or neurologist is also recommended if there is a history of language regression or if there are delays in other areas. Detailed genetic and neurologic evaluations for isolated speech and language impairments are of low yield, and an underlying etiology will be determined in less than 5% of cases. If hypernasality is noted with suspected velopharyngeal insufficiency, then further investigation for velocardiofacial disorder is indicated including referral to otorhinolaryngology and florescent in-situ hybridization study for 22q11.2. If a child has dysmorphic features or is found to have global developmental delays, then a full evaluation is recommended. This evaluation varies with the risk factors and findings and may include brain imaging, electroencephalogram, genetic testing, and/or metabolic testing.

Differential Diagnosis

If a speech or language delay is suspected, the child should be referred for a formal audiology examination, as a child may not have apparent hearing deficits by history. Even mild hearing loss can cause language delays and may not be picked up by newborn hearing screening. Evaluation of a child's nonverbal problem-solving and adaptive skills can determine whether the child may have an underlying cognitive impairment. If there are concerns related to a child's social relatedness and social interactions, an autism spectrum disorder should be suspected. There is considerable overlap among these underlying causes, especially considering the wide spectrum of severity in each area.

Language regression raises concerns for several disorders, including autism spectrum disorders, Rett Syndrome, or Landau–Kleffner syndrome (seizures accompanied by acquired aphasia).

Treatment

Even when there is a question regarding the underlying diagnosis, all young children suspected of having speech or language impairment should be referred promptly to their local Early Intervention Program (EIP). Such programs enrich a child's language experience through both parent training and provision of language-stimulating preschool environments. In addition, immediate speech and language therapy, which can be provided as a component of an EIP, has been shown to improve auditory comprehension and phonologic disorders. Additionally, speech and language therapy may prevent further delays and help reduce behavior difficulties associated with frustrated attempts to communicate.

Treatment of speech-language disorders includes three components: causal, habilitative, and supportive. Causal treatment is focused on repairing defects, correcting dysfunction, or eliminating factors that contribute to the language problem (e.g., cleft palate repair, hearing aids). Habilitative treatment is designed to directly improve the child's language skills (i.e., speech-language therapy, counseling of parents to actively engage in the child's language development). Supportive treatment aims to boost language acquisition (e.g., training programs for speech-related skills, increasing social contacts).

Goals for treatment depend on the nature of the child's speech or language impairment. The overall goal is to communicate with others, whether by spoken language or nonverbally through the use of sign language or communication systems, such as the Picture Exchange Communication System or an augmentative communication device. Some parents may voice concerns that early use of sign language or another communication system will impair a child's ability to speak, but there is evidence that using these systems may actually enhance a child's speech and language development.

In addition to therapy, parent education that focuses on language stimulation activities is essential. Structured/stimulating child care centers, preschool programs are also beneficial, particularly in children with isolated nonpathologic speech-language delay reflecting developmental variation or lack of a stimulating home environment.

Prognosis

While therapy may improve the degree of impairment and prognosis, many children do not "outgrow" speech and language disorders, although these disorders manifest in different ways over time. Developmental continuities exist between oral (including speech) and written (reading and written expression) language disorders. Oral language skills, including phonology, semantics, grammar, and pragmatics, are the foundation for reading. Children with language problems typically are at higher risk for

reading comprehension deficits. Children with persistent specific language impairment at 8½ years of age have been shown to have pervasive problems with spelling, word-level reading, and reading comprehension at 15 years of age. Developmental promotion of language and early identification and intervention for speech and language disorders are vital to provide the greatest long-term functional benefits.

Learning Disabilities

Issa is an 8-year-old boy in your office for concerns of school failure. He has a history of delayed speech and language development, which improved with speech therapy. This year, he had difficulty in his reading and writing class. So far, no behavioral problems have been revealed and he is diligent about studying and his homework. You decide to refer him for psychoeducational testing, requesting intelligence and achievement measures.

Definition

The term "learning disabilities" was used in 1963 by Samuel Kirk, PhD "to describe a group of children who have disorders in development in language, speech, reading and associated communication skills needed for social interaction." He carefully excluded children who had "sensory handicaps such as blindness or deafness. . .generalized mental retardation." Specific Learning Disabilities (SLDs) involve one or more disordered psychological processes involved in understanding or in using language, spoken or written, which may be manifested in problems with listening, speaking, reading, writing, spelling, or performing mathematical computations. Individuals with perceptual disabilities, brain injury, and developmental aphasia are included in this identification. Those who have problems resulting from visual, hearing or motor difficulties, intellectual disability, emotional dysregulation, or environmental, cultural, or economic disadvantages are usually excluded from meeting the criteria for SLD.

The discrepancy definition customarily assumes the child has been exposed to an adequate educational experience and yet shows a difference of one standard deviation or more (>15–20 points) between his/her intelligence level (IQ score) and standard score on achievement testing in oral expression, listening comprehension, basic reading skills, reading comprehension, written expression, or mathematics calculation or reasoning. For example, a 9-year-old with a full-scale IQ standard score of 100 in the mid-average range, would need to show a standard score of <85 in any of the aforementioned areas to be considered as meeting the "discrepancy criteria" for SLD.

Children also may be identified as SLD if they meet the "poor achievement" definition of SLD. The poor achievement is set as a standard score threshold (1½–2 standard deviations below the mean value) below which it is agreed academic performance is so weak there is a significant learning problem. The threshold usually translates into a 2-year lag in academic performance below that expected for the child's age. A standard score of 70 is 2 standard deviations below the mean and represents very weak performance. However, children whose educational achievement and cognitive levels overlap do not meet criteria for the diagnosis of SLD. With weaker cognition, educational achievement also is expected to be weaker.

Epidemiology

Learning disabilities are, by definition, only identified after a child enters a school where specific content instruction is given and performance is measured. For this reason, the incidence and prevalence statistics primarily reflect industrialized countries with government-supported school systems. Taking all categories of learning disabilities, the prevalence is estimated at 5–10% of the total school population. Boys appear to be overrepresented in learning disabilities with a ratio of boys to girls 4:1; however, girls may be underidentified because they often are not as behaviorally challenging in the classroom. Prevalence estimates of dyslexia in school-age children range from 7% to 15%. If the definition is broadened to include all reading disabilities, the prevalence may increase to as much as 18% of school-age children. Math learning disability incidence estimates range from 5.8% to 13.8%. Children with math disability who have comorbid reading disability are estimated at 35–56.7%. A 1992 study of unreferred primary grade children found that 1.3–2.7% had problems with handwriting; 3.7–4.0% had spelling weakness; and 1–3% had weakness in creating written narratives. In 1999, the National Assessment of Educational Progress reported that 77% of US fourth-grade students wrote at less than a fourth-grade level.

Etiology/Pathogenesis

Recent advances in functional neuroimaging have supported prior assertions that certain cognitive functions

can be localized to specific regions in the brain. Language-based learning disorders, such as reading, spelling, and written expression, comprise 90% of all SLD and are considered left hemisphere disorders. Right hemisphere SLD show weaknesses in spatial cognition and/or visuoperceptual abilities leading to difficulties in math calculation and reasoning. Genetic influences appear to be more prominent in children with phonological coding deficits than in those with visual coding deficits.

Clinical Manifestations

Reading Disorder/Dyslexia

While there are many components to reading weakness, it is currently held the most prevalent deficit is a specific language skill resulting in less ability in detecting and manipulating individual speech sounds (phonemes). This leads to poor word recognition and decoding. In the past, it was assumed that visual system deficits were the foundations for reading weakness and the term "dyslexia" was used to describe the pattern of reversing letters when reading and writing. Now "dyslexia" is used to refer to any reading weakness, including specific reading disability, phonemic awareness deficits, and rapid automatic naming weaknesses.

In typical reading development, the child realizes spoken words are comprised of parts (phonemic awareness). Once this recognition occurs, the child associates written letters with these phonemes and an appreciation of written language occurs. The printed words are now accepted by the inherent neural circuitry for processing spoken language. When the child reads the printed word, decoding into phonemes occurs where the words are automatically processing by the language system. The reading *code* is broken. In the USA, 70–80% of children successfully learn this skill. Skilled readers show strong activation in the posterior left occipitotemporal region. Children identified as dyslexic do not show this overactivation of the left occipitotemporal region even after repeated trials of word exposure. Phonologic weakness in the dyslexic reader is persistent and is seen irrespective of primary language, overall cognitive level, or educational level.

Reading ability is evaluated principally by assessing basic skills and comprehension. The best characterization of the child's reading skills will describe the most effective intervention program. The child's ability to assign sounds to letter combinations (phonological awareness), rapid automatic naming speed and accuracy, reading vocabulary, reading rate (basic speed of reading aloud), reading fluency (speed of reading without mistakes), and reading comprehension all should be described in the reading evaluation. A child with significant reading comprehension weakness should be seriously considered for a separate language evaluation. Weak grammatical understanding, often identified in those with language impairment clearly affects reading understanding.

Mathematical Disorder

Published information about math learning disabilities does not have the extensive breadth when compared with reading disabilities. The understanding of problems with math learning may be affected by the variety of yet unidentified cognitive processes involved in typical math competence. This contrasts with word reading which is largely subsumed by the phonological processing deficits. Math has many areas including number computation, algebra, geometry, measurement, and solving word problems, which has led to difficulty in developing specific definitions of math learning disabilities.

In the USA, current identification criteria developed by the U.S. Office of Education specify two types of math learning disabilities: disability in math calculation and disability in math reasoning. *Table 45.9* compares ICD-10 and DSM IV diagnostic criteria for math disorder.

There are no clearly identified areas of the brain presumed to provide the location for processing required in math learning. Certain neural functions appear essential for normal math development. Good attention, working memory, short- and long-term memory are all needed. *Semantic memory* allows number-symbol association, prompt recall of math facts, and contributes to phonologic memory. Long-term *procedural memory* underlies use of strategies and algorithms in math solutions. Developmentally normal *visual spatial abilities* allow the child to correctly align numbers, keep place values, and adhere to operational direction rules while performing operations.

Finally, information processing speed is very important while solving math problems and may be directly affected by the semantic, procedural, short- and long-term, and working memory. Weaknesses in any of these domains will result in slower rate of information assimilation and may result in failure of fact organization.

Evaluation of mathematical abilities usually includes an individually administered, standardized mathematical achievement test, and the performance standard scores are compared with the child's intelligence standard score. Specific areas of calculation, speed of calculation,

Table 45.9
Mathematical disorder criteria of ICD-10 and DSM-IV

	ICD-10	DSM-IV
Code	F81.2 Specific disorder of arithmetical skills	315.1 Mathematics Disorder
Description	Involves a specific impairment in arithmetical skills. The deficit concerns mastery of basic computational skills of addition, subtraction, multiplication, and division rather than of the more abstract mathematical skills involved in algebra, trigonometry, geometry, or calculus	A. Mathematical ability, as measured by individually administered standardized tests, is substantially below that expected given the person's chronological age, measured intelligence, and age appropriate education
	Includes: Developmental:	B. The disturbance in Criterion A significantly interferes with academic achievement or activities of daily living that require mathematical ability
	Acalculia	
	Arithmetical disorder	
	Gerstmann's syndrome	
		C. If a sensory deficit is present, the difficulties in mathematical ability are in excess of those usually associated with it
Excludes	Not solely explicable on the basis of general mental retardation, acalculia NOS (R48.8), arithmetical difficulties:	
	Associated with a reading or spelling disorder (F81.3)	
	Due to inadequate teaching (Z55.8)	

mathematical reasoning, and application of mathematical principles are usually assessed. It is not uncommon for children with language disorders to have acceptable calculation abilities, but struggle with mathematical problems presented in word format.

Disorders of Written Expression

Individuals with disorders of written expression have significant difficulty translating their thoughts into written format at a level consistent with their intelligence. Written expression involves many developmental abilities (fine motor skills, attention, language, and memory domains) and therefore is affected if any of these domains are weak. Variable difficulties may be observed in handwriting (mechanics), spelling, sentence development, punctuation, grammar, development of ideas, organization of those ideas, and developing a cogent written product. Both the quality and quantity of the written product can be affected.

Written expression puts coordination and integrative demands on many neurodevelopmental domains. Cognitive information processing areas involved include mentally resisting distractions and "overcoming inertia" to get started on a task, idea development, concept formation, thinking, reasoning, fluent retrieval of information from memory, expression of information, attention to detail, task analysis and prioritization, planning and organization, appropriate sequencing of ideas and activities, concentration, understanding of language and appropriate communication rules/syntax, working memory, and fine motor graphomotor skills. Individuals with language disorders, ADHD, fine motor weaknesses, visual impairment, and/or any other alternation of sustained alert status will be susceptible to impairment of written expression.

Written expression is assessed formally by administering standardized composite educational assessment instruments and informally by reviewing writing samples such as journal entries, book reports, themes written for class assignments, and even letters to family members or friends.

Diagnosis

It may not be practical to formally assess specific language-based learning problems in a school-aged child in the pediatric office setting. However, a few surveillance questions may help identify the presence of difficulties in language-based learning (*Table 45.10*).

The evaluation of learning disabilities includes taking a careful medical history. Extreme prematurity with or without cerebral hemorrhage, maternal prenatal risk

Table 45.10
Surveillance questions for language-based learning problems

1. Does she/he have trouble expressing her/his thoughts?
2. Is it difficult for her/him to understand or follow directions?
3. Does she/he express herself/himself through gestures rather than verbally?
4. Does she/he have trouble finding the correct word? (word retrieval)
5. Does she/he confuse words that sound alike (e.g., tornado for volcano)? (auditory discrimination)
6. Does it seem to take a long time for her/him to understand directions or answer questions? (processing speed)
7. Does she/he seem to have to repeat things (out loud or to self) in order to understand them? (processing speed)
8. Can she/he tell you the letter that comes after "s" without going through the alphabet? (could also use days of the week, months, etc.) (sequential processing)

factors (medications taken, substance abuse, poor nutrition, maternal chronic medical conditions), perinatal adverse events (severe hypoxia), significantly adverse postnatal course, and minimal developmental intervention are all risk factors for learning difficulties. Environmental adverse factors, such as excessive environmental lead and malnourishment should be identified. Early developmental progression and skills acquisition are important. Impact of any personal chronic medical conditions should be noted. Physical exam findings identifying any obvious or subtle dysmorphic features as well as screening for vision or hearing deficits are important.

The child's social emotional profile should be explored as there is a high degree of comorbid psychiatric diagnoses in children with SLD. Depression and anxiety may occur primarily or as secondary to the child's learning struggles. This assessment may be as brief as administration of an emotional screening instrument (e.g., Pediatric Symptom Checklist) or a more formal interview with the child and family. The family structure including their expectations and stability in the community can be important factors in academic success. Identifying support systems, economic resources available to the family and cultural forces impacting their decisions all should be taken into account when assessing a child who struggles academically.

Standardized intelligence testing is part of the learning disabilities assessment. Broad academic achievement tests are the usual instruments to obtain educational standard scores. In the USA, two widely used tests are the Wechsler Individual Achievement Tests-Fourth Edition (WIAT-4) and the Woodcock-Johnson Tests of Achievement-Third Edition (WJ-TOA-3) as these have corresponding intelligence measures: Wechsler Intelligence Scales for Children-Fourth Edition (WISC-IV) and the Woodcock-Johnson Tests of Cognitive Abilities-Third Edition (WJ-TCA-III) respectively. More specific individual educational achievement tests also may be administered for more precise identification of particular educational strengths and weaknesses.

Treatment

In the USA, the determination of whether a child meets the criteria for supportive supplemental school services is reserved by the local school identification team. Students benefit from academic and classroom accommodations and modifications for learning disabilities. Specialized reading support is recommended for children with dyslexia. The National Early Literacy Panel endorses an evidence-based reading program that utilizes systematic instruction using a phonics-based, multisensory approach to teach the mechanics of reading and writing tasks (decoding and encoding), such as the Orton–Gillingham or Lindamood-Bell programs. Children with mathematics disorder may improve by supporting working memory through better attention and emphasizing the child's self-monitoring of calculation accuracy. Permitting the use of an electronic calculator may be an eventual bypass strategy for the child with persistent calculation inaccuracy. Disorders of written expression are treated by addressing the specific weaknesses that are involved. Children with SLD may develop poor self-confidence due to their academic struggles, which should be addressed with appropriate family and mental health supports.

Prognosis

Identification and intervention for reading disorders may not always guarantee completely normalized reading function. One study found that of those children identified as "reading disabled" in the third grade, 74% would meet that identification in the tenth grade. Children identified later as reading impaired need more time of individual remedial instruction. For example, if identified as reading disabled in kindergarten or the first grade, 30 min of daily remedial instruction can improve reading skills to grade level. If identification is not made until the third grade or

later, 2 h daily remedial instruction is necessary to make comparable progress. Often these students can be taught to compensate, but their phonological processing deficits persist to some degree.

Math computation weakness can have a good outcome with appropriate supports if the child does not have a primary problem of dyscalculia. Math reasoning weakness has a variable outcome as the reasoning weakness must be clearly identified during the evaluation process. Weakness in math reasoning may be due to weak conceptualization of the constructs, weakness in sequential processing, visual–spatial abilities, and cognitive flexibility. Language abilities also have a significant role in math reasoning.

The prognosis for a disorder of written expression is very dependent on the developmental skills weaknesses involved. If the child has poor fine motor skills, assisting with more precise handling of the writing implement and automaticity of letter formation will be very helpful. If vocabulary and/or spelling are not strong, then enhancing phonological skills and word knowledge will enhance written expression. Written expression, however, is very age-dependent and instruction sensitive and the expectations increase as the child becomes older. For this reason, many will have continued struggles with this domain.

46 Behavioral Disorders of Childhood

Mary Margaret Gleason

Psychiatric disorders play an important role in pediatric practice. Worldwide, psychiatric disorders cause substantial suffering in both developing and developed countries, with as many as 20% of children affected by mental health problems that interfere with their functioning. Psychiatric problems have the potential to influence nearly every aspect of a child's life, with interference seen in family functioning, peer relationships, academic performance, and extracurricular activities. In addition, more than most other pediatric problems, psychiatric disorders are directly associated with substantial economic costs, including substantial medical, educational, and juvenile justice expenditures, as well as impact on parent income, even when the disorders are not identified as mental health problems. Most importantly, these disorders have the potential to cause suffering to the individual patient and family and to have adverse impact on future functioning.

In discussions of psychiatric disorders, it must be noted that, although symptoms and impairment can be identified at strikingly consistent rates around the globe, the diagnostic systems employed vary. The two major nosologies are derived from research in western cultures. The American Diagnostic and Statistical Manual (DSM) is currently in its fourth edition and the fifth edition is under development. This system includes a small section focused on disorders commonly seen in childhood, but for the most part, child psychiatric disorders are diagnosed using criteria developed using adult data. The World Health Organization publishes the International Classification of Diseases, a nosologic system in its tenth iteration. Like the DSM, the ICD includes a section focused on disorders specific to childhood, such as separation anxiety disorder, disruptive behavior disorders, attachment disorders, and hyperkinetic disorder, but prevalent emotional disorders are described for children in the same way they are for adults. Generally, the DSM and ICD systems describe similar syndromes, but the specific criteria vary.

The overwhelming majority of psychiatric research is in European and American settings. It is critical to note that, perhaps more than any other category of pediatric disorder, psychiatric disorders must be considered in the context of the child's cultural experience. Family structure and roles vary widely, and these structures shape the expectations of child development of autonomy, acceptable emotional expression, and even beliefs about perceptual experiences. These factors remind clinicians that assessment of family's view of the child's impairment is of utmost importance when assessing the mental health of a child, especially when the child's cultural background differs from those that have shaped the current diagnostic nosologies.

This chapter will review the major categories of psychiatric disorders, including the disorders affecting the youngest patients, attachment disorders, followed by a review of externalizing disorders, internalizing disorders, and psychotic disorders.

Reactive Attachment Disorder

Definition/Background

Attachment disorders are among the earliest presenting mental health disorders in young children. These disorders occur in children who have experienced adverse caregiving and who present with extreme behaviors suggestive of problems of attachment. Both diagnostic systems describe two similar forms of attachment disorders. In the DSM system, these are reactive attachment disorder (RAD), inhibited type and reactive attachment disorder, disinhibited type. The ICD system describes reactive attachment disorder of childhood, which focuses on the inhibited pattern and disinhibited attachment disorder of childhood. More recent research has focused on empirically derived criteria more closely linked to specific attachment behavior patterns which are included in the proposed criteria for DSM V (*Table 46.1*). To understand the concept of RAD, the fundamentals of attachment must be clear. The attachment system is thought to be activated when a child is under stress. In a healthy caregiving relationship, an infant or young child under stress will *preferentially* seek proximity to the primary caregiver and effectively derive comfort from the caregiver.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_46,

Table 46.1
Proposed criteria for DSM-V reactive attachment disorder

A. A pattern of markedly disturbed and developmentally inappropriate attachment behaviors, in which the child rarely or minimally turns preferentially to a discriminated attachment figure for comfort, support, protection, and nurturance. The disorder is manifest as (1), (2), or (3)
1. An inhibited, emotionally withdrawn pattern in which the child rarely or minimally directs attachment behaviors toward any adult caregivers, as manifest by three of the following:
(a) Rarely or minimally seeks comfort when distressed
(b) Rarely or minimally responds to comfort offered when distressed
(c) Limited positive affect and excessive levels of irritability, sadness or fear
(d) Reduced or absent social and emotional reciprocity (e.g., reduced affect-sharing social referencing, turn-taking, and eye contact)
2. A disinhibited, indiscriminate pattern in which the child directs attachment behavior non-selectively, as manifest by two of the following:
(a) Demonstrates overly familiar behavior and reduced or absent reticence around unfamiliar adults
(b) Rarely or minimally checks back with adult caregiver after venturing away even in unfamiliar settings
(c) Willing to go off with an unfamiliar adult with minimal or no hesitation.
3. A mixed pattern of inhibition and disinhibition characterized by two or more criteria from (1) and (2)
B. Child does not meet criteria for pervasive developmental disorder
C. The child has a developmental age of at least 9 months

RAD has been described as patterns of non-attachment, in which the child does not preferentially use the caregiver for comfort. In the emotionally withdrawn/inhibited form of RAD, children show few attachment behaviors, even when in distress, and appear inhibited, affectively negative, and lacking joyful reciprocity. In the socially indiscriminate/disinhibited form of RAD, children show excessive social indiscriminance, including not referencing their parents in new situations, approaching strangers without reticence, and leaving with a stranger.

Etiology

Both forms of RAD are associated with pathogenic caregiving conditions and appear to show a dose dependent response. Milder signs of RAD can be identified in children with lower caregiving adversity and more severe RADs are associated with severe caregiving adversity. It is important to note that adverse caregiving alone is not sufficient to cause RAD, as most children do not develop RAD, even in adverse caregiving situations. Studies are underway to identify prenatal or biological factors that explain individual variation.

Epidemiology

Systematic assessment of the prevalence of RAD is difficult. It is thought to be rare in the general population, although it has not been included in most population based studies of childhood psychopathology. In clinical samples, reports range from a low of 1–20%. This wide range likely represents differences in referral bases and diagnostic approaches. In maltreated samples, approximately 40% of children under 4 meet criteria for at least one form of RAD, and more than half of the children in institutions show the disorder. After removal from institutions, almost no cases of emotionally withdrawn/inhibited RAD are identifiable, although rates of socially indiscriminate/disinhibited RAD remain elevated.

Pathogenesis

To date, no research has identified the factors which put children at highest risk of developing RAD in high-risk caregiving settings. New research focused on institutionalized populations in Romania provide early hints that the inhibited form of RAD is, in fact, strongly related to attachment security and to the quality of caregiving but that the disinhibited form of RAD may have a different underlying deficit, including problems with committed social relationships, adaptive process in institutional care, or problems understanding other people's motivations and knowledge.

Clinical Manifestations

Children with RAD can be identified in clinical contexts by careful history and observation. Although pathogenic caregiving is required for the diagnosis, this requirement may be difficult to establish in an initial interview, especially if the child has been adopted or if the parent is guarded about parenting practices that would constitute maltreatment if they were disclosed. Thus, the lack of

confirmation should not preclude consideration of the diagnosis.

Children with the inhibited form of RAD will be described by their caregivers as seeking their caregivers out in only limited ways. The interview focuses on the signs of RAD described above. These children may have a flat affect or appear depressed. In a clinical interview and observation, such as a pediatric examination, these children are unlikely to use their parent for comfort during the physical exam or immunizations and may be difficult for even the most skilled pediatrician to engage.

Children with the socially indiscriminate form of RAD may be noted to approach unfamiliar adults in the waiting room or office setting without reticence, talking with them and even approaching them physically. The social impulsivity may resemble ADHD in the clinical setting. Older preschoolers with socially indiscriminate RAD may present with co-occurring aggression, but this is not seen in younger children and the data are mixed to date. Aggression and disruptive behaviors are not core symptoms of any form of RAD but may suggest comorbid conditions in these high-risk children.

There are few studies of RAD in children beyond the preschool years. The most rigorous studies examine a construct that defined as RAD, but which employs different criteria from those used in the more substantial literature in younger children. Thus, it is not clear whether the disorder described in school age children is the same disorder and the diagnosis should be applied with caution beyond the preschool years. Unfortunately, the internet abounds with descriptions of RAD which are not based upon peer-reviewed empirical literature. These descriptions characterize children with RAD as dangerous and having sociopathic traits. The risks to families reading these descriptions are multifold. Families who follow the paths suggested on these websites run the risk of missing the opportunity for a careful diagnostic assessment to identify the range of psychiatric disorders that may occur in children who have experienced severe adversity and miss opportunities for interventions for those disorders. Secondly, this characterization of vulnerable children as monsters tends to reduce the family bonds and empathy, both of which are necessary for recovery from the extremes of caregiving adversity.

General Care

Most importantly, clinicians treating children with RAD or suspected RAD should ensure that the child is in a safe caregiving situation now. If some degree of caregiving risk continues, it is critical that the clinician work with social service agencies to mitigate the risks to the child. In addition, because children with RAD are at risk of a range of adverse mental health and developmental outcomes because of their early risk exposure, a full developmental, medical, and mental health assessment should be completed and children with developmental delays, untreated medical conditions, and comorbid psychiatric conditions must be provided access to interventions to address those issues.

Specific Treatment and Prognosis

Only one study has used a randomized, controlled trial to examine the effects of an intervention on RAD. In the Bucharest Early Intervention Project, previously institutionalized Romanian children placed in foster care showed substantial improvement in both forms of RAD signs compared with institutionalized children who received care as usual. This finding related to inhibited RAD is consistent with other studies of post-institutionalized children, in which inhibited signs of RAD were virtually nonexistent after adoption. For the socially indiscriminate form of RAD, the effect was slower and of a lesser magnitude, but was associated with the quality of caregiving. Thus, children with RAD require warm, nurturing, consistent caregiving by someone who verbally engages with the child and is committed to the child's well-being. Even in such a circumstance, signs of socially indiscriminant RAD may persist over years.

Prevention

Because of the clear link with caregiving adversity, RAD can be prevented by ensuring that children worldwide are cared for by individuals who are committed to the child and available to the child when the child is in need. Institutional care that does not allow a child to learn that there is at least one and perhaps a small number of caregivers on whom the child can depend for comfort, nurturing, and love will continue to create cases of RAD. As societies, policies that protect children from pathogenic care are advocated.

Internalizing Disorders

Internalizing disorders include disorders whose symptoms are predominantly emotional and therefore

may be considered "internal" to the child. The main categories include mood disorders – depressive and bipolar disorders – and anxiety disorders. Each will be considered separately, as their presentation, trajectory, and treatment differ.

Depressive Disorders

The depressive disorders in childhood include major depressive disorder, dysthymic disorder, and depressive disorder not otherwise specified, that is, a constellation of depressive symptoms that interfere with a child's life, but do not meet the specific criteria described for the other two syndromes. In general, depressive disorders in children present with depressed or irritable mood, neurovegetative signs such as impaired sleep, appetite, or concentration, and impairment in functioning within important relationships or activities. In contrast to commonly held beliefs, younger children present with similar patterns of depressive symptoms as older children and adults.

Epidemiology

Depression affects a sizable group of children worldwide. In the USA and Europe, point prevalence rates of Major Depressive Disorder range from 1% to 2% in prepubertal children and 2–4% of adolescents, with lifetime prevalence rates up to 20% of children before the age of 18. There is no gender difference in rates of depression until puberty, when rates in girls are approximately double the rates in boys. Rates of depression also vary substantially across different risk groups. Poverty, chronic medical conditions, and exposure to violence are associated with higher rates of depression. A recent review of adverse outcomes of children living in low-income countries with extreme adversities including child soldier status, female genital mutilation, and child labor revealed that more than 50% had depression.

Etiology/Pathogenesis

Pediatric depressive disorders have multifactorial etiologies. As noted above, rates of depression vary with a number of physiologic and environmental risk factors. Major life stressors contribute to depression in children. Family factors and relationships such as harsh parenting, family discord and parental substance abuse all contribute to the risk of depression. The appearance of gender differences in rates of depression at puberty suggest that hormonal differences and social relationship differences may play important roles in the development of depression, although the causal mechanism has not yet been identified.

Heredity clearly plays a role in the development of depression. The transmission of the depression appears to be much more strongly related to the environmental risks associated with being parented by a depressed caregiver, although direct genetic influences exist as well. The environmental effect of parental depression can be relieved by successful treatment of parental depression. Twin studies suggest that in low-risk children, genetic factors appear to play important roles in the development of depression, but that for youth in high social risk settings, environmental factors are more powerful predictors of adolescent depression. Of these, early maltreatment has been most commonly studied. Specific genetic polymorphisms of genes associated with serotonin functioning, brain-derived neurotrophic factor, and cortisol all appear to play roles in development of depression, usually in conjunction with a range of environmental risk settings.

Clinical Manifestations

Pediatric depression has similar patterns of symptoms as depression in older children. Criteria in the DSM-IV and ICD-10 are quite similar and both require a depressed mood or irritability as the core symptoms. The DSM requires that the patient have six of the nine possible other symptoms. Children and adolescents with depression also present with associated neurovegetative signs including change in appetite, sleep, concentration, memory, energy. Appetite and sleep may change in either direction, with reductions or increases in appetite and weight and increase in sleep or decrease in sleep quality. Decreased quality of sleep in depressive disorders can be distinguished from changes in sleep in bipolar disorders because depressed children and adolescents continue to need their sleep and have reductions in their energy. The lack of enjoyment in activities that previously were enjoyable, "anhedonia," is a symptom specific to depression. It may be observed because a child begins to withdraw from social activities or from extracurricular activities, or when a patient doesn't appear happy doing activities he or she used to enjoy.

Suicidal ideation can also present in youth with depressive disorders. Suicidal thoughts can be characterized into two major categories. Active suicidal ideations include thoughts of taking an active step to end life (e.g., intentional ingestion, cutting) and passive suicidal

ideations, in which a person may wish he or she were dead and may not be taking usual safety precautions (e.g., not wearing a seatbelt), but does not have a plan to actively end her life. Suicidality is not uniquely associated with depressive disorders and can be seen in the context of other psychopathology or in general populations. Because completed suicides occur at relative low rates – although no rate is acceptable – reliable predictors are difficult to identify. However, family history of completed suicide, mania or agitation, and past suicide attempts are related to completed suicide. One study examined predictors of high-risk attempts that required medical attention and identified the following risk factors: a history of having been forced to have sex against their will, being a current cigarette smoker, lesbian, gay, bisexual, or unsure sexual identity, or not speaking English at home.

Children and adolescents presenting with depression may present with a chief complaint related to their mood. However, it is also not unusual for them to present with school failure, weight loss, or peer or family interaction problems.

Diagnosis

The diagnosis of major depression depends on a careful history. Children and parents should be interviewed together and separately. Every evaluation focused on psychiatric issues should begin with open ended questions about the patient's concern and current life context. The interview should include attention to potential triggers or exacerbating factors, such as recent breakup, family stressors, academic challenges, medical problems, child maltreatment, or partner violence. The history should review the symptoms of depression, including current and past suicidality. In addition, the history should review symptoms of frequently co-occurring disorders, especially anxiety disorders, disruptive behaviors, substance use or abuse, eating disorders, and sleep problems. Many of these can also be considered in the differential diagnosis. An evaluation of depression must include past medical and developmental history, looking for chronic illnesses that may be increasing the burden of stress on the child or developmental problems that may interfere with peer and/or academic functioning. Family history is of utmost importance, with attention to the psychiatric history of biological family members and household members. If a primary caregiver is reported to have symptoms of depression or other impairing psychiatric disorder, attention to the current level of symptoms and safety of the adult and their family is critical. In addition to the review of possible stressors, review of social functioning is another important facet of the assessment, with attention to school functioning, peer interactions and extracurricular activities.

The mental status and physical examination in children with possible depressive disorders may be normal in the pediatric setting. However, it is important to attend to the following components. Appearance and behavior may reflect limited ability to address hygiene or basic activities of daily living. Depressed children may be slowed in their movements, may make poor eye contact, and may be more withdrawn in their social interactions. Speech may be slowed or of lower than usual volume. In formal psychiatric terms, mood is the description that a patient uses for their own internal state. Affect is the word that describes the range of emotional content that is observable in the patient's facial expression and the degree to which the expressions match the content of discussion. Generally in depression, children's thought process remains intact, meaning that they can put thoughts together in an organized fashion. However, their thought content should be assessed for repetitive themes of hopelessness and explicitly assessed for active or passive suicidal ideation. All moderately or severely depressed patients should be asked about hallucinations and delusions. Since depression may interfere with concentration and memory, it can be useful to assess these formally.

Pediatricians add an important component to the mental health assessment. Physical examination should include height and weight measurements, careful skin examination for signs of self-injurious behaviors, especially cutting on forearms, inner thighs, and under breasts, and for metacarpal abrasions that might reflect purging. Physical exam should also include a thyroid palpation. Laboratory assessment is generally unnecessary, but specific clinical conditions might indicate the need for TSH to rule out hypothyroidism (weight gain, low energy, family history of autoimmune diseases), toxicology tests to identify illicit drug use, and pregnancy test if clinically indicated or if medications are being considered in a sexually active adolescent girl.

Differential Diagnosis

The differential diagnosis of major depressive disorder in children and adolescents is broad. *Table 46.2* reviews the differentiating factors between depression and anxiety disorders, other mood disorders, sleep disorders, substance abuse disorders, and eating disorders. It should be noted that comorbidity with many of these disorders is not uncommon.

Table 46.2
Differential diagnosis of major depressive disorder

Disorder	Similarities	Differences
Anxiety (GAD, panic disorder, separation anxiety, specific phobias, OCD, PTSD)	Sleep, concentration, memory problems, may withdraw from activities	No anhedonia (although avoidance), endorse prominent worrying, sympathetic activation
Adjustment D/O, dysthymia	Same symptoms	Time course, intensity
Sleep disorder	Sleep complaints, fatigue, concentration problems, irritability	Sleep disturbance predated mood symptoms, mood symptoms resolve with adequate sleep
Bipolar disorder	Depressive symptoms identical	Manic history, family history of bipolar disorder
Disruptive behavior disorders (ODD, CD)	Irritability, increased oppositional behaviors	Mood symptoms more situational/relationship specific; do not look depressed with peers
Substance abuse	Mood changes, sleep, energy, concentration, school problems	May be more variable patterns of moods, other social changes
Eating disorder	Weight loss, decreased energy, interest, concentration/memory problems	Body image distortion, refusal to gain weight, electrolyte and physical exam findings, generally more severe weight loss

Treatment of Depression

For children and adolescents with mild depression, non-pharmacological interventions including psychoeducation, school intervention, and supportive therapy should be used as first-line treatment. Mild depression does not include hopelessness, severe neurovegetative symptoms, and does not include active or intense suicidal ideation. For these patients, it is important for pediatricians to know that supportive therapy can be equally effective as evidence-based treatments such as Cognitive Behavioral Therapy (CBT), a form of treatment that focuses on helping the patient learn and use new thinking skills to modify negative behaviors and Interpersonal Therapy (IPT), in which the focus is on a patient's relationships with peers and family members and the way they see themselves. If a response is not seen within 4–6 weeks, more focused therapy should be considered.

For patients with moderate–severe depression or those who have mild depression that is unresponsive to supportive interventions, the evidence-based cognitive behavioral therapy, interpersonal therapy, and selective serotonin reuptake inhibitors should be considered. Although intuitively, the combination of an evidence-based treatment such as CBT and an SSRI might be expected to work synergistically, the combination has not been demonstrated to be more effective in reducing symptoms, although it shows a more rapid response rate than with CBT alone and less suicidal ideation than SSRI alone. It is possible that further follow-up will demonstrate a longer lasting effect of the CBT. Decisions about medication versus therapy can be made based upon availability of therapy, intensity of suicidal ideation or other indices of need for accelerated treatment response, family preference, and family history of response to treatment.

When psychopharmacological interventions are considered, fluoxetine is considered first line because it has the most substantial evidence supporting its efficacy and safety. Escitalopram and sertraline have also been shown to be superior to placebo in treating adolescent – but not school age child – depression. In youth who are at relatively higher risk of developing activation or mania, using a medication with a shorter half life, such as sertraline or citalopram, may be indicated. *Table 46.3* presents clinical indications, formulations, and general dosing targets for medications. Medications such as venlafaxine and buproprion have substantially less data supporting their use in pediatric depression than SSRI's and are not first-line interventions. Hypericum perforatum (St. John's Wort) is approved for use in European countries; however, a search of English language papers does not reveal evidence of randomized controlled trials showing this medication is superior to placebo for treatment of depression in children or adolescents.

All SSRI's are associated with a measurable risk of increased suicidal ideation. This risk has not been associated with an increased risk of completed suicide, but

Table 46.3
Selective serotonin reuptake inhibitor uses

Generic name	Brand name	RCT's support use in depression?	RCT's support use in anxiety disorders[a]?	RCT's support use in OCD?	RCT's support use in PTSD?	Pediatric doses
Citalopram	Celexa	7–17	No	No	No	–
Escitalopram	Lexapro	12–17	No	No	No	5–20 mg
Fluoxetine	Prozac	7–17	7–17	7–17	No	MDD: 5–20 mg OCD: 20–60 mg
Fluvoxamine	Luvox	No	Yes	8–17	No	50–200 mg
Sertraline	Zoloft	6–17	7–17	6–18	No[b]	25–200 mg

[a]Selective mutism, separation anxiety, generalized anxiety, disorder, panic disorder
[b]Specifically, does not add to effect of CBT when combined treatment provided

warrants careful monitoring of children and adolescents when starting an SSRI and with any dose changes. The US FDA recommends weekly monitoring for the first month and bimonthly monitoring for the second month after initiation or changes. Families should be instructed to seek emergency attention if they note signs of mania, activation, self-injurious behaviors, or voiced suicidal ideations. It should be noted that after the introduction of SSRI's in the 1990s, rates of completed suicides decreased, and that since the FDA's black box focused on the association between suicidal ideation and antidepressant use, the rates appear to be rising again.

Prognosis

Depression in children and adolescents is a chronic and relapsing disorder. Approximately 40% will experience a relapse in 2 years and nearly three fourths within 5 years. Better prognosis is associated with complete recovery from the initial incident of depression, parental mental health, lack of history of sexual abuse, and healthy family functioning.

Prevention

The impact of childhood depression and the long-term implications of childhood depression make prevention an important goal. One group at highest risk of depression is children of depressed adults. Family focused interventions show some effect compared with no intervention, but the effect sizes are modest. Treatment of parents with depression may also be an important preventive intervention for children at risk.

Bipolar Disorder

Bipolar disorder is characterized by periods of depression and of mania. Manic episodes classically include periods of elation that are accompanied by increased energy, rapid speech, and grandiosity. Both the DSM and ICD-10 definitions of manic episodes require a week of symptoms and associated symptoms of decreased need for sleep and pressured speech. In the DSM-IV, the primary mood can be either elation or irritability and the DSM specifies that 3 associated symptoms should accompany elation, adding grandiosity, flight of ideas, distractibility, increased goal-directed activity, and excessive risk taking. If the mood is irritable, the patient must demonstrate four associated symptoms. The ICD-10 is less specific, requires "several" associated symptoms, and does not include irritability. Depressive episodes must meet criteria for major depressive disorder, although there are variations of bipolar disorder either with a less intense manic episode (hypomania) or depressive episode (dysthymia). The characteristics of pediatric bipolar disorder continue to be the focus of debate. Specifically, the duration of episode, importance of the primary "cardinal" symptoms, and the intercurrent mood are all under active investigation.

Etiology/Pathogenesis

Bipolar disorder is highly familial. First-degree relatives of adults with bipolar disorder are at eight- to tenfold risk of developing the disorder. Studies in the USA and in Europe have yielded inconsistent findings related to genetic polymorphisms associated with pediatric bipolar disorder and candidate genes related to dopamine, serotonin, and catecholamine systems, and brain-derived

neurotrophic factors. Neuroimaging studies of pediatric bipolar disorder have revealed smaller amygdala, hippocampus, cingulated gyrus, and less gray matter in the dorsolateral prefrontal cortex. To date, the family and community risk factors related to the development of bipolar disorder have not been examined.

Epidemiology

Rates of pediatric bipolar disorder are estimated 1–2% in the general population, although large epidemiological studies have not reported rates of pediatric bipolar disorder in Europe or in the USA. Pediatric bipolar does not show significant gender differences. Rates of clinical diagnoses for bipolar disorder have increased substantially in the last decade, in the USA, as more encompassing diagnostic criteria have been proposed.

Clinical Manifestations

Children with bipolar disorder can present in the prepubertal period, but generally present during adolescence. Onset may be insidious or acute, but many children have a history of unipolar depressive symptoms prior to the onset of mania. The most commonly seen symptoms in pediatric bipolar disorder are increased energy, distractibility, pressured speech, irritability. The specificity of these symptoms is limited and can be seen with other psychiatric disorders. Of the symptoms with more specificity, decreased need for sleep and euphoria are seen in about 70% of patients. The DSM IV criteria require 1 week of symptoms nearly every day to meet the meet the criteria for a manic episode. This criterion should be maintained and children with shorter periods of mania may be considered to have bipolar disorder NOS.

Early research shows that a broadly defined disorder of chronic irritability without episodic mania has different familial patterns, different activity on functional neuroimaging, and different courses than strictly defined bipolar disorder. This empirically defined syndrome of chronic irritability and extreme reactivity in children who do not meet diagnostic criteria for MDD or bipolar disorder has been proposed as a separate mood disorder in the DSM V. The core deficit in this proposed disorder is of emotional regulation and it is considered to be a mood disorder, not a behavioral problem.

Comorbid conditions are common in youth with bipolar disorder, with as many as 50–80% meeting criteria for ADHD, 20–60% for disruptive behavior disorders and a similar rate for anxiety disorder. Youth with bipolar disorder are at elevated risk for suicide attempts and for completed suicide. Rates of substance abuse in this population are also elevated.

Diagnosis

Diagnosis of bipolar disorder depends on a careful history and sometimes multiple observations of a patient. Because of the nonspecificity of some symptoms of bipolar disorder, it is important to review all symptoms and to do a complete review of systems. Systematic measures like the Young Mania Rating Scale can be used to quantify the severity of the symptoms, but should not be considered diagnostic. A careful social history should investigate the social history, with attention to sexual abuse in children presenting with hypersexuality.

The validity of the diagnostic criteria for bipolar disorder in young children has been studied in only one published study to date and the controversy around applying current criteria to preschoolers is even more intense then for older children because of developmental issues, non-specificity of the symptoms, and risk of current treatments in young children.

Differential Diagnosis

The differential diagnosis of bipolar disorder should be considered carefully. Until diagnostic controversies are resolved, and to ensure effective communication across providers, the American Academy of Child and Adolescent Psychiatry Practice Parameters recommend applying the diagnostic criteria strictly. Many of the symptoms overlap with ADHD and the question of comorbidity versus differentiation should be considered. Bipolar disorder tends to present later than ADHD, does not respond to stimulants, and is more likely to be characterized by mood symptoms and fluctuating levels of symptoms, and actual *decreased need* for sleep. Bipolar disorder must also be distinguished from ODD in children who are negativistic, throw tantrums, and are easily annoyed. In children with bipolar disorder, behavioral difficulties should be present during mood episode but should resolve after the episode resolves.

General Care

As with all psychiatric disorders, psychoeducation is an important component of care. Reframing the behaviors as

part of the illness rather than intentionally problematic behaviors may be useful for families. Schools can be enlisted to support the child during transitions.

Treatment

Most research focused on treatment of bipolar disorder has focused on medication treatments and to date, the systematic research has focused solely on the treatment of acute mania rather than prospective treatment of bipolar disorder. Mood stabilizers and antiepileptic agents are commonly used to treat bipolar disorder. Although a number of open label trials have reported positive effects of a range of medications, the number of randomized controlled trials is limited. These studies, which generally last 4–8 weeks and focus on acute mania, have demonstrated that, compared to placebo, lithium, aripiprazole, ziprasidone, risperidone, divalproic acid and olanzapine are effective in treating acute mania. Efficacy is defined as 50% reduction in mania symptoms, and most report 40–61% response rates in the treatment arms and relapse rates are high, reflecting need for more effective treatments. As an adjunct to valproic acid, quetiapine reduces symptoms of acute mania more effectively than valproic acid alone. Published studies document a lack of effect of topiramate and oxcarbamazepine in treating acute mania.

In clinical practice, the AACAP's Practice Parameters recommend lithium, valproic acid, and atypical antipsychotic agents as first-line treatments for pediatric bipolar disorder. Because family history of response to pharmacological agent for bipolar disorder predicts a youth's response, family history may guide choice of a specific agent. In addition, presence of specific symptoms (e.g., psychosis), comorbid conditions such as obesity, or family ability to administer safely medications with a narrow therapeutic window may guide selection of an agent.

Side effects of these medications can be substantial. The atypical antipsychotic agents are associated with weight gain, hyperlipidemia, and glucose intolerance. Olanzapine is responsible for the most substantial weight gain, with a mean weight gain of 7 kg in an 8-week study of patients with psychotic disorders. Risperidone and quetiapine show moderate risk (~4 kg in 8 weeks), and aripirazole and ziprasidone are associated with the lowest risk of weight gain. A similar pattern is seen for the risk of diabetes and dyslipidemia. Extrapyramidal side effects may occur with any antipsychotic, but risperidone has the highest risk among the atypical agents. Ziprasidone is associated with prolonged QTc and should not be used in children with risk of arrhythmias. Preliminary findings focused on treatment for children with chronic irritability and emotional dysregulation, such as that described in the proposed DSM V diagnosis, suggest that these patients may respond to SSRI treatment, although more research is needed.

Studies focused on psychotherapeutic interventions for bipolar disorder are promising, although limited. The best studied psychotherapeutic intervention for pediatric bipolar disorder is child and family functioning cognitive behavioral therapy, which focuses on psychoeducation, developing routines, affect regulation, collaborative problem solving, and social supports. It reduces mood symptoms acutely and when followed, 3 years after treatment if booster sessions are provided. Unfortunately, most communities cannot access this sophisticated form of therapy. In all cases, psychoeducation, family and individual therapy, relapse prevention/medication compliance, and attention to academic supports are important components of treatment for bipolar disorder.

Prognosis

In pediatric bipolar disorder, a relapsing and remitting course is seen. More than two thirds of cases of pediatric bipolar disorder show recovery (at least 8 weeks without symptoms) within a year and more achieve recovery in 4 years. However, about half will relapse as well. Comorbid conditions, psychosis, low maternal warmth, low-income families, alcohol use, and medication nonadherence are all poor prognostic signs. Earlier age of onset of bipolar disorder is also associated with more recurrences and chronicity. Youth with bipolar disorder are twice as likely as children with major depression to make suicide attempts.

Prevention

Because of the high hereditability of bipolar disorder, attempts to provide early intervention and prevention are necessary. To date, two small, open trials have shown promising results of psychopharmacological preventive interventions for youth at risk of bipolar disorder because of their subsyndromal mood symptoms and family history of bipolar disorder. Further research is necessary to understand the role of psychotherapeutic and psychopharmacological interventions for children at high risk of bipolar disorder. Common sense suggests that these youth's prognosis is likely to be improved by adequate treatment for their parents or sibling with bipolar disorder.

Table 46.4
Characteristics of anxiety disorders

Disorder	Clinical characteristics	Common clinical presentation
Separation anxiety disorder	Preoccupation with and distress about separation from primary caregiver	Inability to separate to attend school or child care
Selective mutism	Inhibition of speaking and social interactions in specific social contexts (e.g., school, new people in a child who willingly speaks in familiar contexts)	May be acute onset
Social anxiety disorder	Anxiety related to embarrassing self in social situations or evaluative situations	Avoids large group activities, distress about school (may present with school avoidance)
Generalized anxiety disorder	Pervasive anxiety or worry about multiple (non-specific) topics	Sleep disturbance, concentration difficulties, muscle tension; often co-occurs with depressive symptoms
Panic disorder	Repetitive, non-triggered anxiety attacks including somatic symptoms, feeling of doom, and anticipatory anxiety about future attacks	May occur with or without agoraphobia (fear of not being able to escape a confined place)

Anxiety Disorders

Anxiety disorders are among the most common disorders in childhood. They can be considered excessive fear responses that interfere with adaptive functioning. A number of disorders fall under the broad umbrella of anxiety disorders. This section will focus on separation anxiety disorder, selective mutism, specific phobias, generalized anxiety disorders (GAD) and panic disorder, which seem to share some patterns of presentation and treatment responsiveness. Obsessive compulsive disorder and post-traumatic stress disorder will be addressed separately.

Descriptions of each of the forms of anxiety disorders are presented in *Table 46.4*. In general, classification of each these disorders in DSM and ICD systems are similar, except that in the ICD 10, children cannot meet criteria for both GAD and depression, although in the DSM system, these two disorders co-occur quite commonly.

Etiology

It appears that genes and environment play roles in the development of anxiety disorders in children. Family studies demonstrate that about half of children with anxiety disorders have parents with an anxiety disorder, but the transmission from parent to child is about only 30%. Polymorphisms in the promoter region of the serotonin transporter gene have been implicated as risk factors for development of anxiety disorders in children. Behaviorally inhibited temperament is an early manifestation of risk for anxiety disorder. Parenting practices are among the most powerful ways children learn to interpret possible risks. Parents' own anxiety, their messages to their children about safety or lack thereof, and the degree of intrusive protection all can shape children's anxiety patterns.

Epidemiology

Anxiety disorders occur at high rates across cultures. Between 2% and 25% of children experience anxiety disorders at some point in childhood. Separation anxiety disorder and selective mutism present in preschool and early school age, generally at equal distribution between girls and boys. Other disorders, including social anxiety disorder and panic disorder, are over-represented in girls even in the prepubertal period. GAD tends to show a predominance in girls starting at puberty.

Pathogenesis and Pathology

Increasingly, central nervous system correlates of anxiety can be identified through functional neuroimaging. Anatomical regions implicated in anxiety disorders include the amygdala, the orbitofrontal cortex, and the anterior cingulate cortex. Physiologic studies demonstrate that children with anxiety disorders have higher physiological arousal including increased heart rate under stress, elevated cortisol in response to stress, and increased startle response.

Clinical Manifestations

Although each anxiety disorder described in this section has its own unique characteristics, the comorbidity among these disorders is high. In clinical samples, 50% of children with an anxiety disorder have more than one anxiety disorder. Specifically, panic disorder, separation anxiety disorder, and specific phobia tend to cluster together. By contrast, generalized anxiety disorder and social anxiety disorder tend to be associated more commonly with major depressive disorder.

Anxiety disorders are also commonly comorbid with externalizing disorders. Because younger children may not have insight into their distress as anxiety, it is important that clinicians consider anxiety disorders when children present with school avoidance, oppositional behaviors related to social or evaluative experiences, or unexplained tantrumming. In preschoolers, it appears that anxiety disorders are more closely related to disruptive behavior disorders than to mood disorders, although they can also present with anxiety symptoms that cluster into the same categories as older children and adults.

Differential Diagnosis

The differential diagnosis of a pediatric anxiety disorder is also broad. First, a clinician must explore the specific anxiety symptoms and consider the specific anxiety disorders separately. Impairing separation anxiety symptoms can present when a child has experienced a traumatic event when separated from their parent. Some children may present with separation anxiety because they have concerns about their parent's well-being, such as a parent's medical illness, or a child's perception of parent's vulnerability related to parental mental health problems or family or community violence exposure. Thus, actual and perceived safety should be explored when a child presents with separation anxiety symptoms. In children presenting with selective mutism, it is essential to ensure that an appropriate language and hearing assessment has occurred. Again, if the disorder has an acute onset, consideration of a traumatic experience is warranted. Symptoms of autism spectrum disorder should be reviewed in children presenting with signs of social anxiety disorder. The disorder can be differentiated by good eye contact, reciprocity, language skills in children with social anxiety disorder when they are in comfortable situations. These children also do not generally present with stereotypical behaviors. Generalized anxiety disorder often co-occurs with depressive symptoms. In the ICD-10 system, used in most of the world, these disorders are mutually exclusive and a clinician must identify the syndrome that is most impairing for the patients.

All anxiety disorders can present with impairment in school functioning either because of concentration difficulties or peer interaction problems and sometimes they present with school avoidance. Careful attention should be paid to a child's developmental level and academic performance to ensure that learning disabilities are not overlooked and that bullying is not a contributing factor.

General Care

As with other psychiatric disorders, psychoeducation is especially important for children with anxiety disorders and their families, especially if the anxiety symptoms may have been interpreted as intentional or a sign of weakness. Psychoeducation in the educational setting may also be important if the child has been targeted by bullying or if the symptoms of anxiety have interfered with classroom experiences. In families in which parental anxiety is a contributing or perpetuating factor of the child's anxiety, referrals for the parent's mental health treatment can be an important intervention as well.

Treatment

Both psychotherapy and psychopharmacological interventions have been studied for the treatment of pediatric anxiety disorders. Data support the efficacy of both SSRI's and of cognitive behavioral therapy. Cognitive behavioral therapy for pediatric anxiety disorders includes parent involvement in psychoeducation, relaxation techniques such as diaphragmatic breathing and progressive muscle relaxation, cognitive coping strategies, graduated exposure to feared stimuli. Family workbooks, such as the *Coping Cat*, can be useful adjuncts for pediatricians to share with parents, especially if skilled cognitive behavioral therapists are not readily available. CBT for childhood anxiety is both effective for anxiety and also shows long-lasting effects.

Fluvoxamine, sertraline, and fluoxetine have all been studied as effective treatment for pediatric anxiety disorders in randomized controlled trials. Psychopharmacological treatment for panic disorder in children has not yet been established. To date, it is not clear how the association between suicidal ideation and SSRI's in depressed children may be applied to children with anxiety disorders. Judicious use of medications and careful monitoring of all children on SSRIs seems warranted.

One multi-site study has compared treatment outcomes between CBT and sertraline treatment. This study demonstrated that CBT and sertraline were equally effective in treating pediatric anxiety disorders, but that the combination of the two was more effective. After 12 weeks of treatment, 80% of children on the combination treatment were much improved or very much improved, compared to about 60% of children in each of the monotherapy arms. Thus, children should be treated with CBT and medication for most effective reduction of moderate–severe anxiety symptoms. Adding parent anxiety management training to CBT also adds to the effect of CBT, regardless of parent anxiety level.

Prognosis

The course of pediatric anxiety disorders vary. Typically, anxiety peaks in the general population in the preschool years and then declines. Children with anxiety disorders tend to continue to have anxiety, but the specific disorder may change over time. In a 5-year follow-up of children at risk for anxiety disorders, having separation anxiety disorder at baseline increased the risk of specific phobia, agoraphobia, and major depression four- to ninefold at follow-up. Early childhood agoraphobia increased the risk of GAD fourfold.

Prevention

Prevention of childhood anxiety disorders has not been studied. The evidence does suggest that children at high risk of anxiety disorders can be identified by identifying parents with anxiety disorders. Prevention strategies to be examined may include effective treatment of parent anxiety, early CBT, and other strategies for children at high risk of developing anxiety disorders.

Obsessive Compulsive Disorder

Obsessive compulsive disorder (OCD) is characterized by obsessions and compulsions. Both components of the disorder can cause substantial, though often unrecognized, impairment and distress in children and families. Obsessions are unwelcome intrusive, repetitive thoughts and worries that are not simply about real life worries. Compulsions are repetitive behaviors intended to reduce distress related to an obsession or that stem from rigid internal rules. In the DSM nosology, the symptoms of OCD must be distressing, time consuming (at least 1 h/day), or interfere with functioning. The ICD-10 does not specify the level of impairment or time consumption in OCD. Importantly, children do not necessarily recognize that their thoughts or compulsions are unreasonable.

Etiology/Pathogenesis

Strong evidence supports the role of heredity in OCD. In pediatric onset OCD, hereditability is thought to be between 45% and 65%. Between 10% and 30% of patients with OCD have a first-degree relative with OCD or OCD traits. Neuroimaging studies have identified associations between OCD symptoms and the cortico-striatal-thalamic pathways, with volumetric and metabolic differences in the orbitofrontal cortex, the globus pallidum, and the anterior cingulated gyrus. The pathway is thought to be associated with filtering consciousness and controlling stereotyped behavior patterns. It is clear that OCD is related to abnormalities in central nervous system serotonin. Serotonin is known to act in the frontal cortex-thalamocortical pathways, which are thought to be related to obsessions. Dopamine and glutamate have also been implicated in the pathogenesis of OCD. Perhaps the most controversial etiologic association of OCD is streptococcal infection, first described in 1998 by Swedo and Leonard. Pediatric autoimmune neurodevelopmental disorders associated with strep (PANDAS), describes a group of children with OCD who present with a course of abrupt onset of OCD and tic symptoms in the context of a recent streptococcal infection. The mechanism for this syndrome is thought to be an autoimmune process targeting the basal ganglia. Although a number of lines of research support the existence of a subgroup of children with OCD who have an autoimmune mediated disease, controversy remains. Strict application of the PANDAS criteria (more than one co-occurrence of onset of symptoms, immunologic evidence of streptococcal infection) is important to avoid overdiagnosis of PANDAS.

Epidemiology

Rates of OCD vary widely across studies and with methodologies. Best estimates suggest that prevalence of OCD is 1–3%. In younger children, patterns of magical thinking, ritualistic and rigid behaviors are normative and may not be impairing. Age of onset has two

peaks – first in the school age group and then in early adulthood. There is a slight predominance of boys over girls represented in pediatric OCD. Boys tend to present earlier than girls and present with different comorbities and symptom clusters.

Clinical Manifestations

Pediatric OCD tends to present with symptoms in four clusters – a focus on symmetry; on aggressive, sexual, religious, or somatic obsessions; on contamination/cleaning; or on hoarding. The first two clusters tend to present earlier than the latter two. Some studies suggest gender differences, with girls presenting with contamination-focused OCD and boys being more likely to have a focus on symmetry and "just right."

Another way of classifying the disorder is familial OCD, OCD with tics, sporadic OCD, and PANDAS. This classification system likely highlights the different etiologies among these different groups. Tic-related OCD may account for 10–40% of pediatric OCD and tends to be seen more often in boys and presents earlier than the other forms.

OCD is frequently comorbid with other conditions. In children, other anxiety conditions including separation anxiety disorder and specific phobias co-occur in as many as half of school age children with OCD. In adolescents, like adults, major depression is present in more than half of patients, and anxiety disorders are present in one quarter to one third of adolescents.

Pediatric OCD often presents with other chief complaints. Compulsions that interfere with family or classroom functioning may present with a chief complaint of behavioral difficulties. Even when patients feel that the OCD is a problem, it tends to be underreported because of shame and awareness that their worries are exaggerated or irrational. The average duration between onset of symptoms and diagnosis is 7–8 years.

Diagnosis

A comprehensive history from the parent and child is necessary to understand the range of symptoms. The Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) provides a structured way to review range of symptoms associated with OCD and the severity of the impairment associated with the disorder. In addition to the symptoms of OCD, it is important to review family history, tic and ADHD symptoms, and medical history. It is particularly important to examine the degree to which the symptoms impair the child or the degree to which the family has accommodated the symptoms.

Differential Diagnosis

OCD and autism spectrum disorders share obsessional patterns and some stereotyped behaviors. However, children with OCD show typical social reciprocity, have normal developmental trajectories, and may be aware that their patterns may seem unusual to others. Some compulsions may be so stereotyped that they must be distinguished from a tic disorder. The movement in OCD generally is voluntary and intended to accomplish something, albeit not always a necessary task. In a tic disorder, the movement is purposeless. Lastly, obsessions in OCD must be distinguished from auditory hallucinations. Usually, this distinction is not difficult, as children with OCD have organized thought processes, have very specific, focused unusual behaviors, and are able to describe that the thoughts are internal to them, rather than coming from outside of them.

General Care

Psychoeducation is the cornerstone of support for patients and families with OCD. Children and families can be taught that OCD is an external force which therapy will allow them to fight and overcome. The plan to "Beat back OCD" is used in the most effective forms of CBT for OCD. In addition, families with other affected members should be evaluated for the need for referrals or co-treatment.

Treatment

The treatment of OCD has been well studied in randomized clinical trial, most notably the Pediatric Obsessive Compulsive Treatment Study which compared sertraline to CBT. To date, fluoxetine, sertraline, and fluvoxamine have been shown to be more effective than placebo in treating pediatric OCD. However, an SSRI alone results in remission in only 20% of patients. For pediatric OCD, CBT alone is twice as effective as SSRI alone, with approximately 40% achieving remission. Again, as for other disorders, CBT has the advantage of durability, with

results that persist beyond 24 months even when the patient is no longer in treatment. Family involvement in CBT is essential to treat pediatric OCD. The combination of CBT and SSRI, specifically sertraline, is the most effective for adolescents, although still only 50% of patients remit within 12 weeks. Thus, the recommended treatment for OCD is CBT with an SSRI or CBT alone. When medications are used, doses to treat OCD tend to be higher than those used for depression or other anxiety disorders. In an analysis of the risk of SSRI-induced suicidality in a large group of children with OCD, there were no cases of suicidal ideations.

Prognosis

Studies of pediatric OCD show a heterogeneous course of illness. Generally speaking, about 40% of children and adolescents with OCD will meet full criteria for OCD as adults. An additional 20% continue to have some symptoms, although they do not meet criteria for the disorder. Comorbid disorders (especially disruptive behavior disorders), early onset of OCD, need for inpatient treatment, and poor initial treatment response are associated with more persistence of OCD. Checking/aggressive and cleaning patterns of OCD rather than hoarding are associated with functional impairment related to OCD. Importantly, parental accommodation to the symptoms, depressive symptoms, and limited insight are also associated with worse functioning with pediatric OCD.

A number of predictors of treatment outcome have also been identified. OCD is less responsive to medication treatment if a child has comorbid tics or comorbid externalizing disorders. CBT effectiveness is limited by family dysfunction and severity of OCD symptoms.

Prevention

There are no prevention approaches recognized for reducing the incidence of pediatric OCD. Tertiary prevention, that is reducing the impact of the disorder, may be possible with effective treatment with CBT. Reduction of the factors associated with persistence of OCD may be most important.

Post-Traumatic Stress Disorder

Post-traumatic stress disorder (PTSD) is a syndrome that can occur after exposure to extreme stress, particularly a stressor in which a child's safety or the safety of someone he loves may be threatened. In both the DSM and ICD systems, patients with PTSD suffer from re-experiencing symptoms that can include intrusive thoughts, reenactment, and nightmares related to the trauma. In children, this re-experiencing can present as themes of play and they may have nightmares without being aware of the content.

Epidemiology

Rates of PTSD vary by exposure to stressful events. Pediatric community studies suggest that approximately 5% of children and adolescents meet criteria for PTSD. Rates of exposure to potentially traumatic events vary widely. For example, 50% of preschoolers living in the Gaza strip have seen a home bombarded and 20% have heard a neighbor killed. Hundred percent of American children growing up in inner-city Los Angeles have heard gun shots. Rates of PTSD may vary by trauma type. Children exposed to natural disasters such as earthquakes, hurricanes, and tsunamis develop PTSD at rates between 10% and 50%. Between one third and one half of children exposed to war zones and terrorism meet criteria for PTSD. Unintentional injury and severe chronic medical illnesses have also been associated with elevated rates of PTSD. Interpersonal violence and assault are the most common causes of PTSD in children, with up to 90% of sexual abuse survivors showing PTSD, more than half of children exposed to domestic violence, and about 50% of children who have been physically abused. Factors such as family stability, degree of household disruption, parental safety, being believed when disclosing abuse, and lower chronicity of trauma exposure are all associated with lower rates of developing PTSD after trauma, although these moderators may act differently with different trauma types.

Etiology/Pathology

Clearly, trauma exposure is a necessary component for the development of PTSD. While necessary, it is not sufficient. In general, most social risk factors that increase the risk for mental health problems in general, including lack of social supports, maladaptive family functioning, poverty, and family history of psychiatric disorders, all increase the risk of PTSD. There are also data that suggest genetic factors also contribute to the development of PTSD, although most data are derived from adult studies. In adults, there is some speculation that lower hippocampal volume is a preexisting condition in people who develop PTSD, but this theory is not

supported by imaging studies in children. Early genetic studies suggest that the serotonin transporter and a polymorphism in the glucocorticoid receptor system may interact with trauma exposure to increase the risk of PTSD.

Children and adolescents with PTSD show a number of neurobiological abnormalities. For example, girls with a history of sexual abuse show elevated levels of urinary catecholamines, a marker of stress reaction. Kaufman et al. have demonstrated abnormalities of myelination in the corpus callosum in adolescents with PTSD.

Clinical Manifestations

Across diagnostic systems, PTSD includes re-experiencing symptoms, including play focused on the theme of the trauma, nightmares, and distress related to reminders of the traumatic event, and flashbacks in which the patient feels as if the trauma were reoccurring. The ICD also mentions, and the DSM requires, numbing and avoidance symptoms, dissociation, decreased interest in activities, and a foreshortened sense of future, meaning an inability to imagine the future. The DSM also requires arousal symptoms such as sleep difficulties, anger outbursts, hypervigilance (monitoring of the environment for safety, even when it is not necessary to do so), and hyperstartle responses. Trauma-related symptoms may present soon after the trauma but, in the DSM system, cannot be diagnosed as PTSD until they have been present for a month. Prior to that time, trauma-related symptoms are classified as acute stress disorder, which does not always foreshadow PTSD.

Symptoms of PTSD are often internal and may not have been identified by the patient or parent as being related to the trauma. It is important to ask both the parent and child about the symptoms to ensure the most sensitive assessment possible.

Comorbidity is the norm in PTSD, with nearly 75% experiencing another psychiatric diagnosis, most commonly depression. Other disorders, including externalizing disorders can also be seen with PTSD or after a traumatic experience in the absence of PTSD. Auditory perceptual events can be seen in trauma-exposed children without indicating a psychotic disorder, although these should be examined thoroughly.

Differential Diagnosis

PTSD should be considered whenever a traumatic event is identified and a trauma history is a necessary part of any psychiatric assessment. Although PTSD is most directly associated with trauma exposure, a careful assessment must be done to ensure that other diagnoses are not missed. The re-experiencing symptoms of PTSD are specific to PTSD. Psychotic processes can present with similar patterns, but children and adolescents with psychosis demonstrate disorganized patterns of behaviors and thought, whereas children with PTSD do not. PTSD may also be comorbid with other anxiety disorders, especially separation anxiety disorder and selective mutism in young children. In adolescents, substance abuse can also co-occur with PTSD.

General Care

The most important intervention for pediatric PTSD is ensuring safety. Children with PTSD who are unsafe in their home environment will experience both rational and irrational fears that can worsen symptoms synergistically. Pediatricians should be aware of resources in the community, including domestic violence shelters that may be available for the families. In environmental disasters or chronic war that impact the whole community, creating safety may be a difficult task and sometimes, unfortunately, impossible.

Treatment

Treatment for pediatric PTSD is primarily psychotherapeutic. CBT modified to address traumatic events (TF-CBT) has been shown to be a successful intervention in multiple studies for children with a range of trauma types. This form of CBT includes psychoeducation, focuses on behavioral and cognitive stress management and emotional regulation. When a patient has mastered these skills, they are gradually exposed to the traumatic experience by creating a trauma narrative. Pediatric TF-CBT also includes attention to oppositional behaviors and includes parents as partners. This intervention can be learned through web-based trainings http://tfcbt.musc.edu/. TF-CBT is associated with substantial decreases in PTSD symptoms that are maintained at least 1 year. A preschool version shows promising results as well. Child Parent Psychotherapy is another evidence-based treatment focused on young children. CPP has been shown to reduce symptoms of PTSD in young children exposed to domestic violence and maintain the results over at least 6 years.

Psychopharmacological interventions have received very little study in pediatric PTSD. One small study suggested that imipramine was effective in reducing the

progression from acute stress symptoms to PTSD. A more recent study examined the effect of adding sertraline to TF-CBT to treat PTSD in children with a history of sexual abuse, with only minimal differences between outcomes in the TF-CBT group compared with the combined group.

Despite the paucity of data, children frequently receive medication treatment for PTSD. In adults, SSRI's have been demonstrated to be effective in reducing symptoms of PTSD. Alpha agonists have shown some benefit in an open trial study. After an incomplete response to therapy, a clinician may consider medication, but must recognize that the randomized trials supporting psychopharmacological intervention have been done in adults. Comorbid conditions may be more amenable to psychopharmacological intervention.

Prevention

The most important step toward reducing the burden of PTSD is to reduce children's exposure to potentially traumatic events, including war, terrorism, abuse, and home and community violence. After a trauma has occurred, ensuring safety, reducing separation from parents, believing a child's report of sexual or physical abuse, and managing pain are paramount. Morphine has been shown to be effective in reducing PTSD in burns. Thus, physical and emotional comfort appears to be an important factor in resiliency. Children should be allowed to talk about the trauma at their own paces and parents should support "brave behaviors."

Prognosis

Prognosis for pediatric PTSD is variable. Generally, PTSD is considered a chronic disorder. Depending on the trauma type, more than one fourth of children with PTSD as children will continue to have PTSD as adults. The persistence of symptoms appears to be associated with history of prior trauma and major injury associated with the trauma.

Externalizing Disorders

The externalizing disorders comprise disorders of disruptive behaviors, in which patterns of behaviors interfere with functioning because of observable, "external" behaviors. The triad of disruptive behavior disorders includes attention deficit hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), and conduct disorder (CD) in the DSM system. In the ICD-10 system, these disorders are diagnosed under the umbrella of hyperkinetic disorders, of which there are two major forms: hyperkinetic disorder of activity and attention and hyperkinetic disorder of conduct.

ADHD will be discussed in Chap. 45, "Disorders Cognition, Attention, Language, and Learning".

Disruptive Behavior Disorders

Temper Tantrums

It is not unusual for the presenting concern to a child mental health provider is some form of "temper tantrums", usually describing emotional and behavioral dysregulation that may include crying, yelling, screaming, and aggression towards objects, other people, or self. There is no technical definition of such events and they do not represent a specific disorder, but parents and some providers will be tempted to consider such events to be behavioral difficulties because they may occur when an adult places a demand on the child. However, the differential diagnosis of such behaviors is wide and includes almost every category of mental health issue. For example, a child with a mood disorder, with prominent irritability, may react to perceived insults or injustices with extreme emotional reactions. Children with mood disorders should have concurrent neurovegetative signs such as sleep, appetite, or energy disturbances and may also experience difficulty with memory and concentration. On the other hand, a child with oppositional defiant disorder may react present with a similar patter of responding to adult directions, but would have a pervasive pattern of not following directions, arguing with adults, and/or intentionally annoying other people, but would not show neurovegetative signs. Children with anxiety disorders, including OCD, can present with "tantrums" when exposed to an event or situation that causes extreme anxiety and emotional dysregulation. Children and adolescents developing psychotic disorders may react in unpredictable ways to experiences they misperceive. Finally, children with developmental delays may exhibit tantrumming behaviors when asked to do things that are beyond their developmental level or as a sign of frustration. Thus, a single sign of difficulty organizing an emotional or behavioral reaction to a stressor cannot be considered pathognemonic for any single disorder.

Disruptive Behavior Disorder Diagnoses

Oppositional defiant disorder (ODD) and conduct disorder (CD) together comprise the disruptive behavior disorders (DBDs). In the DSM, ODD is characterized by four or more symptoms of oppositional and defiant behaviors, including losing temper easily, talking back to adults, intentionally defying adults, deliberately annoying others, blaming others for own transgressions, being touchy/easily resentful, easily annoyed, or spiteful and vindictive. In conduct disorder, children present with behaviors that reflect a disregard for the safety of others and of societal norms, including severe aggression, destruction of property, running away from home/school, and theft.

Etiology/Pathogenesis

The etiology of DBDs has been studied less than other disorders. Twin studies suggest some contribution of genetics in the development of DBDs. It is clear that there is a substantial familial nature to the disorders, and strong association with parental psychopathology including antisocial personality disorder as well as depression. One study showed an important interaction between genes and environment, namely that the combination of low activity level of monoamine oxidase-A activity and maltreatment put children at an especially high risk of showing persistent aggressive behaviors.

Prenatal environment, including toxin exposures such as nicotine, and environmental factors like early parenthood also predict persistence of aggression in children. Early parenthood, in combination with either maternal antisocial behaviors or low parental education achievement, increases risk of high aggression ten- or fourfold, respectively. One mediator of these associations appears to be harsh, punitive parenting style, which is among the most common risk factors for early childhood aggression. A cycle of harsh parenting and child disruptive behaviors that mutually reinforce each other can be seen in some families.

Reactive aggression has been thought to be associated with abnormal amygdale or frontal lobe function. On the other hand, premeditated, planful aggression and ODD have been associated with decreased autonomic reactivity.

Epidemiology

Disruptive behavior disorders occur in the community at rates between 5% and 10% of the population in the USA, New Zealand, and Canada, with ODD generally showing a much higher prevalence than CD. In general, boys have a higher risk compared to girls, although this gender difference does not appear until after age 6 and is less prominent than thought in the past. DBDs do seem to present at higher rates in lower socioeconomic groups, although further research is needed.

Clinical Signs

Disruptive behaviors are among the most common chief complaints in mental health settings and can be associated with a range of disorders, including DBDs. Children generally come to clinical attention because of concerns of parents or teachers but not because of the child's own distress related to the symptoms.

Few studies have examined the comorbid conditions of ODD, but the one study that did suggested that fewer than 20% had comorbid ADHD, mood disorders, or anxiety. On the other hand, about half of pediatric CD is associated with another disorder, most commonly ADHD, but also mood disorders and substance abuse. When associated with ADHD, CD is more severe, persistent, and has a earlier age of onset. Importantly, adolescent CD is highly associated with anxiety in girls, but not boys. Girls with aggression are also more likely to have mood disorders and suicidality than boys.

Diagnosis

Assessment of DBDs must be done using multiple reporters, as parents and children tend to report on different types of DBD symptoms. Teacher reports are important to understand the child's behavior in other contexts. Full history must include attention to parenting approaches (including question of abuse) and family history of psychopathology and criminal behaviors.

Differential Diagnosis

Mood disorders can present with irritability and problems with following directions and thus can be confused with ODD. Anxiety that causes social withdrawal may also be interpreted as oppositional behaviors by some adults and must be investigated. Severe aggression can be associated with unipolar depressive disorders, bipolar disorder, psychosis, re-experiencing symptoms of PTSD, and autism spectrum disorders, and each of these diagnoses must be

considered in the assessment of a patient with behavioral difficulties. Toddlers with immature language or older children with delayed language and other delays may also present with acting out behavior in response to frustration. Medical conditions, such as temporal lobe epilepsy are rare, but can present as unprovoked rage in adolescents.

General Care

Parents and children presenting with DBDs have generally heard from many child experts that they have failed. It is important, despite the obvious problems in behavior and possibly interactive difficulties, that the families experience the clinical setting as supportive and ready to problem solve. Scare tactics by parents and pediatricians are unlikely to change the patient's behaviors and have important negative impacts on relationships. General safety must be addressed, including the patients' safety toward themselves and toward other people, and caregivers' ability to keep the child safe and use safe behavioral management techniques.

Intervention approaches must include attention to the child, home life, educational experiences, and peer groups, all of which may influence the DBD. Comorbid conditions should be treated aggressively, as symptoms of mood disorders, ADHD, and substance abuse disorders all may exacerbate behavioral difficulties.

Treatment

Both psychotherapeutic and psychopharmacological interventions have been investigated to treat DBDs, and in general, a multipronged approach is indicated. In younger children in particular, parent management training (PMT) models have been shown to be particularly effective. Most effective PMT interventions focus on increasing parental attention to positive behaviors, planned ignoring, and consistent, structured, and safe consequences for misbehavior. They are associated with reduced signs of DBD, decreased parenting distress, and have sustained results up to 6 years later. Parent groups, such as the Incredible Years Series, and dyadic treatments like the Parent Child Interaction Therapy have been shown to be quite effective. In preschoolers, there are no systematic studies of medications for DBDs, and thus the balance of evidence is strongly in favor of these psychotherapeutic interventions.

For older children, wraparound services have been shown to be most effective for adolescents with severe behavioral difficulties. Multi-systemic therapy (MST) is a home-based, intensive therapy that uses a 7 days per week treatment approach with a Master's level team of therapists and a psychiatrist to provide a goal-directed treatment approach focused on crisis intervention, family systems therapy, and home-based behavioral treatment. It is effective in reducing recidivism, out of home placements, psychiatric symptoms, and substance abuse in adolescents with serious behavior problems. Medications can be useful adjuncts to psychotherapeutic interventions for youth with severe aggression related to a DBD. A recent meta-analysis revealed that methylphenidate can be effective in treating DBDs with or without comorbid ADHD and clonidine is equally effective. Lithium has been shown to be effective in reducing aggression in youth with conduct disorder. Antipsychotic agents, including haloperidol, thorazine, and risperidone are also effective in treating aggression in DBDs. Antiepileptic agents have shown mixed results in reducing aggression.

Prognosis

In preschoolers, rates of stability are somewhat lower and preschoolers with ODD appear to show heterotypic continuity. Most children continue to have a disorder, but a substantial proportion have anxiety in the school age years, while others continue to present with DBDs. The stability of disruptive behaviors from childhood to adolescence and beyond is consistently reported as above 50%, with the highest stability in children who have more severe DBDs. The long-term effects of the early childhood interventions for DBDs suggest that prognosis may be modified by early exposure to evidence-based treatments. Childhood DBDs are associated with antisocial personality disorder as well as with a range of other psychiatric disorders and adverse life events, including substance abuse, depression, delinquency, early pregnancy, and unemployment. However, it is important to note that the majority of children and adolescents with disruptive behavior disorders, especially those with ODD, do not develop psychopathology or delinquency in adulthood.

Prevention

The risk factors associated with DBDs provide guidance about possible prevention interventions. Reduction of prenatal exposures to potential toxins including smoking, substance use, and alcohol could decrease risk in susceptible patients. Secondary prevention programs that target positive parenting in children at high risk because of family poverty,

exposure to harsh parenting, or parental psychopathology can reduce risk of DBDs. One such program is the Nurse Family Partnership, in which prenatal home visits by nurses who continue to visit until the child's second birthday are associated with reduction in criminal behaviors when the children become adolescents. Access to parental psychiatric treatment may also reduce parent symptoms, which are shown to be associated with DBDs. Social service programs that create a safety net for low-income families and that reduce exposure to family and community violence are important preventive strategies.

Psychosis

Psychosis can be defined as a fundamental disturbance in thinking and perception, most commonly characterized by hallucinations and delusions that change a person's experience of reality. Primary disorders of psychosis, such as schizophrenia, are quite rare. Psychosis is more commonly seen as part of an affective disorder syndrome and perceptual abnormalities can also be experienced by patients with a history of trauma exposure or autism spectrum disorders. The major psychotic disorders in the DSM classification are schizophrenia and schizoaffective disorder. Schizophrenia is a disorder that includes psychotic symptoms as well as "negative symptoms" which include blunted or inappropriate affect. The DSM-IV and ICD-10 provide similar requirements for the diagnosis of schizophrenia. In the DSM-IV, two of the major symptoms of hallucinations, delusions, disorganized speech or behavior, and negative symptoms including flat affect, word-finding difficulties, and lack of motivation are needed, in addition to social functioning problems for at least 6 months. In the DSM system, psychotic illnesses with significant mood abnormalities are classified as schizoaffective disorder if the patient has periods of psychosis without mood symptoms or affective disorder with psychosis if affective symptoms have occurred independent of psychosis. The ICD-10 requires at least one major hallucination or delusional symptom or two minor symptoms for at least 1 month. Childhood onset schizophrenia (COS) is considered schizophrenia that presents in the prepubertal period. Adult onset schizophrenia typically presents in late adolescence or early adulthood.

Etiology/Pathology

The etiology of COS is poorly understood. Internationally, offspring of parents with psychosis have a 4–20-fold risk of developing schizophrenia. Data related to pre- and perinatal factors predicting COS are inconclusive. Genetic studies have identified a number of mutations seen at higher rates in COS, including those affecting dopamine, glucocorticoid, dysbindin, neuroregulin, and glutamate. Most importantly, about 4% of COS patients may have a deletion at 22q11, known as velo-cardio-facial syndrome. Mosaic Turner syndrome appears in COS patients at 500 times the rate expected in the general population. Neuroimaging studies of COS show increased ventricular size and associated loss of gray matter in the cortical, frontal, medial temporal, and parietal gray matter. The progression of the loss of gray matter reliably occurs in a progressive back to front pattern and seems to be related to the disease progression.

Epidemiology

The epidemiology of childhood onset schizophrenia (COS) has not been studied systematically, but it is thought to be rare. In the largest US epidemiological study that followed 1,420 children from age 9 to age 16, there is no mention of schizophrenia and rates of psychotic disorders appear to have been too small to report. COS appears to affect boys at approximately twice the rates of girls, until adolescence when the incidence is equal in the genders. The onset of COS is generally in the school age years. Preschool COS is nearly unheard of. The US study of 89 children with COS suggested that nonwhite patients were disproportionately represented, making up 52% of the children in that study. A similar pattern has been described in adult onset schizophrenia in the UK.

Clinical Manifestations

COS presents with an insidious prodromal course, which includes more negative symptoms. These symptoms include blunted or inappropriate affect, which may present similarly to a mood disorder, social withdrawal, disruptive behaviors including aggression, language deficits, academic problems, and other developmental difficulties. The onset of the full disorder usually includes so called positive symptoms, which include hallucinations and/or delusions, as well as negative symptoms, which include paucity of affect, decreased motivation, and low energy. COS presentation tends to also include depression, cognitive impairment, and hostility. COS is more likely to present with auditory hallucinations than delusions, which can include persecutory delusions and somatic

delusions. Children present with disorganized thought processes, which may be evident in their speech or in their play. Because of the insidious onset, children may present with unusual or odd behaviors before the positive symptoms are identified. Most children with COS will demonstrate cognitive decline with the presentation of their illness, with IQ's declining up to 20 points over their adolescence. COS commonly co-occurs with depressive disorders, obsessive compulsive disorder, and anxiety disorders. COS may also present in children with preexisting autism spectrum disorder. In adolescents, substance use is not uncommon with psychosis. Most strikingly, children with COS are severely impaired in most domains of their functioning, including family, peers, and academics.

Diagnosis

The diagnosis of COS requires multiple appointments, including interviews with the child and the parents, and observational assessments. Because the diagnostic criteria for schizophrenia include minimum duration of symptoms and because the disorder is associated with substantial stigma, it is reasonable to make a provisional diagnosis if there is any question about which psychotic disorder best matches the clinical presentation. Because COS is so rare, the diagnostic assessment should include careful assessment for more common disorders.

Differential Diagnosis

A number of disorders may overlap with the presentation of COS. Major depression with psychotic features and bipolar disorder both can present with psychotic symptoms. The differential diagnosis is made based upon the history of mood symptoms without co-occurring psychosis. Medical conditions including CNS lesions, metabolic derangements, and medications can present with psychosis and should be ruled out. Although medical testing should be tailored to the presentation, chemistry panel, thyroid function and liver function tests, and neuroimaging are generally part of the assessment to rule out organic processes. Substance use can also present with similar symptoms and also must be ruled out. Traumatic events can also trigger perceptual events as well as other trauma-related symptoms and must be examined.

General Care

Because psychotic illnesses interfere with every aspect of a child's life, it is important that the interventions focus not only on targeting the primary symptoms but also on providing support for the child. Psychoeducation about the disorder is important, and it can be helpful to provide opportunities for parents to process the diagnosis without the child as well. As with other chronic disorders, a diagnosis of COS may trigger a grief reaction in parents whose child will be expected to deteriorate substantially as the disorder progresses. School accommodations to address language, concentration, and academic processes are critical.

Treatment

The mainstay of treatment for COS is pharmacological. However, this disorder has been the focus of few studies. Early data demonstrated that haloperidol and loxapine, typical antipsychotic agents, reduced symptoms of COS. Two atypical antipsychotic agents, ziprasidone and aripiprazole, have also been shown to be more effective in reducing symptoms of COS than placebo, although it should be noted that in most studies of COS, "response" has been defined as a 30% decrease in symptoms, demonstrating a relatively low effect size. Most recently, molindone, olanzapine, and risperidone were shown to have generally equal efficacy in a 52 week controlled study without a placebo arm. All had high rates of discontinuation because of inadequate efficacy or adverse effects. Of the medications studied, clozapine is the most effective in reducing positive and negative symptoms. However, clozapine carries with it the risk of agranulocytosis, and higher rates of akathesia and weight gain than adults on clozapine. In clinical practice, polypharmacy is not uncommon, but it is clear that more research is needed to identify a safe and effective treatment for COS.

Prognosis

COS is a chronic disorder and appears to have continuity with adult schizophrenia. Earlier age of onset is associated with more severe disorder and worse prognosis. Lower premorbid functioning also predicts poorer outcome. In the past, it was thought that isolated psychotic symptoms in childhood or adolescence did not predict schizophrenia; however, a longitudinal study in New Zealand showed that nearly 10% of those with an isolated hallucination experience in adolescence developed a psychotic illness by age 26.

47 Autism Spectrum Disorders

Kathleen Angkustsiri · Robin L. Hansen

Clinical Vignette

Steven is a 20-month-old boy born at term with no significant medical history except for recurrent ear infections. He had appropriate motor milestones, but his parents became concerned at 14 months because he was not using words and did not respond consistently to his name. He communicates by crying, whining, or leading his mother by the hand to a desired object. Steven does not point or use gestures such as waving or clapping, although will reach his hand toward things he wants. His parents find it difficult to get his attention, and he does not make eye contact readily. His favorite toy is a small car that he carries with him everywhere. He likes to spin the wheels with his finger and watch them out of the corner of his eye. Steven also lines up toys and occasionally flaps his hands.

Definition/Classification

The autism spectrum disorders (ASD) are a group of neurodevelopmental disorders affecting social communication. They include autistic disorder (autism), Asperger's disorder, and pervasive developmental disorder – not otherwise specified (PDD-NOS). The ASDs are currently included in the DSM-IV and ICD-10 under the category of Pervasive Developmental Disorders, which include autism, Asperger's disorder, PDD-NOS, Rett's disorder, and childhood disintegrative disorder. This chapter focuses on autism spectrum disorders (autism, Asperger's disorder, and PDD-NOS).

Etiology

ASDs are biologically based conditions that are thought to involve complex interactions between multiple genetic and environmental factors. There is no evidence to support that ASDs are caused by bad parenting or "refrigerator mothers," as described by Bettelheim. The ASDs are highly heritable, with a 2–8% sibling recurrence rate. The concordance rate for ASDs is 60–92% in monozygotic (MZ) twins compared to 0–10% in dizygotic (DZ) twins, supporting a strong genetic component. Although genetic causes such as chromosomal abnormalities and de novo copy number variations are implicated in 10–20% of cases with ASD, no single genetic etiology accounts for more than 1–2% of cases. ASD-associated syndromes (fragile X syndrome, Tuberous Sclerosis, chromosome 15q duplication syndrome, etc.) likely contribute to autism risk through common neural pathways related to early brain development. Carnitine deficiency and mitochondrial dysfunction may also be related to autism risk. Environmental influences have been implicated, including prenatal exposure to rubella, thalidomide, and valproic acid. Current theories propose that genetic susceptibility modulated by environmental factors is involved in the etiology of ASD.

Potential risk factors include prematurity, low birth weight, and parental age. While some individuals with ASD have dysfunctional immune responses, epidemiologic studies have not supported a causal link between immunization and the development of ASD.

Epidemiology

Autism was first described by Kanner in 1943 and was considered a rare disorder. In the late 1970s, prevalence in the UK, Denmark, and USA was estimated at 5/10,000. Prevalence has been increasing rapidly since then, and the most recent estimated prevalence of ASD worldwide is 63.7/10,000 or 1/157. In the USA, there was a 57% increase from 2002 to 2006. While some of the increase is attributable to better detection, increased awareness, and use of broader diagnostic criteria, some argue that these factors do not fully explain the dramatic rise in ASD. ASDs affect individuals of all social strata and ethnicity with a male to female ratio of 4:1. Exact prevalence data is not available for many countries, although some estimates ranging from 1/55 to 1/699 have been reported from population-based data as listed in *Table 47.1*.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_47,

Table 47.1
ASD prevalence by country

Country	Prevalence	Year
USA	1/110	2006
UK	1/86	2006
Mexico	1/699	1996
Venezuela	1/588	2006
Hong Kong	1/621	2005
France	1/370	2002
Japan	1/55	1996
Canada	1/154	2004
Australia	1/255	2002
Denmark	1/188	2002

Clinical Manifestations/Diagnosis

There is considerable variability in the clinical features of ASD, which include significant impairment in three domains: social interaction, communication, and restricted/repetitive interests or behaviors. Screening is recommended at 18 and 24–30 months and early identification is important to maximize therapeutic effects of intervention ❯ *Table 47.2*. Diagnosis is made based on behavioral observations, history, and standardized assessment. Symptoms must be present by age 3. Diagnostic criteria are listed in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV, ❯ *Table 47.3*) and the International Statistical Classification of Diseases and Related Health Problems (ICD-10; ❯ *Table 47.4*). Revisions to the diagnostic criteria are anticipated in the next version of the DSM-V in 2013.

A diagnosis of autistic disorder requires impairment in a minimum of six total DSM-IV items, with at least two in social interaction and one from the other core domains. A diagnosis of Asperger's disorder requires impairment in at least two DSM-IV items under social interaction, one under restricted/stereotyped interests and behaviors, and no clinically significant language delay or cognitive/adaptive impairment in individuals who do not meet criteria for autistic disorder. PDD-NOS (ICD-10: atypical autism) is the term used when symptoms are subthreshold for autistic disorder or Asperger's disorder but cause pervasive impairment. Gold standard diagnostic tools include the Autism Diagnostic Observation Schedule (ADOS), a semi-structured behavioral assessment, and the Autism Diagnostic Interview-Revised, although the

Table 47.3
Clinical Features/DSM-IV Criteria for autism

(A) *Qualitative impairment in social interaction:*
Marked impairments in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body posture, and gestures to regulate social interaction
Failure to develop peer relationships appropriate to developmental level
Lack of spontaneous seeking to share enjoyment, interests, or achievements with other people
Lack of social or emotional reciprocity
(B) *Qualitative impairments in communication:*
Delay in, or total lack of, the development of spoken language
Marked impairment in the ability to initiate or sustain a conversation with others in individuals with adequate speech
Stereotyped and repetitive use of language or idiosyncratic language
Lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level
(C) *Restricted repetitive and stereotyped patterns of behavior, interests, and activities:*
Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus
Inflexible adherence to specific, nonfunctional routines or rituals
Stereotyped and repetitive motor mannerisms
Persistent preoccupation with parts of objects

A total of six (or more) items from (A), (B), and (C), with at least two from (A), and one each from (B) and (C)
Onset before age 3

Table 47.4
ICD-10 criteria for Pervasive Developmental Disorders (WHO 2007)

	Pervasive developmental disorders A group of disorders characterized by qualitative abnormalities in reciprocal social interactions and in patterns of communication, and by a restricted, stereotyped, repetitive repertoire of interests and activities. These qualitative abnormalities are a pervasive feature of the individual's functioning in all situations
F84.0	*Childhood autism* A type of pervasive developmental disorder that is defined by: (a) the presence of abnormal or impaired development that is manifest before the age of 3 years, and (b) the characteristic type of abnormal functioning in all the three areas of psychopathology: reciprocal social interaction, communication, and restricted, stereotyped, repetitive behavior. In addition to these specific diagnostic features, a range of other nonspecific problems are common, such as phobias, sleeping and eating disturbances, temper tantrums, and (self-directed) aggression
F84.1	*Atypical autism* A type of pervasive developmental disorder that differs from childhood autism either in age of onset or in failing to fulfill all three sets of diagnostic criteria. This subcategory should be used when there is abnormal and impaired development that is present only after age 3 years, and a lack of sufficient demonstrable abnormalities in one or two of the three areas of psychopathology required for the diagnosis of autism (namely, reciprocal social interactions, communication, and restricted, stereotyped, repetitive behavior) in spite of characteristic abnormalities in the other area(s). Atypical autism arises most often in profoundly retarded individuals and in individuals with a severe specific developmental disorder of receptive language
F84.5	*Asperger's syndrome* A disorder of uncertain nosological validity, characterized by the same type of qualitative abnormalities of reciprocal social interaction that typify autism, together with a restricted, stereotyped, repetitive repertoire of interests and activities. It differs from autism primarily in the fact that there is no general delay or retardation in language or in cognitive development. This disorder is often associated with marked clumsiness. There is a strong tendency for the abnormalities to persist into adolescence and adult life. Psychotic episodes occasionally occur in early adult life

Table 47.5
Red flags for ASD

Poor eye contact
No response to name at 12 months (with normal hearing)
No pointing by 14 months
No pretend play at 18 months
Echolalia
Loss of skills (regression)
No reciprocal social smile

administration of both tools may not be practical in all clinical practice. Warning signs that should prompt evaluation for ASD are listed in *Table 47.5*.

Social Deficits

Key features include difficulties with joint attention, social reciprocity, imitation, and nonverbal behaviors (eye contact and gestures). Joint attention develops as early as 8–10 months in typically developing children and includes following eye gaze, following a point (10–12 months), pointing to request ("protoimperative" 12–14 months), and pointing to express interest ("protodeclarative" 14–16 months). This is usually accompanied by directing eye gaze back and forth between another person's eyes and an object of interest. There may be a lack of social referencing, which is when a child looks to another person to share affect or, for example, to determine how to respond in an unfamiliar situation by looking for another person's facial expression. Shared enjoyment with others is limited, and there may be a lack of showing behaviors. One of the fundamental deficits in ASD is lack of emotional reciprocity and "theory of mind," the ability to understand and attribute the mental states (and emotions) of others as different from one's own.

Communication Deficits

Many children diagnosed with ASD are originally evaluated because of language delays. However, over 80% develop language. Individuals with Asperger's syndrome do not have clinically significant language delay by definition, but they may have the unusual speech patterns characteristic of ASD such as echolalia (repetition of words or phrases), difficulty with pronouns, and unusual prosody (stress, pitch, and intonation). There are also deficits in the semantic aspects of language, with difficulty

understanding abstract concepts. This tendency to be overly literal affects pretend play skills, and there may be difficulties with imitation. Individuals with ASD who have language often have trouble with the social use of language (pragmatics) such as turn taking and sustaining conversation.

Restricted Interests

Intense interests in restricted or repetitive patterns of behavior are common in ASD. This may involve unusual interests, such as a preoccupation with fans or license plates, or interests that are typical for developmental level (i.e., trains) but which are abnormal in intensity. There may also be a nonfunctional insistence on routines or sameness (lining up objects, etc.) and focus on parts of objects rather than the whole. Some individuals demonstrate repetitive and stereotyped behaviors, such as hand-flapping or finger flicking. Sensory differences (hyper- or hypo-sensitivity to noise, touch, etc.) are common although not universal. In a minority of cases, individuals with ASD may have savant skills, with isolated exceptional abilities in areas such as math or music.

Regression

Regression, or loss of previously acquired skills, is uncommon in typically developing children but affects 33–41% of children with ASD, typically between the ages of 15 and 24 months. Report of language loss alone may underestimate the prevalence of regression, since parents also report loss of social interest, eye contact, or use of gestures. Many parents report a period of typical development prior to the onset of regression, while others note the presence of developmental delay prior to regression.

IQ

As a result of early intervention, broader diagnostic criteria, and improved evaluative practices, the prevalence of global developmental delay or intellectual disability (ID) in individuals with ASD has decreased over the years, with recent estimates under 50%.

Differential Diagnosis

While some individuals with ASD may also have *intellectual disability* (ID), the distinguishing factor between ASD and ID is that people with ID have social and communication abilities appropriate for their developmental level. Children with *hearing impairment* may have difficulty with receptive language, similar to children with ASD. However, other aspects of communication, such as nonverbal behaviors, eye contact, and joint attention, are usually unimpaired. Many children with *visual impairment* may have poor eye contact and self-stimulatory behaviors that mimic symptoms of ASD. The *Landau–Kleffner syndrome* has a later onset of language regression and a characteristic EEG pattern. Poor eye contact is often attributable to *anxiety disorders*, and individuals with o*bsessive compulsive disorder* (OCD) may have intense preoccupations. However, in OCD, these behaviors cause distress whereas in ASD, individuals prefer activities related to their intense interests. Symptoms of *attention deficit hyperactivity disorder* (ADHD) may include social impairment, but communication and repetitive/restricted interests are not affected.

Management and Treatment

General Management and Treatment

Any child suspected of having an ASD should have a hearing evaluation and referral to a specialist for diagnostic assessment if available. Lead testing is appropriate if risk factors are present. Once diagnosed, high-resolution chromosomes/karyotype and fragile X DNA are indicated. Chromosomal microarray/comparative genomic hybridization (CGH) is gaining utility in identifying chromosomal duplications and deletions and may soon be first-line investigation. Targeted genetic testing, such as MECP2 mutations in females with acquired microcephaly, regression, and loss of purposeful hand movements, or FISH for chromosome 15q duplication in those with hypotonia, intellectual disability, and seizures, should be considered based on symptoms.

Routine MRI is not recommended unless there are clinically relevant findings, such as symptoms suggestive of tuberous sclerosis or increased intracranial pressure. Accelerated head growth and macrocephaly (head circumference >2 SD above population mean) has been reported in over 20% of children with ASD based on MRI and head circumference studies. Interestingly, head circumference is average or slightly lower than average at birth, with rapid growth in the first year of life. Structural differences in the frontal lobes, white matter, and cerebellum have all been identified.

EEG is recommended if there are clinical symptoms suspicious for seizures. Seizures have been reported in

approximately 25–30% of people with ASD, with a bimodal distribution in early childhood and adolescence. Abnormal EEGs in the absence of clinical seizures are reported even more frequently. The evidence relating a history of regression with EEG abnormalities is unclear, and treatment of EEG abnormalities in the absence of clinical symptoms is controversial.

Gastrointestinal (GI) problems, such as constipation and food selectivity/sensitivity, are reported frequently in ASD. A consensus report cited these recommendations with regard to GI disorders and ASD: Individuals with GI symptoms should be evaluated in the same manner as typically developing children; there is insufficient evidence to endorse the use of the gluten-free, casein-free diet to treat the core symptoms of autism, and growth and nutritional status (including protein, vitamin D, calcium, and iron) should be carefully monitored (given self-imposed or therapeutic diets). The report also highlights that GI symptoms may manifest as behavioral changes and despite reports of lymphonodular hyperplasia and increased intestinal permeability, there is no evidence at this time to suggest GI pathology specific to autism (since these findings are also found in typically developing populations). A detailed history and physical examination for immune-mediated food allergies should be pursued, with appropriate work-up if positive.

Sleep disturbances, including delayed sleep onset, night-time wakening, and decreased sleep duration, are reported more frequently in children with ASD. Behavioral interventions may successfully treat sleep problems. Melatonin, a hormone secreted by the pineal gland, is reduced in children with ASD and has shown to be safe and effective for improving sleep in ASD.

Psychiatric comorbidities are common, such as attention deficit hyperactivity disorder (ADHD), anxiety, and depression, especially in older children or adolescents. Screening for psychiatric problems, with proper behavioral and pharmacological intervention, should be performed routinely.

Educational Treatments

Behaviorally based interventions are the most effective treatments for ASD, and many types exist. Applied behavior analysis (ABA), which uses learning principles of how environment can change behavior, is perhaps the best documented, although other models such as developmental theory and relationship-based curricula have also proven effective. The evidence base for a variety of interventions is available at http://www.nationalautismcenter.org/about/national.php. Regardless of the modality, an intensive, comprehensive program which provides structured teaching tailored to the child's individual needs best benefits a child with ASD. Additional therapies important to consider include speech/language therapy, social skills instruction, and/or occupational therapy.

Early intervention agencies often provide intervention to toddlers, with transition to the school system after that. Many children require special education services and benefit from an individualized education plan (IEP). Goals for older children involve generalization of learned skills to new environments, functional skills that promote independence, and socialization with other children.

Pharmacological Treatments

The atypical antipsychotics risperidone and aripiprozole are FDA-approved to treat irritability in children aged 6–17 with ASD. Side effects include weight gain, sedation, and restlessness (akathisia). Rarely, there may be movement disorders as a result of these medications.

Current pharmacological treatments target associated symptoms, such as irritability, impulsivity, anxiety, or sleep. Clinical trials for medications to treat the core symptoms of autism are underway and include memantine, oxytocin, and other neuromodulators.

Prognosis

Due to early, intensive therapy, and broader diagnostic inclusion criteria, projected long-term outcomes have improved. While there is great heterogeneity in outcomes, most individuals continue to improve with milder symptoms into adulthood. However, the majority of individuals remain functionally impaired. The best predictors of good outcome are development of speech by age 5 and normal IQ. It is hoped that early diagnosis and continued autism-specific interventions will improve the long-term outcomes for individuals with ASD.

48 Child Abuse and Neglect

Fadheela Al-Mahroos · Dena Nazer · Vincent J. Palusci · Rachel Clingenpeel

Overview of Child Maltreatment: An International Perspective

Child maltreatment consists of anything which individuals do or fail to do which directly or indirectly harms children or damages their prospect for safe and healthy development into adulthood. It includes physical, sexual, and emotional abuse and neglect.

Child abuse and neglect (CAN) has existed as long as humanity has existed. Infanticide was practiced in many societies and has been documented in China, India, and the Pre-Islamic Arabia. In the year 900 the prominent physician Al-Razi, attributed the prominence of umbilical hernia in children to "the child may have been intentionally struck." CAN cases are well documented in many writings, novels, and in medical professional literatures of the nineteenth century. The full scale of the problem, and the role of physicians in addressing it, has emerged in the latter half of the twentieth century, when documented in the medical literature by Henry Kempe and colleagues in the landmark article "The battered-child syndrome." This was followed in 1972 by another landmark article by Caffey describing "shaken-baby syndrome" consisting of diffuse subdural hemorrhage, diffuse multilayer retinal hemorrhage, and diffuse brain injury and swelling.

Since then, it is well-recognized that child abuse and neglect represent a common public health and social problem across the globe. The United Nations General Secretary's 2006 Study on Violence Against Children has documented that all forms of child maltreatment exist in every corner of the world and that no race or culture is exempted. According to this report, almost 53,000 children died worldwide in 2002 as a result of homicide, and up to 80–98% of children suffer physical punishment in their homes, with a third or more experiencing severe physical punishment resulting from the use of instruments. In addition, 150 million girls and 73 million boys under 18 have experienced forced sexual intercourse or other forms of sexual violence. Between 100 and 140 million girls and women in the world have undergone some form of female genital mutilation or cutting. In sub-Saharan Africa, Egypt, and the Sudan, 3 million girls and women are subjected to genital mutilation or cutting every year. In 2004, 218 million children were involved in child labor. Estimates from 2000 suggest that 1.8 million children were forced into prostitution and pornography, and 1.2 million were victims of trafficking.

The most recent large US study of CAN, conducted in 2005–2006, was the National Incidence Study (NIS–4). This revealed that nearly 3 million children experienced CAN as defined by the Endangerment Standard definition of maltreatment. This is equivalent to one child in every 25 in the United States being affected. Of the children identified as maltreated, 26% were identified as abused, and 77% were identified as neglected. Of the abused children, physical abuse was documented in 57%, emotional abuse in 36%, and sexual abuse in 22%. Another large scale research study is the Canadian Incidence Study of Reported Child Abuse and Neglect – 2003 (CIS-2003). This study revealed that an estimated 217,319 child investigations were conducted in Canada of which 103,297 (47%) child investigations were substantiated. Physical abuse was documented in 24%, sexual abuse in 3%, emotional abuse in 30%, exposure to domestic violence in 15%, and neglect in 28% of the substantiated cases.

A study which reviewed reported child abuse and neglect studies in the seven countries of the Arab Peninsula, documented child abuse in Bahrain, Kingdom of Saudi Arabia (KSA), Kuwait, Oman, and Yemen. The WorldSAFE study (2002) documented the rates of harsh forms of physical punishment in the previous 6 months as reported by mothers in four developing countries, and compared it with the rate in the USA. The rates of harsh treatment such as hitting a child with an object (not on buttocks) were significantly higher in Egypt and India (26% and 36%, respectively) in comparison with Chile and the US (4% each). However, the variation between the five countries is less in the rates of moderate forms of physical punishment. This illustrates that the limited amount of research about child abuse and neglect in developing countries does not imply less occurrence of child abuse and neglect. On the contrary, children in developing countries may be at higher risk due to high rates of poverty and political unrest in many of these countries.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_48,

Root Causes of Child Abuse and Neglect

Child abuse and neglect result from the interplay of a constellation of factors in the victim, perpetrator, family, and society. The World Health Organization adopted the "ecological model" which identified the complex interplay of four risk factors that influence behavior. First are the individual characteristics of the victim and the perpetrator such as age, gender, education, substance abuse, childhood experiences of abuse, and personality traits. The second level is relationships with siblings, parents, and peers which might shape the victim or the perpetrator behaviors. The third is the community level, which is the social context within the neighborhood, school, and other institutions. These might include poverty, unemployment, social isolation, and high rates of drug addiction and alcoholism. The fourth level addresses societal factors such as the culture which accepts corporal punishment, gender inequality, and the use of violence in conflict resolution. Therefore, for every case of child abuse or neglect and in every culture, there is a complex interplay between protective and risk factors. The main challenge for professionals and communities is to determine how to exploit protective factors and control risk factors.

Case Presentation

A 10-week-old baby presented with a history of difficulty breathing, choking, and seizure 3 h ago. The baby was normal when the mother nursed her before she went to work 6 h ago. According to the father, he was trying to feed the child a bottle when she choked and had seizures. Father gave a history of the child slipping from his hand from a height of 1 ft into a plastic tub while he was bathing her. Physical examination showed a cyanotic infant with labored breathing and generalized tonic-clonic convulsions and a left parietal scalp swelling. No skin bruises were seen. Fundoscopy showed bilateral multilayer retinal hemorrhages. The patient expired after 4 days of ventilatory support and intensive care.

A non-contrast-enhanced CT of the brain showed diffuse cerebral edema, interhemispheric and peritentorial subdural hemorrhage, subarachnoid hemorrhage, bilateral cerebral contusions, left parietal scalp hematoma, bilateral temporal bone fracture and bilateral parietal bone fracture with comminuted fragment on the right, and separation of the lambdoid and coronal sutures (*Fig. 48.1*). Plain radiographs of the chest showed multiple rib fractures involving the anterior aspects of the right third to fifth ribs and the left third to seventh ribs with callus formation.

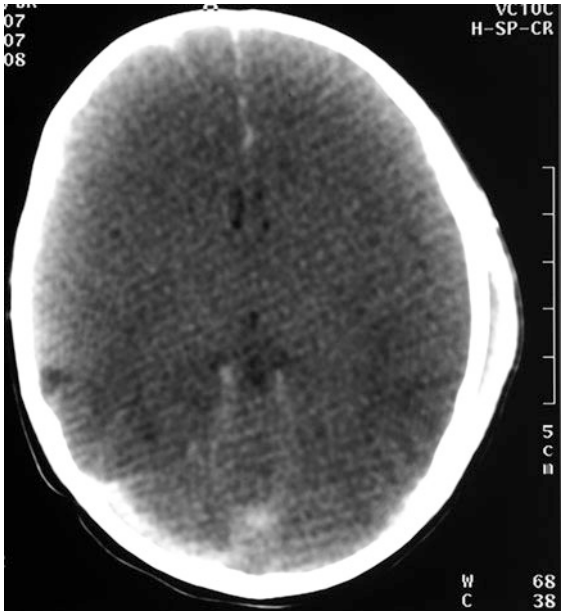

Figure 48.1
Non-intravenous contrast-enhanced CT of the brain showing diffuse brain edema with loss of gray-white matter differentiation, compression of the lateral ventricles, effacement of basal cisterns, interhemispheric and peritentorial subdural hemorrhage, subarachnoid hemorrhage at the cerebral convexity, and left parietal scalp hematoma

There are multiple posterior rib fractures on the left with callus formation involving the third to eighth ribs (*Fig. 48.2*).

The patient's history, physical exam, and radiologic findings are consistent with child abuse and fatal abusive head injuries.

Child Physical Abuse

Child physical abuse can be defined as the intentional use of force that results in physical injuries, including bruises, welts, cuts, burns, fractures, and internal injuries. It also may include shaking, deliberate poisoning, suffocation, drowning, and medical child abuse or factitious disorder by proxy.

Clinical presentation of child physical abuse ranges from normal physical examination to severe head injury and death. The main task in evaluating childhood injuries is to differentiate abusive from accidental injuries. This can be incurred from the location, size, pattern,

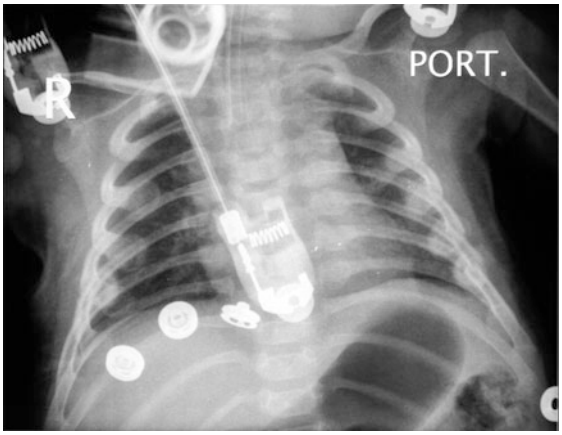

Figure 48.2

severity, possible force used, and the mechanism of injury. In addition, it is important to identify if the injury is developmentally conceivable for the child to sustain accidentally and whether the explanation by the caregiver is plausible.

Skin Injuries

Bruises are the most common presentation of child physical abuse. Bruises appear hours to days after injury. Color changes at different rates and different colors may be present in a bruise; therefore, it is not possible to date bruises based on the color. Bruises are also commonly found after accidental injury in mobile children. However, bruises are rare in pre-ambulatory normal infants. Therefore, any inadequately explained bruise in a nonmobile child should prompt further evaluation for child maltreatment, including a detailed history, careful and complete skin exam, a palpated exam for bony tenderness, and possible imaging.

The typical sites of accidental bruises are the bony prominences in the front of the body such as the forehead, nose, chin, elbows, knees, and shins. The history of an accidental bruise should be conceivable and compatible with the developmental abilities of the child. Injuries that involve soft tissue such as the eyes, ears, cheeks, neck, inner aspects of the arms, chest, abdomen, thighs, back, and buttocks are less common from accidents, and therefore more concerning for inflicted injury. Bruises may take the shape of the instrument used to inflict injury such as a hand, stick, cord, or belt (◉ *Fig. 48.3*). The caregiver's history of an inflicted injury may be vague or incompatible with the location, pattern, or severity of the injury.

Human bite marks are patterned injury typically 2–4 cm across that may include bruising, abrasion, laceration, or all of the above. The classic pattern is one of opposing semilunar marks composed of individual tooth marks. The bites of children typically leave impressions of both dental arches, whereas bites of adults often leave the impression of only one arch; however, this is not absolute. Bite marks should be photographed with and without a measurement standard and may help in forensic identification of the offender.

Accidental scald burns due to a spill of a hot liquid typically appear in a trickle-down or inverted triangle pattern, with the most severe burn at the point of first contact of the hot liquid with the body, and decreasing severity as the liquid flows in the direction of gravity and cools. The flow pattern of scald burns is influenced by the presence of clothing or diapers. Inflicted cigarette burns have a sharply defined "punched out" appearance and measure 0.8–1 cm, corresponding to the size of the cigarette (◉ *Fig. 48.4*). In contrast, accidental cigarette burns, resulting from the child running into a lit cigarette, have an ovoid or 'brushed' appearance resulting from the child's movement away from the hot stimulus, and generally do not have ulcerated centers. Inflicted burns may take the pattern of the inflicting instrument such as an iron, spoon, fork, or knife (◉ *Fig. 48.5*). Forced immersion burns may have a stocking-and-gloves appearance on the

Figure 48.4

Figure 48.5
Hot knife burn on the thigh of an 8-year-old child punished by his mother for stool incontinence

extremities, or may spare flexor creases in the genital area. They produce a pattern of injury with more sharply demarcated proximal borders than accidental scalds, and the pattern of a flowing hot liquid typical of accidental scalds is absent or minimal.

Differential Diagnosis: Skin Injuries

There are many skin conditions that may be mistaken for inflicted injury. Accidental injuries (*Fig. 48.6*) must be distinguished based on appearance and plausibility of the history provided by the caregiver. Congenital skin lesions,

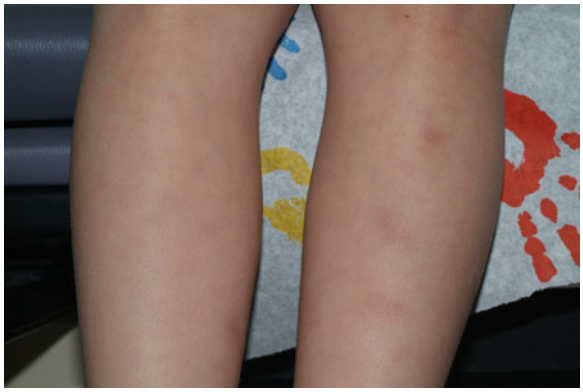

Figure 48.6
Legs of an active 3-year-old girl. Notice the multiple small bruises on her shins. Bruises are not patterned, consistent with the history of falling and are on bony prominences. Diagnosis: accidental bruising

Figure 48.7
A child who presented for an evaluation of suspected abuse and had a hyperpigmented circular mark on her face. She had it since birth, is not tender and did not change in color. Diagnosis: Mongolian spot

such as slate gray nevi or Mongolian spots (*Fig. 48.7*) as well as hemangiomas (*Fig. 48.8*), may be mistaken for bruising. Bleeding diatheses, either congenital or acquired, may produce bleeding and bruising which seems out of proportion to the trauma history, or the patient may be lacking in any history of trauma. These may be distinguished by a careful bleeding history of the patient and family, concurrent symptoms, and laboratory testing if indicated. Skin infection such as bullous impetigo may be mistaken for cigarette burns; the phototoxic reaction

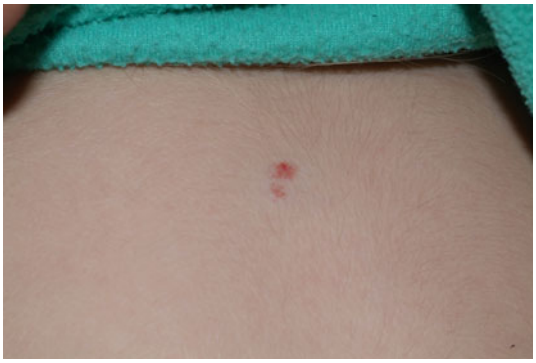

Figure 48.8
A child with a hemangioma on the back. It may be misdiagnosed as trauma and physical abuse

Figure 48.9
A child with multiple circular healed burns on the chest and abdomen. Diagnosis: Maquas (therapeutic burning) which involves using hot metal rods near an area of illness or pain (Photo courtesy of Hisham Nazer, MD)

phytophotodermatitis, resulting from sunlight exposure to skin after contact with psoralen-containing compounds, can also be mistaken for burns or bruises. Therapeutic cultural practices may produce skin findings that can be mistaken for bruises or burns inflicted with malicious intent. Coining (rubbing a coin over oiled skin) or cupping (applying a heated glass to the skin) may produce patterned ecchymoses or petechiae. Therapeutic burning practices may mimic inflicted burns. For example, Maquas (*Fig. 48.9*) involves placing hot metal or coals near areas of illness or pain, and moxibustion involves the burning of the herb moxa or mugwort at acupuncture points. Careful, nonjudgmental history and complete exam are usually sufficient to distinguish these conditions from abusive injury.

Fractures

There is no fracture type that is pathognomonic for abuse, and all fracture types can potentially result from inflicted injury. The diagnosis of inflicted fracture must therefore be made through careful correlation of the history provided by the caregiver with the child's developmental level and physical and radiographic findings. Although any fracture can be caused by abuse, certain patterns are strongly predictive of abuse. Classic metaphyseal lesions, rib fractures particularly posteriorly, scapular fractures, vertebral spinous process fractures, and sternal fractures all have a high specificity for abuse. Common, nonspecific injuries include subperiosteal new bone formation, clavicular fractures, diaphyseal fractures of long bones, and linear skull fractures. There are some fracture types and findings of intermediate specificity, which are concerning, but may be accidental if a clearly plausible mechanism is provided. This group includes multiple fracture, particularly when bilateral; fractures of different ages; epiphyseal separation; digital fractures; vertebral body fractures and subluxations; and complex skull fractures. Physical signs and symptoms of fractures may include swelling, tenderness, deformity, and limited range of motion with or without external bruising. The majority of fractures, both accidental and inflicted, are not associated with overlying bruising. Infants may present with irritability and/or not using the affected limb.

Classic metaphyseal lesions (CMLs), also known as corner fractures or bucket handle fractures, are highly specific for child abuse in children under 1 year of age. Metaphyseal fractures are the fracture type found most often in fatal child abuse cases, and are diagnosed most often in infants under 6 months of age. They represent a disruption of the primary spongiosa of the metaphyses under tension or shear mechanical loading. CMLs associated with subdural hematoma were first described by Caffey. The most common locations for CMLs are the proximal tibia, distal femur, and proximal humerus. CMLs can be easily missed because of subtle signs and

symptoms in the nonambulatory patients who sustain these fractures, and are often identified on skeletal surveys ordered due to other concerning historical or physical exam findings.

Rib fractures from accidental injuries are uncommon in young children, and when accidental rib fractures do occur, they are the result of high-force mechanisms, such as those involved in motor vehicle collisions. Posterior rib fractures in particular are highly specific for abuse (*Fig. 48.2*). Rib fractures may be identified incidentally when a chest film is taken for a respiratory problem or as part of skeletal survey for an infant with head injury. Infants with rib fractures due to abuse typically do not present with a history of trauma. In one study, for children younger than 3 years of age, the presence of a rib fracture had a 95% positive predictive value for child physical abuse.

A concern which is frequently raised is the possibility of cardiopulmonary resuscitation causing rib fractures. The published evidence indicates that rib fractures are exceedingly rare complications of CPR in children, seen in less than 2%, and that, when they do occur, they are likely to be anterior and not posterior rib fractures.

Long bone fractures are common fractures that have a low specificity for abuse. It is important to correlate the shape of the fracture line – transverse, oblique, spiral, or comminuted – with the described mechanism of injury. Spiral fractures have been strongly associated with abuse because of the torsion or twisting of the limb that is implied by this fracture morphology. Spiral fractures are more likely to be abusive in infants than in ambulatory children, but they commonly occur in accidentally injured mobile children, particularly of the femur, which has a relatively low injury threshold under a torsional mechanical load. Spiral fractures should not be considered innately more suspicious for abuse than other fracture morphologies; any long-bone fracture in a nonambulatory child is concerning and requires a plausible history to be considered accidental.

Skull fractures are relatively common after accidental falls in children; however, short falls typically result in simple linear fractures and are associated with a plausible history. In mobile children, the mechanism of injury may not have been witnessed, since they may have short periods of time out of the sight of a caregiver. However, they would have a period of crying or other behavioral indicator to the caregiver that the trauma had occurred. Fractures with a slightly depressed component may also occur from household falls if the fall is onto an object. Skull fractures are also commonly seen in abusive injury to the head, particularly in children under 2 years of age. No pattern of skull injury is diagnostic of abuse. However, diastatic, complex, or significantly depressed skull fractures are much more concerning for abusive injury and are caused by a greater degree of force than is associated with simple household falls.

The age of fractures can be helpful in assessing the plausibility of the fracture history, and multiple fractures of different ages raise the suspicion of abusive injury. Fracture healing manifests as periosteal reaction, also called callus, which is radiographically apparent after 10–14 days, and can be earlier in infants. Subperiosteal new bone formation can be a normal finding in infants under 6 months of age; as a physiologic finding, it is usually found along the shafts of long bones and is symmetrical on both sides of the body. A discrepancy between the history and signs of fracture healing is a red flag to initiate further scrutiny for child physical abuse. Skull fractures cannot be dated with accuracy.

Diagnosis: The Skeletal Survey

Skeletal survey is the standard diagnostic investigation when there is concern for physical abuse of infants and toddlers. It includes anteroposterior (AP) views of the extremities including feet, with the exception of the hands which are imaged in the posterioaterior view; AP and lateral skull; AP and lateral views of the thorax and oblique ribs; AP pelvis; and lateral views of the spine.

Differential Diagnosis: Fractures

In addition to accidental injuries, several bone diseases are considered in the differential diagnosis including rickets, bone infection, hypophosphatasia, and skeletal dysplasia including osteogenesis imperfecta (OI). History, physical examination, laboratory studies, and radiological findings will help identify medical causes of bone fragility. Differentiating OI from child abuse can be a challenge, but as in all forms of abuse, thorough patient and family history and concomitant findings are highly informative. The vast majority of patients who have bone disease increasing fracture susceptibility will have one or more laboratory abnormalities, abnormal-appearing bones on radiography, history of fractures with minor trauma, stereotypical morphologic features, or all of the above.

Osteogenesis imperfecta (OI) is a connective tissue disorder with a wide range of clinical severity, from pre- or perinatal lethality to only premature osteoporosis. Patients with OI have decreased bone formation and increased bone turnover. Ninety percent of affected

patients have a mutation in one of two genes for proteins in type I collagen. There are approximately two hundred genetic mutations that have been associated with OI. Clinical manifestations of OI might include blue sclerae, lucent teeth, hearing loss, easy bruisability, short stature, scoliosis, ligamentous laxity, and Wormian bones of the skull. The diagnosis of OI is predominantly a clinical one; no laboratory study is absolutely sensitive, but fibroblast culture from skin biopsy or DNA testing of leukocytes can verify the clinical assessment. Children with unexplained fractures are unlikely to have OI unless other features of OI are also present.

Abusive Head Trauma (AHT)

Abusive head trauma, previously referred to as "shaken-baby syndrome," is the most serious complication of child physical abuse and is responsible for about 80% of child abuse fatalities. It is predominantly a diagnosis of infancy, and is the leading cause of infant homicide in the United States. The term "abusive head trauma" is preferred because it reflects the various mechanisms or combinations of mechanisms which can produce inflicted head injury. Acute and long-term morbidities are high, and many patients end up with cerebral palsy, mental retardation, seizures, and visual loss. AHT can result from shaking or other causes of acceleration-deceleration and rotational forces, direct contact or impact forces, or combinations of these. The relatively large head size and weaker neck muscles make the infant more susceptible to injury from violent shaking. Analysis of information obtained from perpetrator confessions indicates that the shaking causing AHT is violent and is often repetitive, and is commonly triggered by caregiver frustration with infant crying.

Head injury may be the sole manifestation of AHT. However, it is often also associated with retinal hemorrhages, skeletal injuries, and/or cutaneous injuries. The patient may not have external signs of trauma. The presentation of abusive head trauma is often vague, nonspecific, and lacking in any immediately available history of trauma. Consequently, many cases are missed or misdiagnosed when they first present for medical care. Common presentations of abusive head injury in infants are altered states of consciousness, irritability, choking episodes, difficulty breathing or apnea, vomiting, and seizures. Children may also present with more indolent symptoms such as poor appetite, chronic vomiting, irritability, change in sleep pattern, and increasing head size after remote or repetitive episodes of trauma.

Subdural hematoma (SDH) is more common in AHT than other forms of extra-axial hemorrhages. Epidural hematomas are commonly present in accidental trauma. However, any type of extra-axial hemorrhage can be caused via an abusive mechanism, including subarachnoid, epidural, and intraventricular hemorrhage. The subdural space, between the arachnoid and dura mater, has bridging veins which cross this space, extending from the cortical surface into the dural sinuses. These bridging veins are torn during the abusive event, leading to subdural hematoma formation. The blood may spread into the hemispheric fissure and along the cerebral convexities. Many forms of intracranial injury can occur in cases of abusive head trauma, including cerebral contusion, axonal injuries, parencyhmal tears, and cerebral edema.

Retinal hemorrhages are often closely associated with abusive head trauma, though they are not universally present in these patients. Retinal hemorrhages have many possible causes, and are as a whole nonspecific. However, severe, bilateral, multilayer hemorrhages that extend to the periphery of the retina are highly specific for abusive injury when noted outside the neonatal period in the absence of medical disease or trauma history that adequately explains them. Retinal hemorrhages cannot be dated.

Diagnosis

The first step in diagnosing abusive head trauma is to include it on the differential diagnosis. This may not always occur due to the nonspecific nature of the presenting symptoms and often the absence of trauma in the history provided. Once concern for AHT is raised, CT scan is the preferred initial study for AHT because CT scans illustrate acute hemorrhage and skull fractures well, they are more readily available, require less time, and are more suitable for unstable patients. However, smaller hemorrhages and cerebral lesions can be missed on CT scans, which makes MRI the study of choice in subacute and chronic conditions due to its higher sensitivity and specificity. In comparison with large hematomas that cause symptoms due to mass effect, small subdural hematomas can be clinically silent and found incidentally. In addition, children with suspected abusive head trauma should have dilated eye examinations, preferably by a pediatric ophthalmologist; skeletal survey; and laboratory studies to include chemistry and blood count, urinalysis, liver and pancreas function tests to evaluate for occult abdominal injury, and screening coagulation studies.

Abusive Head Trauma: Differential Diagnosis

The differential diagnosis of abusive head injury is wide, and includes non-abusive trauma such as birth trauma, congenital conditions such as arteriovenous malformations, metabolic conditions such as glutaric aciduria type I, inherited or acquired bleeding diatheses, infectious causes such as meningitis or sepsis, and connective tissue disorders. The complete investigation of all of these entities in each case of suspected abusive head trauma would be not possible; fortunately, it is also not indicated. Patient and family history, clinical presentation, and associated findings should guide the clinician to those entities deserving of further diagnostic investigation.

Abdominal Trauma

Inflicted abdominal injuries are usually caused by blunt trauma resulting in injury to the liver, duodenum, pancreas, or bowel. The average age of children with abdominal trauma due to inflicted injury is 2 years. Symptoms may be vague or nonspecific and include vomiting, irritability, fever, and abdominal pain; therefore, clinical suspicion must remain high. Abdominal wall bruising is often absent. Delay in seeking medical care and the difficulty of diagnosis may lead to peritonitis, sepsis and death. The mortality rate in abdominal injuries is up to 50% and it is the second-leading cause of mortality from child physical abuse after head injuries.

Evaluation of Child Physical Abuse

Cases of abuse require strong skills and training in interacting with children and families. It is important to use non-leading questions when speaking with young children, who can be suggestible. It is also important to obtain the history from the child as well as each parent or other involved caregiver separately. That being said, the history taken in a case of suspected abuse is fundamentally the same as any good, thorough medical history. Good documentation is essential especially when the case is taken to court. Overall, maintaining a high index of suspicion and early detection is important in the evaluation and management of child physical abuse. Maintaining a trusted patient-doctor relationship is essential by emphasizing the role of a helper and a healer rather than a legal investigator. The main priorities are diagnosing and treating any injuries, protecting the child from further abuse, and meeting the child and family's needs. It is imperative to avoid premature accusation or judgment and seek help of a child abuse specialist when needed.

Treatment and Outcomes of Physical Abuse

Treatment of victims of child physical abuse depends on the nature and severity of the injuries. Protecting the child from further abuse is paramount along with the focus on addressing the underlying problems. In addition, removal of the child from his or her environment should be considered if it serves the best interest of the child, but should always be the last resort. Despite the seriousness of some of the physical injuries which can be fatal or result in severe disabilities, many of them will heal completely. However, it is the mental and emotional trauma that may have the most enduring effect and can result in long-term negative consequences including aggression, post-traumatic stress disorders, depression and anxiety, addiction, and other psychiatric conditions, as well as impaired attachment and chronic difficulty in relationships. Children who are physically abused are also more likely to accept and perpetrate violence in their relationships, as well as physically abuse their own children. Breaking this cycle of abuse requires appropriate mental health treatment of the child and the parent, and appropriate intervention to change the parent–child relational dynamic.

Child Sexual Abuse

Case Presentation

A 4-year-old girl is brought for medical evaluation because she was found naked in a bed with an unrelated adult male. She does not complain of pain, but appears frightened, clings to her mother, and says "the man hurt me." Her mother is concerned she may have been sexually abused, physically harmed, and can get an infection. How will you approach this patient? What are the physical and emotional manifestations of child sexual abuse, and what steps will you take for obtaining history, examination, diagnostic testing, treatment, and protection of the child?

Definitions/Classification

The World Health Organization has defined child sexual abuse and exploitation as the involvement of a child in sexual activity that he or she does not fully comprehend, is unable to give informed consent to, or for which the child

is not developmentally prepared and cannot give consent, or that violate the laws or social taboos of society. Child sexual abuse is evidenced by this activity between a child and an adult or another child who by age or development is in a relationship of responsibility, trust or power, the activity being intended to gratify or satisfy the needs of the other person. This may include but is not limited to:

(a) The inducement or coercion of a child to engage in any unlawful sexual activity
(b) The exploitative use of child in prostitution or other unlawful sexual practices
(c) The exploitative use of children in pornographic performances and materials

Rape is defined as forceful, penetrative sexual contact. *Sexual assault* refers to a broader collection of acts, including fondling and other non-penetrating acts and also is further refined in government codes. Other terms imply the relationship of the offender to the victim. *Incest* refers to sexual contact between family members, which is sometimes limited to immediate family but in other contexts can extend to fifth degree relationships (second cousin, once removed). *Sexual exploitation* generally refers to acts without sexual contact, such as having children pose for sexually explicit photographic or video images, having them witness sexual acts, internet solicitation, or by adults inappropriately exposing themselves to children, all for the sexual gratification of the adult. *Female genital mutilation* comprises all procedures that involve partial or total removal of the external female genitalia, or other injury to the female genital organs for nonmedical reasons.

Etiology

Child sexual abuse and sexual victimization are thought to occur because of several factors related to the behavior and mental status of the offender, the societal milieu, and the acceptance of sexuality and cultural history of violence toward women and children. Psychological harm occurs through direct emotional trauma and development of post-traumatic stress and later risk-taking behaviors in adolescence and adulthood. Physical harm occurs through tissue and organ trauma and infections with sexually transmitted agents.

Epidemiology

Although precise incidence data are lacking, sexual abuse of children occurs commonly throughout the world. In the USA, it has been estimated that one or more in four girls and one in ten boys will be victims of sexual abuse by the time they become adults. Similar or higher lifetime prevalence has been noted in Europe, Africa, and Australia. While boys are reported less often than girls, recent studies have suggested that the number of male victims may in fact be higher as a result of a reluctance to report cases among boys. The Canadian Incidence Study reported that confirmed sexual abuse reports involved 0.93 children per 1,000 in 1998. In the USA, the number of CSA victims, while rising during the late 1980s, actually declined during much of the 1990s and early into the twenty-first century. Cases declined from a peak of 144,760 cases in 1991 to 79,640 in 2006, with incidence rates declining from 2.2 per 1,000 children in 1990 to 1.1 per 1,000 in 2006. Early reports from professionals in countries associated with the United Kingdom noted lower rates (3 per 1,000), while later reports have rates similar to those in the USA. Reports from Asia, while limited, show smaller (but increasing) numbers.

Pathogenesis

Many cases of child sexual abuse follow a pattern of recurrent, escalating sexual contact with an offender in a position of authority to the child. A child is "groomed" for increasingly penetrative sexual contact beginning as fondling, then progressing to full sexual intercourse or sodomy. An offender who is known to a child and who victimizes the child over a period of time may pursue behavior to prevent detection and avoid physical injury, with repeated events of fondling or genital contact without full sexual penetration past the oral, anal, or genital openings.

Pathology

The most important determinant for indicating whether sexual abuse has occurred remains witness disclosure from the child, offender, and others. Most disclosures by children are delayed for weeks or more, and retrospective studies suggest that more than half are not revealed until adulthood, if ever. Most children have normal or nonspecific physical examinations. Physical findings diagnostic for acute sexual abuse are thought to be limited to acute lacerations or bruising of labia, penis, scrotum, perianal tissues, or perineum (Fig. 48.10). Laceration of the posterior fourchette or commissure not involving the hymen is also diagnostic of trauma. Acute ecchymosis,

Figure 48.10
Infant with lacerated hymen, posterior commissure, perineum and vagina, with active bleeding. Exploration under anesthesia revealed posterior vaginal tear requiring surgical repair

Figure 48.11
Superficial anal laceration affecting the anterior perianal tissues. Dried blood and forensic evidence present. No involvement of the external sphincter, rectum, or intestinal mucosa. No operative repair required

bruising, or laceration of the hymen and perianal lacerations extending deep to the external sphincter are also indicative, but rare case reports with unusual circumstances have been noted with accidental rather than sexual trauma (*Fig. 48.11*). A second category of diagnostic findings involves identifying residua of healed sexual trauma which can be difficult to interpret when the location, depth, and exact nature of the acute injury are not available for comparison. Healed lesions such as old hymenal transections, complete clefts to the vaginal wall in the posterior of the hymen, scars of the posterior fourchette or fossa navivularis, or missing segments of the posterior hymen are also diagnostic for prior sexual trauma. Untreated, sexually transmitted infections cause tissue and organ damage in patterns similar to but not identical with those found in adults.

Clinical Manifestations

Children can present with oral, anal, genital, or other physical injuries after sexual abuse. These can be mild to life-threatening. Most are brought for medical care with a disclosure of sexual contact, sexualized knowledge or behavior inappropriate for age, or physical symptoms indicating anogenital trauma or sexually acquired infection.

Differential Diagnosis

There are several medical conditions that can be confused with sexual abuse. Erythema and increased vascularity can reflect tissue irritation and inflammation associated with poor hygiene, chemical effects (urine, chlorine, stool, medications), self-manipulation, or nonsexual trauma. Irritation, coupled with the relative thinness of tissues, can lead to friability of the posterior fourchette or commisure and labial adhesions posteriorly, anteriorly, or both. Lichen sclerosis et atrophicus has been associated with easy tissue breakdown and genital bleeding. Accidental straddle injury causes replicable patterns of labial bruising and/or laceration over bony prominences with hymenal sparing. Hymenal and urethal opening size can vary widely in normal children without neurologic or urologic disease. Periurethral bands, intravaginal ridges and columns represent supportive ligaments and have bumps or mounds at their insertion. A linea vestibularis or "linea alba" is sometimes present in the midline and hypopigmentation of the labial or perianal tissues is usually unrelated to trauma. An annular hymen extends completely around the opening to the vagina while a crescentric opening lacks anterior tissue between

Figure 48.12
Normal female genital opening, with thin, almost translucent, hymenal tissue between 3 and 9 o'clock, fine vasculature, crescentric hymenal opening and normal labia, posterior commissure, and vaginal mucosa

10 and 2 o'clock (*Fig. 48.12*). Hymenal septa are present in 5–10% of girls at birth and can dehisce from their insertions spontaneously or with normal hygiene. Some girls have an imperforate hymen. Deep or complete hymenal notches or clefts at 3 and 9 o'clock in adolescents are normal findings, and those in the posterior hymenal tissue are difficult to interpret without knowledge of corresponding prior trauma. Posterior hymen width less than 1 mm has been considered an uncertain finding. Failure of midline fusion occurs when the external perianal epidermis appears to have remnant mucosal epithelium. Perianal venous congestion or pooling and flattened anal folds is normal or associated with constipation. A congenital absence of muscle tissue in the midline has been called diastasis ani. Children may have perianal skin tag formation associated with fissures and constipation.

Treatment

All sexually abused children should be referred for specialized medical and mental health assessment. Medical treatment for suspected sexual abuse includes obtaining medical history in a forensically sound manner, a comprehensive physical examination of extragenital sites, a noninvasive assessment for anogenital trauma, testing and treatment as indicated for sexually transmitted infections, and the collection of forensic trace evidence such as semen or sperm within 96 h of assault. Physicians should have familiarity with normal, nonspecific, and specific findings seen after sexual abuse. Examinations should not cause further trauma and should not be forced upon children. Specialized centers have been developed in several jurisdictions to provide these assessments while minimizing trauma to the child and family, enhancing prosecution, and providing supportive counseling. Children are typically examined while lying supine in the "frog-legged position." Any abnormal findings should be confirmed in the prone knee-chest position. For girls, the labia majora and minora are gently separated. Buttocks are separated gently to reveal the anus. In boys, the foreskin, if present, is gently retracted to reveal the glans penis and the scrotum and testes are palpated. The skin of the genitals and perineum are inspected. A dedicated light or otoscope should be used. A camera or colposcope can be used to record diagnostic, magnified images that can be simultaneously viewed by the child, caretaker, and examiner. In girls, penetrating genital injury can occur to the posterior vulva and hymenal rim, so these areas require careful inspection. Abrasions, bruising, and bleeding lacerations can all be seen in acute sexual assault and should be documented by diagram or photograph. Acute bleeding may warrant anesthesia and operative exploration or repair, but most children allow thorough examination without anesthesia or sedation if properly prepared. Although all sexually transmitted infections (STI) raise suspicion of sexual abuse, acquired HIV, gonorrhea, and syphilis are most diagnostic, whether or not there are other corroborating concerns. Specimens for STI and trace evidence are obtained using site-specific protocols and analyzed using procedures that are evolving. STI screening is not recommended in the USA, but should be obtained when:

(a) The child has signs or symptoms of an STI or an infection that can be sexually transmitted, such as vaginal discharge, genital itching or odor, urinary symptoms, or anogenital ulcers
(b) The suspected assailant is known to have an STI or be at high risk for STIs
(c) There is a sibling, another child, or adult in the child's environment who has an STI
(d) There is physical evidence of genital, oral, or anal penetration
(e) The child or parent requests testing
(f) The child is Tanner III or more advanced in sexual maturity rating

Prognosis

The outcome after child sexual abuse depends on the time to identification and treatment, number and severity of injuries produced, relationship with the offender, protection of the child from further harm, and other additional risk and protective factors. Children have improved prognosis when they are provided prompt, thorough, and compassionate care, appropriate supportive and long-term medical and mental health treatment, and protection from further victimization. Emotionally, many children will have little or no apparent behavioral effect acutely. Supportive parents (especially mothers), feeling safe and having access to resources are particularly protective. Some may experience the helplessness, secrecy and accommodation of the Child Sexual Abuse Accommodation Syndrome. Depression, anxiety, and post-traumatic stress disorder can affect all ages of children both acutely and over the longer term, with anxiety disorders, parenting and medical problems, and substance abuse and other risky behaviors becoming apparent in adolescence or adulthood. Treatment modalities (such as trauma-focused cognitive-behavioral therapy and multisystemic therapy) which directly address trauma and behavior problems and support certain coping strategies and family/peer relationships are most productive.

Prevention

David Finkelhor has noted that few studies have been done to assess the effectiveness of policy initiatives and laws intended to protect children from sex crimes by managing known sex offenders through restricting where they can live and work, how they are registered and monitored, and the length and terms of their incarceration. Prevention strategies that concern education programs for children, families, and youth serving organizations about how to prevent and respond to sex offenses and risky situations have been shown to reduce victimization but have not been universally supported by governments and practitioners.

Child Neglect

Case Presentation

A 16-year-old boy with cerebral palsy presented with severe malnutrition, weight loss, and hypothermia. His weight was 9 kg with a history of severe weight loss and missing medical and therapy appointments. He did not attend school for the past year. At the time of evaluation, his thigh was almost the same diameter as the urine catheter. This case illustrates physical neglect, medical neglect, and educational neglect. The family was assessed and it was determined that the mother was provided with the feedings through the insurance company. She had means of transportation and medical recommendations were conveyed to her multiple times previously. The child was placed in foster care and was admitted 6 months later for surgeries to release his contractures. At the time of this later admission, his weight had doubled and his spasticity had improved.

Definition

The establishment of a single, universal definition of neglect is challenging. Neglect has been defined as omission of care such as supervision or health care resulting in harm or potential harm to a child. However, a child-centered definition has been proposed which defines neglect as all circumstances where a child's basic needs are not met regardless of the contributor. Neglect is an act of omission rather than commission, and as such may be a more difficult form of maltreatment for the provider to diagnose. However, its effects on children can be among the most devastating.

Understanding the rights of children is a crucial point in understanding neglect. The Convention on the Rights of the Child was the first instrument to incorporate the complete range of international human rights as well as aspects of humanitarian law. The child's survival and development rights include rights to adequate food, shelter, clean water, formal education, primary health care, cultural activities and information about their rights. These rights require not only the existence of the means to fulfill the rights but also access to them. It is when any of these needs are not met that a child should be evaluated for neglect.

Etiology

Many factors contribute to neglect such as poverty, absence of community resources, parental characteristics (e.g., substance abuse, depression, intellectual impairment, domestic violence, unemployment, social isolation, and lack of education), and child related factors (e.g., prematurity, low birth weight, and disability) which

place additional demands on the caregivers and increase the likelihood of neglect.

Epidemiology

Neglect is the most prevalent form of child maltreatment in the US. As in other forms of child maltreatment, it is underreported. Neglect occurs worldwide and in all racial, educational and social backgrounds. According to United States data from 2007, an estimated 794,000 children were determined to be victims of child maltreatment. Of those, nearly 60% of victims suffered neglect.

Clinical Manifestations

The clinical manifestations of neglect vary depending on the type of neglect present, which reflect the various basic needs of a child that are not being met.

Physical neglect: Inadequate provision of food, clothing, shelter, and hygiene.

Medical Neglect: Caregivers may delay or fail to seek medical advice despite the presence of recognizable symptoms, they may not adhere to the healthcare recommendations, or they may refuse medical treatment. In diagnosing children with medical neglect, pediatricians should consider if the recommended care offers benefit to the child more than associated morbidity, the child is harmed or at risk of being harmed if the care is not provided, the caregivers understand the recommendations, and the health care is accessible but not used.

Educational Neglect: Children need to be in a learning environment that meets their specific needs whether at a school or through regulated home schooling. Neglect occurs when the child misses school with no satisfactory reason, or special educational needs are not met.

Supervisional Neglect: Failure to provide age-appropriate supervision, such that the child is placed at significant ongoing risk of harm.

Emotional Neglect: Failure to provide minimally adequate nurturance and affection or necessary psychological support.

Failure to Thrive, and Overweight: Both conditions have many etiologies and children need to be assessed carefully prior to diagnosing neglect. Most cases involve both psychological and nutritional problems, thus the classification into either organic or nonorganic is no longer used. These two conditions are discussed thoroughly in other chapters in this book.

Other forms of neglect may involve exposure of children to domestic violence, or encouraging them to participate in illegal activities.

Diagnosis

The same challenges that complicate the efforts to derive a clear and universal definition of neglect, also confront the provider in making the diagnosis. When evaluating children for suspected neglect, a thorough evaluation should be conducted to identify the child's needs that are not met, harm or potential harm resulting from neglect, and evaluation of the family for contributing factors. One should also ask if the family comprehends the needs of the child especially in children who have special needs due to a medical illness or disability. One also needs to assess if the family has the means and resources to meet the child's needs and if these needs were addressed properly by health care providers and necessary referrals and education provided to caregivers.

Prognosis

Neglect has been associated with substantial morbidity and mortality. The impact depends on the type of neglect, severity and the age of the child when it occurred. Adverse effects include behavior problems, academic underachievement, and cognitive deficits. Neglect is also associated with adverse effects on physical and mental health that can persist into adulthood.

Treatment

Health care providers should screen for risk factors for neglect and try and prevent neglect prior to its occurrence. A multidisciplinary approach with parental education, close clinical follow-up, home visitation programs, and referral to appropriate mental health and community services may help in amelioration and prevention of neglect. Individualized response taking into account the unique situation for each family is crucial for effective neglect intervention.

Prevention of Child Maltreatment

Preventing child maltreatment is resource-intensive and complex. This is, in part, due to the multifactorial nature

of child abuse. Public health approach to prevention (primary, secondary and tertiary) provides a structured approach to curtail the incidence and prevalence of child physical abuse. Primary prevention is directed toward the whole population and based on increasing the public awareness about child abuse, its indicators, consequences, normal child development, rearing practices, alternatives to corporal punishment, and anger control strategies. It also includes teaching children social skills and self-protection strategies without deemphasizing adults' primary responsibility for child protection. Secondary prevention focuses on families and children at risk of abuse such as single parents, poor socioeconomic status, and children with history of prematurity or disability or behavioral problems. Tertiary prevention is based on the response to victimized children and their families. It includes providing multidisciplinary child-centered services to meet the medical, social, psychological, and legal needs of children and their families. It also incorporates providing services for the victims and putting child protection laws and policies in accordance with the principles and the legal framework as outlined in the Convention on the Rights of the Child.

Consequences and Outcomes of Child Abuse and Neglect

Child maltreatment is a complex social problem with medical, mental, legal, and societal ramifications. The short and long-term impact of CAN is linked to several factors such as the child's age, the severity, frequency and duration of abuse, and the relationship of the perpetrator with the child. In addition, consequences are linked with the resources available to the family and the extent of treatment and rehabilitation of the child and family.

Younger victims of CAN are at more risk of developing serious mental disabilities. Extensive research indicates that prolonged and intense stress, especially during the brain's sensitive development period in early childhood, can lead to lasting changes in the central nervous system anatomy, physiology, and function. Long-term consequences of child abuse can include mental, behavioral, and psychological disorders such as mental retardation, psychosomatic disorders, poor school performance, addiction, risk-taking behavior, alcoholism, drug abuse, chronic anxiety disorders, depression and suicidal attempts, aggressive behaviors, and criminal acts which perpetuate the cycle of violence.

Several studies of the effects of adverse childhood experiences in adulthood document the increased risk for major causes of death such as coronary heart disease, diabetes, and hypertension among victims of child maltreatment as far as 50 years after the occurrence of abuse. This has been shown in the Adverse Childhood Experiences (ACE) study, from which numerous publications have been derived. A recent study found a significant link between child maltreatment and increased rates of poverty and unemployment.

However, in sharp contrast with the gloomy picture depicted by the aforementioned consequences, it is possible for maltreated children to recover and go on to lead happy and productive lives. Such resiliency is probably related to genetic factors and the presence of supportive circumstances such as supportive non-abusive adults, stable social and economic circumstances, and early intervention. Resiliency is currently the subject of intense research to improve the understanding of the phenomenon and to utilize it in the treatment of abused children.

49 Global Perspectives on Child Development and Behavior

Ilgi O. Ertem · Vibha Krishnamurthy

Developmental Difficulties in Low- and Middle-Income Countries

The majority of the world's children live in low- and middle-income (LAMI) countries as defined by the World Bank. There is still unacceptable disparity between high-income and low- and middle-income countries with respect to indicators for child survival and health. Equally unacceptable is the disparity between countries in the range of supports that are given to children to optimize their developmental potential, and to prevent, detect, and intervene with developmental difficulties. Despite the fact that the United Nations Convention On The Rights Of The Child calls for countries to not only assure child survival, but also to support child development, an estimated minimum of 200 million children in low- and middle-income countries are not reaching their optimal developmental potential due to preventable causes. "Developmental difficulties" including problems in the areas of cognitive, language, social-emotional, behavioral, or neuromotor development will be used in this chapter in place of terms such as developmental disability, or developmental disorder. Approximately 10–20% of individuals around the world have developmental difficulties, most of which are preventable.

Health-care providers in LAMI countries have longstanding experience in combating childhood illness and mortality. The prevention, early identification, and management of developmental difficulties in childhood, however, are new challenges. Nevertheless, there is a wealth of information on this topic, which has been generated by researchers and clinicians working in resource-poor conditions. This chapter will provide information that is specific to low- and middle-income countries on: (1) Prevalence of developmental difficulties and risk factors that impinge on optimal child development; (2) Methods of early identification, assessment, and classification; and (3) Examples of interventions for developmental difficulties in low- and middle-income countries.

Prevalence of Developmental Difficulties and Risk Factors That Impinge on Optimal Child Development

Globally, the rates of developmental difficulties are higher than any other chronic morbidity and developmental difficulties are considered among disease control priorities in LAMI countries. There has been at least 3 decades of research on the prevalence of developmental difficulties in LAMI countries but the exact prevalence is unknown in most countries. This is due to the difficulties in conducting epidemiological studies and the lack of international standards for common definitions and population-based methods of appropriate detection. It is estimated that a minimum of 15–20% of children in LAMI countries experience developmental difficulties, with highest rates in populations where malnutrition and chronic illness such as HIV/AIDS is more prevalent.

Every condition that poses a risk for child survival may also be a risk factor to child development and conversely, factors that threaten child development are often risks to the survival of children. Clinicians and policy makers in LAMI countries need to know which risk factors require intervention at various times throughout the life cycle. Risk factors that can hamper optimal development and that need to be addressed across the life span include: physical and mental health impairments of parents or caregivers; deficiencies in the social and economic environment (including inadequate nutrition, safe housing, inadequate hygiene, lack of wages and jobs for caregivers, gender inequality, low caregiver education, inappropriate child care resources, lack of preschool opportunities and schools, inadequate access to health care and trained health-care providers), exposures to environmental toxins, and exposure to violence, war, and natural disasters.

During the pre-conceptional period, children's developmental outcomes are influenced by young and advanced maternal age, parental consanguinity, problems or deficiencies in maternal health and nutrition,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_49,

inadequate birth intervals, and unintended pregnancies. During the perinatal period, asphyxia, low birth weight, prematurity, perinatal complications including preventable infections such as tetanus, and congenital abnormalities have a significant impact on child development. Maternal mortality, also not uncommon in LAMI countries, is a grave condition that jeopardizes the survival and development of the child at any age. Maternal depression is a prevalent and important risk for the survival, health, and development of the child during the neonatal and early infancy period, as are neonatal complications, neurological insults, and sensory impairments. During infancy and early childhood, malnutrition, iron and iodine deficiency, lack of appropriate child care and preschool programs, frequent acute health problems, chronic illness, inadequacies in nurturing and stimulating qualities of the home or living environment are risk factors that have adverse developmental and behavioral consequences. School-aged children are placed at additional risk from child labor, inadequate schooling and, particularly for girls, early pregnancies.

Methods of Early Identification, Assessment, and Classification

In LAMI countries, despite the overwhelming demands of large populations and poverty, the infrastructure to support child development within the health-care system is often present. For example, India has the world's largest integrated early childhood development services with the goal of improving the health and development of children and families. This system has been operational since 1975, functions in thousands of centers and covers millions of children and mothers. In Turkey, the government staffs local health-care facilities with physicians, nurses, and home-visiting midwives; these are located at a village level throughout the country. In some countries such as Azerbaijan and Georgia for example, widespread accessible health care to children is provided not by general practitioners but by pediatricians. Therefore, the health-care system in many countries can have a crucial role in promoting child development and the prevention, early detection and management of developmental difficulties. There are however, barriers within the health-care system that make the early identification process difficult. First, continuity in care (receiving health care continuously by the same provider), a crucial first step in delivering developmentally appropriate health care, may be absent in LAMI countries. Second, even if a child is followed by the same health-care provider, the amount of information, support, and intervention this provider can deliver will depend on his/her training and experience in providing guidance about child development concepts. Research indicates that health-care providers in LAMI countries do not have adequate training and experience in the prevention, early detection, and management of developmental difficulties in young children.

The third and perhaps most important barrier to early identification is the inadequacy of standardized methods and tools for the early detection of developmental difficulties across countries. Language, social-emotional, cognitive, and behavioral development and functional capacity have become essential components of instruments that aid clinicians in early detection. Developmental monitoring now emphasizes the importance of caregiver–clinician communication and partnership. The recent emphasis on family-centered care has changed the approach from models in which a parent watches while a clinician "tests" the child to models in which a caregiver and clinician use instruments to "talk" about the child's development and to build a joint understanding. Studies suggest that caregivers and health-care providers in LAMI countries may not be well equipped with knowledge about early childhood development, and, therefore, the need for standardized developmental tools is even more important than in high-income countries. However, developmental monitoring must not be based on a mere "screening approach." Developmental "surveillance" or "monitoring" should incorporate an understanding of risks and protective factors and methods for monitoring and support of the development of all children within a health-care system with direct links to available interventions. The following factors must be considered by health-care providers when choosing a method for developmental surveillance or monitoring in LAMI countries:

- Low caregiver education and literacy limit the use of written caregiver-completed questionnaires.
- Evidence suggests that reliance solely on caregiver concerns or checklists about milestones may not be sufficient to identify developmental delays. In populations where many children have delayed development, caregivers may not have a reference as to how children should typically develop. Furthermore, caregivers may not readily express concerns or admit that their child has not reached a certain milestone if they receive health care only sporadically, or do not receive their health care from the same trusted health-care provider each visit, do not believe that interventions exist, or are concerned about stigma related to developmental difficulties.

- The alternative reliance on "child testing" methods that involve direct elicitation of developmental skills by skilled professionals is neither practical nor desirable in LAMI countries. It is difficult and time consuming to elicit the optimal developmental functioning of young children during health-care visits. Testing of the child most often leaves the caregiver "watching" rather than participating in the evaluation, and, therefore, does not capitalize on the partnership of clinicians with caregivers. Caregivers do know their children best and, may be the key resource to support children's development, even more so than in Western countries. Furthermore, objects are often needed to elicit skills and the cleanliness of such objects may be a major concern in developing countries.

There have been two contrasting approaches to the selection of a population that constitutes a normative sample for a standard reference. In the United States, most studies involving cognitive assessment tools have been conducted on population-based samples that do not exclude children with health conditions that pose risks to development. LAMI countries have much higher rates of health-related problems that increase the likelihood of developmental difficulties, necessitating a different approach to standardization. The World Health Organization (WHO) recommends that in populations with a high prevalence of conditions that are hazardous to child health and development (such as malnutrition, low birth weight, chronic infections including HIV/AIDS, parasitic infestations, iron deficiency anemia, and perinatal complications) references for monitoring growth and development should be based on what the WHO refers to as a "prescriptive sample" of healthy, thriving children without these risks rather than geographic whole-population-based references. This approach was applied by the WHO in the construction of the newly launched WHO International Growth Standards and the WHO Motor Development Study. These studies have demonstrated that when child health is optimal, child growth and motor development are similar across countries with diverse backgrounds and one universal standard can be constructed. Conceptually, based on innate biological and psychosocial processes, children from different ethnic, geographic, or cultural backgrounds appear to have enough similarities in functional development that one standard can be constructed, at least for young children. The "prescriptive sample" approach is being used in LAMI countries as exemplified by the standardization studies for instruments developed in Argentina and in Turkey. In summary, the method used for developmental monitoring in LAMI countries should ideally be: (a) family centered; (b) scientifically reliable and valid for use in various cultures; (c) brief, user-friendly, easy to learn and administer, and require minimal documentation procedures; (d) be standardized using a prescriptive sample; and (e) linked seamlessly to systems of service delivery and support for identified difficulties. An example of such an instrument is the Guide for Monitoring Child Development (GMCD) which has been initially developed in Turkey and that is currently undergoing international standardization.

Similar to high-income countries, pediatricians and other primary health-care providers are predominantly responsible for the assessment, diagnosis, and referral to services for young children with developmental difficulties. Although LAMI countries may not have the infrastructure and resources for the multidisciplinary evaluations that are conducted in high-income children to diagnose developmental difficulties, the family-centered principles of a developmental assessment apply and can be adopted to all such clinical encounters around the world. Research on developmental assessment in LAMI countries has mostly been restricted to the use of specific instruments. Cognitive assessment tools have been the most frequently studied components of a developmental evaluation. Although to a very limited extent, a range of key components have also been studied in LAMI countries including the developmental interview, assessment of nurturance and stimulation in the home environment, family competence and social support systems, family mental health, functional development of the child, and language development. Universal systems and guidelines for developmental assessment that are supported by current scientific information and conceptualizations of child development are essential to improve the care of children in LAMI countries.

Research from LAMI countries on classification systems for young children with developmental difficulties is almost nonexistent. Internationally endorsed classifications are necessary to facilitate and advance communication among clinicians, researchers and policy makers as well as to advance clinical conceptualization, assessment, and formulation. Classification systems that can be used for young children with developmental difficulties do exist. The International Classification of Diseases (ICD), Diagnostic Statistical Manual of Mental Disorders (DSM), Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood Revised (DC 0–3 R), and the World Health Organization International Classification of Functioning Children and Youth (ICF-CY), all offer promising approaches to the classification of developmental difficulties in children. The ICD-10 is a disease-oriented categorical approach, although some

codes do reference environmental/contextual aspects of child development. The DC 0–3 system offers a closer focus on the child–caregiver relationship than the DSM system, but both systems are limited to mental health disorders and do not address other developmental disabilities. The WHO promotes the use of the ICF-CY system alone or in conjunction with the ICD system in the classification of childhood disability across the world. The ICF-CY system is ideal in that it offers an approach that overlaps with the bioecological theory of child development and current concepts in developmental interventions. The ICF system classifies the following parameters for a given child: body structures, body functions, activities and participation in community and daily life, and environmental contextual factors such as family and home environment and community attitudes and services.

Examples of Interventions for Developmental Difficulties in Low- and Middle-Income Countries

1. *Community-Based Rehabilitation (CBR)* was introduced by the WHO in 1980s as a strategy for improving the quality of life of disabled people and their families around the world. By definition, the CBR aims to move away from center-based, or institution-based, specialist-based care of disability and move toward the building of local knowledge and practices to address the special needs of people with disabilities within the community. Since its introduction, CBR has been widely applied in many parts of the world for people of all age groups. The CBR also has been used as an intervention strategy for children with developmental difficulties and their caregivers. As defined by the WHO: "Community-based rehabilitation currently in practice in more than 90 countries around the world is a comprehensive strategy for involving people with disabilities in the development of their communities." CBR seeks to ensure that people with disabilities have equal access to rehabilitation and other services and opportunities – health, education, and income – as do all other members of society. The target populations are people with disabilities, families of people with disabilities, communities, Disabled People's Organizations, local, regional, and national governments, international organizations, nongovernmental organizations, medical and other professionals, business, industry, and private sector. A wide range of activities is included beyond medical care and rehabilitation. These are promoting positive attitudes toward people with disabilities, preventing the causes of disabilities, providing rehabilitation services, facilitating education and training opportunities, supporting local initiatives, monitoring and evaluating programs, supporting micro- and macro-income-generation opportunities. WHO is supporting United Nations member states in developing guidelines for CBR, conducting regional and country workshops to promote CBR and the guidelines, supporting member states to initiate CBR, and/or strengthening existing CBR programs. Despite the fragmented nature of the research on CBR, this model holds a promising venue to be used as an intervention approach to developmental difficulties in children.
2. *WHO/UNICEF Care for Child Development Intervention (CCDI)* developed by the World Health Organization Department of Child and Adolescent Health and Development and UNICEF, uses the window of opportunity that arises when the child comes in contact with the health-care system. The CCDI is a standardized interview, which assesses how the caretaker plays with and communicates with the child. Observations and intervention strategies offered to parents during the interview include listening to caregivers and giving specific reinforcement for ways they support their child's development; observing for positive interactions between infants and caregivers during the health-care visit; using basic homemade toys to facilitate interactions; pointing out responses of the infant and the role of the caregiver in eliciting these responses; and providing ideas for age-appropriate stimulation. Health-care workers then explore with the child's caregiver the potential for such interactions in the home; discuss obstacles that caregivers may face to help the child develop; and ways they can overcome these obstacles. The intervention can be delivered anywhere and adds approximately 10 min to the health visit. The training period is approximately 1.5 days. Training materials, comprising of workbooks and videotape for facilitators and trainees have been tested in the field and have been revised by the WHO and UNICEF to be used globally.
3. *Training of health-care professionals on child development and developmental difficulties: Turkey.* Over 2 decades, Ankara University School of Medicine Developmental-Behavioral Pediatrics (DBP) Unit has been collaborating with the Turkish Ministry of Health, the WHO, and UNICEF, to develop training programs for health-care clinicians on child development and children with developmental difficulties. As a result of

these collaborations, training programs have been developed for health-care clinicians at different levels, including general practitioners, home-visiting nurses/midwives, pediatricians, and developmental-behavioral pediatricians. The content of the training programs includes concepts and theories of ECD starting from pregnancy to preschool years, risks to optimal development, ways to decrease risks, preventing developmental delay, common psychosocial problems, techniques for developmental monitoring and for supporting child development, early identification of children with developmental delay, services for children with developmental difficulties, and community resources available for early intervention and rehabilitation. All training methods are interactive, experiential, and problem based. Materials include a book in Turkish on developmental-behavioral pediatrics, DVDs with slides presentations, local video recordings of children and caregivers demonstrating typical development and case scenarios for developmental difficulties. When introduced in a form that is appropriate to the context of their ongoing work, health-care professionals are highly motivated to take on as their mission the promotion of early childhood development.

4. *Training of community workers on child development and developmental difficulties: India.* Ummeed Child Development Center began in 2001 as a not-for-profit center to provide services for children and families with developmental disabilities. Initially, the organization was to provide interdisciplinary care, in a family-centered approach, to children with disabilities. As the center grew, it was evident that providing services to approximately 1,200 families per year was not even addressing the needs of Mumbai, leave alone the country. At current WHO disability estimates, Mumbai alone has 650,000 children with developmental disabilities. Further, children who are at high risk for developmental difficulties are often from families with no access to services.

Most young children in India do not receive routine health care from a physician. However, in many parts of the country, the government's Integrated Child Development Scheme provides services to children under five through anganwadi workers. In addition, there are hundreds of voluntary organizations working with young children in community-based programs. The workers within these organizations are a vital and already existing link to the community. Ummeed designed the Child Development Aide training program to give these individuals the skills to identify and intervene with children at risk and to promote good child development practices for all children.

Professionals from Ummeed, other parts of India, and around the world designed the course curriculum. The emphasis was to develop transdisciplinary community workers who would view the child and family as a whole. The curriculum's focus is the "transactional model" of child development with a family-centered approach to interventions for child development. The pilot project with ten trainees began in July 2009 with funding from USAID.

The trainees are chosen from organizations with a commitment to child development and disabilities and a willingness to support the candidate financially for 6 months. Because trainees are expected to return to the parent organization and train or influence their coworkers, leadership potential is an important factor in selection. After the 6-month training, the CDAs meet every month for 1 year for peer support and mentoring, facilitated by a professional at Ummeed. Future plans for scaling up include a "Train the trainer" program that will equip other organizations to run the CDA training program.

Case Vignette

Rashi works in the Mumbai-based Muktangan School, where most of her students are from the nearby Worli slums. She was chosen for the CDA training program when the school realized that 10–20% of the children enrolled had developmental difficulties, which they did not know how to address. One of her students is Eureka, a 5-year-old girl who lives in an orphanage. Since her arrival, Eureka had struggled with class work, and her teachers did not know what to do with her. They knew she had albinism, but they were puzzled by her inability to talk. She had no interest in playing with other children or communicating with her teachers. She wandered about the class all day, unable to do more than scribble on paper. The orphanage attendant told the teachers she was difficult to feed and mostly just drank milk out of a bottle. Rashi, who had just completed her CDA training, recognized that Eureka's development was like that of a child perhaps half her age. Tailoring her approach to this understanding, she began by guiding Eureka's class teacher on how to engage her in play and to develop communication skills. She asked the teachers to place Eureka's favorite foods and toys within sight but out of reach. She then encouraged Eureka to point to things she wanted. Next Rashi worked on helping the teacher make Eureka more a part of the class by sitting close to the teacher and helping her with simple errands like distributing worksheets and erasing the blackboard. During snack time, Rashi demonstrated to the orphanage attendant ways to encourage

Eureka to try new foods, and soon Eureka was eating with the other children. When Rashi found Eureka had been prescribed glasses but was refusing to wear them, she asked the attendant to bring them to school and convinced Eureka to wear them. Eureka is now an important part of her class. Her friends know her and greet her enthusiastically every morning when she arrives. The teachers and her classmates understand her many gestures, and she is speaking more. Most important, she loves to play with her friends and her teacher, and initiates her favorite games whenever she can. Rashi meets her for one-on-one sessions in the school's resource room to work on her IEP goals, which she has designed along with the class teacher and the orphanage attendant.

50 Children in Disasters

David J. Schonfeld · Robin H. Gurwitch

Introduction

When disasters strike, children are one of the most vulnerable populations affected. The impact of a disaster on an individual child depends on a number of interrelated factors: the nature of the disaster itself including the extent and breadth of damage, loss, and disruption experienced by the child; the socio-emotional impact of the event on the child and family; the disruption of the child's extended support system; and the child's skills in coping with stressful experiences as well as the ability of the family and community to provide appropriate support to promote the child's recovery. In addition to the initial impact of the disaster, the effect on children is also exacerbated by secondary stressors and losses that result from the event and any delays in the recovery of the community and family. This chapter will begin by briefly reviewing a few selected findings from preclinical and clinical research on the impact of stress during critical periods of brain development in animals and humans that have implications for understanding the importance of early interventions for children in the aftermath of a disaster. Findings based on clinical experience and epidemiological research regarding the impact of disasters on children will be summarized and practical recommendations about how to address children's needs within clinical pediatric settings will be offered. Finally, as the acute and ongoing behavioral and mental health needs of children during the aftermath of a disaster are highly likely to exceed the capacity of clinical programs, attention will be given to the unique context of school settings as an important venue for both the identification of needs and the delivery of brief, supportive interventions to promote adjustment and recovery.

Implications from Preclinical and Clinical Research

From an extensive preclinical and growing clinical research literature on the impact of stress on young children, three findings will be highlighted: (1) Stressful situations, if not overwhelming, can promote development and learning. (2) Chronic stress during periods of brain development can lead to permanent changes in brain function and structure. (3) Parents and other caregivers play a key role in determining whether stress promotes or impairs children's development.

Stressful situations, if they are not overwhelming to the young child, can promote healthy development and learning. Indeed, all learning involves presenting novel situations or information. Research has shown that the removal of infant rats from their mother for brief periods of time for gentle handling by lab personnel does cause some distress for the infant rats, but if the infants are effectively nurtured and supported through this experience by their mothers when they are reunited, the rats are better able to tolerate subsequent stressors – they become less fearful in novel environments and more capable of learning in a laboratory model. This is good, since this is what humans do to their young. Preschool and early elementary school attendance can be viewed as such a brief separation that is hoped to enhance children's ability to learn.

Chronic stress leads to changes in brain function and structure. Gunna, Herrera, and Hostinar summarized findings from animal studies that show that severe early life stress leads to inhibition of neurogenesis, disruption of neuronal plasticity, neurotoxicity, and the development of abnormal synaptic connectivity. Young, developing brains are particularly vulnerable to these effects of stress hormones. As a result, uncompensated and chronic stress during critical periods of development increases the risk of difficulty in adjusting to stressful events later in life. In addition, animal models have shown that such chronic stress leads to changes in brain circuitry that limits subsequent learning and effective decision-making. Research involving children is also beginning to document comparable findings linking uncompensated and chronic stress (e.g., chronic abuse and neglect) to changes in brain structure and function.

The Adverse Childhood Experiences (ACEs) studies conducted by the Centers for Disease Control and Prevention and Kaiser Permanente found that the more ACEs children experience, the greater the risk for medical complications during adulthood, including heart disease, cancer, diabetes, liver disease, and emphysema. Contrary to

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_50,

folklore, stressful life experiences during childhood do not necessarily make children stronger or better able to cope with life, but in fact may result in increased morbidity during adulthood. Disaster exposure is a significant adverse childhood experience which adds to the cumulative exposure of adverse childhood experiences.

These findings underscore the need to protect young children from stressful situations as much as possible, intervene quickly after stressful events occur that impact children, and pay particular attention to subsequent stressors that may occur in the lives of children who have already been victims of disasters. It also should lead those in education to become concerned about the impact of stress on learning and to place greater emphasis on helping children impacted by disaster adjust in order to promote subsequent learning.

Parents and other caregivers play a key role in determining the difference between stress that promotes development and that which impairs development. In one set of experiments with rats described by Arie Kaffman, the investigators took advantage of the normal distribution of maternal nurturing behavior. Some rat mothers provide a much higher level of licking and grooming to their infants, and some mothers provide much less than average. Compared to infants raised by mothers that provided less of this nurturing behavior, infants raised by mothers that provided a higher level of licking and grooming were less fearful, less reactive to stressful situations, and performed better on several tasks that were felt to be dependent on the optimal functioning of the hippocampus. In a similar manner, data from a cohort from the National Collaborative Perinatal Project was used to demonstrate that the degree of maternal affection provided to human infants at 8 months of age, as measured by observations of maternal behavior during cognitive and developmental testing in a laboratory setting, predicts emotional distress in later adulthood.

It appears that this high frequency of nurturing behavior in rats during a critical period of brain development is necessary for removal of DNA methylation from the promoter element of DNA that controls the expression of the glucocorticoid receptor in the hippocampus. This in turn controls the rate by which the release of corticosterone in the rat after a stressor is terminated. Rats raised by mothers who were nurturing, in this model, had higher rates of expression of the glucocorticoid receptor in the hippocampus and therefore had shorter periods of exposure to corticosterone after stressful situations. Of particular interest, once established, this pattern of DNA methylation is stable. In this way, an epigenetic phenomenon can explain how early parental nurturance can result in less stress reactivity later in life. Research involving postmortem analysis of human brains from adults who died by suicide showed that those with a history of early life adversity had lower levels of glucocorticoid receptor messenger RNA in their hippocampus and higher levels of DNA methylation in the same promoter region found in the rat model.

Joan Kaufman and Dennis Charney showed that maternal rats respond with increased licking and grooming of their infants when reunited after brief separations; as already noted, this nurturing helps the infant adjust to the possible stress of such brief separations and results in positive infant outcome (i.e., less stress reactivity). When infants are instead removed from their mothers for prolonged separations, their mothers do not compensate when reunited for the prolonged separation through increased nurturing, but instead demonstrate lower rates of nurturing when subsequently reunited with their infants and the infants develop a negative outcome of more stress reactivity. If the infants assigned to the prolonged separations were then cross-fostered to other mothers that had been assigned to the brief separations condition, these "nurturing" mothers provided increased nurturing to these infants. And as a result, these infants initially assigned to the prolonged separation condition later appeared more similar to the infants who had only experienced brief separations. In other words, the foster mothers who had nurturing behavior were able to compensate for the impact of the prolonged separations. These findings have implications for how the caregiving and support of other adults can help to promote the development and adjustment of children impacted by a disaster.

Clinical research on the importance of nurturing adults for children's development is growing. While ACEs, including disasters, can have a significant negative impact on children's brain development and functioning, such damage is not guaranteed or irreversible. A mediating factor is the adults in a child's life. For example, stressed, exhausted, or depressed mothers show increased levels of cortisol and their young children also show increased levels of cortisol which may be even higher than their mother's level. Conversely, supportive, caring adults in a child's life can serve as a buffer for the hypothalamic–pituitary–adrenal (HPA) system, potentially protecting the brain from the harmful effects of significant stressors. Emotional support from adults is associated with improved overall adjustment and normative regulation of the HPA axis following stressful events in children's lives. These positive, supportive adults can provide a positive role model of how to cope with daily life stressors as well as unpredictable stressors such as disasters

or death of a loved one. Given that parental adjustment to a disaster is one of the best predictors of child adjustment, it is critical that when assessing children in the aftermath of these events, parental coping and adjustment is also assessed and supported.

Adjustment Reactions to Disasters in Children

- A survey was conducted by Hoven and colleagues six months after the terrorist attacks of September 11, 2001 of a representative sample of over 8,000 students attending grades 4–12 in New York City public schools. Among other variables, children were asked to provide self-reports of current mental health problems and self-reported impairment in functioning (e.g., not being able to do usual activities, having parents or teachers often upset with them, or having unexplained problems with school work). Children were felt to have a "probable psychiatric disorder" if they reported symptoms consistent with diagnostic criteria for that disorder and also reported impairment in functioning, which could be considered a fairly conservative self-report measure. One out of every four children (27%) met criteria for one or more of the probable psychiatric disorders assessed in the study and also reported problems in their day-to-day functioning. Approximately one out of ten had: post-traumatic stress disorder (PTSD) (11%), major depressive disorder (8%), separation anxiety disorder (12%), and panic attacks (9%). Agoraphobia (or fear of going out or taking public transportation) was reported in 15%. The vast majority (87%) of the students reported at least one ongoing symptom 6 months after the event: 76% reported often thinking about the attacks on the World Trade Center and 45% reported trying to avoid thinking, hearing, or talking about it; 25% found it harder to keep their mind focused; 24% were having problems sleeping; 17% were having nightmares; 18% stopped going to places or doing things that reminded them of the attacks; 11% reported at least six of the PTSD symptoms and qualified for probable PTSD. At least two-thirds of the children who self-reported both symptoms of PTSD and self-impairment also reported that they had not sought care.

Children's reactions to a disaster depend on a number of factors, including the nature of the event. Acts of terrorism, for example, are manmade and intentional and tend to create psychological reactions that are more prevalent and long-lasting when compared to natural disasters. There are as well factors which place children at greater risk for psychological difficulties after any type of disaster. These include: the extent of the children's and their family's direct involvement; the overall disruption of their routine resulting from the disaster; parental adjustment; children's preexisting mental health, coping skills, and vulnerabilities; and their age and developmental level. *Table 50.1* lists common adjustment difficulties that may be seen after a disaster. Reactions include symptoms consistent with acute stress reactions and posttraumatic stress disorder (PTSD). Although most children will experience distress and reactions to the disaster, most will not develop symptoms of sufficient severity or duration to qualify for a psychiatric diagnosis.

PTSD can occur after a traumatic event and is characterized by symptoms of re-experiencing, avoidance, and increased arousal that may occur immediately after a traumatic event and persist or may have a delayed onset. Symptoms of re-experiencing may take the form of dreams, with young children having nightmares that do not necessarily include content of the event. Children may have hallucinations or dissociative flashbacks in which

Table 50.1
Potential symptoms of adjustment reactions in children after a disaster

Sleep problems – difficulty falling or staying asleep; nightmares or frequent waking; resistance to sleeping alone; trouble waking in the morning
Separation anxiety or school avoidance
Anxiety, worries, and fears – worries of a repetition of the event; fears may be related to the event (e.g., fear of storms after a hurricane) or developmentally appropriate fears that may not be clearly associated with the traumatic event (e.g., fear of the dark even though the disaster occurred during daylight)
Irritability
Difficulties with concentration and academic work
Regression – developmental (e.g., secondary enuresis) or social (e.g., children – and adults – may become more clingy, less cooperative, more demanding, more self-centered, or less tolerant of others)
Sadness or depression; a sense of pessimism about the future or decreased future perspective
Avoidance of previously enjoyed activities; withdrawal and decrease in social interactions with peers
Onset of, or increase in, substance abuse
Somatization
Symptoms of posttraumatic stress disorder (PTSD)

they feel as if they are truly reliving the event or they may have intense reactions to cues that resemble the event. Young children may show they are re-experiencing the event through repetitive play. Avoidance after a traumatic event may be manifested by attempts to stay away from any activities, places, or people associated with the event, or efforts to avoid associated thoughts or feelings. Children may begin to withdraw from activities they previously enjoyed or become detached from others. Increased arousal may lead to problems falling or staying asleep, problems with concentration, increased irritability and anger outbursts, or becoming more hyper-alert with an increased startle response. All of these reactions individually are common after a disaster. To qualify for the diagnosis of PTSD, children must have symptoms for more than 1 month in all three areas (reexperiencing, avoidance, and increased arousal) that cause significant impairment in social, academic, or other areas of functioning.

Somatization is a common symptom of adjustment difficulties after a disaster. Because the difficulty is manifested as a physical complaint, this reaction is of direct relevance to all pediatric healthcare providers. Many of the children and families who would benefit from supportive services and/or counseling after a major crisis event will not identify their difficulties as psychological or emotional in nature, but instead may present with physical symptoms to their primary care providers, emergency departments, or pediatric subspecialists. It is therefore important to invite families to share information about recent losses or stressors and to inquire directly, especially after a disaster has occurred.

- Several months after Hurricane Katrina had caused devastating damage in New Orleans that was largely still not repaired, a group of pediatric healthcare providers commented that they had altered the structure of the routine healthcare visit. Now, in addition to the chief complaint, history of presenting illness, past medical history and physical exam, they found the need to add the "Katrina History." Several noted that it was this last additional element of history that often took the most time, yet yielded the information of most diagnostic and therapeutic utility.

Somatization underscores the need for all providers of healthcare to maintain a heightened sensitivity to the impact of trauma, loss, and stress on children and families and to develop effective partnerships with professionals who are able to address more fully these adjustment difficulties. Even when children are under marked distress after a disaster, they may not show any observable signs or may be reluctant to share their feelings with adults, especially those that are unfamiliar to them. It becomes especially important to establish a trusting relationship and create a safe environment where children can feel comfortable disclosing difficult feelings and concerns.

Posttraumatic stress reactions and disorders increase multifold after a disaster and often result in both acute and, if left untreated, long-term adjustment difficulties that can impair functioning in school (and at work when applicable), at home, and in social interactions. Because avoidance of thinking or talking about the disaster is one of the core features of PTSD, children and adults who are suffering from PTSD will often refrain from sharing their symptoms with others. Active screening and outreach become critical after a disaster event in order to identify those experiencing posttraumatic stress reactions.

It is important, though, to recognize that many of the difficulties children experience after a disaster may not be posttraumatic in nature. For example, if a disaster results in the death of someone close to the child, the child may experience bereavement that may be indistinguishable from bereavement resulting from a loss occurring outside the context of a disaster. Significant adjustment difficulties are typically seen as part of bereavement in children and may include any or all of the symptoms listed in *Table 50.1* as well as those seen in PTSD. In some situations, such as when the child witnesses the violent death of a loved one during a disaster, the child may experience a combination of posttraumatic reactions (to witnessing a horrific event) and bereavement (related to the loss of a loved one) which results in "traumatic grief" requiring treatment for both components. In too many situations, though, professionals assume that simply because a death occurred as a result of a disaster, that the child's symptoms are "posttraumatic." This may lead to a misguided focus on helping the child process the events of the disaster itself, rather than focusing on helping the child grieve an ongoing loss.

A major disaster typically initiates a cascade of secondary losses and stressors, any one of which may become the predominant problem for children and families. For example, the floods in the Gulf Coast from Hurricane Katrina resulted in a very large number of secondary losses and stressors including, among others: loss of belongings; loss of homes which often resulted in children experiencing one or multiple relocations; loss of social network of peers and supportive adults in the school and community; difficulty integrating into new peer networks, schools and communities; academic failure in part due to multiple school placements; financial stresses; and parental stress, mental health problems, and

substance abuse issues. Because of the prevalence of secondary stressors after a disaster, healthcare providers should not only inquire about the child's experience on the day of the flooding or other disaster, but also what other impact the evolving disaster and subsequent stressors are having on the child and the child's family. For example, a child may be demonstrating sleep difficulties or anxiety that is due to worries about financial problems and parental stress resulting from the loss of a parent's job due to the disaster, but not be having nightmares or anxiety because of the flood itself. It is critical that healthcare providers think more broadly about the impact of a disaster on children and families, rather than maintaining a narrow focus on posttraumatic symptoms and disorders hypothesized to originate from a singular traumatic event. Not only does this have implications for evaluation and treatment, but it provides important insights into the often lengthy process for community recovery seen after major disasters.

In many situations, the home, school, and community environments and supports for children can remain significantly impaired after a major community disaster for as long as years after the initial event. If one appreciates the impact of these secondary losses and stressors, then it would be anticipated that many children can also have some ongoing adjustment difficulties for many years. Given what is known from the research that chronic stress can cause changes in brain structure and function that has long-lasting impact, it becomes particularly critical that this phenomenon be anticipated. Interventions should begin promptly after disasters to provide support, promote adjustment, and help children and families deal with secondary stressors in order to minimize the cumulative stress experienced by these children.

Identifying Children at Highest Risk of Adjustment Difficulties

Given the high prevalence of adjustment difficulties among children after a disaster, it is important to employ approaches to identify which children are most likely to benefit from additional mental health evaluation and services. *Table 50.2* outlines some of the more common factors associated with an increased risk of adjustment problems in children after a disaster.

Children with prior (or concurrent) psychopathology or unaccommodated traumatic experiences or losses are at increased risk of maladjustment after a disaster. A crisis of any nature often awakens feelings related to a concurrent or even past crisis that were not fully resolved that may now assume a primary focus for the child. This may occur even if the prior event does not seem to be related to the disaster.

Table 50.2
Factors associated with an increased risk of adjustment problems after a disaster

Injury of the child, or death or injury of those close to the child
Child's perception (at the time of the event) that his or her life was in jeopardy
Exposure to horrific scenes (including indirectly through the media)
Prior psychopathology, significant losses, or traumatic events
Separation of child from parents or other important caregivers as result of event
Loss of property or belongings; disruption in daily routine or environment
Parental difficulty in coping
Lack of supportive family communication style
Inadequate community resources and support

- Students were inadvertently exposed to N-butyl mercaptan (an odorant with a skunk-like odor used in natural gas) when a student opened a personal protective device while on a bus. Dozens of children developed symptoms including vomiting, coughing, and choking, with a group requiring transport by emergency medical personnel to the hospital for treatment. The remaining students were transported via another bus to a local children's hospital where they underwent a controlled decontamination: children were greeted by a nurse and child life specialist who explained the decontamination process and children showered one at a time so that no child needed to undress in front of other children; the adults were decontaminated in another area of the hospital. Children were given clean, donated clothing and waited in a conference room where they could eat cookies, watch movies, and play games under the supervision of child life specialists, social workers, and chaplains, until reunited with their parents/caregivers. Despite the nearly ideal conditions for decontamination, two students continued to experience panic attacks for at least several weeks and had difficulty returning to school. The school inquired what could have been done differently to minimize the trauma of the event and it was suggested that they look instead to the histories of the two students. One student had recently transferred to the school and it became known that the reason

for the transfer was because of the very recent murder of a parent. For the other student, further investigation uncovered significant concurrent family issues that were the cause of her distress.

In addition to the risk factors outlined in *Table 50.2*, certain behaviors demonstrated by children in the immediate aftermath of a disaster may warrant immediate referral to mental health professionals for further assessment and appropriate services. These reactions include: dissociative symptoms (e.g., detachment, derealization, and depersonalization), extreme impairment in cognitive abilities or decision-making, panic or intense and unrelenting fear and anxiety, intense and uncontrollable grief, marked somatization, and suicidal ideation or intent.

Disasters challenge the assumptive world of children. Most of the time people function under certain assumptions which allows them to deny, or at least generally ignore, the nearly infinite risks they and those they care about face daily. People generally assume that they themselves and those they care about are healthy and safe and will remain that way – they will not personally experience earthquakes, lightning, random acts of violence, or tragic accidents. When a disaster occurs, even if it does not affect anyone the person knows, it has an impact on people's assumptive world. They are challenged by the reality that disasters do occur and people are killed and seriously injured and their homes and belongings destroyed. It causes people to question their prior assumptions, which had allowed them to conduct their day-to-day lives without becoming overwhelmed with all of the possible tragedies that can (and now they realize actually do) occur. It leaves people feeling anxious, vulnerable, or at least unsettled. Although it may be possible to identify children most likely to have more significant adjustment difficulties after a disaster, it is important to remember that major disasters impact virtually everyone, regardless of their personal involvement in the event or their preexisting risk factors.

Unfortunately, traumatic events and deaths of family and friends are extremely common in the lives of children; the vast majority of children experience the death of someone significant to them by the time they complete high school. Contrary to public perception that children who are raised in communities characterized by chronically high rates of violence "get used to loss," repetitive loss and trauma is instead sensitizing and cumulative. Children in these communities may learn that adequate external support is not provided by adults after each death or traumatic experience and may, therefore, not seek such support or request assistance, but this should not be confused with adjustment and coping. Support may be absent due to lack of awareness and understanding of the problems, lack of resources, or discomfort by adults and child-serving systems such as schools in addressing the situation. Whatever the reasons, the children remain underserved and their coping and long-term outcome likely compromised.

Adults Often Underestimate the Extent of Children's Distress

Parents, teachers, and other adults that support children tend to underestimate the extent of children's reactions to a disaster, especially as it relates to their internalizing symptoms (such as depression). There are a number of reasons why this may occur. Because of the stigma associated with mental illness and therefore even with seeking mental health services in most societies, children may be inclined to keep their adjustment problems to themselves. Parents, too, may have concerns about the stigma of their children needing such services and overlook or discount reactions. Parents and other caregivers who are struggling themselves may be unable or unwilling to recognize their children's distress – they want and often need their children to be coping and therefore fail to see signs of distress. When children see their parents upset, children may also withhold their complaints in hopes of protecting their parents from further distress. Or, children may misinterpret the discomfort that adults demonstrate when they ask questions about the disaster or its implications as a sign that such questions are inappropriate or discouraged and therefore, parents will not know of their children's worries or distress. Parents may not know for which signs or symptoms to look that may suggest distress after a disaster or any stressful or traumatic event. Lack of knowledge or awareness, rather than a lack of concern, is often the reason why parents underestimate their children's adjustment difficulties after a disaster.

Even when parents are aware of their children's distress, they may fail to bring this to the attention of healthcare providers because they may not perceive that they are interested or able to address these concerns. It is often said that adjustment difficulties after a disaster are "just a normal reaction to an abnormal event." But this would suggest that there is no need or benefit in bringing such reactions to the attention of professionals. It implies instead that they should be ignored, suffered in silence, while waiting for spontaneous remission. Healthcare

providers instead need to communicate that adjustment reactions after a disaster may be seen even in individuals that are otherwise psychologically healthy, but can cause significant distress and impairment. They need to convey to children and their families that reactions most often respond to assistance and support. Healthcare providers need to offer that support and/or provide advice on how it can be accessed through other sources.

Psychological First Aid and Basic Supportive Services

The goal of short-term interventions after a disaster is to minimize the onset and duration of adjustment difficulties and to promote children's recovery. In the aftermath of a disaster, children should be helped to understand not only what happened, but what is being done on all levels to assist in recovery, and be provided with a brief intervention that may help to reduce mental health challenges. This intervention, Psychological First Aid (PFA), involves a set of actions intended to provide immediate support to anyone impacted, both directly as well as indirectly, by the disaster. PFA is one of the first steps to helping children build or enhance their resilience, thus increasing their ability to recover quickly and effectively after a crisis event.

PFA ensures that basic needs are met. Children need assistance to meet their basic needs, including safety, security, food, shelter, and communication and reunification with family and other significant caregivers, before they are able to acknowledge and address their emotional needs. This is true for adults, including healthcare professionals – disaster preparedness and response plans should anticipate and actively address the basic needs of these professionals. Efforts to address basic needs also constitute important mental health services; approaches to meet basic needs should be informed by the potential to concurrently provide emotional support. For example, food provided in the aftermath of a disaster can not only provide caloric requirements, but can be used to provide nurturance. Shelters can not only shield people from the elements, but can also provide comfort and a supportive environment.

PFA involves psychoeducation and supportive services which can be provided by anyone (e.g., parents, teachers, neighbors, health and mental health professionals) when they encounter someone in distress. In applying PFA to children, psychoeducation consists of listening to how the child understands the disaster and gently correcting misperceptions and misattributions. The focus of explanations about what has happened should be on a developmentally-appropriate level, providing basic information that is directly relevant; graphic details, speculation, and irrelevant information should be avoided.

PFA includes providing information about common reactions that may occur in the aftermath of a disaster or crisis event; this action often serves to help children recognize that their reactions are not aberrant and can often lead to discussion of concerns and worries (see *Table 50.1* for list of common reactions). Realistic assurances are offered in a timely manner. PFA includes talking to children about how they have coped with challenging situations in the past, even though the disaster situation may be unique. Using positive coping strategies that they found helpful in the past may help in disaster situations. Adults can also model effective coping strategies; children look to adults for not only information but also for how to manage distress.

Because excessive exposure to media coverage of disasters has been linked to increased stress reactions, caregivers should monitor children's exposure to such coverage. Likewise, as children may not have a full understanding of adult conversations about the event, adults should be mindful when talking about the event in the presence of children. Children worry about what is being done and what could happen next. PFA actions also include giving realistic assurances and ongoing information in a timely manner, including what actions are being taken by the family, schools, community, and beyond in the case of federal involvement to address the aftermath of the disaster.

PFA actions include connecting children with others (family, friends, teachers, etc.) and with steps they can take to aid their recovery. Information about available resources that may benefit children is important to communicate to the family, including faith-based and culturally-based resources. Encouraging a return, as available, to the child's school and extracurricular activities can aid in recovery. When children reach out to help others, they also help their own recovery and build resilience. Adults should help children identify ways they can assist others that are personally meaningful and developmentally-appropriate. Finally, PFA includes recognizing when a child may require more help than support and psychoeducation. Risk factors that may necessitate a referral to more comprehensive services are listed in *Table 50.2*. To provide a continuum of care to children after a disaster, it is important that healthcare providers have ready access to mental health professionals with expertise in working with children who have experienced a traumatic or crisis event.

If properly prepared, all adults that interact with children, not just medical staff or mental health providers, have the opportunity to provide assistance to children in the aftermath of disaster. Adults who are less well informed risk either inadvertently contributing to their distress through insensitive comments or, more typically, by ignoring their signs of distress, their requests for assistance, or by trivializing the impact of losses or traumatic experiences.

- A high school experienced a very traumatic school shooting that resulted in the death of one of the students. A few months after the event, cafeteria staff observed that girls within the school were wearing long sleeve shirts when not indicated by the weather. When asked why they thought this was significant, they commented that when the girls held out their trays in the lunch-line, their sleeves retracted and they noticed marks indicating increased cutting behavior. The cafeteria staff explained that they felt it unlikely that other staff or parents had made this observation. In the same school, custodial staff commented that the students appeared more "out of control" since the school crisis. They reported observations of sexual behavior on campus and students rudely refusing to follow well accepted rules – both indications to them that the students were experiencing great distress. They correctly observed that such behaviors were unlikely to be displayed in the presence of authority figures within the school or the children's parents. Within this school, the cafeteria and custodial staff had unique observations regarding the impact of the disaster on students. They also had different access to the students that allowed them to observe and address their distress in ways that likely were not as available to teachers, school administration, and the children's parents.

Providing Advice to Parents

Pediatric healthcare providers can, and should, play an important role in the aftermath of a disaster by conducting their care in a way that minimizes further distress for children and families and by providing anticipatory guidance to parents about approaches that they can take within the home setting to support their children's recovery. This includes advising parents to reduce their children's exposure to frightening reminders of the disaster, including sights, sounds, and even smells. Within a healthcare setting, this might involve ensuring televisions are turned off in waiting rooms and patient treatment areas. Parents and other caregivers should avoid, or at least limit the amount of, exposure of children to news and other depictions of the disaster on television and through other media. When children do view television coverage, parents and other adults should consider watching it along with them to assist them in understanding what they are seeing and to monitor its impact on the children, discussing afterward what they think about the coverage and addressing any concerns that arise. If possible, parents may consider videotaping the coverage for later viewing. This provides an opportunity to pause the coverage to explore comprehension and reactions and, when indicated, to discontinue viewing until a later time.

Healthcare providers should be conscious that children often overhear conversations. Even if they cannot understand what is being said, children can pick up readily on the affective tone and become concerned if the speakers appear distressed (especially if they cannot figure out why). Extra care should be taken to close doors or curtains to minimize children's exposure to others who are injured or suffering. To the extent possible, healthcare providers should convey a sense of control of the situation and interact with children and their families in a calm, gentle, and compassionate manner. Children and families can sense when those in authority are panicked or overwhelmed and in turn become more anxious themselves. Healthcare providers should not only model such behavior for parents, but when they suspect or observe that parents are highly distressed, encourage them to seek their own support so that they can provide a more effective model of coping for their children.

Children are generally aided in stressful situations by the support provided by trusted caregivers. Healthcare providers should, therefore, minimize the need to separate children from important caregivers. When children are unaccompanied, healthcare sites should attempt to assign volunteers to provide consistent support to injured children until they can be reunited with family or other caregivers. Staff within the healthcare settings should provide guidance to the adults accompanying children about how they can support the children and reduce their distress. Having parents and other caregivers serve an active and positive role in the evaluation and treatment process will minimize the likelihood that either the children, or their parents/caregivers, will be disruptive to the delivery of care.

Psychotropic medication is *rarely* indicated for adjustment reactions in the immediate aftermath of a disaster and should be prescribed in consultation with a mental health provider who is experienced in the treatment of posttraumatic disorders and stress reactions in children. Such medication should not be used in order to suppress normative reactions (e.g., crying) or feelings (e.g., sadness)

in response to a disaster or to blunt children's awareness of the event. Awareness of the event and the expression of normative feelings are necessary for children to understand and ultimately adjust to the situation.

Schools as a Site for the Delivery of Recovery Services

- Following a devastating earthquake in a large rural area of Asia, hundreds of thousands of children and families were relocated to temporary housing communities. As the communities sought a return to normalcy, temporary classrooms were established. However, as teachers sought to cover lesson plans, many children would be crying in class or otherwise distressed. Teachers, also impacted by the earthquake, had little tolerance for the crying or other disruptive behaviors. They told children this was a sign of weakness and that they needed to be strong for the younger students. Although the children tried, they continued to show extreme distress in the classrooms. The local and federal government joined with agencies and outside experts to begin to address the distress in the children. Training and consultation about the impact of disasters on children was provided and alternative approaches were offered that were culturally appropriate to address the crying and other signs of distress. Also, simple techniques were taught, such as relaxation exercises, for use with children to reduce their distress. These exercises served as a way to increase positive coping for distress related to the disaster or other stressful situations.

After a major disaster, the number of children that would benefit from additional supportive services will likely exceed the capacity for traditional mental health services. Therefore, alternative models are needed for the delivery of basic supportive services to large numbers of children with minimal additional professional staff and at a site where children can go without feeling stigmatized. Schools emerge as one of the most viable and effective sites to accomplish these goals. School staff are well positioned to provide Psychological First Aid and brief supportive services to large numbers of children in the aftermath of a disaster. They can help to normalize both reactions and acceptance of assistance. They can identify children whose needs exceed those likely to be met through school-based support services based on children's risk factors for distress after disaster (see *Table 50.2*) and/or their level of reactions. Schools can also serve as a venue for provision of more intensive intervention services for identified students, reducing barriers such as transportation and stigma that may prevent students or their families from seeking help. Given that recovery from a disaster typically occurs over months and years, schools are uniquely suited to providing the long-term, longitudinal support and monitoring that is required.

- After an earthquake and tsunami struck a rural area in the Pacific, school staff were eager to learn from experts about how to support and respond to children in need. They shared their cultural considerations with trainers and the trainers provided information and modeling in working with children and families. This allowed for the best level of care to be provided to this small island community. Continued follow-up ensured that as the needs changed with time, these could also be addressed. For example, one small 8-year old boy whose parents had to leave the island to find work was living with relatives. He was extremely anxious and had begun avoiding school. He began drawing images of people drowning and no one around to help. With encouragement, he was able to talk about worries for the safety and security of his relatives. Who would help them if another tsunami occurred? He needed to be home just in case something happened so that he could offer assistance. He worried about the safety of his parents and who would take care of them. Support and acceptance of his concerns and psychoeducation about common worries was provided. Information about how the island was prepared for any future problems was given as were simple ideas for coping with his stress reactions. He was included in developing a preparedness plan for his new home. Slowly, this boy began to return to school. Weekly contact was established with his family so that he knew they were safe. Although small steps, each piece aided in reduction of stress such that he could begin to return to his school routine and begin to see the world with a more positive perspective.

While it is true that the primary mission of schools is to support academic achievement and not to provide counseling, it is also true that in the absence of effective interventions, disasters often have profound and sustained impacts on children's ability to succeed academically. *Figure 50.1* summarizes the impact of disasters on academic functioning, as well as the contributory factors. Despite this, most teachers and school staff (including mental health staff in school settings) have had only limited, if any, professional training on the impact of loss and crisis on children and strategies to provide effective support. Pediatric healthcare providers can, therefore, provide a critical role in advocating for schools to be better prepared to respond to crisis events and providing continued training and consultation on these issues.

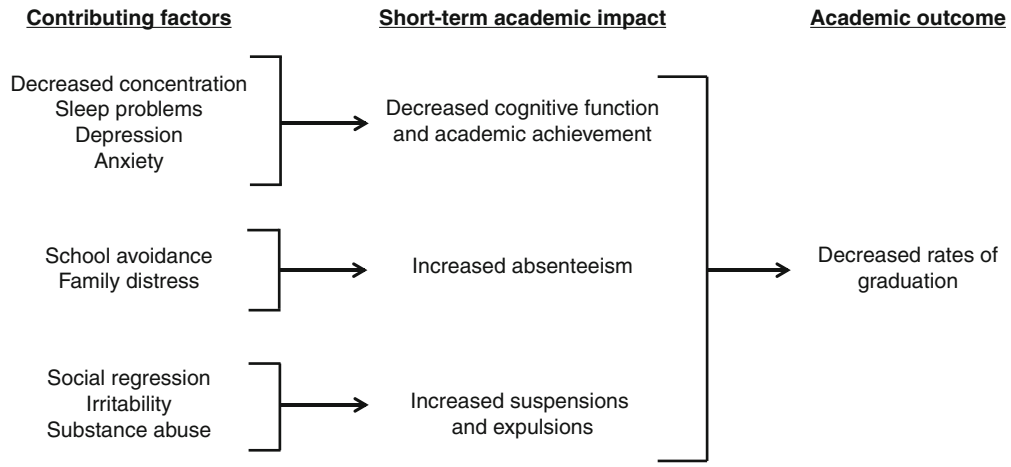

Figure 50.1
Possible impact of disasters on academic functioning in children in the absence of intervention

Long-Term Recovery

The question is often asked by parents and other caregivers: "When can children be expected to 'get over' a disaster?" or, "When can the family and community be expected to be 'back to normal'?" Disasters like other life-changing events – whether they be positive or negative events – do exactly that: They change the lives of all involved. They create indelible marks on a child's life course and have lasting impact. But this does not mean that children are permanently damaged or that long-term adverse impacts are inevitable.

Children's ability to cope and adjust to a disaster is initially compromised in the immediate aftermath of the event. Generally, in the period that immediately follows the event, there is an outpouring of concern and resources; families and communities come together and the resulting sense of cohesion can be uplifting. As a result, children begin to return to school and other routine activities. Parents, caregivers, and others serving children may interpret the return to routine as an indication that nothing else is needed. Unfortunately, while this return to routine is necessary for coping and recovery, it is not sufficient. Children may continue to need supportive services or even more intensive interventions. Many children may appear to be fine and have their needs overlooked.

Unfortunately, typically even modest improvement is seen as a sign that children are resilient and it is assumed that since they have started to "bounce back," they will return to their prior level of adjustment spontaneously. Although the majority of children will continue to improve over time after a disaster, many will not. If supports and assistance are withdrawn, before full recovery has occurred, these children will not return to their baseline adjustment levels but instead establish new baselines characterized by ongoing impairment. Children and school staff must instead be provided sufficient support until they are able to regain at least their baseline level of coping. For some children, if they have adequate internal resources and are provided sufficient support, they may even attain a higher level of adjustment. This posttraumatic growth occurs when children are helped to increase their resilience and learn new coping skills that they can call upon when faced with subsequent challenges. As the research has shown, adults who are in a position to support children play a key role in determining the difference between two ultimate outcomes – stress that promotes development and that which impairs development.

Commemorative and memorial activities often serve as effective mechanisms for promoting a group understanding of the event and acceptance of the resulting circumstances. Schools and other community sites can be important venues after a disaster to provide children with memorial and commemorative activities to help them express and cope with difficult feelings and to draw on the support of a caring community. By planning and taking part in a commemorative event, children can exercise at least some control over how they will remember the events – even if they felt powerless to prevent the disaster – as well as what and how they wish to honor what was lost or permanently altered.

The key to successful commemorative and memorial activities is to ensure that the students are actively involved in the planning and carrying out of the activity, which should be relevant to their interests and developmental needs and employ symbolic activities that are meaningful to survivors. Children are also helped to achieve long-term recovery when given opportunities to contribute actively to assisting others, whether that be victims of the disaster or others in need within their community. Healthcare professionals can lend their voices in support of children's involvement in these activities.

Professional Self-Care

- In the aftermath of a large-scale and devastating earthquake in Asia, paraprofessional mental health workers began to talk with children impacted by this disaster. Each day, they would venture out to the impacted areas and hear story after story of death and destruction. They would listen to the worries, fears, and anxieties of the children of all ages. They would listen as parents, relatives, and other adults would talk about the children and their worries. This began to take a toll on the workers. They were tearful and showing signs of compassion fatigue. The workers received specialized training in the impact of trauma, disaster, and bereavement on children as well ideas to support children's healing and resilience. This helped workers feel better able to meet the needs of those they encountered. However, this alone was not sufficient to address the compassion fatigue. Information about the importance of self-care was discussed and ideas offered, with workers contributing suggestions. Time to talk about the stories they had heard that day was established as one way to process all they were experiencing vicariously. The combination of these efforts led to a reduction in worker distress and an increased energy and new ideas about how to reach out to those in need, thereby contributing to improved services to members of the community.

Disasters that impact children generally also impact the adults within the community. This is true as well for professionals who reside or work within the same community.

Even if not impacted directly, healthcare professionals who have to bear witness to the suffering and distress of children and their families will also find themselves impacted. This is known as vicarious traumatization or secondary traumatization. Those working with children are particularly susceptible and are at high risk for compassion fatigue. As such, disaster response plans should anticipate ways to provide professional consultation and direct support to healthcare providers as they meet the mental health needs of children and families in the aftermath of a disaster. This is particularly important when providers are involved in providing complex services such as death notification (for practical guidelines on death notification in the aftermath of a disaster, see Foltin GL, Schonfeld DJ, Shannon MW, 2006). How well providers are faring also has a direct effect on how those they serve will cope.

Healthcare providers may need to respond to a dramatic surge in the number and acuity of patient demands at the same time they may be struggling to meet increased needs of family members and friends, or feel torn by the competing need to respond to damage to their home or personal belongings. Many of the secondary stressors experienced in the aftermath of a disaster are also present in healthcare settings – economic forces may result in reductions in workforce or loss of support staff or resources. Healthcare workers may find themselves needing to respond to increased demands in often more austere working conditions, especially when working in settings that have experienced devastation or major impacts on the infrastructure of the healthcare delivery system.

To reduce vicarious traumatization and other adjustment difficulties after a disaster, it is critical that professionals identify, acknowledge, and meet their own needs and utilize healthy ways of coping with the distress. For example, developing family disaster plans prior to any disaster may increase healthcare providers' ability to focus on the needs of patients and families, knowing that their family is safe. Healthcare institutions should also establish plans by which they can assist their staff with basic needs and ongoing support of family members (e.g., providing daycare or elder care to allow healthcare workers to increase their working hours without compromising the safety or well-being of loved ones, or supplying temporary housing when the disaster has destroyed or damaged the homes of staff). Such support can mitigate the additional stress that may otherwise impact negatively the quality of care delivered by healthcare workers.

It is important to acknowledge that the same emotional reactions that can be seen in adults within the broader community can also be experienced by healthcare professionals. They should therefore also receive Psychological First Aid, brief supportive interventions, and access to additional mental health services as indicated. Those professionals experiencing marked or persistent distress or demonstrating unhealthy attempts at coping (e.g.,

increased use of alcohol or other substances) should have ready access to services, such as through an Employee Assistance Program.

When healthcare providers can identify personally meaningful ways to help others in the community recover and rebuild after a disaster, they may experience an increased sense of personal and professional satisfaction and increased feelings of self-efficacy. Many healthcare providers are motivated to pursue their careers out of a desire to help others and derive personal fulfillment by doing so.

In summary, there are few situations where people are more in need than in the aftermath of a disaster and where healthcare providers are in a better position to provide the necessary care and support. Understanding the impact on children and families, they can provide guidance and support the recovery of this vulnerable population.

Pediatric Nutrition

Hisham M. Nazer

51 Breast Feeding

Salah Shohieb · Hisham M. Nazer

There is growing interest in ensuring an adequate and appropriate nutrition for the infant from early days of life. Infant nutrition is a well-recognized major determinant of growth and development that has also a considerable influence on health later in adulthood.

Infants should normally be exclusively breast-fed at least until the age of 4–6 months or given expressed breast milk especially if premature or small for dates. If such an option is not possible, a modified artificial formula close to breast milk in composition should be given as an alternative.

The nutritional adequacy of any diet is determined by the clinical status, growth, and development of the child. Parents are extremely receptive to advice regarding a proper feeding regimen for their children to ensure a healthy lifestyle as they grow older.

Breast Feeding

The first half of the twentieth century was marked by decline in breast feeding in the industrialized world and that was followed by a similar decline in developing countries. However, the latter half of the century and extending into the twenty-first century witnessed an upsurge in breast feeding.

The duration of breast feeding varied from 9–12 months in some areas of the world to 2–3 years in others but most children were suckled usually on demand for a year either by their mother or by a wet nurse.

The volume of breast milk that a woman can produce varies widely, from as little as 400–600 mL per day to around 1,200 mL per day. Following birth, the placental inhibition of milk synthesis is removed with rapid decline of the mother's progesterone blood level. The breast fills with high density milk called colostrum.

Changes of the Breast During Pregnancy

There is visible enlargement of the nipple with an increased pigmentation. Each of the right and left breast has an average weight of 150–200 g, which increases to 400–500 g during lactation. Numerous sebaceous glands (Montgomery's glands) produce small elevations on the surface of the areola. These glands secrete a light lipoid material that lubricates and protects the nipple during nursing. Frequent use of soap to wash the nipples is not recommended. This will not only dry them but wash away the natural lubrication as well.

Galactogenesis begins immediately after delivery. For successful lactation, the breast must be primed by different hormones: estrogens, progestins, corticosteroids, insulin, thyroid, and parathyroid hormones.

After delivery, a sharp drop in estrogen levels triggers lactation. Optimal milk quality depends on the availability of thyroid, insulin, and cortisol and on sufficient intake of nutrients and fluids.

Frequent feeding is the only way to prevent engorged breasts. Normal newborn should be placed at the mother's breast every 2–3 h. Five minutes is more than enough time to stimulate the lactational reflexes. Breast-fed infants ingest 50% of the milk in the first 2 min of nursing, 80–90% in the first 4 min and nearly 100% in the first 7 min. The nutritional requirements of the newborn varies according to weight, gestational age, and environmental factors.

Night feeding should be encouraged because they take the advantage of the circadian nature of the prolactin secretion that occurs 60–90 min after sleep onset.

Breast Milk and Premature Newborns

Human milk is of great benefit in the management of premature infants. It improves the digestion and absorption of nutrients, gastrointestinal functions, host defenses, neurodevelopmental outcomes, and maternal psychological well-being.

Human milk may be used as such without any additives (unfortified) or with some additions (fortified).

Unfortified Human Milk for Prematures

Feeding of the premature infants by the breast milk without any additions leads to the following benefits:

- *Host defense benefits:* Where there is decreased rate of various infections due to the presence of specific

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_51,

bioactive factors such as secretory IgA, lactoferrin, lysozyme, oligosaccharides nucleotides, cytokines, growth factors, enzymes, antioxidants, and cellular components.

- *Neurodevelopmental benefits:* Visual functions may be improved due to high quantity of very long-chain poly-unsaturated fatty acids (PUFA) and antioxidant activity.
- *Gastrointestinal benefits:* Human milk promotes rapid gastric emptying and also activates intestinal lactase more than if the preterm baby is formula fed.

Fortified Human Milk for Prematures

Premature infants fed fortified human milk had significantly better growth i.e., positive increments in weight, length, head circumferences, nitrogen balance, and bone mineral content.

Human Milk Fortifiers

This can be performed using a commercially available liquid formula to be mixed with the human milk or a powdered product that has the advantage of not diluting the human milk. Most fortifiers are powdered nutrient preparations that contain protein, carbohydrate, calcium, phosphorus, magnesium, and sodium. The contents of zinc, copper, and vitamins vary.

With the increasing knowledge of the advantages of breast feeding, there is a positive changing trend among mothers to breast-feed their babies for the first 6 months of age. However, it has been seen, in the industrialized countries, that despite all knowledge about the superiority of breast milk, nearly one mother in two discontinues breast feeding before the infant is 6 months of age. This is usually due to the mother's belief that their milk production is becoming too little to benefit their babies (i.e., "the insufficient milk syndrome"). This phenomenon is precipitated by early introduction of supplementary feed and the mother's lack of motivation toward long-term breast feeding. Some have demonstrated that emotional factors could contribute to reduced milk consumption by the baby and subsequently reduced milk supply by the mother. Another cause for the reluctance the mothers have toward breast feeding or prolonged breast feeding is their belief that breast feeding will adversely affect their figures.

The test weighing method for measuring breast-milk consumption remains a valid and reliable method, especially in field studies.

There is a consensus that the appropriate time to start weaning and introducing additional foods to the infants is around 6 months of age, prior to which the baby should be on exclusive breast feeding.

Evidences Concerning the Superiority of Breast Feeding

1. Breast-milk composition includes: immunoglobulins, lactoferrin, lysozyme, oligosaccharides, and lymphocytes and these could well contribute to the protection of the breast-fed infant from infection.
2. Breast feeding is a preventive measure in programs to control diarrhea. In fact, both the promotion of breast feeding in general as well as stressing on the continuation of breast feeding during diarrhea are well-recognized important components of programs against diarrhea.
3. While women are suckling their babies, menstruation does not usually occur (i.e., lactation amenorrhea), nor do they conceive. Breast feeding can reduce the risk of breast cancer to nearly half relative to that in women who bottle feed their babies.
4. The maximum birth-spacing effect of breast feeding is achieved when a mother "fully" or nearly fully breast-feeds and remains amenorrheic. Exclusive breast feeding provides more than 98% protection from pregnancy in the first 6 months.
5. In much of the "Third World," breast-feeding rates are highest among the rural women and those with least education. On the other hand, women who work find it difficult to breast-feed their babies for long.

If breast feeding continues after the age of 6 months, some attention to a dietary source of iron is necessary. Semisolid foods containing meat or vegetable sources of iron plus vitamin C should be given. Bottle-fed infants should continue with their formula fortified with iron or change into follow-on-milk formula. All breast-fed infants require vitamin supplement after the age of 6 months. A limited exposure to the sun is advisable.

Breast feeding secures optimum health, growth, and development for babies and ensures they receive the vital immunity they need to protect them against childhood illnesses. Breast feeding is recognized to reduce the risk of developing gastrointestinal illnesses, especially gastroenteritis, which is a major cause of infant morbidity and mortality in the developing world. It also reduces the risk of other infections of the middle ear, and respiratory system. In later life, breast feeding is associated with

a reduced risk of allergies such as eczema and of insulin-dependent diabetes mellitus.

Mothers who breast-feed also have a reduced risk of developing premenopausal breast cancer as well as some forms of ovarian cancer.

As to the practice of breast feeding in rural areas of the developing world as well as in some traditional societies and Islamic communities, mothers continue to breast-feed their infants until 2 years of age, though partially but still with the supplement of other formulas or even solid foods.

Galactosemia is considered an absolute contraindication for continued breast feeding; however, in conditions like phenylketonuria, because breast milk contains a low concentration of the amino acid phenylalanine, breast feeding may be continued, provided there is regular monitoring of the serum phenylalanine. Occasionally, breast feeding may have to be supplemented with a special low-phenylalanine formula.

A summary of the situations where breast feeding is considered absolutely or relatively contraindicated is listed in *Table 51.1*.

Every effort should be made not to deprive the baby of the mother's breast milk and if needed, the baby's feed may be supplemented with formula feeds.

Maternal tuberculosis remains a serious health hazard in the developing world. Active tuberculosis should be diagnosed and managed antenatally. Contacts should also be investigated and treated accordingly. However, if the diagnosis was made after birth there is a significant risk to the newborn of tuberculosis not only through the mother's milk but also through the direct contact. The mother should therefore be treated with triple therapy while her baby is being isolated from her in the initial weeks of therapy. The baby should also receive a prophylactic dose of isoniazid for 6–12 months in a daily dose of 10 mg/kg body weight.

Table 51.1
Conditions associated with contraindications (absolute or relative) to breast feeding

Absolute	Relative
• Inborn errors of metabolism	• Hare lip and cleft palate
– Galactosemia	• Lactation failure
– Maple syrup urine disease	• Mastitis
• Serious maternal illness	• Maternal tuberculosis
– Psychosis	• Maternal hepatitis B infection
– End-stage liver or renal disease	• Breast cancer
– Heart failure	• Inverted nipples
– Human immunodeficiency virus (HIV)	• Drug therapy
	• Exposure to chemicals as herbicides, pesticides, heavy metals

Changes in Breast Milk After Delivery

There are three phases of milk production: colostrum, transition, and mature milk.

Colostrum is present from delivery to approximately 5 days postpartum. It has the highest concentration of protein, of most immunoglobulin (especially S IgA), and lactoferrin. It is lower in fat compared to mature milk (2% versus 3.5%) and has higher cholesterol levels than mature milk. It provides approximately 67 cal/100 mL. Major functions of colostrum are to provide substances for rapid growth, protect the gastrointestinal tract, and assist in increasing the level of *Bifidobacteria* of the gut. The amounts of colostrums secreted vary widely, ranging from 10 to 100 mL/day with a mean of about 30 mL.

Transitional milk is present between 6 and 15 days postpartum. Immunoglobulin level decreases while lactose and fat levels increase.

It provides between 67 and 75 cal/100 mL.

Mature milk is present from day 15 to weaning. It provides 75 cal/100 mL. One third of mature milk is foremilk, which is thin and low in fat. Two thirds of mature milk is hind-milk. This milk is about four times higher in fat than foremilk.

The composition of breast milk varies with the duration of lactation as well as with the infant feeding practice. Mature breast milk is variable in composition not only between mothers but also in the same mothers between breasts, between feeds, and even during a single feed as well over the course of lactation.

More information on the subject of breast feeding is available in the section on neonatology.

Breast-Milk Jaundice

This is a rare type of jaundice that develops in breast-fed infants around the age of 1 week and lasts for up to

3 months. The specific mechanism responsible for this condition is not identified. Abnormal bilirubin metabolism associated with breast feeding has been considered a possible etiology.

A high level of unconjugated bilirubin in breast-fed infants may be due to various proposed factors. It has been suggested that the unusual steroid metabolite of progesterone, pregnane-3(α) 20 (B)-diol, inhibits the activity of hepatic glucuronyl transferase in vitro. This observation was not confirmed by some subsequent studies. Other observations indicated that the breast milk from mothers with breast-milk jaundice does not inhibit the intestinal absorption of bilirubin. Other factors included the presence of free fatty acids, which are also known to inhibit the conjugation of bilirubin, resulting in jaundice due to accumulation of unconjugated bilirubin. However, there are reports to contradict those in support of the role of free fatty acids and milk lipases in the pathogenesis of breast-milk jaundice.

Subsequently, other factors such as the higher milk glucuronidase in breast milk of mothers with breast-milk jaundice have been suggested. Moreover, infants with breast-milk jaundice had higher concentration of epidermal growth factor in the serum and in the breast milk compared with that of infants without breast-milk jaundice. Although the exact mechanism of the hyperbilirubinemia of the epidermal growth factor are not completely known, the inhibition of gastric motility, increased absorption, and activations of bilirubin transport have been suggested as possible mechanisms.

Recently, prolonged unconjugated hyperbilirubinemia associated with the heam oxygenase-1 gene promoter polymorphism may be a factor in hyperbilirubinemia of these neonates.

However, maternal serum aflatoxin is a risk factor for jaundice in infants where studies reported that maternal breast milk in developing countries had higher rates of aflatoxin concentration than in high-income countries.

Breast-feeding infants remain in good general health, feeding well, and growing normally. This is why breast feeding should not be discontinued. In an attempt to the diagnosis, the breast feeding is discontinued for 1 or 2 days, following which the serum unconjugated bilirubin decreases, to rise again after the reintroduction of breast feeding.

Breast Milk and Gastrointestinal Health

The importance of breast milk in the prevention of neonatal and the preterm gastrointestinal disease states will be illustrated in the following paragraphs expressing worldwide clinical and laboratory experiences:

1. Protective properties of human breast milk:
   This may be *passive protection* of breast milk by lactoferrin and nucleotides and *active protection* by *growth factors*, *cytokines*, and *hormones.*
   These protective factors act as a barrier to antigen absorption in the immature infant's human intestine as a background for three accelerated gastrointestinal diseases as: necrotizing enterocolitis, intestinal allergy, and bacterial gastroenteritis.
2. Human milk actively stimulates the *infant's immune system* by the bioactive factors such as hormones, growth factors, and colony stimulating factors. In addition other factors in breast milk promote gastrointestinal mucosal maturation, decrease the incidence of infection, alter gut microflora, and have *immunomodulatory* and anti-inflammatory functions.
3. *Heparin-binding epidermal growth factor in breast milk:* This epidermal growth factor protects against intestinal epithelial cell apoptosis and necrosis and intestinal ischemia and reperfusion injury.
4. *Soluble CD14 in breast milk*, an important component of the lipopolysaccharide receptor complex, promotes the innate immunity and helps reduce gastrointestinal gram-negative infections.
5. *Breast milk probiotic potential* by 3 lactobacilli strains – 2 lactobacillus gasseri and 1 lactobacillus fermentum lactic acid producing bacteria – was isolated from milk of healthy mothers. The probiotic potential of lactobacilli isolated from milk of healthy mothers is at least similar to those strains commonly used in commercial probiotic products. This fact, together with the presence of prebiotic substances indicates that breast milk is a natural synbiotic food.
6. Breast milk *erythropoietin:* Mammary epithelial cells contribute to the production of erythropoietin in human milk. Erythropoietin receptors are widely distributed in human tissues including the gastrointestinal tract, endothelial cells, spinal cord, and brain. Thus erythropoietin may play a pleomorphic role in erythropoiesis, neurodevelopment, maturation of the gut, apoptosis, and immunity.
7. Breast milk: *essential fatty acids* (long chain) (LCPUFAS) as possible enhancers of the beneficial action of probiotics. Breast milk is rich in long-chain poly-unsaturated fatty acids that have immunomodulatory actions. LCPUFAS promote the adhesion of probiotics to mucosal surfaces, thus augmenting the health promoting effect of probiotics.

8. *Anti-complement activities* of human breast milk: Several natural components abundant in the fluid phase of breast milk have been shown to be inhibitors of complement activation. These include lysozyme, lactoferrin, lactalbumin-alpha, complement regulator protein, and other specific soluble inhibitors of complement activation.
9. *Human-milk glycans* inhibit pathogen in the gastrointestinal tract from adhering to their target receptors on the mucosal surface of the gut. The human milk glycans includes the oligosaccharides in their free and conjugated forms function as soluble receptors thus preventing morbidity and mortality in infancy.
10. *Haptocorrin* (Vitamin-B_{12} binding protein): in human milk with a host-defense role in the gastrointestinal tract of breast-fed infants. It is expressed by human mammary epithelial cells. It may exert a host-defense function, i.e., antimicrobial function against pathogens in the gastrointestinal tract of breast-fed infants.
11. *Hepatocyte growth factors in human milk:* The hepatocyte growth factor is present in sufficient amounts to profoundly affect gastrointestinal maturation in the fetus via the swallowed amniotic fluid and neonate via breast milk and help explain the increased rate of necrotizing enterocolitis in infants of premature rupture of membranes, complicated pregnancies, and the decreased rate in breast-fed neonates.
12. *Prostaglandins in human milk:* Prostaglandins (E2 and F2-alpha) are present in breast milk and may protect and maintain intestinal epithelial cell integrity. The cytoprotective effect of prostaglandins on the gastrointestinal tract may be related to their stability and lack of degradation in milk and gastric digestive juices.
13. *Secretory Immunoglobulin A* (*S IgA*) antibodies in breast milk. A fully breast-fed infant receives as much as 0.5–1.0 g of secretory immunoglobin A (SIgA) antibodies daily. These (SIgA) antibodies have been shown to protect against *Vibrio cholerae*, ETEC, *Campylobacter*, *Shigella*, and *Giardia*.
14. Importance of *breast-milk mucin:* The Rotavirus specifically binds to the milk mucin complex and thus viral replication is inhibited both in vitro and in vivo. Variations in milk mucin glycoproteins may be associated with different levels of protection against infection with gastrointestinal pathogens.
15. Human milk *nucleotides:* The dietary nucleotides optimize the function of rapidly dividing tissues such as those of the gastrointestinal and immune systems. Infants receive nucleotides in human milk where they are present as nucleic acids, nucleosides, and related metabolic products. The nucleotide content of human milk is significantly higher than most cow's milk–based infant formula.
16. Gastrointestinal *regulatory peptides* in human milk: These gut neuropeptides in milk may be important for growth and maturation of the gastrointestinal system in neonates. Neuropeptides were at the same or lower concentrations in milk than in plasma. These neuropeptides are: gastric inhibitory peptide, bombesin, gastrin cholecystokinin, peptide histidine-methionine, and neurotensin.
17. Human *milk proteins:* Human milk contains a wide variety of proteins as:
    (a) Many of these proteins are digested and provide a well-balanced source of amino acids to the rapidly growing infants.
    (b) Some proteins such as lipase, amylase, beta-casein, lactoferrin, haptocorrin, and alpha-antitrypsin assist in digestion and utilization of micronutrient and macronutrients.
    (c) Proteins with antimicrobial activity – immunoglobulins, kappa-casein, lysozyme, lactoferrin, haptocorrin, alpha-lactalbumin, and lactoperoxidase – contribute to the defense of breast-fed infants against pathogenic bacteria and viruses.
    (d) Prebiotic activity such as the promotion of the growth of beneficial bacteria such as lactobacilli and bifidobacteria, may also be provided by human milk proteins.
    (e) Some proteins and peptides have immunomodulatory activities (e.g., cytokines and lactoferrin) whereas others such as insulin-growth factors and epidermal growth factor are likely to be involved in the development of the intestinal mucosa and other organs of the newborn.

52 Formula Feeding

Aziz Koleilat · Hisham M. Nazer

Exclusive breast feeding is the norm in infant feeding. Human milk remains the ideal milk for human babies in spite of all modern and modified commercial formulas available. It remains a superior formula not only because of its content and composition that varies with time, environment, emotions, and many other factors, but because it is safer with better psychological effects due to bonding and contact between mother and baby. All fluid, energy, and nutrients are provided for by breast milk, adapted for every child's age, with few exceptions of small amounts of medicinal supplements.

In a small number of situations there may be a medical indication for supplementing breast milk or for not recommending breast milk at all.

It is useful to distinguish between

1. Infants who cannot be fed at the breast but for whom breast milk remains the food of choice (may include infants who are very weak, have sucking difficulties or oral abnormalities, or are separated from their mother who is providing milk). These infants may be fed expressed milk by tube, cup, or spoon or by wet nurse (another mother).
2. Infants who may need other nutrition in addition to breast milk, like premature infants or infants with other medical diseases.

Infants that should not receive breast milk, or any other milk, including the usual breast milk substitutes and need a specialized formula (may include infants with certain rare metabolic conditions such as galactosemia who may need feeding with a galactose-free special formula or phenylketonuria where some breast feeding may be possible, partly replaced with phenylalanine-free formula).

The general decline in breast feeding is certainly linked to the far-reaching changes that have taken place in modern society.

There are, however, certain situations where breast milk is insufficient to maintain adequate weight gain or some relative or absolute contraindication to breast feeding exist for which reason the baby has to be placed on or supplemented with artificial formula.

In developed countries mothers who are infected with human immunodeficiency virus (HIV) have been advised not to breast-feed their infants. In developing areas of the world with populations at increased risk of other infectious diseases and nutritional deficiencies resulting in increased infant death rates, the mortality risks associated with artificial feeding may outweigh the possible risks of acquiring (HIV) infection.

Bottle formula is resorted to in infants born to mothers who are hepatitis B surface antigen positive, or who are infected with hepatitis C virus (persons with hepatitis C virus antibody or hepatitis C virus RNA-positive blood), febrile mothers, and mothers who are seropositive carriers of cytomegalovirus (CMV).

Switching to bottle formula from the mother's side reflects one of many causes: insufficient prenatal education about breast feeding, inappropriate breast-feeding technique, early hospital discharge, lack of follow-up care and postpartum home health visits, maternal employment, lack of family and broad societal support, commercial promotion, distribution of hospital discharge packs, media commercials, television and general magazine advertising, misinformation, and lack of guidance and encouragement from health-care professionals.

Complementary Feeding

The process starts when breast milk alone is no longer sufficient to meet the nutritional requirements of infants and therefore other foods and liquids are needed, along with breast milk.

Introduction of complementary feeding before 6 months of age generally does not increase total caloric intake or rate of growth and only substitutes foods that lack the protective components of human milk.

Every effort should be made not to deprive the baby of the mother's breast milk. If needed the baby's feedings may be supplemented with formula.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_52,

Nutrient and Water Requirement

Water

Water is required for maintenance, excretion of excess protein, electrolyte intake, and changes in body composition.

Water constitutes approximately 78% of the body weight at birth and decreases to about 60% by the end of the first year of life.

Water requirement of an average newborn weighing about 3 kg is expected to be 80–100 mL/kg; it then increases to about 140–160 mL/kg at around 3 months of age.

The energy needs from complementary foods for infants with "average" breast milk intake in developing countries are approximately 200 kcal/day at 6–8 months of age, 300 kcal/day at 9–11 months of age, and 550 kcal/day at 12–23 months of age. In industrialized countries these estimates differ slightly (130, 310, and 580 kcal/day at 6–8, 9–11, and 12–23 months, respectively).

Estimated Energy Requirement

Estimated energy requirement during the neonatal period is about 120 kcal/kg/day, which is more than the child's requirement during later part of the first year, about 100 kcal/kg/day.

Human milk provides about 40–50% of energy as fat.

Protein

Human milk has the lowest protein concentration among mammals. Average protein content is estimated to be 1.15g/dL except during the first month, when it is 1.3 g/dL.

The total protein content of artificial formula should be lowered in order to be close to that of breast milk. Proteins are made of different amino acids that are linked together. They provide both calories and the amino acid building blocks that are necessary for proper growth. The protein in human milk provides between 10% and 15% of an infant's daily caloric need. Casein and whey are the two major proteins of human milk and most milk-based formulas.

Immunoglobulin, a type of protein unique to breast milk, provides passive transient infection-fighting immunity and is not considered as a nutritional source and is not efficiently metabolized.

Some 0.5–7.5% of infants have a true allergy to the cow's milk proteins that are in cow's milk-based formulas. Infants with true cow's milk allergy can develop abdominal pain, diarrhea, rectal bleeding, skin rash, and wheezing when given milk-based formulas. These symptoms will disappear as soon the milk-based formula is removed from the diet. Since allergy to cow milk protein is different from lactose intolerance, treatment of cow milk protein allergy involves using formulas that are not based on cow's milk or using formulas that contain "predigested" casein and whey proteins. The predigesting process breaks the whole proteins into smaller pieces or into amino acids.

Soy-protein formulas contain no cow's milk, and are reasonable alternatives for infants with true cow's milk protein allergy. Since most soy-protein formulas also contain no lactose, they are also suitable for infants with lactose intolerance. The carbohydrates in soy-protein formulas are sucrose, corn syrup solids, and cornstarch or glucose polymers.

Certain infants have allergy to both cow milk proteins and soy proteins. These infants require a formula in which the cow milk protein (casein) has been "predigested" and specific amino acids added to give a formula that can provide proper nutrition.

Carbohydrate

Lactose is the major carbohydrate in human milk. Galactose and fructose are present in human milk but to a much lesser concentration. Lactose is present in a concentration of 4% in colostrums and 7% in the mature human milk.

Lactose supplies about 40% of the energy needs but also has other functions. It is metabolized into glucose used for energy and galactose needed for development of the central nervous system. Carbohydrates (glucose, lactose, sucrose, galactose, etc.) are sugars or several sugars linked together. Carbohydrates provide energy (calories) for the brain tissues, muscles, and other organs. Lactose is a carbohydrate consisting of glucose linked to galactose. Lactose is the major carbohydrate in human breast milk, cow's milk, and in most milk-based infant formulas. While most infants will thrive on a formula that contains lactose, some infants are lactose intolerant.

Primary lactose intolerance is "rare congenital anomaly."

Temporary lactose intolerance may occur with any condition that damages the intestinal brush border with loss of the lactase activity. Lactose intolerance is due to a lactase enzyme deficiency (low levels of enzyme activity)

in the small intestines. Lactase enzymes are necessary for "digesting" lactose by breaking the link between glucose and galactose. The intestines can then absorb the smaller glucose and galactose molecules. In infants who are lactase deficient, the undigested lactose cannot be absorbed. This, in turn, can cause diarrhea, cramps, bloating, vomiting, and gas. Lactase deficiency is more common in premature infants than in full-term babies.

Lactase deficiency can also develop temporarily during recovery from viral gastroenteritis. For infants with lactose intolerance, formulas that contain no lactose should be used. There are quite a good number of breast milk substitutes that do not contain lactose.

Fat

Fat concentration is about 2 g/dL in the colostrums and increases up to 4 g/dL or even more. Fat is the most variable of human milk constituents. There is a recognized circadian fluctuation in the concentration of fat in human milk with highest concentration in the late morning and early afternoon.

The fatty acid composition of the human milk is relatively stable, with about 42% saturated and 57% unsaturated. Fat in human milk provides 30–35% of the total daily caloric needs for a growing infant. The fats are comprised of cholesterol, triglycerides, short-chain fatty acids, and long-chain polyunsaturated (LCP) fatty acids. The LCP fatty acids (18–22-carbon length) are needed for brain and retinal development. Large amounts of omega-6 and omega-3 LCP fatty acids, predominately the 20-carbon arachidonic acid (AA) and the 22-carbon docosahexaenoic acids (DHAs), are deposited in the developing brain and retina during prenatal and early postnatal growth.

An infant, particularly a preterm infant, may have a limited ability to synthesize optimal levels of AA and DHA from linoleic and linolenic acids. These two fatty acids may be essential. Recently, some infant formulas have added AA or DHA. Increasing evidence suggests that breast-fed infants have better visual acuity at 4 months and slightly enhanced cognitive development than formula-fed infants, even when socioeconomic factors are taken into account. These differences are more pronounced in premature infants.

Breast milk may somehow protect the developing neonatal brain from injury or less optimal development by providing necessary building materials and growth factors.

Human milk is rich in long-chain polyunsaturated fatty acids, which are important in brain development and enhance nervous tissue myelinization.

Vitamins and Minerals

Vitamins

In general, vitamin concentrations in human milk are usually sufficient to meet the newborn's needs.

Vitamin K

Vitamin K is present in higher concentration in both the colostrums and early breast milk than in later milk or breast milk substitute. This is helpful in reducing the incidence of hemorrhagic disease on the newborn.

Vitamin D

Vitamin D content of human milk is low and insufficient to meet the needs of the newborn infant. A brief exposure to sunlight produces sufficient vitamin D to satisfy the breast-fed baby's needs.

Minerals

Mineral concentrations (e.g., calcium, magnesium, zinc, iron) are lower in human milk than in artificial milk. Calcium is more efficiently absorbed because of human milk's high calcium phosphorus ratio of 2:1. Neonatal hypocalcaemia is more common among artificially fed infants due to its higher phosphorus concentration.

Iron

Complementary foods rich in iron should be introduced gradually beginning around 6 months of age. Preterm and low birth weight infants and infants with hematologic disorders or infants who had inadequate iron stores at birth generally require iron supplementation before 6 months of age. Iron may be administered while continuing exclusive breast feeding.

Iron deficiency anemia is extremely rare in young infants fed exclusively on breast milk during the first

6 months, due to many supportive factors that increase iron absorption (70%) compared to those (30%) in cow's milk.

In developing countries, the mother herself may suffer from iron deficiency anemia for which reason an iron supplement in therapeutic dose is needed, compared to a lower dose (5–6 mg/day) for mothers in developed countries aimed at only compensating for increased need in pregnancy.

Many baby milk formulas are fortified with iron including prepacked feeds.

Zinc

The amount of zinc in human milk, though small, is sufficient to meet the requirement of the newborn infant. Acrodermatitis enteropathica is reported to be far more common among artificially fed infants than among those who are breast-fed.

Trace Elements

Human milk also has the added advantage of providing sufficient amount of trace elements that meet the baby's requirement.

The levels of trace elements (e.g., copper, selenium, cobalt) are higher in human milk than in cow's milk.

Weaning

It is the process of introducing breast milk substitutes and/or complementary foods thereby decreasing lactation stimulation and milk production and eventually ending lactation and breast feeding.

Weaning is a crucial and important event in infant nutrition.

In the developed world, almost half of the mothers who start breast feeding stop within 6 weeks. The reasons vary, but in many instances they arise from difficulties that can be overcome with some encouragement and support.

The age at the initiation of weaning varies substantially in both developed and developing countries. Weaning in the developed countries starts early (i.e., before the age of 6 months), with the increasing number of working mothers.

In the developing countries, weaning may be earlier or later than in the developed countries. Most children continue to receive breast milk or an infant formula during weaning till the age of 24 months.

Many commercial formulas have been introduced in the process of weaning. These formulas are less modified forms of cow's milk than the starting formula. Iron deficiency anemia is an important cause of anemia in children in the developing world and is the commonest nutritional disorder during weaning. Weaning milk formulas are usually fortified with iron and vitamin D.

Weaning may start by introduction of formula feeding or water and fruit juice. Gradually the baby will be offered more of the artificial formula and less of the human milk. The process of weaning is not recommended to start before the age of 4–6 months in the exclusively breast-fed infant.

Concept

Moving from Malnutrition to Subnutrition

Malnutrition is one of the most common causes of mortality and morbidity among children under the age of 5 years in the developing countries. It is also an associated feature of some pediatric disorders in the developed world. Traditionally, malnutrition has mostly been associated with poverty, which should mean not only lack of food but also lack of security, psychomotor stimulation, and affection. Severe malnutrition represents the most dangerous degree of malnutrition; it requires special care in hospital with special management.

Although nowadays the term *subnutrition* is preferred to malnutrition, it is necessary to use the latter when referred to the past. In the decade of the 1960s, it was estimated that there were 300 million children in the world affected by under/malnutrition. In the 1980s, this figure had reduced by half, and in the year 2000, the figure given by WHO was 146 million. This implied a further reduction due to the population increase in the developing World. UNICEF's report that the annual subnutrition percentage reduction all over the world was 1.7% for the period 1966–2005. This figure is important from a global health focus as in developed countries, all chronic pediatric malnutrition is stable at less than 1%. The decrease in poverty, thanks to the development of the most heavily populated countries (China and India), has improved the prevalence and also infant mortality rates.

The WHO defines *"malnutrition,"* from a conceptual point of view, as the imbalance between the intake of nutrients and energy and the bodily requirements to live, grow, and carry out specific functions, especially before reaching the age of 5. This initial concept has changed from a mere lack of calories and protein to the present one including other specific deficiencies, a presence of illnesses, and lesser education. Nowadays *the term "subnutrition" is preferred as malnutrition* can exist without weight loss and even in cases of obesity. The term "underweight" is necessary because it signals the first degree of subnutrition (BMI-zs from −1.0 to −2.0 SD) and is the most common situation in developed and developing countries. The term *"stunting"* meaning height reduction (different from short height) from a nutritional origin is interesting as in westernized and transitional countries heights can be seen as shorter than the target height as consequence of a suboptimal nutrition. On clinical grounds, the term *"failure to thrive"* is sometimes used to refer to the state of "underweight" as it sounds less pejorative. The term *"wasted"* indicates an extreme and dangerous thinness. Finally, the terms *"food insecurity"* and *"hunger"* are used but with a more sociological focus. Owing to the lack of a precise measurement for both, they are evaluated according to the degree of subnutrition. With appropriate care management in hospitals and follow-up care, the lives of many such children can be saved.

Recognized risk factors that could lead to severe malnutrition in the developing countries are rural areas, low socioeconomic status, and young age of parents and patients.

The term *"protein-calorie malnutrition"* (PCM) was introduced in the 1920s by Jellife to describe this situation in developing countries, although in developed countries, it was also applied to a very minor population of children in hospital or chronically ill. PCM is usually a result of a diet deficient in energy and protein. PCM and infections such as measles or gastroenteritis are largely responsible for the very high infant mortality rate in the developing countries. Its two most well-known forms are *marasmus* and *kwashiorkor.*

Marasmus is an insufficient intake of proteins and energy while *kwashiorkor* is an almost sufficient intake of calories, but not proteins and because of this, such patients develop edema besides other specific clinical symptoms. Marasmus may follow recurrent attacks of gastroenteritis or intractable diarrhea.

Anthropometrics of Subnutrition

The methods must be *quantitative* and initially *simple* so as to be able to apply to any infant population. Anthropometric evaluation offers a crude assessment of the state

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_53,

of malnutrition. It has a recognized limitation, as it refers to a set of references applicable to children not necessarily the same as the ones under study.

The anthropometric measurements usually include length or stature, weight, skin-fold thickness of the triceps, subscapular region and circumference of the head, upper arm, and upper thigh. Efforts should be focused on establishing the norms for these items applicable to the indigenous population. Undoubtedly, the most used method for subnutrition screening is weight below 3rd centile for age and gender. In a rather imprecise way, this will indicate chronic and recent subnutrition. It is also considered when the weight curve has down crossed more than 2 centile lines on the chart. In an undernourished child, a decrease in height below 3 centile (stunting) indicates an accumulative effect of subnutrition, but to be more certain, at least the height of both parents should be known. This initial procedure should give way to the methods which incorporate height as a reference element for weight and which indicate the most recent effects related to nutrition. This is known as the *Quetelet index* (kg/m^2) which is more generally known as *body mass index (BMI)* which is very informative in the case of an adult whose growth has stopped. In the pediatric and adolescent stages with such variable growth speeds (4.0–15.5 cm/year), it is necessary to have more accuracy.

The relative body mass index (rBMI) is probably the least erroneous when it comes to fixing the degree of nonchronic subnutrition. This is due to the fact that height is used and this quotient is referred to the same quotient as 50 percentile of the age and gender reference population charts according to the formula ($kg/m^2/kgp50/m^2p50) \times 100$ and accurately identifies cases of acute subnutrition.

For *rBMI*, the figures of 85–90% are accepted as underweight and as subnutrition when they are below 85%. The advantage is that it can be calculated just with a growth chart and a simple calculator. The rBMI is less accurate in the cases of stunting where the accumulative effects of subnutrition have diminished the height. In these cases, and before qualifying this lack of height as nutritional, it should be ruled out as familial short height by means of target height which is obtained according to the *formula (paternal height + maternal height)/2 + 12 in the case of boys and −12 in the case of girls*, all data in centimeters. Also the neonatal status must be known (*small gestational age*) because it could affect the growth velocity. Finally, considering previous heights, specially in the first 2 years of life is of a great help as well as evaluating genetic and medical causes for short height.

In practice, the basic measurements usually focus on height (or length) and weight. Weight may be measured fairly accurately if the proper scale applicable to each age group is available and well calibrated. The physician may face some difficulties in trying to get the exact height (length) for the young infant. Such an exercise may often require more than one person and more than one measurement to be exact. In spite of all the difficulties and limitations, the anthropometric measurements remain valuable in the overall evaluation of children with malnutrition.

The body mass index z-score: zs = (BMI patient – BMI p50)/standard deviation of BMI for age and gender gives analogous information to that of the rBMI, the cutoff points are: *underweight – 1 – 2 SD* and subnutrition when it is greater than −2SD. *The z-score* when calculated for weight alone in relation to age and gender enables also to evaluate with greater accuracy chronic and recent subnutrition than the percentile plotting. The incorporation into the clinic of computer programs (*Seinaptracker*) makes this calculation easier and allows a wider use and more accurate diagnosis for the present situation and evolution of the patient. The advantages of using z-score are that it allows to quantitate the degree of underweight (or overweight) estimated by means of the BMI in relation to a national reference growth chart. Then the distance from individual BMI to the mean (or median), evaluated in SD units, permits a comparison with other pediatric population, and particularly to follow quite accurately the evolution of a child or of a determined group (Fig. 53.1).

Causes

In Developed Countries

In developed countries, as opposed to those developing countries, inadequate quantities of food, lesser degree of family education, or a poor health system are rare causes of undernutrition. Catastrophes, economic crises, or war can lead to the appearance of these factors, although they do not usually last as long as in developing countries. On the contrary, illnesses, especially chronic, play a more important role since they can imply anorexia, higher caloric requirements (infections, fever), or impair digestive and absorption functions. In practice, these situations, once the so called *infant – dystrophy* has gone, are represented by the following illnesses: cystic fibrosis, illnesses of the digestive tract which have not been diagnosed in time, chronic renal failure, cancer and its (chemo and radio) therapy, congenital heart disease and neurological (cerebral palsy),

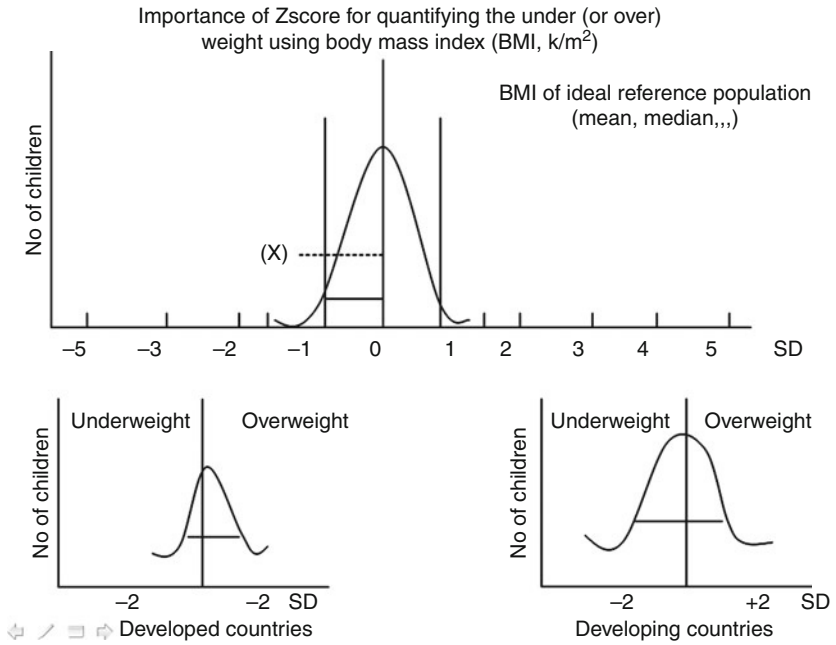

Figure 53.1

In the *upper* part, a normal distribution of BMI is shown. The distance from any individual case (x) to the mean of the reference population by gender and age can be evaluated by means of the z-score formula, obtaining accurate results expressed in standard deviation units. In the *lower* part of the figure, a representative curve of the nutritional status in developed countries is shown, with skewness toward the *right*. In developing countries, there is a skewness toward the *left* but also with a modest increase toward the *right* due to the obesity rise

and muscular illnesses. Less frequent causes but with potential capacity for malnourishment are lead poisoning, severe burns, HIV infections, and anorexia nervosa.

Prematurity must be taken into account, especially when these children are small for gestational age and if they are symmetrical (weight, height, and head circumference all below the 3rd centile) since these will have a poorer growth recuperation in spite of correct nutrition or even if supplemented. On the contrary, an asymmetrical child (reduced weight but with normal height and head circumference) responds better to these nutritional practices. The preterm adequate for gestational age is also a candidate to suffer from malnourishment at a later stage or earlier as consequence of common complications (bronchodysplasia, postsurgical short intestine, oral aversion, etc.); this implies special nutritional attention and focus on food from the beginning.

Another group of interest in the genesis of malnourishment are the *congenital anomalies* such as cleft palate or genetic syndromes in some of which short height is a part and therefore stunting must be discarded.

Within the family atmosphere, it is essential that taste perception of the newborn must be stimulated at the right time (*beikost*) because if this is not the case, the intake of solid food becomes difficult and results therefore in a reduction of food quantity and quality. This block of factors is also known as psychosocial subnutrition (and stunting). This is also known as the *syndrome of lack of affection, negligence, etc.* which although not reaching the stage of child abuse, goes on for a longer period of time. This is discovered on occasion when the family describes the child as temperamental, with sleeping problems and generally difficult to bring up.

The presence of the polymorphism C825T in the gene GNB3 brings less sensation of hunger and less sensation of discomfort or unease about this; this leads to a lower food intake in these patients. It is also possible in this way that a malfunction of satiation gut hormones (CCK, PYY, and GLP) can also contribute in certain cases.

In Developing Countries

In developing countries, the protein-calorie deficiency and also deficiencies in the most common specific nutrients, such as iron, zinc, iodine, and vitamin A among,

primarily exist. To these, other social factors like maternal malnutrition, ignorance, demographic explosion, poor housing conditions, lack of hygiene, poorly developed sanitary system, low family income, and difficult access to basic medical care must be added. Severe repetitive acute infections (diarrhea) or chronic (HIV) are other frequent circumstances predisposing toward malnutrition. These factors are more important than the protein-calorie deficit itself, as are also some previous actions (being given food versus agricultural teaching) with the aim to make up for this scarcity. An important factor is the stopping of breastfeeding early on, specially in circumstances when Beikost is for most part subject to carbohydrates. Food insecurity for young children formerly described in developed countries, occuring when nonfinancial factors such as maternal mental problems are widely applicable here, not only for the low socioeconomic status but also for depression or domestic violence. Nevertheless, it is important to conclude with the idea that malnutrition in developing countries is not due to one single cause and these other factors will certainly contribute.

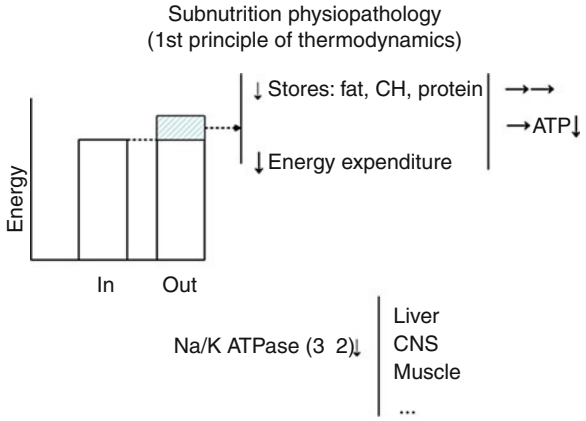

Figure 53.2
Subnutrition pathophysiology. According to the first principle of thermodynamics, the negative energetic balance is covered by a diminution of the stores and also by reducing physical activity (energy expenditure). After a long metabolic path, a reduction of ATP synthesis occurs. This will impair many functions as is shown in the *lower* part of the figure

Physiopathology

The child with severe malnutrition must be treated differently, because his physiology is seriously abnormal due to reductive adaptation. The system slows down and does less activities in order to allow survival on limited calories. This slowing down is known as reductive adaptation. As the child is treated, the body's system must gradually learn to function fully again.

A nutrition deficiency affects practically all organs and systems, especially in a phase of growth. Dietary proteins must provide essential amino acids for diverse synthesis in both facets, the structural and functional roles. Energy supplied by fat and carbohydrates is fundamental for all biochemical and physiological functions of the organs. When faced with a deficiency, the equilibrium is initially reached by metabolizing the energy stores and by a reduction of energy expenditure, mainly on physical activity, growth velocity, and body temperature, because the greater quota (resting energy expenditure 70%) is hardly modified at least in the initial and medium phases and so will be the diet-induced thermogenesis or energy used in digestion, absorption, and transport of nutrients (10%). As a consequence of this adaptation, changes appear which will be analyzed below. Besides the energetic aspect, the adequate intake of micronutrients must be taken into account as these are essential for different metabolic functions as they are components and cofactors in multiple enzymatic processes (*Fig. 53.2*). The physiopathological consequences of energy reduction depend on four major factors:

1. The type of energy restriction
2. The age at which it starts and its duration
3. The previous nutritional state
4. The existence or not of acute repetitive or chronic infections

The classic animal experiences with food restrictions and studies on children with malnutrition have allowed one to show how initially there is a depletion of fat and later a depletion of glycogen. If the situation persists, the protein catabolism will maintain basal needs. Hormonal changes are in a certain way responsible for these situations and among these must be considered the rise in cortisol, the lesser secretion of insulin, as a certain marginal resistance to this. An increase of GH but with a poor response of IGF1 and an increase in production of aldosterone also are found. The fact of a lesser synthesis of ATP in this last context brings with it an impaired function of Na/K ATPase, a sodium pump for the interchange of sodium for potassium at a rate of 3 x 2 with the consequent increase of intracellular Na and a reduction of K. But depending on the tissue where this reduction of

exchange takes place, the clinical consequences are different and of course do not make clear the initial implication in the genesis of the edema. Probably the reduced synthesis of albumin in the liver (fatty or not) could be the most important factor.

Another approach for water retention should be considered. Edema is a well-recognized clinical manifestation of subnutrition of childhood. The relationship between hypoalbuminemia and edema formation is well recognized in kwashiorkor. Since the early 1970s, it has been suggested that the cause of edema in kwashiorkor is hypoalbuminemia followed by reduced oncotic pressure. In marasmus, the low-energy supply stimulates cortisol secretion, which results in wasting of the muscles and as a consequence, essential amino acids become available for albumin synthesis. However, in recent years, the contributory factor of hypoalbuminemia in the pathogenesis of edema in kwashiorkor has been challenged. Further studies have demonstrated that the degree of the edema shows poor correlation with plasma protein concentration. The edema often resolves despite continued hypoalbuminemia. Edema in kwashiorkor was reported among affected children with a serum albumin higher than 17 g/L. The occurrence of edema in subnutrition may be a result of misdistribution of excess water between extra- and intracellular compartments. *Renin* activity in plasma is also increased in kwashiorkor. Subnutrition can also be associated with deficient ability to concentrate urine. The presence of aminoaciduria in this situation points to proximal tubular dysfunction. It is therefore appropriate to consider that the retention of water and salt in kwashiorkor is at least partly caused by altered renal function. Studies on groups of affected children have also shown that the average blood creatinine concentration was higher than in the well-nourished ones, while the urine volume was significantly lower in the group with subnutrition. Furthermore, they show a tendency to retain sodium and fluid whether they are edematous or not. Plasma *free iron* was also claimed to contribute to the mechanism of edema in kwashiorkor.

Clinical Manifestations

A meticulous history and physical examination are fundamental here since laboratory tests yield very little for an early diagnosis of subnutrition. It must be taken into account that the feeling of hunger is rarely expressed and an absence of other symptoms is the norm except for very severe cases. The mother's circumstances must be recorded in the anamnesis. The questions related to the child imply his efficient incorporation into the health system; if he can attend primary care regularly (vaccination, oral hygiene, etc.), developmental milestones and illnesses suffered, especially infections. The somatometric history is of an utmost importance and if possible should include weight and height of parents and of siblings and also previous data of the child. This can signal the beginning and evolution of subnutrition indicated by less weight and height gain. A nutritional record is also extremely important: Probably the most reliable is an absolute recall of what has been eaten in the last 24 h, but this is not fully representative. A prospective record is better of all the food to be taken in the next 5 days which is a way to assess the intake of proteins and energy. It is necessary to know for certain if the child feels hungry. The data related to family food habits and how meals are eaten is fundamental in cases of subnutrition. The following point is the social situation: age and occupation of the parents, possible family stress, and the economic situation in the home. In all cases of subnutrition or underweight, the anamnesis must be oriented toward the coexistence (classic secondary subnutrition) of organic illnesses by means of the presence of other signs and symptoms like anorexia, mood swings, dysphagia or vomiting, the type and number of stools, recurrent fever, and polyuria.

The 5 principles clinical signs of severe malnutrition are: severe wasting, edema, dermatosis, eye signs, and stunting.

Severe Wasting

The outline of the child's ribs are easily seen, skin of the upper arms looks loose, the skin of the thighs looks loose, the ribs and shoulder bones are easily seen, and flesh is missing from the buttocks.

Edema

The extent of edema is common rated in the following way:

+ Mild: both feet.
+ + Moderate: both feet, plus lower legs, hands, or lower arms.
+ + + Severe: generalized edema including feet, legs, hands, arms, and face.

Dermatosis

It is more common in children who have edema than in wasted children.

The dermatosis is classified in the following classification:

+ Mild: discoloration or a few rough patches of skin.
+ + Moderate: multiple patches on arms and/or legs.
+ + + Severe: flaking skin, raw skin, fissures.

Eye Signs

Children with severe malnutrition may have signs of eye infection and/or vitamin A deficiency.

Bitot 's spots : superficial foamy white spots on the conjunctiva.

Pus and inflammation.

Corneal clouding.

Corneal ulceration: which is a dangerous and urgent situation that requires immediate treatment with vitamin A and atropine.

Stunting

Which is unusually low height or length for age, often due to chronic malnutrition.

The standard deviation (SD) is a way of comparing the weight with height of the patient, Patient is considered as severely malnourished if his SD – score is < 3 SD.

The physical examination should be preceded by very precise height and weight measurements as the diagnosis of subnutrition will only be reliably given if the data is accurate. Genetically small children (normal variant of short height) usually have a normal weight for their height (rBMI 90–110%); they even usually have a head circumference in the same percentage. When subnutrition (and stunting) exists, a fall in the weight chart is first seen, and later is the height, but to assess them, a prolonged observation with monthly intervals is required. A thorough examination of systems is necessary for the diagnosis of underlying illnesses which may cause subnutrition or undernutrition. Apart from this quantifiable and clinical data, there is also present a less interaction between mother and child, with less visual, physical, or verbal communication.

The presence of lack of hygiene, nappy/diaper rash, or deficient buccal care implies a situation of abandonment or negligence. This is being so frequent in failure-to-thrive cases. If it is more severe (emaciation), then the skin is dry, inelastic, pale and cold, hair is sparse and falls easily, there is less muscle-mass and easy fatigue, a lack of interest in what is going on, more frequent infections, and slow healing of wounds.

To end this clinical context, it is necessary to mention the social risks of undernutrition. Children are targeted by bullies, judged as unhealthy and faible and if adolescent, rejected by classmates.

Complementary tests: This can be limited initially to a complete blood test, CPR, albumin, alkaline phosphatase, total cholesterol with a urine analysis and culture. One must remember that the markers are never too early and for caloric deficiency are the serum reduction of albumin and total cholesterol. The classic malnutrition markers (IGF 1, pre-albumin, RBP, test for immune responses, amino acid levels, essential fatty acids, vitamins, and trace elements) are found to be altered in only 1% of the cases which occur in the western world, while their determination in developing areas is more complicated and resource consuming. At least one must make sure that there is no lack of iodines, or of vitamins A and D, and specially iron. Cases with an important malnutrition are also candidates to studies of endocrinology, hepatology, cardiology, and especially for gastrointestinal tract disorders due to the therapeutic implications and prognosis that they may have.

Marasmus and kwashiorkor: These are the two syndromes mentioned by McCance as representative of a serious protein-calorie malnutrition.

The marasmus (non-edematous malnutrition) is produced by global energy deficit and comes between 6–18 months of age coinciding with an insufficiency of breast milk, use of formulas, or a too diluted milk, all this accompanied by frequent infections. It is characterized by a slowing down or even stop in weight increase, then followed by a loss of subcutaneous fatty tissue. If the situation continues, then muscular devastation appears also. There are general irritability and usually constipation but with occasional bouts of diarrhea which is difficult to treat. Examination reveals a chronically ill child with apathy and wizened (old man) face attributable to the disappearance of the buccal fat. The child looks thin, wasted, with loss of fat and muscles (Fig. 53.3) but also with distended or scaphoid abdomen and delayed physical development. The eventual development of lactose malabsorption contributes to the abdominal distention. There is an obvious loss of subcutaneous fat with decreased skin-fold thickness, the loss of subcutaneous fat around the buttock shoulder,

Figure 53.3
A marasmic young infant with classic features of apathy, marked wasting with easily seen ribs, and loss of subcutaneous fat

Figure 53.4
A child with severe wasting: **The outline of the child's ribs is easily seen, skin of the upper and lower limbs looks loose, the ribs and shoulder bones are easily seen, and flesh is missing from the buttocks as well as from the rest of the body**

and trunk and limbs complete the clinical appearance (*Fig. 53.4*). Marasmic children are often hypotensive; the presence of bradycardia and hypothermia is ominous. Hypoglycemia is common, but serum albumin and electrolytes are usually normal. It is important to screen marasmic children for associated infections and vitamin deficiencies.

The name *kwashiorkor* (edematous malnutrition) is identified as disease affecting the deposed child, the disease that the first child gets as the mother is expecting another child and tends to neglect the first one or following the arrival of the new baby. In the kwashiorkor, there is an energy intake at the limit but with a predominant protein deficiency generally coming between 18 months and 5 years of age.

Clinical Manifestations. The sign which best defines it is the presence of edema initially in the lower limbs and rapidly ascending even as far as the face. This can conceal the weight loss which always exists, but with growth delay, muscular devastation, anorexia, psychomotor alterations, gastrointestinal disorders with a tendency toward prolonged diarrhea, liver enlargement (steatosis), skin wounds or ulcers, and the hair is sparse, depigmented, reddish gray in color, and falls easily. All of these allow a simple, clinical diagnosis. When this situation continues, initial lethargy and apathy advance to a state of hypotension, hypothermia, coma, and death. Fortunately, both conditions are becoming rare and rarer in the developing countries, where once they widely existed.

Evolution and Prognosis

Long-Term Effects of Subnutrition

A prospective study on children with severe malnutrition addressed the issue of whether early malnutrition results in permanent physical and behavioral deficits or not. The study, which began in the early 1960s and ended in the following decade, demonstrated both *physical stunting and intellectual impairment* among those children. Other studies have also shown some permanent

defect in stature if growth was arrested by malnutrition in early infancy.

Subnutrition is associated with evidence of gastrointestinal damage manifested as chronic diarrhea and failure to thrive. There is also a variable degree of mucosal atrophy of the small and large intestines, with plasma cell infiltration of the lamina propria. The disease is also associated with evidence of pancreatic insufficiency.

Animal studies have further reported that malnutrition resulted in retardation of cellular growth as well as cell division of the brain.

Malnutrition was also demonstrated to adversely affect the IQ status of schoolchildren who were hospitalized during their first year of life. The difficulties of such studies are in the selection of which controls and which standard to use.

Early malnutrition may also result in long-standing *behavioral deficits*. Such observation remains a subject of debate, as it does not apply on certain conditions associated with malnutrition such as cystic fibrosis, where affected children do not necessarily demonstrate reduction in IQ or school performance.

Subnutrition may also be associated with *respiratory* and *myocardial dysfunction*.

Night blindness is a major public health hazard in developing countries caused by insufficient consumption of beta-carotene-rich foods and high prevalence of PEM. An association between PCM, *xerophthalmia*, and night blindness has been reported from Bangladesh as well as from other developing countries. Children with PCM are more susceptible to infections that result in further deterioration of their nutritional status as well as further depiction of vitamin A stores.

In the short term, in the cases of severe malnutrition (weight ZS greater than −4 SD or weight for age at 60–70% or rBMI <70%), death occurs in half of the children under 5 years of age. Even when this reduction is 80%, the risk of death is superior to that of the normal local population and always closely related to infections. Recent data from Ethiopia show a mortality of 21.3% of hospitalized children under 5 years. These figures cannot be applied to the westernized world, where death by this cause is really exceptional.

In the long term, children with chronic malnutrition, even when this has been cleared up, show behavioral disorders such as irritability, apathy, anxiety, and lack of attention. This implies a reduction of about 10 points in cognitive function in relation to children with normal nutrition in the same environment. This will continue beyond adolescence with a weight and height deficit, poor muscle structure which results in less capacity for work.

An association between adiposity and stunting has been described particularly when undernutrition is over; therefore, attention should be paid to the changes in body composition, particularly in abdominal fat accumulation for the risks that it implies. Infertility when adult ages are reached is another risk of long-lasting children and adolescent undernutrition. Both these factors lead to a poor economic level and the situation carries on. These consequences have been shown in the long term even with patients studied recently in the USA. When will these consequences be reverted? This cannot be known, but the sooner the causes are solved and social environment improves, the better.

Treatment

In secondary subnutrition, the treatment of the underlying illness is the first and most important step. The nature of the originating illness makes the second step, dietary therapy, to be more or less effective, as for example in the case of cystic fibrosis. In the cases of primary malnutrition owing to an inadequate intake of energy and/or protein, the nutritional therapy is the most important. A properly selected and available diet is the mainstay of treatment of PCM. Improvement of the general diet with increased consumption of dietary vitamin A to reduce the risk of night blindness and other complications of vitamin A deficiencies is advised. It has been implicated that supplementation with vitamin A capsules alone without dietary supplements may not result in a sustainable reduction in vitamin A-related morbidity.

The association of subnutrition and being in hospital must be taken into account even in the developed world; criteria for hospital admittance is as follows.

Serious and severe subnutrition (rBMI < 80%) Concomitant dehydration, adverse family circumstances, and Failure of primary care therapy.

Treatment of Moderate Subnutrition

This is the most frequent. The energy supply can be increased by intake of higher caloric food than previously taken and nutritional supplements, but in a flexible and progressive way. By doing this, the intake of macronutrients is fundamentally increased, but it is important to keep in mind that this will not prove very effective unless family environment and factors also improve. In the case of

formula-fed babies, it is sufficient if the formula has a correct concentration and its volume is adequate for the weight of the baby.

In the case of children, the caloric intake can follow the *simple rule: kcal per day = height (cm) × 15* and is to be divided between four meals a day; these can be enriched with oils, butter, full fat milk, and cheese. When dealing with moderately undernourished children in a low socioeconomic scenario, dietary counseling can be as effective as food supply itself in medium-term subnutrition, particularly when the cereal-dominated diet is common. Plant foods should be processed to maintain the energy density (avoid diluted gruels) or diminishing the eventual antinutrients (protease and amylase inhibitors or lectins) in pulses by a thorough cooking. The beneficial quality of animal-source foods should be stressed because of their quality of protective nutrient. They should be taken whenever possible, although there is no factorial approach for minimums, due to high-quality protein, high level of minerals (milk), and lack of antinutrients. From a complementary point of view, a multivitamin and microminerals product especially with iron and zinc should be administered.

There is no need to use hydrolysate; the prevalence of Cow's milk allergy in severely malnourished patients is not higher than the habitual incidence (5% of the severe malnutrition cases).

Apart from the treatment, social and economical aspects play a fundamental role and on many occasions escape medical attention. When social workers are available, the weekly house visit has been shown to be very effective. Alternatively, the patient may go to appointments at outpatients to control weight evolution and diet planning. Another factor to keep in mind is behavioral attitude with respect to mealtimes, avoiding distractions (TV) and sweets or snacks between meals.

Treatment of Severe Subnutrition

When talking about prognosis, it has been seen how in children under 5 years of age, half of the deaths are related to severe malnutrition. It must be added here that after analyzing more than 60 studies throughout the world, this mortality figure has not gone down in the last five decades. In 1999, WHO published a manual for the management of severe malnutrition which could be applied to a great number of children even in rather unfavorable hospital conditions. It establishes the following phases.

Initial or acute phase (2–10 days), here preferably oral rehydration is set up (Na 45 mmol/L; K 40 mmol/L). Treatment of hypoglycemia is also set up and of any infections or infestations. Dietary therapy is also started. The formula "F75" (75 kcal/kg and 1 g/kg/day of protein) put forward by WHO has not been tested very thoroughly, and in the cases of marasmus, the use of a conventional formula gives good results. In any case, calorie density should be between 75 and 100 kcal/kg/d and must never exceed 100 kcal/kg/day. If the child was breastfed, this should be kept up, but with the certainty that additional intake will be necessary.

The IV fluids administration is limited in case of shock from dehydration or sepsis. In this case, 15 ml/kg over 1 h should be given. Repeat the same amount of IV fluids for another hour,with one of the following solutions (listed in order of preference):

- Half-strength Darrow's solution with 5% glucose (dextrose)
- Ringer's lactate solution with 5% glucose
- 0.45% (half-normal) saline with 5% glucose.

After 2 h of IV fluids: use of oral or nasogastric rehydration with ReSoMal (5–10 ml/kg) in alternate hours with F-75 for up to 10 h.

If the child fails to improve after the first hour of IV fluids, a septic shock is possible. The blood transfusion is necessary, with 10 ml/kg over 3 h, in association of diuretics administration to avoid the heart failure. (In case of heart failure, give packed cells instead of whole blood) . The risk of developing cardiac arrhythmia could be prevented by starting the treatment with progressive energetic quantity (100 k.cal/kg/day). The energetic quantity will be increased meal by meal after the stabilization of the child's status, to arrive at the end of the protocol to 220 k.cal/kg/day.

Starting with high quantity of liquids could provoke cardiac failure by overload, which explains the necessity of the avoidance of IV fluids as possible.

The second phase or rehabilitation (2–6 weeks) is the one in which the child increases both his dietary intake and weight, and this period supposedly should be spent in hospital. The treatment from the acute phase would be complemented and a diet ("F100" formula or conventional) would be established. In this, there is an increase of 25 kcal/kg/day until a good tolerance is reached always inferior to 150 kcal/kg/d and to 4 g/kg/d of proteins so as to avoid the "*refeeding syndrome*" (fall in plasma Pi due to intracellular migration) which can lead to death by cardiac arrest.

The third phase or follow-up implies the child going back to his family environment which has supposedly improved, at least educationally and to set up an outpatients follow-up.

This plan widely disseminated in the developing world has not, at least initially, lived up to its expectations.

Feeding is a critical part of severe malnutrition management; feeding should begin as soon as possible to prevent fatal complications. The feeding is based on the use of special solutions: F75 (used in the acute phase) and F100 (used in the stabilized phase).

The use of these solutions is based on the physiopathological guidelines; F75 contains 75 K.Cal/100 ml, and F100 contains 100 k.cal. F75 is low in proteins (0.9 g/100 ml) and sodium, high in carbohydrates, which decreases the risk of the renal overload and prevent the hypoglycemia; F100 provides high quantity of calories in limited volume, which prevents all possible cardiac dysfunctions.

The F75 and F100 are given to patients in a special protocol to avoid all possible complications.

The F-75 and F100 could be prepared in hospitals using different types of dried or whole or skimmed cow milk.

Weight Gain During Treatment

Weight gain is classified in three categories and estimated in g/kg/day: well weight gain is >10 g/kg/day, moderate weight gain is: 5–10 g/kg/day, poor weight gain is $<$ 5 g/kg/day.

The causes of the poor weight gain are: feeding preparation errors, tuberculosis, or infections. Tuberculosis is too difficult to be diagnosed; the presence of adenopathy or poor weight gain are the most common signs. The tuberculin test is always negative secondary to the cellular immune deficiency, and the treatment has to be started when the weight gain is absent for more than 10 days after a standard management.

Prevention

The severely malnourished infant is at risk of developing a number of complications such as hypothermia, hypoglycemia, encephalopathy, intractable diarrhea, cardiac failure, and infections. The increase in birth weight should be accompanied by a significant decrease in neonatal morbidity and mortality. Supplementation during late pregnancy can have a significant beneficial effect on birth weight in women who are genuinely at risk because of an inadequate food intake. With appropriate care management in hospitals and follow-up care, the lives of many children can be saved; the fatality rate could be reduced from over 30% in the old protocol to less than 5% if the new protocol is well applied.

At an individual level, the prevention of subnutrition in the pediatric age starts with prenatal nutrition, encouraging breastfeeding, the wise introduction of beikost, and the often ignored food control in the second year of life. All of this is relatively simple for developed countries which also have over 90% coverage of vaccinations and a good health system. However, in the developing countries, this is more complicated, even in situations where nutritional support is offered by other countries.

On certain occasions, pediatric subnutrition is only secondary to the health system shortcomings and which are not easily recognized by those responsible. The importance of political intervention for prevention can be seen here. A preventive chain at national, community, family, and child levels must function (as it did in India with the administration of vitamin A) with specific programs aimed at not only providing adequate nutrition but also for the prevention of infections and hygiene improvement, although these are not always given the priority they deserve. In general, subnutrition is decreasing at the same rate as poverty.

54 Nutritional Modulation of Intestinal Gene Expression

Ian R. Sanderson

Childhood is a time of great change in nutrient intake. This review will examine how nutritional changes alter the expression of genes in the intestine (the point of interaction between the child and the nutritional environment). Unlike other organs, the intestine is not shielded from the major environmental changes of childhood. In the fetus, the intestinal lumen is sterile and the fetal circulation provides nourishment. But after birth, it interacts with an extremely complex environment containing nutrients in varying concentrations. At weaning, this level of complexity increases further.

Altering the expression of genes has become a rapidly developing area of research in medicine. The realization that gene expression is important in a wide range of diseases (and not just in inherited disease) has resulted in the whole field of gene expression being recognized as one which may bring new therapeutic options. Although most recent attention has focused on the benefits of altering gene expression by inserting new genetic material into cells, the expression of genes can also be altered by other means, most notably by changing the molecular environment that cells inhabit. Utilizing the natural responses of a cell to changes in its surroundings offers a new and amenable way to alter the expression of its genes. Many ways of altering these surroundings can be proposed, but no single act alters the environment of the cells of the intestine more than the ingestion of food. Thus, the future of nutrition as a therapeutic tool may lie in its potential for influencing gene regulation. This chapter will examine this emerging field and will lay down some concepts which may prove useful in establishing the scientific basis from which future treatments may develop.

The survival of a child to reproductive age and beyond requires an ability to respond to external demands. Every organ in the body is attuned to this need. Many organ systems have two levels of response to external changes. There is a rapid response, often occurring within seconds of a new stimulus: the contraction of muscle fibers following a neuronal impulse, or the breakdown of glycogen by the liver during hypoglycemia are examples of how cells can quickly change. Such responses do not involve changes in gene expression. The cells maintain themselves in a state of readiness by synthesizing proteins whose activity can quickly alter in response to external stimuli. Behind this immediate response, there lie other slower, but more lasting, responses that require genetic control. For example, when exercise increases on a regular basis, muscle mass increases, as does the activity of the attendant enzymes that serve the increased metabolic needs. Similarly, regular exposure of the liver to drugs induces the expression of enzymes that catalyze their breakdown.

There are few external stimuli on a child more important than its nutritional environment. The metabolic processes underlying the rapid response of cells to nutritional variations have long been documented in humans and other mammals. However, the mechanisms whereby gene expression changes in response to nutritional stimuli are still poorly understood in humans or indeed in any multiorgan animal. This is, at first, surprising because in bacteria, the study of nutritional changes led to the understanding of some of the most fundamental mechanisms of gene expression. The elucidation of the induction of proteins that transport and hydrolyze lactose (the lac operon) after adding lactose to bacterial culture media was the first examination of any form of gene regulation. These observations spawned an explosion of research in other regulatory genes in bacteria and in unicellular, eukaryotic organisms such as yeast. The upregulation of the bacterial genes that handle tryptophan when this amino acid is scarce (the trp operon) has become another well-understood example of nutrient–gene interaction.

Progress in the study of nutrient–gene interaction in eukaryotic cells has been slower for two main reasons. *First*, the molecular mechanisms controlling gene expression are more complex than in bacteria; *second*, it is more difficult to identify the metabolites of nutrients that may be responsible for inducing such changes. This chapter will therefore cover some of the advances in the study of nutrition on gene expression in the human and, where necessary, in other mammals. Nutritional changes ultimately impinge on most cells in the body; however, it is the epithelium of the gastrointestinal tract that first

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_54,

encounters any variation in nutrient intake. Much of this chapter will therefore concentrate on how nutritional factors can alter the expression of genes in intestinal epithelial cells. The relevance of nutrient–gene interactions to human physiology will also be stressed. Finally, because manipulating nutritional intake may be a way of treating disease in children, the chapter will discuss nutritional therapy in childhood in the light of its effects on gene expression.

The effect of nutrients on gene expression may have different implications in different individual situations:

First, genes may be upregulated to better utilize the supply of a particular nutrient when it is scarce. Transporters of nutrients and the enzymes that metabolize them are examples of proteins that may be induced by nutrients.

Second, the expression of genes required for the storage of a particular nutrient may be altered according to that nutrient's abundance.

Third, nutrients regulate the secretion of hormones that control the homeostasis of metabolic processes. For example, insulin synthesis increases after increased carbohydrate intake to maintain glucose homeostasis.

Finally, food is part of our external environment and as such represents a challenge to the cells that come into intimate contact with it. This challenge is met, in the main, the epithelial cells lining the gastrointestinal tract. The ability of these cells to alter the expression of their genes with changes in food intake is one of the ways by which the intestinal epithelium can dominate the intestinal environment.

Certain fundamental characteristics are found in the mechanisms that underlie each of these different aspects of nutrient–gene interactions. They include a specific interaction between the cell and a particular nutrient (sensing) and a pathway by which such an interaction may translate into alterations in gene expression (signal transduction). There is little understanding of these mechanisms at the present time. However, some aspects of the molecular biology of these two functions will be examined later in this chapter.

Effect of Intestinal Contents on Genes in the Intestinal Epithelium

The gastrointestinal tract is the only part of the body that normally comes into contact with nutrients before they are absorbed. The GI tract is therefore exposed with a wider variety of nutrient molecules than any other organ of the body. The picture is further complicated because the lumen of the intestine is not a direct reflection of the food ingested. It also contains bacteria and their by-products and factors secreted into lumen in response to the ingestion of food. The study of nutrients on the enterocyte therefore should consider how changes in diet may affect the area around the apical aspect of a particular epithelial cell. The dissociation between nutrients ingested and the changes observed in the bowel lumen become greater the further one proceeds down the GI tract. The contents of the distal colon are completely different from food, although even here they are affected to some extent by dietary intake. This relationship between ingested nutrients and the local environment of the lumen is a separate issue from the interaction of that local environment with genes in the enterocyte.

It has been traditional to assume that the expression of genes in the small intestinal epithelium is preprogrammed and that their expression is not influenced by events in the lumen of the intestine. However, this view may be incomplete. An alteration in epithelial cell phenotype secondary to nutritional factors would have three possible advantages:

First, the intestine could adapt to absorb nutrients more effectively if specific digestive enzymes and transporters of the epithelium were upregulated by the repeated intake of a particular nutrient.

Second, as all mammals are fed from mother's milk, the opportunity exists for breast milk to influence the development of the epithelium through actions of its own constituents.

Third, if the genes affected in the epithelium were immunologically important, the intestinal epithelium could influence mucosal immune responses, by signaling information to the mucosal immune system and beyond through changes in the expression of epithelial cell genes. Each of these areas is likely to represent important physiological mechanisms which have implications for child health.

Polarity of Epithelia

Many cells in the body do not depend on a separation of functions to different cellular poles. For example, muscle cells receive signals from the entry of glucose at any point on the plasma membrane and, as far as can be judged, the changes in gene expression are not affected by the site of glucose entry. Cells that form epithelia are different in that they exhibit polarity. This separation between the apical side (bordering the lumen in the case of the intestinal epithelium) and the basolateral side is central to epithelial activity. This property is well recognized in the

field of intestinal transport. Ions, small molecules, and macromolecules are all transported differently across the apical membrane than across the basolateral membrane. It is the polarity of the epithelium that gives direction to the movement of these substances across the epithelium into or out of the body. But this property must also be considered when examining all aspects of intestinal epithelial cell function. *Polarity* is also of fundamental relevance in the study of nutrient–gene interactions in the intestinal epithelium. The polarity of the epithelial cells distinguishes the two major mechanisms by which nutrients (and other luminal factors) affect genes – that of a direct luminal effect on enterocytes from an indirect effect mediated through hormones, growth factor, and cytokines.

Furthermore, the intestinal epithelium acts as a barrier to the external environment contained within the gut lumen. The barrier is not complete as the intestine allows macromolecules to be sampled and actively absorbs nutrients. It has become increasingly realized that the enterocyte itself acts as an immune cell. For example, it has receptors for bacterial products, as well as expressing a wide variety of molecules on its surface that contain immunoglobulin domains. The epithelial cell also expresses proteins that may interact with immunocytes within the intestine. These include surface molecules such as class II MHC and cytokines that are released from the epithelium such as chemokines or IL-6.

These signaling proteins enable the epithelial cell to orchestrate events in the intestine. In our research group, the hypothesis used is that changes in the intestinal lumen regulate the expression of signaling molecules by the epithelial cell. By this means, the dietary effects on the intestinal lumen acts through the epithelium to alter indirectly events in the intestine, particularly those of the mucosal immune system.

There are *two* components within the signaling pathway linking diet and luminal bacteria to the mucosal immune system:

First, the afferent limb comprises the mechanisms whereby luminal changes alter gene expression within the epithelium.

Second, the efferent limb is the effect of proteins expressed by the epithelial cell acting on the immune system of the intestine. There is now good evidence for both these pathways.

It is possible to examine molecular events in the epithelium induced by changes in diet (the afferent limb). A useful model is the expression of class II MHC in the epithelium following weaning of mice. Class II MHC is responsible for presentation of antigen and its expression on the intestinal epithelium of the mouse occurs after weaning. It is therefore possible to wean mice on to a normal diet (mouse chow) or defined liquid formula (enteral nutrition) to examine the difference between these types of nutrition. The epithelial cells can then be isolated from the mice at varying time points after weaning to study the expression of class II MHC and invariant chain, which is co-expressed. The effect of the enteral feeding (vivonex) was dramatically different from normal mouse chow. Normal mice chow induced an expression of these genes between 20 and 30 days of age; whereas during this time period, enteral feeding did not result in their expression in the intestinal epithelium. It is known that the class II transactivator (a regulatory nuclear protein) is, for all cell types so far examined, both necessary and sufficient for class II MHC expression.

Experiments were, therefore, designed to examine whether the diet acted through the class II transactivator (CIITA). In the mouse, there are three isoforms of CIITA. Interestingly, a normal complex diet increased the expression of class II MHC through CIITA IV.

In addition to the dietary regulation of class II MHC, there was a slow, time-dependent regulation and this was found to be due to CIITA III. These experiments show that alterations in the diet have recognizable molecular pathways between the intestinal lumen and the signal transduction machinery of the epithelial cell.

Bacterial fermentation of unabsorbed carbohydrate in the intestine results in short chain fatty acid production. Butyrate levels therefore reflect changes in bacterial populations and in the substrates available for bacterial metabolism. Butyrate levels vary greatly in response to external changes. For example, newborn babies have very low butyrate levels in either the small or large intestine. However, with time, butyrate levels rise to adult levels by 2 years. Interestingly, butyrate levels are much higher in bottle-fed babies than they are in breast-fed babies during the first 6 months of life.

Butyrate levels therefore reflect events in the intestinal lumen and we hypothesized that their concentrations may alter epithelial cell signaling. Its effects on IL-8 and monocyte chemotactic protein-1 (MCP-1) expression were examined. Increasing the concentration of sodium butyrate increased IL-8 secretion while simultaneously decreasing MCP-1 expression. These effects were seen in resting epithelial cell lines but were much more marked in cells that have been stimulated with a pro-inflammatory agent such as LPS or IL-1b.

It is known that sodium butyrate alters histone acetylation. The nucleosome consists of a solenoid of histones wrapped around by an integral of two turns of DNA. Butyrate increases histone acetylation and this reduces

the compactness of the histone. The DNA cannot wrap around the large nucleosome in an integral number of turns. The nucleosome can no longer be packaged into tight bundles. This exposes the DNA and makes it more amenable to transcription factors. The working hypothesis is that butyrate altered the expression of chemokines by this process.

To test this hypothesis, a fungicide, trichostatin A (TSA), which is 700 times more potent in inducing histone acetylation than butyrate, was used. If the effects of butyrate on chemokine secretion were due to increased histone acetylation, the TSA would be expected to reproduce them. Experiments with TSA showed that TSA increased IL-8 secretion and decreased MCP 1 secretion. Both TSA and butyrate increased the acetylation of histone. Furthermore, the degree of this increase in IL-8 varies with the degree of histone acetylation. The effect of butyrate on histone acetylation was also reversible.

In summary: These experiments show that sodium butyrate alters the expression of chemokines in the epithelial cell. In addition, short-chain fatty acids alter this expression through histone acetylation. These experiments, however, do not exclude the possibility that additional effects of sodium butyrate may occur through promoter systems. Indeed, recent studies have demonstrated that butyrate downregulates insulin-like growth factor binding protein-3 (IGFBP-3) through acetylation of an inhibitory DNA binding protein. It is a challenge of future work to examine the interaction between chromosomal regulation, as is seen in these experiments, and promoter-based regulation with both butyrate and other luminal molecules.

Evidence for the effect of epithelial cell gene expression on the mucosal immune system (the efferent limb) has come from the ability to selectively alter the expression of genes in the intestinal epithelial cell by transgenic techniques. Chemokine expression by the epithelium has been used as a model to show that the epithelium can orchestrate the mucosal immune system. The chemokine, IL-8 which, in the human, results in the recruitment of neutrophils was the first identified chemotactic cytokine. However, IL-8 is not expressed in the mouse.

To examine the effects of chemokines on the mucosal immune system, a system was developed whereby the chemokine, macrophage inflammatory protein-2 (MIP-2), whose effects are very similar to those IL-8 in the human, was linked to an FABPI (fatty acid binding protein of the intestine) promoter. The promoter is only active in the epithelial cells of the small intestine and proximal colon. The transgenic mice had an increased recruitment of neutrophils into the lamina propria, and into the epithelial cell fraction, where the FABPI promoter was active. These data show for the first time that the epithelial cell can, through the release of chemokines, alter the mucosal immune function of the intestine in vivo. However, changes in the intestinal lumen may affect many chemokines as well as other cytokines which alter immune function. It is likely therefore that the changes in gene expression in the epithelium have far-reaching effects on the rest of the mucosal immune system.

These signaling processes are important not only in health but also in the treatment of disease. For example, the primary therapy of children with Crohn's disease in the UK is treatment with enteral feeds. Although there are many mechanisms by which enteral feeds may have their activity, it is possible that one of them is by radically altering the luminal environment to such an extent that it varies the signals from the intestinal epithelium to the mucosal immune element. This results in a downregulation of the inflammation of Crohn's disease. By this means, there is a decrease in the inflammatory activity of Crohn's disease.

DNA Methylation and Imprinting

The chapter has described examples of nutrient regulation of gene expression in the intestine. However, mechanisms exist within the genome for affecting gene expression throughout the body. Imprinting is an important example of this. Genomic imprinting is the silencing of one of a pair of alleles, allowing preferential expression of a particular gene from either father or mother. For example, the maternally inherited allele of the gene encoding IGF-II is silenced, resulting in expression that is derived almost entirely from the father's DNA.

Elegant studies in the late 1990s demonstrated that the phenomenon was due to differences in DNA methylation between the two alleles. Around 10% of adults exhibit some loss of imprinting (LOI). LOI of the IGF-II is often present in a condition familiar to neonatologists, the Beckwith–Weidman syndrome, where infants are born with abdominal wall defects in association with hypoglycemia and large organs, most noticeably the tongue. In addition, LOI of IGF-II is associated with certain tumors of childhood, particularly nephroblastoma (Wilms' tumor) and hepatoblastoma.

The variable yellow allele (A^{vy}) of the agouti mouse is an excellent tool in which to study DNA methylation. Expression of A^{vy} depends on a specific long terminal repeat (LTR). DNA methylation changes the gene's expression (and yellow color) by different amounts in genetically

identical mice. Although the level of agouti expression alters a number of downstream processes such as obesity and longevity, the relation between DNA methylation and the coat color has enabled researchers to show that diets rich in nutrients that increase donation of methyl groups cause changes in DNA methylation in coat color. These experiments raise the possibly that there is a direct relationship between diet, DNA methylation, and gene expression. More recently, Waterland and colleagues have varied postweaning diet and altered the DNA methylation and imprinting of the IGF-II gene in the maternal of non-agouti mice, thus confirming that diet can alter the expression of genes through LOI.

Conclusions

The possible number of interactions between nutrients and genes is very large, but this chapter has focused on specific examples where such phenomena may be important in childhood health and disease. The contents of the gastrointestinal tract have a major influence on gastrointestinal disease. It is believed that the luminal regulation of epithelial signaling affects the intestinal inflammatory process, especially because the intestine is an organ where the variations of nutrients are greatest.

55 Enteral Feeding

Mahmoud Bozo · Hisham M. Nazer

Enteral nutrition is a safe and effective mode of nutrition in most critically ill children. The early initiation of enteral nutrition may preserve mechanical and immunological gut barrier function and reduce bacterial translocation and the incidence of sepsis and multisystem failure.

Enteral nutrition is a widely used therapy for nutritional treatment of patients with multiple pathologies.

Most babies are expected to respond well on breast milk as on formula feeding. However, there are well-recognized conditions in which special dietary formula and regimens should be adopted. Dietary manipulation from early infancy has made it possible to ensure adequate enteral nutrition to such affected groups. These measures have saved a good percentage of affected children from having to go on to a parenteral nutrition program. The trophic effects of enteral nutrition are such that it is always advisable to try the effect of their continued administration in continuous nasogastric drip infusion even in a nutritionally insignificant amount. It is only in those children with frank intestinal failure that long-term parenteral nutrition should be considered. Total parenteral nutrition is recognized to result in functional and structural atrophy of the gut.

Enteral nutrition has also enhanced the adaptive process in babies with short bowel syndrome, enabling them to tolerate earlier and better enteral nutrition and to gradually do without parenteral nutrition.

The enteral feeding formula should contain a high percentage of medium chain triglycerides, essential fatty acids, fat-soluble vitamins, as well as glucose polymers. In patients with advanced liver disease, up to 4 g/kg/day of protein may be tolerated.

There are well-recognized conditions in which special dietary formula and regimen should be adopted. Adequate enteral nutrition to such group of children saved them from having to go on to a parenteral nutrition program.

Human milk contains many nonnutritional substances such as immunoglobulins, lactoferrin, lysozyme, and macrophages that enhance host defense. The risk of infection is far greater in formula-fed infants than in breast-fed infants

The introduction of an *elemental diet* has also made it possible for patients such as those with Crohn's disease to go into remission without having to suffer from the side effects of prolonged steroid therapy. An elemental diet as the sole means of nutrition for about 6 weeks was reported to be as effective as oral steroids in inducing remission. The exact mechanism of action of an elemental diet in this regard remains uncertain.

Although many patients manipulate their diets to help treat their inflammatory bowel disease, only parenteral nutrition with bowel rest and exclusive enteral nutrition therapy have been shown effective for the treatment of inflammatory bowel disease. Furthermore, literature supports the use of enteral nutrition in benign and malignant diseases. Studies have shown that infections, sepsis scores, and hospital stays were significantly reduced in the enteral nutrition–supplemented group.

Recent evidence demonstrates that early nutritional support is not only safe but likely necessary to optimize infant growth and neurodevelopment.

The use of synbiotics and probiotics is gaining further acceptance. Supplementation with glutamine may be important for wound healing. Enteral feeding in malnourished child may result in rapid growth of gut mucosal protein.

Polymeric formula has direct anti-inflammatory effects on enterocytes in an in vivo model of intestinal inflammation. The precise mechanism by which total enteral nutrition suppresses inflammation, however, is unknown.

The nutritional status of a patient is believed to have a significant effect on wound healing. Early enteral nutrition with or without glutamine reduces anastomatic inflammation. Several reports indicated the favorable response to the introduction of glutamine in the therapeutic management of children with short bowel syndrome.

Immunonutrition with formulas containing immunonutrients such as glutamine, arginine, omega-3 fatty acids, and nucleic acids have been shown effective in reducing the number of postoperative infectious process.

Enteral nutrition is also introduced in the management of children with various hepatic disorders associated

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_55,

with severe malnutrition. Enteral nutrition is safer than parenteral nutrition and is associated with a reduction in infectious complications.

Indications

Enteral nutrition is indicated in varied spectrum of clinical conditions in which regular oral feeding is not possible as in:

- Inflammatory bowel disease
- Digestive motility disorders
- Pancreatitis
- Radiotherapy or chemotherapy cases
- Some cases of esophagitis
- Some metabolic disorders
- Neurological dysphagia

The types of enteral feeding, or tube feeding, are named according to the feeding route used, the site where the feeding tube enters the body, and the point at which the formula is delivered: nasogastric, nasoduodenal, nasojejunal, gastrostomy, and jejunostomy.

The decision of which type of feeding to use is based on the expected duration of tube feeding as well as physiologic and patient-related factors.

The types of tube feeding most commonly used are nasogastric feeding and gastrostomy feeding.

Nasogastric (*NG*) *tube* is usually used when tube feeding will be required for a short time (i.e., less than 3 months).

Gastrostomy tubes are well suited for long-term enteral feeding or in cases of swallowing difficulties.

Jejunal Tube Feeding is used in children who cannot use their upper gastrointestinal (GI) tract because of congenital anomalies, GI surgery, immature or inadequate gastric motility, or a high risk of aspiration.

Types of Feeding

Tube feedings can be administered by bolus feedings, continuous drip feedings, or a combination of both.

Bolus feedings are delivered four to eight times per day. Each feed lasts about 15–30 min. Bolus feedings are more similar to a normal feeding pattern. In some children this pattern may cause bloating, cramping, nausea, and diarrhea.

Continuous drip feeding may be delivered without interruption for an unlimited period of time each day. However, it is best to limit feeding to 18 h or less.

In some cases (like in inflammatory bowel disease), continuous drip feeding is used for 8–10 h during the night, so that it will not interfere with daytime activities. The infusion pump is a better method of delivery than gravity drip.

Nutritional Considerations

The nutritional liquids are almost ready to use, and do not need to be prepared manually. The age and the nature of the disease determine the chosen liquid for enteral feeding.

Addition of a multifiber mixture with prebiotic components to pediatric enteral nutrition is well tolerated, promotes bifidobacteria and reduces stool Ph, indicating an improved gut health. The use of fiber-containing formula should become a standard practice for the majority of children on enteral feeds. It is likely that the available formulas require higher level of fiber.

The enteral feeding formula should contain a high percentage of medium chain triglycerides, essential fatty acids, fat-soluble vitamins as well as glucose polymers. In patients with advanced liver disease, up to 4 g/kg/day of protein may be tolerated.

Pediatric formulas have been designed for different age groups, and for children with certain diseases: examples are special formulation for regurgitating infants; metabolic diseases; cow's milk or multiple food allergies; and intestinal, pancreatic, renal, and hepatic insufficiency.

Exclusive enteral nutrition is a therapeutic concept to induce remission in children and adolescents with active Crohn's disease.

Some Guidelines to Determine the Liquids

1. Proteins: The daily requirement varies with the age and clinical situation, but on average it is about 1.5–3 g/kg/day.
2. Carbohydrates: The majority of enteral nutrition liquid preparation is free of lactose because of potential lactose intolerance in many affected patients. Carbohydrates present 50–55% of the total caloric intake. The daily needs could start from 10 to 14 g/kg/day.
3. Lipids: The long chain lipids are used in almost all enteral nutrition solutions. Lipids present 35% of the total caloric intake. The daily needs are about 2.5 g/kg/day.

In order to determine the energy and nutrient needs, nutritional status should be assessed before tube feeding is started.

56 Parenteral Nutrition

Mohamad Miqdady · Ruba A. Abdelhadi · Hisham M. Nazer

Introduction

Parenteral nutrition (PN) refers to intravenous infusion of nutrients, including glucose, amino acids, lipids, vitamins, and minerals; it provides a total or supplemental nutrition source for an infant or a child.

Maintaining or treating nutritional status is important and increasingly recognized as a major player in recovery and improving mortality and morbidity. Furthermore, as nutritional components increasingly include properties formerly ascribed solely to medications, the term "nutritional pharmacology" has been coined to more accurately describe these nutrients.

Only about four decades old, the science of parenteral nutrition is recognized as one of the most important therapeutic advances in pediatric gastroenterology and continues to improve the survival and clinical outcome of children with medical as well as surgical conditions.

PN demands a high degree of nursing and medical expertise. It remains a priceless therapeutic method of prolonging survival and ensuring adequate growth and development despite the potential complications, the technical challenges, and negative psychological consequences of oral aversion. Major strides have been made in improving its efficiency and minimizing the risk of complications.

PN is indicated when other means of nutrition have failed or are expected to fail as a short- or long- term therapy to prevent and correct malnutrition and to maintain appropriate growth and development. Maintaining good nutritional status is essential in growing children.

In general, PN is indicated when the use of the gastrointestinal tract is not possible or if the absorptive ability is insufficient to meet nutritional requirements. Early prophylactic PN is also required in the very small infants in whom the enteral route fails to work or work adequately. Enteral nutrition, when possible, is always considered the preferred mode of nutrition.

Indications

When enteral feeding is not possible for a variety of medical, surgical, and metabolic reasons, PN is indicated to prevent malnutrition. The list of PN indications has become longer over the past several years and now encompasses a multitude of gastrointestinal and non-gastrointestinal conditions.

Gastrointestinal related indications can be categorized into three main indications (Table 56.1):

1. Malabsorption syndromes: whether it is secondary to medical or surgical causes. Short bowel syndrome remains the commonest and most classic indication for long-term TPN.
2. Need for bowel rest as in acute pancreatitis or Crohn's disease.
3. Congenital or acquired neonatal pathology of the GI tract.

Non- gastrointestinal indications are many (Table 56.2), and may be categorized into the following:

1. High catabolic states: for example, children with malignant disease, post organ transplant or major surgery.
2. Metabolic disorders: like inborn errors of metabolism or end-stage liver disease: in these cases, PN with appropriate amino acid composition is used with close monitoring.
3. Renal: end-stage renal disease, severe tubulopathy, in these cases PN with appropriate electrolyte constituents is used with close monitoring and frequent adjustments.
4. Hematologic/oncologic: may include children with malignant disease or post bone marrow transplant. Children with malignant disease are unable to take adequate amounts of calories enterally due to anorexia, mucositis, and emesis related to chemotherapy.

Children with radiation enteritis may also suffer from GI dysmotility. PN has had a big impact on the management of patients with malignancies.

Contraindications

In general, PN should not be used in clinically unstable patient. Medical disorders in otherwise relatively stable

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_56,

Table 56.1
Gastrointestinal-related indications for parenteral nutrition

I. Malabsorption syndromes:
Short bowel syndrome
Congenital microvillus atrophy
Neonatal surgical emergencies
Multiple intestinal atresia
Intractable diarrhea of infancy
Autoimmune enteropathy
Acquired immunodeficiency syndrome
Intestinal bacterial overgrowth
II. Indication for bowel rest
Acute pancreatitis
Crohn's disease
Ulcerative colitis
Low birth weight, prematurity
Necrotizing enterocolitis
Radiation enteritis
Henoch Schönlein purpura
Intestinal lymphangiectasia
III. Congenital or acquired neonatal pathology of the GI tract
Necrotizing enterocolitis
Extensive small-bowel resection
Omphalocele
Gastroschisis
Meconium ileus
Hirschsprung's disease
Severe motility disorders
Hypo-peristalsis syndrome
Chronic intestinal pseudo-obstruction syndrome

Table 56.2
Non-gastrointestinal indications for parenteral nutrition

V. High catabolic states
Malignant disease
Organ transplant
Major surgery
Significant trauma
Severe burns
VI. Metabolic disorders
Inborn errors of metabolism
Cystic fibrosis
End-stage liver disease
VII. Renal
End-stage renal disease
Kidney transplant
Severe tubulopathy
VIII. Hematologic/oncologic
Malignant disease
Solid tumors
Leukemia
Bone marrow transplant

patient can usually be managed with appropriate adjustment of PN constituents. Fat emulsions have undeniable benefits of providing more than double the amount of calories per gram as compared to carbohydrates or proteins; they also correct essential fatty acids deficiency and these benefits are not to be underestimated. Medical management should be individualized so as the benefits outweigh the risks.

Lipoprotein lipase (LPL) activity is significantly reduced in profound malnutrition, but rapidly improves with the start of anabolism. Malnourished infants and preemies are at a higher risk of developing hypertriglyceridemia secondary to a much slower clearance of the intravenous fat emulsions (IVFEs). Inadequate clearance of IVFEs may result in overload of the reticulo–endothelial system. In such patients it is prudent to start with a relatively small amount and advance slowly with close monitoring.

The contraindications to the use of IVFE may include severe sepsis, metabolic acidosis, respiratory distress syndrome, disseminated intravascular coagulation, and thrombocytopenia. In neonatal hyperbilirubinemia, caution is advised as free fatty acids may displace the unconjugated bilirubin from albumin.

Daily Requirements of Parenteral Nutrition

The total amount of calories, including enteral and parenteral, and other specific nutrients, should meet the child's needs. This section will present general guidelines of the estimated caloric needs according to different age groups. It is important to remember that different disease states may have specific energy, fluid, and nutrient requirements or restrictions. Energy in a child is required for both maintenance of body metabolism as well as for balanced growth and these may dictate the needs. The PN constituents should be adjusted according to the child specific requirements, clinical progress, and monitoring of lab results. The protein requirements of neonates and children will vary according to age. The Dietary Reference Intake (DRI) for total energy and protein intake varies with age.

The recommended DRI for total energy is 102 kcal/kg/day in the first 3 months of age and is less later in life up to the age of 3 years (80 kcal//kg/day). The DRI for total energy decreases gradually with age to become about 47 kcal/kg/day for children over 10 years of age. Furthermore, the DRI for protein also changes with age from 1.52 g/kg/day for the first 6 months of age and gradually becomes 0.95 g/kg/day for children from 3 to 14 years of age.

It is obvious that neonates require more protein per kilogram of body weight than children, and children require more protein than adults. Providing amino acids is a priority and should be started as soon as possible to reverse a negative nitrogen balance. The infused amino acids are primarily to provide structural and visceral proteins and enzymes and not to supply energy. It is customary to start with lower than required amount of amino acids and increase it slowly over few days. Adapting such practices may carry the risk of delay in achieving adequate intake and this should be avoided at all cost.

It is not recommended to exceed 4 g protein/kg/day since it may result in azotemia. It is not only the amount of protein that matters, but the quality of the protein too. For example histidine has been shown to be a conditionally essential amino acid in neonates up to 6 months of age, growth is compromised in its absence. Cysteine prevents calcium and phosphorus precipitation by increasing the acidity of the PN solution; this particularly might be helpful in patients who require higher amounts of calcium or phosphorus.

There is no essential amount of carbohydrate needed by the body; in its absence the human body can synthesize it from proteins and lipids. It is quite important to provide enough carbohydrate to prevent catabolism of body proteins and fats. Carbohydrates are provided as dextrose in PN solution. Generally, carbohydrates should comprise 40–50% of the total caloric intake in infants and children. Carbohydrates are usually calculated as glucose infusion rate (GIR) (mg/kg/min) in children the goal should be 10–14 mg/kg/min achieved slowly and advanced as tolerated. Restrict dextrose to 12.5% when administered by peripheral line.

Lipids are infused as a fat emulsion; they provide essential fatty acids and are caloric-dense energy source. The usual starting dose is 0.5–1.0 g/kg/day and increased as tolerated gradually up to 3 g/kg/day. Lipid emulsions come in 10% and 20% concentrations. The 20% emulsion (50% linoleic acid), 2 kcal/mL, is preferred over 10% lipid emulsion because of improved triglyceride clearance. Infusion of 0.5–1 g/kg/day is enough to avoid essential fatty acid deficiency. It is not recommended to exceed 4 g/kg/day or to exceed 60% of total calories due to the risk of ketosis.

Daily requirements of different electrolytes are estimated to be 2–3 mEq/kg/day for sodium and chloride, 1–2 mEq/kg/day for potassium, 0.65–2 mEq/kg/day for phosphorus, 0.3–2 mEq/kg/day for calcium, and 0.13–0.5 mEq/kg/day for magnesium.

All the above-mentioned requirements should be used as general guidelines and should not replace professional judgment. In general, appropriate weight gain is a sign of adequate intake.

When?

The decision when to start PN, and the route of supplementation, depends on several factors. These include:

- Preexisting nutritional status
- The anticipated course of the underlying disease
- Other organ system involvement
- Energy intake by mouth
- Other patient-specific considerations

Preexisting nutritional status: It is one of the most determinate factors. Patients who are malnourished prior to hospitalization should be identified at the time of admission by nutritional status assessment. Hospitalized pediatric patients have a high prevalence of malnutrition. Moreover, sick patients requiring hospital stay for prolonged periods of time or in the intensive care units are subject to iatrogenic starvation. Unintentional weight loss or failure to gain weight in a growing child should prompt evaluation and intervention. Subjective Global Nutritional Assessment is a tool that has been developed and used to identify children at risk of infectious and other complications due to compromised nutritional status.

The anticipated course of the underlying disease: Diseases that are anticipated to take longer duration before recovery call for PN support earlier.

Significant other organ system involvement: might interfere with oral intake (e.g., neurological or respiratory disorders) or ability to use the enteral route (e.g., postoperative ileus, severe sepsis, hemodynamic instability). Some disease are associated with significant catabolic stress that enteral intake may not be able to keep up with (e.g., malignancy, massive burns, congenital heart disease, chronic lung disease).

Energy intake by mouth: both actual and anticipated. The body can compensate for inadequate nutrient intake for certain period of time, depending on previous nutritional status. It can compensate by breaking down glycogen stores, gluconeogenesis, peripheral lipolysis, and amino acid oxidation from muscle stores. Because of the fact that infants and children have proportionately lower reserves of body protein, carbohydrate, fat than adults, and also have increased metabolic needs, they may require earlier intervention. In general, insufficient oral intake for 3–7 days should trigger for intervention in previously well-nourished children.

Other patient-specific considerations: Decisions about PN are also affected by patient-specific factors including the severity of underlying disease state, duration of potential starvation, and prognosis.

The optimal timing of initiation of PN has not been established, and the decision is based upon clinical

judgment. Earlier initiation of PN is recommended in patients with lower energy reserves such as those with failure to thrive, weight loss, prematurity, or low birth weight, or patients with chronic illnesses.

How?

PN can be delivered via a peripheral or central access. A peripheral access is when the catheter tip is in a vein other than the superior or inferior vena cava. A central access is when the catheter tip is located at or near the right atrium, superior or inferior vena cava.

High-concentration solutions (hypertonic >1,000 mOsm) can be infused safely in central access catheters with high blood flow; this will cause rapid dilution, thereby reducing the risk of thrombophlebitis. This is not possible using peripheral access because of the risk of intimal damage from the catheter and infusate. In peripheral access catheters, it is recommended to use less concentrated solutions (<900 mOsm). Usually PN administered through peripheral access cannot meet the nutritional requirements, except if it is used as a supplement in addition to enteral feeding. Central access catheters can be single, double, or triple lumen catheters, which allow other infusates (like blood products or other medications) to be administered simultaneously without having to interrupt PN infusion. The use of tunneled catheters versus non-tunneled central catheters may decrease the risk of line-associated infections.

The most widely used way of PN administration is by using two bags: the first one contains amino acids, dextrose, electrolytes, vitamins, trace elements, and sometimes medications. The second bag contains the lipid solution. Other less commonly used methods include the administration of all components in one bag or the use of three separate bags (amino acid, dextrose, and lipid bags).

Components

Glucose is the vital energetic substrate especially for the cell, and is stored in the body in the form of glycogen. Glucose is utilized in all tissues. Constant normoglycemia is necessary for efficient functioning of the brain, myocardium, and all nervous tissues. When considering the rate of glucose administration, one should bear in mind that this should not exceed the maximal rate of glucose oxidation, which varies significantly depending on the clinical situation and age. When compared to adults, infants and children have a much higher glucose brain consumption and higher rate of glucose oxidation; this can be up to 15 mg/kg/min. The maximal rate of glucose oxidation is much lower in the critically ill children and premature infants to about 5–6 mg/kg/min. Gluconeogenesis contributes significantly to glucose supply. Carbohydrates should constitute 60% of the total calories provided. Dextrose is provided at an initial dose of 6 mg/kg/min to be increased gradually up to dose of 15 mg/kg/min. One gram of dextrose provides 3.4 kcal.

In addition to hyperglycemia, glycosuria and insulin resistance, excessive glucose intake has other negative consequences of increased energy expenditure, inducing steatosis and liver dysfunction as the liver derives its energy from carbohydrate oxidation as opposed to fatty acid oxidation, and the fatty acids are directed toward VLDL triglyceride production and lipogenesis. Hyperglycemia is also a risk factor for infection, particularly in the critically ill children.

Fat should be used as an extra energy source; intravenous fat emulsions (IVFEs) improve net nitrogen balance, provide a concentrated source of calories in a relatively low osmotic load as more than double the amount of calories are provided per gram of fat compared to carbohydrates and proteins. This also allows a more diversified energy input and reduces the recognized consequences of using glucose alone as the source of energy of fatty infiltration of the liver and greater water retention.

Fat is formed mainly of essential linoleic acid stabilized by egg yolk phospholipids to a mean particle size of 0.13 μm. Linoleic acid is required for cell membrane synthesis and stabilization and a variety of physiological functions; therefore, clinical situation permitting IVFEs should be started as soon as possible in a patient on total PN to prevent essential fatty acid deficiency. Since glucose infusions stimulate insulin secretion and that reduces lipolytic activity and prevents release of tissue linoleic acid stores; the use of IVFEs in the PN also ensures an adequate supplementation of essential fatty acids.

Infants and children at special risk to developing essential fatty acid deficiency are those with malnutrition, small-for-gestational-age newborns, and premature neonates. They have very low stores of essential fatty acids, and will more likely develop essential fatty acid deficiency within 1–2 weeks of lipid-free PN with the restart of anabolism.

Lipids should not exceed 60% of the total calorie input in PN, ideally less than 30% of nonprotein energy intake. Fat is usually administered to provide 20–40% of the total calories. Use of 20% lipid emulsion provides ~2 kcal/mL compared to 0.68 kcal/mL for a 20% dextrose solution. The start dose is usually 0.5 g/kg/day and increased gradually up to a maximum of 3 g/kg/day. The infusion rate should be as slow as 0.10–0.15 g/kg/h to allow fat clearance from the blood. Plasma triglyceride level, liver function

tests, and platelet counts should be routinely monitored. Increased caution is required in the application of parenteral lipid emulsions in the neonate. The glucose/lipid ratio should be optimized for maximal fatty acid oxidation, prevention of steatosis and liver dysfunction, and VLDL triglyceride production and fat overload.

Protein: Amino acids are the vital components of body protein that provide proper nitrogen utilization and retention. The nitrogen source of PN may be selected from a list of available amino acid mixtures designed specifically for infants and children. The nitrogen intake depends on the age, degree of malnutrition, presence of nitrogen losses from the GI tract, and nitrogen losses induced by catabolism. Energy supply should be closely correlated with nitrogen supply. Excessive amounts of nitrogen intake carry the risks of metabolic acidosis, iso-osmolar coma and hyper aminoacidemia, calcium and phosphorus urinary loss, and bone demineralization. Amino acids in PN prevent the breakdown of muscle protein and disturbances of blood clotting and the negative consequences of prolonged catabolic state of delayed wound healing, loss of muscle strength, and immunosuppression. The initial dose is 1 g/kg/day and is increased gradually up to 3 g/kg/day.

Special amino acid formulations have been designed to fit the patients' needs depending on the age and clinical situation. Amino acid solutions in PN can vary in terms of amino acid nitrogen content, electrolyte content, osmolality, and amount of essential amino acids per gram of total nitrogen. Products containing only essential amino acids have been formulated for children with renal failure. Amino acid solutions designed for prematures and malnourished infants have a higher amount of essential amino acids per gram of total nitrogen, higher percent of branched-chain amino acids, and contain taurine, which is absent from standard solutions.

Glutamine: Glutamine supplementation was found to reduce the length of hospitalization and promote enteral nutrition in neonates receiving PN. Glutamine is the most abundant amino acid in muscle and plasma and serves as the primary fuel for rapidly dividing cells, promotes cell growth and synthesis. It was also recognized that glutamine is an essential nutrient for the replication of cells in tissue culture; it is therefore expected that glutamine nutritional requirements are not the same during high catabolic states as compared to during health. It also plays a key role in acid-base homeostasis.

Glutamine supplementation is of particular benefit to preterm infants receiving PN. Recent studies have shown that glutamine-supplemented PN has clinical benefit on preserving gut structure and preventing intestinal atrophy. It is therefore empirical that large multicenter trials be conducted to confirm these observations and evaluate the efficacy of glutamine in high-risk preterm infants.

Other Components of PN Solutions

Electrolytes are also added to the PN infusion in a dose relevant to the patient's age and existing electrolyte imbalance and any associated factor leading to abnormal losses of electrolytes as in intractable diarrhea or the presence of an enterostomy. *Sodium* is the most important cation of the extracellular fluid with a basic requirement of about 2–4 mEq/kg/day. *Potassium* is the most important cation of the intracellular fluid. It is also responsible for the transport of glucose across the cell membrane. The effects of potassium deficiency or excess on muscle excitability, acid-base balance, and cardiac rhythm cannot be overemphasized. Potassium is usually administered at a dose of 2–4 mEq/kg/day. In the case of intractable vomiting or nasogastric suction, sodium, potassium, and chloride supplementations are higher to replace the losses. In the case of an enterostomy, more bicarbonate should be added in addition to higher replacement of sodium.

Other important constituents of parenteral infusion include *magnesium, phosphate, calcium, and trace elements* such as chromium, copper, selenium, zinc, and manganese. Trace elements are added to parenteral fluids to prevent the development of deficiency syndromes depending on the intake of the respective nutrients and their anabolism. The provision of appropriate nutrient solutions requires an understanding of the nutritional relationships between nutrients, electrolytes, vitamins, and trace elements. Zinc is one of the most important trace elements. It plays an important role in cell metabolism.

Many of the nutrient or additives used in parenteral solutions may be contaminated with metals. Trace metal monitoring has been more critical in patients on long-term PN. A proper balance of trace metals can contribute positively to the nutritional metabolism of patients receiving PN.

Multivitamins are also important for metabolic processes. PN fluids usually include vitamin B complex, vitamin C, and fat-soluble vitamins. The precise amount of vitamins to add to various parenteral fluid regimens is not yet resolved because these supplements are very difficult to measure and only few reference laboratories have such facilities. Furthermore, the intakes should be adjusted in patients with high catabolic states and intestinal losses.

The addition of *carnitine* supplement helps optimize fatty acid oxidation. Carnitine levels are very low in prematures and low-birth-weight newborns and should be supplemented, although there are currently no specific

recommendations regarding its supplementation. It is also advisable to add alpha-tocopherol to the IVFEs as an antioxidant.

Prescribing Parenteral Nutrition

At the initiation of PN, it is recommended to start with lower amounts than the set goals and advance slowly depending on the tolerance. Usually it takes several days before achieving patient-specific goals. Double checking the calculations is strongly recommended as calculation mistakes can be hazardous. Different hospitals have their own protocols. This section will describe general practical steps.

Step 1:

The initial step in PN calculations should be to asses protein and energy requirements. In general, energy requirements for children receiving PN may be 10% less than the DRI of enteral intake. For patients who are malnourished, energy requirements should be determined using ideal body weight (IBW) (weight-for-length at the 50th percentile) to allow for appropriate catch-up growth. Similarly, the IBW should be used in overweight or obese patients.

The total energy (kcal)/day = energy (kcal/kg/day) × weight (kg) (or IBW).

The total protein g/day = protein (kcal/kg/day) × weight (kg) (or IBW).

Contribution of energy from different components, generally dextrose and amino acids provide about 70% of the calories, and fat emulsions provide about 30% of calories.

Total energy (kcal/day) × 0.3 = energy from fat (kcal/day)

Total energy (kcal/day) × 0.7 = energy from dextrose and amino acid (kcal/day)

It cannot be stressed more that the requirements are variable and are dependent on the patients' needs dictated by their nutritional and health status, some patients may require much more than their DRI for age.

Step 2:

Calculate the maintenance fluid requirements. This may vary from patient to patient and may also vary overtime according to the child's health condition. Some medical conditions may require restriction of fluid intake, e.g., cardiac or renal disorder. Fluid requirements will be higher in patients with excessive losses, e.g., diarrhea, draining fistulas, fever.

Step 3:

Determination of the volumes of different components. Using a standard 20% lipid solution (1g = 5 mL), it is easy to calculate the daily lipid volume, then divide it over the number of hours of PN infusion. It is recommended to start the lipids at a lower amount at the initiation of PN (e.g., 0.5–1g/kg/day) and advance slowly depending on tolerance.

The rest of the required volume will be the amino acid and dextrose solution. Calculate amino acids, as above, a suggested start is to add 0.5–1g/kg/day and increase according to the DRI and the tolerance. Similar procedure should be used to calculate dextrose (see above daily requirements of PN).

Step 4:

Calculate electrolyte requirements and add that to the amino acid/dextrose solution. See above daily requirements of PN. Adjust as needed.

Step 5:

Calculate the calories in PN and lipid solution, adjust if needed. Keep in mind that these might not match the goals at the initiation of PN.

Step 6:

Additives. If a base is required to be added to PN solution, to treat acidosis, then it should be acetate (sodium or potassium); in such case balance the total amount of Na or K. Bicarbonate should never be added because it will result in precipitation of calcium and phosphorus in the PN solution. Zinc is often added in patients with gastrointestinal losses (e.g., diarrhea, ostomy output), inflammatory bowel disease, cystic fibrosis, or fistulas.

For other additives, suggest checking with pharmacy for compatibility and solubility of the PN solution.

Step 7:

Compare your results with requirements for accuracy (double checking). It is recommended that the clinical pharmacist double check the calculations for accuracy too.

When PN is to be stopped, it should not be stopped suddenly, it should be tapered off slowly, usually over 1–2 h with close monitoring. Avoid any sudden discontinuation of PN, especially in younger children or children with no enteral intake; this carries the risk of hypoglycemia and fluid deficit.

Monitoring

Close monitoring of patients' "tolerance" to PN is extremely important. Although there is no agreed regimen of monitoring, some monitoring parameters needs to be checked daily, others less frequently (weekly, monthly, and annually). The type and frequency of laboratory testing will depend on the stability of the patient and other body system involvement. Institutions usually develop their own monitoring protocols.

There are some general principles that are agreed upon: a baseline laboratory testing should be obtained before starting PN. This may include: complete blood count, electrolytes, glucose, calcium, magnesium, phosphorous levels, as well as kidney and liver profiles.

After initiation of PN, labs are frequently ordered until the goals are reached. It is wise to remember that patients differ in their "tolerance" to PN depending on several factors, these include: their current nutritional status, underlying disease, ability to take enteral feed, age, and several others. The PN composition may need to be adjusted accordingly.

Daily monitoring may include: careful measurements of fluid intake and output, weight, selected laboratory studies (e.g., serum electrolytes, bicarbonate and blood urea nitrogen (BUN), glucose, calcium, magnesium, phosphate, triglycerides), and urine glucose. We would suggest doing the above daily at the initiation of PN, whenever significant changes in the composition of PN are made, and significant change in the patient's condition. Later on, and depending on patient's condition and stability, monitoring may be spaced out.

Weekly monitoring in addition to the above may include: liver aminotransferases, bilirubin, albumin, prealbumin, and complete blood count. Later on, these labs may be checked once a month for more stable patients and for patients on home PN. Monthly labs may also include iron studies. Less frequent labs (biannually or annually) may include trace elements levels (Zn, selenium, and Cu) and vitamins levels.

Adequacy of the amino acid intake in the short term can be determined by either BUN or prealbumin measurements. Both will reflect changes in amino acid intake within 24–48 h. The BUN is a readily available test to titrate amino acid intake provided that the child is well hydrated with normal renal function.

Tolerance to lipid infusion can be judged by triglycerides measurement. Ideally, the triglyceride level should be less than 100 mg/dL. There are no data defining the level at which one should be concerned. The American Gastroenterological Association Technical Review on PN states that IVFE should not be administered to patients whose serum triglyceride levels exceed 400 mg/dL. It is recommended to measure a baseline level in these patients before starting lipids. Intralipids may need to be decreased with triglycerides >250 mg/dL. Sustained levels of serum triglycerides >400 mg/dL may require discontinuation of the fat emulsion. Interpretation of the data linking intravenous fat emulsions to pulmonary dysfunction, and immune function, is complicated, at the best controversial and beyond the scope of this discussion. Some studies show a beneficial effect, some no effect, and some an adverse effect of fat emulsion infusion.

The use of intravenous fat emulsions in patients with coagulation abnormalities is complicated too. In rare cases, intravenous fat emulsion has been associated with thrombocytopenia. Under normal circumstances, they do not induce thrombocytopenia. It should be kept in mind that essential fatty acid deficiency itself is a cause of hematologic abnormalities.

Other causes of elevation of triglyceride levels include sepsis, pancreatic disease, renal disease, and diabetes.

Patients receiving long term PN (especially with limited enteral intake) are at risk for developing iron deficiency since most PN solutions do not contain iron.

Complications

PN has become an essential therapy in most neonatal, medical, and surgical units. The noticeable improvement in techniques and fluid composition have enabled the selected patients to survive longer but at the same time have made them prone to developing some added complications that were not as common previously when PN did not last as long. In spite of all improvement in techniques and adherence to various aseptic measures together with a multidisciplinary approach, PN is not without hazards.

Catheterization of central veins for long-term PN should be performed by one who does such procedures fairly regularly. Complications of insertion are many. Pneumothorax is the most prevalent complication of subclavian vein puncture occurring in up to 5% of attempted catheterization. The pneumothorax may be asymptomatic and resolve spontaneously or may require needle aspiration or closed tube thoracostomy.

Air embolism is a potentially fatal complication of percutaneous catheterization of the subclavian and internal jugular veins or during routine tube changes. Other mechanical complications include: bleeding, especially with blind insertion techniques, pneumomediastinum, hemothorax, and hydrothorax.

Cardiac tamponade and arrythmias may also complicate the central venous catheter (CVC) insertion. Other recognized complications of catheter insertion include *injuries to the trachea, thoracic ducts, and brachial plexus.*

With increased application of PN and improved technical application, the number and frequency of such complications have become much less.

Other recognized complications include *metabolic disorders* like hypoglycemia, hyperglycemia, hypokalemia, hyperkalemia, and hypocalcemia. There is also a potential

complication of *electrolyte disturbances* precipitated by excess gastrointestinal losses resulting in hyponatremia.

Catheter-Related Sepsis

Central line-related sepsis is a serious complication of PN. The incidence varies, but it is reported to be in the range of 5%. This tends to happen more frequently with the surgically inserted CVCs particularly in the event of local hemorrhage following CVC insertion and local suppuration at the skin exit site. This is suggested by temperature variations, hypotension, oliguria, and general deterioration in the clinical condition. Any fever in the absence of an obvious focus of infection must be attributed to catheter-related sepsis until proved otherwise. Sepsis may occur at any time after catheter insertion. Repeated central line infections with septicemia are recognized serious complications associated occasionally with major clinical deterioration of the child who will require not only intensive antibiotic therapy but also replacement of the central line catheter.

Symptoms or signs of sepsis warrant thorough investigations for a focus including complete blood count, C-reactive protein, coagulation studies, blood cultures both central and peripheral.

Antibiotic treatment should be started promptly and should include anti-staphylococcus antibiotics, coagulase-negative staphylococci being the commonest blood culture growth.

All PN solutions must be prepared under a laminar flow hood and filtered. The PN team strongly emphasizes the importance of aseptic techniques not only during the insertion of the catheter but also during changing of dressings, infusion set, and intravenous fluids. Daily care of the CVC skin exit site is required, especially in those who are enrolled for home PN. The caring nurse should be specifically trained in this technique.

Full septic screen is required as soon as such a complication is suspected. The child should be treated with broad-spectrum antibiotics while awaiting the results of cultures.

Outbreaks of *Candidal bacteremia* have been reported in patients receiving PN. Investigations of outbreaks of Candida infections among neonates receiving PN have indicated that the outbreaks were terminated by using syringes only once and resuming intravenous tube changes every 24 h. Very often the source of the Candida could not be identified.

If fever persists over 48 h in spite of therapy, a serious consideration should be made for removing the catheter as well as the addition of antifungal medication especially in immunocompromised patients. Once the catheter is removed, the tip of the catheter should always be sent for culture and sensitivity. The child should be placed on peripheral infusion for a few days before insertion of new central line catheter.

Respiratory failure is also a recognized complication of high daily dextrose loads in PN in patients with obstructive airways disease.

A variety of CVC-associated infection prevention strategies are currently evaluated for efficacy. Intraluminal ethanol lock is showing promising results so far in terms of infection prevention, reduction of relapse rate, and catheter salvage. Ethanol has antimicrobial effects on *Staphylococcus aureus*, *Streptococcus pyogenes*, *Pseudomonas aeruginosa*, and *Escherichia coli*. Ethanol lock has a multitude of advantages. It is an inexpensive excellent disinfectant with intrinsic anticoagulant activity and may be able to clear yeast, which is hard to treat with other locks.

Metabolic Complications of PN

Essentially all kinds of metabolic and electrolyte derangements can happen. The best way to avoid this is by careful calculation and frequent monitoring with prompt intervention.

Hyperglycemia: to avoid this dextrose initial infusion should be limited to 10–15%; increments should be limited to 5% per day.

Hypoglycemia: could be caused by abrupt cessation of PN, which should be avoided.

Hypercapnia: may be due to excessive caloric or dextrose infusion and should be avoided.

Azotemia: ensuring adequate hydration prior to PN initiation is essential; excessive amino acid infusion should be avoided.

Hypertriglyceridemia: serum triglycerides should be monitored frequently. Lipids should be infused over 18–20 h and may be given every other day.

Hypokalemia/hyperkalemia: serum potassium should be monitored daily until stable, then biweekly. Restriction and monitoring are especially necessary in patients with renal insufficiency.

Hyponatremia/hypernatremia: excessive fluid administration should be avoided. Intake/output should be monitored in addition to urine sodium and osmolarity.

Metabolic acidosis/alkalosis: acid–base balance derangements can happen in patients receiving PN. Intestinal or NG output losses should be replaced. May need to add acetate in cases of metabolic acidosis.

Hypocalcemia/hypercalcemia: ionized calcium, PTH, and vitamin D levels should be monitored.

Hypomagnesemia/hypermagnesemia: serum magnesium should be monitored until stable, more relevant in patients with renal insufficiency.

Hypophosphatemia/hyperphosphatemia: serum phosphorus should be monitored daily until stable.

Parenteral Nutrition-Related Bone Disease

PN-related bone disease is a well-known complication that is reported in patients of all ages. The clinician is alerted to this more common than previously thought complication by the findings of high serum alkaline phosphatase, low/normal vitamin D and PTH levels, and hypercalciuria.

Osteodystrophy is a known complication recently recognized in children receiving long-term PN. The patients suffer from bone pain and pathological fractures.

Radiological manifestations include osteopenia, fractures, and rickets. Histopathology reveals osteomalacia, decreased bone mineralization, and osteoid tissue excess.

The exact nature of this disorder is poorly understood. Caution is advised with vitamin D supplementation in long-term PN. Hypercalciuria may be decreased by reducing the sulfur-containing amino acids in particular and balancing the supplies of phosphorus, nitrogen, and energy.

The incidence of PN-related bone disease may be higher than considered at present if more sensitive radiological and biochemical criteria are applied. Children on long-term PN should have their serum alkaline phosphatase and urinary calcium checked routinely. *Dual X-ray absorptiometry (DEXA)* scan can assess the bone mineral density in children on long-term PN.

Parenteral Nutrition-Related Liver Disease and Hepatobiliary Complications

Hepatotoxicity is a well-recognized serious complication of long-term PN. It occurs in up to 90% of patients receiving long-term PN. PN-related liver disease may appear as early as after a few weeks of PN therapy.

The underlying digestive disease plays a role in the development of PN-related liver disease. Ileal resection in short bowel syndrome results in impairment of enterohepatic circulation of bile acids, bacterial overgrowth following ileocecal valve resection, and the impairment of bile secretion without enteral feeding.

Factors playing a role in the pathogenesis of hepatotoxicity in patients receiving PN include the duration of PN, prematurity, primary liver disease, hepatotoxic medications, and infections including bacterial translocation secondary to gut mucosal atrophy, bacterial overgrowth with gram negative sepsis as well as recurrent line sepsis.

Causes of hepatotoxicity also include the direct effect of the artificial nutrition. Excessive glucose supply may induce hyperinsulinism and de novo lipogenesis and steatosis. Metabolic dysfunction may be related to inadequate amino acid supply, presence of toxic products of amino acids metabolites. Liver injury can also result from excess iron, aluminium, and other micronutrient overload.

Hepatomegaly may become clinically apparent as early as within a few days of starting PN. Elevation of the serum alkaline phosphatase and gamma glutamyl transferase activities are the earliest and most sensitive laboratory markers, though not specific. *Hyperbilirubinemia* is a late marker of cholestasis.

Histologically: Hepatic steatosis is the most common and first morphological change seen as a sequel to PN. Cholestasis, portal, and peri-portal cell infiltration may progress to fibrosis, cirrhosis, and end-stage liver disease if PN is not performed correctly.

In an effort to reduce the hepatotoxicity due to PN, *enteral feeding*, even if tolerated in small quantities, should be introduced as early as possible. It has been hypothesized that PN-associated cholestasis is caused by a lack of enteral feeding, impaired bile acid secretion, gut mucosal atrophy and secondary bacterial translocation, and a sequel of events and complications. Therefore, in many centers and certainly in neonatal intensive care units, the trend nowadays is toward earlier enteral feeding in an otherwise healthy premature infant. Recent reviews recommend early introduction of partial enteral feeding to preserve liver functions.

It is essential to closely monitor hepatic function and minimize or reverse the development of liver disease by limiting glucose supply to prevent de novo lipogenesis and steatosis. Moreover, minimizing metabolic dysfunction by using pediatric-adapted amino acid solutions that include taurine, minimizing liver injury caused by excess iron, aluminium overload, providing essential fatty acids in the intravenous fat emulsion, monitoring platelet count and serum bilirubin level and stopping the intravenous fat emulsion in the case of thrombocytopenia or hyperbilirubinemia until they normalize, restarting the IVFE under very close monitoring, cycling the PN

to reduce hyperinsulinism and liver steatosis, using metronidazole to reduce bacterial overgrowth, using ursodeoxycholic acid to minimize liver injury.

All of the above-mentioned complications can be life threatening. But it is the associated cholestasis leading to liver failure that is the most common serious long-term complication, especially among neonates receiving PN.

Home Parenteral Nutrition

Major strides have been made toward lower morbidity and mortality rates associated with PN, and more infants and children are on long-term PN therapy. With the continuing improvement in the parenteral feeding regimens and appropriate provision of macro- and micronutrients, the improved care and insertion techniques of central venous catheters, home PN is the only alternative to prolonged hospitalization for patients requiring long-term PN. Prolonged hospitalization exhausts hospital resources and consumes a great deal of the physicians' and nurses' time as well as that of all members of the PN team.

Home PN helps minimize these costs and care, improves the psychological development of the child, enables the older children to attend school, and offers the patients and their families the best possible quality of life.

Candidates for home PN may be exclusively on PN, or on mixed enteral and PN. This will depend on their clinical condition and diagnosis, the progress made in intestinal adaptation and their tolerance to enteral feeds. These include children with severe and persistent genetic malabsorption syndromes, intractable diarrhea of infancy, villous atrophy, infants with short bowel syndrome secondary to intestinal resection, chronic intestinal pseudo-obstruction syndromes, and some cases of inflammatory bowel disease. The objective of long-term PN in these cases is to ensure normal growth of the child while the inflammatory syndrome subsides or while waiting for the residual intestinal condition to become stable.

Home PN protocols are mainly directed to the group of infants and children whose medical condition is stable on PN in hospital with or without enteral nutrition. With few exceptions, the parents usually express their readiness and competence to care for their child at home. The parents should undergo proper training sessions supervised by the PN team prior to discharging the patient home. Patients and their parents should be intellectually and emotionally able to cope with the heavy burden of daily management of PN. It is also practiced that after discharge, the family will receive regular visits at close intervals by trained personnel to ensure the smooth operation of home PN and to respond to any difficulties or queries that parents may have had in between visits. It is important to ensure that the parents are handling the therapy using fairly aseptic techniques. The parent should also be taught about the early signs of sepsis and be advised to bring their child back to the hospital for further evaluation or to call the team member on duty for further advice on management.

Home PN is usually administered in the same manner as in the hospital. The fluid is infused through a surgically inserted catheter, with its tip in the right atrium (Hickman-Broviac catheter) or through infusion ports under the skin (Port-a-cath).

It is important to program the hours of administration of home PN to run, if possible throughout the night, and allow the family and the child normal activity or schooling during the day. It is also easier to formulate the home PN all in one bag, which facilitated the procedure even further by requiring only one infusion pump. In the course of regular medical checkups and home visits, an attempt should be continued to increase the amount of enteral nutrition to save the child some of the risks of long-term PN.

Reports have recommended home PN programs based on the finding that central line-related infections are far less frequent among these children compared to those receiving their PN in hospital. Recent reports have, however, indicated that complications such as catheter-related thrombosis in children receiving PN at home remain high. While the most life-threatening home PN-related complication is liver disease, several reports suggest that home PN remains the best option for children in need of long-term PN.

Children who will require lifelong PN should be considered for intestinal transplantation as an alternative to lifelong PN and its related long-term complications including PN-related liver disease. This group includes infants with massive intestinal resection and extreme short bowel syndrome, severe motility disorders, intractable diarrhea of infancy, and microvillous inclusion disease.

57 Vitamin Deficiencies and Excess

Gaafar I. Suliman · Hisham M. Nazer

Vitamins are natural chemical compounds required in minute quantities for health and normal nutrition in humans. They are divided into two groups, namely, water and fat-soluble vitamins. The former are procoenzymes that provide active substances necessary for enzyme synthesis and the latter alter conformation of complex molecules and membranes.

Water-Soluble Vitamins

Vitamin B Group Deficiencies

As the sources of vitamin B are present in more or less the same type of animal and vegetable foods, X and X deficiency of one is likely to be associated with deficiencies of others. Clinical manifestations of B vitamin deficiencies are usually seen in famine situations in developing countries, where there is also the added potential risk of improper preparation of food with long-term storage due to shortage of water and cooking facilities. Unlike fat-soluble vitamins, excess of water-soluble vitamins is not of significant concern.

Thiamine (B1)

Thiamine forms the heat labile portion of the B complex and its metabolites are important in carbohydrate metabolism. Thiamine pyrophosphate takes part as the coenzyme of carboxylase in the oxidative of carboxylase in the oxydative decarboxylation of α-keto acids such as pyruvic and α-ketoglutaric acids, where acetylcoenzyme A is subsequently formed. Thiamine pyrophosphate is also a coenzyme for transketolase which works as a direct oxidative pathway of glucose and consequently generates NADP and pentose. Thiamine is also required for the synthesis of acetylcholine required for the central nervous system.

Thiamine is found in unpolished grains, sunflower seeds, brown rice, asparagus, cauliflower, potatoes, oranges, liver, and eggs.

Thiamine Deficiency

Thiamine derivatives and thiamine-dependent enzymes are present in all body cells, thus deficiency could adversely affect all organ systems. However, the nervous system and heart are particularly sensitive due to their high oxidative metabolism.

Thiamine deficiency results in a condition called *beriberi*. Infantile beriberi primarily affects the cardiovascular system with dilatation of the heart and fatty degeneration of the myocardium. Generalized or localized body edema may occur. Nervous system involvement is associated with vascular dilatation and hemorrhage in the brain and peripheral nerve degeneration. Its etiology, epidemiology, and clinical manifestations have special features in infancy.

Epidemiology

In infancy, the disease is virtually confined to breast-fed infants of thiamine-deficient mothers who are subsistent on polished rice and minimal or absent additional food supplements. The peak mortality is usually from 2 to 5 months of age.

The infantile form is an acute disease unlike in adults. The early signs may be subtle and easily missed by the mother. It proves rapidly fatal without treatment; it is acutely fulminate between 2 and 5 months and is milder and less common after 6 months. Beriberi is rare after the age of 1 year. In older children, the disease is similar to that of adults, namely, wet, dry forms, and acute cerebral beriberi.

The prevalence seems to have diminished considerably worldwide, and it has not been a public hazard in recent years, especially in previously endemic areas, due to various interventions including fortification of rice with thiamine.

Clinical Features

Beriberi manifests with pallor, restlessness, vomiting, constipation, poor mental concentration, and apathy. Cardiac

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_57,

involvement is of sudden nature and manifests with restlessness, bouts of screaming, and breathlessness. The baby is pale but cyanosed. It is associated with acute output cardiac failure resulting in death due to peripheral vasodilatation, high output cariomyopathy, and salt and water retention. Chest radiography demonstrates evidence of pulmonary edema and cardiomegaly. Pericardial and pleural effusion may be present. Death may occur within minutes or hours from the onset of the disease. This is referred to as *wet beriberi*.

The aphonic form is another type that presents acutely. It manifests with distressing and increasing cough and choking that commence between the age of 5–7 months. This is rapidly followed by hoarseness, dysphonia, and aphonia, which gives rise to noiseless cry due to laryngeal nerve paralysis or edema of the larynx.

CNS involvement may appear later as peripheral neuritis associated with parasthesia, hyperesthesia, and burning feet. The child finds it difficult to rise from a sitting position due to muscle weakness and tenderness and this is followed by ataxia, loss of coordination, and loss of deep sensation. Polyneuropathy is described as *dry beriberi*.

Wernicke's encephalopathy is a recognized complication of thiamine deficiency and is associated with confusion, apathy, drowsiness, head retraction, signs of meningism and increased intracranial pressure. This usually occurs in children aged 8–10 months.

Diagnosis

The diagnosis rests upon reduced urinary thiamine excretion and is confirmed by absent thiamine pyrophosphate. A loading dose of 10 mg thiamine and lack of response in urinary excretion of thiamine in a deficient child have been suggested as a diagnostic test. The erythrocyte transketolase activity is lowered and blood or urinary glyoxylate values are high. Clinical response to thiamine administration remains the best test for thiamine deficiency. Thiamine as well as its derivatives can be measured quantitatively by high-performance liquid chromatography (HPLC).

Diffferential Diagnosis

Differential diagnosis include meningitis, encephalitis, laryngitis, tetany, congenital heart disease, kwashiorkor and acute poisoning. Therapeutic dose with thiamine is decisive and safe.

Treatment

Immediate: 50–100 mg of I.M./I.V. thiamine hydrochloride and Oxygen therapy give dramatic response within a few hours. Maintenance consists of 5–10 mg/daily for several days. Breast feeding mother should receive similar treatment. Other B vitamins should also be given in addition.

Prognosis: excellent if diagnosed and treated early

Prevention: Education and avoidance of over-dependence on polished rice; and mixed diets should be encouraged.

In *thiamine dependency*, which is rare, large doses of thiamine will be required.

Riboflavin (Vitamin B2)

Riboflavin is important in the formation of the coenzymes flavin mononucleotide and flavin adenine dinucleotide. Riboflavin is important for growth and tissue respiration. It is destroyed by light and is stable to boiling in acid solution. In tissues it forms mononucleotides with phosphoric acid which are coenzymes in flavoproteins. These coenzymes are essential in many oxidation–reduction reactions in the body.

Riboflavin Deficiency

Riboflavin deficiency is usually mild and results from low intake of riboflavin-rich diets, such as pulses, legumes, and animal products including liver, kidney, milk, and cheese. Breast milk or artifical milk intake is sufficient in preventing riboflavin deficiency. A diet is rarely deficient in riboflavin alone and signs usually accompany other deficiency states, like pellagra or severe protein calorie malnutrition.

Clinical Manifestations

The skin and mucus membranes are affected. Sebaceous glands become prominent in the nasolabial folds, alae nasi, external ears, eye lids, and scrotum in males and labia majora in females. Inspissated sebum accumulates in hair follicles, producing plugs of material. Angular stomatitis occurs in the acute form and rhagades in chronic deficiency. Cheilosis of lips and the tongue may be acutely painful and may have magenta color. Photophopia, lacrimation, and conjuctival injection may be present.

Diagnosis

Plugs in hair follicles tend to be rather specific for riboflavin deficiency. The other signs may be caused by other B complex deficiencies. Diagnosis is suspected on clinical grounds and confirmed by low urinary riboflavin excretion of less than 30 μg/day, and by an enzymatic test, reduced red blood cell glutathione reductase is found.

Treatment

This includes dietary support to ensure adequate supply of vitamin B as well as giving 3–10 mg of riboflavin daily. If there is no response within a few days, then it should be given by the intramuscular route as 2 mgs daily.

Nicotinic Acid (Niacin)

Nicotinic acid is a water-soluble vitamin and functions as a coenzyme required for a wide variety of essential metabolic processes. Nicotinamide adenine (NAD) and its phosphorelated form NADP are coenzymes for oxidation–reduction reactions including synthesis of high-energy phosphate compounds, glycolysis, pyrovate metabolism, pentose biothensysis, glycerol and fatty acid metabolism, and for obtaining energy from proteins. Conversion of tryptophan to nicotinic acid may be partially sufficient to meet body requirements.

Liver, salmon, poultry, and red meat are good sources. Breast milk supplies relatively high content of niacin and this meets the needs for infants until the age of 6 months.

Niacin Deficiency (Pellagra)

The disease typically occurs in adults, some cases can appear in children of all ages and manifestations are similar to those in adults. Pellagra is commonly seen in communities whose diet consists of maize as stable diet and this has been shown to have low content of tryptophan or niacin. It used to occur in endemic proportions in parts of the Middle East, Africa, and Southeast Europe. Pellagra also affects communities in India, Brazil, and Cuba that are not maize eaters.

Tryptophan gives rise to nicotinic acid in the body and very low levels of this essential amino acid may result clinically as pellagra. Some drugs like isoniazid compete with pyrodoxal phosphate, a coenzyme required on the metabolic pathway of tryptophan to nicotinic acid. Similarly pyridoxine deficiency from any cause may have the same effect.

Hartnup disease is a rare genetic metabolic disorder where the basic defect involves the intestinal and renal transport of many amino acids, and tryptophan is not exempt. Patients have the typical photosensitive rash and later, the skin becomes rough.

Cerebellar ataxia and psychiatric disturbances may occur; however, these signs are reversed with treatment. The diagnosis can be confirmed by presence of large amounts of monoamino monocabocyclic amino acids in the urine.

Clinical Manifestations

Niacin deficiency is characterized by "dermatitis, diarrhea, dementia, and depression." Other associated features include angular stomatitis and peripheral neuritis.

Prodromal symptoms include stomatitis, glossitis, vomiting, or diarrhea that may precede skin lesions. However, characteristic skin changes are commonly the first manifestation to be noted. The dermatosis is symmetrical and appears on parts exposed to sunlight and trauma, which is sharply demarcated. Erythema progresses to keratosis, scaling, and pigmentation. The hands, wrists, forearms, face, and neck are usually involved, but it may involve the feet and legs.

Mucocutaneous junctions, like the outer canthus of the eye, edge of alae nasi, anus, and genitalia are often fissured and sore. The tongue is described as "raw beef" in appearance which is red, swollen, and painful. Gastritis, diarrhea, and malabsorption may occur.

Neurological changes are usually late and rare in children. CNS symptoms include depression, disorientation, insomnia, and delirium. Encephalopathy is more characteristic than cord, pyramidal tract, or peripheral nerve damage. In advanced cases, demylination of parts of the spinal cord involving the lateral and posterior columns and also the cerebellum may occur.

Laboratory Tests

Excretion in urine of *N*-methylnicotinamide is undetected and its pyridone is reduced. Plasma tryptophan is very low. Clinical features and clinical response to niacin is best to confirm the deficiency state.

Treatment

In critically ill patients, 50–100 mg of niacin should be given intravenously. This treatment may be followed by flushing and burning sensation of the skin. Large doses of niacin may be complicated by cholestatic jaundice or hepatotoxicity.

In the acute form, nicotinamide is given subcutaneously three times a day for several days until marked improvement occurs when an oral dose of 20 mg/day can be substituted. Tryptophan-containing foods supplemented with other B complex vitamins should be added.

Pyridoxine (Vitamin B6)

Pyridoxine consists of three closely related compounds: pyroxine, pyridoxal, and pyridoxamine and their respective 5-phosphorylated forms. The coenzyme pyridoxal-5-phosphate has many roles in amino acid metabolism as well as in lipid, nucleic acid, and glycogen metabolism.

Deficiency

This rarely occurs as an isolated clinical entity as most food stuffs contain this vitamin. Pyridoxine deficiency results from poor intake as in malabsorption and severe malnutrition. It may result from drug antagonism such as isoniazid, oestrogens hydralazine, and penicillamine. It may also result from excessive loss and increased metabolic activity.

The developing nervous system of infants appears susceptible to pyridoxine deficiency. Gamma amino butyric acid (GABA) is present in high concentrations in the developing brain and is formed by decarboxilation from glutamic acid through pyridoxal phosphate as a coenzyme. GABA inhibits synaptic transmission and when its concentration is lowered in pyridoxine deficiency, the threshold of irritability is reduced and convulsions may occur as a result.

Clinical Manifestations

Clinical manifestations include convulsions, especially in infants, peripheral neuropathy, seborrhoeic dermatosis, glossitis, angular stomatitis, cheilosis, and normoblastic normochromic anemia.

Laboratory Tests

Diagnosis is confirmed by the presence of low serum pyridoxal 5 phosphate.

Treatment

In the case of neonatal convulsions suspected to be due to pyridoxine deficiency, up to 100 mg of pyridoxine may be given intramuscularly and a single dose may be sufficient. In case of good response, this may be confirmatory of the diagnosis. In other situations, an oral dose of 10 mg pyridoxine should be given, which is ten times the normal requirements of 1.0 mg/day, and this should give a good response.

Dependency

Myoclonic seizures may occur from birth up to 6 months of age. In B6-dependent anemia, although the blood picture is microcytic hypochromic anemia, yet patients have increased serum iron concentration, saturation of iron binding protein, deposition of iron in the liver and bone marrow, suggesting failure of utilization of iron for hemoglobin synthesis. Treatment consists of vitamin B6 given in a dose of 2–10 mg I.M. or 10–100 mg orally on daily basis.

Toxicity

Excessive intake may cause neuropathy; however, the few studies that have been conducted, have not been substantiated by further studies.

Vitamin B12

Also called cobalamin, vitamin B12 is a water-soluble vitamin with a key role in functioning of the brain and nervous system and also for mylin synthesis. It is a class of chemically related compounds that contain cobalt. Biosynthesis of the basic structure can only be accomplished by bacteria, but transformation into other derivatives occurs in the human body. Its derivatives function as cofactor of 5-methyltetrahydrofolate-homocysteine methyltransferase (methionine synthase).

It is involved in the metabolism of every cell affecting DNA synthesis and regulation, but it is also important in fatty acid synthesis and energy production.

It is found in fish, meat, poultry, milk and milk products, and eggs.

Deficiency

As B12 is found in many animal foods, dietary deficiency is unlikely except in strict vegetarians. Other recognized causes of deficiency include increased requirements as in blind loop syndrome, bacterial overgrowth and parasitic infestation of the small intestine, and due to fish tapeworm infestation.

B12 deficiency can potentially cause severe and irreversible damage to the brain and nervous system. Deficiency at lower levels causes fatigue, depression, and poor memory. It has also been suggested as a cause of mania and psychosis. Early changes lead to spongiform state of neural tissue along with edema of fibers. At later stages, this is followed by decay of meylin in the dorsal parts of the spinal cord, leading to subacute combined degeneration of the cord.

Deficiency may be caused by poor intake or poor absorption. It is rare for features of B12 to develop in early childhood. However, rare congenital defects have been described affecting assimilation of B12. These are less common than acquired deficiency in malabsorption and secondary to terminal illeal resection. In *juvenile pernicious anemia*, intrinsic factor production in the stomach is defective and this leads to megaloblastic anemia, and growth failure.

Clinical Manifestations

Clinical manifestations include anemia, jaundice, glossitis, paresthesia, dementia, and ataxia. Pernicious anemia is characterized by megaloblastic anemia, gastrointestinal symptoms, and neurological symptoms.

The neurological system may present with subacute combined degeneration of the cord with peripheral neuritis and other symptoms include impaired perception of deep, pressure and vibration sense, abolishment of sense of touch and persistent paraesthesias, ataxia of dorsal cord type, decrease or abolishment of deep tendon reflexes.

Diagnosis

Megaloblastic anemia, hypersegmented neutrophils, and thromocyopenia suggest B12 deficiency. Excessive excretion of methylmalonic acid in urine is a reliable index of B12 deficiency (normal amounts 0–3.5 mg/24 h). The diagnosis is confirmed by finding of low plasma level of less than 100 pg/mL.

When B 12 malabsorption results from defective absorptive ileal sites or due to other intestinal causes. The schilling test remains abnormal in pernicious anemia, even though therapy has completely reversed the hematological and neurological manifestations of the disease.

Treatment

Treatment of B12 deficiency depends on the cause. In pernicious anemia, treatment involves parentral administration of 1 mg and this is followed by reticulocytosis within a few days. Pernicious anemia due to B12 deficiency responds to folate therapy, but this has no effect on neurological complications.

In the event of neurological complications, a dose of 1 mg should be given daily for 2 weeks, followed by the same dose as IM on monthly basis route as maintenance therapy for life.

In the case of malabsorption, intramuscular injections of B12 are advisable to ensure a satisfactory response.

B12 is also used in the treatment of cyanide poisoning acting as a blocking agent.

Toxicity: No toxic dose is established.

Folic Acid

Folic acid (vitamin B9) is a water-soluble vitamin and it occurs naturally as folate, pteroyl-glutamic acid, and pteroyl L-glutamate. Folic acid is not biologically active, but its active form, tetrahydrofolate depends on the activity of the enzyme dehydrofolate reductase in the liver. Other derivatives are also produced in the liver or in the upper small intestine. It is essential for formation of nucleotide biosynthesis and homocystine.

Its importance relates to synthesis of DNA and RNA and similarly its action as cofactor in many biological reactions. Thus it is especially important for cell development during rapid cell division and growth, including the red cell development and maturation.

Folic acid is found in many plants and animal tissues. Leafy vegetables such as spinach, lettuce, beans and peas, tomatoes, and sunflower seeds are a principal source of folic acid. Fruits include orange, grapefruit, banana, raspberry, strawberry are recognized source of folic acid, which is also found in animal liver.

Folate Deficiency

Folate deficiency may result from poor intake or secondary to poor absorption as in malabsorption syndromes or due to specific malabsorption of folate. It can occur in the presence of folic acid antagonists, increased requirement as in prematurity, lymphoproliferative malignancy, or increased hemopoesis in different types of hemolytic diseases.

It is the commonest cause of megaloblastic anemia in children. Since folate deficiency limits cell division, erythropoiesis is impaired leading to megaloblastic anemia and hypersegmented neutrophils.

Deficiency of folate in pregnant women has been implicated in neural tube defects in fetuses, especially if this occurred during early pregnancy.

Some drugs interfere with biosynthesis of folic acid such as dihydrofolate reductase inhibitors such as trimethoprin, pyrimethamine, methotrexate, and sulphonamides.

DNA synthesis and repair are also impaired and this has been suggested as a cause of cancer.

Clinical Manifestations

The hemopoetic system is mainly affected leading to megaloblastic anemia although some skin changes and neurological problems do occur. Nonspecific features that may be shared with other water-soluble vitamins include glossitis, diarrhea, depression, and confusion.

Deficiency of folic acid during early pregnancy has been associated with serious neurological abnormalities during fetal development, including neural tube defects and also other brain defects.

Diagnosis

Peripheral blood picture and bone marrow changes show the specific features of megaloblastic anemia, which is not distinguishable from B12 deficiency; however, the shorter time frame suggests the former. Measurement of serum folate level reflects folate status, but the erythrocyte folate level is more specific in determining inadequate folate status.

Treatment

Folate deficiency is treated with supplemental oral folate of 1–5 mg daily. Patients with coeliac disease have a greater chance of developing folate deficiency as well as iron deficiency anemia.

Folic Acid Supplementation Risk for Children

Excessive supplementation of folic acid has been shown to increase the risk of developing malaria and increased mortality. This has prompted WHO to alter their policies for malaria endemic areas like India.

Vitamin C

Vitamin C or ascorbic acid is water -soluble vitamin, which is required for the synthesis of collagen. It plays an important role in the synthesis of the neurotransmitter, norepinepherine essential for brain function. It activates enzymes for hydroxylation of protocollagen proline and lysine to collagen hydoxyproline and hydroxylysine.

It is a potent antioxidant agent that is easily oxidized and destroyed by heat. It can regenerate other antioxidants such as vitamin E from its oxidized form.

Deficiency

Vitamin C deficiency results in scurvy, but is now a rare event worldwide due to availability of dietary sources rich in vitamin C such as citrus fruits, strawberries, tomatoes, and green vegetables. Breast milk contains sufficient quantities for the baby.

Clinical Manifestations

Symptoms of scurvy include bleeding and bruising, hair and tooth loss, joint pain and swelling. In severe cases, tenderness and swelling of legs, knees and ankles, and consequent pseudoparalysis may be present. The child appears weak, in severe pain with arthralgia and joint effusions, thus adopting a frog-like position to relief his pains. The detection of brawny edema often overlies subperiosteal hemorrhage, which occurs at ends of the femur and tibia.

The gums may be affected, leading to bleeding and tooth loss. Subconjuntival hemorrhage occurs and peticheal hemorrhages may result in the skin and mucus membranes. Delayed wound healing is a recognized complication. Such symptoms appear to be related to

weakening of collagen in blood vessels. Microcytic hypochromic anemia due to vitamin C deficiency may be detected.

Early symptoms like fatigue may result from diminished levels of carnitine, which is needed for production of energy from fat, or from decreased synthesis of norepinephrine.

Severe scurvy may cause degeneration of skeletal muscles, bone marrow depression, and adrenal atrophy.

Diagnosis

The diagnosis is based mainly on the characteristic clinical picture and is supported by radiological finding of subperiosteal hemorrhage with calcification and ground glass appearance of metaphysis due to atrophy of bone trabeculae. The diagnosis is confirmed by plasma concentration of vitamin C of less than 1 mg/L.

Treatment

Scurvy is treated by oral supplement of vitamin C of 100–200 mg daily for 1 week followed by 25–50 mg/day given orally. Treatment should be started early once the diagnosis is suspected. Diet should include juices rich in vitamin C.

Transient tyrisonemia in the neonatal period in low birth babies is corrected by administration of vitamin C.

X-Ray changes may take up to a year to disappear.

Toxicity

There has been no reliable scientific evidence that large doses of vitamin C are toxic or detrimental to health.

Fat-Soluble Vitamins

Vitamin A

Vitamin A is essential for vision, growth, cellular differentiation, reproduction, and the integrity of the immune system. There is a close metabolic relationship between vitamin A and protein. It is necessary to maintain a satisfactory level known as total body pool to meet physiological needs in addition to a constant liver reserve that may be required during stress. This is achieved by taking vitamin A (ratinol) and various carotenoids such as B- carotine, a-caroten, and cryptoxanthin that biologically functions as vitamin A.

The best sources are animal liver and fish liver oil, milk, whole egg, and other dairy and egg products. Active carotenoids are abundant in carrots, dark green leafy vegetables like spinach, lettuce, tomatoes, sweet potatoes, and in some fruits like papaya. The absorption and utilization of vitamin A and carotinoides are enhanced by dietary fat, protein, and vitamin E.

Properties

Vitamin A has several functions in the human body of which vision seems most important. Ratinol is combined with the protein opsin forming the photosensitive pigment of the rods, which is required for vision in dim light. The photorecepters of cones contain the same chrophore (ratinal) that are linked with protein iodopsin, which is important for color vision. The influx of calcium as a mediator triggers a nerve impulse allowing light to be perceived by the brain.

Vitamin A acts as a growth promoter. Linear growth of children is significantly associated with plasma retinol concentration. It is also necessary for morphological and functional integrity of the skin.

Vitamin A has anti-infective action and its metabolites are essential to T and B cell growth and function. It enhances immunity, thereby has been demonstrated to reduce childhood morbidity and mortality from common intercurrent infectious diseases including diarrheal diseases, respiratory infections, and proved to have a substantial impact on measles morbidity and mortality.

Vitamin A is important in iron-deficient patients not responding to medicinal iron therapy. There is a strong correlation between serum retinol and hemoglobin in children and pregnant women. Supplementation shows significant increase in retionol, hemoglobin, hematocrit, serum iron, and saturation of transferin. Recent reports have also indicated that vitamin A is essential for hemopoiesis.

Vitamin A functions as regulator of intracranial pressure and it influences the rate of secretion of the cerebrospinal fluid. Hence hyper or hypo-vitaminosis A may lead to increased intracranial pressure. β-carotene and vitamin A have also been shown to be effective in the prevention and treatment of different types of cancer.

Normal serum levels in pregnant women, especially during the first trimester, protects against the recognized association of neural tube defects of babies born to vitamin A-deficient mothers and similarly for meningomyloceles. Vitamin-deficient mothers have less

amounts of vitamin A in their breast milk and newborns usually have little liver stores.

Vitamin A Deficiency

Vitamin A is endemic in many developing countries and its prevalence is particularly high in southeast Asia including India, Indonesia, Bangladesh, and the Philippines. Vitamin A deficiency does not occur as an isolated problem, but it is invariably accompanied by PEM and infections like diarrheal diseases, respiratory infections, measles, malaria, and urinary tract infections, which are common childhood diseases.

Its deficiency interferes with rhodopsin production, impairs rod function, and results in impairment of dark adaptation, leading to night blindness that constitutes the early sign of vitamin A deficiency. This is followed by conjunctiva xerosis where epithelial cells undergo squamous metaplasia, the tear glands become blocked with horny plugs of keratin with diminution of secretions and dryness of cornea. It appears in the temporal quadrant and gives rise to formation of Bitot spots. These are considered early signs of vitamin A deficiency and are particularly responsive to treatment.

If untreated this will lead to corneal xerosis when dryness spreads to the cornea with keritinization of epithelial surface resulting in a dull, hazy, and lusterless dry appearance. This may be followed by keratomalcia or corneal ulceration, which presents as erosion of part or whole thickness of the corneal thickness at its periphery. This may lead to perforation of the retina, extrusion of intraocular contents and loss of the globe, and subsequently lead to corneal scars and xerophthalmic fundus. Treatment of patients suffering from malnutrition should be preceded by restoration of liver stores, else keratomalcia may pursue rapidly.

Deficiency is associated with increased morbidity and mortality from infectious diseases, like diarrheal diseases, acute respiratory infections, measles, malaria, TB, and HIV. Episodes of infection hasten the depletion of vitamin A stores and mild deficiency is associated with increased mortality. It has been demonstrated that deficiency is associated with impaired phagocytosis, reduced activity of T- killer cells, and impaired immunoglobulin response to antigens.

Chronic or acute deficiency leads to deceleration or cessation of linear growth while supplementation leads to restoration of normal growth. It equally leads to metaplasia of skin cells, thus blocks sebaceous glands and hair follicles. Hypovitaminosis A leads to increased intracranial pressure (pseudotumor cerebri) similar to hypervitaminosis A.

Diagnosis

Vitamin A deficiency is suspected by its characteristic clinical manifestations and confirmed by detection of low serum vitamin A of less than 200 ug/L and carotenoids of less than 500 μg/L. Dark adaptation tests may be helpful in the diagnosis. Xerosis conjunctivae can be detected by microscopic examination of the conjunctiva. Examination of scraping from the eye and vagina is recommended as diagnostic test. Vitamin A and retinol in serum is measured by high performance liquid chromatography (HPLC).

Treatment

In the acute phase of Vitamin A deficiency like xerophthamia, treatment involves administration of 1,500 μg/day of retinol orally for 5 days and then continued with IM injections of vitamin A in a dose of 7,500 μg daily until recovery occurs.

In latent vitamin A deficiency, a single dose of 1,500 μg is usually sufficient.

Prevention

Prevention of vitamin A deficiency among young children in developing countries is essential to reduce its complications and to achieve reduction of the high infant morbidity and mortality noted in these countries. Raising vitamin A status in communities with high prevalence of xerophthalmia is an urgent necessity and should be considered a national health priority.

Nationwide program to ensure adequate intake of vitamin A is an essential step in the management. Water misciple oral preparations are preferable since, in the presence of fat malabsorption, absorption of oily preparations may be poor. Deficiency of vitamin A in endemic areas may be prevented with a recommended daily intake of 800 μg retinol in premature infants, 400 μg in term and older infants, and 700–1000 μg in older children.

As for affected children and those at high risk, a periodic administration of large doses is recommended.

200,000 units of vitamin A should be given prophylacticaly every 6 months to pre-school children. This approach should be complemented by fortified food rich in vitamin A like milk, margarine, and bread. Similarly, well-balanced diets should also be encouraged through health education and school health programs.

Vitamin A Toxicity

When ingested in very high doses of preformed vitamin A, either acutely or chronically, it causes many toxic manifestations including headaches, nausea, vomiting, abdominal pain, diplopia, irritability, seizures, alopecia, dryness of mucus membranes, desquamation of the skin, bone abnormalities, and liver damage.

Signs of toxicity appear when chronic daily intakes of 20,000 IU in infants and young children are given. High incidence of >20% of spontaneous abortions, birth defects including malformations of the cranium, face, heart, thymus, and central nervous system was observed in fetuses of women ingesting therapeutic doses of 0.5–2.5 mg/kg of 13-*cis* retinoic acid (isotretinoin) during the first trimester of pregnancy.

Carotinoids in food, if ingested chronically in very large doses, are not known to produce toxic manifestations. They can, however, produce yellow discoloration of the skin and palms, but not the sclera, which differentiates it from jaundice. Hypercarotenosis is benign and can be corrected by lowering of intake of carotenoids.

Hypervitaminosis A leads to increased intracranial pressure (pseudotumor cerebri). Symptoms include vomiting, irritability, drowsiness, bulging of the fontanel, hydrocephalus, diplopia, papillodema, and cranial nerve palsies.

Excessive ingestion of vitamin A for several weeks leads to pruritis, alopecia, seborrheic cutaneous lesions, fissuring of the corners of the mouth, and desquamation of palms and soles.

Vitamin E

Vitamin E comprises a family of eight antioxidants; however, α-tocopherol is probably the only active form. It is found in large quantities in the body and appears to have the greatest nutritional significance. It is a fat-soluble antioxidant and direct hydrogen donor. It intercepts free radicals known to destroy fats, which form an integral part of the cell membrane. It also protects low-density lipoproteins (LDLs) from oxidation. LDLs transports cholesterol from the liver to different tissues in the body and have been demonstrated to inhibit platelet aggregation and enhance vasodilation.

It is found naturally in foods in varying amounts. Its major sources include vegetable oils like sunflower and olive oils, nuts, whole grain, and green leafy vegetables.

Deficiency and Clinical Manifestations

Serum levels tend to be low at birth, particularly in low-birth-weight infants and babies fed on formula milk high in polyunsaturated fat. Vitamin E is associated with hemolysis in the preterm infants at age of 6–10 weeks and hemolytic anemia is perhaps the only commonly observed abnormality in children. Secondary deficiency occurs in severe malnutrition, fat malabsorption syndromes like cystic fibrosis, biliary atresia, coeliac disease, and abetalipoproteinemia.

The developing nervous system is particularly vulnerable to vitamin E deficiency. Severe deficiency results mainly in neurological symptoms including cerebellar ataxia, polineuropathy, myopathy, and pigmented retinopathy.

Diagnosis

Diagnosis is confirmed by a low serum level of less than 5 mg/L (11μmol/L).

Treatment

Treatment includes dietary support with foods rich in vitamin E together with vitamin E supplementation in clinically affected patients. The dose of vitamin E (tocopherol acetate) ranges from 10 to 20 mg/K/day.

Toxicity

Premature infants appear to be vulnerable to a-tocopherol supplementation as a possible cause of hemorrhage. Excessive supplementation has been suggested to accelerate progression of retnitis pigmentosa.

Vitamin K

Vitamin K (phytomenanadione) has a recognized role in controlling the formation of prothrombin and acts as cofactor for synthesis of clotting factors II, VII, IX, and X in the liver. It has a biological role as cofactor for an enzyme that catalyses the carboxylation of glutamic acid resulting in its conversion to gamma-carboxyglutamic acid, which is important in the calcium-binding function of some proteins. The ability to bind to calcium ions is required for activation of vitamin K-dependent coagulation factors.

Vitamin K1 is a naturally occurring fat-soluble compound and it found in high concentrations in liver, soya beans, cotton and olive oil. It is, however, found in smaller quantities in vegetables such as spinach and tomatoes. *Vitamin K2*, on the other hand, is produced by gut flora in the body.

Deficiency

Vitamin K is usually obtained from intestinal bacterial synthesis and only a small proportion comes from external sources. Breast milk is an especially poor source and thus, breast-fed infants are susceptible to deficiency. In the first few days of life, the gut is sterile and hypoprothrombinemia may occur. Deficiency may occur in malabsorption or by impaired entrohepatic circulation.

Vitamin K deficiency may manifest from early life as hemorrhagic disease of the newborn. Bleeding may occur in the umbilicus, gums, nose, intestine, or under the skin, and massive hemorrhage may occur in the gastrintestinal tract. Intracranial hemorrhage may also occur.

Later in life, vitamin K deficiency is a potential hazard in malabsorption, progressive liver disease, resulting in prolonged prothrombin time and tendency to bleeding.

All coagulation factors dependent on vitamin K including prothrombin, factors II, VII, IX, and X are depressed; therefore, remain as a cause of bleeding.

Warfarin, an anticoagulant, interferes with vitamin K function, while broad-spectrum antibiotics can interfere with endogenous production of vitamin K by bacteria. Cyclosporines and salicylates, on the other hand, interfere with vitamin K recycling in the gut.

Diagnosis

The diagnosis is established by prolongation of blood coagulation time, prolonged prothrombin time and partial thromboplastin time.

Treatment

In cases of hemorrhagic disease of the newborn, 1 mg of vitamin K should be given. In later childhood, the dose is increased to 5 mg daily. I.M. injections are best avoided in the presence of severe bleeding. Fresh frozen plasma or whole blood transfusion may be necessary in some patients.

Prevention

Because of the risk of bleeding, breast-fed infants should receive prophylaxis of 1 mg vitamin A. preterm infants may receive 0.5 mg intramuscularly.

Toxicity

Vitamin K and its water-soluble analogues, except phytonadione, have induced hemolysis in large doses and children with G6PD are especially susceptible. Large doses in the newborn have caused anemia, hyperbilirubinaemia, and kernicterus in preterm infants.

58 Rickets

Trond Markestad

Nutritional rickets due to deficiency of vitamin D, dietary calcium, or both is among the most common disease entities among young children in the Middle East, Asia, and Africa. It has also reoccurred in high-income countries among immigrants from parts of the world where rickets is common and among children on restricted diets. Rare forms of rickets are due to genetic diseases affecting vitamin D metabolism or response to vitamin D, or diseases resulting in renal loss of phosphate.

Definition and Pathology

Osteomalacia denotes inadequate mineralization of organic bone tissue, both children and adults, while *rickets* is the manifestation of inadequate mineralization of *growing* bone, i.e., before the fusion of the epiphyses. As the proliferating osteoid tissue in the metaphysis fails to mineralize, deformation and stunted growth occur. Inadequate mineralization also occurs in the shafts of the long bones and in membranous bone leading to pathologic softness and deformation.

Pathogenesis

The extracellular fluid concentration of calcium (Ca) and phosphate (P) are tightly regulated, mainly through the actions of parathyroid hormone (PTH) and the hormonal form of vitamin D, 1,25-$(OH)_2$D (*Fig. 58.1*). Both Ca and P concentrations must be appropriate to permit adequate deposition of Ca-Pi crystals in the bone matrix.

Ca homeostasis is mainly controlled at the intestine in that serum concentration of 1,25-$(OH)_2$D determines how large a fraction of the dietary Ca that is absorbed. When serum Ca drops (i.e., as a result of low dietary intake), 1,25-$(OH)_2$D synthesis is stimulated. This stimulation is indirect in that hypocalcemia initiates increased synthesis of PTH which, in turn, stimulates the synthesis of 1,25-$(OH)_2$D from 25-OHD in the renal tubular cells. The increased 1,25-$(OH)_2$D level raises serum Ca by promoting intestinal Ca absorption. High PTH and 1,25-$(OH)_2$D may together also mobilize Ca from bone and reduce Ca excretion in the kidneys. In this way, an adequate extracellular concentration of Ca, which is of vital importance for the living organism, may be maintained at the expense of bone mineralization.

Phosphate (P) homeostasis is mainly controlled at the kidney, since intestinal P absorption is nearly complete and largely independent of hormonal regulation. A high phosphate content of the diet will lead to a high serum concentration of P, which, in turn, will cause a drop in serum Ca, partially through a direct inhibitory effect on 1,25-$(OH)_2$D synthesis. The fall in serum Ca will stimulate PTH secretion which, in turn, will induce phosphaturia and raise serum Ca. On the other hand, a low serum concentration of P promotes 1,25-$(OH)_2$D synthesis and inhibits PTH secretion, and consequently reabsorption of P is increased in the kidneys.

Lack of vitamin D, disorders in the regulation of vitamin D metabolism or response to 1,25-$(OH)_2$D, and inadequate supplies or pathologic losses of Ca or P may all cause rickets. On the basis of etiology and pathogenesis, rickets may be classified as *calciopenic* or *phosphopenic* rickets (*Table 58.1*).

Symptoms and Signs

Skeletal

The most important symptoms of rickets are bone deformity and, in advanced cases, stunted growth (rachitic dwarfism). Bone pain and tenderness may be significant symptoms in *calciopenic* rickets.

The relative growth rates of different bones and therefore the relative distribution of skeletal manifestations change with age, since the most rapidly growing bones will be the most severely affected. Thus, symptoms and signs will be particularly prominent in the skull at birth and in early infancy; in the wrist, costochondral junction, and knee during the first year of life; and in the lower extremities later during childhood. The weight bearing will increase the deformity of the lower limbs when the young child begins to walk.

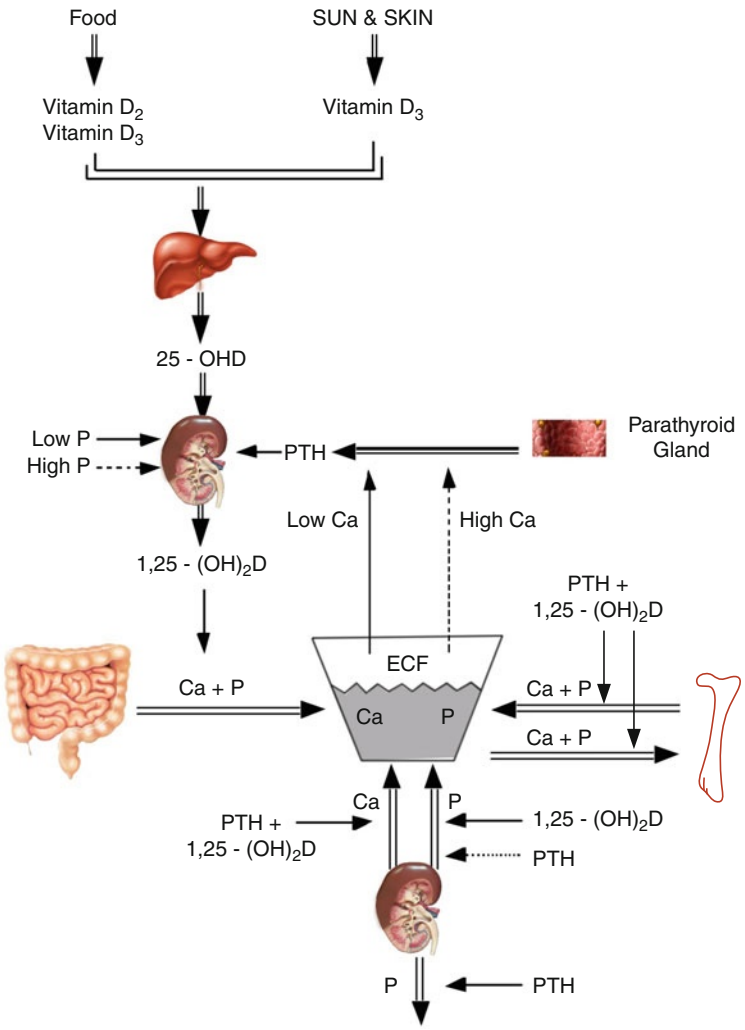

Figure 58.1
Biochemical pathways of vitamin D, and endocrine regulation of Ca and P homeostasis. ECF, extracellular fluid, PTH, parathyroid hormone, ⟶ stimulation; ⇢ inhibition

Skull

Craniotabes describes the thinning of the skull, and is detected as a "ping-pong ball" consistency when pressing on the parietal or occipital bones. It is important to note, however, that craniotabes along suture lines may be normal in breast-fed and in preterm babies in early infancy, and that localized craniotabes is a frequent and normal finding in newborns, particularly if the head has been engaged in the pelvis for a long time. Craniotabes is also seen in other diseases, such as osteogenesis imperfecta. *Frontal bossing* describes a prominence of the central parts of the frontal and parietal bones giving the head a box-like appearance (caput quadratum). This impression may be augmented by flattening of the head (particularly the occiput) or asymmetry caused by the softness of the skull and relative immobility of the infant. *Wide sutures*, a large *anterior fontanelle* and delayed closure of the fontanelle, may be other features, but they are nonspecific and may be normal variants.

Extremities

Swelling around joints because of widening and lateral bulging of uncalcified tissue at the metaphysis is

Table 58.1
Biochemical characteristics of various forms of rickets

Type of rickets	Serum Ca	Serum P	ALP	PTH	25(OH)D	1,25-$(OH)_2$D	Urine AA

↓=Decreased, ↑=Increased, Urine AA=urine aminoacids, N=Normal, V=Variable
[a]May be elevated on diagnosis if received even small doses of vitamin D within the last few days
[b]Rare as a single cause, more often seen together with vitamin D deficiency
[c]Within normal reference range, but inappropriately low considered low serum P

particularly noticeable at the wrist, knee, and ankle. Increased width of the epiphyseal line can be palpated at the wrist and ankle (*double malleolus*). After the first year, *deformities* like genu varum, genu valgum, coxa vara, and saber shins (anterior convexity of the tibia) may develop.

Thorax

Rachitic rosary describes the enlargement of costochondral junctions of the ribs (◉ *Fig 58.2*), and *Harrison's groove* the horizontal depression of the chest wall corresponding to the insertion of the diaphragm. *Pectus carinatum* (pigeon chest) and other thoracic deformities may also develop.

Spine and Pelvis

Scoliosis, dorsolumbar kyphosis, and lumbar lordosis may develop. Children with lordosis commonly have a deformity of the pelvis, particularly forward projection of the promontory, sacrum, and coccyx. In females, these changes may later cause difficulties during pregnancy and childbirth.

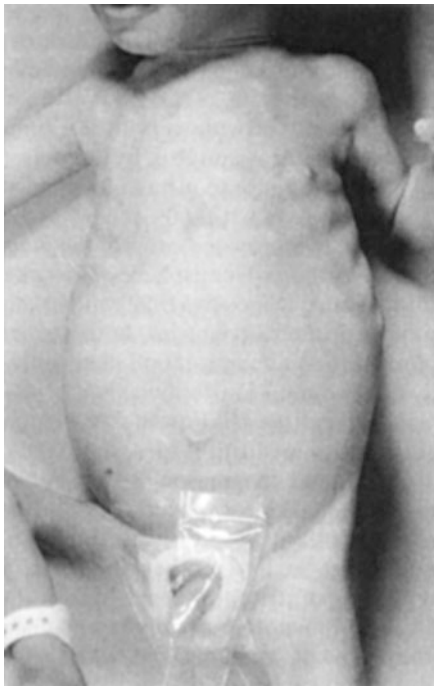

Figure 58.2
Rachitic rosary in a patient with florid rickets. (Courtesy of Prof. Hishan Nazer, Amman, Jordan)

Teeth

The temporary and permanent teeth may be abnormal, with delayed eruption, enemal hypoplasia and irregular pits, and increased tendency to caries.

Muscular

Muscular hypotonia is typical of *calciopenic* rickets and may be caused by 1,25-$(OH)_2$D deficiency. Hypotonia may be marked during infancy (floppy infant) and cause delayed motor development.

Tetany

Hypocalcemic tetany may occur at any stage of *calciopenic* rickets and even before other clinical findings or radiographic features are evident, but is *not* a feature of *phosphopenic* rickets. In latent tetany (serum Ca usually 1.75 to 1.90 mmol/L), the child may be irritable and show positive Chvostek or Trousseau signs. In manifest tetany, convulsions are most frequently observed, but carpopedal spasm and laryngospasms may occur. Serum Ca levels are usually below 1.60 mmol/L.

Malnutrition and Infection

Children with *calciopenic* rickets, especially caused by vitamin D deficiency, are often wasted in addition to being stunted in growth. Poor muscular development, possibly because of 1,25-$(OH)_2$D deficiency, association of vitamin D deficiency with a poor social environment, and poor feeding because of muscular hypotonia and malaise, may all contribute. Pot belly is also a characteristic feature of the muscular hypotonia of rachitic babies, so rickets per se may be confused with primary malnutrition and malabsorption syndromes.

Children with calciopenic rickets (particularly vitamin D deficiency rickets) are prone to infections, especially pneumonia. The soft thorax, muscular hypotonia, and concomitant malnutrition may represent the most significant risk factors, but active vitamin D metabolites may also have a direct effect on the immune system.

Radiographic Signs

The pathologic features discussed above are best visualized by x-ray film. In the metaphysis of the long bones, the following features are typical and most easily seen in the distal end of the radius and ulna: wide and irregularly calcified epiphyseal cartilage (the growth plate), concave and ragged border between calcified and noncalcified structures ("cupping" and "fraying"), and increased width of the metaphysis ("splaying") (*Fig. 58.3*). In more advanced cases, changes are also observed in the shaft, namely, diffuse rarefaction, thinning of the cortex, radiolucent transverse bands, greenstick fractures, and deformities.

The first sign of healing is typically the reappearance of a calcified transverse line that is separated from the distal end of the shaft by a radiolucent zone of osteoid tissue. The calcified line may appear within 2 weeks of the vitamin D and Ca treatment in nutritional rickets. As the osteoid tissue becomes calcified, the radiolucent zone between the calcified line and the shaft gradually disappears. The recalcification of the rachitic metaphysis may, however, also start at the visible end of the shaft and progress toward the epiphyseal cartilage. In the healing of advanced rickets, calcification of osteoid tissue under the periosteum of the shaft may present radiographically as a cortical envelope of uniform or lamellated density.

Figure 58.3

Biochemical Signs

Serum alkaline phosphatase (ALP) is almost always elevated. The serum concentrations and urinary excretion of Ca and P, urinary excretion of aminoacids, and serum concentrations of PTH and vitamin D metabolites will vary according to the etiology and stage of disease as discussed below for each rachitic syndrome (*Table 58.1*).

Differential Diagnosis

The combination of clinical signs, biochemical and radiographic features are rather specific. The main challenge is to define the specific cause of rickets. However, various *clinical* skeletal deformities may also be normal variants (e.g., bow legs, thorax deformities, and craniotabes), or represent a multitude of skeletal dysplasias. *Hypocalcemia* of rickets may be confused with hypocalcemia of hypoparathyroidism and magnesium deficiency, especially since tetany may occur before bony changes are evident on radiographs or serum ALP is significantly elevated. However, serum P is high in hypoparathyroidism and hypomagnesemia, but normal or low in rickets, except when rickets is caused by renal failure. It is important to note that serum P is normally considerably higher in children than in adults, and that an improper technique of sampling blood may give a falsely high value because of hemolysis.

Calciopenic Rickets

Calciopenic rickets denotes that the Ca supply is inadequate for normal bone mineralization. By far, the most common cause is *nutritional rickets*, i.e., vitamin D deficiency, lack of Ca in the diet, or a combination of both. Intestinal malabsorption of vitamin D or Ca (e.g., celiac disease) may be underlying causes. Inadequate synthesis of 25-OHD, which is the substrate for 1,25-$(OH)_2$D synthesis, may occasionally fail in cases of severe liver failure. Very rare causes are genetic disorders of vitamin D metabolism or end-organ resistance to the effect of 1,25-$(OH)_2$D.

Nutritional Rickets

Until recent years, nutritional rickets was thought to be due to vitamin D deficiency, except in rare cases of extreme diets with a very low Ca content. It is now acknowledged that low Ca diets may be the most important cause in parts of Africa (e.g., Nigeria and South Africa) and Asia (e.g., Bangladesh), and that a combination of low Ca intake and lack of vitamin D may be a quite common cause in many parts of the world and among some ethnic groups. Diets with less than approximately 300 mg elemental Ca per day have been identified as a major risk factor. Inhibition of Ca absorption by diets rich in oxalates (green, leafy vegetables) or phytate (unleavened bread) may add to the Ca deficiency. With a low Ca diet, vitamin D metabolism is stimulated to increase fractional absorption of Ca from the intestines. The increased synthesis of 1,25-$(OH)_2$D leads to a higher consumption and subsequent risk of frank vitamin D deficiency in children who are inadequately exposed to sunshine or vitamin D supplementation.

In nutritional rickets from vitamin D deficiency, lack of sunshine exposure or insufficient dietary intake of vitamin D leads to inadequate synthesis of 1,25-$(OH)_2$D.

Food items generally provide very little vitamin D, although fatty fish are important sources in some areas. The most important natural source is, by far, dermal synthesis of vitamin D_3 in response to ultraviolet (UV) irradiation from sunshine. This is why as much as 60–90% of the children in the polluted and overcrowded cities in the industrialized nations of the northern hemisphere had rickets in the late ninteenth and early twentieth century. Since the 1930s–1940s, the disease has become rare in these countries, however, because of vitamin D fortification of central food items or widespread use of individual vitamin D prophylaxis.

Paradoxically, the disease is now most common in the sunny subtropical countries in North Africa, the Arab countries, India, and China, and the main reason is that cultural habits cause inadequate sunshine exposure of women of childbearing age, and of infants. Typically, the infant with rickets is born to and breast-fed by a mother who herself is vitamin D deficient because of strict adherence to the cultural habit of wearing a veil. The mother usually has no clinical symptoms or signs of osteomalacia. Vitamin D is stored in the body, mainly in fatty tissues. The infant is born vitamin D deficient because the stores acquired in utero are proportional to the mother's vitamin D nutritional status during pregnancy. Furthermore, the vitamin D content of breast milk is proportional to the nursing mother's vitamin D nutritional status. The lack of vitamin D in breast milk will augment the infant's deficiency, but the vitamin D content of breast milk is inadequate even when the mother has a normal vitamin D nutritional status.

In Northern Europe and North America, nutritional rickets has reappeared as a significant clinical problem among children of families with extreme vegetarian diets, and among immigrants, particularly from Asia and Africa. Increased skin pigmentation, habits of clothing, traditional diets that limit vitamin D and Ca uptake and lack of tradition to take vitamin D supplements may all contribute to the risk of rickets in immigrant populations.

Clinical Features

Nutritional rickets during infancy and early childhood is usually due to vitamin D deficiency. Congenital rickets and rickets in early infancy occur, but the typical age of manifestation is between 4 and 18 months. When dietary Ca deficiency is the major cause, the typical age of debut is 3–6 years or during the pubertal growth spurt (adolescent rickets).

Symptoms and signs are described above. Important but not obligatory features of advanced rickets are muscuar hypotonia, irritability, and malnutrition. At least for rickets due to vitamin D deficiency, *three stages are described* on the basis of clinical and laboratory data:

- *Stage 1*: is characterized by low serum Ca, occasionally to the point of causing tetany, but normal serum P, and normal or minimal changes on radiographs. This stage is caused by insufficient intestinal Ca absorption, and is transient until compensatory mechanisms come into play.
- *Stage 2*: Secondary hyperparathyroidism has reestablished a normal serum Ca by mobilizing bone release and renal reabsorption of Ca, but serum P is decreased because of increased renal excretion. Clinical and radiographic signs of rickets become evident.
- *Stage 3*: Continued deficiency of 1,25-$(OH)_2$D and hyperparathyroidism result in insufficient mobilization of Ca from bone to maintain normal serum Ca. Hypocalcemia as well as hypophosphatemia evolves. Clinical symptoms, findings, and radiographic changes are more severe. Tetany may again become an important symptom.

Diagnosis and Differential Diagnosis

The diagnosis of nutritional rickets is based on a typical history, clinical findings and laboratory data, and a rapid response to vitamin D treatment. Muscular hypotonia may improve within days, radiographs within 2–3 weeks, and healing usually occurs within 8–12 weeks.

Serum concentrations of Ca and P are normal or low, dependent on the stage of rickets as described above. Serum ALP is elevated except that it may occasionally be normal in early stage1 rickets. Generalized aminoaciduria reflects secondary hyperparathyroidism and is not specific for nutritional rickets.

Measurement of vitamin D and its metabolites in serum is not uniformly available, not always diagnostic, and usually not necessary. Typically, 25-OHD, which reflects the vitamin D nutritional status, is below 25 nmol/L and PTH is elevated (secondary hyperparathyroidism). The 1,25-$(OH)_2$D is low or normal (but inappropriately low given the hyperparathyroidism) at diagnosis, but increases to very high levels within days of starting vitamin D therapy. High levels of 1,25-$(OH)_2$D may be seen even at the time of diagnosis due to recent sunshine exposure or inadvertent intake of vitamin D through food items.

If the medical history is not typical for vitamin D or Ca deficiency, malabsorption syndromes may need to be considered. Vitamin D is a lipid-soluble vitamin, and malabsorption may per se result in vitamin D deficiency if the child is not exposed to sunshine. Children on antiepileptic medication, especially phenytoin and phenobarbital, may develop vitamin D deficiency because of drug induction of hepatic enzymes that degrade vitamin D.

Iron deficiency anemia is commonly associated with viamin D deficiency rickets, and a hematological syndrome with anemia, leucomoid blood smear, and hepatosplenomegaly has been described.

Treatment and Prophylaxis

Sunshine exposure or artificial ultraviolet light will cure vitamin D deficiency rickets, but oral or intramuscular administration of vitamin D_3 or D_2 is needed for reliable treatment. A daily intake of 50–100 μg (2000–4000 IU) until healing, or a dose of 10–15 mg (400,000 to 600,000 IU) given as one dose or divided into two to four doses over 2–4 days with no further vitamin D therapy, are equally effective. The large dose may be given intramuscularly, but oral administration is probably equally or more effective, except if the child is vomiting. One dose of 15 mg will not cause vitamin D toxicity in a child with rickets, and it will not disguise vitamin D-resistant forms of rickets.

With malabsorption, a daily oral vitamin D intake of 100–200 μg, or one or a divided dose of 15 mg is usually adequate to cure rickets, but higher doses or the active metabolite 1,25-$(OH)_2$D may rarely be indicated, particularly if the child has severe liver disease.

Tetany should be treated with 10% calcium gluconate by slow intravenous infusions, 1–2 ml/kg up to a total of 10 ml over 10 min. Vitamin D treatment may trigger a further temporary drop in serum Ca due to rapid deposition in mineral-deficient bone ("hungry bone syndrome"). Therefore, oral Ca should be given, at least during the first 1–2 weeks of vitamin D therapy. If the diet is low in Ca, tapering doses of Ca supplements are advantageous until the healing of rickets. Ca supplementation is particularly important if serum Ca is low. If serum Ca is very low, hospitalization may be necessary the first few days of treatment to observe for tetany. A recommended early dose is 1 g of elemental Ca per day in divided doses as, for example, calcium lactate or calcium carbonate.

After healing of rickets, a daily oral prophylactic dose of 10 μg (400 IU) of vitamin D or sunshine exposure of the skin should be provided. Commercial infant formulas are generally fortified with vitamin D and no supplements are needed.

Prognosis

Nutritional rickets rarely cause permanent sequelae, but it may take 4–5 years before skeletal deformities are corrected.

Vitamin D-Dependent Rickets Type I

In this rare disorder, there is a lack of renal tubular enzymes converting 25-OHD to 1,25-$(OH)_2$D. Serum concentrations of 1,25- $(OH)_2$D are therefore very low, or inappropriately low given the secondary hyperparathyroidism despite adequate 25-OHD levels. The disease is inherited in an autosomal recessive mode. Clinical and standard laboratory findings are similar to those described for nutritional rickets, and become manifest during the first year of life.

The treatment of choice is lifelong physiological doses (0.25–2 μg/day) of alpha-calcidiol (1α-OHD) or calcitriol (1,25-$(OH)_2$D). Initially, Ca supplementation may be beneficial. The aim is radiographic healing and maintenance of serum Ca in the low, P in the normal, and PTH in the high range of normal in order to avoid hypercalciuria and nephrocalcinosis. It is important to note that hypercalcemia can evolve rapidly during calcitriol treatment, particularly at the time when rickets is healed and the need for 1,25-$(OH)_2$D is reduced. The family should therefore be warned of symptoms of hypercalcemia, such as lethargy, poor feeding, nausea, vomiting, constipation, or abdominal pain. Pharmacological doses of vitamin D may also be effective, but is not recommended because of the long half-life and unpredictable effect, particularly a risk of vitamin D toxicity.

Vitamin D-Dependent Rickets Type II

These rare patients have end-organ resistance to the effect of 1,25-$(OH)_2$D, and calciopenic rickets develop despite extremely high serum levels of 1,25-$(OH)_2$D. The disease is inherited as an autosomal recessive trait, and the onset is usually between 6 months and 3 years. There are several clinical variants, and some have alopecia as a distinctive feature.

The patients may benefit from large doses of alpha-calcidiol or calcitriol (15–50 μg/day) and large dietary supplements of Ca. Intravenous Ca may be necessary to initiate healing.

Renal Osteodystrophy (Renal Rickets)

The pathogenesis of renal osteodystrophy is complex and includes renal phosphate retention, malabsorption of Ca secondary to inadequate 1,25-$(OH)_2$D synthesis, and secondary hyperparathyroidism.

Clinical and Investigational Features

Growth failure occurs early. Serum P and the Ca x P product and PTH are elevated, although the Ca value

may be decreased. Serum ALP may be increased. On radiographs, subperiosteal erosions of the middle and distal phalanges typical of hyperparathyroidism may be seen in addition to typical features of rickets.

Prophylaxis and Treatment

Prophylaxis should be started before growth failure is significant and before any radiographic or biochemical evidence of osteodystrophy. Hyperphosphatemia should be controlled by judicious dietary restrictions and the use of phosphate binders, such as calcium carbonate, calcium acetate, or non-calcium binders if there is tendency to hypercalcemia. Acidosis may be controlled with sodium bicarbonate. Calcitriol or alpha-calcidiol is given in doses of 15–50 ng/kg/day (0.01 – 0.05 μg/kg/day) to increase intestinal absorption of Ca and to counteract hyperparathyroidism. As noted above, hypercalcemia can occur rapidly during treatment with active vitamin D metabolites, making clear instructions and close monitoring necessary.

Phosphopenic Rickets

The primary causes of rickets in these conditions are nutritional deficiency, which is limited to specific circumstances such as prolonged parenteral nutrition, feeding of small premature infants, severe malabsorption, or increased renal loss. Serum P is low and, typically, serum Ca is normal and PTH normal or mildly elevated.

Rickets of Prematurity

The fetus acquires 80% of bone minerals during the last trimester. For infants born preterm, it is not possible to provide Ca and P anywhere near the rate of placental transfer through the diet. Small premature babies (particularly babies with a birth weight less than 1000–1500 g) who are fed breast milk or a regular commercial infant formula may therefore develop osteopenia and rickets even if the vitamin D intake is adequate. Preterm babies fed breast milk are at particular risk of rickets because of the low P content of the milk although the Ca content is also too low for adequate mineralization. Biochemical evidence of P depletion (low serum P and low urinary excretion of P, but normal serum Ca and relatively high urinary excretion of Ca) may develop within 2–4 weeks, and rickets within 2–4 months of age. Preterm infants with bronchopulmonary dysplasia are at particular risk. ALP is usually, but not always, markedly elevated, and 1,25-$(OH)_2$D levels are high.

Craniotabes may be obvious, but there are generally few or no physical signs of rickets. Severe osteopenia and typical metaphyseal features of rickets are seen on radiographs, often together with fractures, particularly of the ribs.

Rickets may be prevented by securing a daily intake of 10 μg of vitamin D from the first week of life, and a supplement of 50–60 mg of elemental Ca and 30–40 mg of inorganic phosphorus per kilogram per day to infants with a birth weight below 1500 g, who receive breast milk. For infants on a regular formula, the dose may be somewhat lower. For preterm infants fed breast milk, supplements containing Ca, P, and other nutrients that are insufficient in breast milk, are commercially available. The amount of Ca and P does not prevent some degree of osteopenia, but larger doses may be poorly tolerated and cause malabsorption of other nutrients. However, if biochemical evidence of bone disease (ALP $>$ 1000 U and/or P below 1.7–1.8 mmol/L) or radiographic changes occur, the mineral supplements may be increased. Commercial formulas specially designed for preterm infants have higher contents of Ca and P and do not need to be supplemented.

Hypophosphatemic Rickets due to Renal Loss of Phosphate

Increased renal loss of inorganic phosphate (P) can be caused by a number of complex primary or secondary renal tubular defects, such as the Fanconi syndromes and distal renal tubular acidosis, or by conditions with isolated renal phosphate leak, particularly X-linked, autosomal dominant, and autosomal recessive hypophosphatemic rickets.

In isolated renal phosphate loss, a group of hormones, *phosphatonins*, plays a central role in that they stimulate phosphaturia. The best-described phosphatonin is fibroblast growth factor-23 (**FGF23**). The mechanisms of control of FGF23 and its role in normal P homeostasis are not well understood, but a kidney–intestine–bone hormonal axis controlling P homeostasis and bone mineralization exists. In the inheritable entities with isolated phosphaturia, genetic mutations cause increases in FGF23 and possibly other phosphatonin levels, which inhibit reabsorption of P in the proximal renal tubules. The phosphatonins also lower 1,25-$(OH)_2$D somewhat due to suppression of the 1 alpha-hydroxylase activity in

the renal tubular cells. In these conditions, the serum 1,25-$(OH)_2$D levels are usually still within the normal reference range, but inappropriately low given the low serum P, and PTH is normal or only slightly increased.

Familial Hypophosphatemic Rickets

This group is the most common cause of rickets in populations where nutritional rickets is combated through general prophylactic programs.

X-linked hypophosphatemic rickets (XLH) is the most common entity in this group with a prevalence of approximately 1 in 25,000. A mutation in the *PHEX* gene (phosphate-regulating gene with homologies to endopeptidases on the X-chromosome), which is situated on chromosome Xp22.1, results in phosphaturia, at least partially through increased FGF23 levels. *Autosomal dominant hypophosphatemic rickets* and *autosomal recessive hypophosphatemic rickets* are very rare conditions.

In XLH, symptoms usually appear between the end of the first year to 3 years of age and are dominated by slow growth, bowing of the legs, and clinical findings of rickets. The patients may have poor dental development and tooth abscesses, but usually not the enamel defects typical of calciopenic rickets. Muscular hypotonia, bone tenderness, and tetany are not features of this condition. In XLH, the male is generally more severely affected than the heterozygous female who does not even need to show any clinical evidence of disease, but just fasting hypophosphatemia. The clinical expression may, however, be extremely variable. The autosomal and recessive forms usually present later in childhood than XLH or even in adulthood.

In XLH, serum P is always low (usually < 0.9 mmol/L), but serum Ca is normal, and there is no evidence of hyperparathyroidism (normal PTH and no aminoaciduria) or general tubular defects (no glucosuria, proteinuria, bicarbonaturia, or kaliuria). Since reduced tubular reabsorption of P is the primary defect, urinary excretion of P is high despite low serum P.

Treatment

The mainstay of therapy is a combination of active vitamin D metabolites (calcitriol or alpha-calcidiol) and phosphate supplementation. In XLH, a dose of 20–60 ng/kg/day divided in two doses (usual total maintenance dose, 0.5–1.0 μg/day) and phosphate in a dose of 0.5–1.0 g/day elemental phosphorus for young children and 1–4 g/day for older children. Phosphate intake may be limited by diarrhea and needs to be increased gradually, starting with approximately 40 mg elemental phosphorus per kg/day. Because of rapid urinary excretion of P, the phosphate supplement needs to be divided in four to six doses per 24 h. Phosphate may be supplied as Joulie solution or neutral phosphate tablets. The doses of active vitamin D metabolites and phosphate must be adjusted by close monitoring of serum Ca, P, ALP and PTH, and urinary excretion of Ca. Excessive vitamin D metabolites may lead to hypercalcemia, hypercalciuria, and nephrocalcinosis, while excess phosphate may lead to decreased intestinal Ca absorption resulting in secondary hyperparathyroidism and more bone lesions. Urine Ca/creatinine ratio above 0.25 mg/dl or above 0.7 mmol/L in the second morning void, or greater than 4 mg Ca per kilogram per day may cause nephrocalcinosis and progressive deterioration of renal function. Renal ultrasound should be performed regularly to monitor for nephrocalcinosis. The aim of the therapy is healing of rickets, normal linear growth rate, and avoidance of complications.

Low serum P and elevated serum ALP may be detected several months before rickets develops, and with early treatment rickets may be avoided.

Corrective osteotomies should not be attempted until active rickets is healed, judged by radiographs and normal serum ALP and Ca levels. Active vitamin D metabolites should be discontinued 1 week before surgery if surgery requires immobilization because of risk of postoperative hypercalcemia.

Hereditary Hypophosphatemic Rickets with Hypercalciuria

This rare genetic condition is mainly reported from the Middle East. Renal loss of P leads to hypophosphatemia and subsequent elevated serum 1,25-$(OH)_2$D and ALP. High 1,25-$(OH)_2$D levels leads to increased intestinal Ca absorption, hypercalcemia, hypercalciuria (even when the serum Ca is normal), and decreased serum PTH. Most patients present with rickets and short stature. The patients frequently develop renal stones as a result of increased urinary secretions of both Ca and P. Therapy consists of oral phosphate supplementation in frequent doses.

Tumor-Induced Rickets (TIO)

Small tumors of mesenchymal origin may cause hypophosphatemic rickets or osteomalacia through the secretion of phosphatonins from the tumor. Such tumors are mainly seen in adults, but pediatric cases have been

reported. The tumors are very small but may be detected with specific scintigraphic methods. A typical feature is very low serum 1,25-$(OH)_2$D levels. Removal of the tumor will cure the condition.

Other Rare Causes of Isolated Hypophosphatemic Rickets

Renal loss of P may occasionally occur in *polyostotic fibrous dysplasia* (as in McCune-Albright syndrome), neurocutaneous syndromes (e.g., epidermal nevus syndrome and neurofibomatosis) because of increased production of phosphatonin.

Fanconi Syndromes

Hypophosphatemic rickets may accompany multiple defects in the proximal renal tubule. Such defects may be part of the clinical picture of a variety of genetically transmitted inborn errors of metabolism (cystinosis, fructose intolerance, galactosemia, Lowe syndrome, tyrosinemia, and Wilson's disease), and some acquired diseases such as exposure to toxins (cadmium, lead, and mercury). Most commonly, however, it is idiopathic, and occurs sporadically or as a dominant or recessive trait.

Hypophosphatemia and increased urinary loss of P is accompanied by excessive loss of all or some of the following substances: bicarbonate leading to metabolic acidosis, potassium leading to hypokalemia and sodium leading to hyponatremia. Glucosuria, proteinuria, aminoaciduria, and hyposthenuria may be detected.

Clinical expression and age of debut vary according to the primary defect. Idiophatic Fanconi syndrome may present as early as during the first year of life. The idiopathic form is diagnosed by identifying the general tubular defect and by excluding the variety of secondary forms.

The idiopathic form is treated similarly to familial hypophosphatemic rickets. Management of secondary forms depends on the primary disorder.

Renal Tubular Acidosis (RTA)

Osteopenia and rickets may develop in these conditions through two mechanisms: In proximal renal tubular acidosis (RTA), phosphate is lost in the proximal renal tubules due to the tubular defect, and in both proximal and distal RTA, metabolic acidosis causes dissolution of bone to buffer a persistent acidosis.

Administration of bicarbonate to correct metabolic acidosis will stop bone dissolution and the secondary hypercalciuria. In proximal RTA with phosphate loss, oral phosphate and active vitamin D metabolites, similar to what is described for familial hypophosphatemic rickets, are needed in addition to bicarbonate.

Conditions Resembling Rickets

Hypophosphatasia

Hypophosphatasia is an autosomal recessive disorder that may present as a congenital lethal form with extremely poor mineralization, a severe infantile form, and later milder forms where the clinical and radiographic features may be confused with those of rickets. Important diagnostic characteristics are low serum ALP concentrations and large quantities of phosphoethanolamine in the urine.

Hyperphosphatasia

Hyperphosphatasia is an autosomal recessive disorder with elevated serum ALP, but normal serum Ca and P concentrations. Bowing and thickening of the diaphysis, variable bony texture with dense and radiolucent areas, and general demineralization on radiographs are other typical features.

Skeletal Dysplasias

Some of these conditions may be confused with rickets because of bone deformity and occasionally because of metaphyseal changes on radiography (metaphyseal chondrodysplasia). However, serum Ca, P, ALP, PTH, and vitamin D metabolites are normal.

59 Obesity

Mohammad El Baba

Over the past three decades, the prevalence of obesity and overweight has increased throughout the world in both adults and children. Once considered a problem only in developed countries, overweight and obesity are now dramatically increasing in low- and middle-income countries. Children around the world are becoming more vulnerable to overweight and obesity-related health risks both in the short- and long term.

Definition

Obesity is defined as excessive fat accumulation that presents a risk to health. Body mass index *(BMI)* is widely accepted method to screen for overweight and obesity for children aged 2–19 years. *BMI* is defined as the ratio of an individual's weight to height squared (kilogram/meter^2) or determined from published tables, nomograms, or calculators. *BMI* is often used to assess weight status, because it is relatively easy to measure and correlates with body fat. It is also used to estimate a person's risk of weight-related health problems.

The World Health Organization (WHO) defines "overweight" as a *BMI* equal to or more than 25, and "*obesity*" as a BMI equal to or more than 30. Outside the United States, *The International Obesity Task Force (IOTF)* standards have been widely used to classify overweight and obesity in children. The standards are based on data from six different international countries and provide age and gender-specific cutoff points for BMI for overweight (25 kg/m^2) and obesity (30 kg/m^2) in children 2–18 years of age using dataset-specific centiles linked to adult cutoff points. In general, ***IOTF*** data appears to give lower estimates for the prevalence of obesity, especially in younger children.

In the United States, the percentile distributions relative to gender and age in the *Centers for Disease Control and Prevention (CDC)* 2000 growth charts are now the preferred reference.

BMI-for-age weight status and the corresponding percentiles are divided into four categories:

1. Underweight: Less than the 5th percentile
2. Healthy weight: 5th percentile to less than the 85th percentile
3. Overweight: 85th to less than the 95th percentile
4. Obese: Equal to or greater than the 95th percentile (BMI of >30 kg/m^2)

For children 0–2 years of age, the weight-for-recumbent length percentiles from the CDC 2000 growth charts are appropriate for evaluating weight relative to linear growth. Children with weight-for-length percentiles more than the 95th are considered overweight.

When compared with WHO child growth standards, CDC charts reflect a heavier, and somewhat shorter, sample than the WHO sample. This results in lower rates of under nutrition (except during the first 6 months of life) and higher rates of overweight and obesity when based on the WHO standards.

Alternative Measures of Fatness

Skinfold Thickness

This is a measurement of double layer of skin and subcutaneous fat at certain sites of the body by using special calibers. Sites commonly used are triceps and subscapular areas. Equations can then be used to estimate fat mass from the skinfold measurements. It is considered an attractive tool because measurements are noninvasive, predictive of total body fat, and may be useful in the monitoring of nutritional therapy in children. Limitations for routine clinical use of skinfold thickness measurements include the lack of validated reference data for different population groups and the considerable potential for measurement errors without training and experience.

Waist Circumference

Abdominal obesity is evaluated clinically by measuring the waist circumference or the ratio of waist circumference to the hip circumference. Compared with BMI, waist circumference in children provides a better estimate of visceral fat whereas BMI is better at estimating subcutaneous fat. Research has linked accumulated

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_59,

visceral fat to increased risk for cardiovascular disease in adults and an adverse lipid profile and hyperinsulinaemia in children.

Prevalence

Using the IOTF standard definition of pediatric overweight and obesity, the worldwide prevalence of overweight and obesity in children and young people aged 5–17 years is approximately 10%, with that of obesity alone being 2–3%. Certain regions and countries have particularly high rates of pediatric obesity: more than 30% of children and adolescents in the Americas, and approximately 20% of those in Europe, are overweight or obese, with lower prevalence rates being seen in the Asia-Pacific region.

Data from *National Health and Nutrition Examination Surveys (NHANES)* (1976–1980 and 2003–2006) show that the prevalence of obesity in the United States has increased: for children aged 2–5 years, prevalence increased from 5.0% to 12.4%; for those aged 6–11 years, prevalence increased from 6.5% to 17.0%; and for those aged 12–19 years, prevalence increased from 5.0% to 17.6%.

The relationship between socioeconomic status and childhood obesity has been observed. Overweight tends to be more prevalent amongst lower socioeconomic status children in developed countries, while developing countries show obesity to be more prevalent among higher income sectors of the population, and among urban rather than rural populations.

Etiology

Obesity results when body fat accumulates as a result of imbalance between energy intake and expenditure. Etiology is multifactorial and obesity is viewed as a neuroendocrine and metabolic disorder, which results from interaction between environmental, behavioral, and genetic factors. Etiologic classification of obesity is summarized in *Table 59.1*.

Table 59.1
Etiology of obesity in children and adolescents

Acquired Obesity
Environmental and behavioral factors:
Decreased physical activity
Prolonged television viewing
Dietary factors
Social factors:
Socioeconomic status
Ethnicity
Iatrogenic factors:
Medications
Endocrine disorders:
Hypothyroidism
Cushing syndrome
Growth hormone deficiency
Insulinoma
Pseudohypoparathyroidism
Hypothalamic lesions
Genetic obesity:
Single gene disorders
Polygenic obesity
Syndromic obesity
Others:
Parental factors
Intrauterine factors and birth weight
Breast feeding
Viral infection
Sleep deprivation

Decreased Physical Activity

Lack of physical activity is a major factor in increasing the risk of obesity. Studies from United States and Europe have demonstrated a decreasing trend in physical activity among children and adolescents.

Decreased physical activity in children is attributed to several factors. Walking and cycle riding has decreased in frequency, along with increasing use of cars and public transportation. Living in an unsafe neighborhood is another barrier to exercise.

Daily participation in school physical education among adolescents dropped from 42% in 1991 to 28% in 2003. In addition, less than one-third of high school students meet recommended levels of physical activity.

Television Viewing

Television viewing is one of the most studied factors that influence childhood obesity. Prolonged television viewing

may increase the risk by decreasing energy expenditure and increasing food intake. The amount of time spent in watching television was found to be closely associated with increased levels of childhood obesity and that reducing television, computer, and video game use could be an effective intervention to prevent childhood obesity.

Some data have linked television food advertising and childhood obesity and proposed that limiting the exposure of children to marketing of high-caloric food could be part of the efforts to reduce childhood obesity.

Dietary Factors

A recent cross-sectional study demonstrated an association between the patterns of food intake during adolescence and the prevalence of excess central body fat. The intakes of dairy and grains, especially whole grains, as well as total fruits and vegetables were inversely associated with central obesity among adolescents.

Several studies have linked obesity in children to the consumption of large amounts of sweetened drinks and 100% fruit juice.

Evidence is limited on dietary patterns that contribute to excessive energy intake in children and teens. However, large food and beverages portion sizes, eating meals away from home, frequent snacking on energy-dense foods, and consuming beverages with added sugar are often assumed as contributing to excess energy intake of children and teens. Obese children tend to skip breakfast. Several studies suggest that eating breakfast is associated with a reduced risk of becoming overweight and a reduction in the BMI in children and adolescents.

Socioeconomic Status

Overweight tends to be more prevalent among socioeconomically disadvantaged children in developed countries and children of higher socioeconomic status in developing countries. In more recent years, most studies have demonstrated an inverse relationship, and, in contrast to former times, very few positive associations were found. Parental education seems to be the major factor underlying the relationship between low socioeconomic status and elevated childhood obesity rates.

With regards to ethnicity, data from the United States indicate that differences in prevalence of obesity exist among Hispanic (21.8%), African American (21.5%), and white children (12.3%), with rapid increases occurring among African American and Hispanic children.

Iatrogenic

Medications

Obesity can result as a side effect to several medications such as valproate, cyproheptadine, steroids, and progestins. Overeating and weight gain have been observed in children and adolescents receiving Lithium and antipsychotic medications such as olanzapine and clozapine.

Endocrine Disorders

Endocrine disorders comprise less than 1% of children and adolescents with obesity and frequently associated with other symptoms. Most children with endocrine disorders have short stature and delayed puberty. The disorders are usually identified by means of characteristic clinical symptoms and not by laboratory screening.

Hypothyroidism: Common findings in hypothyroid children are short stature, fluid retention, and apparent overweight.

Cushing syndrome: Cushing syndrome in children usually causes short stature and generalized obesity. Central obesity is more common in adults and usually involving face, neck, trunk, and abdomen.

Growth hormone deficiency (GHD): Children with GHD present with growth failure, increased weight/height ratio, and delayed puberty. Obese children without endocrine disorders usually have decreased growth hormone levels and diminished response to pharmacologic stimuli.

Hypothalamic lesions: Hypothalamic insults such as infections, trauma, neoplasm, or surgical resections are usually associated with obesity.

Insulinoma: Extremely rare in children. Obesity is explained by low blood sugar resulting in increase food intake.

Genetic Obesity

Single gene disorders: Single gene mutations leading to obesity in humans are rare and accounts for severe early onset obesity induced by an increased energy intake. Mutations in the genes for leptin, leptin receptor, prohormone convertase 1 (PC1), and pro-opiomelanocortin (POMC) have been shown to lead to autosomal recessive forms of

obesity in humans. Mutations in the melanocortin-4 receptor gene (MC4R) are the most common single gene defects currently identified in populations with severe obesity. It accounts for 2–6% of extreme obesity in children and adolescents.

Polygenic obesity: Whole-genome scan studies have demonstrated the presence of different obesity susceptibility loci in different ethnic groups, which supports the notion that different gene combinations are responsible for the pathogenesis of obesity in different populations. A genome-wide association studies of obesity-related traits showed that a polymorphism of the fat mass- and obesity-associated gene was correlated with childhood and adult obesity in different populations.

Syndromic Obesity

Genetic obesity syndromes arise from genetic or chromosomal defects and involve obesity as part of their presentation.

Prader–Willi syndrome: is the most common syndromic form of obesity. Features of the syndrome include central obesity, neonatal hypotonia, hyperphagia, hypogonadism, short stature, behavioral abnormalities, and mild-to-moderate cognitive impairment. The syndrome is caused by the deficiency of one or more paternally expressed imprinted transcripts within chromosome 15q11–q13.

Bardet–Biedl syndrome: is characterized by early onset truncal obesity associated with rod-cone dystrophy, polydactyly, learning disabilities, and progressive renal disease.

Alstrom syndrome: is characterized by mild truncal obesity, short stature, dilated cardiomyopathy, and type 2 diabetes.

Others

Parental obesity: Parental obesity, especially maternal, is one of the strong risk factors for childhood and adolescent obesity.

Intrauterine factors and birth weight: Small for gestational age babies who are given high-caloric diet are at higher risk for obesity. Maternal smoking during pregnancy is another risk factor for childhood obesity.

Breast feeding: Several studies have demonstrated that breastfeeding is associated with a modest but consistent protective effect against later obesity.

Viral infection: Prevalence studies suggest that humans with antibodies to one strain of adenovirus tend to have higher rates of obesity and lower serum cholesterol and triglycerides.

Sleep: Cross-sectional studies have shown a consistent increased risk of obesity amongst short sleepers in children and adults. The mechanism may include activation of hormonal responses leading to an increase in appetite. Activation of inflammatory pathways by short sleep may also be implicated in the development of obesity.

Comorbid Conditions of Childhood Obesity

Self-esteem: Studies have shown a modest relationship between obesity and low self-esteem in children. The risk is increased in children who were subjects to parental criticism and weight-based teasing from peers. Other potential risk factors include: adolescents appear more at risk than young children; girls are more affected than boys; and children who believe that they were responsible for being overweight than children who attributed their weight to external causes.

Body image: Many studies have linked overweight and body dissatisfaction.

Depression: The relationship between obesity and depression in children and adolescents has not yet been established. However, clinical samples of obese children display higher levels of depression compared to average-weight-controlled children. A recent study has shown an increased risk for depression amongst overweight and underweight girls as well as obese boys.

Social stigma: Overweight and obese children are particularly vulnerable to weight bias from their peers, which can begin as early as age 3. The trend continues and, in some cases, worsens among elementary and middle school children. In several studies, school children tend to associate obese children with negative characteristics such as being lazy, dirty, lying, argues, mean, and stupid. Obese children are also more likely to be victims of bullying by their peers. Obese adolescents are commonly stereotyped as being lazy, eating too much, and unable to participate in sports.

Some studies have even suggested that overweight children may be vulnerable to weight bias at school by teachers and educators. Another surprising and unfortunate source of weight stigma toward obese children is parents.

Endocrine

Insulin resistance: Childhood obesity, specifically truncal obesity, is associated with insulin resistance *(IR)*, which is considered to be an important link between adiposity and

the risk of type 2 diabetes, fatty infiltration of the liver, and cardiovascular disease. IR is defined as a decrease in the ability of insulin to stimulate the utilization of glucose by muscles and adipose tissue and to suppress hepatic glucose production and output. Beside obesity, other factors can influence insulin sensitivity, such as physical activity, ethnicity, and gender.

The standard method for measuring IR is the euglycemic-hyperinsulinemic clamp, but this study is invasive and time-consuming. Simpler methods have been developed to assess IR based on markers derived from an oral glucose tolerance test or fasting insulin level and fasting glucose-to-insulin ratio.

Failure of pancreatic B-cell to maintain normoglycmia will lead to impaired fasting glucose *(IFG),* impaired glucose tolerance *(IGT)*, and eventually to overt type 2 diabetes. Individuals with IFG and/or IGT have been referred to as having prediabetes, indicating the relatively high risk for the development of diabetes. Diabetes mellitus is defined as a fasting glucose greater than or equal to 126; IFG, a fasting glucose 101–125; and IGT, a blood glucose between 140 and 200 mg/dL after an oral glucose challenge.

Metabolic syndrome: Metabolic syndrome refers to a combination of clinical findings and metabolic disorders comprising of abdominal obesity, insulin resistance, hypertension, and dyslipidaemia. Although there is no universally accepted definition of metabolic syndrome in children, modified adult criteria have been used to identify children and adolescents with metabolic syndrome, which include the presence of at least three of the following abnormalities: obesity (usually with a waist circumference higher than the ninetieth percentile), dyslipidemia (increase of triglycerides and decrease of high-density lipoprotein or HDL), hypertension, and abnormal glucose metabolism (elevated fasting glucose or type 2 diabetes).

Hyperandrogenism and *Polycystic Ovarian Syndrome (PCOS)*: Obesity in adolescent girls and women is associated with hyperandrogenism and PCOS. It is believed that visceral obesity and insulin resistance have a role in promoting adrenal hyperandrogenemia as well as a tendency toward glycemic intolerance. PCOS is characterized by menstrual irregularity, acne, hirsutism, and hyperandrogenemia.

Early menarche: Obese girls are observed to experience earlier menarche. A cross-sectional study has linked higher relative weight with early menarche after controlling for age and race.

Delayed maturation in adolescent boys: Overweight boys tend to show delayed onset of sexual maturation.

Pulmonary

Sleep disorder and obstructive sleep apnea: Several studies have shown that obese children are at higher risk for abnormal sleep patterns, decreased oxygen saturation during sleep, hypoventilation, and obstructive sleep apnea.

Obesity hypoventilation syndrome (OHS, Pickwickian syndrome): This syndrome is defined as obesity and alveolar hypoventilation. The classic symptoms consist of severe obesity associated with hypoventilation, somnolence, polycythemia, and right ventricular hypertrophy and failure. Most patients with OHS have obstructive sleep apnea, loud snoring, choking during sleep hypersomnolence, fatigue, and impaired concentration and memory.

Asthma: The relationship between asthma and obesity is controversial. However, several cross-sectional studies have suggested an association between childhood overweight and asthma. A meta-analysis of 12 studies examining the relationship between weight and asthma has shown that both high birth weight and high BMI during childhood were predictive of future asthma.

Obese children may also have more severe asthma symptoms and more medications use than normal-weight children.

Gastroenterological

Liver steatosis (nonalcoholic fatty liver disease NAFLD): This refers to a spectrum ranging from a relatively benign fatty liver infiltration to nonalcoholic steatohepatitis (NASH) that can potentially progress to fibrosis, cirrhosis, and liver failure.

The pathogenesis of NAFLD and its sequelae are incompletely understood but probably involve abdominal obesity with insulin resistance leading to accumulation of fat in hepatocytes and the generation of reactive oxidative species resulting in oxidative hepatocyte damage. NAFLD associates with clinical elements of the metabolic syndrome including insulin resistance, dyslipidemia, and hypertension.

Most children with NAFLD/NASH are asymptomatic. Some patients complain of fatigue, malaise and, vague right upper quadrant abdominal discomfort. Acanthosis nigricans can be found in up to 50% of children with NASH. Elevations of hepatic transaminases are predictors of the presence of NAFLD and NASH although degree of elevation has little predictive value and does not distinguish between steatosis and steatohepatitis. Hepatic ultrasound or magnetic resonance imaging may confirm the presence of fatty liver but they provide little or no information on the presence or degree of fibrosis or cirrhosis.

Liver biopsy is the only reliable means to distinguish between steatosis and steatohepatitis fibrosis or cirrhosis. It is indicated in selected cases with persistent elevation of transaminases to determine the severity of the fatty liver disease and to exclude other causes of liver disease. Weight reduction and regular exercising are the only established treatments for NASH. Efficacy of pharmacologic approaches remains to be proven and include Vitamin E and metformin.

Gallstones: Obesity accounts for the majority of gallstones in children with no underlying medical conditions. One study from Germany confirmed a higher prevalence of gallstones in obese asymptomatic children and adolescent (2%) compared to a prevalence of 0.6% in unselected cohort of children and adolescents.

Gastroesophageal reflux disease (GERD): Morbidly obesity is a risk factor for the development of GERD. Although the exact mechanism linking GERD to high BMI is not known, increased intragastric pressure, incompetence of the lower esophageal sphincter, and frequency of lower esophageal sphincter relaxation may be involved in the pathophysiology of this disease in morbidly obese patients.

Cardiovascular

Hypertension: Obesity is frequently associated with hypertension in both adults and children. In many screening studies, the prevalence of hypertension in children and adolescents has been shown to be as high as 10% among those with BMI $\geq$97th percentile. In addition, overweight adolescents have more than an eightfold increased risk of developing hypertension as adults.

Hyperlipidemia: Increased levels of LDL cholesterol, decreased levels of HDL cholesterol, and raised serum triglyceride levels occur among obese children and adolescents, particularly those with increased triceps skinfold.

Obese children and adolescents are also at higher risk for abnormal vascular wall thickness, endothelial dysfunction, left ventricular hypertrophy, and the development of early aortic and coronary arterial fatty streaks and fibrous plaques. In a recent cohort study, it was demonstrated that children with higher BMI were at increased risk for coronary heart disease in adulthood.

Neurologic

Pseudotumor cerebri: Also known as idiopathic intracranial hypertension *(IIH)* is a condition characterized by increased intracranial pressure in the absence of clinical, laboratory, or radiologic evidence of intracranial pathology. The etiology of IIH is unclear but some studies suggest that obesity, particularly in females, is a risk factor. Pediatric studies have suggested that older children with IIH were more likely to be obese than younger children.

Presenting symptoms are usually headache, vomiting, altered vision, papilledema, and isolated sixth cranial nerve palsy. Young children may present with irritability, listlessness, somnolence, and diplopia. In the setting of obesity, weight loss has been associated with resolution of papilledema and of IIH.

Orthopedic

Slipped capital femoral epiphysis (SCFE): Obesity is a significant risk factor in the development of idiopathic SCFE. Patients commonly present in early adolescence with symptoms of hip or referred knee pain.

Blount disease (Tibia vara): is more common in obese children and is characterized by progressive bowed legs and tibial torsion.

Others: Obese children are more likely to report fractures, musculoskeletal pain, and impaired mobility.

Skin

Obesity is associated with a number of dermatologic diseases including acanthosis nigricans, keratosis pilaris, hyperandrogenism and hirsutism, striae distensae, and with fat redistribution. Acanthosis nigricans is the most common skin manifestation of obesity and appears as symmetric, velvety, hyperpigmented plaques most commonly observed in the axilla, groin, and posterior neck. It is frequently associated with hyperinsulinemia and insulin resistance. Obesity also increases the incidence of cutaneous infections, including candidiasis, furunculosis, and folliculitis.

Prevention and Treatment

Pediatrician and primary care providers should assess obesity risk in all children by integrating information about the patient's BMI, risk factors, and current eating and physical activity behaviors. The likelihood of health risks increases in the overweight category (85th to 94th percentile) and is influenced by parental obesity, current lifestyle habits, as well as BMI trajectory and current cardiovascular risk factors. Those children should receive

prevention counseling, and should receive support in establishing healthy life style.

Obese children (BMI above the 95th percentile) are very likely to have obesity-related health risks, and should be encouraged to focus on weight control practices.

Prevention strategy should be performed at every stage including perinatal period. In a recent systematic review, prenatal insults including maternal smoking, malnutrition, and diabetes were found as particularly important determinants of future obesity risk.

Perinatal measures should include:

1. Careful control of gestational diabetes to avoid large for gestational age infants, which could lead to obesity.
2. Careful control of maternal weight before pregnancy and careful control of maternal weight gain during pregnancy.
3. Discourage smoking as smoking during pregnancy is an important risk factor for childhood obesity at any age.
4. Breast feeding should be encouraged as systematic reviews concluded that breastfeeding has a protective effect against later obesity both in childhood and adulthood, although degree of protection was small in some cases. Longer duration of breast feeding was associated with a reduced risk of obesity during early childhood.
5. Avoid prolonged bottle feeding and avoid early introduction of solid food as both may increase obesity risk.

Dietary Prevention and Treatment Option

Based on evidence-based data and clinical experience, the 2007 Expert Committee recommended that clinicians advise patients and their families to adopt and maintain the following specific eating behaviors:

- Limiting consumption of sugar-sweetened beverages.
- Encouraging consumption of diets with recommended quantities of fruits, vegetables, and dietary fiber.
- Limiting television time to <2 h/day and removing televisions from children's primary sleeping areas. If the child is less than 2 years of age, then no television viewing should be the goal.
- Eating timely regular meals, particularly breakfast, and avoiding snacking throughout the day.
- Limiting eating out at restaurants, particularly fast food restaurants and restaurants that serve large portions of energy-dense foods.
- Encouraging family meals in which parents and children eat together.

In the management of obesity, dietary changes alone are insufficient to have much effect without other long-term lifestyle changes, such as increased physical activity and psychological support. Dietary intervention in combination with exercise programs has been reported to have better success rates than dietary modulation alone.

For the management of mildly to moderately obese child without complications, a weight maintenance regimen is usually preferred. For the very obese child, or the moderately obese child with significant comorbidity, a balanced low-caloric diet is recommended. A more restricted very low calorie diet is only recommended when children suffer severe obesity with complications that justify such treatment. Risks associated with the rapid weight loss include cholelithiasis, hyperuricemia, decreased serum proteins, and diarrhea. Long-term effects of strict dietary control include reduced linear growth and loss of lean body mass.

Exercise

Assessment of physical activity levels should be performed at each well-child visit to determine whether they are meeting recommendations of adequate physical activity per day. Assessment and anticipatory guidance of decreasing time spent in sedentary behaviors such as television-viewing, playing video games, and using the computer should be performed at each well-child visit.

Programs designed to promote exercise should contain activities modified to the specific physical and emotional needs of the child. Parental modeling and supportive help from family and school is crucial to guarantee lasting positive effects of physical activity therapy.

Medications

Pharmacotherapy for childhood obesity should be limited to those with BMI over the 95th percentile, who have failed diet and intensive lifestyle modification, or those who have significant comorbidities of their obesity.

The Food and Drug Administration in the United States has approved two medications for the treatment of adolescent obesity: sibutramine for patients >16 years of age and orlistat for patients >12 years of age.

Sibutramine: a serotonin and norepinephrine reuptake inhibitor thus promotes satiety and decrease hunger.

In a multicenter randomized placebo-controlled trial, a significant decrease in BMI was noted in adolescent patients 12–16 years of age treated with sibutramine. Side effects include tachycardia, hypertension, insomnia, and anxiety.

Orlistat: an intestinal lipase inhibitor acts by blocking absorption of fat from the diet. Side effects include steatorrhea, oily spotting from the rectum, and abdominal cramping.

Metformin: inhibits hepatic gluconeogenesis and enhances insulin sensitivity. It is approved for the treatment of type 2 diabetes mellitus in children 10 years and older. Its long-term effect on weight reduction is still unknown but may be useful for the treatment of obese adolescents who are at risk for type 2 diabetes mellitus or have insulin insensitivity associated with polycystic ovary syndrome.

Bariatric Surgery

Bariatric surgery is becoming more commonly offered to severely obese adolescents. Most centers recommend strict selection criteria that include: BMI more than 50 or more than 40 with medical condition; physical, emotional, and cognitive maturity; insufficient weight loss from at least a 6 month effort in a formal program of lifestyle modification.

60 Animal and Human Bites

Richard J. Whitley

Introduction

Animal and human bites are among the most common causes for evaluation in physicians' offices and emergency departments, particularly during summer months. While dog bites are the most common, accounting for approximately 80% of all such visits, cat bites are associated with the highest rate of common infections, namely 50%. Certain bites (rabid animals) and at-risk populations warrant special consideration.

Etiology

Dog, cat, or mammal bites are most frequently associated with infection caused by *Pasteurella multocida* (as well as other species), *Staphylococcus aureus*, streptococci, anaerobes, and, less frequently, *Capnocytophagia* species, *Moraxella* species, *Corynebacterium* species, and *Neisseria* species. Rodent bites can be a source of *Streptobacillus moniliformis, Streptobacillus minus*, the cause of rat-bite fever. Reptile bites are usually attributed to gram-negative enteric bacteria or anaerobes. Lastly, human bites are usually associated with *S. aureus*, *Haemophilus* species, *Eikenella corrodens*, and anaerobes. Human bites should also raise concern for the possibility of transmission of hepatitis B virus and human immunodeficiency virus. Wild animal bites, including foxes, skunks, raccoons, bats, or unprovoked bites by ill-appearing dogs, should raise the concern for the possibility of rabies.

Management of Human and Animal Bite Wounds

The first and most important intervention is to vigorously clean and irrigate the wound bite with the exception of puncture wounds. For fresh wounds, a culture is not required. However, for wounds greater than 8–12 h in duration that have evidence of infection (see below), cultures should be obtained. Radiographs are appropriate if there are penetrating wounds of joints or underlying bones. For bites that are infected, a decision regarding debridement should be made. Wound closure is only appropriate for selected fresh and non-puncture bite wounds. Assessment must include evaluation for tetanus immunization, risk of rabies, risk of hepatitis B virus from human bites, and human immunodeficiency virus. Antimicrobial therapy should be initiated for moderate or severe bite wounds, facial bites, wounds in immunocompromised and asplenic individuals, as well as bites with obvious signs of infection. Follow-up should be within approximately 48 h. For individuals known to be hepatitis B virus and human immunodeficiency virus infected, standard prophylactic precautions should be instituted. For individuals who are bitten by wild animals (raccoon, foxes, bats), as well as unprovoked bites from ill-appearing domestic animals, they should receive rabies immune-prophylaxis in consultation with local infectious diseases specialists. In the developed world, most domestic animals are immunized against rabies and, therefore, concern for acquisition from cats and dogs is minimal.

Clinical Findings

Clinical findings usually involve localized rubror and edema at the site of the bite. There may be evidence of lymphadenitis or lymphangetic spread. Pain can be significant. Usually, localized warmth is present at the site of infection.

Treatment

First-line oral therapy consists of amoxicillin-clavulanate. Alternative oral antibiotics would include a regimen of extended spectrum cephalosporin or trimethoprin-sulfamethoxazole plus clindamycin. If intravenous therapy is required, the treatment of choice would include

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_60,

ampicillin sulbactam or, with reptile bites, ampicillin sulbactam plus gentamicin. For individuals who are allergic to penicillin, the primary regimen should include trimethoprim and sulfamethazole plus clindamycin or, alternatively, gentamicin.

61 Bacterial Sepsis and Shock

Jeffrey Alten · Priya Prabhakaran

Introduction

Severe sepsis and septic shock caused by bacterial infections are important causes of mortality and morbidity among children worldwide. Severe sepsis has a mortality of about 4.2% (2.3% in previously healthy children and 7.8% in chronically ill children). The incidence is greatest in children less than 1 year of age and contributes to 50% of the mortality in this age group. Survival from severe sepsis has improved from earlier years, attributable to the discovery that early recognition, aggressive resuscitation, and timely treatment improve outcomes in infants and children with severe sepsis.

Microbiology of Sepsis in Children

The epidemiology of sepsis varies depending on the age of the child, immunization status, integrity of the immune system, and presence of comorbidities. The etiologies of invasive childhood bacterial infections have been significantly modified by widespread immunization against Hemophilus influenza type B (Hib), as well as pneumococcal serotypes. It is convenient to classify the most common bacterial infections based on age of the child. The organisms that should be considered in the septic neonate include Group B Streptococcus, Listeria monocytogenes, and Gram-negative enteric bacteria such as *Escherichia coli*, *Klebsiella pneumoniae*, Enterobacter species, and *Pseudomonas aeruginosa*. Staphylococci, particularly coagulase negative species, are becoming an important cause of sepsis in hospitalized neonates. Of note, herpes simplex virus can cause septic shock often indistinguishable from bacterial septic shock. It is not uncommon for neonates with severe herpes infections to have a concomitant bacteremia due to Gram-negative organisms, presumably caused by bacterial translocation from the intestines. In a recent large international severe sepsis therapy trial, *Staphylococcus* species were the most common cause of sepsis in children. In children under 1 year of age, community-acquired organisms such as *Pneumococcus* and *Neisseria meningitides* are frequent causes of sepsis. In the developing world, these two organisms, in addition to Salmonella species and Hemophilus influenza type B, are the most frequent causes of sepsis in infants. The most frequent pathogens remain the same in healthy school-aged children. In addition, sepsis without a clearly defined focus of infection such as meningococcemia becomes more common in this age group. Disseminated staphylococcal and streptococcal infections, often associated with a source in bone, joint, lung, or heart is a frequent cause of sepsis in children over 6 years of age. The incidence of methicillin resistance among *Staphylococcus* species has increased dramatically in developed countries.

Children with preexisting morbidities, such as congenital heart disease, genitourinary abnormalities, cancer, burns, sickle cell disease, severe malnutrition, and immune deficiencies, are at an increased risk of developing severe sepsis. In addition, neonates and other children that are hospitalized or who have had significant exposure to health care facilities are at increased risk of developing sepsis; importantly with infections caused by atypical organisms which may be resistant to the usual, first-line antibiotic therapy. Multidrug-resistant Gram-negative organisms have become increasingly prevalent among hospitalized children, especially in developing countries, and should influence the choice of initial antibiotic therapy. Knowledge of specific bacterial infections associated with underlying dysfunction in specific components of the immune system is essential. ❯ *Table 61.1* shows the common bacterial infections that are associated with specific pediatric conditions.

Definition of Sepsis and Septic Shock

The clinical spectrum of bacterial sepsis ranges from the early signs of bacterial invasion or toxin release in the body (such as tachycardia and fever) to circulatory collapse, multiple organ system failure, and death. To further classify this spectrum, consensus definitions for pediatric sepsis were developed by pediatric experts to help determine the severity of a child's illness and follow response to treatment. Each category represents an increase in severity of illness.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_61,

Table 61.1
Specific organisms associated with sepsis in pediatric patients with comorbidities

Condition	Organism
Sickle cell disease (asplenia)	*Pneumococcus*, *Salmonella*
Asplenia, polysplenia	*Pneumococcus*, *Salmonella*
Nephrotic syndrome (complement deficiency)	*Pneumococcus*
Complement deficiency (C6-9)	*Neisseria* species (meningococcus, gonococcus)
Neutropenia	*Streptococcus mitis*, *Streptococcus* viridans, Gram-negative
AIDS	Pneumococcus
Burns	*Pseudomonas*

Systemic inflammatory response syndrome (*SIRS*): An inflammatory state affecting the entire body that represents the body's immune response to an insult that may or may not be infection. The presence of two or more of the following criteria (one of which must be abnormal leukocyte count or temperature) identify patients with SIRS:

1. Core temperature (rectal, oral, bladder, esophageal) $> 38.5°C$ of $< 36°C$
2. Tachycardia > 2 standard deviations above a child's normal-for-age heart rate, or for children < 1 year, bradycardia $<$ 10th percentile
3. Respiratory rate > 2 standard deviations above child's normal for age
4. Leukocyte count either high or low for age or leukocyte differential with greater than $> 10\%$ immature neutrophil forms

Sepsis: Systemic inflammatory response syndrome (SIRS) due to suspected or proven infection.

Severe sepsis: Sepsis associated with either cardiovascular organ dysfunction, acute respiratory distress syndrome, or with any two or more other organ dysfunctions. The consensus definitions for organ dysfunction are the following:

1. *Cardiovascular*: Hypotension or need for vasoactive medicine to keep BP in the normal range, or two or more of the following: unexplained metabolic or lactic acidosis, oliguria, capillary refill > 5 s
2. *Respiratory*: PaO_2/FiO_2 ratio < 300 or $PaCO_2 > 65$ Torr or > 0.5 FiO_2 to maintain saturations $> 92\%$ or need for mechanical ventilation
3. *Neurologic*: Glasgow Coma Score ≤ 11 or acute deterioration in mental status
4. *Hematologic*: Platelet count $< 80{,}000/mm^3$ or 50% decrease in platelet count or INR > 2
5. *Renal*: Serum creatinine ≥ 2 times upper limit for normal or twofold increase in baseline creatinine
6. *Hepatic*: Total bilirubin ≥ 4 mg/dL (not applicable for newborn) or ALT > 2 times upper limit for age

Septic Shock: Sepsis with cardiovascular dysfunction despite administration of ≥ 40 mL/kg isotonic fluid over 1 h.

While these categorical definitions do not exactly define prognosis, morbidity and mortality likely increases along the continuum of SIRS to septic shock. Increasing number of organ dysfunction in children with severe sepsis increases the likelihood of mortality.

Pathophysiology of Shock

Shock can be defined as a condition of insufficient delivery of oxygen and nutrients to meet the metabolic demands of the body. Oxygen delivery (DO_2) is directly proportional to cardiac output and the oxygen content in arterial blood (CaO_2). Cardiac output depends on heart rate (HR) and stroke volume. Stroke volume is a function of preload, myocardial contractility, and afterload.

$$DO_2 = CO \times CaO_2$$
$$CO = HR \times SV$$
$$CaO_2 = (Hb \times 1.34 \times SaO_2) + (0.003 \times PaO_2)$$

Oxygen delivery is an estimate of global oxygen availability, and may not be reflective of regional hypoperfusion and or ischemia. Severe sepsis induces a state of very high metabolic and oxygen demand. Inadequate DO_2 evokes compensatory mechanisms in an attempt to restore the balance between oxygen demand and delivery. In the early stages of shock, abnormalities in oxygen transport balance are compensated via tachycardia and systemic vasoconstriction to improve organ perfusion and oxygen delivery. The ability of children to vasoconstrict causes systemic blood pressure to be preserved until later stages of shock when frank decompensation may occur. Children who have compensated shock frequently have normal or even elevated blood pressure, and as the shock state progresses, compensatory mechanisms are overwhelmed leading to hypotension and organ dysfunction. Irreversible shock follows when cellular dysfunction is so severe that death occurs even if

cardiovascular function is restored to an adequate level. In order to achieve the best possible outcomes, shock should be diagnosed early and treated aggressively, before decompensation occurs.

Early Recognition of Septic Shock

History

A history focused on the child's activity level, intake and output, presence of fever, skin color or temperature, abnormal breathing, or rash is invaluable in making the diagnosis promptly, and may also aid in localizing the site of infection. History of risk factors for severe infection should be obtained, including immunization status, recent exposure to infectious illnesses, medication history (particularly recent use of systemic steroids), and presence of chronic illness.

Clinical Findings and Physical Exam

Rapid and repeated careful physical examination is essential to diagnose early shock and help localize the most likely source of the precipitating infection. Early recognition of shock requires a high index of suspicion, as only subtle changes in vital signs (i.e., mild tachycardia, mild tachypnea, or slight delayed capillary refill) may be the first signs of developing septic shock. In some forms of severe sepsis and septic shock, children present with "warm shock." Patients in warm shock have decreased systemic vascular resistance (SVR) with relative hypovolemia from vasodilatation and venous pooling of blood. There is low diastolic blood pressure, and wide pulse pressure with resultant clinical findings of "bounding pulses and warm extremities." Despite the potential reassurance of "adequate pulses," the oxygen delivery in these patients is not adequate, thus they are in shock. Children (especially infants and neonates) will more commonly present with "cold shock." These patients have elevated SVR, with a narrow pulse pressure, cool mottled extremities, and reduced peripheral pulses. There will often be tachypnea as a compensation for metabolic acidosis, which may develop into increased work of breathing if ARDS develops or there is underlying pulmonary disease. The child will frequently have fever and a "toxic" or ill appearance. Of note, neonates and young infants may have septic shock without fever. As shock evolves, there will start to be clinical evidence of compromised organ function with worsening tachycardia, tachypnea, decreased urine output, and altered mental status. Decrease in systolic blood pressure is a late finding in septic shock, and represents decompensated stage of shock, which can rapidly be fatal. As the child progresses to irreversible shock, severe hypotension, lethargy, and respiratory failure are late and ominous findings.

Diagnostic Testing

Cultures should be obtained from all pertinent sites (CSF, blood, urine, genitourinary tract, skin lesions), if possible before initiation of antibiotics. Antibiotic therapy should not be delayed while waiting to obtain cultures, though. There are no specific laboratory tests to diagnose shock. Leukocyte count obtained on complete blood count may help support the diagnosis; while platelet count, liver function tests, coagulation studies, arterial blood gases, serum lactic acid, and serum creatinine will all help determine the degree of organ dysfunction. Serial blood gases and/or lactate levels may be useful in assessing the response to treatment. Bedside glucose measurement should be performed in all infants and neonates with septic shock, as their limited glycogen stores put them at risk for severe hypoglycemia. Ionized calcium should also be measured in all infants and neonates as it is often low in septic shock which may decrease myocardial contractility. Chest x-ray should be performed to evaluate for pulmonary disease. Echocardiography to assess cardiac function should be performed, especially in children with evidence of compromised cardiac output in cold shock states.

Management of Septic Shock

Successful management and treatment of septic shock requires timely treatment of underlying cause and immediate reversal and stabilization of the hemodynamic derangements to optimize perfusion to compromised vital organs and limit the cellular damage before it becomes irreversible.

Antibiotics

Once the diagnosis of septic shock has been made, appropriate antibiotic therapy must be administered immediately, as ineffective or delayed antibiotic therapy is associated with increased mortality from septic shock. Antibiotics should not be delayed because of inability to obtain cultures. Broad-spectrum empiric antibiotics must

be chosen based on the most likely organism implicated. This will depend upon the age of the child (see ❯ Microbiology of Sepsis in Children above), location of infection, and the severity of illness. Knowledge of local sensitivity patterns is also very important in choosing antibiotics that are likely to be effective. In addition to initial broad-spectrum antibiotics to cover all of the most likely pathogens, some special considerations include: empiric treatment for MRSA should be considered in all children; Gram-negative and anaerobic coverage should be added for children with potential GI or GU source; immunocompromised, malnourished, and hospitalized children should receive initial empiric treatment with anti-pseudomonal antibiotics; and neonates should receive treatment for Listeria monocytogenes and herpes simplex virus. The antibiotic coverage should be tailored to the results of initial and repeat cultures as well as poor clinical response to initial empiric coverage.

Initial Treatment of Shock

The principle of treating shock is to reduce the imbalance between the oxygen demands of the tissues and oxygen delivery. While most therapy in early shock is directed toward increasing oxygen delivery, measures to curtail oxygen requirement are equally important and become more so as the shock state progresses. Fever, pain, and agitation all increase the metabolic rate and oxygen demand significantly. Children in shock frequently have increased oxygen demand by the muscles of respiration as they attempt to hyperventilate to compensate for metabolic acidosis. Aggressive control of fever, management of pain and sedation, and consideration of early intubation and mechanical ventilation to reduce oxygen demand of work of breathing, even in the absence of respiratory failure, are all very effective methods of decreasing oxygen requirements.

Airway and Breathing

As with all critically ill children, the first step of management is to support the airway and ensure adequate oxygenation and ventilation. Most children with septic shock will be tachypneic as compensation for their underlying metabolic acidosis, and should be given oxygen via face mask to help improve oxygen delivery to tissues. Children with septic shock can have as much as 40% of their cardiac output shunted to their respiratory muscles to support increased work of breathing. Mechanical ventilation can eliminate the excessive oxygen demand and help restore the balance between oxygen delivery and consumption by shunting cardiac output from the respiratory muscles to other vital organs. In addition, mechanical ventilation can help facilitate the use of sedation and improve fever control, which will also decrease the patient's oxygen demand and consumption. In the later stages of shock, there may be more recognized clinical indications for mechanical ventilation such as respiratory failure – in the presence of inadequate ventilation and/or oxygenation, obstructed airway, excessive work of breathing, or altered mental status, endotracheal intubation and mechanical ventilation should be instituted.

Caution should be exercised when performing endotracheal intubation in children with septic shock, as they are at risk for developing a sudden decrease in cardiac output from acute drop in preload. This may occur due to positive intrathoracic pressure caused by mechanical ventilation, inhibiting blood return back to the heart. Hypotension in this situation should be treated by aggressive fluid resuscitation (see below). The decrease in CO may also be due to the vasodilating properties of the medicines used to intubate the child with – which neutralize the compensatory endogenous vasoconstriction that is occurring in the child with septic shock. Medicines such as benzodiazepines, propofol, barbiturates, and opiates should be used with extreme caution for this reason. Some have suggested ketamine as the premedication of choice to facilitate mechanical ventilation due to its ability to release endogenous catecholamines with resultant increase in SVR and relative preservation of cardiovascular stability. Despites its ability to preserve hemodynamics, etomidate should not be used in children with septic shock because it suppresses the child's adrenal axis.

Fluid Resuscitation

Management of decreased oxygen delivery in shock begins with rapid intravenous administration of isotonic fluids. Vascular access should be established quickly, and placement of intraosseous catheter should be performed if IV access cannot be obtained within minutes. Children in septic shock have relative (due to vasodilation and capillary leak) and/or absolute hypovolemia. Early restoration of effective circulating volume is associated with improved outcomes. A 20 mL/kg bolus of isotonic fluid such as 0.9% normal saline or Lactated Ringer's should be given as rapidly as possible (over 5 min) for initial resuscitation.

Reassessment of the child's end-organ perfusion and vital signs should be performed after this and any repeat fluid bolus to determine if the child needs continued fluid resuscitation. The following are physiologic goals that should guide the fluid resuscitation: normalization of heart rate and blood pressure, improvement in capillary refill and perfusion to the extremities, normal mental status, and urine output $>$ 1 mL/kg/h. Repeated 20 mL/kg isotonic fluid boluses should be given until these physiologic goals are met. Patients with severe septic shock will often require 60–80 mL/kg or more of isotonic fluid in the first hour of resuscitation. Ongoing capillary leak must be monitored and adequate volume should be administered to prevent further hypovolemia. Hypocalcemia and hypoglycemia should be evaluated for and corrected during the fluid resuscitation. A urinary catheter should be placed to accurately follow urine output continuously. Central venous access should be established in children who respond poorly to the first 3–4 boluses, and those with insufficient physiologic physiologic reserves at baseline. Central venous pressure (CVP) monitoring may be a helpful adjunct for monitoring. The development of hepatomegaly, gallop rhythm or new crackles on auscultation, in addition to a marked increase in CVP without concomitant improvement in hemodynamics are signs of possible fluid overload denoting that more fluid is unlikely to be beneficial. Children in septic shock frequently become progressively more edematous with ongoing resuscitation due to continuing capillary leak. The development of edema or anasarca should not deter continuing fluid administration, if it is indicated for restoration of hemodynamics and improvement in oxygen delivery. Serial physical examinations are crucial, and resuscitation should be modified based on the evolving clinical scenario.

The use of colloid for fluid resuscitation in children with septic shock is controversial. A large randomized controlled trial of crystalloids versus colloids (4% albumin) for resuscitation of shock in adults showed that these were equivalent. In a subgroup analysis, patients with severe sepsis had a trend toward improved mortality when resuscitated with 4% albumin as opposed to normal saline. In children, a randomized controlled trial in children with dengue shock demonstrated earlier reversal of shock in patients who received 5% albumin, and a clinical practice paper on meningococcal septic shock in children used 5% albumin for resuscitation with mortality lower (5%) than predicted. Crystalloids are less expensive and more readily available than albumin and should be used for initial resuscitation. Until there is more evidence on the safety and efficacy of albumin resuscitation in children with septic shock, it should be reserved for consideration in children that have already received over 60 mL/kg fluid resuscitation with isotonic crystalloid.

Due to its crucial role in oxygen delivery, packed red blood cell transfusion should be given to keep the hemoglobin above 10 g/dL, and can be used as colloid during fluid resuscitation. This hemoglobin goal is part of an algorithm that has demonstrated decreased mortality in adult septic patients, and has been adopted as a pediatric goal in septic shock by expert consensus.

Vasoactive Medications

Children who remain in shock despite 60 mL/kg of fluid resuscitation (fluid-refractory shock) should be started on vasoactive infusions preferably via a central venous line. Children with fluid-refractory shock should be treated in a pediatric intensive care unit with invasive monitoring devices such as central venous and arterial lines.

Low dose dopamine may be started in a peripheral IV while central venous access is obtained. Dopamine is the first-line vasoactive drug of choice in pediatric septic shock not responsive to fluid resuscitation alone. It may be started at 5 μg/kg/min and rapidly titrated up to 10 μg/kg/min for goals of improved perfusion and blood pressure. If physiologic hemodynamic goals are not met with dopamine and fluid alone (fluid-refractory, dopamine-resistant shock), epinephrine (titrated between 0.02 and 0.3 μg/kg/min) is indicated for children who are hypotensive and in "cold shock." Vasoconstrictors such as norepinephrine (titrated between 0.02 and 0.3 μg/kg/min) are the treatment of choice in children who are vasodilated and in warm shock. For children with warm shock and lowblood pressure resistant to norepinephrine, the addition of vasopressin has been used with some success.

Fluid resuscitation should continue while titrating up on vasoactive medications unless hepatomegaly or pulmonary edema develops. In addition to the physiologic goals mentioned above, titration of vasoactive medicines can also be guided by serial serum lactate levels and superior vena cava saturations, with goal $\geq$ 70%. In children with femoral venous access, the trend in inferior vena cava saturations can be used to assess the adequacy of resuscitation. For children with normal blood pressure and cold shock, afterload reduction may be an important adjunct as these patients often have some level of myocardial dysfunction contributing to their shock; type III

phosphodieterase inhibitors (Milrinone 0.5 mcg/kg/min) or vasodilators such as sodium nitroprusside and nitroglycerin may be beneficial.

Hormonal Therapy

Children with septic shock are at risk for adrenal insufficiency. The exact role of steroid replacement therapy, its safety, and the identification of pediatric septic patients that will benefit from steroid therapy is not well defined. At this point, there is no high-level evidence to support the use of steroids in children who are not at risk for adrenal insufficiency. The consensus of experts recommend patients with septic shock at risk for adrenal insufficiency (recent systemic steroid exposure, purpura fulminans, congenital adrenal hyperplasia, or history of hypothalamic/pituitary insufficiency) or patients that have catecholamine resistant shock should receive hydrocortisone therapy after a random serum cortisol is drawn, if possible. There has not been consensus on the exact dose of shock or stress dose steroids. The dose range has been reported from 2 mg/kg/day to 100 mg/kg/day. The common practice at our institution is to send a random serum cortisol, followed by 100 mg/m^2 dose of hydrocortisone IV and treatment with 100 mg/m^2/day to be continued until the child's shock resolves if there is evidence of adrenal insufficiency (defined as dramatic hemodynamic improvement with steroid therapy or random cortisol less than 18 mg/μL). Steroids are stopped if there is no evidence of adrenal insufficiency or clinical improvement in the child's hemodynamics after the initial hydrocortisone bolus.

Children with septic shock are at risk for hypocalcemia which may contribute to myocardial dysfunction. Serial serum–ionized calcium should be monitored and corrected to the normal value. Due to the risk of neurologic injury and myocardial dysfunction, hypoglycemia must be avoided. Neonates and infants are especially at risk due to their poor glycogen stores. Children in septic shock should receive continuous infusion of 10% dextrose in their intravenous fluids. Hyperglycemia may be a risk factor for mortality in children with septic shock. Some clinicians advocate treatment with insulin infusions to keep glucose in the normal range, although the validity of this therapy is still under investigation.

Refractory Shock

Patients with refractory shock despite all the above measures should have all reversible causes of refractory shock ruled out (pericardial tamopnade, tension pneumothorax, intrabdominal hypertension, adrenal insufficiency, and hypothyroidism) and then referred to a center capable of providing pediatric ECMO support.

Summary

Bacterial sepsis continues to be a major source of morbidity and mortality in children worldwide. Early recognition (fever, tachycardia, tachypnea, abnormal white blood cell count, and presence of organ dysfunction) and immediate aggressive treatment has been shown to improve outcomes in pediatric patients with bacterial sepsis. Within the first hour of treatment, in addition to the standard ABCs of resuscitation, the child should receive up to 60 mL/kg fluid boluses and dopamine initiation if still in shock after 60 mL/kg of fluid. Blood, urine, respiratory, and other indicated cultures should be sent, and appropriate broad-spectrum antibiotics should also be initiated within the first hour. Fever control and consideration of early intubation and mechanical ventilation to significantly decrease the body's oxygen demand should be given to any child in septic shock. Escalation and direction of further fluid and vasoactive medicine resuscitation is determined by repeated examination and clinical response to the first hour of therapy.

62 Bone and Joint Infections

Mohammad Al-Shaalan

Skeletal infections are not uncommon in children. They form a group of infections which involve bones and joints. Being deep, their presentations and diagnosis may be difficult. Therefore a high index of suspicion is always needed in their identification.

Osteomyelitis

Osteomyelitis means inflammation of the bone, which is most of the time caused by a microbial infection. Most of the cases occur in children and elderly. Approximately 1 in 5,000 children is affected.

Etiology

The causes of osteomyelitis vary according to age. However, *Staphylococcus aureus* predominates in all age groups. Other causes include *Streptococcus pyogenes*, *Streptococcus pneumonia*, *Kingella kingae*, and rarely gram-negative bacilli. Vaccination against *Haemophilus influenza* type b has eliminated this organism as a cause in children below 3 years of age. It is likely that conjugate pneumococcal vaccine will reduce the impact of pneumococcus as well. *K. kingae* has been reported to cause small outbreaks in childcare centers. Community acquired methicillin-resistant S*taphylococcus aureus* has emerged as an important cause of osteomyelitis constituting up to 10% of staphylococcal cause. Therefore this should be considered when empiric therapy is started bending the culture results (*Tables 62.1–62.3*).

Some underlying diseases may predispose the host to osteomyelitis that is caused by certain organisms like *Salmonella* in patients with sickle cell anemia, *Streptococcus pneumoniae* in asplenic patients, and *Serratia* or *Aspergillus* in patients with chronic granulomatous disease.

Pathogenesis

The organisms get access to the bone through one of the following routes: (1) hematogenous spread, (2) direct inoculation, (3) spread from infected contiguous site. In children, most of the infections occur by hematogenous route. Thirty to 40% of infected patients report a history of preceding trauma. Recent study implicated trauma as one of the predisposing factor for osteomyelitis as it may cause some contusion in the bone, which acts as a nidus for infection.

Metaphyses of long bones are involved in most of the cases. The blood vessels at the metaphysis are tortuous and the circulation is sluggish. Therefore, the organism has a chance to proliferate in that area and form a nidus of infection.

In infants up to 18 months of age, there are transphyseal vessels through which the infecting organism may get access to epiphysis causing inflammation there and pyogenic arthritis. In addition, the cortex of the infant bone is thin and thus it is easy for the infected material to escape through the cortex into the subperiosteal space and the surrounding softer tissues. In joints where the joint capsule is inserted, distal to metaphyseal plate as in hip, ankle, elbow, and shoulder, the pus may track through the cortex into the joint space. After infancy, transphyseal vessels are obliterated and thus the growth plate acts as a barrier to dissemination of the infection. However, the periosteum is loosely attached to the cortex and the pus may break through the cortex, resulting in subperiosteal abscess with periosteal reaction and bone formation.

Once the child reaches the adolescent age, the periosteum is attached firmly to the cortex and the infected material may erode through the periosteom to form a chronic sinus. It may as well spread through the Haversian Canals to the other nearby bony structure.

Clinical Features

Acute Hematogenous Osteomyelitis

Acute hematogenous osteomyelitis (AHO) is defined as a clinical episode in which a patient had at least one or more of the following: fever higher than 37.5°C, leucocytosis (white blood cell count (WBC) >13,000/mm^3), raised erythrocyte sedimentation rate (ESR) (>20 mm), or

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_62,

a positive blood culture plus one or more of the following: positive technetium bone scan, bony point tenderness and/or swelling, and redness or findings consistent with osteomyelitis on plain x-ray, CT scan or MRI or a positive microbiological culture from a bone biopsy or bone aspirate. Patients with AHO with septic arthritis (SA) of the adjacent joint were considered to have AHO. Presentation varies according to age. In newborn, systemic signs are minimal. The baby usually has pseudoparesis, erythema, soft tissue swelling, abscess or joint swelling, and erythema. Thirty to 40% of newborn with osteomyelitis have multiple bony involvement. In infants and children, the systemic signs are prominent with fever, poor appetite, pain at the site of infection, and severe tenderness over the area involved.

Table 62.1
Organisms causing osteomyelitis in children

Age group	Main causes
Neonates	*Staphylococcus aureus*
	Group B Streptococcus
	Group A Streptococcus
	Enterobacteria
	Streptococcus pneumonia
	Candida
Infants and children <5 years	*Staphylococcus aureus*
	Haemophilus influenzae
	Streptococcus pneumoniae
	Group A Streptococcus
	Brucella
Children >5 years	*Staphylococcus aureus*
	Streptococcus pneumoniae
	Group A Streptococcus

Subacute Osteomyelitis

Some patients may have an insidious onset with low-grade fever and minimal local signs extending more than 2 weeks.

Chronic Osteomyelitis

Patients with chronic osteomyelitis present with signs and symptoms of chronic illness like loss of appetite, loss of weight, anemia, and generalized weakness. Locally, there could be disuse atrophy and draining sinuses.

Special Presentations of Osteomyelitis

Osteochondritis

Osteochondritis occurs following injuries with nail or sharp objects that penetrate through sneaker. The floor of the sneaker is usually colonized with *Pseudomonas*. Thus the penetrating nail becomes contaminated with

Table 62.2
Causative organisms according to age

Organism	0–4 years (n = 28)	5–9 years (n = 18)	10–14 years (n = 16)	Total (n = 62)
Staphylococcus sp.	14 (50%)	11 (61%)	14 (88%)	39 (63%)
Staphylococcus aureus	8 (28%)	9 (50%)	14 (88%)	31 (50%)
Coagulase-negative	6 (21%)	2 (11%)	14 (88%)	8 (13%)
Staphylococcus sp.	8 (29%)	4 (22%)	2 (12%)	14 (23%)

Table 62.3
Acute haematogenous osteomyelitis: comparison of isolated organisms

Isolated organism	Current study no. (%)	Nade study no. (%)
Staphylococcus aureus	34 (76%)	42 (75%)
Methicillin-resistant *Staphylococcus aureus*	4 (9%)	0
Streptococcus pneumoniae	2 (4%)	3 (5%)
Streptococcus pyogenes	2 (4%)	6 (11%)
Group B *Streptococcus*	2 (4%)	0
Yersinia entercolitica	1 (2%)	0
Haemophilus influenzae	0	2 (4%)
Staphylococcus haemolyticus	0	1 (2%)
Escherichia coli	0	1 (2%)
Bacillus proteus	0	1 (2%)

Source: Goergens E et al (2005) Acute osteomyelitis and septic arthritis in children. J Paediatr Child Health 41:59–62; Nade S et al (1974) Antibiotics in the treatment of acute osteomyelitis and acute septic arthritis in children. Med J Aust 2:703–705

Pseudomonas, which results in implanting it into the foot causing localized infection, which is called osteochondritis. Unlike other forms of osteomyelitis, osteochondritis does not cause major damage to the bone and therefore it needs only a short course of antibiotic therapy directed against *Pseudomonas* usually for 7–10 days in addition to local debridement.

Vertebral Osteomyelitis

In children, vertebral osteomyelitis occurs secondary to hematogenous spread. In rare occasions, spread from contagious pyelonephritis may be the source. In drug addicts, gram-negative bacillary vertebral osteomyelitis may occur. Lumbar area is the most commonly involved part of spine. Affected children usually present with high fever, back pain, and local tenderness over the involved vertebra. Young infants usually present with fever, refusal to walk, or abdominal pain. Plain bone radiography findings may be subtle; however, most of the affected children will have destruction of the anterior part of the involved vertebra with new bone deposition and osteophyte formation. This is in contrast to tuberculous spondylitis in which new bone formation and osteosclerosis does not occur.

Diskitis

Intervertebral disks continue to have blood supply from the nearby vertebra up to 30 years of age. Therefore hematogenous infection of the intervertebral disk can occur. Infection usually starts with disk destruction followed by loss of intervertebral space. Later on, infection extends into the anterior part of the vertebra endplate cartilage. Wedging of the vertebra and paraspinous abscess are rare.

On isotope scanning, there is increased uptake at the site of infection. MRI is very sensitive in outlining the involved disk and nearby soft tissues. Therefore it is the investigation of choice.

In 50–60% of the patients, organism can be grown from the aspirate or biopsy of the involved disk. Most commonly isolated organism is *Staphylococcus aureus.*

Osteomyelitis in Sickle Cell Disease Patients

Bone pain in sicklers is a challenge to the treating physician. This is because of common vaso-occlusive crisis in patients with sickle cell disease, which results in bone infarction and pain and fever. This causes confusion in differentiating it from osteomyelitis to which these patients are at higher risk. Around 18% of sicklers will develop osteomyelitis at one time or another. The clinical features of osteomyelitis resemble those of vaso-occlusive crisis. Even ESR and c-reactive protein (CRP) are of little help in differentiating between the two. Blood culture can be positive in up to 30–50% of cases with osteomyelitis. *Salmonella nontyphi* species are the most commonly isolated organisms (*Table 62.4*). *Staphylococcus aureus* and gram-negative bacilli may be the cause but at a lesser frequency. Diagnosis of osteomyelitis in sicklers relies on radiological studies. Plain x-ray is of little help. Radioisotope bone scan has low sensitivity and specificity. However when combined with bone marrow isotope scan, sensitivity improves. In osteomyelitis, bone marrow scan is normal and bone scan shows high uptake. In bone infarction, both bone marrow scan and bone scan show reduced uptake. MRI is becoming the radiological method of choice for diagnosing osteomyelitis in sicklers. It is more sensitive than other modalities. In typical osteomyelitis with squestra, T2-weighted scan will show high-intensity uptake with central low intensity. T1-weighted with gadolinium will show an area of increased uptake around an area of nonenchancing center. If there is a defect in the periosteum, the MRI will show the communication between the marrow and the surrounding soft tissue collection.

Table 62.4
Relative prevalence of *Salmonella* in sicklemic patients with osteomyelitis

Study	No. of patients	% of isolates		
		Salmonella	*Staphylococcus aureus*	Others
Nelson	8	50	8	42
Givner	3	100		
Barett-Connor	12	42	8	50
Seeler	9	77	11	11

Chronic Multifocal Osteomyelitis

This is a disease of older children, 8–12 years of age. However, other age groups can be involved. It is characterized by recurrent episodes of pain and fever. The disease involves multiple sites of long bones, which range in number from 2 to 18 and characteristically involves the metaphysis. On plain x-ray, it is characterized by bone rarefaction and marginal osteosclerosis. Histologically there is evidence of chronic inflammation with plasma cell infiltration. No organisms are isolated from these lesions. Prognosis is good and treatment consists of non-steroidal anti-inflammatory drugs or steroids.

Osteomyelitis Associated with Brucellosis

Brucellosis rarely results in osteomyelitis in children. However when it occurs it is usually in the form of spondylitis. Other sites like long bones can be involved but is very rare.

Diagnosis

It is usually difficult to diagnose osteomyelitis. Presence of clinical features is the first clue to diagnosis. Some blood tests may be helpful including total white blood cell count (WBC), c-reactive protein (CRP), and erythrocyte sedimentation rate (ESR). WBC is not very sensitive and not very useful. CRP is raised in 82–96% of the affected patients and it usually rises early and declines within 1 week of therapy. ESR is also helpful being raised in 70–100% of affected patients. It may rise early in the therapy and then decline within 3 weeks of therapy. Aspiration and culturing of infected tissue from involved site is the gold standard; however this is not achievable all the time. It is usually positive in 45–83% of patients. Blood culture is positive in 24–74% of patients. Collectively, having tissue and blood cultures may give a yield up to 70%. Imaging studies play a major role in diagnosing osteomyelitis. Plain x-ray is not very sensitive and usually lags behind clinical presentation by 10–14 days. The major findings in plain x-ray are osteolytic lesion with periosteal reaction *Table 62.5*.

Table 62.5
Radiographic findings among 153 patients with osteomyelitis

Radiographic findings	Days from onset				
	1–6	7–10	11–20	21–30	31–
Bony destruction	5	17	31	17	6
New bone formation		4	19	15	1
Periosteal reaction		5	9	1	1

Radionuclide studies are more sensitive and usually show positive results earlier. Bone scan or Gallium scan are of similar sensitivity, approaching 80%. Indium-labeled WBC, technetium-labeled WBC, or indium-labeled immunoglobulin have a better sensitivity and specificity and are particularly helpful in cases where there is an implanted devise and in osteomyelitis of small appendicular bones. Magnetic resonance imaging has emerged as an excellent tool of diagnosing osteomyelitis. Its sensitivity approaches 100% and it is very helpful in detecting soft tissue and bone marrow infections. It is particularly helpful in differentiating osteomyelitis form soft tissue infections.

Management

There are special considerations in treating osteomyelitis. These include

1. Trial to reach a microbial diagnosis as much as possible
2. Prolonged duration of therapy
3. Close follow-up
4. Looking for complications

Taking in consideration the age of the patients, the initial empirical therapy is as follows:

1. Medical:
   (a) Initial antibiotics coverage:

(a) Neonates:	Cefotaxime and Nafcillin
(b) Children <5 years:	Cefuroxime
(c) Children >5 years:	B-lactamase resistant penicillins like Cloxacillin

In areas where the prevalence of MRSA is high, a consideration of starting vancomycin initially is warranted, especially in seriously sick children.

2. Surgical:

Initially, bone aspiration for diagnosis and debridement should be done, especially if there is evidence of subperiosteal abscess. In addition, for patients with traumatic bone injury, surgical debridement is required as part of management.

Sequential therapy starting with intravenous therapy followed by oral therapy is now the method of choice. Most of the patients will require intravenous medication for 5–7 days, after which the child becomes afebrile and his/her clinical symptoms improve. The criteria to switch to oral therapy include: (1) resolution of clinical symptoms, (2) availability of adequate oral therapy, (3) assured compliance, and (4) close follow-up. When switching to oral therapy, the antibiotic dosage should be the high dose, and the antibiotic of choice is usually directed by the isolated organism if any, or the used parenteral antibiotic ◉ *Table 62.6*.

The duration of therapy is usually 4–6 weeks for acute infection. However, shorter duration of therapy for 3 weeks has been advocated recently for patients with acute and non-complicated osteomyelitis. Chronic osteomyelitis may require a prolonged period of treatment.

Periodic follow-up of affected patients is mandatory. The check-up list includes clinical examination, plain bone radiography of the affected bone, and ESR. ESR takes 7–14 days to decrease. Therefore a slight increase in the first 5–7 days of therapy is expected and does not indicate worsening of the condition as long as there is clinical response.

Table 62.6
Commonly used antibiotics to treat osteomyelitis and septic arthritis

Antibiotic	Intravenous dose (mg/kg/day)	No. of doses/day	Oral dose (mg/kg/day)	No. of doses/day
Cloxacillin	150	4	75–100 (bad taste)	4
Vancomycin	45	3		
Cefuroxime	150	3		
Cephalexin			100	4
Clindamycin	30	3	30	3
Ceftriaxone	100	2		
Cefotaxime	150	3		

Prognosis

This depends on how prompt and adequate therapy was given. However neonates are at an increased risk of developing complications such as disruption of growth phase, which may result in shortening or elongation of the affected bone.

Septic Arthritis

Septic arthritis is a serious infection which affects 2–40/100,000 children. Special consideration of septic arthritis in children includes the variability of the causative organisms according to the age and geographical areas. In addition the clinical presentation may be subtle, which makes high index of suspecting the prime factor in diagnosis. Septic arthritis is defined as a clinical episode in which a patient had at least one or more of the following: fever higher than 37.5°C, leucocytosis (WBC $>$ 13,000/mm^3), raised ESR ($>$20 mm), or a positive blood culture plus one or more of the following: technetium bone scan consistent with septic arthritis (and not osteomyelitis), joint pain and tenderness and restricted range of movement, joint effusion detected clinically or with ultrasound or a positive culture from aspirated joint fluid or pus cells, and/or bacteria detected on microscopy of joint fluid and a negative culture (only acceptable if patients had received prior antibiotic therapy).

Etiology

In developing countries where *H. influenzae* type b vaccine is not universally adopted, *H. influenzae* continues to play a major role in causing septic arthritis among children 3 months to 5 years of age. In addition, Brucellosis is endemic in many of the Middle East countries and one of the major presentations of brucellosis in children is arthritis or arthralgia (◉ *Table 62.7*).

Clinical Features

Newborn and infants have subtle symptoms, which include joint swelling, erythema and tenderness, fever, and pseudoparalysis. Usually, there is no limitation of movement at the affected joint.

Older children have more severe symptoms with joint swelling, erythema, and tenderness associated with significant limitation of joint movement. Fever and other systemic signs of infections are prominent.

Diagnosis and Differential Diagnosis

Septic arthritis should be differentiated from other causes of arthritis, which include trauma, hemarthrosis in hemophiliacs, collagen vascular disease, transient toxic synovitis, bursitis, cellulitis, and malignancy. Clinical features in addition to supportive laboratory tests are usually helpful in diagnosing septic arthritis. Acute reactants are usually raised. Aspirated synovial fluid has special characteristics, which vary with different causes of arthritis (Table 62.8).

All patients with suspected septic arthritis should undergo aspiration of the affected joint by an experienced person. The aspirated fluid should be sent for analysis and culture. Special consideration and advice to the lab are warranted when organisms like brucella or mycobacteria are suspected because special culturing procedures are required.

Other helpful diagnostic tests include imaging studies. Plain radiography usually shows widening of the joint space, but this is a nonspecific finding. Ultrasound scan is very helpful in assessing the amount of effusion in the affected joint and also could be used to help for aspiration.

Radionuclide studies show an increased uptake in the affected joint and may help in differentiating septic arthritis from inflammation of surrounding soft tissues.

Table 62.7
The predominant organisms at different age groups

Age group	Causative organisms
In infants <3 months	*Staphylococcus aureus*
	Group B Streptococcus
	Enteric organisms
	Group A Streptococcus
	Haemophilus influenzae
	Candida
In older infants and children <5 years of age	*H. influenzae*
	Staphylococcus aureus
	Streptococcus pneumoniae
	Group A Streptococcus
	Salmonella
	Brucella
Children >5 years of age	*Staphylococcus aureus*
	Streptococcus pneumoniae
	Brucellosis
	Salmonella

Treatment

Medical Therapy

The choice of antibiotic depends on the suspected causative organism.

1. In neonates, a third-generation cephalosporin and anti-staphylococcal antibiotic like cloxacillin or naficillin are good initial antibiotic coverage until the causative organism is identified. Most of the neonates will require 4–6 weeks parenteral therapy as there are no studies showing efficacy of oral antibiotics.
2. Infants and children <5 years of age:

   Coverage in these patients should include *H. influenzae* and *Staphylococcus aureus*. Therefore,

Table 62.8
Synovial fluid characteristics

	Pyogenic infection	Chronic granulomatous diseases	Collagen vascular
Appearance	Turbid	Turbid serosanguinous	Turbid
Cell count	15,000–200,000	2,500–100,000	200–70,000
(average)	(65,000)	(28,000)	(15,000)
Glucose	Very low	Low	Mildly low
Culture	Usually positive	May be positive	Negative
Mucin clot	Poor	Poor	Fair–poor
Viscosity	Decreases	Decreased	Decreased

cefuroxime is good initial choice. Alternatives include penicillinase-resistant penicillin like cloxacillin and third-generation cephalosporin like cefotaxime. After discovering the causative organism, the specific antibiotic should be given. The initial therapy is usually parenteral. After clinical improvement (resolution of fever, improved movement at the affected joint), the antibiotic can be changed to oral route as long as compliance is assured and follow-up of serum bactericidal titter is available.

3. Children >5 years of age:

   Only staphylococcal coverage is required initially until the causative organism is discovered. The rest of management is similar to infant and children <5 years of age.

Surgical Therapy

All patients with hip and most of those with shoulder involvement should undergo arthrotomy to preserve the blood supply.

Physiotherapy

Initial bed rest and placing the affected joint in physiological position is required until the pain eases and the child starts to feel better. This can be achieved by splint, traction, or cast.

After the pain eases (usually in 3–5 days), passive movement should be encouraged in order to prevent contracture.

63 Congenital Infections

Sami Al-Hajjar

The infant who is born with an infection acquired transplacentally during the first, second, or early third trimester may have what is termed *congenital infection.* Infection acquired in utero may result in abortion, stillbirth, developmental anomalies, intrauterine growth retardation, or clinical or asymptomatic infection, with the risk of subsequent sequelae of chronic postnatal infection.

Table 63.1 lists the different etiologic agents of congenital infections and possible sequelae.

The most common causes of congenital infections are cytomegalovirus (CMV), rubella, *Toxoplasma gondii, Treponema pallidum*, herpes simplex virus (HSV), human immunodeficiency virus (HIV), human parvovirus B19, hepatitis B virus, and Epstein-Barr virus. In rare instances, these infections are due to varicella-zoster virus, *Mycobacterium tuberculosis* and *Listeria moncytogenes.*

The acronym TORCH (*Toxoplasma, gondii* other, rubella, CMV, herpes simplex) has been used for the last two decades to increase awareness of the common etiologic agents in congenital infection. The "O" in TORCH (other) includes a list of pathogens that grows longer over time, including not only syphilis and varicella but also newer pathogens such as HIV and parvovirus B19 (*Table 63.1*). Lymphocytic choriomeningitis virus (LCMV) is a significant teratogen whose role in congenital infections has only recently gained appreciation. Approximately 88–93% of infants have chorioretinopathy and/or other ocular manifestations, including chorioretinitis, scarring, atrophy, nystagmus, esotropia, microphthalmos, cataracts, and vitreitis. Individuals who are exposed to rodents from living conditions or other exposure, such as pet handlers and laboratory personnel, are at particular risk for infection.

Certain other organisms may cause intrauterine infection but are usually transmitted just before delivery. This pattern is characteristic of HSV, *Enterovirus* group B streptococci, *Listeria*, and others. These intrauterine infections differ little from those caused by the same organisms when acquired just after delivery or during the first week or so of extrauterine life. For this reason, they are usually classified as "perinatal" rather than congenital infection. Recognition of pathogens causing congenital infection is critical, and the validity of the TORCH designation and screening for limited pathogens has been questioned.

Pathogenesis

Congenital infection occurs secondary to the exposure of the fetus during maternal infection. Most infections that occur in the mother during pregnancy appear to be limited to the respiratory or gastrointestinal tracts, and either resolve spontaneously without therapy or are treated with antimicrobial agents, and therefore do not pose a risk to the fetus. However, the infecting organism may invade the bloodstream, and this can lead to fetal infection. Transplacental spread after maternal infection and invasion of the bloodstream is the usual route by which the fetus becomes infected. Less frequently, the fetus may be infected by extension of the infection into the adjacent tissues and organs, including the peritoneum or the genitalia, or as a result of invasive methods for the diagnosis and therapy of fetal disorders such as the use of monitors, sampling of the fetal blood, and intrauterine transfusion.

Clinical Manifestations

Congenital infection in the great majority of infants will be missed during the early months of life. Ninety-five percent or more of newborn infants with congenital CMV have inapparent infection; comparable figures for the other congenital infections are toxoplasomis, 75%; rubells, 65%; syphilis, 50%; and most hepatitis B. In contrast, less than 1% of HSV infections in the neonate are subclinical. Despite striking differences in the nature of the microorganisms involved, signs and symptoms in the symptomatic cases overlap to a considerable extent. In fact, most of the clinical manifestations of congenital infections are also common to other noninfectious disease states. *Table 63.2* illustrates the frequency of clinical finding in infants with congenital infection.

[a]Association of effect with infection has been suggested and is under consideration

Diagnosis

Because the incidence of congenital infection in the fetus and newborn infant is high (0.5–2.5%) and because a significant number of congenitally infected infants are asymptomatic, the diagnosis of congenital infection in the infant relies on a high index of suspicion plus a combination of clinical and laboratory evaluations. The maternal history may provide important information about maternal infection. For example, the occurrence of maternal viral illness with an associated maculopapular rash suggests rubella in the neonate, whereas ulcerative genital lesions point toward HSV. It should be noted, however, that most maternal viral infections that lead to fetal or neonatal infection are asymptomatic in the mother. Therefore, the absence of a history of viral infection in the mother certainly does not rule out the possibility of such infection in her neonate.

Certain specific neonatal manifestation may provide helpful clues to strongly suspect specific etiologic agents on clinical grounds alone. For example, congenital rubella is characterized by purpura, heart defect, bone lesions, a "salt and pepper" appearance of the retina, and central cataract. An infant with a pink or dark red maculopapular or vesicolobullous skin, rash, rhinitis, and osteochondritis or periosteitis should be suspected of having congenital syphilis. Congenital CMV is probable in the infant with microcephaly, periventricular calcification, and "blueberry muffin" skin rash (*Fig. 63.1*), whereas toxoplasmosis is probable in infant with hydrocephalus, diffuse intracranial calcifications, and chorioretinitis. Chorioretinitis in the absence of major findings such as microcephaly is more likely due to toxoplasmosis and not CMV. LCM virus infection should be considered among infants who have chorioretinitis and congenital hydrocephalus or microcephaly, lack hepatosplenomegaly. However, the signs

and symptoms of many infections can overlap, and co-infection with more than one organism is possible. Therefore, in most cases, the investigation of suspected congenital infection usually requires simultaneous testing for a number of organisms. This should be tailored to the clinical situation.

The possibility of sepsis must always be considered, and the differential diagnosis of a symptomatic infant also includes hemolytic diseases and metabolic disorders such as galactosemia and tyrosinemia. The laboratory diagnostic approach to congenital has been tempered by the TORCH designation as TORCH titers are most frequently ordered by clinicians to diagnose congenital infection. In most case, however, the test is used inappropriately and is nondiagnostic. It must be remembered that a single investigation or specimen cannot be used to confirm the presence of one or the whole series of agents that can cause congenital infection.

The TORCH battery of serology tests has a poor diagnostic yield, and the appropriate diagnostic studies should be selected for each etiologic agent under consideration. Neonatal immunoglobulin G (IgG) titers are often difficult to interpret because IgG is acquired from the mother by transplacental passage. Of course, a negative antibody titer in the cord and maternal serum is sufficient evidence to exclude the diagnosis of congenital infection. Immunoglobulin M (IgM) titers to specific pathogens have high specificity and moderate sensitivity; they should not be

Figure 63.1
Purpuric "blueberry muffin" skin lesions in a newborn with congenital CMV infecion

employed to exclude infection. It is well known that IgM antibodies to rubella, CMV, and toxoplasma infection are long lasting. In many cases, IgM antibodies last for several months after primary infection with these pathogens . Because of this, it is very difficult to differentiate between acute and past infection utilizing current available IgM immunoassays. Recently, IgG avidity assays, which measure antibody maturity, have been shown to reliably discriminate between acute and past infection .Thus, in recent (acute) infection, for example, CMV, the body produces low-avidity IgG. After 2–4 months, the body begins to produce high-avidity CMV IgG. Low CMV IgG avidity suggests acute CMV infection occurred within the past 2–4 months. High CMV IgG avidity suggests that CMV infection occurred at some point in the past. This has been demonstrated to be the case for CMV, toxoplasma, and rubella. Avidity indices of 50% or less are considered low-avidity indices.

Total cord IgM level has been used as a screening test for congenital infection, but it lacks both sensitivity and specificity. Increased levels of total IgM ($\geq$20 mg/dL) occur only in one third of asymptomatic newborn infants with congenital infection and approximately 3% of uninfected infants. It is now apparent that infected fetuses first produce specific IgM between 19 and 24 h of gestation. When cordocentesis is performed before 20 weeks of gestation, the diagnosis of fetal infection can be made by isolation or detection of the agent itself, for example, by culture (CMV), by demonstration of the organism in inoculated mice (*Toxoplasma)* or by detection of both CMV or *Toxoplasma gondii* by polymerase chain reaction (PCR). The nonspecific and specific diagnostic tests are outlined in *Table 63.3*. It is important to remember that serologic tests not specific for IgM antibody require maternal serum for interpretation. Establishment of the specific agent is important for prognostic evaluation and for possible treatment. A combination of tests, including serology, avidity, and polymerase chain reaction, may be necessary to improve accuracy of diagnosis.

Table 63.3
Diagnostic evaluation of suspected congenital infection

Nonspecific tests	Specific tests[a]
Complete blood and platelet counts	**Viral culture**[b]
Lumbar puncture	Nasopharynx, urine, stool, skin lesion
Roentgenogram of long bones	Blood for HIV
Computerized tomography scan of head	Optional: cerebrospinal fluid (CSF), conjunctiva

64 Endocarditis

Aaron K. Olson

Infective endocarditis (IE) is a dreaded, albeit uncommon, complication of structural heart disease. Mortality was exceedingly high in the pre-antibiotic era, but has subsequently improved. Morbidity, including prolonged antibiotic administration and surgery, remains significant. This chapter will give an overview of IE in pediatric patients including those without structural heart disease.

Definition

IE is a microbial infection on the endocardial surface of the heart. IE typically involves native or prosthetic valves, but can also involve septal defects and intravascular foreign objects. Infective endarteritis is a similar infection involving arteries such as the ductus arteriosus. Historically, the terms acute and subacute have been used to classify endocarditis. Acute IE was usually due to *Staphylococcus aureus*, *Streptococcus pyogenes*, or *Streptococcus pneumoniae* while the subacute form typically involved viridans streptococci. Currently, IE is classified by the causative organism.

Epidemiology

IE is a rare disorder and occurs less frequently in children than adults. Approximately 1 of every 1,280 hospital admissions in American children in the early 1980s was for IE. This rate represents an increase from the mid-1900s. The underlining epidemiology of structural heart disease in children has also changed since the mid-1900s in the Western world, leading to changes in the predisposing factors for IE.

The incidence of rheumatic heart disease (RHD) has significantly decreased since the mid-twentieth century. At that time, 30–50% of pediatric IE cases were associated with RHD. Currently, IE patients rarely have underlying RHD in the Western world. However, RHD remains a problem in the developing world and is presumably a significant factor in the development of IE in these areas.

Patients with congenital heart disease (CHD) are living longer and now account for the largest percentage of IE cases. A recent nationwide database search showed that CHD was present in approximately 42% of IE admission in the United States. The most common underlying CHD diagnoses in this database were tetralogy of Fallot (TOF), ventricular septal defect (VSD), hypoplastic left heart syndrome, and aortic valve disease. However, these results do not necessarily represent the absolute risk of acquiring IE due to a specific congenital lesion. For example, VSDs are one of the most common forms of CHD. However, the lifetime risk for acquiring IE in patients with a VSD is lower than many other lesions. The highest lifetime risks for IE per 100,000 patient years are: prosthetic valve replacement after prosthetic valve IE, 2160; previous IE, 740; and valve surgery for native valve IE, 630. These lesions, along with cyanotic congenital heart disease and surgically constructed systemic-pulmonary shunts and conduits, are generally considered the highest risk groups for acquiring IE. Acquired valvular dysfunction (such as from RHD), hypertrophic cardiomyopathy and most other forms of CHD increase the risk of IE over the general population, but to a lesser degree than the highest risk group. For example, the risk per 100,000 patient years with congenital aortic stenosis is 271 and with a VSD is 145. For comparison, the lifetime risk in adults without cardiac disease is 5 per 100,000 patient years. Isolated secundum atrial septal defects and mitral valve prolapse without regurgitation do not increase the risk of IE above the general population. Finally, corrective procedures, whether surgical or percutaneous, eliminate the attributable risk for IE after 6 months as long as there is no residual defect.

In the absence of structural heart disease, IE is often associated in patients with central indwelling catheters or in patients with *S. aureus* bacteremia. Children with congenital or acquired immunodeficiencies (but no structural heart disease) do not appear to be at an increased risk for IE.

Pathogenesis

Microorganisms have a difficult time attaching to and propagating on intact cardiac endothelium. Most experts believe the following sequence of events is necessary for the development of IE: formation of nonbacterial thrombotic

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_64,

endocarditis (NBTE) on the surface of a cardiac valve or other location of endothelial damage, bacteremia, adherence of the bacteria in the bloodstream to the NBTE and proliferation of the bacteria within a vegetation. As noted, endothelial damage is often the inciting event. Structural heart disease often creates turbulent blood flow and high-velocity jet streams. This abnormal flow damages the cardiac endothelium and creates a substrate for thrombogenesis. Depositions of sterile clumps of platelets, fibrin, and occasionally red blood cells adhere to the damaged endothelium and form a NBTE. Central IV catheters can also cause a NBTE by rubbing against and damaging endothelium. When a NBTE becomes colonized with microorganisms, IE ensues.

Endogenous microorganisms populate all mucosal surfaces. Trauma to these surfaces transiently releases many different microbial species into the blood stream. Examples of activities that can lead to bacteremia include tooth extractions, teeth cleanings, flossing, brushing teeth, or even chewing food. However, bacteremia alone is not sufficient for IE. The inoculation number and type of microorganism appear to be critical factors. Mediators of bacterial adherence serve as virulence factors in the development of IE. Bacterial surface structures present on streptococci, staphylococci, and enterococci serve as important adhesins in animal models of IE. Organisms with these structures are responsible for the majority of cases of IE.

After colonization, bacteria within the vegetation proliferate. Adherent microorganisms trigger further deposition of fibrin and platelets; essentially isolating the bacteria from host immune defenses. The bacteria rapidly multiply and reach maximal microbial densities of 10^8 to 10^{11} colony-forming units per gram of vegetation on left-sided lesions. The innermost organisms become metabolically inactive, reducing the action of many antimicrobial agents.

Pathology

Vegetations usually occur on the atrial side of atrioventricular valves (tricuspid and mitral valves) and the ventricular side of semilunar valves. Vegetations also occur on prosthetic material (for example, VSD patches or artificial valves) in the heart or vasculature. Local extension of the infection produces many of the pathological complications in the heart. Large vegetations can lead to obstruction of surgical shunts. Valvular involvement can cause hemodynamically important regurgitation and new-onset heart failure. Other described cardiovascular complications include ruptured cordae tendineae, perivalvular abscess, fistulas, pericardial empyema and tamponade, sinus of Valsalva or ventricular aneurysms, and myocardial infarction due to embolism.

Distant organs are also affected by IE. Renal pathology, such as glomerulonephritis or infarction, can result from either embolic events or an immune complex–mediated process. Embolism can also cause ischemia and hemorrhage to other organ systems such as the central nervous system or abdominal organs.

Clinical Manifestations

IE is often an indolent disease and many clinical findings are nonspecific. Common symptoms include prolonged low-grade fever, myalgias, arthralagias, headaches, generalized malaise, history of anorexia, rigors, diaphoresis and weight loss. These features constitute the so-called subacute form of endocarditis. Any patient with structural heart disease and this cluster of symptoms requires evaluation for IE.

Occasionally, patients present in a toxic state with high, spiking fevers and/or heart failure. This constitutes the "acute" form of IE, which is often associated with *S. aureus* infection. Urgent intervention may be necessary including early antibiotics, intensive care, and surgery.

Neonatal IE presents in a similar manner to sepsis or heart failure from other causes. Feeding difficulties, respiratory distress, and tachycardia are common. Septic emboli occur more frequently than in older children. The emboli lead to infections outside of the heart such as meningitis, pneumonia, and osteomyelitis. Neurologic signs and symptoms may also occur and include new-onset seizures, apnea, and hemiparesis.

Specific extracardiac manifestations of IE are well described in adults. These findings include Roth spots, Osler nodes, and Janeway lesions. Roth spots are exudative, edematous hemorrhagic lesions of the retina. Osler's nodes are painful, violaceous nodules on the pulp of the fingers and toes. Janeway lesions are macular, blanching, nonpainful, erythematous lesions on the palms are soles. In children, these findings are uncommon. Splinter hemorrhages are also commonly described in adults with IE, but this is considered a nonspecific finding in children.

The cardiac examination in children with IE is highly variable. The type of underlying structural heart disease and the site of infection have major implications on the findings. Valvular infections can produce leaflet destruction leading to a new or worsening regurgitant murmur. With severe regurgitation, patients may present with new-onset heart failure. Cyanotic heart disease often requires

systemic to pulmonary artery shunts for pulmonary blood flow and maintenance of acceptable systemic oxygen saturations. IE of these shunts may not a significantly change in a patient's murmur. However, oxygen saturations may decrease due to partial obstruction and decreased pulmonary blood flow. Finally, patients with catheter-related IE may have no cardiac findings at all.

Diagnosis and Laboratory Evaluation

The signs and symptoms of IE can be nonspecific; therefore criteria were developed to aid diagnosis. The Modified Duke Criteria employs a combination of clinical, microbiologic and echocardiographic criteria to determine the likelihood of IE. This criterion is the current diagnostic standard and has been confirmed in the pediatric age group. Patients are stratified into to definite, possible or rejected IE. The Modified Duke Criteria for definite IE is met with two major, or one major and three minor or five minor criteria. Possible IE is defined as one major and one minor or three minor criteria. Rejected IE occurs with any of the following: a firm alternate diagnosis; "IE syndrome" resolves within 4 days of antibiotic therapy; or if the case does not meet "possible IE" criteria. The two major clinical criteria are evidence of endocardial involvement and a positive blood culture typical for IE. Evidence of endocardial involvement includes a positive echocardiogram (specifically defined as a vegetation, paravalvular abscess, or valve dehiscence after surgery) or new valvular regurgitation (by auscultation, not echocardiogram). A positive blood culture is a major criterion when there is any of the following: growth on two occasions of a microorganism "typical for" IE (*S. viridans*, *S. aureus*, *S. bovis*, HACEK group or community-acquired enterococcus); at least two persistently positive cultures drawn >12 h apart; all of three or a majority of ≥4 separate cultures are positive (with the first and last sample drawn at least 1 h apart); or evidence of infection with *Coxiella burnetii*. Minor criteria are as follows: a predisposing heart condition or injection drug use; fever ≥38°C; vascular phenomena (major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions); immunologic phenomena (glomerulonephritis, Osler's nodes, Roth spots, rheumatoid factor); microbiologic evidence consisting of either a positive blood culture not meeting major criterion as noted above (excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with IE.

Blood Cultures

Positive blood cultures are a major criterion and are also important for antibiotic selection. In suspected IE, three blood cultures over 24 h from separate venipuncture sites are recommended. If the cultures are negative at 24 h, then an additional two cultures may be obtained. Bacteremia from IE is continuous; therefore it is not necessary to obtain cultures during fever spikes. In adults, 20–30 ml of blood per culture is recommended. This amount is not feasible in children. Typically, 5–7 ml of blood in children and 1–3 ml of blood in infants are recommended. Anaerobic organisms rarely cause IE, therefore emphasis is placed obtaining aerobic cultures. If possible, antibiotics are not started until blood cultures are obtained.

The most commonly cultured organisms in IE are the gram positives *S. aureus*, viridans group streptococci and coagulase-negative staphylococci. Recently, IE discharge data on children was compiled from a large collection of American hospitals. This data showed that *S. aureus* was the most common organism (57% of cases), followed by viridans group streptococci (20% of cases) and coagulase-negative staphylococci (14% of cases). Other studies have shown that viridian group streptococci is slightly more common than *S. aureus*. Rarely encountered gram positive causative organisms include pneumococcus, *Escherichia coli*, *Hemophilus influenzae*, group A streptococcus, group B streptococcus, group D streptococcus.

Gram negative bacteria are the causative agents in less than 10% of cases of pediatric IE and are primarily due to the HACEK group of fastidious coccobacilli. The HACEK group includes *Haemophilus parainfluenzae*, *H. aphrophilus*, *H. paraphrophilus*, *Actinobacillus [Haemophilus] actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* species, and *Kingella kingae*. These organisms grow slowly in standard culture media. Therefore, the laboratory should retain initially negative blood cultures for at least 2 weeks to evaluate for gram negatives. Certain groups are at higher risk for these organisms and include neonates, immunocompromised patients, and injection drug users.

Fungal endocarditis is usually caused by *Candida* species and rarely *Aspergillus*. The use of central venous catheters to deliver hyperalimentation and high glucose solutions appears to be associated with Candida endocarditis. Additional risk factors include injection drug users and immunocompromised individuals. Fungal vegetations are often large and friable leading to embolization and serious complication.

Culture-negative endocarditis is diagnosed when a patient has clinical and/or echocardiographic evidence

of IE but the blood cultures are repeatedly negative. This occurs in about 5–7% of cases. The most common cause of culture-negative IE is current or recent antibiotic treatment or infection with a fastidious organism that grows poorly in vitro. These fastidious organisms include filamentous fungus, *Coxella burnetti* (Q fever), *Brucella, Legionella, Bartonella* (*Rochalimaea*), and *Chlamydia*. When the clinician encounters culture-negative IE, it is important to consult with the microbiology lab in order to maximize the chance of culturing the causative organism.

IE associated with central venous catheters, prosthetic material, or prosthetic heart valves is usually caused by *S. aureus* or coagulase-negative staphylococci. These infections may be inoculated at the time of the procedure and typically present within 60 days of surgery. However, coagulase-negative staphylococci can present up to 1 year after surgery.

Echocardiography

Echocardiography is the primary modality for detection of endocarditis as well as being a major diagnostic criterion. Echocardiograms can establish vegetation location, size, and response to therapy. Associated problems can also be determined such as the extent of valvular damage, ventricular size and function, the presence of pericardial effusion, and abscess formation. In adults, transthoracic echocardiography (TTE) is not considered sensitive enough for vegetation detection; therefore transesphogeal echocardiograms (TEE) are recommended. TTE is usually sufficient in pediatric IE with a reported sensitivity of 81%. TEE can be a useful adjunct in children with poor echocardiographic imaging (due to body habits or pulmonary hyperinflation), a prosthetic valve causing acoustic "shadowing" or in those with a normal TTE despite a high index of suspicion for IE. It is important to note that the absence of vegetation on echocardiography does not rule out IE. Conversely, an echogenic mass may represent a sterile thrombus, sterile prosthetic material (such as a surgical stitch), or normal anatomic variation. *Figure 64.1* shows an example of a mitral valve vegetation in a child imaged by TTE.

Serial echocardiography is an important part of the ongoing care for acute IE. Certain echocardiographic findings are predictive of complications and may require surgical intervention. These features include: persistent vegetation after systemic embolization, anterior mitral valve vegetation particularly if greater than 10 mm in size, one or more embolic events during the first 2 weeks of antimicrobial therapy, increase in vegetation size after 4 weeks of antimicrobial treatment, acute valvular dysfunction leading to heart failure and a large abscess or extension of the abscess despite appropriate antibiotic treatment.

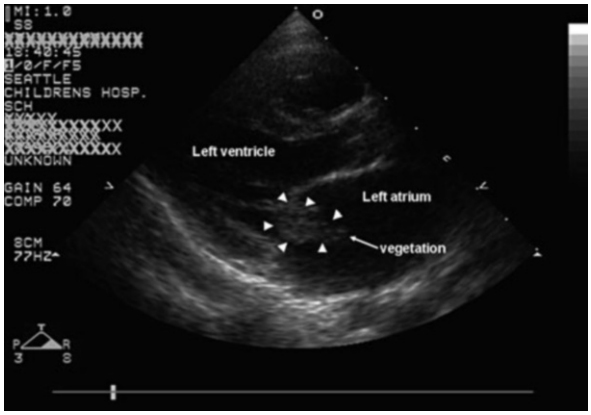

Figure 64.1
An example of mitral valve endocarditis in a child as visualized with a transthroacic echocardiogram. The margins of the vegetation are demarcated by arrowheads. The large size (~20 mm) of this vegetation required surgical removal due to a high risk of embolization

Other

Additional laboratory abnormalities are often present. An electrocardiogram should be performed to evaluate for arrhythmias and atrioventricular block, which may be a sign of an abscess within the conduction system. IE can cause anemia either through hemolysis or chronic disease. Leukocytosis is not always present, but immature cells are often present on blood smear. Elevations in the inflammatory markers C-reactive protein and erythrocyte sedimentation rate are common. Hematuria and other renal abnormalities can be found in IE patients who develop immune complex–mediated glomerulonephritis. Rheumatoid factor is also often elevated.

Differential Diagnosis

As noted, the clinical manifestations of endocarditis are usually nonspecific. Many disorders share similar features including other infections, malignancies, and rheumatologic conditions. However, it remains incumbent upon the clinician to strongly consider IE in any child with an unexplained fever and a history of structural heart disease.

Treatment

Antibiotics are the mainstay of IE treatment. A complete discussion of antibiotic treatment for every potential organism and clinical situation is beyond the scope of this chapter. For in-depth recommendations, the reader is encouraged to consult the American Heart Association (AHA) statement (most recently updated in 2005) entitled, "Infective Endocarditis: Diagnosis, Antimicrobial Therapy, and Management of Complication." Several general principles provide the basis for antibiotic treatment in IE. In clinically stable patients, antibiotics may be withheld for 48 h or longer until information from the blood cultures is available. The choice of antibiotics is then based upon the cultured organism and sensitivity to various antibiotics. Evolving antibiotic resistance patterns makes consultation with an expert in infectious disease necessary to assure proper therapy. Antibiotics are typically administered for 2–8 weeks. Additionally, bacteriocidal antibiotics should be chosen if available to minimize the possibility of a treatment failure or relapse. Intravenous treatment is the preferred route in order to achieve high bacteriocidal concentrations in the relatively avascular vegetations.

Occasionally, patients with IE present in an unstable hemodynamic condition; the so-called acute endocarditis. This situation warrants initiation of antibiotics prior to obtaining results from the blood cultures. Empiric treatment should focus on covering streptococci and staphylococci, the most common causative organisms in IE. The antibiotic coverage should include a penicillinase-resistant penicillin, penicillin G, and gentamicin. Vancomycin should be considered where rates of methicillin-resistant *S. aureus* are high. Blood cultures from three separate venipuncture sites are still recommended. However, the cultures can be obtained over 1 h.

As noted, viridans Group Streptococci is one of the most common causes of IE. For penicillin-susceptible streptococci IE of native valves, 4 weeks of IV treatment with penicillin G or ceftriaxone is recommended. A 2-week course of therapy with either of these antibiotics combined with gentamycin is an alternative strategy. However, this should only be used in uncomplicated cases of patients with symptoms for less than 3 months.

Staphylococci are classified as either coagulase-positive (*S. aureus)* or coagulase-negative (including *S. epidermidis*). Antibiotic recommendations are similar between the classes. For the purpose of this chapter, only recommendations for native valve staphylococcal IE will be discussed. Importantly, the vast majority of staphylococci are resistant to penicillin G and ampicillin. For methicillin-susceptible *S. aureus*, a semisynthetic penicillinase-resistant penicillin, such as Nafcillin, is given for 6 weeks. 3–5 days of gentamycin is sometimes added in seriously ill patients, however the clinical utility of this is unclear. Vancomycin treatment for at least 6 weeks is used in cases of methicillin-resistant staphylococci (which includes virtually all cases of coagulase-negative staphylococci). In addition, rifapin (at least 6 weeks) or gentamicin (2 weeks) is used with vancomycin for coagulase-negative staphylococci IE.

Gram negative IE is most commonly caused by the HACEK group of fastidious coccobacilli in children. Uncomplicated native valve infections should be treated for 4 weeks with ceftriaxone or another appropriate third or fourth generation cephalosporin or ampicillin/salbactum.

Fungal IE is rare and has a poor prognosis. Antifungal agents alone are almost always ineffective. Surgery (discussed below) is necessary to treat the infection and prevent complications. Surgical treatment is recommended after 1–2 weeks of medical therapy if the patient's status permits, but should be done earlier if embolic events occur. Amphotericin B is the most effective antifungal agent and should be given for 6–8 weeks.

In cases of culture-negative IE, empiric therapy with two or more agents is used for 6 weeks. During this time, continuing efforts to identify an organism should be pursued.

In general, the bacteremia from IE typically resolves within several days after initiating appropriate antibiotic therapy. S. *aureus* bacteremia may persist for 5–10 days when vancomycin is used. During treatment, repeat blood cultures should be obtained to assess the adequacy of the antibiotics and to document the resolution of bacteremia. Finally, blood cultures should be performed once or twice after antibiotic completion to ensure a successful cure.

Medical therapy alone is not always adequate for successful IE treatment. Surgery may be necessary during an active infection depending on the location and clinical course. Surgical indications typically fall into three categories. First, surgery may be necessary when antimicrobial treatment is unsuccessful or has a high likely hood of being unsuccessful. Persistent bacteremia after 2 weeks of appropriate antibiotics is generally considered a treatment failure necessitating surgery. Abscesses and fungal vegetations are exceedingly difficult to eradicate medically and therefore, surgery is recommended. Second, experts recommend removal of vegetations showering systemic emboli or at high risk of embolizing with a catastrophic consequence. The risk of embolization is associated with vegetation size and infecting organism. Fungal IE and vegetations

measuring greater than 10 mm are at high risk for embolization and should be removed surgically. Finally, valvular damage from IE may lead to uncontrollable heart failure, requiring surgery for hemodynamic stability. Other rarely encountered indications for surgery include myocotic aneurysms and unstable prosthetic valves.

Prognosis

The prognosis of children with IE depends on a number of factors including the severity of the underlying cardiac lesion, the causative organism, presence of prosthetic material, and the clinical course of the patient. Overall mortality from IE has significantly dropped. In the pre-antibiotic era, IE was almost uniformly fatal. Currently, reported mortality rates in children are between 5% and 11%. However, mortality approaches 50% in select patients such as those with Tetralogy of Fallot/pulmonary atresia. In adults and children with congenital heart disease, risk factors for mortality include vegetation size of 20 mm or greater, age <1 year, heart failure, and *S. aureus* as a causative organism. In patients without preexisting heart disease, risk factors for mortality included premature/neonatal age and *S. aureus* infections.

Patients may need surgery after an episode of IE has resolved. Because a previous episode of IE places a patient at high risk for recurrence, experts recommend closing a hemodynamically unimportant VSD following successful treatment. Additionally, valvular damage from IE may worsen over time and eventually require valve replacement or repair.

Prevention

Antibiotic prophylaxis to prevent IE during certain medical and dental procedures has been a standard part of the care for patients with structural heart disease for the last half century. However, no prospective randomized trial has been undertaken to demonstrate the effectiveness of this practice. The rational for prophylaxis is that certain medical and dental procedures cause bacteremia which, in turn, can lead to IE in patients with predisposing conditions. Administration of antibiotics just prior to these procedures may reduce the bacteremia and prevent IE. While the biologic plausibility is high, the results of observational studies have not demonstrated any benefit from IE prophylaxis. At best, research has shown that a large number of prophylaxis doses would be necessary to prevent a very small number of IE cases.

Given this and other data, the American Heart Association (AHA) and other international organization significantly revised IE prophylaxis guidelines. Importantly, these recommendations are only guidelines and clinical judgment is still indicated. The AHA cited four key points as support for these changes. First, IE is much more likely to result from frequent exposure to random bacteremias associated with daily activities (e.g., tooth brushing) than from bacteremia caused by a dental, gastrointestinal, or genitourinary procedure. Second, prophylaxis may prevent an exceedingly small number of cases of IE, if any, in individuals who undergo these procedures. Third, the risk of antibiotic-associated adverse events may exceed the benefit from prophylactic antibiotic therapy. Finally, maintenance of optimal oral health and hygiene may reduce the incidence of bacteremia from daily activities and is therefore more important than prophylactic antibiotics for a dental procedure to reduce the risk of IE.

A complete description of the IE prophylaxis guidelines is beyond the scope of this chapter. For complete details, the reader is referred to the 2007 AHA guidelines entitled, "Prevention of Infective Endocarditis." To summarize, antibiotic prophylaxis is now reserved only for patients with the highest risk of developing adverse outcomes from IE. The high-risk group includes those with prosthetic heart valves, a history of IE, unrepaired cyanotic congenital heart disease (including palliative shunts and conduits), completely repaired congenital heart defects with prosthetic material or device (whether placed by surgery or by catheter intervention) during the first 6 months after the procedure, repaired congenital heart disease with residual defects at the site or adjacent to the site of the prosthetic device and cardiac valvulopathy in a transplanted heart. The procedures for which prophylaxis is recommended include all dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa; procedures on the respiratory tract that involve incision or biopsy of the respiratory mucosa; procedures in patients with ongoing GI or GU tract infection; procedures on infected skin, skin structure, or musculoskeletal tissue; and surgery to place prosthetic heart valves or prosthetic intravascular or intracardiac materials. The choice of antibiotics depends upon type of procedure, patient allergies, and concurrent antibiotic treatment. In general, amoxicillin is the first choice and is given as a single oral dose 30–60 min before the procedure. The amoxicillin dosage is 50 mg/kg up to a maximum of 2 g. The guidelines also give recommendations for patients unable to take oral medications, already on antibiotics or with allergies to penicillins.

65 Fever of Unknown Origin

Asa'd Al-Toonsi

Fever is a universal phenomenon of illness and occurs as part of the acute inflammatory response, which includes leukocytosis, elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), and a drop in levels of free serum iron. A useful definition of fever is a temperature more than 38°C. The most accurate method of measuring temperature is rectally or from freshly voided urine, followed by orally, which may be affected by drinking hot or cold liquid. Measuring the skin temperature, or the use of thermometers that measure tympanic temperature, is not reliable as skin temperature may be affected by environmental factors, and the infrared beams from tympanic thermometers may hit the external ear canal wall instead of the tympanic membrane.

Fever results from pyrogens such as interleukins 1 and 6 and tumor necrosis factor released from monocytes and tissue macrophages in response to infection, injury, autoimmune disease, or malignancy. Regardless of the triggering factor, the response is the same. These pyrogens act on the temperature-regulating centers in the hypothalamus to elevate the thermostat set point. The body then initiates heat conservation measures, including vasoconstriction, piloerection, and shivering, to drive body temperature up to a new level. These mechanisms, together with conscious heat conservation measures such as covering the body with blankets, act to bring up the body temperature to the new set point, which may be 38–40°C. When the set point is reached, or the stimulus is removed, the body initiates cooling measures, including vasodilation and sweating, in order to maintain the set point. There are also endogenous antipyretics, or cryogens (e.g., arginine, vasopressin, α-melanocyte-stimulating hormone, glucocorticoids, and, in some cases, tumor necrosis factor), that act to modulate the increase in body temperature to prevent it from rising to dangerous levels.

A second mechanism of fever involves increased heat production that exceeds heat loss, which may be seen in hyperthyroidism; exposure to excessive environmental temperature; or malignant hyperthermia. The third mechanism includes defective heat loss, as seen with ectodermal dysplasia, heat stroke, and poisoning with anticholinergic drugs.

Fever enhances host defense responses by enhancing neutrophil migration, increasing antibacterial substances produced by neutrophils (e.g., superoxide dismutase), increasing antiviral and antitumor activities of interferon, increasing T-cell proliferation, and decreasing growth of microorganisms in the fever-induced iron-poor environment. However, fever sometimes may be maladaptive (e.g., in association with hypoglycemia and shock). Drugs such as acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs act by interfering with prostaglandin synthesis through inhibition of cyclooxygenase. Because they do not suppress interleukin-1, they have no effect on the proliferation of T-helper cells and thus do not adversely affect the body's ability to fight infection. On the other hand, corticosteroids decrease the quantity of interleukin-1 released from monocytes and macrophages, thereby decreasing the body's ability to fight infection.

The pattern of fever is of minimal significance as an indicator of a specific disease but may provide a clue to the diagnosis on a few occasions. Intermittent fever is characterized by the return of temperature to normal at least once a day. This pattern of fever is seen in pyogenic infections, especially abscess collections, but it may also be seen in tuberculosis, lymphoma, or juvenile rheumatoid arthritis (JRA). Remittent fever is also fluctuating but does not return to normal. Sustained fever has little or no fluctuation and may be seen in typhoid fever. Relapsing fever is characterized by afebrile periods of one or more days between the episodes of fever. This pattern of fever is classically seen in malaria, but it may also be seen in rat-bite fever and lymphoma.

Fever Without Localizing Signs

Fever is the single most common chief complaint made to physicians who evaluate ambulatory children. Febrile illnesses account for 30% of outpatient visits and 20% of emergency department encounters. Fever without localizing signs is fever of acute onset and short duration, with no apparent etiology after careful history and physical examination. It has been estimated that between 5% and 10% of children presenting with fever will have no localizing signs, although in some series, this figure has been as high as 22%, with peak incidence during the second year of life.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_65,

Approximately 5% of children with fever without localizing signs are bacteremic. A number of studies showed that if these children are not treated with antibiotics at the time of initial presentation, 5–10% will return with meningitis, 10% with localized bacterial infection, and another 30% with continued fever and persistent bacteremia, depending on the type of organism isolated. Children with fever without localizing signs may be at high risk of having serious infection, including infants younger than 2 months, those who appear toxic, or those with temperatures above 40°C, especially when accompanied by leukocytosis of more than 15,000/mm^3 and left shift. Children at low risk of having serious illness are those who are younger than 36 months, those appearing well, or those with fevers less than 39.4°C or leukocytosis less than 15,000/mm^3.

The management of high-risk children varies from septic workup with complete blood count and differential, with or without expectant treatment with empirical antibiotic coverage (e.g., amoxicillin-clavulanate or ceftriaxone) on an outpatient basis pending culture results, to hospitalization for those who appear seriously ill. On the other hand, low-risk children are managed more conservatively; they may not require any investigation, or only simple investigations, such as complete blood count or urinalysis, and follow-up may be all they require.

Fever and Occult Bacteremia

The incidence of bacteremia in children aged 3–36 months presenting with fever greater than 39°C is 3–5%. The child with bacteremia may appear clinically well apart from fever with or without an identifiable focus of infection. Bacteremia may be transient with spontaneous resolution, especially in cases with quantitatively low colony counts. Persistent bacteremia may be complicated with serious focal or generalized infection. For a bacteremic child discharged from the emergency department, the overall risk is 35% for persistent fever, 12% for persistent bacteremia, and 7% for meningitis, depending on the pathogen isolated.

The likelihood of a child with fever having an infectious disease depends on the age of the patient, the degree of fever, and the clinical status. In younger children, hypothermia may be seen with equal or greater frequency than fever in the course of septicemia. Infants 2–3 months of age are more likely to have focal bacterial infections with bacteremia or overwhelming sepsis when their temperature exceeds 40°C. After 3 months of age, the severity of illness and likelihood of bacteremia or septicemia is proportional to the degree of temperature elevation. With rectal temperature less than 38.9°C, the rate of bacteremia is 1%. It increases to 4% with temperatures of 38.0–39.4°C, and then to 8% with temperatures of 39.4–40°C. At temperatures of 40–41.4°C, the rate of bacteremia becomes 11%. Children with temperatures above 41.1°C have rates of serious illness exceeding 60%.

Fever of Unknown Origin

There is no general consensus on the definition of fever of unknown origin (FUO), especially in children. A reasonable definition of FUO in children is fever exceeding 38.3°C orally in children more than 3 years old or rectally in children less than 3 years old of more than 2 weeks' duration and uncertain diagnosis after 1 week of study in the hospital. It is important to differentiate FUO from fever without localizing signs because the differential diagnosis of each clinical condition is different. In patients with fever without localizing signs, urgent investigation to rule out sepsis is required, and it is acceptable to start expectant treatment. In patients with FUO, on the other hand, hospitalization is usually required but expectant treatment is not required.

Epidemiology

The results from old studies of children with FUO show that infection was found in 28–52% of these children, mainly as systemic illness, upper and lower respiratory tract infections, and skeletal infections. Unusual infections constituted 10–15% of all infections responsible for FUO (*Table 65.1*). Collagen-vascular diseases comprised 5–20% of the causes of FUO. Malignancy, mainly leukemia and lymphoma, contributed to 2–13% of cases, miscellaneous causes were responsible for 10–16%, and 5–30% of all cases of FUO were undiagnosed.

More recent studies of children with FUO did not differ much in their findings from the old series (*Table 65.1*). The findings from studies in the English literature show that infections were found in 22–43% of children with FUO, with infections such as Epstein-Barr virus (EBV) and *Bartonella henselae* (cat-scratch disease) becoming more frequent causes of FUO. In one study, EBV was the leading infectious cause of FUO, while bartonellosis was the third-leading infectious cause in those children. This finding may be explained by the fact that such diseases were probably underdiagnosed in the past and are diagnosed more frequently today due to

Table 65.1
Results from studies of children with fever of unknown origin

Diagnostic category	5–7 days	3 week outpatient or 1 week inpatient	2 week	>1 week, no diagnosis after 1 week in hospital	3 week outpatient or 1 week inpatient	≥3 week	≥3 week	≥2 week
Number	165	99	100	20	54	109	113	146
Infection	91	29	52	7	18	24	41	64
Collagen-vascular	9	11	20	3	8	7	15	11
Neoplasm	3	8	6	1	7	2	11	4
Miscellaneous (including inflammatory bowel disease)	18	24	10	3	11	3	25	5
No diagnosis	9	11	12	6	10	73	22	62

the availability of more sensitive and specific tests and better understanding of such diseases, or it may truly be due to increased incidences of these diseases. Collagen-vascular diseases were diagnosed in 6–13% and malignancy in 2–10% of cases, while miscellaneous causes were found in 3–18% of cases of FUO in these recent studies. An interesting finding is that, despite extensive workup and the utilization of modern technology, a large number of children with FUO remained with no diagnosis.

Clinical Presentation

FUO, in most instances, is an unusual presentation of a common illness rather than a presentation of a rare disease. However, the physician should be open-minded and not disregard rare diseases, especially when investigative procedures are exhausted. Systemic infections presenting as FUO include tuberculosis, brucellosis, salmonellosis, rickettsial diseases, spirochetes (such as leptospirosis), and viral infections such as EBV, cytomegalovirus, human immunodeficiency virus (HIV), and hepatitis viruses. Localized infections include upper respiratory infections, urinary tract infections, osteomyelitis, and occult abscesses. In certain parts of the world, other infections, such as malaria or leishmaniasis, may be seen more frequently as causes of FUO.

Fever may precede the appearance of other manifestations of illnesses such as rheumatoid arthritis (which constitutes 90% of collagen-vascular disease presenting with FUO) or systemic lupus erythematosus (SLE) by weeks or months, occurring when the serologic markers for these diseases are not yet present. Acute rheumatic fever should be considered in the differential diagnosis of FUO, as the fever sometimes predates other clinical features that may be discovered during subsequent clinical examination. Vasculitic diseases, such as Kawasaki disease and Wegener granulomatosis, may present as FUO. The former should be considered when the acute-phase reactants are extremely elevated.

Inflammatory bowel disease (IBD) accounts for 4% of FUO in children, with the majority due to Crohn disease, which may present with fever months or years before gastrointestinal symptoms become apparent. The finding of growth failure, as well as finger clubbing, reactive arthritis, pyoderma gangrenosum, iron deficiency anemia, and elevated ESR, are additional clues to the diagnosis.

Evaluation of the Child with Fever of Unknown Origin

Hospitalization is usually required for proper evaluation of the patient with FUO for many reasons (*Fig. 65.1*):

To try to relieve parents' anxiety and fears and gain their confidence to encourage cooperation

To document the fever and determine if there is any specific pattern to it that could help in reaching the diagnosis

To allow observation and daily evaluation of the child for appearance of new signs or availability of new information that may direct the diagnosis toward a specific etiology

To try to identify causes (*Table 65.2*), including such unusual causes as Munchausen syndrome by proxy or pseudo-FUO

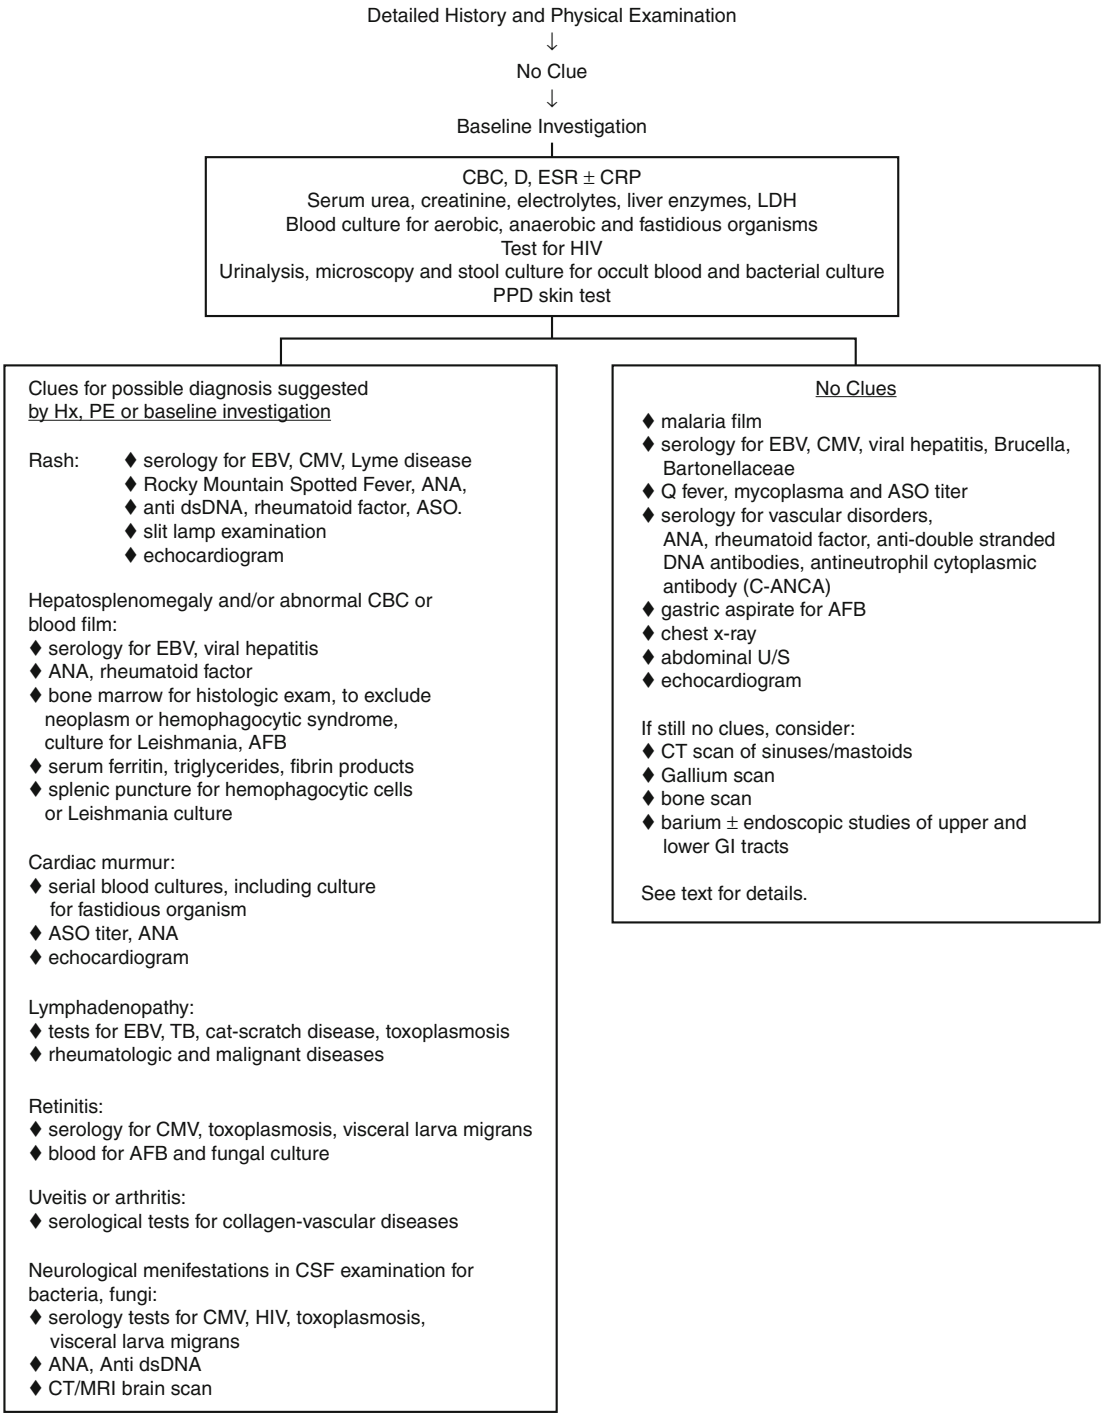

Figure 65.1

Evaluation of the child with fever of unknown origin. *AFB* acid-fast bacilli, *ANA* antinuclear antibodies, *ASO* antistreptolysin O, *CBC* complete blood count, *CMV* cytomegalovirus, *CRP* C-reactive protein, *CSF* cerebrospinal fluid, *CT/MRI* computerized tomography/magnetic resonance imaging, *D* differential leukocyte count, *EBV* Epstein-Barr virus, *ESR* erythrocyte sedimentation rate, *GI* gastrointestinal, *HIV* human immunodeficiency virus, *Hx* history, *LDH* lactate dehydrogenase, *PE* physical examination, *PPD* purified protein derivative (of tuberculin), *TB* tuberculosis, *U/S* ultrasound

Table 65.2
Some causes of fever of unknown origin

Infections (22–52%)	Collagen-vascular diseases (5–20%)
By site	Rheumatoid arthritis
Upper and lower respiratory infections	Systemic lupus erythematosus
Urinary tract infection	Polyarteritis nodosa
Osteoarticular	Behçet disease
Endocarditis	*Neoplasm (2–13%)*
Periodontal	Leukemia
Meningitis	Lymphoma
By organism:	Neuroblastoma
Salmonellosis	Histiocytosis
Shigellosis	*Miscellaneous (3–18%)*
Yersiniosis	Inflammatory bowel disease
Brucellosis	Hemophagocytic syndrome
Tuberculosis	Pseudo-fever
Tularemia	Munchausen syndrome by proxy
Chronic meningococcemia	Drug fever
Cat-scratch disease	Diabetes insipidus
Q fever	Thyrotoxicosis
Mycoplasma	Fever secondary to brain injury
Lyme disease	Ectodermal dysplasia
Malaria	Familial dysautonomia
Leishmaniasis	Atypical Kawasaki disease
Visceral larva migrans	Rheumatic fever
Leptospirosis	Periodic fever
Epstein-Barr virus	Sarcoidosis
Cytomegalovirus	Wegener granulomatosis
Viral hepatitis	
Human immunodeficiency virus	
Histoplasmosis	
Blastomycosis	

History

A careful history, with all the details of the present illness, should be taken. Minor complaints should not be ignored. Special attention should be paid to signs that may suggest specific organ involvement. History of rash may indicate a specific infection. JRA may be associated with a salmon-pink rash that appears with spikes of temperature and disappears when the fever subsides. While rheumatic fever is associated with the characteristic rash of erythema marginatum, it usually does not last more than a day or two. Joint pain or swelling raises the possibility of collagen-vascular disease. However, arthritis may also be an extraintestinal manifestation of IBD. Back pain associated with limping indicates diskitis or a vertebral abscess. Bone pain may be due to osteomyelitis or the expanding bone marrow from malignant cells in leukemia. A history of diarrhea may be important when diagnoses such as IBD, amebiasis, or giardiasis are considered. Genitourinary or respiratory symptoms may be due to a specific infection or be part of vasculitis syndromes such as Behçet disease or Wegener granulomatosis.

History of contact with a person who is ill is important in diseases such as tuberculosis. History of exposure to pets can be valuable in zoonotic diseases such as brucellosis, toxoplasmosis, cat-scratch disease, or visceral larva migrans. History of ingestion of undercooked meat or unpasteurized milk or dairy products may give clues to the diagnosis of brucellosis or Q fever. History of travel to areas endemic for certain diseases, such as malaria or leishmaniasis, should not be overlooked. Even a history of travel many years in the past to an endemic area might be relevant, as in histoplasmosis, coccidioidomycosis, or blastomycosis infections. A detailed history of all medications, including topical medications, should be obtained. Family history may reveal hereditary or familial conditions such as diabetes insipidus, familial dysautonomia, and familial Mediterranean fever, or direct the diagnosis toward an underlying immune deficiency disease that is presenting with FUO due to an unusual infection with opportunistic organisms or chronic viral infections. Social history may give clues to the diagnosis of Munchausen syndrome by proxy, pseudo-fever, or certain infections that may be seen with more frequency in people of low socioeconomic status, such as tuberculosis.

Physical Examination

Physical examination should be thoroughly performed at initial evaluation and at repeated evaluations. The general condition, and how well the child appears, usually indicate how serious the disease is. Measurements of growth parameters are important, as they may be the only clue to the diagnosis of IBD. Growth failure may also be associated with infection due to HIV or tuberculosis. Hypertension may be part of polyarteritis nodosa or SLE.

Absence of sweating and dehydration are seen in fevers due to diabetes insipidus or ectodermal dysplasia. Ophthalmoscopic examination should be done for all patients being evaluated for FUO. Retinal lesions may be seen in cytomegalovirus infection, toxoplasmosis, visceral larva migrans, disseminated tuberculosis, and disseminated fungal infections.

Skin rashes with specific distribution or a particular appearance may be diagnostic, such as erythema migrans associated with Lyme disease or the butterfly rash that is one of the features of SLE. Other important skin lesions are pyoderma gangrenosum and erythema nodosum, which are seen in patients with IBD. Mouth ulcers, in association with perineal ulcerations, uveitis, and central nervous system involvement, are diagnostic of Behçet disease. Perianal fistulas or skin tags are seen in patients with Crohn disease. The finding of cardiac murmur should alert the physician to the possibility of endocarditis. The murmur of mitral valve regurgitation is often the first clinical sign that gives a clue to the diagnosis of rheumatic fever presenting as FUO. Hepatomegaly, splenomegaly, and lymphadenopathy indicate a systemic disease, such as viral infections (e.g., EBV, cytomegalovirus) as well as toxoplasmosis, lymphoma, leukemia, hemophagocytic syndrome, histiocytosis, or rheumatoid arthritis.

Examination of the patient for gait abnormalities and assessment of individual muscle strength may demonstrate proximal muscle weakness suggesting inflammatory myositis, such as dermatomyositis. Joints must be examined for range of movement and signs of arthritis, such as redness, hotness, or swelling. Point tenderness and asymmetry in position or movement of the extremities, especially in the young child, indicate possible osteomyelitis, while point tenderness over the back may indicate diskitis.

Laboratory Evaluations

Baseline laboratory investigation is necessary at the initial assessment of the child with FUO. In many cases, the history, physical examination, and baseline laboratory investigation do not give clues to the diagnosis. At this stage, a more detailed investigation is required and, as more and more results of these investigations become available, rare causes of FUO are considered.

The baseline investigation should include a complete blood count and differential leukocyte count. An elevated leukocyte count with predominant immature forms and toxic granulations suggests a bacterial infection, especially when the patient appears toxic, but normal or low leukocyte counts could still be seen in bacterial infections. The presence of atypical lymphocytes in the peripheral blood smear suggests a viral infection, while the presence of blasts may indicate leukemia. Pancytopenia may be due to leukemia, leishmaniasis, parvovirus B19 infection, or overwhelming sepsis. Significant thrombocytosis, usually present in the second week of illness, may be the only clue to the diagnosis of atypical Kawasaki disease. The ESR is a nonspecific marker of inflammation. Markedly elevated values may determine the need for further evaluation, and the ESR is a helpful tool in monitoring disease activity.

In laboratories with the facility to measure the CRP, a single measurement may be normal in the presence of infection. However, there are some studies that show increased sensitivity of CRP as a marker of infection when measured serially over 24–48 h following presentation. Elevated CRP may be seen in patients with rheumatic fever, Kawasaki disease, or other inflammatory conditions. A renal profile, including serum creatinine, urea, sodium, and potassium, may help in pointing toward nephritis, which may be seen in SLE or polyarteritis nodosa. Abnormally elevated values may be seen in the child with fever due to dehydration from diabetes insipidus or ectodermal dysplasia. Liver enzymes may be abnormal in many conditions that could cause FUO, such as viral hepatitis, EBV infection, and several other infections. Elevated serum transaminases may be seen in diseases with multiorgan involvement, such as Kawasaki disease and hemophagocytic syndrome. Elevated serum lactate dehydrogenase suggests malignancy.

Blood should be cultured for aerobic and anaerobic bacteria. The blood culture should be incubated for 3–4 weeks to detect slow-growing, fastidious organisms, such as *Brucella* or the HACEK organisms (*Haemophilus aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*), which have a predilection for bacterial endocarditis. A series of three to five blood cultures, obtained at intervals within 24 h from different sites, are recommended when bacterial endocarditis is suspected. A blood smear for malaria becomes part of the initial investigation in patients living in an endemic area, with a history of malaria, or with a history of visiting endemic areas.

Urinalysis and microscopy may show red blood cell casts or granular casts that indicate nephritis. Hemoglobinuria may be due to hemolysis associated with malaria, and hematuria may be seen with leptospirosis. Urine culture should be part of the initial investigation even if the patient has no urinary symptoms suggestive of urinary tract infection. The stool should be tested for the presence of occult blood and cultured for enteric pathogens such as *Salmonella*, *Shigella*, and *Yersinia*.

Bone marrow aspiration for histologic or microbiologic evaluation should not be part of the initial baseline investigation unless there is an indication from the history, physical examination, or blood count and peripheral blood smear. Lumbar puncture for cerebrospinal fluid examination is indicated when the clinical picture suggests central nervous system disease.

A tuberculin test should be done on all patients. A positive test can help in the diagnosis, but a negative test does not rule out tuberculosis. Tests for HIV infection are an important part of the baseline investigation of FUO, particularly when there is a prolonged history of fever and/or chronic ill health, if the patient has recurrent or unusual infections, or in the presence of risk factors for HIV.

Radiologic studies should not be done routinely for every patient with FUO. Chest radiographs should be obtained only if there are signs of pulmonary disease. However, some authorities advocate a chest radiograph as part of the routine screening procedures for the child with FUO. Other radiologic studies, such as computerized tomography (CT), magnetic resonance imaging, isotope bone scans, or gallium scanning, also should not be done routinely, particularly cranial CT, which is the least helpful in the absence of clinical signs. They may be indicated when focal lesions are suspected.

When the initial clinical evaluation and baseline laboratory investigations give no clue to the diagnosis, more detailed investigations are performed, including serologic tests for cytomegalovirus, EBV, viral hepatitis, *Brucella* titers, and *Leishmania* antibodies. Additional tests include antinuclear antibodies, rheumatoid factor, anti-double-stranded DNA antibodies, antistreptolysin O titer, slit-lamp examination of the eyes for the presence of uveitis, abdominal ultrasound, CT scan of the sinuses and mastoids, and an echocardiogram.

Unusual Causes of Fever of Unknown Origin

Pseudo-Fever of Unknown Origin

A significant number of children, initially thought to have FUO, have pseudo-fever (no documented fever or insignificant fever). Common features of pseudo-FUO include mild self-limited illnesses, lack of objective abnormal physical findings, discordance of fever and pulse rate, behavioral problems, parents with misconceptions concerning health and disease or families under stress, and normal ESR and platelets. The physician evaluating children for FUO should pay particular attention to excluding this group of children from those with true FUO.

Children with pseudo-FUO are recognized by the physician after a careful, timely history is obtained, interviewing the parents and sometimes the grandparents. These individuals may be overly concerned about the possibility of a serious disease such as malignancy, or may have had previous experience of a serious or life-threatening illness, or may be from disturbed families. The historical interview allows them to express their concerns about the child's condition. Details about the timing and degree of fever and how the temperature was measured, and the number of days missed from school due to subjective morning complaints, should be obtained. The clinical examination should reveal a healthy child with no significant illness. The physician should then attempt to relieve the parents', grandparents', or child's fears and concerns about illness and reassure them.

Munchausen Syndrome by Proxy

Munchausen syndrome by proxy is a form of child abuse in which a disease is inflicted on the child by one of the parents, usually the mother, or by a child guardian who has psychosocial disturbances. The child can present with several forms of complaint that may be recurrent or changing. One presentation of this syndrome is FUO, in which the parent falsely reports a rise in temperature at home or in the hospital, or immerses the thermometer in hot water or shakes it to obtain a high reading. The diagnosis can be very difficult and requires a high index of suspicion. A timely evaluation of the child in the hospital and documentation of absence of fever, measured by a nurse who should be attending during the period when temperature is checked, particularly at the time when the parent reports fever, as well as observation of the parent–child interaction, may help in establishing the diagnosis. A test that may also be helpful in such cases is concomitant measurement of urinary temperature on a specimen supposedly collected for urinalysis.

Drug Fever

Drug fever is found in 1.5% of children with FUO in reported series and can be caused by many drugs. The diagnosis is established by the disappearance of fever within 48 h or three to five half-lives from discontinuation of the drug and the reappearance of fever within hours when the drug is restarted. Five mechanisms have been described for drug fever. The most common mechanism is a hypersensitivity reaction in which the patient may have

rash, urticaria, or symptoms of serum sickness. This type of reaction can occur with any drug. Altered thermoregulatory mechanisms include those seen with thyroid hormone supplement, which raises body temperature by increasing heat production from the increased metabolic rate, or decreased heat loss due to impaired sweating caused by the anticholinergic activity of atropine, tricyclic antidepressants, and phenothiazines. Fever can occur in relation to administration of drugs that have intrinsic pyrogenic activity (e.g., amphotericin B and bleomycin). Fever also can be caused by the pharmacologic effect of the drug; examples include the febrile reaction seen when antibiotics are given to patients with syphilis or leptospirosis (the Jarisch–Herxheimer reaction) and idiosyncratic reactions such as malignant hyperthermia in susceptible patients when given an inhaled anesthetic such as halothane or isoflurane.

Prognosis

The outlook for children with FUO is better than that for adults. Studies on pediatric patients show that the risk for serious illness in children with FUO is around 40%, compared to approximately 70% in adults. Also, malignancy is less common in children than adults.

Most of the children with FUO have a self-limiting or treatable illness. The fever occasionally disappears during evaluation of the patient in the hospital. Some children continue to have fever without diagnosis. Most of these children appear well on long-term follow-up. One study followed 40 children with FUO and prolonged fever referred for rheumatologic evaluation. Most of them had complete recovery within 24–48 months, while eight had neurologic abnormalities on follow-up. Whether these abnormalities were complications of prolonged fever could not be determined by the study group. This finding raises the possibility of neurologic and possibly other complications of prolonged fever.

The mortality rate from FUO varies between different pediatric studies. In one study, 9 of 54 children with FUO died. In another study, 9% of children with FUO died. Other pediatric series had a much lower mortality from FUO. These figures demonstrate the seriousness of FUO and the need for meticulous evaluation to reach the diagnosis.

66 Healthcare-Associated Infections in Pediatrics

Robert S. Baltimore

Introduction/Definitions

Formerly, infections associated with hospitalization were termed nosocomial infections but in recent years, the term healthcare-associated infections (HAI) has been considered a better term to indicate that the issues extend to physicians offices, home nursing, and any interactions with healthcare facilities. Thus, HAI are infections that patients acquire during the course of interacting with a healthcare setting. HAI are not infrequent complications of serious illnesses. HAI occurring in hospitals are defined as infections not present or incubating at the time of admission that develop during admission or less than one incubation period after discharge. Illness from HAI may be any degree from minor infections to life-threatening ones. In practice, infections with an onset 48 h or more after admission are assumed to be HAI unless the infection is clearly community-acquired and follow-up surveillance 1 or 2 weeks after discharge should be sufficient to detect infections that were not apparent during admission. Severely ill and immunocompromised patients have a greater risk of acquiring HAI, so this problem is greatest in intensive care units (ICUs), transplant centers, and oncology units. Studies have demonstrated that nosocomial infections are frequently associated with preventable risk factors. Adherence to recommended techniques for patient care will benefit all patients but have the greatest effect in units where the sickest patients are cared for.

Certain patients are at increased risk because of the severity and possible immunosuppressive nature of their illness, and their need for invasive monitoring and life-support equipment. Studies of HAI rates in Pediatrics have therefore been largely limited to neonatal intensive care units and critical care units that care for children beyond the neonatal period. The epidemiologic factors which are associated with high susceptibility to nosocomial infection have been studied in infants, children, and adults.

Epidemiology and Rate of Nosocomial Infections in Pediatrics

Rates of nosocomial infections in pediatrics. Several studies have established the expected rates of HAIs in children hospitalized in general care wards and have defined the most common types of HAIs, the organisms responsible, and the risk factors. Rates of HAIs have generally been defined as the number of HAIs divided by the number of patients at risk times 100. The denominator is usually the number of admissions or discharges in the unit studied. This rate is sometimes expressed as a percentage. Risk may also be calculated according to the rate of infection per day of hospitalization. This is usually expressed as number of HAIs or specific types of HAIs such as bloodstream infections (BSI), or infection associated with the presence of certain devices (e.g., urinary catheters, assisted ventilation) per 100, 1,000, or 10,000 patient-days or device-days.

The method of obtaining data to determine the rate of infection may vary from one institution to another. Research surveillance studies use defined methodology that needs to be uniform if multiple institutions combine their data. As shown in ❯ *Table 66.1* there are many resources that can be used to identify nosocomial infections. Clinical ward rounds by a trained surveyor generally yields the most information but other sources may add information not available at the bedside or the patient's chart. ❯ *Table 66.2* lists the relative sensitivity of various sources of data indicating that active surveillance on a continuous basis is the most accurate method and data obtained from either the microbiology laboratory or the pharmacy is considerably less sensitive. Relying on clinicians to report nosocomial infections to a central collection point (passive surveillance) is notoriously inaccurate and greatly underestimates the rate of infection. Total daily hospital bedside surveillance is usually impractical as there is often neither sufficient time nor personnel to carry it out. Therefore, intensive surveillance is often limited to the highest-risk units such as the intensive care

units, oncology units, and surveillance of surgical procedure outcomes.

Each hospital must have a source of information for the criteria of diagnosing nosocomial infections. In the United States, most collaborative studies use the definitions recommended by the Centers for Disease Control and used in the National Healthcare Safety Network (NHSN).

In the United States, it has been estimated that one-third of infections in hospitalized patients are nosocomial. Thus, nosocomial infections occur in two million patients per year, result in four million extra days of hospitalization with costs of 4.5 billion dollars.

One of the earliest reported studies having to do with rates and risk factors for nosocomial infections dealt with children. In the early 1960s, T.E. Roy and associates reported on an extensive survey of hospital infections at the hospital for sick children in Toronto, Ontario, Canada. They found a 6.5% overall rate of hospital-acquired infections. This figure is somewhat higher than the rate of 3.2% reported in a 1970 study from Children's Hospital Medical Center in Boston, in which there were twice as many surgical patients as medical patients. In both studies, the rates were substantially higher on those services that dealt with debilitated patients and certain types of surgical patients. In the Toronto study, the two surgical wards had rates of 10.55% and 24.64%; however, rates were lower than average when surgery was performed on "clean" sites (2.1%).

Clean surgical cases are those in which there is an incision through prepared normal skin and the operative field does not include infected tissue, abscess, or entry into normally unsterile areas such as the bowel, the upper respiratory tract, or the lower female genital tract. *Table 66.3* shows that in surgically related HAI, the type of surgery and the degree to which the surgical field is likely to be contaminated with microorganisms determines the risk of infection.

In the Boston study, higher than average HAI rates were found among debilitated patients (e.g., a rate of 21.4% in patients on the tumor therapy ward,) and surgical patients (neurosurgery patients, 18.5%), but they were lower than average on services whose patients enjoyed good general health and had short hospital stays such as dental, ophthalmology, and otolaryngology patients.

More recent studies by The Pediatric Prevention Network Study in the United States (Stover et al.) looked at HAI rates in 43 Children's hospitals. In 1998, the nosocomial infection rate was 8.9 nosocomial infections per 1,000 patient days in newborn ICUs (NICUs) and 13.9 nosocomial infections per 1,000 patient days in pediatric ICUs (PICUs). In that study in the NICU, the device-associated rates were reported by device-days by birthweight ($>$2,500, 1,501–2,500, 1,001–1,500, and $\leq$1,000 g), bloodstream infections 4.4, 4.7, 8.9 and 12.6 per 1,000 device-days, and ventilator-associated pneumonia 0.9, 1.1, 4.9 and 3.5 per 1,000 device-days, respectively. In the PICU, the median nosocomial infection rates were 6.5 for BSI, 3.7 for ventilator-associated pneumonia, and 5.4 for urinary tract infection all per 1,000 device-days.

In a report from the Centers for Disease Control and Prevention in the United States, the overall rate of nosocomial infections in all services was 3.37% in 1978 and on pediatric services, it was 1.2%. The sites of infection were more commonly the gastrointestinal (GI) tract and the respiratory tract in children than in adults. A study published in 1984 from the Children's Hospital of Buffalo was one of the very few to examine the rate of nosocomial infections in various units within a children's hospital.

Table 66.3
Surgical wound classification

Type of wound	Definition	Estimated rate of infection
Clean	Elective surgery with primary closure and no drains: No breaks in sterile technique nor entry into non-sterile organs	<5%
Clean-contaminated	The alimentary or respiratory tract is entered without significant spillage or mechanical drainage	~10%
Contaminated	Fresh trauma or operations with a major break in sterile technique, gross spillage from the GI, infected biliary, urinary tract, etc.	~20%
Dirty wound	Presence of organisms in ordinarily sterile tissue before the operation – "Clean" incision into a collection of pus – Traumatic wounds with devitalized tissue – Fecal contamination – Delayed surgical treatment of dirty contaminated wounds	~30% or greater

The rate of nosocomial infections was 4.1 nosocomial infections per 100 patients discharged. The rate in the intensive care nursery unit was 22.2 infections per 100 discharges and the rate in the pediatric intensive care unit was 11.0 infections per 100 discharges.

The most common sites of nosocomial infection in pediatric patients are bloodstream infections followed by surgical site infections, lower respiratory tract and urinary tract infections. In adults, the most common sites are urinary tract infections followed by surgical site infections, lower respiratory tract and bloodstream infections. For pediatric patients outside of the neonatal period, the most common organism causing nosocomial infections is *Staphylococcus aureus*, followed by *Escherichia coli*, coagulase negative staphylococci, and *Klebsiella* species. Nosocomial infections in neonates are most commonly caused by coagulase negative *staphylococci*, followed by *Staphylococcus aureus*, *E. coli*, group *B Streptococcus* and *Klebsiella* species.

Neonatal intensive care unit rates. The pediatric population in which HAI have been studied most extensively is the patients in the neonatal ICU (NICU). In an early report, Hemming and associates demonstrated a high rate of nosocomial infections (24.6%) at the University of Utah Medical Center, neonatal regional ICU for infants hospitalized for greater than 48 h. By comparison, the nosocomial infection rate for the entire hospital was 7.3%. It was 5.4% for the general pediatric ward and 0.6% for the well-baby nursery. In another study of nosocomial infection in a neonatal ICU from Boston, it was hypothesized that proper staffing, adequate working space around incubators, control of traffic flow, and the presence of convenient scrub areas would decrease the rate of nosocomial infections. This was confirmed in a prospective study when a new nursery was built with improvements in all of these areas. The nosocomial infection rate for serious infections fell from 5.2% to 0.9%. The rates in this study were lower than in others because the unit transferred out newborns who required surgery. In the Pediatric Prevention Network study, the overall nosocomial infection rate was 8.9 per 1,000 patient-days, the bloodstream infection rate in the NICU was a median of 8.6 per 1,000 central venous catheter-days, and the ventilator-associated pneumonia rate was a mean of 2.5 per 1,000 ventilator-days. For all categories, the infection rates were inversely proportional to the birthweight. In a more recent study by the Centers for Disease control, the rate for HAIs for NICUs was 16.2–17.6 per 100 patients or 5.2–5.9 cases per 1,000 patient-days.

Pediatric and adult intensive care units. In an early study of patients in an adult surgical ICU by Northey and associates reported a nosocomial infection rate of 23.4% in 1974. Upper respiratory and urinary tract infections were the most common. If one takes into consideration the published nosocomial infection rates in pediatric patients with the underlying predisposing illnesses, the rate is similar to patients in a pediatric ICU and the data for neonatal and adult ICUs; 15–20% is a good approximation of the expected rate in a pediatric ICU. In the Pediatric Prevention Network study, the overall PICU HAI rate was a median of 13.9 per 1,000 patient-days; the bloodstream infection rate was 8.5 per 1,000 central venous catheter days, and the ventilator-associated pneumonia rate was 3.7 per 1,000 ventilator-days. In the later CDC study, HAI rate was 12.2–14.9 per 100 patients, or 5.8–19.0 per 1,000 patient-days.

Risk of Nosocomial Infections

General Risk Factors

Prior colonization with healthcare-acquired microorganisms. Several classic studies have addressed the question of the risk factors associated with the development of HAI. Most of the earlier studies were in adult populations. Studies from the Denver Veterans Administration Hospital by Selden and associates attempted to quantify the factors associated with risk of infection from a strain of *Klebsiella pneumoniae*, which was the cause of a large cluster of nosocomial infections, primarily in ICU patients, and was resistant to multiple antibiotics. They found that asymptomatic gastrointestinal colonization frequently preceded manifest infection. In a prevalence study, it was shown that 18% of those who were GI carriers of the *Klebsiella* strain had an infection due to the organism during their admission, while only 3% of those who were not colonized were infected. In a separate prospective longitudinal study, those who became carriers of *Klebsiella* during hospitalization, but were culture-negative on admission, had a 48% incidence of nosocomial *Klebsiella* infection. Length of hospitalization was another major factor. The rate of colonization rose steeply after 3 days of hospitalization to a maximum prevalence of 66% for those who were hospitalized for longer than 30 days. The therapeutic interventions associated with acquisition of *Klebsiella* in the gastrointestinal tract were inhalation therapy, nasogastric suction, and antibiotic therapy. These factors probably account for the high rates of HAI in patients who have been in an ICU. These findings were validated in subsequent studies.

Colonization of the upper respiratory tract with hospital-acquired flora is also associated with the development of nosocomial infections. The prevalence of pharyngeal colonization with gram-negative bacilli was studied in Texas by Johanson and associates. Colonization rate was proportional to the estimated degree of illness: it was low (2%) in physiologically normal inpatients and nonhospitalized normal subjects; moderately ill patients had a 16% rate of colonization, and moribund patients had a rate of 57%. It was assumed that the sicker patients had defective clearance mechanisms and that they also had more contact with contaminated materials. Patients receiving antibiotics also had a higher prevalence of gram-negative bacilli in the pharynx. This is attributed to the suppression of normal flora by antibiotics, allowing new organisms to colonize mucosal surfaces. Although pharyngeal colonization does not mean that there is active infection, it frequently precedes invasion, especially in patients who aspirate or already have other respiratory infections.

Catheters. The use of intravascular catheters and intravenous (IV) infusions are frequently implicated in the development of HAI. Septicemia rates associated with IV cannulae have varied in studies from 0% to 8%. The care of the infusion set and the cannulation site are important variables. The degree of risk is related to the method of insertion, type of catheter, type of infusion, and, to a very large extent, duration of catheter placement. There have been extensive studies of colonization of the catheter insertion site in the skin but it is related only indirectly to the development of sepsis. Bloodstream invasion, local skin infection, thrombophlebitis, and a particularly virulent form of septic thrombophlebitis are associated with IV catheters in the critically ill. Numerous studies of risk factors for nosocomial infections in sick neonates have shown that catheters are a major risk factor for nosocomial bloodstream infections, possibly the most important single factor.

The factors predisposing to nosocomial urinary tract infection are related to instrumentation (including surgery) and indwelling urethral catheters. Rates are higher among females, the elderly, and the critically ill. Breaks in the closed system or improper care of the drainage bag predispose to bacteruria. To reduce the rate of nosocomial urinary tract infections, it is important to preserve a closed system, and to reduce the length of catheterization or the number of catheterizations as much as possible.

Exposure to antibiotics. Prior use of broad spectrum antibiotics appears to be an important risk factor for the development of nosocomial infections. Some recent studies have focused on the particular importance of the expanded-spectrum cephalosporins and have shown that prior exposure to these antibiotics is a risk for colonization with antibiotic-resistant nosocomial bacterial flora. Susceptibility to colonization with nosocomial flora increases the risk of HAI and is the main reason of controlling the rate of HAI by reducing unnecessary use of antibiotics.

The indigenous microbial flora present on the skin and mucus membranes play an important function in protecting from invasion by pathogens and may therefore be considered part of host defenses. Established colonization with numerous organisms of low virulence limits dominance of any one species, and minimizes acquisition of exogenous pathogenic organisms. The mechanisms by which indigenous flora afford protection include competition for the host nutrient sources (bacterial interference), and blocking of cell-surface receptors or mucus blanket adhesions by other bacteria (colonization resistance). Both normal flora as well as pathogens appear to attach

to human tissue by very specific binding between specialized surface elements of the microorganisms (pili, and other specific proteins and carbohydrates) and molecules on the skin and mucosal surfaces. There is some evidence that if normal flora microorganisms, principally nonpathogenic bacteria and fungi, are abundant, there are very few molecules on host surfaces for pathogens to attach to. However, the more numerous and well-established normal flora can be partially or totally eradicated by the use of antibiotics. Should normal flora be lacking, new flora will more easily attach to the exposed receptor molecules on these surfaces. If these new flora have pathogenic potential, such as the ability to invade, generate toxins, or resist antibiotics they may proliferate more quickly than the normal flora can regenerate. This is felt to be the major mechanism for the spread of antibiotic-resistant flora in the hospital because so many patients have a disturbance of their usual normal flora.

Specific Environmental Risk Factors

A number of general principles of risk for nosocomial infections have been discussed above. In addition, there have been large numbers of reports of increased risk of nosocomial infections associated with environmental contamination and the use of devices discussed below. In many cases, problems with these devices have been reduced through recognition of their potential to cause HAI.

Inhalation equipment. While it has been recognized for a long time that the use of inhalation equipment was associated with risk of nosocomial respiratory infection, the mechanism was unknown until the equipment itself was studied. Pierce and Associates reported on the relationship between contamination of reservoir nebulizers and the occurrence of nosocomial necrotizing pneumonia. Aerosols from this type of equipment may contain large numbers of gram-negative bacilli, which are blown from the contaminated reservoir fluid into the patient's respiratory tract. Decontamination of this equipment virtually eliminated nosocomial gram-negative necrotizing pneumonias. Outbreaks of gram-negative pneumonia have been reported to be due to contaminated nebulized medication. The use of room humidifiers in the hospital has also been linked to the aerosolization of bacteria and colonization of exposed patients.

Intravenous solutions and catheters. Infections associated with infected intravenous infusion sites and contaminated IV solutions have become a major source of concern for infection control physicians. All patients who require intravascular fluid therapy are at risk for infection from contaminated IV solutions, medication, and tubing. A tragic example of this risk was a large multistate outbreak of infection due to *Erwinia* and *Enterobacter* in the 1970s from a defect in the manufacturing of the infusion bottles, which was subsequently corrected. Many hospitals reported unexpected episodes of sepsis due to these species with rates of infection and death that were related to the seriousness of the underlying diseases of these patients, although occasionally otherwise healthy patients were infected. Held and Associates recently reported two cases of life-threatening sepsis due to *Burkholderia cepacia* in children with hemophilia. Both had indwelling central venous catheters that were flushed with a heparin-vancomycin solution. This solution was prepared by an out-of-state pharmacy and investigation traced the source of the bacteria to the flush solution. In the past decade, there have been numerous reports of solutions contaminated with this particular species.

Viral Infections

In pediatric practice, there is a great risk of nosocomial infection from viruses. Spread of viruses does not appear to be as clearly related to contaminated equipment, antibiotic use, or inanimate reservoirs as is found in bacterial infection. Viral infections are introduced by infected patients, healthcare workers, or parents, and then spread to patients via infected secretions or direct person-to-person spread. Almost any virus that is spread by respiratory or gastrointestinal tract secretions or excreta can cause HAI if routine care techniques are not enforced or if a particularly infectious virus disease goes undetected. Strict observance of special transmission-based precautions (Droplet, contact or both, see *Table 66.4*) plus respiratory etiquette (*Table 66.5*) are important in limiting spread in healthcare setting. Surveillance studies have indicated certain viruses discussed below to be of special concern for nosocomial infections in pediatrics.

Respiratory syncytial virus has been shown in several studies by Hall and colleagues to be a significant nosocomial pathogen in pediatric hospital units. Infection due to respiratory syncytial virus can cause significant disease in any infant and could be responsible for life-threatening decompensation in infants who are already in an unstable state. Infants with congenital cardiac disease and those with pulmonary disease such as bronchopulmonary dysplasia are at especial risk. Studies have shown that transmission by close contact is responsible for dissemination to noninfected individuals; aerosols traveling a

Table 66.4
Transmission-based precautions

Precaution category	Components	Typical organisms
Contact precautions	• Private room • Requires putting on gown and gloves before room entry • Remove gown and gloves before the leaving room • Perform hand hygiene immediately after removal of gown and gloves before touching anything • Dedicated equipment • Essential movement/transport only	• Vancomycin-resistant enterococcus (colonization or infection) • Methicillin-resistant staphylococcus (colonization or infection) • Resistant gram-negative rods • Clostridium difficile colitis • Zoster in a normal host • Respiratory syncytial virus • Parainfluenza virus • Rotavirus
Droplet precautions	• Private room • Masks if within 3 ft of patient • Essential movement/transport only • Mask on patient during transport	• Influenza • Invasive meningococcal disease • Pertussis • Mycoplasma pneumoniae
Airborne precautions	• Private room – door closed • Negative-pressure room • Masks – N95 or HEPA • Essential movement/transport only • N95 mask during transport	• Suspected or confirmed Tuberculosis • Varicella/chickenpox[a] • Disseminated zoster[a] • Zoster in an immunocompromised host[a] • Measles

[a]Requires contact precautions as well

Table 66.5
Components of universal respiratory etiquette (also known as respiratory hygiene/cough etiquette)

• Applies to all patients, persons accompanying patients, visitors

• Source control measures
  • Cover the mouth/nose when coughing
  • Give the patient a surgical mask to wear
  • Use tissues if surgical mask is not available to contain secretions

• Hand hygiene after contact with respiratory secretions
• Spatial separation of person with respiratory infections in common waiting areas

considerable distance are not a major factor. Appropriate handwashing as well as limiting of number of contacts should be emphasized as the major means of infection control. The use of masks and goggles has been shown to further reduce dissemination of respiratory syncytial virus but is not ordinarily employed due to expense, interference with care activities, and marginal effect.

Varicella (chickenpox) is often transmitted in pediatric hospitals via aerosol dissemination. This viral infection is a particular threat to immunocompromised patients who can develop a progressive fulminant form of the disease, which has a high mortality. Immunosuppressed patients who lack antibody to varicella virus must be separated from any patients with chickenpox to prevent exposure to aerosols of their respiratory secretions. Therefore, patients with varicella, those suspected of having varicella or nonimmune patients exposed to varicella 8–21 days after exposure (the shortest and longest possible incubation periods) must be isolated in negative-pressure rooms that do not exhaust back into the hospital. Screening hospital personnel for antibody to varicella virus can pinpoint those individuals who could become infected and, therefore, transmit chickenpox to patients at risk. With varicella vaccine now available, the safest policy for hospital personnel is either to vaccinate all individuals who lack a history of having had chicken pox or who are determined by testing to lack a protective level of antibodies to the virus.

Influenza. Ordinarily, influenza is spread by droplets and the major precaution in addition to standard precautions is wearing a simple surgical-type mask. In recent years, there has occasionally been a requirement for additional precautions including gown, and gloves as well as negative-pressure rooms because of fear of spread of particularly virulent infection. The pandemics of Severe Acute Respiratory Syndrome (SARS caused by coronavirus) and

H1N1 influenza outbreaks demonstrated such a tendency for spread that, in many locales, simple droplet precautions were deemed insufficient.

Diarrheal disease due to viruses has long been noted to cause considerable morbidity in children's hospitals but only in the past few years have these viruses been identifiable. Rotavirus, the most common viral diarrheal agent, has been extensively studied in children and an enzyme-linked immunoassay (ELISA) is available for rapid and specific identification of the agent in stool. In neonates and young infants, this assay is not helpful as it is often positive in asymptomatic patients. In addition, other viruses such as norovirus (formerly Norwalk agent), astrovirus, minirotavirus, and calicivirus have been identified in infantile gastroenteritis. Methods for identification of some of these viruses may not be available except in specialized centers.

Prevention and Control of Nosocomial Infections

Physicians should be familiar with current recommendations concerning the control of the factors most frequently associated with transmission of HAI. Discussion of all of these measures is beyond this chapter and the reader is referred to contemporary texts for a fuller discussion. The Centers for Disease Control and Prevention is actively involved in prevention of HAI and keeps the medical community informed about risk factors and control through the journal *Morbidity and Mortality Weekly Report* and their Web site at www.cdc.gov.

General measures. Routine culturing of the environment, preparation of equipment, isolation techniques, and disinfection should be under the control of the surveillance and control team. The guidelines for these operations will not be dealt with here. Physicians need to be familiar with the appropriate precautions necessary to prevent spread of infection from patients to hospital staff, visitors, and other patients. Recommendations are usually modified for the needs of a specific hospital and incorporated in an infection control manual, which may be in the form of a printed text or available through the institution's computer workstation. The recommendations may allow significant individualization for a particular patient's age, mental status, underlying disease, local epidemiology, and hospital resources.

Standard precautions (Table 66.6). Standard precautions combine the major features of previously recommended Universal Precautions and Body Substance Isolation (Table 66.6). They are based on the principle that all blood, body fluids, secretions, excretions (except sweat), nonintact skin, and mucous membranes may contain transmissible infectious agents. Standard precautions apply to all patients, regardless of suspected or confirmed infection status, in any setting in which healthcare is delivered. The components include hand hygiene (Table 66.7); use of gloves, gown, mask, eye protection, or face shield, depending on the anticipated exposure; and safe injection practices. Equipment or items in the patient environment likely to have been contaminated with infectious body fluids must be handled in a manner to prevent transmission of infectious agents. For some interactions (e.g., performing venipuncture), only gloves may be needed; during other interactions (e.g., intubation), use of gloves, gown, and face shield or mask and goggles is necessary.

Universal Respiratory Etiquette

Universal respiratory hygiene/cough etiquette has been added to the other elements of standard precautions. These elements were initially deemed necessary during the SARS-Coronavirus activity in emergency departments and other outpatient areas during the widespread SARS outbreaks in 2003. The strategy proposed has been termed respiratory hygiene/cough etiquette (Table 66.5). The strategy is targeted at patients and accompanying family members and friends with undiagnosed transmissible respiratory infections, and applies to any person with signs of illness including cough, congestion, rhinorrhea, or increased production of respiratory secretions when entering a healthcare facility such as an emergency department, outpatient clinic, or any waiting area.

The elements of respiratory hygiene/cough etiquette include (1) education of healthcare facility staff, patients, and visitors; (2) posted signs, in language(s) appropriate to the population served, with instructions to patients and accompanying family members or friends; (3) source control measures (e.g., covering the mouth/nose with a tissue when coughing and prompt disposal of used tissues, using surgical masks on the coughing person when tolerated and appropriate); (4) hand hygiene after contact with respiratory secretions; (5) spatial separation, ideally >3 ft, of persons with respiratory infections in common waiting areas when possible; and (6) covering sneezes and coughs and placing masks on coughing patients.

Special Precautions

Special precautions are care elements required to prevent transmission of infections and are employed in addition to standard precautions. Decisions about which precautions are

Table 66.6

Recommendations for application of standard precautions for the care of all patients in all healthcare settings applies to all body fluids except sweat[a]

Component	Recommendations[b]
Hand hygiene	After touching blood, body fluids, secretions, excretions, contaminated items; immediately after removing gloves; between patient contacts
Personal protective equipment (PPE)	
Gloves	For touching blood, body fluids, secretions, excretions, contaminated items; for touching mucous membranes and nonintact skin
Gown	During procedures and patient-care activities when contact of clothing/exposed skin with blood/body fluids, secretions, and excretions is anticipated
Mask, eye protection (goggles), face shield	During procedures and patient-care activities likely to generate splashes or sprays of blood, body fluids, secretions, especially suctioning, endotracheal intubation
Soiled patient-care equipment	Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; perform hand hygiene
Environmental control	Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient-care areas
Textiles and laundry	Handle in a manner that prevents transfer of microorganisms to others and to the environment
Needles and other sharps	Do not recap, bend, break, or hand-manipulate used needles; if recapping is required, use a one-handed scoop technique only; use safety features when available; place used sharps in puncture-resistant container
Patient resuscitation	Use mouthpiece, resuscitation bag, other ventilation devices to prevent contact with mouth and oral secretions

[a]Table adapted from http://www.cdc.gov/hicpac/pdf/isolation/Isolation2007.pdf (Accessed July 28, 2010)
[b]Subsequent updates include wearing surgical masks for performing lumbar punctures for diagnosis or for injections and for application of universal respiratory etuquette

to be employed in specific situation require categorization of diseases by how they are transmitted. The term *transmission-based precautions* is used to indicate that infectious diseases are categorized by whether they are spread by droplets, aerosols, or direct contact. The appropriate special precautions for hospitalized patients are determined by the mode of transmission of each suspected or proven infection.

Hand hygiene (Table 66.7). The term "hand hygiene" has replaced "handwashing" to emphasize the importance of alcohol gel hand rubs that can be used in place of soap and running water for most situations calling for cleansing of the hands in routine medical practice. Infection control experts consider hand hygiene to be the single most effective and certainly least expensive practice to prevent transmission of pathogens and prevention of HAI. Nevertheless, one recent review documents that even this simple directive has been insufficiently adhered to by medical personnel. In a review of 12 published studies, compliance with recommended hand hygiene was under 50% even in intensive care units. Proper handwashing methodology is summarized in Table 66.7. For handwashing, other than presurgical scrubs, hands should be vigorously lathered and rubbed together for at least 15 s with soap and warm running water. Hands should be rinsed and dried with a paper towel and the towel used to turn off the faucet. Gloves should be worn when touching blood or other body fluids and mucous membranes, to reduce the likelihood of transmitting organisms to patients during invasive procedures, and to prevent transmission of pathogens from an infected patient to another patient. Wearing gloves does not replace the need for handwashing. Adherence to handwashing recommendations is important as contamination of skin due to punctures or defects in a glove is possible. With the widespread use of alcohol-based hand rubs, there is evidence of improvement in hand hygiene compliance among healthcare personnel at many healthcare centers.

Intravenous Therapy

Intravenous devices are associated with a large proportion of HAI. Proper insertion and use of these devices is

Table 66.7
Hand hygiene

When	Before and after every patient contact
	Before and after putting on gloves (sterile or non-sterile)
	Before doing invasive procedures
	After use of bathroom facilities
	Between contaminated body sites
	Before eating or drinking
	After contact with laboratory specimens
	Whenever hands are contaminated
With what	*Soap and water hand hygiene* • Turn on faucet • Apply soap to all surfaces of hands • Rub hands together for 15 s • Make sure to cover thumbs, areas in between fingers, under nails • Rinse thoroughly • Pat dry with clean paper or cloth towel instead of rubbing • Use towel to turn off faucet

	Alcohol-based hand rub hygiene[a]
	• Push dispenser once
	• Coat all surfaces of your hands including
	  • Between fingers
	  • Under fingernails
	  • Back of hands and wrists
	• Rub hands together briskly, until dry
	• No rinsing needed

[a]Soap and water hand hygiene should be employed when hands are grossly contaminated or visibly dirty or when in contact with patients colonized or infected with Clostridium difficile or items contaminated by such patients. Alcohol-based hand rubs are not effective when there is visible dirt on the hands and are not optimally effective in decontamination of spores.

recommended as a method of reducing risk of infection. Because central catheters remain in place for an extended period of time, they have been especially concerning as a source of nosocomial bloodstream infections (central line–associated bloodstream infection – CLABSI). In the United States, it has been estimated that there are 9.7 million central catheter-days in ICUs (54% of ICU days). There have been an estimated 48,600 patients in the ICUs who have a CLABSI (5 BSI/1,000 catheter days) and of major concern, there have been 17,000 deaths attributable to CLABSIs in the ICU. Although the catheter utilization rate is lower outside of the ICU setting, as many or more CLABSIs occur outside the ICU setting.

Certain factors have been shown to increase the risk of catheter-related infections. In adults, the duration of catheterization is >3–4 days adds additional risk of infection but in children duration has not been demonstrated to be associated with extra risk. Other factors increasing risk of infection are increased diameter and number of ports on catheter, location (risk greater for femoral, less for internal jugular, and less for subclavian), and type of catheter (tunneled catheters have a lower risk than non-tunneled catheters). Antimicrobial/Antiseptic coated catheters may have a lower risk than non-coated catheters. Additional risk factors include thrombosis at the site of a central catheter, infusion with TPN or other lipid-rich infusate, and impaired skin integrity such as with burns, and dermatitis.

Recently recommendations for intravenous therapy have been revised and expanded. While it is beyond the scope of this chapter to discuss the use of each type of intravascular device available, among the recommendations for prevention of IV catheter-associated infections are the following general suggestions from the Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America guidelines. Additional recommendations can be found in the referenced articles and detailed information regarding diagnosis and management of intravascular catheter-related infections are contained in a practice guideline of the Infectious Diseases Society of America.

- Intravenous cannulae should be inserted only when clearly indicated. In general, "keep open" intravenous infusion should be discouraged if it is for the convenience of the medical staff. Remove any device as soon as its use is no longer indicated.
- Educate healthcare workers regarding the indications for intravascular catheter use, proper procedures for the insertion and maintenance of intravascular catheters, and appropriate infection control measures to prevent intravascular catheter-related infections.
- Use a catheter checklist to ensure adherence to infection prevention practices at the time of central catheter insertion and for dressing changes.
- Assess knowledge of and adherence to guidelines periodically for all persons who insert and manage intravascular catheters.
- Monitor the catheter sites visually or by palpation through the intact dressing on a regular basis, depending on the clinical situation of individual patients. If patients have tenderness at the insertion site, fever without obvious source, or other manifestations suggesting local or BSI, the dressing should be removed to allow thorough examination of the site.
- Record the operator, date, and time of catheter insertion and removal, and dressing changes on a standardized form.

- Observe proper hand hygiene procedures either by washing hands with conventional antiseptic-containing soap and water or with waterless alcohol-based gels or foams. Observe hand hygiene before and after palpating catheter insertion sites, as well as before and after inserting, replacing, accessing, repairing, or dressing an intravascular catheter. Palpation of the insertion site should not be performed after the application of antiseptic, unless aseptic technique is maintained.
- Maintain aseptic technique for the insertion and care of intravascular catheters.
- Wear clean or sterile gloves when inserting an intravascular catheter as required by the Occupational Safety and Health Administration Bloodborne Pathogens Standard.
- Sterile gloves should be worn for the insertion of arterial and central catheters.
- Wear clean or sterile gloves when changing the dressing on intravascular catheters.

Catheter Site Care

- Disinfect clean skin with an appropriate antiseptic before catheter insertion and during dressing changes. Although a 2% chlorhexidine-based preparation is preferred, tincture of iodine, an iodophor, or 70% alcohol can be used.
- No recommendation can be made for the use of chlorhexidine in infants aged <2 months.
- Do not submerge the catheter under water. Showering should be permitted if precautions can be taken to reduce the likelihood of introducing organisms into the catheter (e.g., if the catheter and connecting device are protected with an impermeable cover during the shower).
- Use aseptic technique including the use of a cap, mask, sterile gown, sterile gloves, and a large sterile sheet for the insertion of central catheters or for guidewire exchange.
- Do not routinely replace CVCs, PICCs, hemodialysis catheters, or pulmonary artery catheters to prevent catheter-related infections.
- Do not use guidewire exchanges routinely for non-tunneled catheters to prevent infection.
- For catheter-site dressing changes, use either sterile gauze or sterile, transparent, semipermeable dressing to cover the catheter site.
- Replace catheter-site dressing if the dressing becomes damp, loosened, or visibly soiled.
- Change dressings at least weekly for adult and adolescent patients depending on the circumstances of the individual patient.
- Do not use topical antibiotic ointment or creams on insertion sites (except when using dialysis catheters) because of their potential to promote fungal infections and antimicrobial resistance.

Recommendations for Umbilical Catheters

1. Remove and do not replace umbilical artery catheters if any signs of CLABSI, vascular insufficiency, or thrombosis are present.
2. Remove and do not replace umbilical venous catheters if any signs of CLABSI or thrombosis are present.
3. Replace umbilical venous catheters only if the catheter malfunctions.
   (a) Cleanse the umbilical insertion site with an antiseptic before catheter insertion. Avoid tincture of iodine because of the potential effect on the neonatal thyroid. Other iodine-containing products (e.g., povidone-iodine) can be used.
   (b) Do not use topical antibiotic ointment or creams on umbilical catheter insertion sites because of the potential to promote fungal infections and antimicrobial resistance.
   (c) Add low doses of heparin (0.25–1.0 U/mL) to the fluid infused through umbilical arterial catheters.
4. Remove umbilical catheters as soon as possible when no longer needed or when any sign of vascular insufficiency to the lower extremities is observed. Optimally, umbilical artery catheters should not be left in place >5 days.
5. Umbilical venous catheters should be removed as soon as possible when no longer needed but can be used up to 14 days if managed aseptically.

A milestone in improving the safety of catheter-related bloodstream infections in the ICU was achieved by Pronovost and associates who virtually eliminated central line–related infections by following the above recommendations as a "bundle" in a study of 103 ICUs.

67 Infection Associated with Medical Devices

J. Elaine-Marie Albert · Howard E. Jeffries

Healthcare-associated infections (HAIs) occur worldwide and affect both developed and resource-poor countries. Infections acquired in healthcare settings are major causes of death and morbidity among hospitalized patients. They are a significant burden both for patient and for public health. The World Health Organization conducted a study in 55 hospitals of 14 countries representing four WHO Regions (Europe, Eastern Mediterranean, Southeast Asia, and Western Pacific). This prevalence study found that on average 8.7% of hospital patients had HAIs; data from the United States of America (USA) reveal a similar prevalence. Based on these figures, at any given time, over 1.4 million people worldwide suffer from infectious complications acquired while in the hospital. In December of 2010, the *Lancet* published a review of available scientific data on HAIs in countries with limited resources. In developing countries, the number of HAIs is 15.5 per 100 patients; this is in sharp contrast with the 8–10 per 100 patients reported in the USA and Europe. This review demonstrated for the first time the magnitude of HAIs as a major patient safety problem in the developing world.

The WHO and the Centers for Disease Control (CDC) define a HAI, formerly called a nosocomial infection, as "a localized or systemic condition that results from an adverse reaction to the presence of an infectious agent (s) or its toxin(s)." There must be no evidence that the infection was present or incubating at the time of admission to the acute care setting. Infections acquired in the hospital but appearing after discharge are also considered HAIs. HAIs may be caused by infectious agents from endogenous or exogenous sources. Endogenous sources are body sites, such as the skin, nose, mouth, gastrointestinal tract, or vagina that are normally inhabited by microorganisms. Exogenous sources are those external to the patient, such as patient care personnel, visitors, patient care equipment, medical devices, or the healthcare environment. Medicine has become more complex with new invasive technologies creating potential routes of infection. Further, aggressive and irresponsible use of antibiotics has created a cadre of drug-resistant bacteria. HAIs have become more prevalent. Nowhere is this more notable than in the intensive care unit (ICU). The frequency of infections associated with the use of invasive devices (central vascular lines, ventilators and urinary catheters) is exponentially higher in the ICU. This chapter will explore HAIs acquired due to commonly used medical devices.

Catheter-Associated Bloodstream Infections

Central venous catheters (CVCs) are used extensively worldwide for the delivery of vasoactive and/or high-osmolarity medications, monitoring of intravascular status, and removal of blood for laboratory evaluation. More than five million patients in the USA received central venous access in 2007. As central venous catheters have become more common, so have the many complications that are associated with them. The most common complications are infectious and thrombotic, both of which are associated with increased length of intensive care unit (ICU) and hospital stay, increased medical costs, and increased morbidity and mortality. The most common adverse result of CVC use in the ICU is catheter-associated bloodstream infection (CA-BSI). In the USA, CA-BSIs have been reported to occur in 3–8% of placed CVCs. Mortality from CA-BSIs has been quoted as high as 30%, depending on the severity of the patient's underlying illness. CA-BSIs can be difficult to treat and increase hospital length of stay by an average of 2 weeks. Mermel's study from 2001 estimated that the annual cost of managing CA-BSIs in the USA could be as high as $2.3 billion.

There are two different types of CVCs: those placed percutaneously and those placed surgically. Percutaneous CVCs come in two forms: (1) temporary, CVCs, which are placed centrally into the subclavian, jugular, or femoral veins via direct access of the vein; (2) percutaneously inserted central venous catheters (PICCs), which are entered in a peripheral vein and threaded to a central location.

Tunneled catheters and totally implantable venous access devices represent two different types of surgically

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_67,

implanted CVCs. Totally implantable venous access devices, often called portacaths, are fully enclosed beneath the skin. They are accessed via an infusion port that is connected to a catheter that enters a central vein. This type of access device is frequently used in hematology/oncology patients. There are lower size limits for portacath use; so, typically these are found in school-aged children and up. They have a lower infection risk than tunneled CVCs, as they are completely enclosed by skin when deaccessed. Tunneled catheters are surgically implanted CVCs in which the distal end of the catheter exits the skin. Catheters may contain a Dacron cuff, located just before the exit site, which keeps the CVC from migrating. These devices are used in patients who require very long-term central venous access, i.e., for chemotherapy or hemodialysis. Rates of infection associated with this type of catheter are lower than those for percutaneously placed CVCs.

A myriad of risk factors for CA-BSIs have been defined. Several studies have identified weight under 8 kg, duration of catheter placement, severity of underlying disease, changing the CVC over a guide wire, and obstruction with thrombus as risk factors. Cardiac failure and cancer are two disease processes that carry a high risk for CA-BSI. An increased number of catheter lumens may also increase the risk of infection. In the adult population, the location of the CVC is directly associated with increased risk of infection. The subclavian or jugular is preferred over the femoral vein. The higher levels of skin flora in the femoral region make infection more common in those CVCs in adults. This assertion has not been borne out in pediatric studies.

There is controversy about whether or not catheter material is a risk factor for infection. Catheters are commonly made from one of three materials: polyvinyl chloride (PVC), silicone, or polyurethane. Many companies have stopped producing PVC catheters because of the risk that phthalates or other organic plasticizers might leach out during use. In 2002, the US Food and Drug Association expressed concerns regarding exposure to the PVC plasticizer DEHP (bis(2-ethylhexyl)phthalate). DEHP was widely found in many medical devices such as IV catheters and tubing, blood bags, and extracorporeal support tubing. Animals exposed to DEHP in the laboratory experienced a variety of adverse effects, to include testicular atrophy and liver dysfunction. The FDA recommended that exposure to DEHP be limited in infants and children, particularly in the developing male. Subsequently, given this public health concern, PVC is being utilized with far less frequency than other materials. Silicones are one of the most thoroughly tested and widely used groups of biomaterials; they are well known for their intrinsic biocompatibility and biodurability. They are soft and relatively nonthrombogenic. Polyurethane is being increasingly used for catheters. Compared with silicone catheters of the same French size, polyurethane catheters have a larger internal diameter, allowing increased flow rates. Polyurethane is also biocompatible and nonthrombogenic.

The greatest controversy amongst experts in this area is the duration of use of CVCs. There have been very few studies to adequately address this question. There is consensus that prolonged duration of central venous access is a consistent risk for CA-BSI. What is debated is what length of time "prolonged duration" represents. Many authors feel that, in the setting of proper management, CVCs can be safely left in place for up to 14 days before the risk of infection begins to increase dramatically. Early removal of CVCs has been the focus of several US national CA-BSI prevention strategies. Unfortunately, long-term CVC use is often unavoidable in many critically ill children.

Multiple studies have also demonstrated that total parenteral nutrition (TPN) is also a known risk factor for CA-BSI, as the intralipid component is at high risk for bacterial and fungal contaminations. Further, lack of enteral nutrition is thought to lead to changes in the mucosa of the gastrointestinal tract, leading to bacterial translocation. Early institution of even low volume, trophic feeds reduces the risk of CA-BSI. A recent study from 2010 also lists transfusion of blood products as a risk factor for bloodstream infections. The authors do note that this may be because patients receiving multiple blood product transfusions tend to be sicker and thus have a higher baseline risk for CA-BSI.

For many years, there has been research on the best way to either interrupt or slow down the bacterial colonization on the plastic surface of the CVC. Initial research focused on coating the extraluminal surface of the catheter with the goal of preventing bacteria from adhering. This provided some reduction in the occurrence of CA-BSI; however, newer technologic innovation has resulted in the ability to bind antibiotics to the inner lumen. Intraluminal colonization is also a major source of infection; this is particularly true in patients receiving complex infusion therapies, especially blood products and intralipids. Catheters coated with antimicrobial or antiseptic agents decrease microorganism adhesion and biofilm production. Biofilm provides an ideal surface for microbial adherence; hence, decreasing the formation of biofilm should decrease the risk of catheter-related infection. Commercially available CVCs are typically coated with either chlorhexidine/silver sulfadiazine or

minocycline/rifampin. These catheters release silver, antimicrobials, and/or disinfecting agents in an untargeted way to kill the bacteria in the ambient surroundings of the catheter. In 2010, a major biomedical supply company released a newly developed plastic surface which kills bacteria on contact. This represents a novel and very promising approach to effectively tackle the problem of catheter-associated infection. Both of these types of CVCs are more expensive than traditional CVCs which may limit their use in some institutions. However, given the cost of managing a CA-BSI, the acquisition and use of antibiotic-coated CVCs may prove to be significantly less costly. There are an increasing number of studies that suggest that antimicrobial catheters may provide a decrease in infection in patients with a short-term need for CVCs.

Coagulase-negative staphylococci are the most common microorganisms associated with CA-BSIs. Other microorganisms commonly involved include *Staphylococcus aureus*, *Candida* species, *Enterococci*, and gram-negative bacilli.

Fever is the most frequent clinical and the most sensitive manifestation of a CA-BSI. Hemodynamic instability, respiratory decompensation, and altered mental status may also be manifestation of a CA-BSI. Inflammation and purulence at the insertion site are relatively uncommon but are generally fairly specific indicators of infection. CVC dysfunction (i.e., difficulty flushing or failure to draw) may be an indicator of distal thrombus, which has been shown to be associated with CA-BSI. Suppurative thrombophlebitis, endocarditis, osteomyelitis, and sepsis are all potential complication of a CA-BSI.

Given any of the previously detailed clinical findings, pursuit of laboratory confirmation of infection should be undertaken. The Centers for Disease Control in the USA gives strict criteria for determining a CA-BSI; the World Health Organization criteria are essentially identical. A CA-BSI must meet at least one of the following criteria:

1. Have a recognized pathogen cultured from one or more blood cultures
2. At least one of the following signs or symptoms: fever (>38.8°C), chills, or hypotension and signs and symptoms of bacteremia or sepsis
3. If the patient is an infant of less than 1 year of age, she must have at least one of the following signs or symptoms: fever (>38.8°C, rectal), hypothermia (>37.8°C, rectal), hypotension, apnea, or bradycardia

Common skin flora (i.e., coagulase-negative staphylococci, viridans group streptococci) must be cultured from two or more blood cultures drawn on separate occasions. This means that blood from at least two blood draws was collected within 2 days of each other and both cultures are growing the same common organism. Classifying a CA-BSI requires that the organism that is cultured from the blood cannot be related to an infection at another site. That is to say that a patient who has surgical site infection with *Klebsiella* and subsequently a blood culture that is positive for the same organism does not have a CA-BSI. The CDC recommends that blood cultures be drawn from the CVC and from a peripheral vein prior to initiation of antibiotic therapy. Interestingly, there is little evidence to support obtaining blood cultures from each lumen of multilumen CVC.

Treatment of CA-BSIs has two main components: antimicrobial therapy and catheter management. The former involves the early selection of broad empiric antimicrobials with subsequent narrowing of coverage once organism and sensitivity data are available. The second component involves decision making about whether the catheter should be removed, exchanged, or if it can be salvaged with therapy. As with all HAIs, the authors recommend consultation with the Infectious Diseases Service for assistance with antibiotic selection and duration of therapy.

The initial choices for empiric CA-BSI therapy are determined by suspected causative organism, the patient's underlying risk factors, and severity of illness. As a rule of thumb, empiric therapy should consist of an antimicrobial for treatment of coagulase-negative staphylococci (the most common causative organism) and one for treatment of gram-negative organisms. Vancomycin remains a common choice for coverage of coagulase-negative staphylococci where methicillin resistance is high. Patients who are neutropenic in the setting of their CA-BSI must have empiric antibiotic therapy that covers gram-negative bacilli (particularly Pseudomonas). A beta-lactam (i.e., piperacillin-tazobactam), a carbepenem (i.e., meropenem), or third or fourth generation cephalosporin (i.e., ceftazidime) are all appropriate empiric choices. The risk of infection with a multidrug resistant (MDR) organism must be considered when selecting empiric antibiotic therapy. Heretofore, amphotericin B and fluconazole have been the antifungal agents of choice for the treatment of candidemia. Amphotericin B has a sizeable side-effect profile. Fluconazole does not provide adequate coverage against *Candida glabrata* or *Candida kruzei*, both of which are increasingly common etiologies of fungemia. Azoles (i.e., voriconazole) and echinocandins (i.e., micafungin) are increasingly being used in the pediatric population with good success.

In general, duration of therapy is guided by the patient's clinical course; 10–14 days of therapy is the

current baseline. However, patients with persistent bacteremia (defined as a positive blood culture after >72 h of antibiotic therapy) may require weeks of antibiotics, especially if the CVC cannot be removed or replaced.

In general, the decision to remove a CVC in a pediatric patient is often fraught with difficulty. Our population has a much greater vascular access challenge than does the adult population. The risks and benefits of CVC removal for CA-BSI must be weighed on an individual basis. Many providers prefer to attempt to "treat through the line" instead of empirically removing it, given the greater challenge of vascular access in the pediatric population. However, there are occasions when CVC removal is warranted; the primary of these is fungemia. Treatment of fungemic CA-BSI without removing the CVC is rarely successful and carries a high mortality. Conversely, there are studies that report successful pediatric bacterial CA-BSI management without CVC removal. Very careful monitoring of patient status and the acquisition of blood cultures is required. The CVC should be promptly removed if there is evidence of clinical worsening or persistent positive blood cultures. Antibiotic lock therapy (ALT) may be warranted in patients with tunneled CVCs.

ALT works on the hypothesis that organisms living within the biofilm on the luminal surfaces of a CVC represent a reservoir for infection and are difficult to eradicate with systemic therapy alone. ALT is not sufficient as a sole therapeutic modality; it must be used in conjunction with systemic antibiotic treatment. It can be particularly useful in patients with tunneled CVCs and frequent CA-BSIs for whom CVC removal is not an option. ALT has been noted to be quite effective for intraluminal infections due to coagulase-negative staphylococci and gram-negative organisms. ALT has not been found to be effective for extraluminal infections. While there are case and anecdotal reports to the contrary, ALT has also not been a useful adjunct for management of infections due to *S. aureus*, *Pseudomonas aeruginosa*, MDR organisms, or *Candida*.

ALT consists of filling the CVC lumen(s) with a high-concentration antibiotic heparin or a 70% ethanol solution for hours or days at a time. Antibiotic concentrations needed to kill bacteria living within a biofilm are 100–1,000 higher than those needed to kill bacteria floating freely within the bloodstream. The choice of antibiotic lock solution will vary from institution to institution. However, the most common antibiotics are vancomycin, ceftazidime, and clindamycin. The antibiotic lock solution should be instilled into each lumen of the CVC for 8–12 h, once or twice per day. If a catheter has more than one lumen and both cannot be accessed simultaneously, then alternate lumens with each dose of the antibiotic lock solution. Some institutions report the use of 72 h dwell time for high-concentration vancomycin lock in hemodialysis catheters only. ALT should be continued for a minimum of 7–14 days or until resolution of bacteremia and clinical symptoms. The potential risks of fungal superinfection and emergence of antimicrobial resistance secondary to ALT have not been fully elucidated by current studies.

Prevention measures should address those areas of known risk for CVC infection. Type (temporary versus permanent), location, and duration of CVC placement are three risk factors that can be addressed through prevention strategies. Hospitals can also select the material from which a catheter is made with a goal to decrease CA-BSIs. The most important CA-BSI prevention measures are diligent hand hygiene and use of sterile technique with CVC insertion and dressing changes.

Strategies for prevention of CVC infections

Effective	Ineffective
Strict hand hygiene	Antimicrobial creams
Closed system for blood draws and medication administration	Antibiotic or antiseptic impregnated dressings
Limit duration	Changing CVC over a guide wire
Local skin preparation	Routine changing of CVC to different sites
Aseptic technique	Antibiotic prophylaxis
Removal if infection suspected	
Limiting entry to central lines	
Surgical asepsis for insertion	
Established frequency of dressing change	
Antibiotic-coated catheter for short-term use	

CVC insertion should be performed using sterile technique. This includes hand hygiene, sterile equipment setup, sterile gloves, long-sleeved surgical gown, a surgical cap and mask, and a full barrier sterile drape. All persons in the room should have on a surgical cap and mask, to include the patient if she is not intubated or on positive pressure ventilation. Prior to starting the insertion procedure, the site should be cleaned with antiseptic solution (i.e., chlorhexidine gluconate or povidone-iodine). Sterile technique should be maintained throughout CVC placement. The CVC insertion site should be dressed with a semiocclusive

sterile dressing. The use of antiseptic impregnated dressings remains controversial and has not shown a clear impact on reduction of BSIs.

An equally important part of the prevention process is CVC maintenance, both of the line and the insertion site. Well-recognized sources for CA-BSI are needleless connectors, catheter hubs, and injection ports that have become contaminated during patient care. Attempting to limit the number of times the CVC is accessed represents one way to address this problem. Another is to decrease contamination risk by vigorously cleaning access ports with an appropriate antiseptic, as well as accessing the port only with sterile equipment. The most common antiseptics used are chlorhexidine gluconate (CHG) and 70% isopropyl alcohol. The exact duration of cleaning remains up for debate; times found in the literature vary from 15 to 60 s, not counting the drying time. "Scrub the hub" campaigns have been used in many medical centers to educate bedside providers about methods to reduce the risk of infection. Daily CHG bathing has been shown to decrease colonization with MRSA and VRE; it is also thought to decrease the risk of CA-BSI.

Consistent, daily review of the need for continued central venous access is associated with a reduction in CA-BSI rates. This practice reminds providers to remove CVCs that are not longer necessary and posing a preventable infection risk.

In 2006, Pronovost et al. reported that the use of insertion and maintenance bundles for CVCs was directly associated with decreased infection rates. His group implemented bundles in 103 adult ICUs in the USA and found a reduction in CA-BSIs by up to 66% in some centers. These bundles were comprised of features that were known to reduce infection. These include use of sterile technique and a full field barrier during CVC placement, adherence to strict hand hygiene policies, limiting the number of times the CVC is accessed, and strict observance of the CDC line maintenance policy. Care bundles are a group of processes that have been created to ensure the delivery of quality health care. They represent a group of medical interventions that, when used conjunctively, improve clinical outcomes. Bundles can provide a link between evidence and its application at the bedside. A well-designed bundle also includes a metric for measuring the processes. An evaluation of CA-BSI reduction via the use of insertion and maintenance care bundles in PICUs was done by Jeffries et al. in 2009. This observational study of 26 freestanding children's hospitals found that implementation of care bundles, staff empowerment to implement best practices, and improved communication between members of the care team led to a significant decrease in BSIs.

Central venous catheter insertion and maintenance bundles (used with permission from Jeffries et al.)

Category	Insertion	Maintenance
Hand hygiene	Hand hygiene consistent with local guidelines and/or policies	Hand hygiene consistent with local guidelines and/or policies
Dressings	Apply transparent semipermeable dressing (use gauze only with bleeding and/or oozing)	Replace dressing if it becomes damp, loosened, or visibly soiled; apply transparent semipermeable dressing (use gauze only with bleeding and/or oozing)
Sterile barrier	Maximum sterile barrier (large sterile drape, sterile gloves, sterile gown, cap, and mask)	Aseptic gloves and sterile dressing
Sterile technique	Maintain sterile technique throughout	Use aseptic technique throughout
Skin preparation	Prepare skin with antiseptic/detergent CHG 2% except for patients with a contraindication	Prepare skin with antiseptic/detergent CHG 2% except for patients with a contraindication

Summary recommendations for the prevention of CVC infection:

1. Hand hygiene with every CVC contact.
2. Sterile technique during catheter insertion and care.
3. Disinfection of access ports with CHG or 70% alcohol before accessing. CHG requires longer scrub and dry times (30 s each) than does alcohol.
4. Remove any intravascular catheter that is no longer essential.
5. Healthcare worker education and training regarding the severity of CA-BSIs, proper CVC insertion and maintenance techniques, and prevention procedures.

Ventilator-Associated Pneumonia

Hospital-acquired pneumonia (HAP) is defined as pneumonia that occurs 48 h or more after admission and was

not developing at the time of admission. Ventilator-associated pneumonia (VAP) is a type of HAP that appears greater than 48 h after endotracheal intubation. Healthcare-associated pneumonia (HCAP) is defined as pneumonia that occurs in a nonhospitalized patient with extensive healthcare contact. It will not be discussed in this chapter. VAPs are the second most common HAI. Many physicians use the terms HAP and VAP interchangeably, as the vast majority of HAPs are VAPs. The most significant risk factor for HAP is mechanical ventilation. Intubation increases the risk of pneumonia 6- to 21-fold. VAP occurs in about 5% of mechanically ventilated patients and carries a 20% mortality rate.

Significant risk factors for developing VAP include:

- Chronic lung disease
- Reintubation and/or prolonged intubation
- Altered mental status or coma
- Neuromuscular blockade
- Immunodeficiencies
- Genetic syndromes, particularly those with associated neuromuscular weakness
- History of aspiration
- Cardiothoracic surgery
- H_2 blocker or proton pump inhibitor (PPI) therapy
- Transport out of the PICU
- Previous antibiotic exposure
- Hospitalization during the fall or winter season
- Mechanical ventilation for acute respiratory distress syndrome
- Frequent ventilator circuit changes

Tracheal intubation bypasses the protective mechanisms of the upper airway and allows bacteria to enter the lower respiratory tract, possibly leading to pneumonia. The pathogenesis of VAP is related to the bacterial load entering the lower respiratory tract and the relative virulence of those microorganisms. Microaspiration of oropharyngeal and gastric secretions is thought to be the primary manner in which the lungs are infected with organisms. Approximately, 45% of healthy adult subjects aspirate during sleep; this number increases in the severely ill. While there is not equivalent data in the pediatric populations, we do know that a reasonable number of healthy children have gastroesophageal reflux (GER) that is severe enough to require pharmacologic therapy. GER is often more severe in chronically ill and/or developmentally disabled children. It follows that these groups may also be at a greater risk of VAP in the setting of respiratory failure and need for mechanical ventilation. The stomach and upper gastrointestinal tract are relatively sterile secondary to the bactericidal activity of acidic gastric secretions. Gastric pH is increased due to severe illness, acid suppressing medications, and enteric feedings. A number of adult studies have demonstrated that gastric ulcer prophylaxis increases the risk of VAP.

Hospitalized patients often become colonized with microorganisms acquired from the hospital environment. There is data to support the assertion that over half of critically ill patients may be colonized with hospital flora within 72 h of admission. Tracheostomy or endotracheal tubes may become contaminated in the process of routine nursing care or via the contaminated hands of medical team members. Poor infection control processes can lead to cross-contamination of organisms between patients.

VAP can be caused by a wide variety of pathogens. Differences in host factors and in the local hospital flora also influence the patterns of pathogens seen. The vast majority of bacteria isolated from VAP patients are gram-negative aerobes, i.e., *Pseudomonas*, *Escherichia coli*, and *Klebsiella pneumoniae*. *S. aureus*, both methicillin resistant and sensitive, and *Streptococcus* species can be the causative agents of VAPs. Immunocompromised patients may develop VAPs secondary to fungi and viruses. A study comparing bronchioalveolar lavage (BAL) and protective brush specimens (PSB) in adults with VAP found that PSB are as effective in identifying infectious pathogens. Interestingly, this study also found very few instances of pneumonia caused by anaerobes.

Methicillin-resistant *Staphylococcus aureus* (MRSA) is a serious pathogen that has become endemic in some areas. In many ICUs, patients are screened on admission for MRSA colonization; MRSA pneumonia carries a higher mortality rate in the pediatric population. Infection with MDR organisms is a growing problem in many hospitals. Risk factors for acquiring an infection caused by a MDR organism include antibiotic use within the last 30 days, prolonged hospitalization, and high prevalence antibiotic resistance in the community and/or hospital. The definition of multidrug resistance in gram-negative organisms is not standard across infectious disease experts. The number of antibiotics to which an organism must be resistant varies from at least two up to at least eight, depending on the source used. Pan-resistance rates also exhibit local variability. However, the term defines organisms with diminished susceptibility to all of the antibiotics recommended for the empiric treatment of VAP. Broadly, these antibiotic categories might include carbapenems, beta-lactams, and cephalosporins (third and fourth generation).

A mechanically ventilated patient with, purulent tracheobronchial secretions in conjunction with a new or progressive pulmonary infiltrate on chest x-ray, should raise concerns about VAP and should be followed by the initiation of empiric antibiotic therapy. Additional signs of possible VAP include tachypnea, worsening pulmonary function, worsening hypoxemia, and/or increasing inspired oxygen need.

Establishing the diagnosis of VAP in mechanically ventilated pediatric patients can be quite challenging. In addition to the presence of clinical and radiologic findings that can be attributed to other causes, the diagnostic criteria for pediatric patients can be cumbersome and confusing. Unlike other HAIs, there is no laboratory standard for the diagnosis of VAP. No recommendations exist for invasive testing for children with VAPs. The CDC and WHO agree on the general requirements for diagnosing VAP; the CDC's criteria are a bit more specific, dividing criteria in to age-specific categories. The key criterion that must be met by all patients is having two or more serial chest radiographs with at least one of the following: a new or progressive, persistent infiltrate, consolidation or cavitation appearing greater than 48 h after initiation of mechanical ventilation. In infants less than 1 year old, pneumatoceles are also acceptable chest x-ray findings. Pediatric patients must also have at least three of the clinical criteria listed in the table below.

Clinical Criteria for VAPs

- Temperature instability with no other recognized cause (for children >1 year old or <12 years old, fever >38.4°C or hypothermia <36.5°C; for children ≥12 years old, fever >38.4°C)
- Leukopenia (<4,000 WBC/mm^3) or leukocytosis (≥15,000 WBC/mm^3) with a bandemia (≥10% of total WBCs)
- New onset of purulent sputum (≥25 neutrophils/hpf) or a change in character/volume of Respiratory derangement; apnea, tachypnea, increased work of breathing
- Change in auscultated lung exam: wheezing, rales, rhonchi
- Worsening gas exchange ($PaO_2/FiO_2 \leq 240$)
- Bradycardia (<100 beats/min) or tachycardia (>170 beats/min)

If there is laboratory data available, then the patient need only have one of the aforementioned clinical criteria and one of the laboratory criteria listed below.

Laboratory Criteria for VAPs

At least one of the following:

- Positive blood culture not related to another source of infection.
- Positive pleural fluid culture.
- Positive quantitative culture from a BAL or PSB.
- On microscopic exam, ≥5% of BAL-obtained cells contain intracellular bacteria.
- Histopathologic exam with at least one of the following:
  - Abscess formation or foci of consolidation with polymorphonucleocyte accumulation in bronchioles and alveoli
  - Positive culture of lung parenchyma
  - Evidence of fungal hyphae or pseudohyphae

Empiric antimicrobial choice should be based on available gram stain or culture data, the presence of underlying disease processes, recent antibiotic therapy, and any risk factors for MDR organisms. These include prolonged hospitalization, recent antibiotic treatment, high frequency of antibiotic resistance in the hospital or community, and immunosuppressive disease and/or therapy. One should also take into consideration the local bacterial flora of the hospital and community. For critically ill patients and for those with risk factors for MDR organisms, broad-spectrum, multidrug therapy is recommended. Antimicrobial therapy should be narrowed as soon as the infecting organism and its susceptibility pattern have been identified.

In patients with no known risk factors for MDR pathogens, third generation cephalosporins (i.e., ceftriaxone) or beta-lactams (i.e., piperacillin-tazobactam) are acceptable empiric choices. For those with known risk factors for infection with an MDR organism, empiric two- or three-drug combination therapy is recommended. The therapeutic regimen should include either an antipseudomonal cephalosporin (i.e., ceftazidime) or an antipseudomonal carbapenem (i.e., meropenem), or a beta-lactam. An aminoglycoside such as gentamicin should represent the second class of antimicrobials. Finally, vancomycin should be added to the drug regimen if MRSA is a frequent nosocomial pathogen in the institution or in the community. Linezolid is another agent with excellent MRSA coverage; it may be particularly useful in patients with renal dysfunction. Resistance to linezolid is uncommon, as is treatment failure. These antimicrobials should be immediately discontinued if the culture is not positive for MRSA. Use of all three drug classes may be acceptable in a severely unstable ICU patient with VAP.

If patients have recently received antibiotics, empiric therapy should generally be with a drug from a different class since earlier treatment may have selected pathogens resistant to the initial class.

Colistin, polymyxin, or inhaled aminoglycosides (i.e., tobramycin) may be considered as potential additional antibiotics in patients with MDR gram-negative bacilli. Aerosolization may increase antibiotic concentrations at the site of infection. This method of antibiotic delivery is common in patients with cystic fibrosis.

There are many causes of pulmonary infiltrates and fever, which can be difficult to distinguish from VAP. Leukocytosis, purulent tracheobronchial secretions, or respiratory abnormalities can be associated with most of these causes.

The differential diagnosis of VAP includes the following:

- Acute respiratory distress syndrome
- Aspiration pneumonitis
- Atelectasis
- Infiltrative tumor
- Lung contusion (especially following a trauma)
- Pulmonary embolism
- Pulmonary hemorrhage
- Radiation pneumonitis

The mouths of ICU patients become colonized with aerobic pathogens due to an inability to maintain normal oral hygiene. Decontamination of the oropharynx with CHG and other antiseptics or antibiotics has been evaluated in numerous studies. A 2007 study in adults found that CHG oral care significantly reduced the incidence of VAP. However, within the last year, there was a report about CHG staining tooth enamel; per the report, this could be reversed by routine dental cleaning. CHG use remains contraindicated in the neonate due to concerns about systemic absorption.

The goal of selective decontamination of the digestive tract (SDD) is to prevent oropharyngeal and gastric colonization with aerobic gram-negative bacilli and *Candida* species and thereby prevent VAPs. The most commonly cited regimen includes a mixture of antibiotics that are applied topically to the oropharynx or administered through a nasogastric tube. SDD has not been studied in the pediatric population.

Aspiration of oral and/or gastric secretions is the primary route of bacterial entry into the lungs and is believed to be a primary factor in the development of VAP. Elevating the head of the bed 15–45° is thought to decrease the likelihood of aspiration by decreasing the risk of reflux of gastric contents.

Secretions and gastric microaspirate pool below the glottis, just on top of the endotracheal tube cuff. The continuous aspiration of subglottic secretions (CASS) has been shown, in adult studies, to decrease the incidence of VAP. There are special endotracheal tubes that allow for CASS via a suction port just above the cuff. These endotracheal tubes are considerably more expensive than traditional ones. Furthermore, they are not made for patients who require a tube size less than 6.0.

Several companies manufacture silver coated endotracheal tubes. These have been demonstrated to delay the onset of VAP. However, these tubes did not decrease length of stay (ICU or hospital), duration of ventilator days, or mortality. Again, these tubes are primarily manufactured for the adult population, given that they are infrequently made in pediatric sizes.

Several studies have noted an increased incidence of VAP when the gastric pH is increased with the use of H2 blockers, antacids, or proton pump inhibitors (PPIs). Sucralfate was found to have lower association with VAP when compared with H2 blockers and antacids. However, this is an infrequently used medication in the PICU.

Strategies to prevent ventilator-associated pneumonia

General strategies	Strategies to prevent aspiration	Strategies to reduce colonization of the gastrointestinal tract
Minimize the duration of ventilation	Elevate the head of the bed of intubated patients to between 15° and 45°, unless there are contraindications	Orotracheal intubation is preferable to nasotracheal intubation
Perform daily spontaneous breathing trials	Avoid gastric distention	Perform regular oral care with an antiseptic solution at least twice daily
Use weaning protocols	Minimize unplanned estuations and reintubations	Limit GI prophylaxis to patients who are at high risk for developing a stress ulcer or stress gastritis

Use noninvasive ventilation when possible	Use a cuffed endotracheal tube with inline or subglottic suctioning	Replace oral suction devices daily to minimize contamination
Adhere to infection control guidelines from the CDC and WHO	Maintain an endotracheal cuff pressure of at least 10 cm H_2O	Use sterile water to rinse reusable respiratory equipment
Conduct active surveillance for VAP		Remove condensate from ventilatory circuits before moving or turning patient
Educate healthcare personnel who care for patients undergoing ventilation about VAP		Change the ventilatory circuit only when visibly soiled or malfunctioning
		Store and disinfect respiratory therapy equipment properly

Catheter-Associated Urinary Tract Infections

Urinary tract infections account for over 40% of all HAIs. Eighty percent of these infections are associated with indwelling urinary catheters. While UTIs are associated with less morbidity than other HAIs, they should not be taken lightly. UTIs in the critically ill patient can lead to bacteremia, urosepsis, and death. The acquisition of urinary tract infections following urinary bladder catheterizations is associated with nearly a threefold increase in mortality among hospitalized adult patients. An estimate of the economic impact of CA-UTIs suggests that patients with HA-UTIs secondary to indwelling catheters spend an average of 2.4 additional days in the hospital.

Urinary catheters should be used only when necessary and left in place for as little time as medically feasible. They should not be used solely for the convenience of healthcare workers. The need for continued indwelling catheter use should be addressed daily on rounds by the medical team. Intermittent or "straight" urethral catheterization can be a useful alternative to indwelling catheterization, though this is not without infectious risks.

The WHO and the CDC have defined bacteriuria as the presence of $\geq 10^5$ colony forming units (cfu)/mL of bacteria from a urine culture with a maximum of two isolated species. Bacteriuria in patients with indwelling urinary catheters occurs at a rate of approximately 3–10% per day of catheterization. It can be further subdivided into asymptomatic or symptomatic. Asymptomatic bacteriuria occurs in the absence of fever $>38^\circ$C and suprapubic or costovertebral angle tenderness, with a urine culture of $\geq 10^5$ cfu/mL of bacteria. The clinical significance of asymptomatic bacteriuria in catheterized patients is unclear. Only about 20% of these patients go on to develop symptomatic UTIs.

Symptomatic bacteriuria (the traditional "UTI") is defined as urine culture with greater than 10^5 cfu/ml, presence of fever $>38^\circ$C, suprapubic or costovertebral angle tenderness, and/or otherwise unexplained systemic symptoms. Examples of these include worsening respiratory status, hypotension, presence of systemic inflammatory response syndrome, and altered mental status. A UTI is still present if the patient has a urine culture with $>10^3$ cfu/mL, in conjunction with pyuria, leukocyte esterase, or nitrite on urinalysis, and systemic symptoms. Of note, per CDC definitions, if a patient develops the aforementioned symptoms within 48 h of removal of a urinary catheter, she is still considered to have a CA-UTI.

Patients with indwelling catheters often do not develop the "classic" signs (abdominal and/or costovertebral angle pain, dysuria, or frequency) of a UTI. Hence, evaluation for UTI is warranted when a patient with an indwelling urinary catheter develops fever and unexplained systemic symptoms.

Female sex and diabetes mellitus are independent risk factors for both asymptomatic bacteriuria and UTIs. Other risks include prolonged catheterization and improper catheter and collection system management.

Similar to CA-BSIs, infection associated with urinary catheterization may be extraluminal or intraluminal. A biofilm forms along the outside of the catheter in the urethra, leading to entry of bacteria into the bladder. This is called extraluminal infection. Intraluminal infection is an ascending infection and is directly associated with bedside management of the catheter. Urinary stasis because of drainage failure and contamination of the collection system are the most common reasons for

intraluminal infection. Notably, with CA-UTIs, extraluminal is far more common than intraluminal infection.

The bacteria responsible for the majority of UTIs come from gastrointestinal tract flora. These bacteria can represent normal flora such as *Escherichia coli* and *Proteus* or hospital acquired such as multidrug resistant *Klebsiella*. *Candida* is a common colonizing organism of urinary catheters. These Candidal infections are frequently asymptomatic and do not commonly progress to candidemia.

Most studies suggest that antimicrobial prophylaxis is not useful for prevention of bacteriuria. Indeed, antibiotics are frequently ineffective in the treatment of bacteriuria in the asymptomatic catheterized patient. For symptomatic patients with fever or signs of sepsis, treatment of bacteriuria with appropriate systemic antibiotics, as well as removal or replacement of the urinary catheter, is warranted.

Empiric antibiotic treatment should be started in a clinically symptomatic patient with a suspected CA-UTI. Empiric therapy should, ideally, be based on local antibiograms, the urine Gram stain, and, if present, previous culture results. Gram-negative bacilli may be treated empirically with a third-generation cephalosporin (i.e., ceftriaxone) or a beta-lactam (i.e., pipercillin-tazobactam). Older children and teenagers may be treated with a fluoroquinolone (i.e., ciprofloxacin). Gram-positive cocci are less common pathogens. Typically, these represent enterococci or staphylococci. Again, pipercillin-tazobactam or another beta-lactam antibiotic would be an appropriate choice here. The addition of vancomycin may be appropriate if there is a high level of resistant gram-positive organisms in your geographic area. Antimicrobial choice should be narrowed as soon as culture and susceptibility results become available. There is controversy in the literature about the optimal duration of therapy. The prevailing opinion is that treatment for 10–14 days is generally appropriate. Another source of discussion is when to transition to enteral antibiotics. When the patient has had resolution of systemic symptoms, is able to tolerate enteral feedings, and has a negative urine culture, the medical team can consider a change to enteral antibiotics.

Only two interventions are consistently effective in preventing CA-UTI. They are avoiding urethral catheterization unless there is a compelling indication and prompt removal of unnecessary catheters. Given that it is not always possible to forgo urinary catheterization, other methods of prevention of UTIs must be investigated.

UTI Prevention Strategies

Effective prevention	Ineffective prevention
Limit duration of catheter use	Systemic antibiotic prophylaxis
Use sterile technique at insertion	Bladder irrigation with normal saline or antibiotic containing solution
Maintain closed drainage system	Antiseptic added to drainage bag
	Antimicrobial-coated catheter
	Daily antiseptic perineal cleaning

Handwashing with soap and water or an alcohol-based product should be done immediately before and after any manipulation of the catheter site or apparatus. To minimize the risk of infection, urinary catheters should be always placed using sterile technique and equipment. Sterile gloves, a perineal drape, sponges, an appropriate antiseptic solution for periurethral cleaning, and a single-use packet of lubricant jelly should be used for catheter placement. Use of the smallest catheter that allows good urinary drainage is associated with a decreased risk of infection. Indwelling catheters should be properly secured after insertion to prevent meatal injury and traction on the urethra.

A sterile, continuously closed collection system should be used with indwelling catheters. If the system is disconnected from the catheter without maintenance of sterile technique, it should be replaced. Ideally, the indwelling catheter and collecting system should not be disconnected. Irrigation should be avoided unless obstruction is a serious concern (i.e., in hemorrhagic cystitis associated with chemotherapy). There are newer catheter types that have ports through which closed irrigation may be done. Neither continuous nor intermittent irrigation of the bladder with antimicrobials has been shown to decrease CA-UTIs and should not be performed as a routine infection prevention measure. When irrigation is performed, aseptic technique should be pursued. The catheter-collecting system junction should be cleaned with chlorhexidine gluconate, a povidone iodine solution, or a 70% isopropyl alcohol solution before disconnection. A large-volume sterile syringe and sterile irrigant should be used. These supplies should be discarded after each irrigation event. If the catheter becomes chronically obstructed and requires frequent irrigation, it should be removed and replaced only if medically necessary. There is a strong

possibility that the catheter itself is contributing to the obstruction. Further, catheter concretions that lead to obstruction can harbor bacteria. Unobstructed flow of urine should be maintained at all times. The catheter and collecting tube should be neatly secured to the patient's thigh to prevent meatal trauma. The drainage bag should be below the level of the bladder and should be emptied regularly using a separate collecting container for each patient. Avoid contacting the draining spigot and nonsterile collecting container with each other.

At times a small volume of fresh urine is necessary for analysis and bacterial culture. Ideally, there is a sampling port through which a sample can be obtained using aseptic technique. If this is not available, the distal end of the catheter can be cleansed with a chlorhexidine gluconate, a povidone iodine solution, or a 70% isopropyl alcohol solution; subsequently, urine can then be aspirated with a sterile needle and syringe. Larger volumes of urine (i.e., a 24-h urine collection) can obtained from the drainage bag of the collecting system.

Daily cleansing of the urethral meatus with povidone-iodine solution, soap and water, or CHG impregnated wipes has not been shown to reduce CA-UTIs. In fact, there is evidence that frequent meatal cleaning can lead to mucosal irritation and breakdown that actually increases risk of infection.

Indwelling catheters should not be changed at arbitrary fixed intervals. Instead, there should be daily review of the need for continued indwelling catheterization.

Conclusion

Hospital-acquired infections add to the functional disability and emotional stress of the patient and, in some cases, lead to disabling conditions that reduce the quality of life. HAIs are also one of the leading causes of death for hospitalized patients. The economic costs of management are considerable. The increased length of stay for infected patients is the greatest contributor to cost. Prolonged stay not only increases direct costs to patients and payers but also indirect costs due to lost work and diminished productivity. The increased use of drugs, the need for isolation, and the use of additional laboratory and other diagnostic studies also contribute to costs.

The CDC has extensive guidelines for diagnosis, management, and reporting of HAIs in the USA. The majority of so-called developed nations have a similarly complex system for monitoring HAIs. However, in developing nations HAIs are a serious and undermanaged problem. The burden of HAIs is one of the key areas of work of the WHO First Global Patient Safety Challenge: Clean Care is Safer Care. The WHO recently released data that demonstrated that the number of HAIs in developing nations was twice as high as that of their high income counterparts. Inadequate infrastructure and equipment, poor hygiene and waste disposal, lack of basic infection control knowledge and methods of implementation, as well as a lack of medical and nursing practice guidelines and policies are among the key factors that increase the risk of HAIs. Implementing system-wide surveillance, training, education, using indwelling devices appropriately and following proper procedures, and ensuring optimal hand hygiene practices are some of the solutions that must be tailored to the reality of these settings. To be successful, these solutions ultimately require a change in healthcare workers' behavior. Surveillance is the key to the reduction of HAI, as it enables hospitals to understand the magnitude of the problem, what interventions are needed, and to assess their impact. While HAI surveillance systems exist in many developed countries, only 23 out of 147 developing countries, or 16%, report a functioning national surveillance system.

HAIs are caused by a wide variety of pathogens during the course of medical care treatment. These infections can be devastating and even deadly. As our ability to prevent HAIs grows, these infections are becoming increasingly unacceptable. Elimination of HAIs is of major importance for both developed and developing nations. Infection control, provider education programs, and continued surveillance lead to decreased HAIs and improve outcomes in medical care.

68 Infections in the Immunocompromised Host

Ibrahim Bin-Hussain

Introduction

Infections are considered a major cause of morbidity and mortality in immunocompromised children. The survival rate in this particular population has increased over the last 3 decades. This is mainly due to the advancement in medical technology leading to improvement in diagnosis capabilities as well as supportive care including antimicrobial therapy.

Immunodeficiency can be divided into primary and secondary immunodeficiency disorders. Primary immunodeficiency disorders including combined T-cell and B-cell immunodeficiencies, antibody deficiency, disease of immune dysregulation, congenital defects of Phagocyte number or function or both, defects in innate immunity, autoimmunity disorders, complement deficiencies, and cytokine defects. Secondary immunodeficiency disorders include human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS) – both of which lead to altered cellular immunity – dysgammaglobulinemia, defective phagocytic function or neutropenia. Cancer leading to neutropenia, lymphopenia, humoral deficiencies and altered physical integrity especially with the use of chemotherapeutic agents leading to disruption barrier integrity with mucositis leading to easy access of microorganisms, solid organ transplant leading to deficiencies in cellular and phagocytic immunity, malnutrition which leads to impaired immunity, and complement activity.

Fever is the main manifestation and occasionally the only sign of infection in immunocompromised children. When approaching a patient with immunodeficiency in the context of infection, one needs to look at the net state of immunosuppression. The net state of immunosuppression can be evaluated by the host defense defects caused by the primary disease, dose and duration of the immunosuppressive therapy (the longer duration of immunosuppressive therapy, the higher risk of infection), presence of neutropenia, and anatomical and functional integrity because defect in the skin or mucosa can lead to easy access for the microorganisms, metabolic factors, and infection with immunomodulating viruses (HIV, HBV, HCV, CMV, EBV, and HHV-6).

Risk of infections can be classified as high, intermediate, and low. High risk includes hematologic malignancies, AIDS, HSCT, splenectomized patient, and congenital immunodeficiency especially severe combined immune deficiency (SCID). Intermediate risk includes solid tumors, HIV/AIDS, and solid organ transplantation. Low-risk patients include patients with corticosteroid therapy, local defects, and diabetes.

Etiology

The pathogens in immunocompromised patients can be predicted based on the immune defect. For example, if there is an anatomical disruption in the oral cavity it lead to infections caused by alpha hemolytic streptococci, anaerobes, *Candida* species, and herpes simplex virus (HSV). Patients with urinary catheters will be at risk for infection caused by gram negative bacteria including *Pseudomonas* spp., enterococci, and possibly candida. If there is a skin defect including central venous catheter (CVC), the patient will be at risk of *Staphylococcus* species (both coagulase-negative *staphylococci* and *Staphylococcus aureus, Bacillus* species, atypical *Mycobacterium*, and Gram-negative organism. If a defect in the phagocytic function, either quantitative or qualitative, predispose what to invasive diseases like invasive pneumonia caused by bacterial pathogens: Gram-positive (staphylococci, streptococci, and *Nocardia* species) and Gram-negative bacilli (*Escherichia coli, Klebsiella pneumoniae, P. aeruginosa)*, other enterobacteriaceae, and fungal pathogens like *Candida* species and *Aspergillus* species.

Patients with defective cell-mediated immunity are at risk of infections caused by intracellular pathogens (i.e., viral, fungi, mycobacterial, and intracellular bacteria). Intracellular pathogens include *Legionella* species, *Salmonella* species, *Mycobacteria*, and *Listeria* species, *Histoplasma capsulatum*, *Coccidioides immitis*, *Cryptococcus neoformens*, *Candida* species, *Pneumocystis jiroveci*, cytomegalovirus, Varicella-zoster virus, Epstein-Barr virus, live viral vaccines (measles, mumps, rubella, and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_68,

polio) and protozoal, *Toxoplasma gondii*, *Strongyloides stercoralis*, *Cryptosporidia*, *Microsporidia*, and *Isospora* species.

Patients with immunoglobulin deficiencyo are at risk of sinupulmonary infection caused by *S. pneumoniae, Haemophilus influenzae, and* CNS infection from viral infections, especially enterovirus, leading to chronic meningoencephalitis as well as gastrointestinal infection due to giardiasis. Patients with complement deficiency are at risk of diseases caused by *S. pneumoniae, H. influenzae, and Neisseria* species. Splenectomized patients are at risk of invasive diseases (e.g., sepsis, meningitis) caused by encapsulated organism including *S. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis*.

In evaluating patients with immunodeficiency, one can predict the pathogen based on the primary immune defects, the organs involved, and the clinical presentation of the patient. For instance, *Staphylococcus aureus*, *Burkholderia cepacia*, *Serratia marcescens*, *Pseudomonas* and *aspergillous* infection should be considered for a chronic granulomatous diseased (CGD) patient with soft tissue infection, lymphadenitis, liver abscess, osteomyelitis, pneumonia, and sepsis.

Diagnosis

In centers dealing with immunocompromised patients, the microbiology laboratory as well as the radiology service need to be well equipped and trained in diagnosing these patients. Patients with fever should be worked up with complete blood count with differential, renal, and hepatic profile, blood culture from central line (if present), and peripheral culture. Chest X-rays are not done routinely unless the patients have respiratory symptoms. Other investigations need to be guided by the presentation of the patient. Patients with diarrhea should have stool checked for bacterial culture, ova and parasite, viral culture, rotavirus, and electron microscopy for viral studies, in addition to microspora, cryptosporidium, and isospora. In addition to chest X-ray, patients with respiratory symptoms required nasopharyngeal aspirate for rapid test for viruses and PCR multiplex – a newly developed laboratory procedure that can screen multiple viruses and other respiratory pathogens in the same setting. Patients with skin lesions should have skin biopsy from the lesion, which will be sent for culture (bacterial, fungal, and mycobacterium) in addition to histopathology for Gram-stain and special staining for fungal as well as acid fast stain (AFB stain).

Management

There are several objectives in managing infections in immunocompromised patients. The first and foremost objective is to assure patients' survival and prevent infectious morbidity. Decrease days of hospitalization and decrease exposure to multidrug resistance organism, decrease number of days of antibiotic use to minimize selection of resistance organism. Modification of antimicrobial therapy in immunocompromised patients is the rule rather than the exception. Timely modification of antibiotic therapy is very important to control breakthrough infection.

There are several questions to be addressed to choose the effective antimicrobial therapy when evaluating patients. In addition to history and physical examination, it is important to determine which arm/arms of the immune systems that is/are affected? what the clinical syndrome/site of infection is? (to predict what are the likely pathogens), what clinical specimen(s) should be obtained (empiric/definitive therapy)? and which antimicrobial agents have predictable activity against pathogens? With these in mind, one can predict pathogen and choose the right antimicrobial agents.

Patients with Wiskott–Aldrich syndrome are at risk of bacterial pneumonia as well as sepsis with Gram-positive organisms including MRSA. In this situation, medication should include agents active against Gram-negative pathogen plus anti-staphylococcus agents, for example, cefotaxime or ceftriaxone plus naficillin; if MRSA or penicillin resistant *S. pneumonia* is suspected, one can use vancomycin.

The pathogen in immunocompromised patients can be predicted by the system involved during the presentation. For example, the presentation and etiological agents in pneumonia in immunocompromised patients are different than immunocompetent persons. In evaluating pneumonia in immunocompromised patients, one needs to know that the pulmonary complication is present in up to 60% of immunocompromised patients and mortality is up to 80% of those who require mechanical ventilation. The initial evaluation needs rapid assessment of the vital signs including oxygen saturation, complete blood count with differential, renal profile, blood culture, and imaging of the lung either chest X-ray or CT scan. The organism can be predicted based on the primary immune defect. At certain point in the history, the defect in the immune system, the presence or absence of neutropenia, history of antimicrobial exposure, the presence of potential pulmonary pathogens in previous cultures, and the presence of indwelling catheters should be looked at.

The pattern and distribution of radiological abnormalities can predict the pathogen and the time and the rate of progression and time to resolution of pulmonary abnormalities.

For definitive diagnoses invasive procedures may be needed including bronchoalveolar lavage (BAL), transbronchial biopsy, needless biopsy, thorascopic biopsy, and open lung biopsy. In obtaining the biopsy from this patient, it is very important to send it for histopathology for special staining, for viruses, bacteria, fungi, pneumocystis, mycobacterial pathogen, and also culture for viral, fungal, bacterial, and mycobacterium.

Other laboratory tests that will help in diagnosing pneumonia are nasal washings or swabs for direct fluorescent antibody, PCR for respiratory viruses and atypical pneumonia, culture and staining, CMV antigenemia or CMV viral load testing, *Aspergillus* galactomannan assay, and 1,3 beta D glucan.

The radiological finding in immunocompromised patient can be focal (lobar or segmental infiltrate), diffuse interstitial infiltrate or nodular (with or without cavitation). Focal infiltrate can be due to Gram-positive or Gram-negative bacteria, *Legionella*, mycobacteria, and fungal infection. Also the noninfectious etiology includes infarction, radiation, and drug-related bronchiolitis obliterans organizing pneumonia (BOOP). Diffuse interstitial infiltrate is caused by viral infection, *Pneumocystis jiroveci*, less likely mycobacterium, disseminated fungal infection, atypical pneumonium including *Chlamydia*, *Legionella*, and *mycoplasma*. Other noninfectious etiology causing diffuse interstitial infiltrate include edema, acute respiratory distress syndrome (ARDS), and drug-related radiation. For nodular infiltrate with or without cavitation the infectious etiology include *Aspergillus* infection, and other mycoses, *Nocardia*, bacteria either Gram-positive or Gram-negative, anaerobes, and *Mycobacterium* TB, as well as noninfectious etiology including disease progression like metastasis and drug toxicity.

The management of immunocompromised patients with pulmonary infiltrate will depend on the patient presentation. If the patient is acutely ill, it is very important to begin empiric therapy to cover the likely pathogen based on the presentation of the patient and the primary immune defect with simultaneously comprehensive evaluation.

Subsequently, therapy should be adjusted based on culture and clinical response. In providing empirical antibiotic therapy in patient with pulmonary infiltrate and defect in cell-mediated immunity one need to consider *Pneumocystis jiroveci*, nocardia, legionella, mycoplasma, in addition to aerobic Gram-positive cocci and Gram-negative bacilli therefore it is advised to use trimethoprim-sulfamethoxazole, macrolides including erythromycin or clarithromycin and agent active against Gram-positive and Gram-negative; for example, third-generation cephalosporin with or without aminoglycoside with anti-Gram-positive either nafcillin or vancomycin based on the incidence of methicillin-resistant *Staphylococcus aureus* (MRSA) and penicillin resistant *Streptococcus pneumoniae*.

Infection in Cancer Patients with Fever and Neutropenia

The fever is defined in the context of febrile neutropenia as a single oral temperature of more than 38.3°C or more than 38.0°C for at least 1 h and is not related to the administration of pyrexial agents including blood, blood product, IVIG, and pyrogenic drugs, especially Ara C.

Neutropenia is defined as absolute neutrophil count (ANC) less than 500/mm^3 or less than 1,000/mm^3 with predictive decline to less 500/mm^3 48 h.

Risk Factor for Infection in Cancer Patients

The most important risk factor is the presence of neutropenia as well as the degree and duration of neutropenia. The lower the neutrophil count, the higher the risk of infection. The longer the duration of neutropenia, the higher the risk of infection. Usually, neutropenia is considered high risk if $\geq$ 7 days and low risk $<$ 7 days. Other risk factors include associated medical comorbidity, primary disease, and status (remission or relapse). Low-risk patients are clinically defined by neutropenia as anticipated lasting less than 7 days, clinically stable, and having no medical comorbid conditions.

Epidemiology

About 50% of neutropenic patients who become febrile have established or occult infections and about 25% of patients with ANC less than 100 cells/mm^3 have bacteremia.

The risk varies depending on the underlying disease, for example, patients post allogenic bone marrow transplantation are at higher risk than autologous bone marrow transplantation while AML has the higher risk than ALL. The lowest risk is in patients with cyclic neutropenia.

Evaluation

In evaluating a patient with fever and neutropenia, it is important to keep in mind that signs and symptoms can be muted or subtle. Profoundly neutropenic patients can sometime have life-threatening infections and yet be afebrile especially if they presented with abdominal pain. Careful and comprehensive physical examination is critical and should be repeated at least daily because these patients are dynamic and their condition can change rapidly.

Other important points in the history include the nature of chemotherapeutic agents, steroids, or other immunosuppressive agents because these can predict the degree of immunosuppression, the duration of neutropenia, and the severity of neutropenia. The history of antibiotic prophylaxis is also important because the antibiotic used as prophylaxis should be avoided in treating these patients. Reviewing the recent documented infection with susceptibility can help in determining the empiric therapy. For example, if the patient has a previous infection with multidrug resistance pathogen, empiric therapy can be used to cover these pathogens. If the patient had recent surgical procedure, this means there is break of the skin and is at risk for certain pathogens including Gram-positive cocci (coagulase negative *Staphylococci and Staphylococcus aureus*). Allergy history is an important factor in selecting empirical therapy as allergic medications need to be avoided.

Detailed and thorough physical examination is important with focus on certain sites that can be a portal of entry of pathogens including periodontium, pharynx, lower esophagus, lung, skin, perineum, bone marrow aspiration site, and catheter entry and exit sites.

After history and thorough physical examinations, blood culture from central and peripheral lines should done in order to identify the source of infection. For example, if the blood culture is positive from the central culture but negative from peripheral culture, the likely source is the central line. If both are positive, time is needed to positively determine the source of infection. Routine surveillance culture is not indicated as it is not cost effective and has low predictive value. Other cultures should be guided by the sites of infection. For example, a patient with respiratory symptoms needs to have nasapharyngeal aspirate for viral study, PCR multiplex, and atypical pneumonia. Patients with gastrointestinal symptoms, for example, with diarrhea, the stool needs to be sent for viral study, culture and sensitivity, ova and parasite. Chest X-ray should not be done routinely in all patients with fever and neutropenia because it has low yield in patients without respiratory symptoms. It is only done in children who have respiratory symptoms. If negative, a chest CT scan to be considered to better evaluate patient not responding to therapy.

Site of Infection

Most patients with fever and neutropenia have no identifiable site of infection and no positive culture results. Bloodstream infection is documented in about 20% of patients with fever and neutropenia. Disruption of the skin or soft tissue including vascular access or catheter insertion site can be a point of entry. In those centers, who are dealing with cancer patients, it is very important to monitor the infection rate and pathogen as well as the resistance pattern in the same center. The local data will help to select the appropriate empirical antimicrobial therapy (*Table 68.1*).

Management

There is no ideal regimen because there are variables which include the risk status of the patient, microflora and their sensitivity patterns, toxicity indication, preference, and the cost. Prompt initiation of broad-spectrum therapy when neutropenic patients became febrile is the key to successful management. In 1960 the mortality rate was up to 80% initially but with the introduction of empiric therapy against gram-negative organism the mortality rate now is close to 5%. There is no ideal regimen because this can be determined based on the isolate and its susceptibility in the same center as each center for example, one cannot extrapolate from different centers the likely pathogen, the same thing that a center can have a different pathogen and different susceptibility pattern in adult versus pediatric population with febrile neutropenia (*Table 68.2*).

Monotherapy Versus Combination Therapy

Monotherapy and combination therapy has equal efficacy. The monotherapy needs to have antipseudomonal activities including antipseudomonal penicillin with or without beta-lactamase inhibitor, carbapenem, and third- or fourth-generation antipseudomonal cephalosporins. The combination therapy includes antipseudomonal beta-lactam with Aminoglycoside. Both monotherapy and combination therapy have equal efficacy but it is important to look at the local data to be able to predict the empiric therapy either combination therapy or monotherapy.

Table 68.1
Common bacterial pathogens in neutropenic patients

Common Gram-positive pathogens
Coagulase-negative staphylococci
Staphylococcus aureus, including methicillin-resistant strains
Enterococcus species, including vancomycin-resistant strains
Viridans group streptococci
Streptococci pneumonia
Streptococcus pyogenes
Common Gram-negative pathogens
Escherichia coli
Klebsiella species
Enterobacter species
Pseudomonas aeruginosa
Citrobacter species
Acinetobacter species
Stenotrophomonas maltophilia

Table 68.2
Recommendation from Clinical Practice Guidelines for empirical initial therapy in neutropenic patients with fever

Guidelines	Monotherapy	Combination therapy
IDSA (Infectious Disease Society of America), Freifeld et al. CID 2011	High Risk:* Cefepime Imipenem-cilasiatin Meropenem Piperacillin-tazobactam	Low Risk:
NCCN (National Comprehensive Cancer Network) 2008	Ceftazidime Cefepime Imipenem-cilasiatin Meropenem	Aminoglycoside + antipseudomonal penicillin Aminoglycoside + extended spectrum cephalosporin Ciprofloxacin + antipseudomonal penicillin
IHQ (infectious Diseases Working Party of the German Society of Hematology and Oncology) Link et al. 2003	Piperacillin-tazobactam Ceftazidime Cefepime Imipenem-cilasiatin Meropenem	Aminoglycoside + acylaminopenicillin Aminoglycoside + third-or fourth-generation cephalosporin
SEQ (Chemotherapy Society of Spain), 2001	Cefepime Meropenem	Not recommended for routine use

*Other antimicrobials (aminoglycosides, fluoropuinolone, and/or vancomycin) may be added to initial regimen for complicated presentation or if resistance is suspected or proven

It is worth stressing that vancomycin should not be used routinely for empiric therapy in febrile neutropenia and there is a special indication for vancomycin. The vancomycin indication includes hemodynamic instability or other evidence of severe sepsis, pneumonia documented radiographically, positive blood culture for gram-positive bacteria before final identification and susceptibility testing is available, clinically suspected catheter-related infections (e.g., chills or rigors with infusion through catheter and cellulitis around the catheter entry/exit site), skin or soft-tissue infection at any site, colonization with methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococcus, or penicillin-resistant *Streptococcus pneumoniae*, and severe mucositis, if fluoroquinolone prophylaxis has been given and ceftazidime is employed as empirical therapy. If the patient started empirically on vancomycin the need for continuation of vancomycin should be re-assessed on daily basis. Overuse of vancomycin in more than 90%, and selection for resistant organism and emergence of vancomycin resistance enterococci.

The factors influencing antimicrobial selection include the types of bacterial isolates found in the institution, antibiotic susceptibility patterns, drug allergies, presence of organ dysfunction, chemotherapeutic regimen whether the patient was receiving prophylactic antibiotics, and condition of the patient at diagnosis, for example, presence of signs and symptoms at initial evaluation and presence of documented sites requiring additional therapy.

The center-specific factors include the patterns of resistance, effect on microbial ecology, high presence of vancomycin resistance enterococci (VRE), or extended spectrum beta-lactamase (ESBL) producing organism. The patient-specific factors including recent antibiotic use such as current prophylaxis as drug allergy, and the underlying organ dysfunction. The signs and symptoms present at the initial evaluation determine.

In the recent year more interest in the outpatient therapy for patient with fever and neutropenia. The advantages of ambulatory management of febrile patients with neutropenia especially those at low risk include lower cost particularly with oral outpatient therapy, fewer superinfections caused by multidrug-resistant nosocomial pathogens, improved quality of life for patient, greater

convenience for family or other caregivers, and more efficient utilization of valuable and expensive resources. The disadvantage includes the potential risk for developing serious complications such as septic shock at home, risk of noncompliance particularly with oral therapy, false sense of security or inadequate monitoring for response to therapy or toxicity, and the need to develop a team and infrastructure capable of treating substantial numbers of low-risk patients.

There are several requirements for successful outpatient treatment programs for patients with febrile neutropenia which include institutional infrastructure and support, a dedicated and experienced team of healthcare providers, availability of institution-specific epidemiological data and susceptibility and resistance data, microbiologically appropriate treatment regimen, frequent follow-up monitoring of outpatient, adequate transportation and communication capabilities, and access to management team 24 h a day, 7 days a week.

Modification of Therapy

There are certain clinical events or manifestations that require modifying the initial antimicrobial therapy; for example, if a patient has breakthrough bacteremia and if Gram-positive is isolated (add vancomycin especially if there is a risk of MRSA or pneumococcal resistance penicillin). If Gram-negative organism is isolated consider resistant Gram-negative and can change the regimen or broaden the coverage (carbapenems if the data in the center showed that the carbapenems has better sensitivity than cephalosporin or beta-lactam antibiotic). If the patient has catheter-associated soft tissue infection, vancomycin should be added. Patients with severe oral mucositis or necrotizing gingivitis are at risk of anaerobic bacteria as well as viruses; add agent that is active against beta-lactamase-producing anaerobic bacteria including clindamycin, metronidazole, and acyclovir should be considered. If the patient has diffuse pneumonia, continue with the broad-spectrum anti-Gram-negative coverage (add trimethoprim-sulfamethoxazole and macrolide to the therapy). Increasing neutrophil count on patients who developed new infiltrates while on antibiotic can be related to the recovery of neutropenia. If the patient is stable observe if the neutrophil count is not rising, antifungal therapy should be considered as the patient is at risk for fungal infection. In addition to other evaluation *Aspergillus* galactomannan and B-D glucan (fungitell) should be done with chest CT scan. Depending on the CT scan findings bronchoalveolar lavage or lung biopsy should be considered. Patient with prolonged fever and neutropenia needs to be observed if recovery of neutropenia is not imminent. Antifungal therapy can include either regular amphotericin B, or lipid formulation of amphotericin B including liposomal amphotericin B (amBisome) or amphotericin B lipid complex (ABLC), caspofungin or voriconazole depending of the availability of medications and epidemiology of the institution.

69 Meningitis

Melissa Ketunuti · Matthew P. Kronman

Definition and Introduction

Meningitis is defined as an inflammation of the meninges, the protective membranes covering the brain and spinal cord. There are numerous causes of meningitis, the most common category being infectious, including viral, bacterial, fungal, and parasitic infections. Meningitis, particularly acute bacterial meningitis, is a pediatric illness that continues to cause significant disease burden, with mortality rates remaining unchanged in the last 15 years. The introduction of the pneumococcal, meningococcal, and *Haemophilus influenzae* type-B (HiB) vaccines has altered the epidemiology and prevalence of meningitis in developed countries. However, these vaccines are not available in many parts of the developing world, and bacterial meningitis caused by these vaccine-preventable infections continues to cause significant illness.

Etiology and Epidemiology

Bacterial Causes

In the United States, the majority of meningitis cases are due to viral agents, but the highest morbidity and mortality rates are due to bacterial meningitis. The predominant bacterial pathogens causing meningitis differ depending on the age and immune system of the host.

Neonates

Bacteria that cause meningitis in neonates (0–28 days) are distinct from those causing meningitis in older children and adults. Neonatal infections stem from exposure to maternal gastrointestinal and genitourinary flora and include Group B *Streptococcus* (GBS, *Streptococcus agalactiae*), *Escherichia coli,* and *Listeria monocytogenes.* In neonates, the highest meningitis disease burden is from GBS. Since the widespread initiation of intrapartum antibiotics in 1996, a decrease has occurred in the United States incidence of all early-onset GBS infections from approximately 2 cases per 1,000 live births in 1990 to 0.3 cases per 1,000 live births in 2004. The incidence of neonatal bacterial meningitis since intrapartum antibiotic initiation is approximately 0.25–1 cases per 1,000 live births, with premature infants being at higher risk with an incidence of 2.5 cases per 1,000.

Older Children and Adults

In the latest United States surveillance study, the most common etiologic agent of bacterial meningitis across all age groups was *Streptococcus pneumoniae* (61%), followed by *Neisseria meningitidis* (16%) and GBS (14%) (Table 69.1). *H. influenzae* and *L. monocytogenes* are less frequent causes of bacterial meningitis, accounting for 7% and 2% of cases, respectively.

S. pneumoniae is the second most common cause of meningitis in American children, and continues to be the leading cause of meningitis in both children and adults worldwide. *S. pneumoniae* is a ubiquitous organism with nasopharyngeal carriage rates ranging from 21% to 59%. Pneumococcal infections, including meningitis, are most prevalent in the winter months following upper respiratory tract viral infections. The incidence of pneumococcal meningitis peaks in children at 1 year of age, but is prevalent throughout childhood and peaks again in adults over 60 years of age. Children with certain congenital CSF abnormalities (i.e., spina bifida or meningoceles), cochlear implants, complement deficiencies, and asplenia are at an increased risk for acquiring bacterial meningitis. Approximately 20–25% of children with pneumococcal meningitis have a predisposing risk factor.

N. meningitidis is the second most common bacterial pathogen causing meningitis in the United States and is the leading pathogen in children 2–18 years of age. Two incidence peaks exist for meningococcal infection: the first peak occurs in children less than 5 years of age, and the second peak in people 15–24 years of age. Although the majority of meningococcal cases (95%) are endemic, outbreaks occur in association with daycare centers, college dorms, and military barracks. Meningococcal cases are more common in the winter months following influenza virus infections, which are thought to break down protective mucus membranes.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_69,

Table 69.1
Meningitis epidemiology in the United States since the introduction of the HiB, pneumococcal, and meningococcal vaccines

Pathogen	1986	1998–2003
H. influenzae	45%	7%
S. pneumoniae	18%	61%
N. meningitidis	14%	16%
Group B *Streptococcus*	5.7%	14%
L. monocytogenes	3.2%	2%

Adapted from Dery MA, 2007

There are 13 identified *N. meningitidis* serogroups as determined by differences in the bacterial polysaccharide capsule. The serogroups have varying epidemiological features and are responsible for different disease manifestations. Serogroups B, C, and Y are the most prevalent serotypes in the United States. Worldwide, the majority of endemic meningococcal cases are caused by serogroups A, B, and C. Serogroups B and C cause disease in Europe and the Americas, and serogroups A and C cause disease in Asia and Africa. Although all serogroups have the potential to cause epidemic disease, certain serogroups have caused recurrent outbreaks. In the United States, the majority of these outbreaks are due to serogroup C and Y. Worldwide, serogroup A is the most common agent responsible for epidemics of meningococcal meningitis, especially in the sub-Saharan "meningitis belt" which extends from Ethiopia to Senegal.

H. influenzae type B (HiB) was the most common cause of bacterial meningitis in the United States prior to the introduction of the HiB vaccine. It now has been largely eradicated from the United States and other developed countries but continues to cause significant disease burden worldwide. According to the World Health Organization (WHO), HiB is estimated to cause approximately three million serious illnesses and an estimated 386,000 deaths annually in children less than 5 years old, chiefly through meningitis and pneumonia. The incidence of HiB meningitis is currently highest in sub-Saharan Africa and Latin America and typically occurs between 6 and 18 months of age. Sickle cell disease, asplenia, and HIV infection predispose children to HiB infection.

Other Bacterial Causes of Meningitis

Meningitis caused by *Mycobacterium tuberculosis* is a severe and deadly disease. The World Health Organization estimates that one third of the world's population is infected with tuberculosis. However, defining the incidence and prevalence of tuberculous meningitis has been challenging as diagnostic criteria are not universal and criteria for the initiation of empiric treatment differ. Tuberculous meningitis is estimated to complicate 0.3% of untreated tuberculosis infections in children, and more commonly affects children between 6 months of age and 4 years of age.

Borrelia burgdorferi (the etiologic agent of Lyme disease) causes meningitis in children living in endemic regions in the United States, such as the southern New England area, the eastern mid-Atlantic States, Wisconsin, and Minnesota. Other bacterial pathogens such as *Pseudomonas aeruginosa, Salmonella* species, *Klebsiella* species, and *L. monocytogenes* are rarer causes of meningitis and are more commonly identified in immunosuppressed or elderly patients. In particular, patients on chronic steroid treatment are at greater risk of contracting *Listeria* meningitis.

Viral Causes of Meningitis

While bacterial agents cause the majority of morbidity and mortality related to infectious meningitis, viral pathogens are the most common infectious cause of meningitis overall. Viruses cause an aseptic meningitis, which refers to meningeal inflammation not caused by a bacterial pathogen. The most common viral infections resulting in meningitis in children are enteroviruses, including coxsackieviruses and echoviruses. Enteroviruses predominate in the summer months and are most common in children younger than 1 year of age.

The herpes simplex virus (HSV) is an important cause of aseptic meningitis. HSV can cause neonatal meningitis as well as aseptic meningitis in older children and adults. HSV infection occurs in 1 in 3,200 deliveries in the United States; transmission of HSV occurs during delivery, either when mothers have an active primary infection, or less commonly through shedding and reactivation of latent virus.

Fungal and Parasitic Causes

Fungal and parasitic meningitis are uncommon and primarily restricted to patients with immunosuppression, such as HIV infection, autoimmune disease, diabetes, a history of solid organ or bone marrow transplantation, and cancer. The most common fungal meningitis worldwide is *Cryptococcus neoformans* in the HIV population.

Pathogenesis

Meningitis is usually caused by the hematogenous spread and subsequent seeding of organisms from a distant site, either from a local infection or colonization. Pathogenic bacteria often colonize the nasopharynx but can also arise from the genitourinary tract, gastrointestinal tract, or skin colonization. Bacteria seed the blood stream by damaging the local mucosa and are then transported to the vasculature surrounding the central nervous system (CNS). Organisms are thought to breach the blood–brain barrier through microbial interactions with host receptors, though the exact mechanism is still unclear. Infection subsequently spreads across the pia, arachnoid, and subarachnoid spaces. Once inside the CNS, pathogens are more likely to proliferate because of limited host defenses in the CNS. The subsequent inflammatory cascade that follows bacterial infiltration leads to the characteristic clinical symptoms of meningitis. Other rarer forms of CNS seeding are through retrograde neuronal spread and direct extension from a local infection.

History and Clinical Manifestations

Recognizing the signs and symptoms of meningitis is crucial; delays in treatment worsen outcomes. *Table 69.2* provides a list of important historical information when a diagnosis of meningitis is being considered.

Acutely, bacteremia can manifest as septic shock and cardiovascular instability. Patients with meningitis, particularly meningococcal meningitis, can have fulminant and rapidly progressive disseminated intravascular coagulation (DIC) characterized by petechiae and purpura. An initial bacteremia leads to meningeal seeding which causes an inflammatory reaction. Inflammation of spinal nerves causes neck pain and stiffness (meningismus) and is demonstrated using the Kernig and Brudzinski maneuvers. The Kernig sign is elicited by flexing the hips and extending the knees to elicit pain in the back and neck. The Brudzinski sign involves flexing the neck and eliciting involuntary flexion in the hips. The absence of meningeal signs lowers the likelihood of meningitis but can be absent in younger children. Importantly, the absence of fever does not rule out meningitis.

Clinical presentation in young infants differs in comparison to older children. Neonates and infants will often present with nonfocal symptoms such as irritability, temperature instability, jaundice, and poor feeding. Older children are better able to localize symptoms such as photophobia, and neck pain, and can display focal neurological findings and meningismus on examination. Occasionally, meningeal inflammation results in an increased intracranial pressure (ICP) which is a clinical emergency. Increased ICP can manifest as changes in consciousness, papilledema, diplopia, emesis, a bulging fontanelle, seizures and, in the late stages, Cushing's triad (hypertension, bradycardia, and hypopnea). Seizures from cerebritis, infarction, or electrolyte imbalances occur in up to 30% of patients with meningitis.

Tuberculous meningitis usually stems from a caseous lesion in the meninges or cortex that developed following lymphohematogenous seeding. Infection usually involves the brainstem and often presents with palsies of cranial nerves III, VI, or VII. Hydrocephalus and SIADH are common complications. Tuberculous meningitis typically progresses through three stages, and this progression of disease may be rapid, as is often seen in young children, or gradual. The first stage develops over 1–2 weeks and is characterized by general malaise and loss of developmental milestones. The second stage involves the more abrupt onset of neurological signs, including cranial nerve palsies, hypertonia, meningismus, emesis, and lethargy. The third stage is characterized by coma, paraplegia, decerebrate posturing, and death. Clinical outcome correlates to the

Table 69.2
Important historical information when considering a meningitis diagnosis

Neonates	All children
Maternal infection Maternal HSV status Prolonged rupture of membranes Prematurity	Chronic illness Recent illness Sickle cell disease Immunocompromised states (HIV, cancer, immunosuppressive agents) Cardiac disease Renal disease (especially nephritic syndrome) Diabetes mellitus Asplenia Central nervous system shunts Cochlear implants Immunization history Medication history (including IVIG, NSAIDS, and antibiotics) Ethnicity (specifically Alaska Natives and American Indian) Travel to endemic regions

HSV herpes simplex virus, *HIV* human immunodeficiency virus, *IVIG* intravenous immunoglobulin, *NSAIDS* nonsteroidal anti-inflammatory drugs

stage during which treatment in initiated, making early recognition essential. See Chap. 95, "Tuberculosis" for a more thorough discussion of *M. tuberculosis*.

Lyme meningitis often presents as cranial nerve palsies (particularly cranial nerve VII) with a lymphocytic basilar meningitis. Incidence is highest in the summer months and typically affects children between 5 and 9 years old. Compared to other causes of bacterial meningitis, Lyme meningitis typically has a less acute onset and progression. See Chap. 84, "Lyme Disease".

Viral meningitis usually presents as a nonspecific febrile illness, and while its clinical symptoms are generally less severe than those of bacterial meningitis, at times the symptoms can be indistinguishable from those of bacterial meningitis. Oftentimes, aseptic meningitis cannot therefore reliably be distinguished from bacterial meningitis on clinical exam alone, and further testing needs to be performed.

A third of neonatal HSV manifests as CNS disease and 60% of neonates with HSV meningitis will have skin lesions. Frequently, however, no maternal clinical evidence of HSV is present. HSV neonatal meningitis usually occurs within the first 6 weeks of life and can be a severe or fatal illness with CNS sequelae. In neonates, HSV meningitis can progress to encephalitis, which has a mortality rate of 75% in untreated infants. See Chap. 108, "Herpes Simplex Virus Infections" for more detail.

Diagnosis

Diagnosis of bacterial meningitis requires a lumbar puncture. Cerebrospinal fluid (CSF) should be sent for culture, and between 70% and 85% of CSF cultures are positive in non-pretreated patients. Analysis of the CSF should also include Gram stain and measurements of the cell count, glucose, and protein, as these measures can help to determine the etiology of meningitis while awaiting culture results. Interpretation of CSF findings in children can be challenging, however, given that CSF findings vary with age, particularly in neonates (*Table 69.3*). Slight elevations in white blood cell (WBC) count and elevations in protein can be normal in neonates.

The results of CSF analysis can indicate the most likely pathogens, with different typical profiles for bacterial, viral, Lyme, and tuberculous meningitis (*Table 69.4*). In general, children with bacterial meningitis have significantly elevated CSF leukocyte counts (pleocytosis) with a neutrophilic predominance, while children with viral or tuberculous meningitis have a lesser elevation in CSF WBC counts and a lymphocytic predominance. Glucose concentrations tend to be lower and protein concentrations higher in bacterial meningitis. The values in *Table 69.4* are general guidelines to assist with the interpretation of CSF values.

Occasionally, CSF can only be obtained following initiation of empiric antibiotics. Studies suggest that *N. meningitidis* is cleared from the CSF within 2–6 h of antibiotic administration, and *S. pneumoniae* within 4 h. However, no reliable data are available regarding CSF interpretation following antibiotic administration; consider consultation with an infectious diseases expert for assistance in interpreting CSF results obtained after antibiotic administration.

Differential Diagnosis

Signs and symptoms of infectious meningitis are often difficult to distinguish from other noninfectious causes of meningitis. Noninfectious meningitis, although rare, must be considered in the differential diagnosis. There are reported cases of drug-induced meningitis, particularly from nonsteroidal anti-inflammatory drugs, trimethoprim-sulfamethoxazole, intravenous immunoglobulin and the immunosuppressant OKT3. Autoimmune illnesses such as systemic lupus erythematosus and Kawasaki disease can also cause the symptoms of aseptic meningitis.

Table 69.3
Normal cerebrospinal fluid findings in healthy children

Age	WBC Count (cells/mm^3)	Protein (mg/dL)	Glucose (mg/dL)	Opening pressure (cmH_2O)
0–28 days	9 (0–19)	<115	>50 (or >75% of serum glucose)	5–10
29–56 days	3 (0–9)	<89	>50 (or >75% of serum glucose)	5–10
Children and adolescents	0–10	15–45	>50 (or >75% of serum glucose)	5–10

Table 69.4
Typical cerebrospinal fluid analysis by selected causes of meningitis

	WBC count (cells/mm^3)	Glucose (mg/dL)	Protein (g/L)	Opening pressure (cmH_2O)
Bacterial meningitis	>100 with a neutrophil predominance	<40 (or a CSF to serum ratio $\leq$ 0.4)	>100	>20
Viral meningitis	5–50 with a mononuclear predominance	normal	50–100	<20
Lyme meningitis	10–50 with a mononuclear predominance	10–45	50–150	<20
Tuberculous meningitis	10–50 with a mononuclear predominance	10–45	>100 (typically extremely elevated)	>20

Note: Children with a CSF WBC > 9 cells/mm^3 are thought to be at higher risk for having meningitis, although typical WBC counts in meningitis are higher

Many of the findings of meningitis, including an increased ICP, can also be caused by encephalitis, cerebral mass lesions, intracranial abscesses, epidural abscesses, strokes, and hydrocephalus. Neurologic changes can stem from a multitude of afflictions, including sepsis, toxic ingestions, seizures, and physical trauma.

Treatment

Bacterial meningitis is a clinical emergency that requires prompt, empiric treatment, without which mortality rates approach 100%. A suggested flowchart for the approach to the patient with suspected bacterial meningitis is presented in *Fig. 69.1*.

Antibiotics must be chosen based on pathogen probability (which is often dictated by age, clinical findings, and geographic location) and ability to attain bactericidal activity in the CSF. In neonates, conventional treatment includes ampicillin and cefotaxime to provide coverage against the most common pathogens in this age group. In children older than 1 month of age, treatment should include vancomycin plus a third generation cephalosporin to provide empiric treatment against resistant *S. pneumoniae* until culture results are available. Multidrug resistant *S. pneumoniae* is thought to account for approximately 30% of all cases of pneumococcal meningitis; this resistance pattern profile mandates that empiric treatment include antimicrobial agents that target resistant isolates of *S. pneumoniae*.

Once a bacterial pathogen is identified, antimicrobial treatment can be narrowed and tailored to the organism (*Table 69.5*). Individual patient treatment will vary based on organism susceptibilities. Typical first-line treatment selections are presented in *Table 69.6*. Typical treatment duration by pathogen is presented in *Fig. 69.1*. Repeat lumbar puncture after 24–48 h of antimicrobial therapy should be considered for patients with persistent symptoms or a known highly resistant isolate. Consultation with an infectious diseases expert should be sought for persistent symptoms despite appropriate antimicrobial therapy or persistently positive CSF cultures.

Treatment with dexamethasone is recommended in children older than 6 weeks with *H. influenzae* meningitis. Some studies suggest that dexamethasone may also curb the severity of hearing loss in *S. pneumoniae* bacterial meningitis if administered before the first dose of antibiotics, but the evidence is less clear and expert opinions vary.

Acyclovir is the drug of choice for neonatal HSV meningitis, dosed at 60 mg/kg/day divided every 8 h. Typical treatment duration is for at least 21 days; see Chap. 108, "Herpes Simplex Virus Infections", for more detail. The majority of other causes of viral meningitis, including enterovirus, are self-limited, and no treatment is recommended.

Cryptococcal meningitis is typically treated with Amphotericin B and flucytosine; consultation with an infectious diseases specialist is recommended.

Prognosis

Overall morbidity and mortality has significantly decreased since the introduction of HiB, pneumococcal, and meningococcal vaccines. However, survival rates for those who acquire bacterial meningitis have not changed in the last 15 years. The mortality rate is approximately 5–10%, with death being more likely in patients who

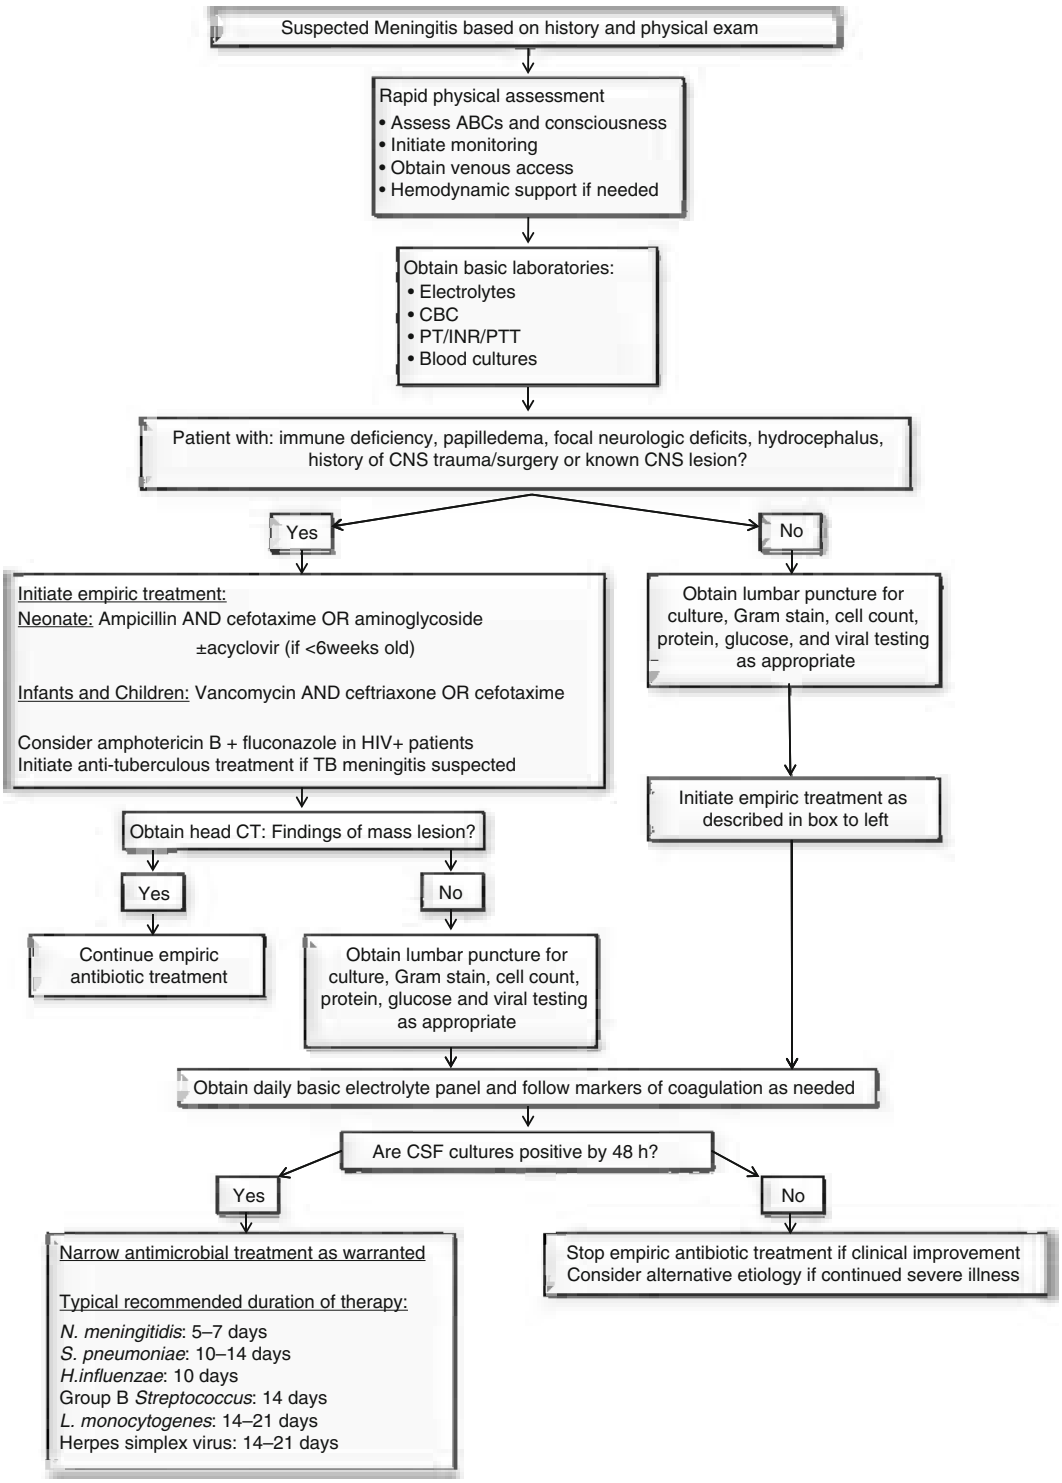

Figure 69.1

Recommended acute management of suspected meningitis. *CBC* complete blood count, *CNS* central nervous system, *CSF* cerebrospinal fluid, *HIV* Human immunodeficiency virus, *INR* international normalized ratio, *PT* prothrombin time, *PTT* partial thromboplastin time, *TB* tuberculosis

Table 69.5
Recommended empiric meningitis treatment by age group

Age group	Likely pathogen	Empiric treatment
Neonates (<28 days)	GBS, *E. coli, L. monocytogenes, Klebsiella* sp., HSV	Ampicillin + Cefotaxime or Aminoglycoside ± Acyclovir
Infants (1–23 months)	GBS, *E. coli, S. pneumoniae, N. meningitidis, H. influenzae*	Vancomycin + third generation cephalosporin[a]
Children and adults (2–50 years)	*S. pneumoniae, N. meningitidis, H. influenzae*	Vancomycin + third generation cephalosporin[a]
Adults >50 years	*S. pneumoniae, N. meningitidis, H. influenzae, L. monocytogenes,* aerobic gram-negative bacilli	Vancomycin + ampicillin + third generation cephalosporin[a]
Those with shunt devices or surgical intervention	*Staphylococcus aureus*, Coagulase-negative *Staphylococci, Propionibacterium acnes*, *P. aeruginosa*	Vancomycin + Cefepime or Meropenem
Those with compromised cellular immunity	*L. monocytogenes,* gram-negative enteric bacilli, *P. aeruginosa*	Vancomycin + Cefepime or Meropenem

GBS group B *Streptococcus*, *HSV* herpes simplex virus
[a]Ceftriaxone or cefotaxime

Table 69.6
Typical first-line treatment by causative organism

Microorganism	Typically recommended treatment
N. meningitidis	Penicillin G or Ampicillin
S. pneumoniae (Penicillin susceptible)	Penicillin G or Ampicillin or third generation cephalosporin[a]
S. pneumoniae (Penicillin-resistant)	Vancomycin + third generation cephalosporin[a]
H. influenzae	Third generation cephalosporin[a]
S. agalactiae (GBS)	Penicillin G or Ampicillin
L. monocytogenes	Penicillin G or Ampicillin
E. coli	Third generation cephalosporin[a]
P. aeruginosa	Cefepime or Ceftazidime ± Aminoglycoside
S. aureus (Methicillin susceptible)	Nafcillin or Oxacillin
S. aureus (Methicillin resistant)	Vancomycin
Enterococcus sp.	Ampicillin or Vancomycin + Gentamicin

[a]Ceftriaxone or cefotaxime

present with coma, prolonged seizures, shock, severe respiratory distress, a low peripheral WBC count, or a high CSF protein level. Those presenting with focal seizures are more likely to have adverse neurological outcomes. Young age, male gender, symptoms lasting greater than 48 h prior to admission, persistent fever (>7 days), delayed CSF clearance, and absence of petechiae also predict worse outcomes. It is likely that the absence of petechiae is related to the causative pathogen; petechiae are more common with *N. meningitidis* infection which, if treated, has better outcomes than *S. pneumoniae* meningitis. Penicillin-resistant *S. pneumoniae* is associated with poorer outcomes.

Morbidity following bacterial meningitis is approximately 15% and primarily consists of neurologic deficits, including hearing loss, hemiparesis, quadriparesis, facial nerve palsies, visual field defects, and developmental delays. Five percent to 30% of patients experience hearing loss, with a higher likelihood in patients infected with *S. pneumoniae* or with low CSF glucose levels. Other neurologic sequelae are more likely in patients with coma, seizures, fever greater than 7 days, and a low CSF-WBC count.

Prevention

Vaccines

The introduction of the pneumococcal, meningococcal, and HiB vaccines has led to a significant reduction in the number of bacterial meningitis infections and has changed meningitis epidemiology. However, these vaccines are not available in many developing countries where these three pathogens continue to cause significant disease burden.

The incidence of HiB meningitis in the United States has decreased by 94% since the introduction of the HiB conjugate vaccine in 1990. The HiB vaccine is administered as a 4-dose series at ages 2, 4, 6, and 12–15 months. Prior to its licensure, HiB accounted for approximately 45% of acute bacterial meningitis cases. Although there are occasional nontypable *H. influenzae* meningeal infections, HiB is now an uncommon pathogen.

The heptavalent pneumococcal conjugate vaccine (PCV7) was introduced in 2000 and included the seven serotypes that caused 83% of pneumococcal disease at that time. Since its introduction, the rates of pneumococcal meningitis have declined by approximately 30% overall, with the largest decrease (64% between 1998 and 2005) in children less than 2 years old. Although the overall rates of meningitis have decreased, the incidence of pneumococcal meningitis caused by serotypes not included in the vaccine (non-PCV7-serotypes) has increased by 60%. The introduction of PCV7 has also correlated with a decrease in antibiotic-resistant pneumococcal disease. In 2010, PCV7 was replaced by a 13-valent pneumococcal conjugate vaccine (PCV13), which is also administered as a four-dose series at ages 2, 4, 6, and 12–15 months. The impact of this vaccine has yet to be determined.

Since the introduction of the HiB and pneumococcal vaccines, *N. meningitidis* has emerged as the most common cause of meningitis in children greater than 2 years old in the United States. The conjugate meningococcal vaccine (MCV4) includes four common meningococcal serogroups (A, C, Y, and W-135) and was licensed in 2005. Most meningococcal disease is caused by these four strains. However, more than 50% of disease in younger children is caused by serogroup B, a serogroup not included in the vaccine. A new conjugate meningococcal vaccine against serogroup A was introduced to sub-Saharan Africa in late 2010, with a goal of widespread immunization to prevent *N. meningitidis* serogroup A epidemics in the Sub-Saharan "meningitis belt."

Since the introduction of these vaccines, the median age of patients with bacterial meningitis has increased from 15 months of age to 39 years of age between 1986 and 2003. The number of cases per year has also decreased from 12,920 to 4,450.

Chemoprophylaxis

Chemoprophylaxis is indicated for those exposed to patients with meningitis caused by HiB and *N. meningitidis*. Chemoprophylaxis is recommended for all household contacts exposed to HiB when there is an unvaccinated contact younger than 4 years old or a child younger than 12 months in the household. It is also recommended for childcare attendants when there are two or more cases occurring within 60 days at that facility. Four days of oral rifampin is the recommended chemoprophylaxis.

In cases of *N. meningitidis* meningitis, all household contacts, all daycare contacts present for 7 days before the onset of the illness, and those exposed to the patient's secretions should be treated with chemoprophylaxis. Recommended treatment is usually rifampin for 2 days, but ceftriaxone, ciprofloxacin, and azithromycin can also be used.

70 Otitis Media

Marah Gotcsik

Definition/Classification

Otitis media is inflammation of the middle ear. Dependent upon presentation, associated symptoms, and duration of symptoms, the diagnosis can be further classified as follows:

Acute otitis media (AOM) is infection of the middle ear with acute onset, middle-ear effusion (MEE) on exam, and presence of signs and symptoms of middle-ear inflammation. *Treatment failure AOM* is defined by lack of improvement despite 48–72 h of appropriate antibiotic therapy. Diagnosis of *Recurrent AOM* requires three or more episodes in 6 months or four or more episodes in 12 months.

Otitis media with effusion (OME) is middle-ear effusion without signs or symptoms of active infection. *Chronic OME* (COME) is when this effusion persists for more than 3 months.

Chronic suppurative otitis media (CSOM) is chronic inflammation of the middle ear and mastoid cavity presenting with otorrhea through a perforated tympanic membrane. The World Health Organization definition requires 2 weeks of otorrhea for diagnosis, whereas others have suggested 6 weeks of symptoms as a diagnostic requirement.

Epidemiology

Otitis media is one of the most common pediatric diagnoses worldwide, and the prevalence may be increasing: United States surveillance data by the Centers for Disease Control showed a 150% increase to 24.5 million office visits per year with a principal diagnosis of otitis media from 1975 to 1990. At least 70% of children have at least one episode of AOM before 2 years of age, and AOM is the most common reason for antibiotic prescription for children in the United States.

Approximately 90% of children are diagnosed with OME before school age. Most episodes resolve spontaneously, but 30–40% of children have recurrent OME and 5–10% of episodes last 1 year or longer.

Numerous host and environmental risk factors have been studied in association with AOM and OME (see *Table 70.1*). The significance of genetic predisposition to the development of otitis media has been demonstrated with twin studies showing heritability as high as 70%. Studies have examined race and likelihood of developing otitis media without clear consensus.

CSOM, though rare in the developed world, remains a major cause of morbidity and mortality in the developing world and within certain racial groups. Unfortunately, the lack of consensus definition and variability in methods makes meta-analysis studies difficult. The highest prevalence of CSOM is in Alaska Native, Native Greenland, Native American, and Australian Aborigine children (prevalence 7–46%). Children in the South Pacific Islands, Africa, Korea, India, and Saudi Arabia have a relatively high prevalence of 1–6% with some subregions being more affected than others. Highly developed countries, such as the US and UK, have the lowest prevalence at $<1\%$.

Recurrent AOM is associated with development of CSOM, suggesting similar risk factors for both disease processes. In the antibiotic era, rates of CSOM have decreased, further supporting a link between nontreatment and progression to chronic disease. Additional identified risk factors include inadequate antibiotic treatment, frequent upper respiratory tract infections, nasal disease, and poor living conditions with poor access to medical care. It is encouraging that with intervention in these identified areas there can be a direct impact on health; one study targeting improvements in housing, hygiene, and nutrition resulted in a 50% decrease in CSOM in Maori children.

Pathogenesis

Development of otitis media is strongly associated with impairment of the structure and function of the eustachian tube. At baseline, the middle-ear space maintains a negative air pressure relative to the environment. This pressure is periodically relieved by opening the eustachian tube, for example, in the setting of yawning and chewing. If this pressure equalization cannot be achieved, inflammation can occur resulting in otitis media.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_70,

Table 70.1
Risk factors for development of otitis media

Host factors	Environmental factors
Age <2 year	Bottle propping
Atopy	Child care attendance
Chronic sinusitis	Crowding in housing
Ciliary dysfunction	Low socioeconomic status
Cleft palate/Craniofacial anomalies	Non-breast feeding in infancy
Immunocompromise	Passive smoke exposure
Male sex	Winter season (respiratory virus exposure)
Trisomy 21	

Craniofacial anomalies with distortion of ear and eustachian tube anatomy are an obvious cause of eustachian tube dysfunction. However, normal pediatric anatomy is also associated with impairment of pressure equalization. In infants and children, the eustachian tube can be as short as half the length of the adult eustachian tube and is comprised of highly compliant cartilage positioned at a near horizontal angle (as opposed to the adult eustachian tube which is more firm and lies in a 45° angle in relation to the axial plane). The characteristics of the pediatric eustachian tube compromise the ability to effectively ventilate the middle ear. Inflammation due to upper respiratory tract infections (URI), allergic rhinitis, and gastro-esophageal reflux further impairs eustachian tube function. Additionally, nasopharyngeal secretions can reflux or be insufflated into the middle-ear space, serving as nidus for infection.

Both bacteria and viruses have been implicated in otitis media. AOM and OME have similar associated pathogens, whereas CSOM is has a distinct microbial profile (*Table 70.2*).

Upper respiratory tract infections are important in the pathogenesis of AOM. AOM has been identified as a complication of 37% of URIs in children, as high as 50% with coronavirus, respiratory syncytial virus (RSV), and adenovirus infection, and as high as 60% in human metapneumovirus infection.

In studies examining middle-ear fluid in patients with AOM, viruses are isolated 20–50% of the time, alone or together with bacterial otopathogens. The most frequently isolated virus types from middle-ear fluid are RSV, parainfluenza, and influenza (A and B).

Bacteria are isolated from middle-ear fluid in AOM 50–90% of the time. Historically, the most common bacteria associated with otitis media is *Streptococcus pneumoniae*. Following introduction of PCV7, vaccine serotypes of *S. pneumoniae* have been nearly completely eliminated, with *Haemophilus influenzae* becoming more prevalent. As with other *S. pneumoniae* infections, there is some evidence that non-vaccine serotypes are increasing to fill this niche – including identification of a multidrug resistant serotype 19A. The introduction of the 13-valent pneumococcal vaccine (PCV13) in 2010 will undoubtedly be associated with further changes in the bacterial otopathogens of AOM.

Development of OME is also associated with URI. URI can lead to OME nearly one quarter of the time, with a slightly higher incidence in the setting of influenza. Middle-ear fluid in COME was previously thought to be sterile based on culture results. However, the advent of PCR technology has allowed identification of bacterial DNA and mRNA in culture-negative middle-ear fluid. One hypothesis for this finding is the presence of biofilms – aggregated bacteria growing on a surface, surrounded by an extracellular matrix. Supporting this hypothesis are recent studies with visualization of biofilm on microscopy during placement of tympanostomy tubes in patients with COME.

Although CSOM is associated with recurrent AOM, the associated bacterial pathogens are different. Bacteria can reach the middle ear via the eustachian tube or via the external ear through the perforated tympanic membrane. There is wide variability in the prevalence of the pathogens; however, *Pseudomonas aeruginosa* is the most common, isolated from 18% to 67% of ear cultures. *P. aeruginosa* is implicated in the progressive destruction of middle-ear and mastoid structures. Unlike AOM and OME, fungi are a common pathogen, isolated from 50% of ear cultures from populations in hot, humid regions. Biofilms are also gaining attention as a possible cause for chronic infection in CSOM.

Pathology

The bony structures of the ear, the inner ear mucosa, and the tympanic membrane can readily heal from acute infection – including acute infection with perforation – without long term disability. In children with history of otitis media, tympanic membrane abnormalities present at 8 years of age nearly completely resolve by 18 years of age.

CSOM can result in damage of the typmanic membrane, the ossicles, and the mastoid space leading to osteoneogenesis, bony erosions, and osteitis of the temporal bones and ossicles.

Table 70.2
Pathogens identified by culture or PCR in middle-ear fluid of patients with AOM, OME, and CSOM

	AOM	OME	CSOM
Bacteria	*Streptococcus pneumoniae*	*Streptococcus pneumoniae*	Aerobic
	Haemophilus influenzae	*Haemophilus influenzae*	*Pseudomonas aeruginosa*
	Moraxella catarrhalis	*Moraxella catarrhalis*	*Staphylococcus aureus*
	Streptococcus pyogenes		*Escherichia coli*
	Staphylococcus aureus		*Proteus mirabilis*
	Streptococcus agalactiae (neonates)		*Klebsiella* species
	Gram negative bacilli (neonates)		*Haemophilus influenzae*
			Anaerobic
			Bacteroides
			Fusobacterium
Viruses	Respiratory syncytial virus	Rhinovirus	
	Influenza	Respiratory syncytial virus	
	Adenovirus	Coronavirus	
	Parainfluenza		
	Rhinovirus		
	Coronavirus		
Fungi			*Aspergillus* species
			Candida species

Clinical Manifestations

Acute Otitis Media

Specific signs and symptoms: Otalgia is the most common complaint in children with AOM. Although not a sensitive marker of disease, it does have a high positive predictive value for presence of infection. Other specific signs are otorrhea following acute tympanic membrane perforation, hearing loss, vertigo, nystagmus, and tinnitus. Ear swelling and facial paralysis are signs that may suggest a more invasive process within the mastoid space or the temporal bone, respectively.

Nonspecific signs and symptoms: Fever is present in one third to two thirds of patients with AOM, although fever $>40^{\circ}$ may suggest bacteremia or alternate focal infection. Additional nonspecific symptoms are irritability, headache, anorexia, vomiting, and diarrhea.

Otitis Media with Effusion

OME, by definition, has minimal symptoms, with mild hearing loss being the most common complaint. Symptoms of an underlying process resulting in oropharyngeal inflammation (URI, allergic rhinitis, gastro-esophageal reflux) may be present.

Chronic Suppurative Otitis Media

Patients with CSOM present with chronic otorrhea and may also have significant hearing loss. Conductive hearing loss of 20–60 dB may be present due to tympanic membrane perforation and damage to the ossicles. Sensorineural hearing loss may also occur in CSOM in association with loss of cochlear hair cells due to inflammation.

Diagnosis

Proper diagnosis of otitis media is imperative, especially in the era of increasing antibiotic resistance. Unlike other disease processes, otitis media remains a clinical diagnosis based on history and physical exam with pneumatic otoscopy.

Assessment of the tympanic membrane (TM) should include color, translucency, position, and mobility. A normal TM has a ground glass appearance, is translucent with

clear visualization of the bony landmarks, and has good movement with pneumatic otoscopy.

Proper equipment is paramount to adequate visualization of the TM. The best light source is a halogen bulb with at least 100 ft-candles and a well-charged battery. Speculum choice is also important. When available, reusable specula are preferable because of their length, size options, and glossy finish which facilitates light transmission into the ear canal. In choosing a speculum, the largest lumen possible that can comfortably fit into the cartilaginous portion of the canal should be selected. Small speculums not only limit the field of view, but may pass into the bony portion of the canal resulting in pain.

Visualization alone can provide clues to the presence of effusion but is not adequate for diagnosis. Pneumatic otoscopy is highly sensitive and specific for the presence of middle ear effusion. Pneumatic otoscopy is a multistep procedure designed to assess the TM response to both positive and negative pressure. The speculum is inserted into the ear with the no pressure on the bulb. Slight pressure is applied to the bulb to create positive pressure. Next, the seal is momentarily broken to allow for neutralization of pressure. Finally, the bulb is released to create negative pressure. It is important to realize that a normal eardrum will move with 10–15 mm H_2O, whereas a pneumatic otoscope can deliver as much as 1,000 mm H_2O when the bulb is fully depressed.

Tympanometry may be used as an adjunct to pneumatic otoscopy if available. With a tympanometer, the compliance of the TM is assessed by the reflection of sound waves off the TM (*Fig. 70.1*).

Acute Otitis Media

Although AOM is a common pediatric problem throughout the world, development of international diagnostic criteria has proved challenging. Previous definitions have been too broad, without clear distinction between AOM and OME. This lack of consensus has limited the ability to study diagnosis and treatment practices.

In 2004, the American Academy of Pediatrics (AAP) and American Academy of Family Practice (AAFP) published clinical practice guidelines on diagnosis of acute otitis media with more specific criteria:

1. History of acute onset of signs and symptoms
2. Presence of MEE (bulging TM, limited or absent mobility of the TM, an air-fluid level behind the TM, or otorrhea)
3. Signs and symptoms of middle-ear inflammation (direct erythema of the TM, bullous myringitis, and distinct otalgia)

Otitis Media with Effusion

The commonly accepted diagnostic criteria for OME are:

1. Presence of MEE
2. No signs or symptoms of AOM

The 2004 AAP, AAFP, and American Academy of Otolaryngology – Head and Neck Surgery clinical practice guidelines strongly recommended that pneumatic

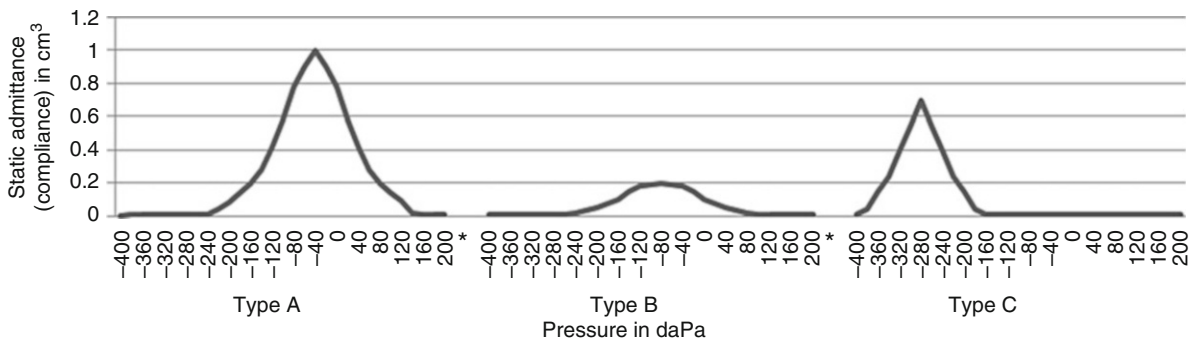

Figure 70.1

Examples of tympanometry curves Type A: Normal TM compliance. Type B: Poor compliance of TM with limited to no movement, in extreme cases can be flat. Type B curves are strongly associated with MEE. Type B curves can also be found with TM perforation in the setting of high measured volume. Type C: Decreased amplitude of compliance and shifted to the left, suggesting increased negative pressure in the middle ear. Type C curves are not diagnostic of middle-ear effusion

otoscopy should be used as the primary diagnostic method for OME to assess for MEE, based on grade A evidence.

Chronic Suppurative Otitis Media

The World Health Organization (WHO) diagnostic criteria of CSOM are:

1. Tympanic membrane perforation
2. Purulent otorrhea present continuously for at least two weeks

Treatment

Acute Otitis Media

In the developed world, there is large variation in practice of antibiotic prescription for AOM. In the setting of increasing antibiotic resistance, management practices for AOM have been reevaluated with emphasis on limiting antibiotic usage when possible. If left untreated, 61% of patients with AOM will have resolution of symptoms within 24 h, improving to 80% within 2–3 days. There is no significant difference in the incidence of suppurative complications, including mastoiditis, if antibiotics are initially withheld. This has led to a trend of expectant management with emphasis on pain control at the initial diagnosis of AOM. In certain groups with a high burden of disease, such as Australian Aborigines, national guidelines continue to support initiation of treatment at presentation. Rural populations may also not be appropriate for initial observation as close follow-up must be possible if a patient is not receiving antibiotics.

Numerous countries have adopted guidelines supporting a watch-and-wait approach to AOM, including the Netherlands, where there is the lowest rate of antibiotic prescription for AOM. The 2004 AAP guidelines stratify treatment by age and certainty of diagnosis. In otherwise healthy children with certain diagnosis, children under two years of age receive treatment, whereas those children greater that two years of age without significant ear pain or fever can be observed with follow-up. In cases of uncertain diagnosis, treatment is only recommended in children less than six months of age or if the child is six months to two years of age with significant ear pain or fever.

General Care

Supportive care is an important part of AOM management, including pain and fever control. There is no evidence for the use of antihistamines or decongestants in treatments of AOM.

Specific Treatment

Antibiotic choice in AOM is focused on medications with efficacy against *S. pneumoniae, H. influenzae,* and *Moraxella catarrhalis.*

First Line Therapy

Amoxicillin is widely accepted as first line therapy for non-penicillin allergic patients. However, the dosage and duration of treatment is highly variable. The Dutch College of General Practitioner Guidelines support lower dose therapy 30 mg/kg/day amoxicillin as compared to the AAP recommendations of 80–90 mg/kg/day. The rationale for higher dosing includes increased drug concentration in the middle ear and for the treatment of resistant strains of *S. pneumoniae*. In cases with fever >39 C or severe otalgia, the AAP recommends amoxicillin-clavulanic acid as first line therapy because of the potassium clavulanate's ability to inhibit B-lactamase-produced by many *H. influenzae* and *M. catarrhalis.*

In penicillin allergic patients there is less consensus, and recommendations include cephalosporins (cefdinir, cefuroxime, cefpodoxime, ceftriaxone), macrolides (azithromycin, clarithromycin, erythromycin), and sulfonamides (co-trimoxazole).

Treatment Failure Therapy

In cases of treatment failure, the AAP recommends amoxicillin-clavulanic acid, ceftriaxone, or clindamycin dependent on severity and if allergy to penicillin is present. The India-WHO Collaborative Programme also recommends amoxicillin-clavulanic acid as well as cefaclor.

Although tympanocentesis can be used in severe cases of treatment failure AOM, placement of tympanostomy tubes is reserved for children with recurrent otitis media. For children with tympanostomy tubes, AOM manifesting with otorrhea can be treated with ofloxacin otic solution or ciprofloxacin-dexamethasone otic solution.

Duration of Treatment

The recommended duration is also variable. The previous accepted duration of therapy for AOM was 10 days. Although this recommendation remains for younger children, children older than five years have demonstrated successful therapy with five to seven days of antibiotics. Older children may also be successfully treated with 1–5 days of azithromycin or 1–3 days of intramuscular ceftriaxone.

Future Development

As more national guidelines are endorsing the watch-and-wait approach to AOM, antibiotic prescribing patterns and development of complications must be monitored closely.

Otitis Media with Effusion

General Care

Just as with AOM, the rate of spontaneous resolution in OME is high. Of children with OME developing following AOM, 75% have spontaneous resolution of MEE in 3 months. Of children with incidentally identified OME, 42% have resolution within 6 months with 72% showing improvement in tympanometry curves at that time. Therefore, the watch-and-wait approach is also prudent in OME.

During this period of observation, hearing assessment every 3–6 months in addition to otoscopic evaluation with pneumatic otoscopy is important for ongoing surveillance. Asymptomatic effusions can be managed conservatively without intervention.

Specific Treatment

There is no clear role for medications in treatment of OME. Antihistamines and decongestants are not indicated for treatment. Antibiotics and corticosteroids have not been shown to have lasting effect. In children with persistent effusion lasting more than 4 months complicated by hearing loss, developmental delay (or risk for developmental delay), damage to the tympanic membrane, or otalgia or balance problems, tympanostomy tube placement may be indicated to remove the middle-ear effusion.

Future Development

Development of widely accepted and followed consensus guidelines may allow for further understanding of observation and management of OME.

Chronic Suppurative Otitis Media

The hallmarks of management of CSOM are treatment of the infection and closure of the tympanic membrane.

Mastoidectomy with tympanoplasty is curative, but there is limited access to tertiary centers offering these services for many of the children who are most affected. If the infection has spread deep into the middle ear, there is diffuse mucosal disease, or cholesteatoma has developed, the patient will likely be refractory to medical therapy alone. For patients without evidence of suppurative complication, the WHO has created a conservative medical management algorithm focused on aural toilet in conjunction with antibiotic treatment. Topical treatment has been shown to be superior to systemic therapy as well as being more cost-effective. Neomycin-polymyxin is recommended as first line therapy, with transition to quinolones, such as ofloxacin or ciprofloxacin, or gentamicin if drainage persists 2 weeks and ear culture is positive for *Pseudomonas*. If the drainage resolves on this regimen, the patient must then be followed for closure of the tympanic membrane. If the perforation persists, tympanoplasty can be performed with goal to restore hearing. If the perforation persists and otorrhea recurs, mastoidectomy is indicated.

Prognosis

In general, prognosis following an episode of otitis media is good. However, suspicion should be maintained for the many complications that can develop, most associated with local spread of infection.

Intratemporal Complications

Hearing loss is the most prevalent complication of otitis media. Conductive hearing loss is most commonly due to MEE and, less frequently, atelectasis of the middle ear due to high negative pressures. Average hearing loss is 20–30 dB, with a range of 0–60 dB. Sensorineural hearing loss can also be present due to increased tension on the round window membrane and inflammation of the cochlear hair cells. Hearing loss in CSOM is more severe than in AOM

and OME. Hearing loss may be associated with impaired development of speech and language with resultant poor school performance.

Tympanic membrane perforation can occur in AOM and OME. The TM usually heals within 2–3 months. For chronic perforations, lasting longer than 3 months, tympanoplasty is indicated.

Mastoiditis, although decreasing incidence in the antibiotic era, is the most common suppurative complication of otitis media. As the mastoid gas cell system is connected to the middle ear, all episodes of otitis media likely result in some degree of mastoiditis. If the infection spreads to the periosteum, mastoiditis with periosteitis develops. Presenting signs are fever, otalgia, postauricular erythema and mild tenderness, and possible anterior/inferior displacement of the pinna. The most severe form of mastoiditis occurs when infection spreads from the periosteum into the bone resulting in osteitis with potential for development of subperiosteal abscess. In mastoiditis with osteitis, postauricular erythema and tenderness are more pronounced, and the pinna is clearly displaced anteriorly and inferiorly. CT scan can be used to assess the extent of disease. Mastoiditis with periosteitis can be treated with parenteral antibiotics, tympanocentesis, and myringotomy. Mastoiditis with osteitis additionally requires mastoidectomy.

Cholesteatoma is a cystic mass of keratinized squamous cell epithelium and cholesterol in the middle ear. Cholesteatoma can be congenital or acquired, with acquired disease associated with chronic otitis media. Implantation cholesteatoma can develop following traumatic perforation of the TM or as a complication of ear surgery. In children, the most common location of cholesteatoma is the posterosuperior quadrant of the pars tensa. On otoscopy, a defect in the TM may be visualized with white greasy flakes of debris and sometimes foul smelling drainage. Findings on otoscopy can be subtle or difficult to visualize, making CT scan a useful diagnostic tool when there is high suspicion of disease. The squamous epithelium can extend inward, creating an expanding cystic cavity that causes progressive erosion of the ossicle, the mastoid space, and the temporal bone. Therefore, prompt surgical management is indicated.

Tympanosclerosis can occur with chronic middle-ear inflammation or as the result of trauma to the TM, including tympanostomy tube placement. On otoscopy, whitish plaques are visualized on the TM. Nodular deposits in the submucosal layers of the middle ear are also present. Conductive hearing loss can result if the ossicles become embedded in these deposits.

Suppurative labyrinthitis is a rare complication of AOM and OME, but can be seen in CSOM. The affected child presents with sudden onset of vertigo, nausea/vomiting, disequilibrium, and severe sensorineural hearing loss.

Facial paralysis can occur as a complication of AOM due to the facial nerve's course through the middle ear. Treatment consists of parenteral antibiotics, tympanocentesis, and myringotomy. Immediate surgical mastoidectomy is indicated in children with CSOM or cholesteatoma.

Intracranial Complications

Intracranial complications of meningitis, epidural abscess, subdural empyema, focal encephalitis, brain abscess, lateral sinus thrombosis, and otitic hydrocephalus have decreased in the antibiotic era, but remain a significant problem in underdeveloped countries, especially in the setting of cholesteatoma and CSOM. Due to spreading infection, 24–44% of children presenting with an intracranial complication will be found to have more than one intracranial complication at the time of diagnosis.

Meningitis can occur due to direct spread of infection through the dura, inflammation due to an alternate intracranial complication (such as abscess), or can be a concurrent infection with hematogenous spread from the upper respiratory tract. Hematogenous spread is the most common etiology. Treatment is parenteral antibiotics.

Epidural abscess is a collection of granulation tissue and pus between the dura and the temporal bone and can result when the temporal bone is compromised by cholesteatoma or infection. Earache, low-grade fever, and temporal headache may be present, as well as profuse, creamy, pulsatile otorrhea. Many cases of epidural abscess are asymptomatic. Treatment is surgical drainage and directed therapy with parenteral antibiotics.

Subdural empyema, although more common in sinusitis, is a rare but serious complication of otitis media. A pus collection develops in the subdural space, usually due to direct extension of infection. Presentation can be severe with toxic appearance, fever, and focal neurologic signs. Treatment is parenteral antibiotics and neurosurgical drainage if indicated.

Focal otitic encephalitis is non-suppurative brain inflammation associated with chronic otitis media or one of the associated suppurative complications. Presentation may be similar to brain abscess, necessitating MRI to distinguish the two entities. Treatment consists of antibiotics for the inciting infection.

Brain abscess can occur with AOM, CSOM, and cholesteatoma. Infection progresses to the brain from a localized subdural abscess or leptomeningitis. Otogenic

brain abscess are located in the temporal lobe or the cerebellum, depending on site of infection invasion. Multiple abscesses are common. The bacteria found in abscesses are the most common bacteria associated with AOM and CSOM. Signs of general and focal neurologic signs generally appear 1 month following acute infection. Systemic signs maybe absent. Treatment is surgical debridement and parenteral antibiotics.

Lateral sinus thrombosis can occur as a result of mastoid inflammation. The infection spreads though the mastoid space into the sinus, and finally into the venous system leading to thrombus formation. Signs of infection are signs of systemic infection, increased intracranial pressure, and sequelae of septic thromboembolism. Lateral sinus thrombosis has a high co-diagnosis with other intracranial complications. Treatment is parenteral antibiotics. There is no consensus on use of anticoagulation. Otitic hydrocephalus, markedly increased intracranial pressure, is highly associated with lateral sinus thrombosis.

Prevention

Otitis media is associated with environmental factors and genetic predisposition to disease. Some of the major environmental associations such as crowding and child care attendance may be difficult to impact in large scale prevention efforts. Due to these challenges, vaccines targeting the most frequent pathogens may be the most effective means to prevent otitis media. The introduction of PCV7 showed decrease in AOM diagnosis, but increase in presence of non-vaccine serotypes. Introduction of PCV13 as well as development of a vaccine against non-typable *H. influenzae* has the potential to substantially decrease rates of AOM.

For children with recurrent otitis media, daily antibiotic prophylaxis reduces the probability of developing AOM, OME, and CSOM. There is no continuing benefit after antibiotics are stopped, but this management strategy may be beneficial during high risk periods. Usual dosing regimens are half the daily treatment dose of amoxicillin or sulfonamides.

71 Sexually Transmitted Diseases

Margaret R. Hammerschlag

Definition/Classification

Sexually transmitted diseases (STD) are infections caused by a varied group of organisms, including bacteria (*Neisseria gonorrhoeae, Chlamydia trachomatis, Treponema pallidum*), viruses (herpes simplex virus, HIV, human papilloma virus), and parasites (*Trichomonas vaginalis*) that are transmitted predominantly by sexual activity. STDs can also occur in young children, which can have serious social and medical legal implications. Children can acquire an STD during delivery from their mothers, if they happen to be infected, from sexual abuse or from consensual sexual activity as adolescents. Identification of an STD in a young child can initiate an investigation of sexual abuse. However, the diagnosis or how the infection was acquired may not be certain.

The Committee on Child Abuse and Neglect of the American Academy of Pediatrics defines child sexual abuse as "... when a child is engaged in sexual activities that he or she cannot comprehend, for which the child is developmentally unprepared and cannot give consent, and/or that violate the law or social taboos of society." Sexual activities can include all forms of oral–genital, genital, or anal contact by or to the child, and nontouching abuses, such as exhibitionism, voyeurism, or using the child in the production of pornography. Some of these activities are more likely to result in transmission of an STD. If the abuse is limited to nontouching activities, acquisition of an STD would be highly unlikely.

Epidemiology of STDs in Children Being Evaluated for Suspected Sexual Abuse

Studies of STDs in children over the past 20 years have demonstrated significant variability in the prevalence of infection. In many of the earlier studies, only symptomatic children were tested, which often gave higher prevalence of gonococcal infection than studies that tested all children being evaluated for suspected sexual abuse. Studies of *C. trachomatis* infection were not done until the 1980s. Studies of STDs in sexually abused children published since the 1990s have reported low rates of infection. Ingram et al. reported from North Carolina that among 1,538 children ages 1–12 years presenting to a tertiary referral center with a report of fondling, oral–genital and/or genital–genital sexual contact, 2.8% (39 females and 2 males) had *N. gonorrhoeae*, 1.2% had *C. trachomatis* (18 females and 0 males), 0.1% had syphilis, and 0.1% had herpes simplex virus (HSV). Robinson et al. isolated *N. gonorrhoeae* from 2/105 (1.9%) and *C. trachomatis* from 1/77 (1.3%) girls age 0–10 years attending a sexual abuse clinic in London. None of the males tested positive for an STD. Similarly, De Villiers and colleagues in South Africa detected *N. gonorrhoeae*, *C. trachomatis*, and syphilis in fewer than 2% of girls, no STI infections in boys, and no cases of HIV or HSV among 191 children presenting for sexual abuse; however, specific diagnostic methods were not described.

Four studies examining the epidemiology of STDs in children and adolescents being evaluated for suspected sexual abuse have been published since 2005 (*Table 71.1*). Three were retrospective chart reviews from Vienna, Austria, Auckland, New Zealand and Miami, Florida. Despite differences in population and methodologies, the results of the retrospective studies were fairly consistent. Charts from a total of 4,350 children were reviewed and included children from 0 to 17 years seen over a 4–7 year period. The prevalence of STDs, specifically gonorrhea and *C. trachomatis*, ranged from 0.4% to 1.8%. No child was found to have syphilis or HIV by serology. These findings are consistent with earlier published studies; however, the inclusion criteria varied greatly study to study; Simmons and Hicks only included girls who were seen within 72 h following an assault and were younger than 11 years of age, whereas the other studies included adolescents. Not every child was tested for every STD. Giradet et al. prospectively examined children 0–13 years of age being evaluated for suspected sexual abuse/assault at four tertiary care centers in the United States (Houston, TX, Atlanta, GA, Harrisburg, PA, and Brooklyn, NY). All children were tested at multiple anatomic sites for *N. gonorrhoeae* and *C. trachomatis* by culture and vaginal and urethral swabs and urine were also tested using two nucleic acid amplification tests (NAATs). Wet mounts were performed for *T. vaginalis* and cultures for HSV were done if lesions were present. Urine and

swabs of external genitalia were tested for HPV using L1 consensus PCR. Sera were also obtained for testing for syphilis, HIV, and type-specific antibody for HSV-1 and 2. A total of 536 children were enrolled, 485 (90.5%) were female. None of the 51 boys enrolled were positive for any infection. Forty (8.2%) of the girls were found to have one or more STDs. The prevalence of STDs varied between study sites, ranging from 1.7% in Texas to 7.8% in Atlanta. *C. trachomatis* and *N. gonorrhoeae* were detected by culture and/or NAAT in 15 (3.1%) and 16 (3.3%) of the girls enrolled, respectively. *T. vaginalis* was detected by wet mount in 5 of 85 (5.9%) symptomatic girls tested. Serologic evidence of syphilis was found in only one of 384 (0.3%) children. This child was also positive for *N. gonorrhoeae*. None of the children were positive for HIV. Cultures for HSV were obtained from only 12 children whose lesions were suggestive of herpes – five (41.7%) were positive, but only one of the culture-positive children had type-specific HSV-2 antibody. HPV DNA was detected in urine and/or genital swabs in 11.8% participants with adequate samples, but only 14 (2.6%) children had genital warts.

Clinical Manifestations: Symptoms, Signs

Most children being evaluated for suspected sexual abuse who are found to have an STD will be asymptomatic. Gonorrhea is more likely to be associated with purulent vaginitis, but rectal and pharyngeal infections are usually asymptomatic. Vaginal infection with *C. trachomatis* has not been consistently associated with vaginal discharge in children. Giradet et al. reported that the majority (67.5%) of the children with a confirmed STD had normal or nonspecific anogenital findings, only 53 (10.9%) presented with a history of a vaginal discharge and only 6.8% had clear evidence of penetrating anogenital trauma on physical examination. Of the girls with vaginal discharge, an STD was identified in 13(24.5%) compared to only 27 of 432 (6.3%) of girls who did not have a history of vaginal discharge ($p < 0.001$). Gonococcal infection was more likely to be associated with a vaginal discharge, 11 of 16 (68.8%) girls with a positive culture and/or NAAT for *N. gonorrhoeae* were symptomatic, compared to 8 of 15 (53.3%) girls with positive culture and/or NAAT for *C. trachomatis*. Three of five (60%) girls who had *T. vaginalis* identified on wet mount had a history of vaginal discharge. Clinical diagnosis of HSV infection can be problematic, only 5 of 12 (41.7%) children with genital lesions suggestive of herpes in the multicenter study were culture positive for HSV. Like adults, children with acquired genital herpes can have recurrences, although data on the duration and number are limited. Acute HSV-2 genital infection can also be associated with aseptic meningitis which is frequently self-limited (Mollaret's meningitis). This may also recur without recurrence of genital lesions.

Diagnosis

N. gonorrhoeae. The identification of *N. gonorrhoeae* in a child beyond the immediate neonatal period (defined as beginning at birth and including the first month of life) is indicative of some kind of sexual contact. The Centers for Disease Control and Prevention (CDC) 2010 STD Treatment Guidelines recommends that specimens for culture of *N. gonorrhoeae* be collected from the vagina in girls, the

pharynx and anus of girls and boys, and the urethra in boys being evaluated for suspected sexual abuse.

Culture remains the preferred method for detection of *N. gonorrhoeae* in children, primarily because it has the highest specificity. If possible, specimens should be plated directly onto selective media; however, this is generally not feasible in most practice situations. There are swab transport systems that can be used, including several commercially available systems that use selective media. Specimens then should be plated on enriched selective media. Presumptive isolates need to be confirmed as *N. gonorrhoeae,* Gram stain morphology and oxidase is not sufficient, especially when selective media are not used. The 2010 CDC STD Treatment Guidelines recommends that that presumptive isolates of *N. gonorrhoeae* obtained from children being evaluated for suspected sexual abuse be confirmed by at least two tests that involve different principles: biochemical, enzyme substrate, serological, or nucleic acid hybridization test methods. Use of multiple confirmatory tests is necessary as some of these confirmatory methods, specifically biochemical and serologic, can misidentify other Neisseria species as *N. gonorrhoeae.* This is especially important when testing specimens from the rectum and pharynx.

Use of NAATs has supplanted culture for detection of *N. gonorrhoeae* in adults in many laboratories. Currently, there are three commercially available, FDA-approved NAATs for *N. gonorrhoeae* and *C. trachomatis* in the United States: polymerase chain reaction (PCR) (Amplicor, Roche Molecular Diagnostics), strand displacement amplification (SDA) (ProbeTec, Becton Dickinson), and transcription-mediated amplification (TMA) (Aptima C2, GenProbe). PCR and SDA are DNA amplification; TMA is an RNA amplification assay. All three are FDA approved for use in genital sites (cervix, vagina, urethra) and urine from adolescents and adults. None are currently approved for extragential sites (pharynx or rectum) or have approval for any site in children. NAATs offer several advantages over culture-based methods including higher sensitivity and enabling the use of noninvasive specimens (urine, vaginal swabs), these assays have some limitations, especially for detection of *N. gonorrhoeae.* The gonococcus has the capacity for genetic variation and recombination that can affect the genetic sequences that are targets for amplification and are fully competent for exogenous DNA uptake throughout their life cycle. This enables frequent horizontal interspecies exchange of genetic material between *Neisseria* species leading to commensal *Neisseria* species acquiring gonococcal sequences and vice versa which can lead to both false-positive and false-negative results with certain NAATs. PCR and SDA have been demonstrated to have cross reactivity with other *Neisseria* species including *N. cinerea, N. flavescens, N. lactamica, N. sicca*, and *N. subflava.* This has important implications especially when testing extragential sites. Black et al. recently evaluated the use of SDA and TMA using urine and genital swabs versus culture for diagnosis of *N. gonorrhoeae* and *C. trachomatis* in children, 0–13 years of age. All children were tested at multiple sites for *N. gonorrhoeae* and *C. trachomatis* by culture and vaginal and urethral swabs and urine were also tested with SDA and TMA. Positive NAATs for *N. gonorrhoeae* were confirmed by an in-house PCR using an alternate target, the *Hinf*I fragment of the 4.2-kb cryptic plasmid. Sixteen of 485 (3.3%) girls had a positive result for *N. gonorrhoeae* by any test: 12 (2.5%) by culture, 14 (2.9%) by vaginal NAAT, and 14 (2.9%) by urine NAAT. All participants who had a positive vaginal culture for *N. gonorrhoeae* had positive urine NAATs. All positive NAAT results were confirmed by the alternative target PCR. These data suggest that NAATs, specifically SDA and TMA, may be alternatives to culture for the detection of *N. gonorrhoeae* in vaginal swabs and urine in prepubertal girls. As the prevalence of gonorrhea in children being evaluated for suspected sexual abuse is low, confirmatory testing is essential. Culture is still preferred for extragential specimens and any specimen from boys.

C. trachomatis. The CDC currently recommends that children being evaluated for suspected sexual abuse be tested for *C. trachomatis* at the anus in boys and girls and from the vagina in girls. The CDC does not recommend obtaining urethral specimens from boys as available data suggests that the likelihood of recovering *C. trachomatis* is too low to justify the trauma of obtaining an intraurethral specimen, but recommends a specimen from the meatus if obvious discharge is present. Pharyngeal specimens from children of either sex are also not recommended, as the prevalence of infection at this site is very low. Culture currently remains the method of choice for detection of *C. trachomatis* in children being evaluated for suspected sexual abuse. The CDC specifies that only standard tissue culture systems should be used. Cycloheximide-treated McCoy cells are used by most laboratories. The isolation of *C. trachomatis* in tissue culture should be confirmed by the microscopic identification of the characteristic intracytoplasmic inclusions, preferably by staining with a species-specific fluorescein-conjugated monoclonal antibody. Use of genus-specific antibody for culture confirmation can lead to misidentification of *C. pneumoniae* as *C. trachomatis* in pharyngeal specimens. Enzyme immunoassays (EIAs) are not acceptable as confirmatory tests and have been associated with

false-positive results, especially when used with vaginal and rectal specimens due to cross-reactions with bacteria present in the anogenital tract and nonspecifically react with fecal material. However, because confirmation is dependent on visual identification of inclusions, there is still a subjective component that could lead to misidentification of artifacts as chlamydial inclusions. This appears to have recently happened in a large commercial laboratory in the United States where instead of using a fresh positive control for each culture run they used a "previously positive" specimen to save time (M. Hammerschlag, personal communication). The incidence of *C. trachomatis* infection in children being evaluated for suspected sexual abuse increased from 2% to nearly 50% after the procedure was changed. Review of the laboratory's procedure confirmed that technicians were identifying cellular debris as inclusions.

NAATs are approved for detection of *C. trachomatis* from genital sites (cervix, vagina, urethra) and urine from adolescents and adults. None are approved for extragential sites (pharynx or rectum) or have approval for any site in children. These methods have been found to have excellent sensitivity for detection of *C. trachomatis*, >98%, in genital specimens and urine from adult men and women, while maintaining high specificity. As with *N. gonorrhoeae,* data on the use of available NAATs for detection of *C. trachomatis* in children are limited. The multicenter study by Black et al. also evaluated the use of SDA and TMA compared to culture for diagnosis of *C. trachomatis* in children. *C. trachomatis* cultures were performed at the clinical or hospital laboratories of each center, according to their own standard protocols. Fifteen (3.1%) of 485 female participants had a positive result for *C. trachomatis* by any test (7 [1.4%] by culture; 11 [2.3%] by vaginal NAAT; 13 [2.7%] by urine NAAT). All participants who had a positive vaginal culture had positive urine NAAT. Two girls had positive *C. trachomatis* cultures from rectal swab specimens, but negative vaginal swab specimens by both culture and NAATs (vagina and urine). All NAAT-positive/culture-negative specimens were confirmed by PCR testing at the CDC.

Syphilis. The prevalence of syphilis in children being evaluated for suspected sexual abuse is very low, <1% in most studies. The diagnosis of syphilis was based on serologic screening and the majority of these children were asymptomatic. Cases of symptomatic syphilis appear to be uncommon and are mostly limited to anecdotal reports. Clinical findings have included primary chancres, manifestations of secondary syphilis including rash and condyloma lata, which can be misdiagnosed as genital warts. The major confounding variable in the diagnosis of syphilis in children beyond the neonatal period is differentiating between acquired and congenital infection. As most pregnant women in the United States are screened for syphilis during pregnancy, congenital infection could be ruled out if maternal records can be accessed. However, this may not always be possible and for some the clinical manifestations of congenital syphilis may overlap with those of acquired syphilis. Serology remains the primary method for diagnosis. A non-treponemal test, either the rapid plasma reagin (RPR) or venereal disease research laboratory (VDRL) tests, which, if positive is then confirmed by a *T. pallidum*-specific test. These tests are useful for monitoring the efficacy of treatment; however, a number of other infections and diseases, including malaria, leprosy, and autoimmune conditions (systemic lupus erythematosus), can lead to the induction of anticardiolipin antibodies and cause false-positive results with RPR and VDRL (12, 24). The antibodies detected by RPR and VDRL are IgG and are transported across the placenta during pregnancy. The most frequently used *Treponema*-specific test is the fluorescent treponemal antibody absorption (FTA-ABS) test. Other available *Treponema*-specific tests are the *T. pallidum* hemagglutination assay (TPHA) and *T. pallidum* particle agglutination assay (TPPA). Anti-treponemal antibodies are usually present for life even after successful treatment, thus they cannot be used to monitor the efficacy of treatment or to distinguish between active and past infection. These assays also detect IgG antibody, thus will cross the placenta. Currently, there are no treponemal-specific IgM assays available. Because performance of the RPR and FTA-ABS is very labor intensive, many laboratories are now using treponemal EIAs for high-throughput screening, then confirming positive results with a non-treponemal test, reversing the traditional syphilis screening sequence. Currently, there are more than nine commercially available EIAs for *T. pallidum* antibodies. Some of these assays will also detect IgM antibodies in addition to IgG. As with FTA-ABS and other treponemal-specific tests, these antibodies remain positive throughout life. Several recent studies have demonstrated significant variation in performance of these assays; some may not be appropriate as stand-alone tests for screening or confirmatory syphilis serology. None of these assays have been evaluated for diagnosis of syphilis in children and are not recommended for diagnosis of congenital syphilis in infants.

If a child has lesions of primary or secondary syphilis, that is, chancre or condyloma lata, *T. pallidum* can be visualized in tissue exudates using dark-field microscopy and direct fluorescent-antibody-*T. pallidum* (DFA-TP) test or by PCR. Epidermal or mucosal lesions in primary

and secondary syphilis tend to contain high numbers of treponemes. Because of the technical challenges of dark-field microscopy and DFA-TPA should only be performed in an experienced laboratory. There are no FDA-approved, commercially available NAATs for detection of *T. pallidum*.

Herpes simplex virus (*HSV*). The overwhelming majority of published studies of STIs in children being evaluated for sexually abused have only tested for HSV in children who presented with suggestive genital lesions. The prevalence of HSV, mostly HSV-2, infection in these studies has been <5%. One study from South Africa performed cultures for HSV on all the children being evaluated ($n = 227$), none were positive for HSV. As most studies have only tested symptomatic children, there is no way of knowing how common asymptomatic infection may be in these children, even as more evidence emerges about the frequency of asymptomatic and subclinical infections in adults.

Culture. If active genital lesions are present, the vesicle should be unroofed for sampling of vesicular fluid for culture by swabbing the base of the lesion. However, the overall sensitivity of viral culture of genital lesions in adults is only approximately 50% compared to PCR. The diagnostic yield is highest in the early stages of disease when lesions are typically vesicular rather than in the later stages when lesions have largely crusted. Viral isolation rates are also higher with primary compared to recurrent genital herpes, particularly in the setting of asymptomatic recurrences with subclinical shedding.

NAATs. Real-time HSV PCR assays have emerged as a more sensitive method to confirm HSV infection in clinical specimens and are particularly useful for the detection of asymptomatic HSV shedding in adults. The main limiting factor in adopting real-time HSV PCR as the primary diagnostic tool in many clinical reference laboratories is the cost of the assay, which substantially exceeds that of viral isolation culture techniques. In addition, the lack of uniform validation of the PCR assay as a diagnostic method for detecting HSV in clinical specimens other than cerebrospinal fluid has limited its availability in some commercial laboratories. These are all in-house assays, there are no commercially available, FDA cleared PCR assays. PCR has not been evaluated at anogenital sites in children.

Tzanck smear. The Tzanck smear, which may demonstrate the cytopathic effect of the virus (multinucleate giant cells), and can be performed on lesion scrapings from patients with active genital lesions. However, it has limited utility since it has low sensitivity and specificity and should not be used in anogenital specimens from children and will not differentiate HSV from varicella-zoster virus.

Serology. Type-specific antibodies to HSV develop during the first several weeks after infection and persist indefinitely. The availability of type-specific serology using surface glycoproteins (Gg2 and Gg1 for HSV-2 and HSV-1, respectively) to distinguish HSV-1 and HSV-2 enables the clinician to determine if the patient is at risk of acquisition or has evidence of prior infection with either subtype. The presence of HSV-2 indicates anogenital infection, but the presence of HSV-1 can be consistent with either anogenital or orolabial infection. The sensitivities of HSV IgG type-specific tests vary from 80% to 98% in adults. False-negative results may occur at early stages of infection; the specificity of these assays is greater than 96%. Several FDA-approved type-specific HSV serologic tests are commercially available. Data on use of these assays in children are very limited. Giradet et al. tested sera from 283 children for HSV-1 and 2 antibodies using an immunodot enzyme assay with a monoclonal antibody inhibition for confirmation performed at the CDC. Antibody to HSV-1 was detected in 45.6%, antibody to HSV-2 was detected in seven (2.5%) children, three children had antibody to both. Only one of five culture-positive children had HSV-2 antibody. These data suggest that type-specific serology for HSV has a poor predictive value for diagnosis of HSV infection in children being evaluated for suspected child abuse. The performance of even FDA-approved tests can be inconsistent in a low-prevalence population.

Trichomonas vaginalis. Most published studies of STIs in sexually abused children have testing for *T. vaginalis* was limited to girls presenting with vaginal discharge. The presence of motile trichomonads on wet mount of vaginal secretions is diagnostic of infection, but this occurs in only 50–70% of culture-confirmed cases in adult women. The organisms remain motile in saline for 10–20 min after collection of the sample. Care should be taken in interpretation when trichomonads are reported present in urine specimens from children collected for another purpose. As the morphology of *Pentatrichomonas* (*Trichomonas*) *hominis,* a nonpathogenic intestinal flagellate, is very similar to that of *T. vaginalis*, care must be taken to make sure that specimens are not contaminated with fecal material. This could present a problem in children that are not toilet trained and in diapers and with bagged urine specimens.

Culture. Culture on Diamond's medium has a high sensitivity (95%) and specificity (>95%). Incubation periods of 2–7 days are needed to indentify *T. vaginalis* in culture. There are very few reports of use of culture in children. A commercial "In Pouch" *T. vaginalis* culture system can be used and is readily available (BioMed Diagnostics, White City, Oregon).

Rapid antigen and NAATs. Several rapid diagnostic kits using DNA probes and monoclonal antibodies have been developed commercially, with a sensitivity of 90% and a specificity of 99.8% in vaginal specimens from women with clinical vaginal discharge. The Affirm VP III Microbial Identification System (Becton Dickinson) test is a direct nucleic acid probe hybridization test for detection of *T. vaginalis, Gardnerella vaginalis*, and *Candida* spp. It has been reported to have sensitivities of 80–90% in adult women with vaginitis but has not been validated or approved for used in genital specimens from prepubertal girls or urethral specimens from men. False-positive results have been reported when used in children and adult men. The OSOM TV (Genzyme Diagnostics) is an objective rapid antigen detection test that has been demonstrated to perform very well in adolescent women with sensitivities significantly higher than wet mount or culture. Again, this test has not been validated or approved for use in children. GenProbe has introduced a TMA-based NAAT for *T. vaginalis* (APTIMA TV) that is expected to receive FDA clearance in 2011. Preliminary studies have demonstrated that this assay is highly sensitive and specific compared to wet mount microscopy, culture and an in-house PCR for the diagnosis of trichomoniasis in women and men. However, there are no data on use of this assay in children of either sex.

Human papillomavirus (*HPV*). The association of genital warts and sexual abuse in children is complicated by the long period of latency before lesions become clinically apparent and possibility of nonsexual transmission, either vertically during delivery or horizontally after birth. Criteria for diagnosis of HPV infection in children; clinical versus detection of HPV DNA, is also not standardized. Most published studies of HPV infection in children being evaluated for sexual abuse have relied on the presence of clinical lesions consistent with genital warts for the diagnosis of HPV infection.

Detection of HPV DNA. Several studies have evaluated detection of HPV DNA in children being evaluated for suspected sexual abuse; however, the results have been contradictory and have demonstrated poor correlation of detection of HPV DNA by PCR and presence of genital warts. There is also a great deal of heterogeneity of the PCR methods used; most were in-house assays which have used generic primers followed by either probing or sequencing of the products. Nested-PCR assays were used in some studies. Use of generic HPV PCRs may be less sensitive than specific HPV 16 PCR. Even so, the association of the presence of HPV DNA with abuse is not very strong; although HPV DNA has been detected in genital and rectal swabs in 15% of girls thought to be abused, it has also been detected in vaginal and/or anal specimens from 2.1% of healthy children with no history of abuse. There is only one FDA-approved test available for detection of HPV DNA in cervical specimens from adult women (Hybrid Capture II, Digene Corporation), and several more are currently being evaluated. The primary use of these assays is for detection of high-risk types HPV in the management and prevention of cervical cancer. HPV DNA testing is not recommended for persons with anogenital warts and has not been evaluated for detection of HPV in children. Routine screening of children suspected of being sexually abused for HPV DNA is not indicated at this time.

Treatment of STDs in Children

Because of the forensic implications and low prevalence of infection, the CDC recommends that children being evaluated for suspected sexual abuse not be treated prophylactically, but based on the results of microbiological studies.

Gonococcal infections. The treatment of choice for uncomplicated urogenital gonococcal infections in children is single-dose intramuscular ceftriaxone: for children <45 kg, 125 mg, >45 kg, 250 mg. Although oral single-dose cefixime is recommended for the treatment of uncomplicated genital gonococcal infections in adults, it has not been studied for this indication in children and is not recommended by the CDC. Single-dose cefixime is recommended for children by the Canadian Guidelines on Sexually Transmitted Infections: children under 9 years of age, 8 mg/kg PO in a single dose to a maximum of 400 mg, for children 9 years of age or older, 400 mg as a single oral dose. Quinolones are not recommended by either set of guidelines because of high level of quinolone resistance in many populations, in some area exceeding 60%. Options are limited for patients that are allergic to beta-lactam antibiotics. Spectinomycin is no longer available in the United States. Azithromycin as a single 2 g oral dose is an alternative regimen in adults but there are no data in children. Macrolide resistance has also been increasing, especially in Europe.

C. trachomatis. The current recommended regimen for children <45 kg is erythromycin base or ethylsuccinate, 50 mg/kg/day po in four divided doses for 14 days. For children who are ≥ 45 kg but <8 years of age, azithromycin, 1 g po in a single dose. Children ≥ 8 years can also be treated with 1 g azithromycin or doxycycline, 100 mg bid for 7 days.

Syphilis. Children with acquired primary or secondary syphilis should be treated with benzathine penicillin G, 50,000 Units/kg IM up to the adult dose of 2.4 million units in a single dose. If there is a credible history of penicillin allergy, the child should be desensitized. There are no alternatives to penicillin for the treatment of syphilis in children.

HSV. Recommended regimen for the first episode of genital HSV infection in children 2–12 years of age is acyclovir, 1,200 mg/day po divided q 8 h for 7–10 days, with a maximum of 80 mg/kg/day, for recurrences 1,200 mg/day po divided q 8 h for 5 days, with a maximum of 80 mg/kg/day or 1,600 mg/day po q 12 h. For suppressive therapy, 80 mg/kg/day in three divided doses to a maximum of 1,000 mg/day or 400 mg po bid. The need for continued suppression should be assessed after 1 year of treatment.

T. vaginalis. There are no regimens specifically recommended for treatment of children. One can use metronidazole, 30 mg/kg/day po qid to a maximum of 400 g/day for 7 days.

HPV. There are no regimens specifically recommended for treatment of genital warts due to HPV in children. Treatment should be done in consultation with a dermatologist.

72 Viral Exanthem

Mohammad Al-Shaalan

Illustrative Case

An 18-month-old boy was brought to the clinic because of 1 day history of erythematous rash over hands and forearms as well as feet. This rash was associated with fever. The rash was judged by physician to be urticarial in nature and he was given oral prednisone for 3 days. His condition improved slightly but 1 day after stopping the steroid, fever recurred and the rash became more widespread to involve the trunk and face. It was noticed to be more pronounced in the diaper area. His conjunctiva and lips were also red. He was admitted to the hospital and was judged to have Steven-Johnson syndrome and was given parenteral methylprednisone for 5 days. His condition improved slightly and was discharged from the hospital. At home, he was noted to have skin peeling of the hands and feet. His fever relapsed 2 days after discharge. He was seen again in a tertiary hospital and he was found to have high fever of 39.7°C, strawberry tongue, fissured red lips, and maculopapular skin rash over the trunk and limps. His complete blood count showed a platelet of 768,000/mm^3 and his ESR was 105 mm/first h. He was diagnosed to have Kawasaki disease and was given intravenous immunoglobulin and his condition improved dramatically. Fortunately, his echocardiogram came to be normal and the repeated echocardiogram in 6 weeks was also normal.

Children presenting with rash and fever may face the treating physician with a challenge. Although some diseases have typical rashes (e.g., chicken pox), others may have rashes that are difficult to differentiate.

Therefore, such children need a systematic approach that could help in reaching correct diagnosis. Such approach includes:

1. Thorough history including antecedent symptoms; rash morphology, distribution and course; associated symptoms of itching or pain; contact with persons with similar rashes, travel, contact with pets, and drug history
2. Complete physical examination with attention to vital signs, mucus membrane involvement, lymphadenopathy, organomegaly, and distribution of the rashes, characters of the rashes, skin examination for ulcers, genital examination, and scalp examination

Once clinical assessment has been done, an initial idea may have been reached which will help in selecting laboratory aids to reach the diagnosis. For example, scalp involvement is rare except in chicken pox or ringworm infection. Palmer and solar involvement is common with secondary syphilis and blenorrhegica keratosis of Rieter's disease. Other diseases that involve palms and soles include hand-foot-mouth disease, chickenpox, herpes simplex, drugs, endocarditis, RMSF, EM, and atypical measles.

Definition of Exanthematous Lesions

Macular or Maculopapular Lesions

Macules are nonelevated discolored skin lesions. Papules are raised lesions that measure <0.5 cm in diameter. Most of the cases of maculopapular exanthems are caused by viral diseases; however, it may be caused by drug reaction or connective tissue diseases.

Vesiculopustular Lesions

Vesicles are small fluid-filled skin lesions that measure <0.5 cm in diameter, larger lesions are termed bulli. Vesicular lesions are caused by viral illness like herpes viruses and enteroviruses.

Nodular Lesions

Nodules are deep-seated skin lesions that are firm in consistency. These lesions are caused by fungal or mycobacterial infections especially when associated with local lymphadenopathies. Erythema nodosum is characterized by erythematous nodular lesions that are usually distributed symmetrically over the lower limbs. Rarely upper parts of the bodies may be involved. Erythema nodosum is commonly caused by streptococcal, fungal,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_72,

and myobacterial infection, sarcoidosis, and drugs, for example, contraceptive pills.

Ulcerglandular Lesion

Ulcerated lesions that are associated with localized lymphadenopathy are mostly of infectious origin. Some of these diseases are associated with generalized maculopapular skin rashes. Therefore, any patient with generalized skin rashes should be examined for local eschar or ulcer.

Purpuric Lesions

These lesions represent extravasation of the blood from the vessels or severe vasculitis. They present as small petechiae, purpura, or ecchymoses. Purpuric lesions in children are of special concern to the pediatrician because they might be due to an overwhelming infection like meningococcemia or severe sepsis with DIC. Other diseases that my present with petechial lesions include RMSF and enteroviral infection.

Common Exanthematous Diseases of Childhood

Measles

Measles is an exanthematous disease caused by an RNA paramyxovirus. After an incubation period of 8–10 days, a prodrome of coryza and fever start. This prodrome is associated with the pathognomic feature of measles which is the Koplik's spots (*Fig. 72.1*). These Koplik's spots appear as salt-like dots on erythematous base. It occurs mainly over the buccal mucosa, but it can be seen in the conjunctiva and rectal mucosa. The prodrome lasts for 2–4 days to be followed by appearance of macular rashes which start in the face and proceed caudally and peripherally to involve the whole body in 2–3 days. The rash tends to coalesce and form blotchy spots. After 3–5 days, the rash fades in the same way it appeared. Measles is still a major disease of childhood mostly in some of the developing countries. It also causes outbreaks in many developed and developing countries. Around 450,000 deaths occur annually as a result of measles infection. Recent strategies for measles eradication included introduction of an extra vaccine dose at school entry as well as mass vaccination for children in areas where measles is still endemic.

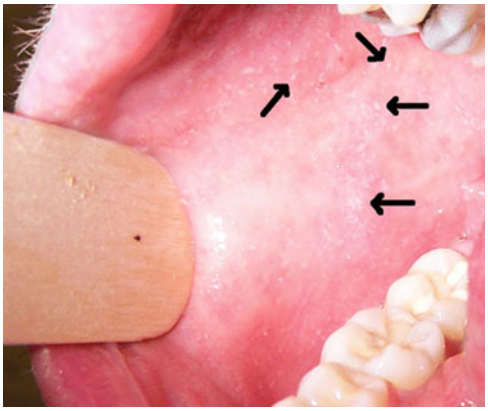

Figure 72.1
Koplik spots

Rubella

Rubella, or German measles, is caused by an RNA togavirus. Children of all ages may be affected but it occurs more commonly in adolescents. As many as 5% of 19–30 year old women are seronegative for rubella making them at high risk of acquiring infection during pregnancy and thus risking to have congenitally infected babies. Incubation period is 14–21 days. The rashes appear suddenly or after a prodrome of mild coryza. The rash is characterized by fine discrete macules that involve the trunk more than extremities. By 3–4 days of illness, the rashes spread to extremities and fade from the trunk. Most of the patients will have generalized lymphadenopathy with predilection to occipital region. Older patients may have an associated arthritis.

Erythema Infectiousum

Erythema infectiousum or fifth disease is caused by parvovirus B19. In children, it starts with erythematous rashes of both cheeks (slapped cheeks). Reticular or fine macular rashes appear on the trunk (*Figs. 72.2* and *72.3*). The rashes have a characteristic feature of fading and exacerbation triggered by local irritation, high temperature, and emotional stresses. Associated clinical features include lymphadenopathy and arthritis or arthralgia in older patients.

Exanthem Subitum

Roseola or sixth disease is caused by human herpes virus-6. Classic presentation includes 3–5 days of high fever in young

Figure 72.2
Slapped cheek erythema

Figure 72.3
Reticular rashes

child without systemic toxicity followed by lysis of temperature and appearance of diffuse macular rashes. Most of the patients have lymphadenopathy especially of occipital region and more than 50% have red tympanic membranes. Recently, it has been found that roseola can present in atypical form with fever and rashes appearing at the same time. In older children, it may cause mononucleosis-like symptoms. After acute infection, the virus remain dormant in salivary gland cells, monocytes/macrophages, hematopoietic stem cells, and microglia cells.

Hand-Foot-Mouth Disease

This is an exanthem caused by enteroviruses, the commonest of which is coxsackei A16. It commonly affects young children. After an incubation period of 3–6 days, a prodrome of low-grade fever, sore throat, and abdominal pain begin, followed by eruption of exanthem over the dorsal surfaces of the hands and feet in 2–4 days, as well as palmar and solar surfaces. These exanthems are typically gray vesicles surrounded by erythematous border (*Fig. 72.4*). They are painful and last for 7–14 days. Mucous membranes of the mouth is also involved in most of the cases and characterized by vesicular lesions that are painful but not to the extent of the herpetic lesions. Also, the gingiva is not as involved as in herpes. Diagnosis is usually clinical, however when needed, viral culture of the vesicular fluid can be done. Treatment is supportive and most of the time self-resolving. Occasional cases of HFMD caused by enterovirus 71 may be severe and may cause some mortality.

Papular Purpuric Gloves and Socks Syndrome (PPGSS)

PPGSS is characterized by petechial and confluent purpuric rashes with edema that is limited to the hands and feet and associated with itching. Enanthem aphthous ulceration of mouth mucosa may occur. The disease is self-limiting and only needs analgesia.

Gianotti–Crosti Syndrome (GCS)

GCS is an acrodermatitis papulovesicular exanthema that occurs secondary to a number of viral infections including hepatitis B, EBV, RSV, parainfluenza, coxsackie, parvovirus, and HHV 6. The exanthematous rashes involve the cheeks, extensor aspects of extremities, and gluteal area (*Figs. 72.5* and *72.6*). Affected patients have positive Kobner phenomenon which is noticeable with tight clothing. GCS is a self-limited disease and only observation is needed.

Epstein–Barr Virus

It is a DNA virus belonging to herpes virus group. It causes a variety of clinical diseases. The most classical form is infectious mononucleosis, which is more common in adolescents. Its presentation consists of generalized lymphadenopathy, hepatosplenomegaly, facial and acral edema, and palatal enenthem. Diffuse skin rashes may be

Figure 72.4
Hand foot mouth rashes

Figure 72.5
Gianitti Crosti rashes

Figure 72.6
Gianitti Crosti rashes

present. Patients with IM who receive ampicillin therapy develop diffuse macular coalescent rashes 1 or 2 days after receiving ampicillin.

Cytomegalovirus (CMV)

CMV can cause infectious mononucleosis-like syndrome. In addition, it may present with subtle symptoms of upper respiratory tract infection and diffuse skin rash. Congenital CMV infection may present with diffuse petechial or purpuric rash.

Adenovirus Infections

Exanthem occurs less frequently with adenoviral infections. When present, it is usually in the form of diffuse macular rashes. Diseases that are commonly caused by adenoviral infections include pharyngoconjunctival fever, pneumonia, gastroenteritis, and cystitis.

Scalded Skin Syndrome (SSSS)

This illness is caused by *Staphylococcus aureus* phage II, which is able to produce an exfoliative toxin resulting in the manifestation of generalized erythoderma followed by skin peeling especially in areas which are exposed to friction or trauma (Nikolsky's sign). Most of the patients have a focus of staphylococcus infection including skin abscess, boil, osteomyelitis, septic arthritis, or other foci. Bacteremia and septicaemia are rare. It may resemble toxic epidermal necrolysis (TEN); however, in skin biopsy the line of separation of skin is intraepidermal in SSSS and subepidermal in TEN.

These patients require supportive therapy by maintaining hydration and relieving the pain. In addition, systemic antibiotics effective against *S. aureus* like cloxacillin or methicillin need to be administered to eradicate the organisms secreting the inflicting toxin.

Toxic Shock Syndrome (TSS)

When first identified, it was related to using tampons by menstruating women. However, it is now known to occur in children and persons who do not use tampons. The major causative organism is *S. aureus*; however, recently group A streptococcus is being recognized as another major cause.

Affected patients present with fever, hypotension, and generalized erythema. In addition, mucus membranes involvement is common with conjunctivitis and strawberry tongue manifestation. Case definition of TSS is based on the following criteria: fever of 38.9°C or more; presence of diffuse macular erythroderma; desequamation 1–2 weeks after onset of illness particularly of palms and soles; hypotension defined as a systolic blood pressure of 90 mmHg or less for adults and below the fifth percentile for children younger than 16 years of age; or an orthostatic drop in diastolic blood pressure of 15 mmHg or more with a change from lying to sitting, orthostatic syncope or orthostatic dizziness; Involvement of three or more of the following organ systems: gastrointestinal, muscular, mucus membrane, renal, hepatic, hematological, and central nervous system. TSS can be confused with many febrile illness with macular rashes and mucus membrane involvement like Kawasaki disease, scarlet fever, measles, RMSF, or leptospirosis.

Kawasaki Syndrome

First identified in Japan, this disease now occurs in all races and all communities. It commonly affects children <2 years of age; however, it can occur in children up to age 10 years. Affected children usually present with remittent fever and severe irritability. In 2–3 days, rash appears which is usually polymorphus; however, any type of rashes may occur. Perianal area erythema is common as well as erythema at the site of previous BCG vaccination. Hand and feet edema and erythema appear at the same time.

Periungunal skin peeling occurs by the end of 7–10 days. The peeling may involve the hands and rarely other part of the body. Thrombocytosis becomes apparent by the end of the first week.

Mucus membrane involvement is common with conjunctivitis and strawberry tongue, lip erythema and fissuring is characteristic. Cervical lymphadenopathy occurs in 50% of the patients with single or multiple lymphadenopathy. The lymph node may be tender.

Scarlet Fever

Scarlet fever is an exanthematous skin disease caused by Group A streptococcal infection. It is associated with systemic illness. The infection mostly occurs in the throat. However, skin lesion may result in surgical scarlet fever. The patient usually present with sore throat for 1–2 days followed by skin eruption that involves trunk and extremities. The rash is sandpaper in texture and is accentuated in the flexural surfaces resulting in Pastia's lines (*Fig. 72.7*). There is facial flushing with sparing of perioral area. The course of illness is 5–7 days and it responds to antibiotic therapy promptly.

Figure 72.7
Pastia's lines in scarlet fever

73 Antibacterial Therapy

Mohammad Al-Shaalan

Antibacterial therapy has made a big revolution in medicine; however, a judicious use of these drugs is very important in order to decrease the emergence of resistance. The antibiotic use can be one of the following ways:

- Empirical as in suspected sepsis in infant below 3 months of age and initial management of meningitis
- Specific as in streptococcal pharyngitis, otitis media, and cellulitis, or prophylaxis as in UTI prophylaxis

When used as empiric therapy, usually broad spectrum antibiotics are used, however this should only be for 24–48 h until the result of cultures are obtained and then narrowed to specific therapy according to isolated organism. Specific therapy should be chosen for the most likely organism, unless the patient is seriously sick in which case it should be broad until the causative organism is isolated (*Table 73.1*).

The duration of antibiotic therapy is mostly of arbitrary choice; however there is some agreed duration for specific conditions. Longer duration should be considered for those infection caused by slow-growing intracellular organism like Mycobacterium tuberculosis and Brucella spp, in situation where the achieved antibiotic level is usually low like bone and in situation where relapse is not desirable like CNS infection.

It is always advisable to monitor the use of antibiotics in each health center. Steps that are helpful to streamline the antibiotics use include:

- Appropriate history and physical examination leading to adequate tentative diagnosis
- Antibiotic use only if a bacterial infection is highly expected
- Obtaining cultures as possible
- Considering the use of the least expensive and narrowest spectrum antibiotic possible
- Attention for the side effects and drug interaction of the used antibiotic
- Prophylaxis antibiotic use should be limited to minimum and used in those situations where there is evidence of their value
- Follow the AAP/CDC guideline for judicious use of antibiotics

Pharmacokinesis

This indicates the mechanics of absorption, distribution, metabolism, and elimination. Antibiotics can be used orally, parenterally, or can be applied topically. All serious bacterial infections should be treated parenterally. Oral route can be used to treat mild to moderate infections like otitis media, sinusitis, or mild skin infection. Absorption of some antibiotics may be reduced if taken with foods; therefore, the patients should be advised to take them either 1 hour before or 2 hour after the meal. Examples of such antibiotics include azithromycin, clarithromycin, ampicillin, cloxacillin, clofazimine, doxycycline, piperazine citrate, rifampin, and thiabendazole. Topical antibiotics for which there is a systemic formulation should be limited in its use to decrease emergence of resistance.

The distribution of an antibiotic is determined by many factors which include molecular weight, lipid solubility, ionization, and protein binding. Drugs that have high volume of distribution tend to be of small molecular weight, water soluble and of low protein binding.

The two main routes of antibiotics elimination are either kidneys or liver or both. Accordingly, dosage should be modified if one of these organs is affected (*Table 73.2*). The following drugs need no modification with renal impairment; azithromycin, Ceftriaxone, chloramphenicol, clarithromycin, doxycycline, isoniazid, itraconazole, nafcillin, pyrimethamine, and rifampin.

Variations do exist among children of various age groups and between children and adults. Neonates tend to be a slow metabolizer, having large volume of distribution and having low excretion. This is due to immaturity of liver metabolism, larger extracellular water, and lower glomerular filtration, respectively.

Therefore, consideration for dosing as well as frequency of administration should be considered for younger age groups as well as in those with impaired liver or renal function.

Pharmacodynamics

The aim of using an antibiotic is to prevent the growth of bacteria either by suppressing their proliferation

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_73,

Table 73.1
Treatment of common infections

Condition	Management	Alternative therapy	Comment
Acute otitis media	Amoxicillin (high dose)	Cefuroxime axetile, augmentin, cefaclor, azithromycin, or clarithromycin	Recurrent or persistent OM need evaluation with tympanometry, tympanocentesis, and hearing assessment
Chronic suppurative OM	Coamox-clavulinate (augmentin) + local therapy	Ceftazidime or piperacillin	Use of ceftazidime or piperacillin require IV
Sinusitis	Same as otitis media		
Pharyngitis	Penicillin V	Ampicillin, amoxicillin, or cephalexine	
	1–5 years 125 mg PO BID		
	6–12 years 250 mg PO BID		
Peritonsiller cellulites or abscess	Clindamycin and cefotaxime	Tazocin or meropenem	Consider drainage for abscess
Retropharyngeal abscess	Clindamycin and cefotaxime	Tazocin or meropenem	Admission is indicated
Tracheitis	Cloxacillin+cefotaxime		Admission is indicated. In areas with high MRSA, consider vancomycin instead of cloxacillin
Epiglottitis	Cefuroxime	Cefotaxime	Admission is indicated
Pneumonia			
<3 months	Ampicillin+cefotaxime	Ceftriaxone	Usually need admission
3 months–5 years	Outpatient: amoxicillin Inpatient: cefuroxime		In community where MRSA prevalence is high, vancomycin should be considered especially in those who are toxic or has empyema
>5 years	Outpatient: azithromycin/ clarithromycin or erythromycin		
	Inpatient: Cefuroxime with or without azithromycin/ clarithromycin or erythromycin		
Osteomyelitis and septic arthritis	Neonates: cefotaxime Children >3 months of age: cloxacillin		In areas where MRSA prevalence is 5–10%, consider empiric therapy vancomycin or clindamycin Unvaccinated children <5 years of age need coverage for *H. influenzae* with cefotaxime or cefuroxime
Neonatal sepsis:	Gentamicin and ampicillin	Cefotaxime plus ampicillin	
Bacteremia	Ceftriaxone		
UTI	Mild: Coamox-clav, cotrimoxazole, cephalexine, cefuroxime, cefdinir, or cefpodixime		Consider prophylaxis if there are genitourinary abnormalities
	Severe: ceftriaxone		Need hospitalization
Brucellosis	Children <8 years : Rifampin and cotrimoxazole		Intravenous gentamicin for 5–7 days can be given to admitted patients
	children > 8 years : Rifampin and doxycycline		

Table 73.1 (Continued)

Condition	Management	Alternative therapy	Comment
Periorbital cellulitis	Cefuroxime	Cloxacillin and cefotaxime	In children <1 year without any precipitation wound or sinusitis, consider doing spinal tap and use of cefotaxime until meningitis is ruled out
Orbital cellulitis	Cefotaxime and cloxacillin		
Impetigo	Topical fusidin or mupirocin		Consider systemic cloxacillin if extensive

Amoxicillin high dose of 80–90 mg/kg/day PO in two divided doses for 5–7 days
Augmentin with high amoxicillin forms include 200 mg amoxicillin/28.5 mg clavulanic acid, augmentin 400 mg amoxicillin/57 mg clavulanic acid, and augmentin 600 mg amoxicillin/49 mg clavulanic acid. The dosage is based on amoxicillin at 80–90 mg/kg/day in two divided doses PO
Penicillin V 1–5 years 125 mg PO in two divided doses, 6–12 year 250 mg PO in two divided doses
Cephalexine 80–100 mg/kg/day in three or four divided doses PO
Cefdinir 14 mg/kg/day in two divided doses PO
Cefpodixime 10 mg/kg/day in two divided doses PO (maximum dose 400 mg/day)
Cefuroxime axetile 30 mg/kg/day in two divided doses PO
Cefuroxime 150 mg/kg/day IV every 8 h
Ampicillin 200–400 mg/kg/day IV in four to six divided doses
Azithromycin 10 mg/kg as loading dose then 5 mg/kg once daily for 4 days PO
Clarithromycin 14 mg/kg/day in two divided doses PO
Erythromycin 40 mg/kg/day in four divided doses PO or IV
Ceftriaxone 100 mg/kg/day once or twice daily IV
Cefotaxime 100–150 mg/kg/day in three divided doses IV
Gentamicin 7.5 mg/kg/day in three divided doses IV
Cloxacillin 150 mg/kg/day in four divided doses IV
Vancomycin 45 mg/kg/day in three divided doses IV
Clindamycin 30 mg/kg/day in three divided doses PO or IV
Rifampin 20 mg/kg/day in two divided doses PO
Cotrimoxazole 10 mg/kg/day in two divided doses PO
Doxycycline 4 mg/kg/day in two or single dose PO

(bacteriostatic) or by killing them (bactericidal). Antibiotics destroy organisms through various mechanisms (*Table 73.3*). The effect, activity, and toxicities of any medication are its pharmacodynamic characters. In order for a drug to have an activity against a specific organism, such organism must be susceptible. Some organisms are usually sensitive to certain antibiotic like Group A Streptococci is usually sensitive to penicillin.

Others are inherently resistant to some antibiotics, like Pseudomous is always resistant to first- and second-generation cephalosporins. Some organisms acquire resistance in response to antibiotic use or as a result of acquiring resistant gene through plasmid or transposone transfer such as methicillin-resistant *Staphylococcus aureus* and *Streptococcus pneumoniae*.

In order for an antibiotic to be effective, it must attain a level above or equal to organism MIC. MIC is the minimum antibiotic concentration required to kill the organism in vitro. Certain antibiotics are having an activity that is time dependent like β-lactam, macrolid, clindamycin, and vancomycin. These antibiotics need to have a level above MIC for at least 50% of the dose interval in order to be effective. Other antibiotics are concentration dependent, meaning that they have a post-antibiotic effect, which extends their killing ability even if concentration dropped below MIC. Such antibiotics include aminoglycosides and fluoroquinolones.

Instructive Case

A 3-month-old girl was admitted with history of fever and irritability. Anterior fontanelle was bulging and no focal neurological signs. Cerebrospinal fluid culture grew Streptococcus pneumoniae with the following MIC: penicillin 0.12 mcg/ml, cefotaxime 0.12 mcg/ml, and vancomycin 0.5 mcg/ml. In this case, the best treatment is cefotaxime because the cutoff point of sensitivity is 0.5 mcg/ml. This organism is intermediately resistant to penicillin and because the infection involves CNS, it is not suitable to use penicillin. However, if infection involves other part of the body, high-dose penicillin is usually effective.

Table 73.2
Modification of doses with renal and hepatic impairment

Modify in renal impairment	Modify in hepatic disease	Modify in both
Penicillins	Azithromycin	Aminosalicylic acid
Cephalosporins	Clindamycin	Amphotericin
Aminoglycosides	Clofazimine	Clarithromycin
Aztereonam	Erythromycin	Chloroquine
Imipenem	Isoniazid	Cotimoxazole
Capreomycin	Ketoconazole	Cycloserine
Vancomycin	Praziquantel	DDI
Acyclovir	Rifampin	Ethionamide
Amantidine		Grisovulvin
Foscarnet		Metronidazole
Ganciclovir		Pyrazinamide
Fluconazole		Thiabendazole
Flucytosine		
Paromomycin		
Quinacrine		
Quinine		

Table 73.3
Mechanisms of antibacterial action

Mechanism of action	Antibiotics	Type of activity
Inhibition of cell wall synthesis	Penicillins	Bactericidal, time dependant
	Cephalosporins	
	Vancomycin	
Protein synthesis inhibition	Clindamycin	Bacteriostatic, time dependant
50S inhibitor	Macrolide	
	Chloramphenicol	
30S inhibitor	Tetracyclines	Bacteriostatic, concentration dependant
	Aminoglycosides	
DNA gyrase inhibition	Fluoroquinolones	Bactericidal, time dependant
DNA synthesis inhibition	Metronidazole	Bactericidal
RNA polymerase inhibition	Rifampicin	Bactericidal
Cytoplasmic membrane destruction	Polymyxines	Bactericidal

Instructive Case

A 4-month-old boy with complex congenital heart disease was operated upon. Three days postoperatively, he started to have fever. His complete blood count showed elevated WBC and decreasing platelet. He was started empirically on ceftazidime and gentamicin. Blood culture grew Enterobacter cloacae. An Enterobacter cloaca is included in what is being known as SPICE organisms (Serratia, Pseudomonas, indole positive Acinetobacter and Morganella, Citrobacter and Enterobacter). These organisms are inherently resistant to β-lactam. Therefore, in such case, meropenem or an effective non-β-lactam antibiotic is advisable.

Mechanisms of Resistance

Some bacteria are de novo resistant to certain antibiotics, however with increasing pressure of antibiotics use, bacteria started to escape antimicrobial actions by acquiring resistance (Table 73.4). The major mechanisms of resistance are:

1. Production of an enzyme that degenerate or inactivate the antibiotic, for example, production of β-lactamases by *S. aureus* and *Enterobactericia*
2. Prevention of the antibiotic from reaching its site of action as in *Pseudomonas* and *S. epidermidis*
3. Altering the site of action as in *S. pneumoniae*
4. Increased efflux of antibiotics

Recently, there are major concerns of rising resistance against antibiotics. In some situations, these resistant organisms are the predominant cause of infections. There are situations where the resistant organism is resistant to all of the available antibiotics. This is apparent in some of the Gram-negative bacilli and vancomycin-resistant enterococci and vancomycin-resistant staphylococcus aureus. Table 73.5 shows some examples of these challenging organisms.

Penicillins

Penicillins are derivative of β-lactam. The basic constituent of all penicillins are β-lactam ring and thiazolidone ring. Penicillins vary in their characteristics by alteration in the side chains that are attached to the β-lactam ring. The mechanism of action of all penicillins is through attachment to penicillin-binding proteins (PBP). PBP(s) are transpeptidases that mediate the cross-linking of peptidoglycan polymers. This in turn results in inhibition of bacterial cell wall synthesis. Although they were effective against broad spectrum of organisms when initially introduced, resistance arose quickly. Most of the resistance to penicillin is by production of β-lactamases, which results

Table 73.4
Mechanisms of antibiotic resistance

Mechanism of resistance	Antibiotics affected	Organisms exhibiting
Detoxifying enzymes		
β-Lactamsases	β-Lactams antibiotics	S.spp., Enterobacteriaceae, Neisseria spp., Enterococci, Pseudomonas, Bacteroids
Acyltransferase, neucleotidyltransferas, phosphtransferas	aminoglycosides	Enterobacteriaceae, Pseudomonas, Enterococci, Staphylococci
Acetyltransferase	Chloramphenicol	Neisseria, *H. influenzae*, Enterobacteriacea
Methylating enzymes	Macrolides	Pneumococcus, Staphylococci
Alteration of the binding site	β-Lactams	Pneumococcus, MRSA, *H. influenzae*, Neisseria Streptococci
	Aminoglycosides	
	Macrolides	
	Vancomycin	
	Quinolones	
	Tetracycline	
	Vancomycin	
Impaired access of antibiotics		
Decreased permeability	β-Lactams	Pseudomonas, Enterobacter, Serratia, Klebsiella Pseudomonas, Enterobacteria
	Aminoglycosides	
	Tetracycline	
	Chloramphenicol	
	Quinolones	
Efflux of antibiotics	Tetracycline	
	Erythromycin	

in destruction of the penicillins. In addition, some bacteria acquire resistance by alteration of the PBP rendering them inaccessible to the antibiotics. The major side effect of penicillin is anaphylaxis, however it occurs rarely. Other side effects include autoimmune reactions like serum sickness and hemolytic anemia. Interstitial nephritis may occur especially with penicillinase-resistant penicillins. There are four classes of penicillins (◉ *Table 73.6*).

Natural Penicillins

These are penicillin V and penicillin G and its derivatives. Penicillin V is available in oral form and it has good bioavailability of 40%. Penicillin G is available in oral form (buffered penicillin G), intravenous form (aqueous penicillin G), and intramuscular forms (procaine penicillin and benzathine penicillin). Oral penicillin G has

Table 73.5
Challenging organisms

Organism	Challenge	Precaution
Streptococcus pneumoniae	Increasing resistance to penicillin	Resistant pneumococci is one of the cause of pyogenic meningitis
MRSA	Resistance to methicillin group	Community-acquired MRSA is increasing. MRSA should be considered as a cause of serious infections
SPICE (Serratia, Pseudomonas, indole positive Acinetobacter and Morganella, Citrobacter and Enterobacter)	Resistance to β-lactam and β-lactam-β-lactamase inhibitor	Becoming increasing cause of hospital-associated infections

Table 73.6
Commonly used penicillins

Drug	Dose	Route	Main uses	Side effects
Natural penicillin				
Penicillin G	400,000 U/kg/day q 4 h	IV, IM	Pharyngitis due to GAS, syphilis, peritonsiller abscess and retropharyngeal abscess	Anaphylaxis, intestitial nephritis
Penicillin G	25–50 mg/kg/day q 6 h	PO		
Penicillin G Procaine	25,000–50,000 U/kg od	IM		
Benzathine pen G	25,000 U/kg one dose	IM		
Penicillin V	25–50 mg/kg/day q 6h	PO		
Penicillinase resistant				
Cloxacillin	50–100 mg/kg/day q 6h	PO	Osteomyelitis, septic arthritis, infected implanted devices	Diarrhea, nausea, leukopenia, nephritis Interstitial nephritis I
	100–200 mg/kg/day 6h	IV		
Naficillin				
Methicillin				
Semisynthetic penicillin				
Ampicillin	200–400 mg/kg/day qh	IM, IV	Meningitis in neonates, UTI, shigellosis (if sensitive), otitis media, sinusitis, UTI	GIT symptoms, rash
Amoxicillin	50–100 mg/kg/day q 6h	PO		
Extended spectrum penicillin				
Pipercillin	200–400 mg/kg/day q 6h	IV	Pesudomonas infections, enterobacterecia and streptococci	Skin rashes, CNS effects like siezure and drowziness
Ticarcillin				
Mezlocillin				
Azlociilin				

a bioavailability of 20% of that achieved after similar dose given intramuscularly. Therefore, it can be used for treatment of mild infection; however, penicillin V has a better bioavailability. Procaine penicillin is available for intramuscular use and its main use is for treating syphilis except congenital syphilis when intravenous aqueous penicillin G is preferred. Benzathine penicillin is a long acting formula which maintains a detectable, although low, serum level of 1–2% of that achieved by similar dose of aqueous penicillin G given intravenously. Therefore, it is used for highly sensitive organisms, which can be inhibited by low serum concentration. Its main use is for rheumatic fever prophylaxis and Group A streptococcal infection.

Penicillins remain the drug of choice for Group A streptococcal infections, Group B streptococcal infections, syphilis, actinomycosis, leptospirosis, anthrax, and meningococcal infections. Once used to be 100% sensitive to penicillin, Streptococcus pneumoniae that are resistant to penicillin are increasing in number. In some countries, up to 50% of S. pneumoniae are relatively or highly resistant to penicillin. Therefore, in cases of pneumococcal meningitis, the initial therapy should be with third-generation cephalosporins and vancomycin until the availability of the sensitivity results. Most of the staphylococci and almost all Gram-negative bacilli are resistant to this group of penicillin antibiotics.

β-Lactamase-Resistant Penicillins

Soon after introduction of natural penicillins, staphylococci start to acquire resistance. Most of this resistance was mediated by inducible β-lactamases. Therefore, a search for alternative effective antibiotics resulted in introduction of penicillinase-resistant penicillins (oxacillin, methicillin, nafcillin, cloxacillin, and dicloxacillin). Methicillin is rarely used now except in neonates because of its low protein binding. Oxacillin and nafcillin are available in oral and parenteral forms; however their bioavailability when given orally is less than that of cloxacillin and dicloxacillin. Cloxacillin and dicloxacillin are available in oral forms only. This group of antibiotics is effective against most of the Staphylococcus aureus strains, 50–70% of the coagulase negative Staphylococci, Group A Streptococci, and Group B Streptococci. They are with the exception of methicillin also effective against Streptococcus pneumoniae. They share with the natural penicillins the hypersensitivity reactions in addition to interstitial nephritis, phlebotoxicity, neutropenia, and alteration in the liver transaminases. Soon after introduction of these antibiotics, resistant Staphylococci start to arise. Almost half of coagulase-negative Staphylococci are resistant to these antibiotics. Staphylococcus aureus that are methicillin resistant also start to appear. Their prevalence is variable; however, they are mostly nosocomially acquired and tend to be more prevalent in long-term care facilities and in large teaching hospitals. Methicillin-resistant Staphylococci are also resistant to all other penicillins, all cephalosporins, and most of the other antibiotics with the exception of vancomycin and teicoplanin. Some MRSA are also susceptible to trimethoprim-sulfamethoxazole, rifampicin, fluoroquinolones, and clindamycin.

Aminopenicillins

This group of penicillins is semisynthetics. They include ampicillin, amoxicillin, bacampicillin, and cyclacillin. Ampicillin is available in oral and parenteral forms whereas the others are available in oral form only. They are broader spectrum than the previous groups. Their activities encompass Group A Streptococci, Group B Streptococci, some of the Staphylococci, Enterococci, some of the Enterobacteriaceae (*E. coli*, Klebsiella, Enterobacter, Salmonella, and Shigella), Listeria monocytogenes, some of the Enterococci, and some of the Haemophilus influenzae type b. Recently, an increasing number of ampicillin-resistant Enterobacteriaceae, Haemophilus influenzae, and Enterococci are noticed especially in developing countries. Ten to fifty percent of Salmonella and Shigella are resistant to ampicillin. Twenty to thirty percent of *H. influenzae* is resistant to ampicillin.

Broad Spectrum Penicillins

This group of penicillins includes carboxypenicillins (carbenicillin and ticarcillin) and ureidopenicillins (piperacillin, mezlocillin, and azlocillin). These antibiotics are only available in parenteral form. Their spectrum of activity include most of the Enterobacteriaceae, Pseudomonas, Gram-positive cocci with the exception of most of the Staphylococci, oral anaerobes, some of Bacteriodes, and some of Enterococci. They are susceptible to penicillinase and therefore are ineffective against penicillinase producing bacteria like *H. influenzae*, enteric Gram-negative bacilli, and Staphylococci. Carbenicillin is rarely used nowadays because it is supplanted by more active ticarcillin. Ticarcillin and ureidopenicillin have similar range of activity and toxicity and therefore can be used interchangeably. The main use of these antibiotics is in

febrile neutropenic patients where they are used in combination with aminoglycoside as empiric therapy. In addition, they are effective in treating patients with intraabdominal infection when Pseudomonas is suspected to be one of the causative organisms. Pneumonia in cystic fibrosis patients is usually treated with a combination of one of these antibiotics and an aminoglycoside antibiotic. These antibiotics can be used alone in the treatment of pyelonephritis or pneumonia that is caused by Pseudomonas. The main side effects of this group of penicillin include, in addition to hypersensitivity reactions, hepatotoxicity, neutropenia, thrombocytopenia, and seizure when used in very high dosage.

Cephalosporins

Cephalosporins are another class of β-lactams. Their basic structure consists of β-lactam ring, dihydrothiazine ring, and variable side chains. β-Lactam ring and dihydrothiazine ring confer the basic antibiotic activity whereas the side chain determines the spectrum of activity and the pharmacokinesis of a specific antibiotic in the group. Cephalosporins act as bactericidal agents through inhibition of cell wall synthesis. As other β-lactam, they bind to PBP(s) on the bacterial cell membrane and thus interfere with the transpeptidation and cross-linking of the peptidoglycan segments. This in turn results in bacterial cell death. Although this is the basic mechanism of action, other additive or alternative action is speculated in which the autolysins play the major role. Most of the bacteria have their own autolysins, which are usually kept under control by protein inhibitors. When the β-lactam antibiotics bind to PBP(s), these inhibitors are released from the cells allowing the autolysins to act and lyse the cell. There are four generations of cephalosporins based on their spectrum of activities (*Table 73.7*).

First Generation

This class includes oral agents (cephalexin, cephradine, and cefadroxil) and parenteral agents (cephalothin, cephradine, cephapirin, and cefazolin). Cephalexin and cephradine have short half-life and thus need to be given four times daily whereas cefadroxil has a prolonged half-life allowing once or twice daily dosing. Among parenteral agents, cefazolin has the longest half-life and can be given every 8 h. In addition, it achieves higher blood level than the others and thus higher activities. These agents have a good activity against most Gram-positive cocci including *S. aureus*, *Streptococci* other than group D and viridans *Streptococci*. Their spectrum of activity against Gram-negative bacilli is limited to some of the E. coli, Kleibsiella species, and Proteus mirabilis. They are not effective against other Enterobacteriacea or Pseudomonas. The main use of these antibiotics is for mild to moderate infections like streptococcal pharyngitis, skin and soft tissue infection, and mild urinary tract infection caused by susceptible organisms. Cefazolin is used commonly as perioperative prophylaxis in orthopedic, cardiovascular, or abdominal procedures. Cephalothine is very painful if given intramuscularly and therefore it should be given by intravenous route only.

Second Generation

The members of this class have a better Gram-negative coverage with maintenance of Gram-positive coverage. This class includes agents that can be given orally (Cefaclor, cefuroxime axetil, cefprozil and loracarbef) and others that can be given parenterally (cefamandole, cefuroxime, cefoxitin, cefotetan, and cefmetazole). These antibiotics have almost the same range of activities with some minor differences. They have an excellent coverage for methicillin-sensitive Staphylococcus aureus, most of the Streptococci with the exception of some of the viridans group, Neisseria species, non-typable and typable Haemophilus influenzae, and some of the Enterobacteriaceae (E. coli and Klebsiella species). Their coverage for other Enterobacteriaceae is variable. These antibiotics are ineffective for Pseudomonas species. Cefoxitin, cefotetan, and cefmetazole are active against most of the anaerobes. Therefore, they are effective in treatment of intraabdominal infections like peritonitis following perforated viscus. In addition, they are effective in cases of pelvic inflammatory disease when given in combination with doxycycline or erythromycin. Cefuroxime is the safest and most stable for β-lactamase. Cefprozil and Cefaclor are less stable for β-lactamase. The main uses of second-generation antibiotics are in lower respiratory tract infections, otitis media that is resistant to therapy with amoxicillin, bone and joint infections in children below 5 years of age when the possibility of *S. aureus* and *H. influenzae* as causative agents is entertained, and urinary tract infection. The use of cefuroxime in treatment of meningitis is discouraged because of the delay in CSF sterilization in comparison with third-generation antibiotics.

Table 73.7
Commonly used cephalosporins

Drug	Dosage (mg/kg/day)	Route	Spectrum of activity	Side effects
First generation				Anaphylaxis is very rare Skin rashes Coagulopathy specially with moxalactam.
Cephalexine	50 QID	PO	Streptococci, S. aureus, some of the Enterobactercia	
Cephazoline	80 q 8 h	IV, IM		
Cephradine	25–50 QID	PO		
Cephalothine	80–160 QID	PO		
Second generation				
Cefuroxime axetile	40 BID	PO	S. aureus, Streptococi, Entrobactrecia, H. influenzae	
Cefaclor	40 TID	PO		
Cefuroxime	75–150 q8h	IV		
Cefamandole	100–150 q6h	IV, IM		
Cefotetan	40–80 q 12 h	IV, IM	Entrobactercia and anaerobes	
Cefoxitin	80–160 q8h	IV, IM		
Third generation

Cefepime				

Third Generation

This group of cephalosporins has a broad spectrum of activity against most of the Gram-negative bacilli including *Enterobacteria* and *H. influenzae*. Only ceftazidime and cefoperazone are active against *Pseudomonas*. Third-generation cephalosporins are generally β-lactamase stable, however some of the Gram-negative bacilli produce expanded spectrum β-lactamases that are able to hydrolyze these agents. This is mainly manifested by Pseudomonas aeruginosa, Klebsiella species, Enterobacter species, Citrobacter species, Serratia marcescens, and Acinetobacter species. Therefore, these antibiotics should be used with caution against these organisms, and preferably used in combination with an aminoglycoside when serious infection with these organisms is suspected. Cefotaxime and ceftriaxone have good coverage against *S. aureus*; however, they are not adequate to treat serious infections caused by this organism. All third-generation cephalosporins are effective therapy for *H. influenzae* and *S. pneumonia*; however, recently there are increasing reports of cephalosporin-resistant *S. pneumoniae*. When meningitis due to *S. pneumoniae* is suspected, the initial therapy should be with a combination of cefotaxime or ceftriaxone and vancomycin until the organism is proved to be susceptible to ceftriaxone or cefotaxime by susceptibility tests. This group of antibiotics is not effective against Enterococcus, methicillin-resistant *S. aureus*, *Listeria monocytogenes*, *Stenotrophomonas maltophilia*, and *Burkholderia cepacia*. Third generation is generally safe with wide therapeutic-toxicity index. Mild to moderate hypersensitivity reactions occur in 3–5%. These are

mainly in the form of mild skin rashes. Type 1 reaction is very rare. Platelet aggregation defect and prolonged prothrombin time have been described with use of moxalactam and cefoperazone. Therefore, their use is limited. Mild anemia, thrombocytosis, and neutrophilia as well as mild elevation of the liver transaminases may occur with use of these antibiotics, but are usually transient and improve with discontinuation of the medication. Ceftriaxone is highly protein bound and thus may displace bilirubin, which may exacerbate neonatal hyperbilirubinemia and thus it should be avoided in neonates. In addition, pseudolithiasis and biliary sludging has been described with ceftriaxone use; however, this is usually transient and resolves after discontinuation of therapy.

Fourth Generation

These agents are just recently released for clinical use. They have a broad spectrum activity with effective coverage of almost all Gram-negative bacilli including *Enterobactericia* and Pseudomonas. They are effective againist *S. aureus* and *Streptococci*; however, they are not active against *Enterococci* or MRSA.

Aminoglycosides

Aminoglycosides are bactericidal agents. They act by inhibiting protein synthesis through inhibiting 30S ribosome. It remains controversial how aminoglycosides are bactericidal although inhibition of protein synthesis is not enough for organism killing. Aminoglycosides are highly polar and water soluble molecules, therefore their absorption after oral intake is poor and they should be given parenterally. Their volume of distribution is that of extracellular fluid and thus it is altered in cases of edema, heart failure, and dehydration. They poorly cross the cellular barrier and therefore their intracellular concentration is low except streptomycin. Because they poorly cross biological membrane, their concentration in CSF, bile prostate, and vitreous fluid is very low; however, they achieve a good level in bone, synovial fluid, and peritoneal cavity. The main excretion route is the kidneys and it is mainly through glomerular filtration. Aminoglycosides have almost similar spectrum of activities; however, amikacin is less susceptible to the modifying enzymes of other aminoglycosides and thus may be effective against some Gram-negative bacilli that are resistant to other aminoglycosides. Tobramycin is slightly superior to gentamicin, but this is not significant. The commonly used aminoglycoside is gentamicin because it is the least costly. The spectrum of activity of aminoglycosides includes Gram-negative bacilli, most of the Staphylococci, some of the Enterococci, Brucella, Francisella tularensis, Yersinia pestis, and some of the nontuberculous Mycobacteria. Aminoglycosides are used in combination with ampicillin or vancomycin in treatment of intraabdominal infections. Hospital-acquired Gram-negative bacilli infections are usually treated empirically with aminoglycosides until the sensitivity of the organism is available. In serious Pseudomonas infections, aminoglycosides are used in combination with an antipseudomonal β-lactam. Streptomycin is the drug of choice in cases of tularemia and plague. It is also used in combination with other antimicrobials to treat brucellosis, tuberculosis, and Enterococcus endocarditis when Enterococcus does not have high resistance (i.e., MIC $<$2,000 mcg/ml). Although resistance is not common, it is increasingly seen with increasing pressure of antibiotic use. The main mechanism of resistance is by production of modifying enzymes which include phosphoryltransferase, acetyltransferase, and adenyltransferase. These enzymes are found in some of Gram-positive cocci, like *Staphylococcus aures*, *Streptococcus pyogenes*, *Enterococcus fecalis*, and *Streptococcus pneumoniae*, and some of Enterobacteriaceae and Pseudomonas. In spite of this known mechanism of resistance, the prevalence of resistance to aminoglycosides among Enterobacteriaceae and Pseudomonas is still low. Other less common causes of resistance to aminoglycosides include alteration in the ribosomal binding or inhibition of transport of the antibiotic to the site of action. The main side effects of aminoglycosides are nephrotoxicity and ototoxicity. Nephrotoxicity is more common in those who have altered renal function either acutely or chronically. It is usually nonoliguric and reversible with discontinuation of therapy; however, it may prolong the illness of the affected patient and occasionally it may be permanent. In contrast to nephrotoxicity, ototoxicity is usually irreversible. These side effects are dose related and therefore it is advisable to maintain serum concentrations within the therapeutic range and to limit the duration of therapy to short periods (7–14 days). Use of single daily dose has shown to be of the same efficacy with reduction in the incidence of toxicity. The rationale behind the single daily dose is related to the dependence of aminoglycosides on their concentrations in bacterial killing. Therefore, with higher concentration achieved with single larger dose, the killing is better. ❯ *Table 73.8* lists commonly utilized aminoglycoside antibiotics.

Macrolides

These are bacteriostatic agents (Table 73.9). They act by inhibition of protein synthesis through binding to peptidyltransferase on 50S ribosome, and thus inhibit peptide bond formation. Erythromycin is the prime drug in this group. Erythromycin base is poorly water soluble, and thus its absorption after oral intake is poor. Therefore, it is linked to some salts that make it more stable in gastric acid and increase its absorption. The salt formulas that are available include: erythromycin stearate, erythromycin succinate, erythromycin propionate, and erythromycin estolate. Erythromycin has a broad spectrum of activity against most of *S. aureus*, some of Streptococcus pneumoniae, Group A and B Streptococci, Mycoplasma species, Chlamydia species, Campylobacter jejani, Bordetella pertussis, and Legionella. Erythromycin is the drug of choice for atypical pneumoniae caused by Mycoplasma pneumoniae, Legionella maltophila and Chlamydia pneumoniae, chlamydia psittaci, or Chlamydia trachomatis. It is also the drug of choice for Campylobacter enteritis. It can be used as an alternative therapy for Group A Streptococci pharyngitis and for syphilis in patients who are allergic to penicillin. It is also an alternative to penicillin for rheumatic fever and endocarditis prophylaxis. Although erythromycin is an effective medication against many of pediatric infections, it has a reputation of being not well tolerated due to high incidence of gastrointestinal upset, namely, gastritis, vomiting, and diarrhea. These symptoms occur in 25% of patients. Other than these, erythromycin is a fairly safe medication with low incidence of other side effects like skin rashes and cholestasis with estolate formula. Azithromycin and clarithromycin are the new macrolides that have the same efficacy as that of erythromycin and yet are less toxic to gastrointestinal system. These macrolides have better pharmacokinesis characteristics. Azithromycin is well absorbed with 37% bioavailability after a single 500 mg dose. It also has a prolonged half-life of 50 h that render it suitable to be given in single daily dose and for

Table 73.8
Commonly used aminoglycosides

Drug	Dose (mg/kg/day)	Route	Spectrum of activity	Side effects
Streptomycin	20 divided every 12 h	IM	M. tuberculosis, brucella, Yersinia pestis, tuleremia	Nephrotoxicity, ototoxicity, neuromuscular blockade, bone marrow suppression, and eosinophilia
Kanamycin	15–30 divided every 8 h	IV, IM	Rarely used, Enterobactericia, Klebsiella	
Gentamicin	7.5 divided every 8 h or once daily	IV, IM	Gram-negative bacilli, S. aureus, brucella	
Tobramycin		IV, IM		
Netilmicin		IV, IM		
Amikacin	15–22 divided every 8 h	IV, IM		
Spectinomycin	30–40 single dose	IM	For Neisseria gonorrhea	

Table 73.9
Macrolides in clinical use

Drug	Dose (mg/kg/day)	Route	Main uses	Side effects
Erythromycin	40 every 6 h	PO, IV	Otitis media, pharyngitis, pneumonia especially those due to chlamydia, mycoplasma, or legionella	Gastritis, vomiting, diarrhea, cholestasis especially estolate form
Azithromycin	10 mg as a loading dose then 5 mg once daily for 4 days	PO, IV	Same as above	Same as above but less frequent, mild elevation of liver transaminases and mild decrease in WBC
Clarithromycin	14 divided every 12 h	PO	Same as above, atypical mycobacteria and Helicobacter gastritis	Same as above

short duration course. Clarithromycin also has similar characteristics with oral bioavailability of 55%, however its half-life of 5–7 h is shorter than that of azithromycin and therefore it is given in twice daily dosage. Both of these new macrolides have broad spectrum of coverage with good activity against most *Streptococci* and *S. aureus* and excellent activity against *H. influenzae*, *Mycoplasma*, *Chlamydia*, *Legionella*, and *Bordetella*. Azithromycin has been reported to be active against *Brucella* and *Helicobacter pylori*. The main clinical uses of azithromycin are upper and lower respiratory tract infections. In children, it is used as a primary or alternative therapy for otitis media in a dose of 10 mg/kg in the first day followed by 5 mg/kg once daily for the subsequent 4 days. It is also used as an alternative to penicillin for treating Group A streptococcal infection in a dose of 12 mg/kg once daily for 5 days. Clarithromycin is one of the main drugs in treating atypical mycobacteria infections especially in AIDS patients. In addition, it is useful in the treatment of *Helicobacter pylori* gastritis. Both of these new macrolides are safe and have lesser incidence of gastrointestinal symptoms in comparison to erythromycin. Only 3–5% of patients using azithromycin and 5–9% of those using clarithromycin will report nausea, vomiting, or diarrhea. Other side effects of skin rashes and mild elevation of liver transaminases occur rarely. Unlike erythromycin, azithromycin has no reported drug interaction with terfenadine, warfarin, cyclosporine, theophylline, or carbamazepine.

Quinolones

The first quinolone known is nalidixic acid, which is mainly used in the treatment and prophylaxis for UTI. Recently, new derivatives are introduced, which are the fluoroquinolones. These antibiotics act by inhibition of DNA gyrase, which is responsible for DNA nicking and thus supercoiling. Although they have been claimed to cause cartilage defects in animals, this has never been proven in humans. Therefore, many authorities find no reason to contraindicate their use in children when needed.

Sulfonamides

Sulfonamides are synthetic agents that act by depriving bacteria from folic acid through their competitive inhibition of PABA, thus preventing conversion of PABA to dihydrofolic acid which is the precursor of folinic acid. They are used in children mainly for UTI and upper respiratory bacterial infections like sinusitis and otitis media. They are contraindicated to be used in jaundiced infants below 1 month of age as they displace bilirubin from albumin and thus may result in hyperbilirubinemia. Their other side effects include skin rashes and bone marrow suppression. Trimethoprim is another folate antagonist, which acts by inhibition of dihydrofolate reductase. In combination with sulfamethoxazole, trimethoprim has been used to treat common childhood respiratory problem like otitis media and sinusitis and urinary tract infections. In addition trimethoprim/sulfamethoxazole (cotrimoxazole) is the drug of choice for treatment of *Pneumocystis carinii* infection.

Carbapenem

Carbapenems are one of the β-lactam antibiotics. The basic constituents of these agents are β-lactam ring and formimidoyl thienamycin ring. The two known antibiotics of this group are imipenem-cilastatin (Primaxin) and meropenem. The third is biapenem and it is still investigational drug. Imipenem and meropenem have similar range of antibacterial activity but differ in their pharmacokinetic features. Imipenem is easily hydrolyzed by kidney dehydropeptidase I resulting in lower concentration of the patent drug in the urine and thus lesser efficacy in urinary infections. In addition, the metabolite is more toxic to the kidneys than patent drug. Combining imipenem with cilastatin in 1:1 ratio has decreased the hydrolysis of Imipenem by dehydropeptidase resulting in 70% of imipenem being secreted unchanged in the urine. Meropenem and biapenem are not metabolized in the kidney and are more stable.

Carbapenems drugs are small in size, are water soluble, and have low protein-binding tendency resulting in their large volume of distribution. Their concentration in all body fluids including CSF is excellent.

These antibiotics have broad spectrum activity, covering Gram-positive and Gram-negative cocci as well as Gram-negative bacilli. Also they are effective against most of anaerobic organisms. As β-lactam antibiotics, they may have cross allergy with other β-lactam but usually rare. Therefore, they can be used as alternative to other β-lactams unless there is history of anaphylaxis to penicillin in which case they should be used cautiously. The main side effects are similar to other β-lactams and include skin rashes and gastrointestinal symptoms. Anaphylaxis is very rare. The major side effect of imipenem is its high potential of inducing seizure especially in high doses which make it

unfavorable to use in meningitis. This has not been reported with the newer carbapenem agents. The recommended dose of imipenem is 50 mg/kg/day in four divided doses. 100 mg/kg/day can be used in life-threatening infections; however, lower dose is recommended for patients who have history of seizure. The maximum allowed daily dose is 4 g. Meropenem is used in a dosage of 20 mg/kg/dose every 8 h, however in meningitis higher dosage of 40 mg/kg/dose every 8 h is recommended.

Monobactam

The only available monobactam is aztreonam. It differs from other bicyclic β-lactam (penicillin, cephalosporins, and carbapenem) in having the nitrogen at the N-1 position replaced by sulfonic acid group. This has resulted in stabilization of the β-lactam ring and its assistance in acetylation of the transpeptidases of the organisms. Azterenam is stable to most of the β-lactamases with the exception of extended spectrum β-lactamases and metallo β-lactamases. It is available in parenteral form as its bioavailability after oral intake is poor. It has a serum half-life of 1.5–2 h and it is 50–70% protein bound. Aztereonam has a good activity against most of the Enterobacteriaceae, Neisseria meningitidis, Neisseria gonorrhea, Haemophilus influenzae, and Pseudomonas aeruginosa. It has limited activity against Acinetobacter, Stenotrophomonas maltophilia, and Flavobacterium. It has no activity against anaerobes or Gram-positive organism. Aztereonam has few side effects including skin rashes, nausea, vomiting, and diarrhea. Although it is one of the β-lactam group, it has no cross reaction with other β-lactam antibiotics. The main uses of aztreonam is in cases of urinary tract infection caused by susceptible organism, intraabdominal infection usually in combination with clindamycin or ampicillin and metronidazole, pelvic inflammatory disease in combination with clindamycin and tetracycline, and in febrile neutropenic patients in combination with an aminoglycoside and vancomycin. The recommended dose for children is 120 mg/kg/day in four divided doses. In cystic fibrosis patients, higher dose is required 200 mg/kg/day in four divided doses.

Vancomycin

Vancomycin is a glycopeptide that acts by inhibition of cell wall synthesis. It is not absorbed when given orally, therefore the only indications for oral vancomycin is pseudomembranous colitis, otherwise it should be given by intravenous route. Intramuscular route is not recommended because of pain associated with injection and inability to monitor the drug level due to variable absorption. The main uses of vancomycin are to treat infections caused by Gram-positive cocci including MRSA, coagulase negative *Staphylococci*, *Enterococci*, and *Corynebacterium jekium*. The last decade witnessed an increasing resistance of Streptococcus pneumoniae to penicillin and in these situations, vancomycin should be used especially in pneumococcal meningitis (◉ *Table 73.10*). The only Gram-negative organism covered by vancomycin is *Flavobacterium meningosepticum*, which is increasingly reported to cause meningitis in premature babies.

The main side effects are gastrointestinal (nausea and vomiting) and red man syndrome, a reaction manifested by macular erythematous eruption mainly over the neck. It is more common if vancomycin is infused rapidly.

Other Antibacterial Agents

Tetracyclines are not used frequently in children because they are contraindicated to be used in any child who is 8 years or lower. This is because of their tendency to accumulate in growing bone especially teeth resulting in permanent greenish-brown staining. They act by binding to ribosome 30S and thus inhibit the binding of aminoacyl-tRNA, which in turn cause disruption of peptide formation. These medications are the first choice in treatment of leptospirosis, Lyme disease, brucellosis, rickettsial diseases, cholera, relapsing fever, non-gonococcal urethritis, trachoma, and anthrax.

Clindamycin is a bacteriostatic antibiotic, which acts by inhibition of protein synthesis through binding to 505 ribosome and this prevents transpeptidation. It is effective in Gram-positive cocci and anaerobic organism. Its main uses are against anaerobic infections in cases of intraabdominal abscesses or diabetic foot. In children, it is more effective in eradicating the carriage state of

Table 73.10
Cutoff limit MIC of pneumococci

Pneumococci	Penicillin	Vancomycin
Susceptible	≤0.06 mcg/ml	≤1
Intermediately resistant	0.12–1	–
Resistant	≥2	–

group A Streptococci from the pharynx. The main side effect of clindamycin is pseudomembranous colitis.

Metronidazole is one of the standard agents for treatment of anaerobic infections. The mechanism of action of metronidazole is thought to be through production of toxic derivatives that destroy DNA. In addition to anaerobic infections, metronidazole uses include treatment of *Helicobacter* infections, intestinal protozoa infections, bacterial vaginosis, trichomoniasis, and pseudomembranous colitis. The major side effects of metronidazole include GIT symptoms, metallic taste, seizure, encephalopathy, skin rashes, and leukopenia; however, these are rare.

Chloramphenicol is a bactereostatic antibiotic that acts by binding to ribosome S 50 and prevents protein synthesis. Until the availability of third-generation cephalosporins, it was the standard choice of treating bacterial meningitis. The wide use of chloramphenicol is hampered by its hematological toxicities. Two types of hematological toxicities can arise: dose-related anemia which usually occurs by 3–5 days after starting therapy and idiosyncratic aplastic anemia that can arise 2 weeks to 12 months following chloramphenicol discontinuation. This idiosyncratic reaction is not related to the dose or route of administration and it can occur even after ophthalmic application. It is estimated to occur at a rate of 1/10,000–50,000 patients exposed to the drug. The other major side effect is gray baby syndrome, which arises when young infants are exposed to high serum level of the drug. It is attributed to cellular hyperventilation, which in turn results in hypotension, vasomotor collapse, pallid cyanosis, and abdominal distention with vomiting. This tragedy can be prevented through close monitoring of the level. In spite of all these drawbacks, chloramphenicol is a very potent antibiotic, which covers a wide variety of organisms including *S. aureus*, *S. pneumoniae*, *Neisseria*, *H. influenzae*, *Salmonella*, *Pseudomonas pseudomallei*, and anaerobic organisms. It has a good penetration to CSF and thus it suitable for treatment of brain abscess. It is also effective in treating rickettsial infections.

New Antibiotics for Gram-Positive Organisms

Gram-positive organisms (Staphylococcus aureus, coagulase-negative Staphylococci, Streptococcus pneumoniae, Enterococcus species, Streptococcus pyogenes, and Streptococcus agalactiae) are major causes of community as well as hospital infections. These organisms are becoming resistant to some of the antibiotics that are used to be effective. New antibiotics are therefore needed:

Linezolid: A new antibiotic that is effective for treating Gram-positive organism including MRSA, CONS, and VRE. This antibiotic is well tolerated by children and does not need dose modification with renal insufficiency. Myelosuppression is being reported rarely in adults and even less in children.
Daptomycin: This is a lipopeptide with good activity against most of the multiple-resistant Gram-positive cocci like MRSA, CoNS, enterococci, and pneumococci. For some patients, muscular bruising occurs, but it is reversible and it is advised that CPK be followed weekly while the patient is on daptomycin therapy. It is not recommended for pneumonia because it dose not achieve a good level in lung tissues.
New glycopeptide: Like oritavancin and dalbavancin, these are on the pipeline and have a better coverage than vancomycin and teicoplanin.
Ceftobiprole: This is a cephalosporin with a good coverage for Gram-positive cocci including MRSA. It also exhibits an extended acting against Gram-negative bacilli similar to that of cefepime.
Tigecycline: This is a tetracycline and therefore it should not be used in children below 8 years of age. It has an excellent coverage for multiple Gram-positive cocci including MRSA and enterococci.

Therapy of Multidrug-Resistant Gram-Negative Bacilli

The common GNB causing infection in human and specially hospitalized ones are becoming more resistant to available antibiotics.

This is exemplified by:

- Pseudomous resistance to ceftazidime, ciprofloxacine, and carbapenem
- Multiresistant acinetobacter species
- Expanded spectrum β-lactamase (ESBL) producing entrobacterecia (Escherechia coli 5%, Kleibsella pneumonie 20%, Enterobacter species 30%)

The increasing number of resistance is related to a number of factors:

- Long hospital stay
- Use of invasive devices

- Complicated surgery
- Extremes of ages
- Inadvertent use of antibiotics
- Immunocompromised status

Although it is recommended to limit the use of empirical antibiotics, there are situations where physicians are enforced to do them; however their use should be guided by the following:

1. Use of optimal dose as lower doses are known to promote resistance
2. Modify the antibiotic to the narrowest spectrum possible once the susceptibility is available
3. Try to obtain a microbiological diagnosis as much as you can, that is, get blood, urine, sputum cultures
4. Avoid prolonged use of antibiotics
5. Follow the center-based guideline for the use of antibiotics

What makes the problem worse is the shortage of available effective antibiotics for those hard and difficult to treat organisms. The armamentarium is really narrow and it includes only few antibiotics when faced by such multiresistant organisms. The available choices include:

- Colistin
- Tigacycline
- Fosfomycin

Colistin

It is an old drug that is now reinvented for use in infections caused by multiresistent Gram-negative bacilli. Colistin is a polypeptide that inhibits bacterial cell wall synthesis. It is available in two forms: colistin sulfate for oral and topical use and colistimethate sodium for parenteral use. Both forms can be delivered by inhalation. Colistin was available 50 years ago, but was abandoned because of its nephrotoxicity and neurotoxicity. However, with increasing resistance among Gram-negative bacilli bacteria and shortage of new effective antibiotics, it regains its popularity. It is now more pure and less toxic, but caution is warranted especially in those with impaired renal function. It is available in two brands: Colomycin at a dose of 6–9 mg/kg/day divided into two or three doses per day and ColyMycin at a dose of 2.5–5 mg/kg/day in two or three divided doses. The use of colistin is limited to infection with multiple-resistant Gram-negative bacilli including Pseudomonas aerogenosa, Enterobacterecia, and Acinetobacter bumanii. It is always recommended to contact the microbiology laboratory interpretation of susceptibility testing. Kidney function should be monitored regularly while the patient is receiving this medication.

Tigecycline

As mentioned above, this new tetracycline has an activity against some of the Gram-negative bacilli that are resistant to other antibiotics like Kleibsella pneumoniae, Serratia marcenense, Enterobacter cloacae, and Escherichia coli. It is not effective against Pseudomonas aerogenosa.

Fosfomycin

It is a phosphonic acid derivative that acts by inhibiting bacterial cell wall. It is available in oral and parenteral forms. In the USA, it is approved for treatment of uncomplicated lower urinary tract infection; however, in many other countries like Germany, Japan, Spain, Brazil, and others, it has been used for treatment of sepsis, deep-seated infection and soft tissue infection, and it is currently. It has an excellent activity against many of multiresistant organisms like methicillin-resistant staphylococcus auresus, Enterococcus faecalis, Pseudomonas aerogenosa, Kleibsella pneumoniae, Serratia marcescens, Escherichia coli, Proteus mirabilis, Haemophilus influenzae, and Streptococcus pneumoniae. It is one of the antibiotics that can be used as a salavage therapy in situation where a multiresistant organism is encountered.

74 Antiviral Therapy

David W. Kimberlin

Introduction

Though work on the synthesis and evaluation of compounds with antiviral activity began shortly after the discovery of penicillin in the 1940s, the rapid recent advances in antiviral development did not begin until several decades later. Much of the early emphasis in antiviral research focused on infections caused by the herpesviruses, in large part due to the recurrent or persistent nature of herpesvirus diseases. In the late 1940s and early 1950s, Hitchings and colleagues demonstrated that purine and pyrimidine antimetabolites, such as 5-bromouracil and 2,6-diaminopurine, inhibited the nucleic acid biosynthesis of viruses, bacteria, protozoa, and malignantly transformed cells. Direct clinical value of these observations was limited by both the toxicity and lack of potency of these early compounds. As such, these early landmark discoveries ultimately reinforced the widely held view of that era, as well as the subsequent two and a half decades, that chemotherapeutic agents with activity against DNA viruses are invariably toxic to the host. The scientific merit of this work was recognized by the global medical community in 1988 when Hitchings and Elion were awarded the Nobel Prize for their efforts in early antiviral development.

Despite these initial limitations, researchers steadfastly continued the quest for antiviral agents that were safe and effective, shifting focus from purine and pyrimidine bases to nucleosides. These compounds were screened against both tumor cells and viruses, reflecting the fact that they usually targeted active host cellular or viral replication processes. This resulted in the synthesis of 5-iododeoxyuridine (IUdR, idoxuridine) in 1959 by Prusoff, and the subsequent demonstration of its antiviral properties in vitro and in vivo. Due to its significant activity against herpes simplex virus (HSV) in 1962, IUdR became the first antiviral compound approved for clinical use, specifically for the topical therapy of primary and recurrent HSV ocular disease. Subsequent development of nucleoside analogues resulted in the synthesis of such compounds as 5-trifluoromethyl-2'-deoxyuridine (trifluorothymidine) and 9-(β-D-arabinofuranosyl)adenine (ara-A, vidarabine) in the 1960s. Due to the fact that most of these compounds did not distinguish between viral and host cellular functions, toxicity remained a significant problem with the systemic administration of these agents. Indeed, the first antiviral compound licensed for systemic use in the United States was not an anti-herpesvirus agent at all, but rather was amantadine, which was licensed in 1966 for the prophylaxis of influenza virus infections. In 1977, vidarabine became the first anti-herpesvirus agent to be licensed in the United States for systemic administration; this followed studies earlier in the 1970s demonstrating its utility in the management of infections caused by varicella-zoster virus (VZV) and HSV.

The obstacles encountered in the development of these first generation antiviral drugs emphasize several important generalizations that continue to influence the development of new antiviral compounds: (1) although many compounds demonstrate antiviral activity in vitro, most are associated with unacceptable toxicity due to interference with human host cell functions; (2) effective antiviral agents typically target a specific viral protein, thus producing a restricted spectrum of antiviral activity; (3) antiviral drug resistance is frequently the consequence of single nucleotide changes that result in critical amino acid substitutions in the target viral protein; (4) the presence of an intact host immune system is vital to the effective resolution of disease in the host, regardless of the presence or absence of an antiviral drug; (5) clinical efficacy is dependent upon adequate concentrations of the antiviral drug reaching the site of infection, including the achievement of adequate intracellular concentrations of drug; and (6) the in vitro assay systems utilized for the determination of antiviral susceptibility are not standardized, and correlation between in vitro drug concentration and in vivo clinical response is not established for most antiviral agents.

The significant progress in the development of effective anti-herpesvirus compounds in the 1970s directly paved the way for the dramatically rapid advances in the development of antiretroviral drugs in the 1980s and 1990s directed against human immunodeficiency virus (HIV). Likewise, the importance of advances in molecular biology and the resulting understanding of virus host-cell

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_74,

interactions cannot be overemphasized. The convergence of scientific experience with the emergence of a previously unknown viral entity (HIV) is stunning. A discussion of systemic antiviral small molecule drugs with activity against herpesviruses, respiratory viruses, and hepatitis B viruses will be presented in this chapter. However, the HIV-specific drugs (antiretroviral drugs and protease inhibitors) will not be reviewed due to the immensity of the subject and the extremely rapid therapeutic developments currently being enjoyed in that field.

Systemic Anti-Herpesvirus Agents

Acyclovir

The licensure of acyclovir in 1982 opened the field of clinical antiviral drug intervention and heralded the era of rapid development of new drugs. By requiring the presence of a virus-encoded enzyme to begin the process of intracellular phosphorylation, acyclovir became the first antiviral agent to target virus-infected cells rather than all host cells. Acyclovir's remarkable safety profile and impressive clinical utility have established the standard by which all subsequent antiviral drugs have been judged.

Antiviral Activity

Acyclovir (9-[2-hydroxyethoxymethyl]guanine) is a selective inhibitor of the replication of HSV-1, HSV-2, and VZV. Acyclovir concentrations required to inhibit the viral cytopathic effects of HSV-1, HSV-2, and VZV by 50% (ED_{50}s) are 0.04, 0.10, and 0.50 μg/mL, respectively. Acyclovir has a lesser degree of in vitro activity against Epstein-Barr virus (EBV) and human herpesvirus-6 (HHV-6) but lacks in vitro activity against cytomegalovirus (CMV).

Mechanism of Action

Acyclovir is converted by the HSV or VZV thymidine kinase (TK) to its monophosphate derivative, an event that occurs to a much lower extent in uninfected cells. Subsequent diphosphorylation and triphosphorylation are catalyzed by cellular enzymes, resulting in acyclovir triphosphate concentrations that are 40–100 times higher in HSV-infected cells than in uninfected cells. Acyclovir triphosphate prevents viral DNA synthesis by inhibiting the viral DNA polymerase. Acyclovir triphosphate is a much better substrate for the viral polymerase than for cellular DNA polymerase α, resulting in little incorporation of acyclovir into cellular DNA.

Pharmacokinetics

Bioavailability of the oral is only 15–30%. Steady-state peak plasma concentrations of 1.6 μg/mL and 20 μg/mL are achieved following an 800 mg oral dose and a 10 mg/kg intravenous dose, respectively. Acyclovir is minimally metabolized, and approximately 85% is excreted unchanged in the urine. In patients with normal renal function, the serum half-life is 2–3 h. The dosage of acyclovir must be adjusted in patients with impaired renal function.

Adverse Effects

Acyclovir has consistently demonstrated a remarkable safety profile. Reversible nephrotoxicity can occur, especially in patients receiving large doses of acyclovir by rapid intravenous infusion. In adults, however, oral acyclovir therapy has not been associated with nephrotoxicity. Acyclovir administration to neonates and young infants has been associated with neutropenia, although perhaps to a lesser degree ($\leq$20% developing neutropenia) than originally thought. High concentrations of acyclovir following intravenous administration in patients with impaired renal function can result in central nervous system complications such as agitation, hallucinations, disorientation, tremors, and myoclonus.

Resistance

Viral resistance to acyclovir can result from mutations in either the viral TK gene or the viral DNA polymerase gene. HSV isolates demonstrate acyclovir resistance in approximately 5% of transplant patients and patients with AIDS. Acyclovir-resistant HSV has also been documented rarely in immunocompetent adults and infants. Foscarnet is the drug of choice in the management of patients with acyclovir-resistant HSV and VZV infections.

Therapeutic Uses

HSV and VZV Infections Recommended doses of oral and intravenous acyclovir for clinical treatment are provided in *Table 74.1*. Acyclovir treatment is indicated for life-threatening infections and for disease associated with severe morbidity and death, such as HSV encephalitis, neonatal HSV infections, and VZV infections in compromised hosts. Acyclovir therapy is also indicated for mucocutaneous HSV infections in immunocompromised hosts and for disseminated HSV and VZV infections in otherwise normal hosts, including pregnant women. Acyclovir is effective for the treatment of primary genital HSV infections, reducing the median duration of viral shedding, pain, and length of time to complete healing. Intravenous and oral acyclovir therapies are almost

Table 74.1

Dosing of antiviral drugs in pediatric patients with normal renal function

Drug	Indication	Route	Age	Usually recommended dosage
Acyclovir	Neonatal HSV infection	IV	Birth to 3 months	60 mg/kg per day in three divided doses for 14–21 days
	HSV encephalitis	IV	≥3 months to 12 years	30–45 mg/kg per day in three divided doses for 14–21 days; FDA-approved dose for this indication and age range is 60 mg/kg per day in three divided doses, but nephrotoxicity may be increased at this higher dose
		IV	≥12 years	30 mg/kg per day in three divided doses for 14–21 days
	Varicella in immunocompetent host	Oral	≥2 years	80 mg/kg per day in four divided doses for 5 days; maximum dose, 3,200 mg/day
	Varicella in immunocompromised host	IV	<1 year	30 mg/kg per day in three divided doses for 7–10 days
		IV	≥1 year	1,500 mg/m^2 per day in three doses for 7–10 days; some experts recommend the 30 mg/kg per day dose
	Zoster in immunocompetent host	IV	All ages	Same as for varicella in immunocompromised host
		Oral	≥12 years	4,000 mg/day in five divided doses for 5–7 days
	Zoster in immunocompromised host	IV	<12 years	30 mg/kg per day in three divided doses, for 7–10 days
		IV	≥12 years	30 mg/kg per day in three divided doses, for 7–10 days
	HSV infection in immunocompromised host (localized, progressive, or disseminated)	IV	<12 years	30 mg/kg per day in three divided doses for 7–14 days
		IV	≥12 years	30 mg/kg per day in three divided doses for 7–14 days
		Oral	≥2 years	1,000 mg/day in three to five divided doses for 7–14 days
	Prophylaxis of HSV in immunocompromised hosts who are HSV seropositive	Oral	≥2 years	600–1,000 mg/day in three to five divided doses during period of risk
		IV	All ages	15 mg/kg in 3 divided doses during period of risk
	Genital HSV infection: first episode	Oral	≥12 years	1,000–1,200 mg/day in 3–5 divided doses for 7–10 days
				Oral pediatric dose: 40–80 mg/kg per day divided in three to four doses for 5–10 days (maximum 1.0 g/day)
		IV	≥12 years	15 mg/kg per day in three divided doses for 5–7 days
	Genital HSV infection: recurrence	Oral	≥12 years	1,000 mg in five divided doses for 5 days, or 1,600 mg in two divided doses for 5 days, or 2,400 mg in three divided doses for 2 days
	Chronic suppressive therapy for recurrent genital and cutaneous (ocular) HSV episodes	Oral	≥12 years	800 mg/day in two divided doses for as long as 12 continuous months

Table 74.1 (Continued)

Drug	Indication	Route	Age	Usually recommended dosage
Adefovir	Chronic hepatitis B	Oral	≥12 years	10 mg once daily in patients with adequate renal function; optimal duration of therapy unknown
Amantadine	Influenza A: treatment and prophylaxis	Oral	1–9 years	Treatment or prophylaxis: 5 mg/kg per day, maximum 150 mg/day, in two divided doses
		Oral	≥10 years	Treatment or prophylaxis: <40 kg: 5 mg/kg per day, in two divided doses; ≥40 kg: 200 mg/day in two divided doses
		Oral	Dose by weight, not age	Alternative prophylactic dose for children >20 kg and adults: 100 mg/day
Cidofovir (Vistide)	Cytomegalovirus (CMV) retinitis	IV	Adult dose	Induction: 5 mg/kg once weekly × two doses with probenecid and hydration
				Maintenance: 5 mg/kg once every 2 weeks with probenecid and hydration
Entecavir	Chronic hepatitis B	Oral	≥16 years	0.5 mg once daily in patients who have not received prior nucleoside therapy; 1 mg once daily in patients who are previously treated (not first choice in this setting); optimum duration of therapy unknown
Famciclovir	Genital HSV infection, episodic recurrent episodes	Oral	Adult dose	Immunocompetent: 2,000 mg/day in two divided doses for 1 day
				HIV-infected patients: 1,000 mg in two divided doses for 7 days
	Daily suppressive therapy	Oral	Adult dose	Immunocompetent: 500 mg/day in two divided doses for 1 year, then reassess for recurrence of HSV infection
	Recurrent herpes labialis	Oral	Adult dose	Immunocompetent: 1,500 mg as a single dose
				HIV-infected patients: 1,000 mg/day in two divided doses for 7 days
	Herpes zoster	Oral	Adult dose	1,500 mg/day in three divided doses for 7 days
Foscarnet	CMV retinitis in patients with acquired immunodeficiency syndrome	IV	Adult dose	180 mg/kg per day in two to three divided doses for 14–21 days, then 90–120 mg/kg once a day as maintenance dose
	HSV infection resistant to acyclovir in immunocompromised host	IV	Adult dose	80–120 mg/kg per day in two to three divided doses until infection resolves
	VZV infection resistant to acyclovir	IV	Adult dose	120 mg/kg/day, divided every 8 h, up to 3 weeks
Ganciclovir	Acquired CMV retinitis in immunocompromised host	IV	Adult dose	Treatment: 10 mg/kg per day in two divided doses for 14–21 days; Long-term suppression: 5 mg/kg per day for 7 days/week or 6 mg/kg per day for 5 days/week
	Prophylaxis of CMV in high-risk host	IV	Adult dose	10 mg/kg per day in two divided doses for 1–2 weeks, then 5 mg/kg per day in one dose for 100 days or 6 mg/kg per day for 5 days/week
Lamivudine	Treatment of chronic hepatitis B	Oral	≥2 years	3 mg/kg once day (maximum 100 mg/day) (children coinfected with HIV and hepatitis B should use the approved dose for HIV)

Oseltamivir	Influenza A and B: treatment	Oral	Birth to <12 months	3 mg/kg/dose twice daily
		Oral	1–12 years	≤15 kg: 30 mg, twice daily; 16–23 kg: 45 mg, twice daily; 24–40 kg: 60 mg, twice daily; >40 kg: 75 mg, twice daily
		Oral	≥13 years	75 mg twice daily for treatment
	Influenza A and B: prophylaxis	Oral	1–12 years	Same as treatment for patients 1–12 years of age, except dose given once daily
		Oral	≥13 years	75 mg once daily
Rimantadine	Influenza A: treatment	Oral	≥13 years	200 mg/day in two divided doses
	Influenza A: prophylaxis	Oral	≥1 year	1–9 years of age: 5 mg/kg per day, maximum 150 mg/day, once daily
				≥10 years of age, <40 kg: 5 mg/kg per day in two divided doses; ≥40 kg: 200 mg/day in two divided doses
Telbivudine	Chronic hepatitis B	Oral	Adult dose	600 mg once daily
Tenofovir	Chronic hepatitis B	Oral	Adult and adolescent dose	300 mg once daily
				8 mg/kg once daily
			2– 8 years old (for HIV)	
Valacyclovir	Chickenpox	Oral	2–<18 years	20 mg/kg per dose three times daily for 5 days, not to exceed 1 g per dose three times daily
	Genital HSV infection, first episode	Oral	Adult dose	2 g/day in two divided doses for 10 days
	Episodic recurrent genital HSV infection	Oral	Adult dose	1 g/day in two divided doses for 3 days
	Daily suppressive therapy for recurrent genital HSV infection	Oral	Adult dose	1,000 mg, once daily for 1 year, then reassess for recurrences
	Recurrent herpes labialis	Oral	>12 years	4 g/day in two divided doses for 1 day
	Herpes zoster	Oral	Adult dose	3 g/day in three divided doses for 7 days
Valganciclovir	Acquired CMV retinitis in immunocompromised host	Oral	Adult dose	Treatment: 900 mg twice daily for 3 weeks
				Long-term suppression: 900 mg once daily
	Prevention of CMV disease in kidney or heart transplant patients	Oral	4 months to 16 years	Dose once a day within 10 days of transplantation until 100 days post-transplantation according to dosage algorithm based on body surface area and creatinine clearance (see Drug Package Insert)
Zanamivir	Influenza A and B: treatment (see Influenza, p 400)	Inhalation	≥7 years (treatment)	10 mg twice daily for 5 days
	Influenza A and B: prophylaxis	Inhalation	≥5 years (prophylaxis)	10 mg, once daily for as long as 28 days (community outbreaks) or 10 days (household setting)

IV indicates intravenous, *IO* intraocular, *IM* Intramuscular, *SC* subcutaneous, *IU* international units

equally efficacious, with topical treatment providing less benefit. Acyclovir probably reduces the ocular morbidity of zoster ophthalmicus. The advantages of treating previously healthy individuals with herpes labialis, recurrent genital herpes, varicella, and herpes zoster are less dramatic, and the treatment of patients with these conditions should be individualized.

The most frequent indication for long-term suppressive oral therapy is in patients with frequently recurrent genital infections, in whom daily administration of acyclovir reduces the frequency of recurrences by at least 75%. Acyclovir has been shown to maintain a high degree of efficacy and little toxicity even after more than 5 years of continuous suppressive therapy. The use of prophylactic acyclovir therapy in pregnant women has been explored in several small studies, but the numbers of patients evaluated to date are insufficient to prove definitively its safety or efficacy in this population.

Valaciclovir

Valaciclovir (2-[2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl-methothy]ethyl-L-valinate hydrochloride, Valtrex) is the L-valyl ester of acyclovir. This esterification serves only to increase the oral bioavailability of acyclovir, and administration of valaciclovir produces higher serum levels of acyclovir than comparable oral doses of acyclovir.

Antiviral Activity

Due to the fact that valaciclovir is converted to acyclovir prior to its monophosphorylation as acyclovir in HSV-infected cells, the spectrum of antiviral activity is identical to that of the parent compound.

Mechanism of Action

As expected with a prodrug, valaciclovir has the same mechanism of action as acyclovir and requires viral TK-dependent conversion of acyclovir to the monophosphate form.

Pharmacokinetics

After oral administration of valacyclovir, rapid and complete conversion to acyclovir occurs with first-pass intestinal and hepatic metabolism. The bioavailability of valacyclovir in adults exceeds 50%, which is 3 to 5 times greater than that of acyclovir. Peak serum concentrations, attained about 1.5 h after a dose has been given, are proportional to the amount of drug administration, and the area under the drug concentration time curve approximates that seen after intravenous acyclovir. All other pharmacokinetic characteristics are similar to those of acyclovir.

Valacyclovir oral suspension recently has been studied in children 1 month to 12 years of age. Bioavailability was estimated to be 45–51% in all age groups except 3–<6 month olds, in whom the bioavailability is lower at 22%. Approximate dose proportionality in C_{max} and AUC(0-∞) was seen across the 10–25 mg/kg dose range (i.e., dose-normalized differences generally within $\leq\sim$30%), with the exception of children in the 2–<6 year age range, for whom a near doubling in C_{max} and AUC(0-∞) was noted with only a modest increase in dose from 20 to 25 mg/kg in children beyond infancy (>12 months of age).

Adverse Effects

The safety profile of valaciclovir is similar to that of acyclovir. Clinical trials have shown that valaciclovir is very well tolerated and relatively nontoxic at dosages of up to 1 g three times per day. Primary side effects of the medication include gastrointestinal upset, vomiting, and headache.

Resistance

As valaciclovir is rapidly and efficiently converted to acyclovir following gastrointestinal absorption, the mechanisms of antiviral resistance are the same as for acyclovir.

Therapeutic Uses

Recommended doses of valacyclovir for clinical treatment are provided in ❯ *Table 74.1*. The indications for valacyclovir in adults are the same as those for acyclovir. In the United States, valacyclovir is licensed for the treatment of pediatric patients with orolabial HSV recurrences (12 years of age and older) and chickenpox (2–<18 years of age).

Famciclovir/Penciclovir

Penciclovir (9-[4-hydroxy-3-hydroxymethylbut-1-yl] guanine) is an acyclic nucleoside analog of guanosine. Famciclovir is the inactive diacetyl ester prodrug of penciclovir, with high oral bioavailability, rapid tissue distribution, and a long intracellular half-life.

Antiviral Activity

The spectrum of antiviral activity of penciclovir is similar to that of acyclovir. Penciclovir has demonstrable in vitro activity against HSV-1, HSV-2, VZV, EBV, and hepatitis B virus (HBV). As a prodrug, famciclovir lacks antiviral activity and, instead, produces antiviral effects only

following its conversion to penciclovir after oral administration.

Mechanism of Action

Penciclovir is the quite similar to acyclovir with respect to mechanism of activation. Like acyclovir, penciclovir is converted to its monophosphate form by viral TK. Penciclovir monophosphate is then converted to the triphosphate form by cellular enzymes. Like acyclovir triphosphate, penciclovir triphosphate serves as a competitive inhibitor of viral DNA polymerase and is incorporated into the nascent DNA chain. Penciclovir triphosphate has approximately 1/100th the potency of acyclovir triphosphate in inhibiting viral DNA polymerase, but by virtue of its high intracellular concentrations and long half-life, it remains an effective antiviral agent.

Pharmacokinetics

Hydrolysis in the intestinal wall and first-pass metabolism in the liver remove both acetyl moieties of famciclovir, converting it to penciclovir. Approximately 80% of the drug is absorbed after oral dosing, with drug absorption being unaffected by pH. Food delays absorption but does not affect the final plasma drug concentration. Peak serum concentrations of penciclovir are achieved 1 h following administration of a 500 mg dose of famciclovir, and the plasma half-life of penciclovir is 2 h. Renal clearance accounts for about 70% of drug elimination, with penciclovir being excreted unchanged in the urine by both glomerular filtration and tubular secretion. Dosage adjustment is required in patients with renal impairment.

Famciclovir pharmacokinetics have recently been assessed in a single-dose pediatric study of infants 1–12 months of age who were administered famciclovir sprinkles orally. Infants under 6 months of age had significantly lower systemic exposure compared with 6–12 month olds.

Adverse Effects

Safety analyses of famciclovir in humans have found the drug to be well tolerated and exceptionally nontoxic. Famciclovir increases digoxin levels and causes nausea (4.5%), diarrhea (2.4%), and headache (9.3%) in some patients.

Resistance

Penciclovir- and acyclovir-resistant mutants are roughly similar with respect to both phenotypic and genotypic alterations. Mutations in the viral TK that bestow acyclovir resistance will usually also confer cross-resistance to penciclovir.

Therapeutic Uses

Recommended doses of famciclovir for clinical treatment are provided in *Table 74.1*. Famciclovir is approved in the United States for treatment in immunocompetent hosts of primary and recurrent genital HSV infections and of herpes zoster. In placebo-controlled trials of the treatment and suppression of recurrent HSV lesions, famciclovir decreases pain and results in earlier healing of lesions by 2 days. In the management of herpes zoster, famciclovir accelerates cutaneous healing by 1 day and shortens the duration of postherpetic neuralgia when compared to placebo. A 7-day course of famciclovir (500 mg three times daily) is as efficacious as a 5-day course of acyclovir (800 mgfive times daily) for the treatment of herpes zoster in immunocompetent patients, with equivalent rates of healing, duration of acute pain, and drug side effects between the two treatments.

Ganciclovir

Ganciclovir (9-[1,3-dihydroxy-2-propoxymethyl] guanine) is another acyclic nucleoside analog of guanosine which, when compared to acyclovir, has an additional hydroxymethyl group. This additional group on the acyclic side chain conveys a markedly different spectrum of activity and adverse events profile than the previously discussed antiviral agents.

Antiviral Activity

Ganciclovir demonstrates striking activity against CMV, with inhibitory concentrations of 0.2–3.0 μg/mL for susceptible clinical isolates. Such marked anti-CMV activity is in contrast to that of acyclovir, penciclovir, and their respective prodrugs.

Mechanism of Action

As with acyclovir and penciclovir, ganciclovir requires intracellular phosphorylation to its active triphosphate derivative. In HSV- and VZV-infected cells, the initial monophosphorylation is accomplished by the viral TK. However, CMV does not encode a thymidine kinase; instead, the enzyme that catalyzes the initial phosphorylation of ganciclovir in CMV-infected cells is the phosphotransferase encoded by the UL97 gene. Cellular enzymes subsequently convert the monophosphate form to the active triphosphate derivative. Ganciclovir triphosphate serves as a competitive inhibitor of herpesviral DNA polymerases, though it has also some activity against cellular DNA polymerases. Incorporation of ganciclovir triphosphate into the growing viral DNA chain

results in slowing and subsequent cessation of DNA-chain elongation.

Pharmacokinetics

Following an intravenous dose of 5 mg/kg, ganciclovir peak and trough plasma concentrations average 8–11 μg/mL and 0.6–1.2 μg/mL, respectively. Concentrations of ganciclovir in the central nervous system range from 24% to 70% of those in the plasma, with brain concentrations of 38% of plasma levels. The pharmacokinetics of ganciclovir in the neonatal population are similar to those of adults. The plasma half-life of ganciclovir is 3–4 h, and the route of drug excretion is virtually entirely renal. In patients with renal impairment, therefore, dosage adjustments are required.

Adverse Effects

The primary adverse events attributable to ganciclovir therapy are hematologic. Up to 40% of adult patients and 68% of neonates receiving parenteral ganciclvoir experience neutropenia (absolute neutrophil counts $<$1,000 cells/mm^3), and thrombocytopenia occurs in up to 20% of adult ganciclovir recipients. The likelihood of neutropenia following oral administration of ganciclovir is lower, with 14–24% of patients developing an absolute neutrophil count of $<$1,000 cells/mm^3. These hematologic abnormalities are reversible upon cessation of drug. Alternatively, use of colony stimulating factors (G-CSF, GM-CSF) may also expedite bone marrow recovery from ganciclovir toxicity. Additional adverse effects seen with administration of ganciclovir include anemia, liver function abnormalities, headache, rash, fever, nausea/vomiting, and diarrhea.

Resistance

Ganciclovir resistance among CMV isolates is conferred by mutations in either the UL 97 gene or the CMV DNA polymerase gene. Of these two mechanisms of antiviral resistance, ganciclovir-resistant CMV isolates with mutations in the UL97 open reading frame are the predominant phenotype. Mutations in the CMV DNA polymerase can confer cross-resistance to foscarnet.

Therapeutic Uses

Recommended doses of ganciclovir for clinical treatment are provided in ❯ *Table 74.1*. The frequent occurrence of side effects limits the utilization of ganciclovir to those patients with potentially severe CMV disease. In the management of CMV retinitis, intravenous ganciclovir will result in stabilization or improvement of disease in approximately 75–85% of patients. Among solid organ transplant recipients, ganciclovir monotherapy is effective in the treatment of CMV pneumonia. In bone marrow transplant patients, however, CMV hyperimmune globulin should be administered concurrently with intravenous ganciclovir in the management of CMV lung disease. Ganciclovir monotherapy is ineffective in the treatment of CMV colitis in bone marrow transplant patients.

Prophylactic administration of intravenous ganciclovir is effective for the prevention of CMV disease in transplant patients. Several different regimens have been evaluated in these patients, including initiation of antiviral therapy at the time of transplantation, upon isolation of CMV from any body site following transplantation, and preemptively at the time of administration of antilymphocyte antibody. Prophylactic ganciclovir use also decreases HSV shedding in transplant patients.

Valganciclovir

Valganciclovir is the L-valine ester prodrug of ganciclovir. Because it is well absorbed after oral administration, it may represent a favorable option to intravenously administered ganciclovir for the treatment and suppression of CMV infections in immunocompromised hosts.

Antiviral Activity

Due to the fact that valaganciclovir is converted to ganciclovir prior to its phosphorylation in CMV-infected cells, the spectrum of antiviral activity is identical to that of the parent compound.

Mechanism of Action

As expected with a prodrug, valganciclovir has the same mechanism of action oas ganciclovir and requires phosphorylation by the UL97 gene product to the monophosphate form.

Pharmacokinetics

Valganciclovir is rapidly converted to ganciclovir, with a mean plasma half-life of about 30 min. The absolute bioavailability of valganciclovir exceeds 60% and is enhanced by about 30% with concomitant administration of food. Oral valganciclovir produces exposures of ganciclovir exceeding those attained with oral ganciclovir and similar to those reported after standard intravenous administration of ganciclovir. Oral valganciclovir pharmacokinetics in young infants have been compared with parenteral ganciclovir. Intravenous ganciclovir clearance nearly doubled and AUC_{12} was cut by almost half over the first 6 weeks of life. In comparison, only a marginal

decrease in AUC_{12} was noted following administration of valganciclovir oral solution, possibly due to the fact that bioavailability increased by 32% over the same time period.

Adverse Effects

The most common side effects associated with valganciclovir therapy include diarrhea (41%), nausea (30%), neutropenia (27%), anemia (26%), and headache (22%). Long-term (up to 5 years) treatment with valganciclovir is well tolerated in patients with AIDS, and the type and incidence of adverse events experienced long-term appear to be similar to those observed at 1 year.

Resistance

As valaganciclovir is rapidly and efficiently converted to ganciclovir following gastrointestinal absorption, the mechanisms of antiviral resistance are the same between the two drugs.

Therapeutic Uses

Recommended doses of valganciclovir for clinical treatment are provided in ❯ *Table 74.1*. Valganciclovir has similar indications to ganciclovir. However, based on limited controlled trials published to date, it is currently only approved for the induction and maintenance therapy of CMV retinitis. Orally administered valganciclovir appears to be as effective as intravenous ganciclovir for induction treatment and is convenient and effective for the long-term management of CMV retinitis in patients with AIDS.

The greater systemic exposure to ganciclovir delivered by valganciclovir when used prophylactically is safe and is associated with delayed development of viremia in solid organ transplant recipients, compared with oral ganciclovir. Valganciclovir is also effective as preemptive therapy and as treatment for CMV disease in solid organ transplant recipients.

Cidofovir

Cidofovir {(S)-1-[3-hydroxy-2 (phosphonylmethoxy)-propyl]cytosine} is a novel acyclic phosphonate nucleoside analog.

Antiviral Activity

Cidofovir has demonstrable activity against HSV and CMV. Due to its unique phosphorylation requirements for activation, the drug usually maintains activity against acyclovir- and foscarnet-resistant HSV isolates, as well as ganciclovir- and foscarnet-resistant CMV mutants. Cidofovir exhibits marked activity against CMV, with inhibitory concentrations of 0.1 μg/mL for susceptible clinical isolates.

Mechanism of Action

Cidofovir has a mechanism of action that is similar to other nucleoside analogues such as acyclovir and ganciclovir. In its native form, however, cidofovir already has a single phosphate group attached. As such, viral enzymes are not required for initial phosphorylation of drug. Rather, cellular kinases sequentially attach two additional phosphate groups, converting cidofovir to its active diphosphate form. This active compound then serves as a competitive inhibitor of DNA polymerase. While cidofovir is taken up by both virally infected and uninfected cells, the active form of the drug exhibits a 25- to 50-fold greater affinity for the viral DNA polymerase as compared to the cellular DNA polymerase, thereby selectively inhibiting viral replication.

Pharmacokinetics

Following intravenous administration of cidofovir, plasma half-life is 2.6 h, though cidofovir persists in cells for prolonged periods. In addition, active intracellular metabolites of cidofovir have long half-lives of 17–48 h. Such prolonged intracellular activity allows for an intermittent dosing schedule that is very attractive when compared to ganciclovir or foscarnet. Ninety percent of the drug is excreted in the urine, primarily by renal tubular secretion.

Adverse Effects

The principle adverse event associated with systemic administration of cidofovir is the development of nephrotoxicity. Cidofovir concentrates in renal cells in amounts 100 times greater than is seen in other tissues, producing severe proximal convoluted tubule nephrotoxicity when concomitant hydration and administration of probenicid are not employed. When present, renal toxicity manifests as proteinuria and glycosuria. Due to poor oral bioavailability (2–26%), cidofovir can only be administered intravenously or topically.

Resistance

Ganciclovir resistance conferred by mutations within the CMV DNA polymerase gene can be cross-resistant to cidofovir and sensitive to foscarnet.

Therapeutic Uses

Recommended doses of cidofovir for clinical treatment are provided in ❯ *Table 74.1*. Cidofovir has been evaluated

for the treatment of CMV retinitis in patients with acquired immunodeficiency syndrome (AIDS), and it delays retinal disease progression. The drug should be administered with probenecid, and hydration should be assured. The safety and efficacy of cidofovir in children have not been studied.

Intralesional injection of cidofovir has been reported in several small, uncontrolled studies in patients with laryngeal papillomatosis caused by HPV infection. Recent uncontrolled studies, however, have reported less impressive therapeutic responses to cidofovir therapy, raising further questions about cidofovir's efficacy and safety in laryngeal papillomatosis. Case reports and small case series suggest that cidofovir may be beneficial in the management of adenovirus infections and BK virus infections in immunocompromised patients.

Foscarnet

Unlike the antiviral drugs discussed so far, foscarnet (trisodium phosphonoformate) is not a nucleoside derivative. Rather, this compound is an inorganic pyrophosphate analog. This basic difference provides foscarnet with a broader spectrum of activity than is available with the almost all of the other antiviral drugs discussed in this chapter.

Antiviral Activity

Foscarnet has demonstrable activity against all known human herpesviruses and HIV. While the drug concentrations required for inhibition of viral replication vary markedly, they generally range from 10 to 130 μM for HSV, 100–300 μM for CMV, and 10–25 μM for HIV. Foscarnet has proven useful in the treatment of disease caused by acyclovir- and ganciclovir-resistant isolates of HSV, VZV, and CMV.

Mechanism of Action

Foscarnet does not require intracellular metabolism to produce an active form of the drug. Rather, it directly inhibits viral DNA polymerase by blocking the pyrophosphate binding site and preventing cleavage of pyrophosphate from deoxynucleotide triphosphates. It is a noncompetitive inhibitor of viral DNA polymerases or HIV reverse transcriptase, and is not incorporated into the growing viral DNA chain. Once inside the cell, however, it is roughly 100-fold more active against viral DNA polymerases and HIV reverse transcriptase than cellular DNA polymerase α.

Pharmacokinetics

Plasma peak concentrations average 509 μM and 766 μM following intravenous administration of 60 mg/kg and 90 mg/kg foscarnet doses, respectively. Oral bioavailability is less than 20%. Initial plasma half-life ranges from 4 to 8 h in persons with normal renal function, but a more prolonged terminal half-life of up to 88 h occurs secondary to deposition of drug in bone. At steady state in CMV-infected individuals, the concentration of foscarnet achieved in the cerebrospinal fluid averages 66% of the plasma level. The major route of foscarnet elimination is renal, with most of the drug being excreted in an unmetabolized form. Dosage adjustments are required for the administration of foscarnet to patients with renal impairment.

Adverse Effects

The administration of foscarnet is frequently associated with the occurrence of adverse events, most commonly nephrotoxicity and metabolic derangements. Increases in serum creatinine occur in more than half of foscarnet recipients, though in most instances these adverse effects are reversible upon withdrawal of drug. Saline hydration can decrease the risk of nephrotoxicity. The metabolic abnormalities associated with foscarnet can include either elevations or decreases in serum calcium, phosphorus, and/or magnesium. Additional adverse effects include headache, tremor, altered sensorium, fever, nausea/vomiting, and abnormal liver function tests. Though hematologic abnormalities such as neutropenia and anemia also can occur, their incidence with foscarnet administration is much less than is seen with ganciclovir. The high concentrations of unmetabolized foscarnet excreted in the urine can produce genital ulcerations due to local toxicity from mucocutaneous contact. The skeletal and dental abnormalities seen in animals, as well as the fact that the drug must be diluted in large volumes of fluid, have precluded the systematic evaluation of foscarnet in infants and young children.

Resistance

Because foscarnet acts directly on the herpesviral DNA polymerase and does not require intracellular activation by viral or cellular enzymes, antiviral resistance is conferred only by mutations within the DNA polymerase gene. Passage of HSV and CMV isolates in the presence of drug can select for resistant variants. In addition, clinical HSV, VZV, and CMV isolates that are resistant to foscarnet have been reported. While cross-resistance with other antiherpesvirus agents has been described,

foscarnet-resistant mutants that remain amenable to treatment with acyclovir, ganciclovir, or cidofovir can occur.

Therapeutic Uses

Recommended doses of foscarnet for clinical treatment are provided in *Table 74.1*. Foscarnet administered intravenously has proven efficacious for the treatment of CMV retinitis, with approximately 90% of patients experiencing stabilization of their retinal disease; however, most will experience subsequent progression of infection and require re-induction. Foscarnet may also be effective in the management of CMV gastroenteritis or pulmonary infections in AIDS patients or transplant recipients, though studies of the drug in these conditions have not been well controlled. Notably, foscarnet is not beneficial in the treatment of CMV pneumonia in bone marrow transplant recipients.

Mucocutaneous disease produced by acyclovir-resistant HSV isolates is effectively treated with foscarnet. Additionally, acyclovir-resistant VZV disease in AIDS patients appears to respond to a change in antiviral therapy to foscarnet.

Antiviral Agents Active Against Respiratory Viruses

Oseltamivir

Oseltamivir is one of two licensed medications that specifically target the neuraminidase protein common to influenza A and B viruses.

Antiviral Activity

The influenza neuraminidase enzyme is highly conserved, being common to type A H1N1, type A H2N2, type A H3N2, type A H5N1, and type B influenza viruses. Therefore, this class of antiviral agents has activity against both influenza A and B viruses.

Mechanism of Action

The mechanism of action for this class of compounds is the specific inhibition of the influenza neuraminidase, with subsequent interference with the deaggregation and release of the viral progeny. Oseltamivir is an ethyl ester prodrug that, following hydrolysis by hepatic esterases, is converted to the active compound, oseltamivir carboxylate.

Pharmacokinetics

At least 75% of orally administered drug reaches the systemic circulation in the form of oseltamivir carboxylate. Coadministration with food has no significant effect on the peak plasma concentration. Neither oseltamivir nor oseltamivir carboxylate is metabolized by cytochrome P-450 isoforms. The primary route of elimination of oseltamivir is by conversion to the active drug, with more than 90% of the prodrug being metabolized to oseltamivir carboxylate. Oseltamivir carboxylate is not further metabolized, and it is entirely eliminated by renal excretion through glomerular filtration and anionic tubular secretion. Serum concentrations of oseltamivir carboxylate increase in the presence of declining renal function, and dose adjustment is recommended for patients with a CrCl below 30 mL/min.

Adverse Effects

The most common adverse effect reported with oseltamivir use is nausea, with or without vomiting. In controlled clinical trials, approximately 10% of patients reported nausea without vomiting, and an additional 10% experienced vomiting. The nausea and vomiting episodes were generally mild to moderate and usually occurred on the first 2 days of oseltamivir administration. Fewer than 1% of study subjects discontinued participation in the clinical trials prematurely because of nausea and/or vomiting. Food may help to alleviate these gastrointestinal side effects in some patients. Insomnia and vertigo were also reported more frequently among oseltamivir recipients than those receiving placebo.

Resistance

Oseltamivir-resistant influenza A viruses can emerge during treatment and also can be propogated in person-to-person spread during influenza epidemics. The seasonal influenza A H1N1 virus which predominated prior to the 2009 H1N1 pandemic was resistant to oseltamivir. However, 2009 H1N1 (which now has usurped the prior seasonal strain) is oseltamivir-susceptible. Thus, resistance patterns for oseltamivir must be monitored season by season to ascertain the utility of this antiviral agent.

Therapeutic Uses

Recommended doses of oseltamivir for clinical treatment are provided in *Table 74.1*. Oseltamivir is licensed for the treatment of influenza infection in patients 1 year of age and older, and is indicated for the prophylaxis of influenza in patients 13 years of age and older. Duration of illness is reduced by approximately 1.3 days when oseltamivir is administered within 2 days, compared to

placebo. Among patients treated within 24 h of the onset of symptoms, illness duration is reduced by almost 2 days. Oseltamivir recipients also had a more rapid return to normal health and activity compared with patients receiving placebo.

Compared with placebo, administration of oseltamivir for 6 weeks during the peak of influenza season significantly reduces the risk of contracting influenza. The protective efficacy for the prevention of culture-proven influenza approached 90%, which is comparable with that achievable with amantadine and rimantadine for influenza A.

Data generated by the NIAID Collaborative Antiviral Study Group before and during the 2009 H1N1 pandemic determined that the appropriate dose of oseltamivir in infants birth through 11 months of age is 3 mg/kg per dose given twice daily. This same group assessed dosing in premature neonates and estimated that 1 mg/kg per dose is the appropriate amount to administer in this at-risk group.

Zanamivir

Zanamivir is the second licensed medications that specifically target the neuraminidase protein common to influenza A and B viruses.

Antiviral Activity

Zanamivir also interferes with the function of the influenza neuraminidase enzyme, with subsequent interference with the deaggregation and release of the viral progeny.

Mechanism of Action

The mechanism of action for this class of compounds is the specific inhibition of the influenza neuraminidase, with subsequent interference with the deaggregation and release of the viral progeny.

Pharmacokinetics

Zanamivir has poor oral bioavailability and is therefore administered by oral inhalation. More than 75% of an orally inhaled dose of zanamivir is deposited in the oropharynx, most of which is swallowed. Approximately 13% of the dose distributes to the airways and lungs, and the remainder is retained in the delivery device. Inhaled zanamivir provides local concentrations in respiratory tract mucosa that greatly exceed inhibitory concentrations for influenza A and B viruses. Between 4% and 17% of an inhaled dose of zanamivir is absorbed systemically. Although serum zanamivir concentrations increase with decreasing CrCl, no adjustment in dosing is necessary in cases of renal insufficiency. Unabsorbed drug is excreted in the feces.

Adverse Effects

Zanamivir is well tolerated. The most serious adverse event associated with its use is respiratory distress. Decline in pulmonary function and bronchospasm have been reported in some patients receiving zanamivir. Many, but not all, of these patients had underlying airways disease, such as asthma or chronic obstructive pulmonary disease. Although influenza itself can cause such deteriorations, zanamivir is generally not recommended for the treatment of patients with underlying airways disease because of the risk of adverse events and the lack of demonstrated efficacy in this population.

Resistance

Antiviral resistance can be induced in vitro and has been detected in vivo. Cross-resistance between zanamivir and oseltamivir has been demonstrated as well in resistant isolates generated in vitro. Emergence of zanamivir resistance appears to occur less commonly than with oseltamivir or the adamantanes.

Therapeutic Uses

Recommended doses of oseltamivir for clinical treatment are provided in *Table 74.1*. Zanamivir is indicated for the treatment of uncomplicated illness due to influenza A and B virus of no more than 2 days' duration. Zanamivir therapy hastens clinical improvement by approximately 1.5 days in adults and children.

Inhaled zanamivir, 10 mg once daily administered for 4 weeks as seasonal prophylaxis, reduces the likelihood of laboratory-confirmed influenza infection (with or without symptoms) by 31%, influenza disease by 67%, and influenza disease with fever by 84%. A study of zanamivir administered once daily to healthy household contacts of influenza-infected index subjects demonstrated a 79% reduction in influenza illness.

Amantadine/Rimantadine

Amantadine (1-adamantanamine hydrochloride) and rimantadine (a-methyl-1-adamantane methylamine hydrochloride) are symmetric tricyclic amines that are closely related structurally to one another. Amantadine holds the unique status of having been the first antiviral agent to be licensed for systemic use in the United States for the prophylaxis of influenza.

Antiviral Activity

Both amantadine and rimantadine specifically inhibit the replication of influenza A. Inhibitory concentrations of susceptible isolates range from 0.1 to 0.4 μg/mL for amantadine and from 0.01 to 0.1 μg/mL for rimantadine. These concentrations are clinically relevant as the amount of either amantadine or rimantadine that is achievable in the blood or respiratory secretions is approximately 1.0 μg/mL. These compounds are not active against influenza B viruses.

Mechanism of Action

The target of the inhibitory action for both amantadine and rimantadine is the influenza A virus M2 protein. The M2 protein is an integral transmembrane protein that functions as an ion channel and is activated by pH. The M2 channel permits ions to enter the virion during the process of viral uncoating. This results in destabilization of protein–protein bonds, allowing the viral DNA to be transported into the nucleus. In addition, the M2 channel acts to modulate the pH of intracellular compartments, particularly the Golgi apparatus. In some species, this stabilizes the influenza A virus hemagglutinin (HA) during intracellular transport. These activities of the M2 ion channel are blocked by both rimantadine and amantadine.

Pharmacokinetics

Amantadine has a favorable oral bioavailability, with peak plasma concentrations being reached within 2–4 h following administration of the capsule, tablet, or liquid formulation of drug. As mentioned, levels achieved in respiratory secretions are similar to those of plasma. In healthy adults, plasma half-life of drug is 12–18 h, though this is prolonged in the elderly and in patients with renal insufficiency. Additionally, children with cystic fibrosis require larger doses of amantadine to achieve plasma concentrations similar to healthy adults. In excess of 90% of administered amantadine is excreted unchanged in the urine. Dosage adjustments are necessary when elderly persons or patients with renal insufficiency receive amantadine.

Rimantadine is also well absorbed orally, though time to peak plasma concentrations is somewhat longer at 2–6 h. While rimantadine levels in plasma are approximately half of those achieved with amantadine, rimantadine concentrates in nasal secretions and produces levels similar to amantadine at this site. Plasma half-life ranges from 24 to 36 h. Due to differences in the pharmacokinetics of rimantadine in elderly persons and patients with advanced hepatic or renal disease, the amount of drug administered to these persons should be decreased. Eighty-five percent of administered drug is metabolized by the liver, with the metabolites then being excreted in the urine; the 15% of administered drug that is not metabolized is excreted unchanged in the urine.

Adverse Effects

Minor dose-related gastric upset and central nervous system effects are quite common with administration of amantadine. Up to a third of healthy adult amantadine recipients will experience the somewhat disconcerting side effects of nervousness, insomnia, poor concentration, nausea, or anorexia. These central nervous system events are even more common in elderly patients, with 20 and 40% experiencing adverse CNS effects even when receiving reduced amantadine dosages. Discontinuation of drug due to unpleasant side effects occurs in 6–11% of patients taking amantadine as influenza prophylaxis. Extremely high plasma levels of amantadine in the setting of renal insufficiency or overdose can result in more severe reactions such as seizures, coma, cardiac arrythmias, and death. Long-term amantadine administration has been associated with livedo reticularis, peripheral edema, orthostatic hypotension, and urinary retention.

Rimantadine is much better tolerated than amantadine, with fewer than 5% of recipients of prophylactic rimantadine discontinuing drug due to unpleasant side effects, including neurotoxic effects. As compared to placebo, rimantadine (300 mg per day) administration is associated with higher rates of minor gastrointestinal complaints but not adverse neurologic events. Thus, rimantadine has a more favorable therapeutic index than does amantadine for the treatment and prevention of influenza A infections.

Resistance

Resistance of influenza A clinical isolates to amantadine and rimantadine is conferred by single amino acid substitutions at one of five positions (amino acids 26, 27, 30, 31, and 34) of the transmembrane domain of M2. Since 2005, virtually all circulating influenza A viruses have been resistant to amantadine and rimantadine, and for the time being, this class of drugs is no longer effective in the management of influenza disease in humans.

Therapeutic Uses

Prior to universal resistance among influenza A viruses worldwide, amantadine and rimantadine were used for the treatment and prophylaxis of influenza infection. Licensed doses of both drugs are provided in *Table 74.1*. However, at the current time neither amantadine nor

rimantadine are recommended for treatment or prophylaxis of influenza.

Antiviral Agents Active Against Hepatitis B Virus

Adefovir

Adefovir dipivoxil is one of three small molecules approved for use in the treatment of hepatitis B virus (HBV) infection in patients within the pediatric age range.

Antiviral Activity

In addition to HBV, adefovir diphosphate competitively inhibits deoxyadenosine triphosphate as a substrate for HIV-1 reverse transcriptase, resulting in chain termination following its incorporation in HIV DNA. The concentration required to inhibit enzymatic activity by 50% (IC_{50}) for HBV DNA polymerase is 0.1μmol/L, compared with >100 μmol/L for human DNA-α polymerase. In vitro, adefovir has an additive effect when combined with lamivudine, entecavir, or telbivudine.

Mechanism of Action

Adefovir dipivoxil is the oral prodrug of adefovir, which is an acyclic nucleotide analog of deoxyadenosine-5'-monophosphate (dAMP). Conversion of the prodrug to the active adefovir diphosphate is accomplished by cellular adenylate kinase. Adefovir diphosphate then acts as a competitive inhibitor of deoxyadenosine triphosphate for viral DNA polymerase, resulting in DNA chain termination following its incorporation in HBV DNA. The inhibition constant (K_i) for adefovir diphosphate against HBV DNA polymerase is 4-fold to 700-fold lower than the K_i for human DNA polymerases.

Pharmacokinetics

Adefovir dipivoxil is absorbed rapidly following oral administration. Following a single oral dose, the bioavailability is ∼59%. Food does not significantly impact absorption of adefovir dipivoxil, so the drug may be administered without regard to meals. Half-life at steady state is ∼7 h. Following absorption, adefovir dipivoxil is cleaved to adefovir by extracellular esterases. Adefovir then is phophorylated to the active moiety adefovir diphosphate by cellular adenylate kinase. The intracellular half-life of adefovir diphosphate is estimated to be 16–18 h. Adefovir is excreted renally as unchanged drug by tubular secretion and glomerular filtration. Dosing in patients with baseline creatinine clearance values <50 mL/min requires adjustment in the dosing interval. The dose of adefovir dipivoxil does not need to be adjusted in patients with hepatic impairment.

Adverse Effects

Adefovir dipivoxil generally is well tolerated over prolonged periods of administration. In randomized, controlled trials, diarrhea, headache, and abdominal pain occurred slightly more frequently in adefovir-treated patients compared with placebo-treated patients. Long-term administration may result in nephrotoxicity, but the risk in patients with adequate renal function is low. In vitro, adefovir does not inhibit cytochrome P450. No clinically relevant drug interactions have been reported in clinical trials.

Resistance

Resistance to adefovir becomes a limiting factor with prolonged use. The N236T mutation and the A181V mutationin the HBV polymerase both confer in vitro and in vivo antiviral resistance to adefovir diphosphate. Rates of resistance to adefovir at 1, 2, 4, and 5 years are 0%, 3%, 18%, and 29%, respectively. HBV strains with the A181V mutation also are resistant to lamivudine.

Therapeutic Uses

Recommended doses of adefovir dipivoxil for clinical treatment are provided in *Table 74.1*. Adefovir has been studied in pediatric patients with HBV infection and is approved for use in children 12 years of age and older. It is the preferred oral treatment option for children ages 12–15 (after which they can be treated with entecavir) who require antiviral treatment. In adults, adefovir dipivoxil therapy is associated with a 12% rate of HBeAg seroconversion, 21% rate of undetectable serum HBV DNA, and 53% rate of histological improvement in HBeAg-positive patients after 1 year of therapy. Once seroconversion occurs, it is sustained in 91% of patients. In adults, persistence of high levels of HBV DNA after 48 weeks of adefovir therapy predicts the emergence of resistance. The optimal duration of adefovir treatment in children is not known.

Entecavir

Entecavir is the second of the three small molecules approved for use in the treatment of hepatitis B virus (HBV) infection in patients within the pediatric age range, albeit the outer limits of this group (16 years of age and older).

Antiviral Activity

Entecavir triphosphate selectively inhibits HBV polymerase. It is only a weak inhibitor of cellular DNA polymerases and has no activity against HIV polymerase.

Mechanism of Action

Entecavir is a guanosine nucleoside analogue, which, following phosphorylation to the active triphosphate form, exhibits potent activity against HBV polymerase. Entecavir triphosphate inhibits HBV polymerase base priming, reverse transcription of the negative strand from the pregenomic messenger RNA, and synthesis of positive-strand HBV DNA.

Pharmacokinetics

Entecavir peak plasma concentrations occur between 0.5 and 1.5 h following oral administration in adults. Steady state is achieved following 6–10 days of once-daily administration, with approximately twofold accumulation. Due to decreases of approximately 20% in area under the curve (AUC) when administered with food, entecavir should only be given at least 2 h before or after a meal. The intracellular half-life of entecavir triphosphate is 15 h. Approximately two-thirds to three-quarters of drug is excreted unchanged in the urine. Pharmacokinetic studies of entecavir have not been conducted in children younger than 16 years of age.

Adverse Effects

Entecavir is not a substrate, inhibitor, or inducer of the cytochrome P-450 enzyme system. As such, entecavir pharmacokinetics are unlikely to be affected by drugs that affect or are metabolized by the cytochrome P-450 system. As with other therapies for chronic HBV infections, severe acute exacerbations of hepatitis B have been reported in patients who have discontinued entecavir therapy. Therefore, hepatic function should be closely monitored with both clinical and laboratory follow-up for at least several months in patients who discontinue HBV therapy.

Resistance

Both in vitro and in vivo data suggest that emergence of resistance to entecavir is rare in nucleoside-naive patients. However, approximately 7% of lamivudine-refractory patients with HBV infection develop entecavir resistance–associated substitutions when preexisting lamivudine resistance mutations are present. Additional mutations within the HBV viral polymerase are required for entecavir resistance to develop. Respective 5-year entecavir-resistance rates in nucleoside-naïve and lamivudine-refractory patients are 1.2% and 51%. Entecavir is active against adefovir-resistant mutants, and since additional mutations are required to develop resistance to entecavir, the drug also remains active against lamivudine-resistant mutants. Emergence of entecavir-resistance mutations is usually associated with virologic rebound during therapy.

Therapeutic Uses

Recommended doses of entecavir for clinical treatment are provided in *Table 74.1*. Entecavir is indicated for the treatment of chronic HBV infection in adults with evidence of active viral replication and either evidence of persistent elevations in serum aminotransferases or histologically active liver disease. Entecavir is superior to lamivudine in the treatment of chronic HBV infection and is the most potent anti-HBV agent available. Among patients with lamivudine-refractory chronic HBV infection, changing to entecavir (1 mg once daily) was superior to continuing lamivudine (100 mg once daily). Entecavir also is superior to adefovir dipivoxil in nucleoside-naïve, HBeAg-positive patients. The optimal duration of therapy with entecavir is not known. A Phase IIB pharmacokinetic and efficacy trial of entecavir in pediatric patients 2 years of age and older is nearing completion, and a Phase III trial in this age group has already started.

Lamivudine

Lamivudine is the third of the three small molecules approved for use in the treatment of hepatitis B virus (HBV) infection in patients within the pediatric age range. Of the three, it is licensed in the broadest age range, down to 3 years.

Antiviral Activity

Lamivudine inhibits the reverse transcriptase of both HBV and HIV, and is indicated for the treatment of HIV and chronic HBV infection.

Mechanism of Action

Lamivudine is a nucleoside analogue that is phosphorylated to lamivudine triphosphate by cellular kinases. As with other nucleoside analogues, lamivudine triphosphate exerts its antiviral effects via incorporation in the growing HBV DNA chain.

Pharmacokinetics

Lamivudine at a dose of 4 mg/kg administered twice daily produces an AUC_{12} of 5.16 mg·h/L and $t_{1/2}$ of 1.76 h. This $t_{1/2}$ in children is less than the $t_{1/2}$ in adults (3.5 h).

Adverse Effects

Adverse reactions include pancreatitis, paresthesia, peripheral neuropathy, neutropenia, anemia, rashes, nausea, vomiting, and hair loss.

Resistance

Lamivudine-resistant HBV mutants occur in up to one-third of subjects by the end of 1 year of therapy, and in up to two-thirds by the end of 4 years of drug exposure. Lamivudine resistance is usually manifest as breakthrough infection defined as reappearance of HBV DNA in serum after its initial disappearance. Most patients continue to have lower serum HBV DNA and ALT levels compared with pretreatment values, perhaps due to decreased fitness of the lamivudine-resistant mutants. Upon cessation of lamivudine therapy, most patients experience an increase in serum HBV DNA concentrations.

Therapeutic Uses

Recommended doses of lamivudine for clinical treatment are provided in *Table 74.1*. In the treatment of chronic HBV infection, lamivudine decreases serum HBV DNA by 3–4 log copies per mL in most patients. Among patients who are positive for HBeAg, approximately 20% achieve HBeAg seroconversion and undetectable serum HBV DNA at the end of 1 year of lamivudine therapy. Slightly more than half of patients experience improvement in histologic liver abnormalities. Similar findings have been seen in children.

Telbivudine

Telbivudine is the HBV antiviral drug which has been most recently approved by the FDA, in 2006. It is not licensed for use in children; it is approved for use in older adolescents and adults (16 years of age and older).

Antiviral Activity

Telbivudine preferentially inhibits HBV second strand (DNA-dependent) DNA synthesis. In comparison, lamivudine preferentially inhibits first strand (RNA-dependent) DNA synthesis. Telbivudine is active only against hepadnaviruses. In vitro, telbivudine-5'-triphosphate has no inhibitory effect on host cell DNA polymerases α, β, or γ at concentrations up to 100 μmol/L. In contrast, the mean 50% effective concentration (EC_{50}) inhibiting HBV DNA polymerase is 0.12–0.24 μmol/L, illustrating the specificity and potency of the drug for HBV replication. At concentrations up to 10 μmol/L, telbivudine has minimal toxic effect on host-cell mitochondria and does not increase lactic acid production.

Mechanism of Action

Telbivudine is the unmodified L-enantiomer of the naturally occurring nucleoside D-thymidine. Host-cell kinases phophorylate telbivudine to telbivudine-5'-triphosphate, which then is incorporated into HBV DNA, resulting in viral DNA chain termination. Coadministration of telbivudine with lamivudine does not produce additive or synergistic effects.

Pharmacokinetics

Telbivudine is rapidly absorbed after oral administration. Absorption is not influenced by food. The half-life of telbivudine is ~40 h. Approximately, 40% of the dose is excreted via the kidneys as the unchanged active substance, likely via renal filtration. Systemic exposure to telbivudine is increased in patients with impaired renal function, and in patients with moderate to severe renal impairment (creatinine clearance <50 mL/min) or end-stage renal disease requiring dialysis, the dosing interval requires adjustment. Dosage adjustment is not required for patients with impaired hepatic function.

Adverse Effects

Elevated blood CK concentrations are the most frequent adverse event possibly or probably related to telbivudine. Cases of myopathy during telbivudine therapy have been identified, but they did not correlate with the magnitude or timing of CK elevations. Nevertheless, treatment should be discontinued if persistent, unexplained muscle-related symptoms are noted. Patients receiving telbivudine along with other drugs associated with myopathy, such as cyclosporin or HMG-CoA reductase inhibitors, should be monitored closely for signs and symptoms of myopathy.

Resistance

The key determinant of telbivudine resistance is the M204I mutation in the YMDD motif. The principle mutations conferring in vivo lamivudine resistance do not produce cross-resistance to telbivudine, but cross-resistance can be induced in vitro. Telbivudine is active or has slightly reduced activity in vitro against adefovir-resistant HBV strains.

Therapeutic Uses

Recommended doses of telbivudine for clinical treatment are provided in *Table 74.1*. Telbivudine is licensed for use in adolescents and adults (≥16 years of age). It has not been studied in pediatric patients with HBV infection.

In HBeAg-seropositive and -seronegative adults, telbivudine is superior to lamivudine after 1 and 2 years of therapy. Telbivudine also has better early viral suppression compared to adefovir at week 24 in HBeAg-positive patients, regardless of whether the patients were treated initially with telbivudine or switched from adefovir to telbivudine. The early virological suppression resulted in better rates of HBeAg seroconversion, ALT normalization, and viral suppression.

75 Laboratory Diagnosis of Viral Disease

Sami Al-Hajjar

Unlike the automation and standardization of clinical chemistry and hematology laboratories, the only major changes in the methodology and operation of clinical microbiology laboratories since 1920 have been tests associated with antibacterial susceptibility. Although tissue culture techniques were introduced in diagnostic virology, their application was generally limited to a few large public health laboratories. However, with the development of newer simpler and rapid methods, the science is changing. This reflects evolving technology and differing priorities in various health-care settings. As the science pf antiviral chemotherapy advances, it is likely that priorities will come into a better focus and that hospitals will move toward a more standardized approach to viral illness and diagnostic laboratories.

Viral Diagnosis

There are a number of clinical situations where viral diagnosis may be particularly helpful. These include:

1. Viral diseases in which there are important public health considerations (e.g., influenza and arbovirus encephalitis)
2. Viral diseases in which there are significant risks to susceptible persons exposed to the patient (e.g., measles, hepatitis B, and varicella)
3. Situations involving important prognostic considerations (e.g., congenital infections, encephalitis, and infections in immunocompromised hosts)
4. Situations where withdrawal of antibiotics might serve the patient's interest (e.g., respiratory virus infections and viral meningitis)
5. Situations where therapeutic action depends on viral diagnosis (e.g., treatment with an antiviral agent, hospital infection control, and therapeutic abortion for rubella in pregnancy)
6. Cases where a viral diagnosis will teach the medical staff important lessons about diseases or epidemiology and improve subsequent care of similar patients

In order to identify the range of suspected viruses in any one individual patient, the onus is on the clinician to provide comprehensive information and/or liaise with laboratory staff.

Specimen Collection for Viral Diagnosis

It is difficult to overemphasize the importance of collecting proper clinical specimens for viral laboratory diagnostics. Unless the clinician pays close attention to the details of timing, collection, and handling, the laboratory can be of little help; for most acute viral illnesses, specimens obtained early in the illness (i.e., the first 1–4 days of symptoms) are most likely to contain recoverable virus.

Specimens should be collected with sterile implements and quickly transported to the laboratory (as any delay will mean some loss of virus particles). In addition to their heat lability, many viruses do not withstand drying. Swabs of mucosal surfaces, skin scrapings, and tissues are placed in a transport medium that contains a protein, a buffer at neutral pH, and antibiotics to kill or suppress the growth of bacteria and fungi.

Viruses vary in their ability to survive ambient temperatures. Specimens for virus isolation should always be transported to the diagnostic laboratory on ice, and, unless a delay of more than 4 days is anticipated, specimens should be held at 4°C and not frozen. If specimens are frozen, they should be kept at −70°C since conventional freezer temperatures (−10°C to −20°C) are detrimental to infectivity of many viruses.

The site of specimen collection should correlate with the clinical presentation and local epidemiology pattern. However, if there is deep or generalized disease (e.g., non-vesicular rash, meningitis, fever or unknown origin, congenital infection), it is advisable to sample multiple sites. *Table 75.1* shows a general listing of syndromes, common etiological agents, and appropriate specimens.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_75,

Table 75.1
Specimens and viruses by clinical syndrome

Syndrome	Common	Uncommon	Specimens
Aseptic meningitis	Enteroviruses (Coxsackie, echo), mumps	Polio, LCMV, HSV-2, adenovirus	NP-throat, CSF, urine, stool, serum for LCMV
Encephalitis	Arboviruses[a], HSV-1, -2	Mumps, measles, influenza, rubella, VZV, rabies, EBV[a], enteroviruses	NP-throat, stool, CSF, brain biopsy (if herpes suspected), serum
URI, bronchitis, "flu"	Rhinovirus, parainfluenza, influenza, adenovirus, enterovirus, RSV	Measles, coronavirus (NL,HK), bocavirus	NP-throat, nasal aspirate
Croup	Parainfluenza	RSV, adenovirus, influenza	NP-throat, nasal aspirate
Pneumonia	RSV, adenovirus, influenza, metapneumovirus	Parainfluenza, CMV, rhinovirus, measles, rubella, HSV, VZV, enterovirus	NP-throat, stool, tracheal, aspirate, nasal aspirate, urine, serum
Bronchiolitis	RSV, influenza	Influenza, adenovirus, rhinovirus	NP-throat, nasal aspirate
Rashes – vesicular	VZV, HSV-1, -2	Vaccinia, enterovirus	Vesicular fluid, NP-throat, stool (for enterovirus), serum
Rashes – non-vesicular	Measles, rubella, enterovirus	EBV[a], Hepatitis B virus	NP-throat, stool (for enterovirus), serum
Congenital infection	CMV, HSV-2, rubella	Parvovirus B19	NP-throat, stool, pleural fluid, pericardial fluid, serum
Pleurodynia, pericarditis	Enterovirus (Coxsackie and echo)	Polio virus, mumps, influenza, adenovirus	NP-throat, stool, pleural fluid, pericardial fluid, serum
Eye lesions (keratitis, keratoconjunctivitis, conjunctivitis)	HSV-1, -2, adenovirus	Measles	Eye swabs, NP-throat, nasal washing
Gastroenteritis	Rotavirus norovirus[a], adenovirus	Enterovirus (newborns), influenza	Stool, NP-throat, urine
Hepatitis	Hepatitis A, B, C[a], D, EBV[a], CMV, VZV	Enterovirus, adenovirus, HSV-1, -2	Serum, NP-throat, stool, urine
Parotitis	Mumps parainfluenza, influenza	Adenovirus, LCMV, EBV[a], enterovirus	NP-throat, urine, nasal aspirate, serum

CMV cytomegalovirus; *CSF* cerebrospinal fluid; *EBV* Epstein-Barr virus; *HSV* herpes simplex virus; *LCMV* lymphocytic choriomeningitis virus; *NP* nasopharyngeal aspirate; *RSV* respiratory syncytial virus; *VZV* varicella-zoster virus
[a]Not cultivable in the routine laboratory; electron microscopy or serologic diagnosis available

Recognitions of Viruses in Clinical Specimens

Virus Isolation

The gold standard for viral isolation is the viral culture. Viruses are intracellular parasites and require living cells in order to replicate in the clinical laboratory. Living cells can be provided in the form of suckling mice, embryonated chicken eggs, and cell cultures. Today, most clinical laboratories prefer to use cell cultures rather than mouse and egg inoculation.

Virus identification depends on viral entry and proliferation in cells grown as a monolayer under sterile tissue culture conditions. Cytopathic effect (CPE) is a pattern of cell destruction resulting from viral infection that occurs in a characteristic pattern depending on the cell line and infecting virus. Members of the orthomyxovirus (influenza virus) and paramyxovirus (parainfluenza virus, or mumps) groups may fail to produce a clear-cut CPE in infected cell cultures, but they may be detected first, or sometimes exclusively, by demonstration of the phenomenon of hemabsorption (these viruses produce hemagglutinin molecules that protrude from the lipid bilayer of the

infected cell and bind to the guinea pig or other erythrocytes that are added to the tissue culture tube). Once CPE is detected by visual inspection under the microscope by a skilled technologist, confirmatory tests are performed to identify positively the virus.

A recent advance in a viral culture methodology involves centrifugation of the patient specimens onto cell monolayers in the bottom of glass shell vials, and, after a 1-to-2-day period of cultivation, staining for viral antigen in the cells by using a labeled monoclonal or polyclonal antibody. The centrifugation step shortens the time of development of viral antigen or CPE. The monoclonal antibody, if directed at viral antigens produced early in the replication cycle, can detect a virus even before the development of CPE. For example, use of the "shell vial" technique in the laboratory enables detection of 50–60% of cytomegalovirus (CMV)-positive specimens within 24 h and a cumulative total of 90% within 48 h. The remaining 10% are detected by traditional viral CPE and require a mean of 10 days for positive results. This technique has been applied to the rapid detection of several viruses, including herpes simplex, measles, adenovirus, influenza, parainfluenza, respiratory syncytial virus (RSV), and varicella-zoster viruses.

Rapid Diagnostic Methods

Same-day diagnosis is the "wave of the future" in microbial diagnostics. However, rapid diagnosis is a "directed approach" that requires prior consideration of the virus suspected. Viral isolation, in contrast, is an "open-ended approach" that may yield interesting, unanticipated results.

Viral Cytopathology

The analysis of viral cytopathology is the oldest form of rapid diagnosis. An example of this form of testing is the Tzank preparation used to diagnose herpes virus infections. The technique is performed by scraping the base of a skin vesicle and transferring the scraping to a microscope slide. The slide is allowed to air dry and then stained with Giemsa, Wright, or Papanicolaou stain. Slides are viewed under a standard microscope. The finding of multinucleated giant cells is diagnostic of a herpesvirus infection. This method has been largely superseded by fluorescent antibody staining and other antigen detection methods that are more sensitive and can also identify the specific herpes virus present.

Electron Microscopy

Electron microscopy (EM) has been used for many years for the rapid detection of viruses in clinical specimens. This technique relies on the identification of viruses by their characteristic morphology. One limitation of EM is that virus must be present in sufficient quantity (approximately 10^5–10^6 particles/mL) in order to be detected. The most potent usefulness lies in detecting viruses in fecal contents; EM is not used widely for routine diagnosis because it is expensive, cumbersome, and insensitive. Newer rapid tests are available for most viruses that previously were diagnosed by EM.

Immunofluorescence

Immunofluorescence (IF) has been used for rapid diagnosis of respiratory tract infections, and vesicular exanthems and examination of tissues. The method is rapid, precise, and sensitive when careful attention is paid to be the technique of obtaining and processing the specimens, using appropriate controls, and having a well-trained laboratory staff to interpret the results. Clinical specimens are applied to a slide, dried, fixed, and stained. A fluorescence microscope is used to read the slides for either fluorescing organisms or infected cells. Staining may be direct, using a specific antimicrobial antibody with attached fluorescence dye, or indirect, using an unlabeled specific antimicrobial antibody followed by fluorescein-labeled antibody directed against the initial antibody.

The indirect test may be more sensitive than the direct test, although a recent study suggests the sensitivity is comparable. For RSV and measles, the sensitivity of IF exceeds that of cell culture. For the others, particularly when high-quality reagents are not available, the sensitivity appears to be somewhat lower. Immunofluorescence has also been successfully used to detect and distinguish herpes simplex and varicella-zoster viruses in vesicle fluids. The IF method is also very useful in the examination of tissue specimens. This technique is the preferred method for rapidly diagnosing (a) herpes simplex encephalitis in brain biopsies and (b) rabies in animal brain.

Immunofluorescence has the following advantages:

1. One can prepare a slide and stain for a number of different organisms at a single time; the adequacy of the specimen can be determined, and slides may be made and sent to the reference laboratory for reading.

2. IF is more sensitive than cultures since it does not require intact viable viruses; as a result, a specimen may be positive by IF in the face of negative cultures.

Enzyme Immunoassay

Enzyme immunoassay (EIA), or enzyme-linked immunosorbent assay, utilized multiple antigen–antibody reactions to detect low concentrations of microbial antigen. EIAs are available now for the diagnosis of respiratory viruses (RSV, influenza, parainfluenza, adenovirus, and metapneumovirus) enteric viruses (rotavirus, norovirus, and adenovirus), and herpes simplex virus. The major advantages of the EIA are ease of interpretation, objectivity, and ability to detect antigen in specimens collected and handled in a manner that disrupts intact infected cells needed for IF. These assays can be automated. The advantages of the EIA include the potential for nonspecific reactions that may give false-positive results and the ability of the test to identify the presence of only one infectious agent, unlike IF, in which the presence of any one of several agents can be determined on a single specimen by one procedure.

Nucleic Acid Hybridization

Recent advances in molecular cloning have made hybridization possible. With the availability of large quantities of cloned viral DNA, the use of nucleic acid hybridization has become practical possibility for detection of certain viruses in clinical specimens. Hybridization assays are available for the direct detection of herpes simplex virus, CMV, and human papillomavirus. Probes for hepatitis B core and surface antigen genes, human immunodeficiency virus (HIV), Epstein-Barr virus (EBV), adenovirus, and type A rotavirus are currently available.

Polymerase Chain Reaction

The polymerase chain reaction (PCR) is the most sensitive method for revealing the presence of otherwise undetectable quantities of the genome of RNA or DNA of human viruses. PCR is a powerful new technique developed in 1985 and is an alternative to direct hybridization methods. It can be used to amplify a small piece of viral DNA or RNA in clinical specimens up to a millionfold, allowing detection of small quantities of infectious agent in a single sample. PCR has the sensitivity to detect as few as ten infected cells or one virus in as many as one million cells in clinical specimens. Because PCR is very sensitive, slight contamination of laboratory specimens by stray DNA can lead to amplification of DNA not in the original specimen. It is being used currently to detect HIV, herpesviruses, influenza virus, hepatitis viruses, rotavirus, EBV, CMV, and parvovirus. The use of PCR for the diagnosis of CNS disease has been well evaluated for HSV encephalitis and enterovirus meningitis. The use of this highly sensitive technique has increased our understanding of the etiological role of viruses in CNS disease. For example, it has been demonstrated that varicella-zoster virus (VZV) and HSV type 2 (HSV-2) can cause meningitic symptoms without causing concurrent skin lesions.

Multiplex PCR is a newer diagnostic technology that allows testing for multiple viruses simultaneously with a very high specificity and sensitivity. The xTAG RVP assay (Luminex Molecular Diagnostics; Toronto, ON, Canada) is one example and is approved by the US Food and Drug Administration (FDA). This test detects 12 different viruses and has a sensitivity of 96.4% and a specificity of 95.9%. Multiplex PCR is also available for diagnosis for CSF and enteric viruses.

Viral genome quantification (VL) has within a few years become an integral part of the clinical management of patients suffering from infection with HIV, HBV, HCV, or human CMV. Besides providing prognostic information on individual cases, particularly for HIV and human CMV, genome quantification plays a most important role in monitoring the patient's response to antiviral treatment. VL testing assesses the success of antiviral therapy, including, but unable to distinguish between, different factors involved. These include treatment failure due to viral (development of antiviral resistance) and host factors (one of which is noncompliance). Several studies have proven the value of VL determination as a surrogate marker for clinical markers of therapeutic success. The increasing availability and clinical use of potent anti-(retro)viral chemotherapy has sparked the development of a variety of commercial assays for viral genome quantification. It is being used currently to detect HIV and has been in use in research laboratories to identify other viruses, such as the herpesviruses, influenza virus, hepatitis viruses, rotavirus, EBV, CMV, and parvovirus.

Microchip Assay

DNA microarray testing, which so far is available only in research settings, is a newer technology designed for much broader-spectrum viral detection. The microchip has

approximately 22,000 oligonucleotide probes representing about 1,800 fully or partially sequenced viruses and it can detect all known viruses, as well as possible novel viruses that are related to known viral families, without a priori knowledge of their whole nucleotide sequences. This panviral microarray was used as part of the global effort to identify severe acute respiratory syndrome-associated coronavirus in 2003.

This method addresses the problems associated with both earlier methods, and reduces the detection time to less than 30 min. Because it is based on a rapid hybridization and no enzymatic amplification is used, it is not affected by impurities in the sample. At the present it can detect 500 copies or more of an infectious agent per sample. It can be adapted to any type of sample such as blood, stool, or tissues. The size of the chip is less than 1 cm^2 and the active site is less than 1 mm^2.

Serology

One of the classic methods of diagnosing viral infection is the detection of virus-specific antibodies or antigens in serum. Some of the assays, such as radioimmunoassays, EIAs, Western blots (protein is electrophoresed through a gel to separate molecules according to size, blotted onto a membrane, and then hybridized with antibody against a specific protein of interest), and IF, measure antigen–antibody interaction. Assays such as complement fixation, latex agglutination, and immune adherence hemagglutination depend on the capacity of antibody, upon interacting with antigen, to perform some non-virus-related function.

Most acute primary viral infections induce a dependable rise in antiviral immunoglobulin G antibody. Diagnosis can be made through measurement of antibody levels in paired sera obtained early in the course of disease (acute) and late or after recovery (convalescent) 14–21 days later. Exceptions involve the following situations:

1. Infections in immunodeficient hosts who cannot form antibody (including certain young infants).
2. Some superficial infections such as respiratory infections, which may occasionally fail to induce an antibody response despite significant illness (e.g., RSV in infants). Regardless of the method employed, serologic demonstration of an antibody response may provide evidence of infection in the absence of virus isolation from culture. Unfortunately, documentation of infection is delayed because of the need to assess convalescent serum for antibodies and is limited by the multiplicity of viruses infecting humans.
3. Acute infections acquired in the presence of passively transferred antibody (e.g., neonatally acquired CMV infection).

Most recent serologic diagnosis has emphasized the detection of specific immunoglobulin M (IgM) antibodies, which allows a diagnosis to be made from a single specimen obtained early in the illness. Specific IgM antibody testing is most useful in disease with a sufficiently long incubation period in which specific IgM antibodies are present at the time of clinical presentation; this is currently the method of choice for the diagnosis of rubella, measles, hepatitis A virus, and a number of arbovirus infections. There continues to be technical problems with many IgM assays, including interference with rheumatoid factors, which needs to be absorbed from serum.

Recently, IgG avidity assays, which measure antibody maturity, have been shown to reliably discriminate between acute and past infection. Thus in recent (acute) infection the body produces low-avidity IgG. After 2–4 months, the body begins to produce high-avidity IgG. For example, low CMV IgG avidity suggests acute CMV infection occurred within the past 2–4 months. High CMV IgG avidity suggests that CMV infection occurred at some point in the past. This has been demonstrated to be the case for CMV, toxoplasma, and rubella. Avidity indices of 50% or less are considered low-avidity indices.

For several infections, the testing of acute and convalescent specimens or the identification of virus-specific IgM antibodies is not necessary because the infections are typically chronic, and detection of any virus-specific antibodies more often signifies current infection. Examples include HIV, human lymphotropic T-cell virus, and hepatitis C virus.

The Future for Viral Diagnosis

Detection technologies will continue to evolve, allowing faster, more sensitive, and less extensive methods for pathogen discovery. Multiplex PCR assays are already widely implemented, but microarray technology is less advanced.

76 Vaccination

Abdulrahman M. Al Mazrou

BCG Vaccine

Nature and Contents

Bacillus Calmette-Guérin (BCG) vaccine is an attenuated live vaccine containing suspension of a live attenuated strain of *Mycobacterium bovis*. The chemical composition of BCG vaccines varies widely among different preparations. Furthermore, the vaccines differ substantially in the level of residual virulence as well as immunogenicity. The vaccine is available in a lyophilized form, and sodium glutamate is used as a stabilizer in some products.

Mechanism of Protection

The mechanism of protection of BCG is largely unknown. Cellular immunity has been shown to play the major role in protection; however, the specific antigenic determinants and the mechanisms involved are not clear.

Storage and Handling

- Storage and shipment
  - Unreconstituted vaccine should be stored at 2–8°C and *never* frozen. Both forms should be protected from light.
- Stability
  - Unreconstituted form is stable for 1–2 years if stored as recommended within the expiry date specified. Products containing sodium glutamate may remain stable for up to 1 month at 37°C.
  - Reconstituted vaccine is stable for only few hours and should be discarded at the end of the vaccination session.

Efficacy

The effectiveness of BCG vaccine is difficult to determine and available data from field trials of the vaccine have yielded conflicting results. However, a meta-analysis of the published literature on BCG efficacy concluded that BCG significantly reduces the risk of T.B. infection by an average of 50%. Furthermore, protection against tuberculous meningitis was 64%, against disseminated T.B. 78%, and against death due to T.B. 71%. In another meta-analysis of 10 randomized clinical trials and eight case-controlled studies, the protective effect of BCG against serious forms of T.B. in children (meningitis and miliary T.B.) was found to be >80%. In a 60-year follow-up study, the long-term efficacy is estimated to be 52%.

Recommended Use

1. In areas with high incidence of T.B. (i.e., rate of new infection >1% per year), universal immunization of infants is recommended.
2. Newborn infants whose mothers have infectious tuberculosis at the time of delivery and isoniazide prophylaxis is not feasible (either due to resistant infecting strain or compliance cannot be assured).
3. Individuals with negative tuberculin skin tests who are continuously exposed to persons infected with bacilli resistant to isoniazide and rifampicin.

Adverse Reactions

Side effects of BCG vaccination are generally uncommon. Their rates, however, vary depending on the methods of administration, the strain and the dose of the vaccine, and the age and immune status of the vaccinee.

Local ulceration and regional lymphadenitis are the most common complications occurring in up to 5% of immunocompetent recipients following intradermal administration. Rates are higher among newborns than among older infants and children.

Moderately severe reactions include suppurative adenitis, and injection-site abscess may be seen in 1% of all vaccinee.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_76,

Severe complications include osteitis and BCG dissemination which may be fatal. Dissemination occurs almost exclusively in persons with impaired immunity, and its frequency is approximately one in one million vaccinees.

Contraindications and Precautions

BCG is contraindicated in:

1. Individuals with altered immune status due to:
   (a) Primary immune deficiency involving cellular immunoresponses or interferon-gamma/IL-12 pathway defect.
   (b) Malignancy, e.g., leukemia, lymphoma.
   (c) Immunosuppressive therapy, e.g., corticosteroids, cytotoxic, etc.
   (d) Patients with confirmed HIV infection even if asymptomatic.
2. Persons with burns or extensive skin disease.
3. Individuals with positive tuberculin skin tests.
4. BCG should not be given within 4 weeks of development of, or vaccination against measles or mumps as these are known to suppress the tuberculin reaction.
5. Pregnancy: although no harmful effects on the fetus have been observed, it is preferable to delay BCG until after delivery.

Practical Hints

1. The normal local response to BCG vaccination includes formation of a papule which ulcerates within 2–3 weeks after vaccination and gradually heals with formation of a scar within 3 months.
2. In a newborn with a positive family history of congenital immunodeficiency in a sibling (e.g., severe combined immunodeficiency or interferon-gamma/IL-12 pathway defect), BCG vaccine should be withheld until such disorder is excluded in order to avoid BCG dissemination which may be fatal.
3. There is no correlation between presence or size of tuberculin delayed hypersensitivity reaction after BCG and protection against disease.
4. Tuberculin reactivity caused by BCG vaccination ranges from no indurations to an indurations of >15 mm. However, skin reactivity wanes with time and is unlikely to persist >10 years after vaccination in the absence of *M. tuberculosis* exposure and infection.
5. BCG-induced reactivity that has weakened might be boosted by administering a tuberculin test 1–2 weeks after the initial test. This phenomenon should not be confused with cutaneous conversion which may denote infection with T.B.
6. Malnutrition is not a contraindication for BCG vaccination.
7. Some authorities consider ulceration and scar formation at the BCG inoculation site as an indication of successful vaccination and immunity.

Diphtheria Toxoid

Nature and Contents

Diphtheria toxoid is prepared by formaldehyde detoxification of diphtheria toxin. The vaccine contains no bacterial antigens. The toxoid is available in monovalent preparations, in combination with tetanus toxoid (DT or Td) and in combination with tetanus toxoid and pertussis vaccine (DTP, DTaP) with or without other vaccines, including inactivated polio (IPV), Haemophiluse influanze b (HIB), and Hepatitis B virus (HBV) vaccines. The products are available in adsorbed form with Aluminum hydroxide or Aluminum phosphate. A plain (non-adsorbed) monovalent preparation is also available. Thimerosal is used as a preservative in some products.

The quantity of toxoid differs from one preparation to another and between different manufacturers. It ranges between 2 and 25 flocculation units (Lf) with the adult preparation (Td) containing the smallest amount (2 Lf).

Mechanisms of Protection

Immunization with diphtheria toxoid induces formation of neutralizing antibodies (antitoxin) which protect against the potentially lethal systemic effects of diphtheria toxin. The vaccine does not, however, prevent local infection with *C. diphtheriae.*

An antitoxin level of 0.01–0.02 U/mL is usually associated with a negative Schick test and may provide some protection; level of 0.1 U/mL or more provide full protection.

Storage and Handling

- Storage and shipment
  - All forms of adsorbed preparations should be stored and shipped at 2–8°C. No freezing is allowed.
- Stability
  - If stored as recommended, it is stable for approximately 2 years after leaving manufacturer's cold store.
  - Exposure to a higher ambient temperature for short period of time (<7 days) does not reduce the potency.
- Normal appearance
  - Turbid and whitish suspension. Vaccines that contain clumps of material that cannot be suspended with vigorous shaking should NOT be used.

Efficacy and Immunogenicity

Following completion of vaccination series, the risk of developing diphtheria is substantially reduced. Furthermore, vaccinated persons who develop disease have milder illness. Protection lasts at least for 10 years.

Recommended Use

1. Primary immunization
   (a) Three doses of diphtheria toxoid (as a component of DTP) starting at 6–8 weeks of age with 4–8 weeks interval between the doses is recommended for all infants.
   (b) A fourth dose is given 6–12 months from the third dose, and a booster dose is given at 4–6 years of age. Subsequently, a dose is given every 10 years.
2. Contacts of a diphtheria case
   (a) Immunized close contacts of a case of diphtheria should be given a booster dose of a preparation containing diphtheria toxoid unless they have received a dose within 5 years.
   (b) Unimmunized/incompletely immunized individuals should have their series initiated/completed in a timely fashion.
3. After recovery from diphtheria
   (a) Patients recovering from diphtheria do not necessarily become immune and should be immunized according to their age.

Dose and Route

The dose is usually 0.5 mL of a preparation appropriate for age and any special contraindication. All preparations with adjuvant should be given intramuscularly.

Adverse Reactions

Local reactions including swelling, redness, and pain at injection site are common after diphtheria toxoid, and most frequent and severe in older children and adults. Systemic reactions may occur particularly if preparations containing whole-cell pertussis vaccine (WCPV) are used.

Contraindications and Precautions

- Anaphylactic reaction to a vaccine component.
- Adults and children older than 7 years should only be vaccinated with Td preparation.
- When a combination vaccine is used, it is important to ensure that no contraindication to any component is present (see pertussis vaccines and tetanus toxoid below.

Practical Hints

1. Polysaccharide vaccines that are conjugated with CRM 197 (cross reacting material) diphtheria protein do not provide immunity to diphtheria.
2. Preparations containing between 15 and 25 Lf of diphtheria toxoid is intended for use in children <7 years and is marked as "D." The preparations for older children and adults contain 2 Lf and marked as "d."
3. Since diphtheria preparations are adsorbed products, it is important to ensure that it is given intramuscularly as spillage into subcutaneous tissue may lead to significant local reaction.
4. To further promote immunity against diphtheria, diphtheria toxoid and tetanus toxoid (Td) combination should be used whenever tetanus prophylaxis is needed following injuries if the last dose of diphtheria has not been given within 10 years.

5. Antibodies (antitoxin) passed through the placenta provides passive immunity to the newborn during the first few months of life.
6. Even when diphtheria booster doses are not received for 20–30 years, booster responses can still be elicited and no need for repeat of primary series.

Haemophilus Influenzae B Vaccine (HIB)

Nature and Contents

The currently available conjugated HIB vaccines are composed of a purified capsular polysaccharide of HIB, known as polyribosylribitol phosphate (PRP), linked (conjugated) to a protein carrier. The size of the polysaccharide, the type of the protein carrier, and the kind of linkage used is different from one vaccine to another. The characteristics of the four HIB conjugate vaccines are outlined in *Table 76.1*. Thimerosal is used in some vaccines as a preservative, and aluminum hydroxide is used as adjuvant in PRP-OMP.

Mechanism of Protection

HIB conjugate vaccines protect against invasive HIB diseases by:

- Induction of antibodies against HIB capsular polysaccharide, i.e., anti-PRP, which are bactericidal and opsonic.
- Reduction of asymptomatic HIB nasopharyngeal colonization rate, resulting in reduced exposure of unprotected individuals to HIB. This has probably contributed to the observed reduction of HIB diseases in non-vaccinated children after introduction of conjugate vaccines in several countries.

Table 76.1
Characteristics of HIB vaccines

Vaccine	Polysaccharide	Protein carrier	Link
PRP-D	Medium	Diphtheria toxoid	Spacer
PRP-CRM197	Small (Oligosaccharide)	CRM197 = nontoxic mutant diphtheria toxin	None
PRP-OMP	Medium	*N. Meningitidis* outer member protein complex	Spacer
PRP-T	Large	Tetanus toxoid	Spacer

Storage and Handling

- Storage and shipment
  - All forms of the vaccines should be stored at 2–8°C and should not be frozen.
- Stability
  - If stored as recommended, unreconstituted forms are stable for 2 years after leaving manufacturer's cold stores.
  - After reconstitution of lyophilized formulation, the vaccine should be used within 24 h.
- Normal appearance
  - Clear and colorless liquid except reconstituted PRP-OMP which is slightly opaque, white suspension.

Efficacy and Immunogenicity

All HIB conjugate vaccines are highly immunogenic after a single vaccine dose in children older than 18 months of age and in adults. However, significant differences exist in immunogenicity in infants among the different vaccines as outlined below.

PRP-D

Of the four conjugate vaccines, PRP-D is the least immunogenic in infants. Less than half of the fully vaccinated infants develop protective-antibody levels. In efficacy trials, it was found to be effective in Finland; however, it failed to show efficacy in Alaska.

PRP-CRM (HbOC) and PRP-T

The immune response to these two vaccines is roughly similar. After a single dose at 2–4 months of age, no significant response is elicited in most cases. However, after two doses and certainly after three doses, the immune response is excellent with almost 90–100% efficacy.

PRP-OMP

Unlike other conjugate vaccines, PRP-OMP induces a good immune response in the majority of infants after a single dose at 2 months of age. After two doses, more than 90% of infants will have protective antibodies. Of

note, a classical booster response is not seen after the second dose. Furthermore, addition of a third dose at 6 months of age does not boost levels or the proportion of responders. In efficacy trials, PRP-OMP has a proven efficacy even in a high-risk population.

Recommended Use

Vaccination with a conjugate HIB vaccine is recommended for all children below the age of 5 years, starting from 2 months of age. Older children and adults with increased risk of invasive HIB diseases such as those with sickle cell disease, bone marrow transplant, congenital or functional asplenia, HIV, or IgG2 deficiency are candidates for HIB conjugate vaccination.

- Any of the three conjugate vaccines (PRP-T, PRP-CRM, PRP-OMP) is acceptable for immunization of young infants. The number of doses recommended and the timing are summarized in *Table 76.2*.
- PRP-D is only acceptable for vaccination of older children (15 months of age) and for the booster dose in vaccinated infants.
- All the doses are given by intramuscular injection.

Table 76.2
Recommended schedule of vaccinations

Age at first immunization (months)	Product	Number of primary doses	Booster
2–6	HbOC	3	Yes
	PRP-T		(12–15 months)
	PRP-OMP	2	Yes
			(12–15 months)
7–11	HbOC	2	Yes
	PRP-T		(12–18 months)
	PRP-OMP		
12–14	HBOC	1	Yes
	HRP-T		(2 months Later)
	PRP-OMP		
≥15	HbOC	1	No
	PRP-T		
	PRP-OMP		
	PRP-D		

Adverse Events

Adverse events are few and usually mild. Local reactions include pain, redness, and/or swelling at injection site which are seen in approximately 25% of recipients but are typically mild and resolve within 24 h. Systemic reactions such as fever and irritability are infrequent. No severe adverse event has been reported.

Contraindications

Conjugate HIB vaccines are contraindicated in patients with history of severe allergic reaction to any component of the vaccines.

Practical Hints

1. Infants and children who experience an invasive HIB disease before the age of 2 years frequently remain susceptible after recovery, and therefore, they should be vaccinated according to the age-appropriate schedule. This can be done 1 month after onset of the disease or as early as possible after full recovery.
2. Children who develop invasive HIB diseases at or after the age of 2 years do not require vaccination after recovery as the infection will most likely induce formation of protective antibodies.
3. Children who develop invasive HIB disease after completing the recommended doses of conjugate HIB vaccines (i.e., one dose >15 months of age, or primary as well as booster doses <15 months of age) are at increased risk of having IgG2 deficiency, and immunological evaluation is recommended.
4. Following immunization with HIB vaccines, HIB antigen may be excreted in the urine for days to weeks and will be detected by latex particle agglutination. This should be considered when evaluating a febrile infant who has been immunized recently. Antigenemia is less common and occurs only very early post vaccination.
5. If possible, it is recommended to use the same vaccine product for all the primary doses. However, for the booster dose any of the four products is acceptable. When necessary, it is also acceptable to interchange the products.
6. It should be noted that carrier proteins do not induce sufficient immune responses to be considered immunizing agents versus diphtheria, tetanus, or meningiococcus.

Hepatitis A Vaccine

Nature and Contents

Hepatitis A vaccine (HAV) is an inactivated vaccine prepared by propagation of HA virus in human fibroblasts and inactivated by formalin. Aluminum hydroxide is used as adjuvant, and phenoxy ethanol is used as a preservative.

HAV is available either as a single agent or in combination with other vaccines like hepatitis B or typhoid vaccine.

HAV antigen content (expressed as IU) in the combined formulations is half that in the monovalent.

Mechanism of Protection

HAV induces anti-HAV protective antibody similar to natural infection.

Efficacy and Immunogenicity

All the licensed HAV have shown high levels of immunogenicity. Protective levels of anti-HAV develop in 95–100% of vaccinee 1 month after a single dose. Efficacy in preventing clinical disease is also high.

Recommended Use

1. Pre-exposure Prophylaxis
   (a) HAV is recommended for individuals at increased risk of infection or increased risk of severe disease.
   (b) Several countries have adopted universal HA vaccination and have included HAV in the routine childhood vaccination schedules starting from age of 1 year. Assessment of the disease burden and the local epidemiology of HA in each community is essential prior to consideration of universal vaccination.
   (c) HAV is recommended for the following individuals:
      (i) Residents of areas of intermediate or high endemicity.
      (ii) Travelers to areas with high rate of HA infection.
      (iii) People with high-risk behaviors such as illicit drug use.
      (iv) People with hemophilia A or B receiving plasma-derived replacement clotting factors.
      (v) Individuals who handle nonhuman primates such as veterinarians, researchers, zoo workers.
      (vi) Individuals who have chronic liver disease or those receiving hepatotoxic medications or infected with hepatitis C or B viruses as they are at increased risk of fulminant hepatitis if they became infected with HAV.
2. Post-exposure vaccination
   (a) HAV is possibly as effective as immunoglobulin in prevention of HA clinical disease following exposure if given within 1 week. All susceptible close contacts of patients with Hepatitis A should receive one dose of HAV as soon as possible.
3. Outbreak Control
   (a) HAV is effective in control of outbreaks and is preferred to immunoglobulin, particularly in outbreaks occurring among specific population.

Dose and Schedule

1. For monovalent formulations, two doses are required separated by at least 6 months. Currently, available vaccines are not approved for children younger than 1 year of age. The dose for adult is double that for children.
2. If the combined HA and HB vaccine formulation is used, three doses are given at 0, 1, and 6 months.
3. The vaccine is given by intramuscular injection.

Adverse Reactions

HAV is a safe vaccine with mainly local injection site reactions. Adults are affected more frequently than children. Malaise, headache, and fever were the reported systemic reaction.

Contraindication and Precautions

1. The only contraindication to HAV is severe allergy to any component of the vaccine.
2. If indicated, the vaccine can be given to pregnant women, breast-feeding mothers, and immunnocompromized individuals.

Practical Hints

1. Pre-immunization serologic testing for HAV antibody is neither necessary nor required. However, if the cost of vaccination is higher than serology testing, it may be considered in individuals who are likely to be previously infected.
2. Since only one dose is given for the vaccination with the combined HAV and typhoid vaccine, a booster dose using a monovalent HAV should be given 6 month later.
3. If the vaccination series was started with one formulation and that formulation is not available at the time of the booster dose any other formulation can be used.
4. Although the benefit from post-exposure vaccination is more when the vaccine is given within 7 days, it can be given after that period along with immunoglobulin if indicated at the same visit but at different site.

Hepatitis B Vaccine

Nature and Contents

Currently licensed hepatitis B vaccines (HBV) consist predominantly of purified particles of the surface antigen of hepatitis B (HBsAg). HBsAg is produced from recombinant yeast or cells (recombinant vaccines). An earlier vaccine derived from the plasma of chronic carriers (Plasma-derived vaccine) is no longer available.

Currently available HBV contain 5–40 μg HBsAg protein per milliliter adsorbed onto aluminum hydroxide. Thimerosal is used as a preservative in some products. The vaccine is available as a single agent and in fixed combination with other vaccines, including HAV, DTaP, IPV, HIB.

Mechanism of Protection

HB vaccines protect against HB infection and clinical disease by:

1. Inducing antibodies (anti-HBs) against HBsAg
2. Priming the immune system to form immune memory which protects against significant HBV infection (symptomatic and/or chronic infection) even though anti-HBs concentration may become low or undetectable.

Storage and Handling

- Storage and shipment
  - All types of HB vaccines should be stored at 2–8°C and must NOT be frozen
- Normal appearance
  - Slightly opaque, white suspension after thorough agitation.

Efficacy and Immunogenicity

A course of three intramuscular doses of HB vaccine induces formation of protective levels of anti-HBs $\geq$ 10 milli international units [mIU] per milliliter) in 90% of healthy adults and 95% of healthy infants and children. Seroconversion rate is lower in adults over 40 years of age, and it decreases with age. The immune response to the combined formulations is similar to that of single-agent vaccines. Immunocompromised individuals such as HIV patients and those on hemodialysis have poor antibody response to the vaccine. Although the incidence of loss of detectable serum antibody 10 years after vaccination is considerable, immune memory remains intact and protects against chronic HBV infection in vaccinees who have demonstrated initial seroconversion even though anti-HBs concentration may become undetectable.

Recommended Use

1. Universal vaccination of infants

   The World Health Organization recommends vaccination of all infants against Hepatitis B in countries with moderate or high endemicity. Failure of programs directed at vaccination of only high-risk groups in areas with low endemicity make universal vaccination of infants and children with HBV the preferred strategy in all countries. Furthermore, better immunogenicity of HBV in infants and children coupled with requirement of smaller doses than adults makes this the most cost-effective strategy.
2. Immunization of high-risks groups
   (a) Infants born to HBsAg-positive mothers
   (b) Those who are at increased risk of exposure to blood or blood products such as:
      (i) Patients receiving repeated infusions of blood (e.g., thalassemia) or certain blood products (e.g., Factor VIII or IX concentrate)
      (ii) Hemodialysis patients

(iii) Health-care workers who are at risk of needle-stick injury
(iv) Dentists, dental assistants, and hygienists
(c) Sexual and household contacts of hepatitis B virus carriers
(d) Patients with chronic liver diseases are at risk of severe acute infection should they become infected.

Schedules of Vaccination

- The routine HB vaccination schedule involves administering three doses of HBV with at least 1 month between first and second doses and 4 months between second and third doses.
- For infants of HBsAg-positive mothers, the first dose should be given at birth (along with hepatitis B immunoglobulin), the second dose at 1 month of age, and the third dose at 6 months of age.
- An alternative 4-doses schedule for post-exposure prophylaxis or for more rapid induction of immunity has been approved for one of the vaccines (Engerix-B) at 0, 1, 2, and 12 months.
- The doses recommended differ according to the indication and the particular product (see *Table 76.3*).
- All the doses should be administered by intramuscular injection at the anterolateral aspect of the thigh in infants and at deltoid in older children and adults.

Table 76.3
Recommended doses μg(mL) of Hepatitis B vaccines

Group	Recombinant	
	Recombivax HB	Engerix-B
Infants of HBsAg-negative mothers and children <15 years	2.5 (0.25)	10 (0.5)
Infants of HBsAg-positive mothers	5 (0.5)	10 (0.5)
Children and adolescents 15–19 years	5 (0.5)	20 (1)
Adults ≥ 20 years	10 (1)	20 (1)
Dialysis patients and other immunocompromised individuals	40 (1)[a]	40 (2.)[b]

[a]Special formulation for dialysis patients to be given at 0, 1, and 6 months
[b]Two 1.0 mL doses administered at one site in a four-dose schedule at 0,1,2, and 6–12 months

Adverse Reactions

- The most frequently reported adverse reactions after the vaccine are low-grade fever and pain at the injection site, which occur in 1–6% of children and adults.
- Allergic reactions are infrequent and anaphylaxis is very rare.

Contraindications

The only contraindication to the vaccine is hypersensitivity to any component of the vaccine. Pregnancy is not a contraindication, and the vaccine should be given to pregnant women if they are at risk of exposure to HB infection during pregnancy.

Practical Hints

1. The available vaccines are interchangeable, and the vaccination course may be completed using a single product or any combination of the available products.
2. Immunogenicity of HBV is diminished when it is administered in the buttock in adults and when given by the intradermal route; therefore, these practices should be avoided.
3. Concurrent administration of hepatitis B immunoglobuline (HBIG) does not interfere with the antibody response to HB vaccine. However, when HBIG is indicated, it should be given in a different syringe at a different site.
4. There is no increase in adverse effects when HBV are given to immune individuals (i.e., anti- HBs positive) or to carriers (HBsAg positive). However, it is not indicated in the first instance and not useful in the latter.
5. Routine prevaccination serologic testing to detect carriers or immune persons is not indicated and not cost-effective except may be in situations where the likelihood of previous exposure to HB infection is high.
6. Routine postvaccination testing for immunity is not indicated; however, in the following situations, it is recommended to test for anti-HBs level 1–3 months after the third dose of the vaccine:
   (a) In those who are known to be poor responders such as hemodialysis patients and immunocompromised individuals. In those who are at increased risk of exposure to HB infection and whose future management depends on knowledge of their response such as health-care workers.

7. Infants born to HBsAg-positive mothers should receive HBIG within 12 h of birth and HBV series should be started at birth. They should be tested 1–3 months after the third dose of vaccination for anti-HBs and HBsAg. If found to be negative for both, additional 1–3 doses of vaccine should be given followed by testing for anti-HBs.
8. Premature babies whose weight is less than 2,000 g have poor response to HBV, and the vaccine should be delayed till they reach 2 kg or their chronological age become 1 month. However, if the mother is HBsAg positive, HBV and HBIG should be given within 12 h of birth, and this dose of vaccine should not be counted.
9. At present, booster doses of vaccine are not recommended for children and adults with normal immune status. However, for hemodialysis patients, it is recommended to do annual testing for anti-HBs and to give a booster dose when the antibody level declines <10 mIU/mL.

Human Papilloma Virus Vaccine

Nature and Contents

The currently licensed human papillomavirus (HPV) vaccines are:

1. Quadrivalent HPV vaccine (Gardasil)
2. Bivalent HPV vaccine (cervarix)

The antigens of both vaccines are the L1 major capsid protein of HPV produced by using recombinant DNA technology. It is noninfectious and nononcogenic.

- *The Quadrivalent HPV*: each 0.5 mL dose contain between 20–40 μg of L1 proteins from HPV types 6, 11, 16, and 18. It is adsorbed on aluminum adjuvant, and it contains no thiomersal or antibiotics.
- *The bivalent HPV vaccine*: each 0.5 mL contain 20 μg each of HPV types 16 and 18 adjuvented with ASO4 (aluminum and lipid compound).

Mechanism of Protection

The mechanism of protection of HPV vaccine against cervical and other anogenital cancers is related to its efficacy in prevention of persistence of infection by HPV types 16 and18 which are implicated in the majority of cases of the histopathological changes leading to malignancy.

Following vaccination, neutralizing antibodies are produced in high levels which may be responsible for the prevention of persistence of infection by the viruses contained in the respective vaccine.

Storage and Handling

Both vaccines should be stored at 2–8°C and not be freezed. It should be protected from light.

Efficacy

- For females previously uninfected by vaccine-related HPV type, both vaccines are highly immunogenic and has proven efficacy in prevention of persistence of infection by vaccine virus and in prevention of precancerous and cancer lesions of cervix and other anogenital lesions.
- There is some evidence that some protection might be achieved against lesions caused by non-vaccine oncogenic HPV types particularly HPV type 31.
- In individuals who were previously infected by vaccine related HPV types, the vaccine efficacy is low.
- The duration of protection is not yet known. However, high neutralizing antibodies has been demonstrated for up to 5 years. Furthermore, robust immune memory is induced in vaccinees.

Recommended Use

Since the risk of infection and the burden of disease caused by HPV varies between different communities depending on the sexual behavior, the decision to adopt HPV vaccine requires consideration of these factors.

1. When it is indicated, HPV is recommended to be given prior to onset of sexual activity at or above 9 years of age.
2. Females $\geq$ 9–26 years of age maybe given the vaccine even if they have started sexual activity because they are unlikely to have been infected with all HPV types in the vaccine.
3. Females older than 26 years of age are not candidate for routine HPV vaccination.

4. HIV-infected females are at increased risk of infection and sequelae of HPV and should be vaccinated, although the efficacy of the vaccine may be reduced.
5. Males between 9 and 26 years of age may be vaccinated by the quadrivalent HPV vaccine to reduce their risk of genital warts.

Doses and Route

Both vaccines are administered in three dose schedule, at 0, 1 or 2, and 6 months by intramuscular route. The minimum interval between the first and second doses of vaccine is 4 weeks and between the second and third is 12 weeks. The minimum interval between the first and third dose is 24 weeks.

Adverse Reactions

Similar adverse reactions were reported from both vaccines. Local injection site reactions are common and include pain, redness, and swelling. Systematic reaction included fatigue, headache, and myalgia. No serious side effects were found.

Contraindications and Precautions

Both vaccines are contraindicated for persons with a history of immediate hypersensitivity to any vaccine component. The quadrivalent vaccine is produced in yeast and is contraindicated for individuals with immediate hypersensitivity to yeast.

- Anaplylactic latex allergy is contraindication for the prefilled syringes of the bivalent vaccine (single dose vials of the bivalent vaccine contain no latex)
- Both vaccines should not be used in pregnancy due to lack of data on safety.
- Syncope may occur after vaccinations in adolescents and young adult.

Practical Hints

1. Women should continue to receive regular cervical cancer screening (with pap smear) according to the recommendation even if they have received full course of HPV vaccine because the vaccine covers only 70% of the etiologies of cervical cancers.
2. Screening for infection with HPV or for changes in Pap smear is not recommended prior to vaccination.
3. Females who have had an abnormal Pap test or have current HPV infection or genital warts should get the vaccine. However, they should be informed that the vaccine will have no helpful effect on existing infection or abnormality.

Influenza Vaccine

Nature and Contents

Two types of influenza vaccine are currently in use:

- Trivalent inactivate influenza vaccine (TIV)
- Live attenuated influenza vaccine (LAIV)

The TIV is composed of either subvirion or purified surface antigens of three strains of influenza viruses prepared by propagation in embryonated eggs and chemical treatment for splitting (disruption) and inactivation.

Each 0.5 mL dose contains 15 μg of hemagglutinin of each of the three viral antigens. It may contain traces of antibiotics and egg proteins. In some products, thiomersal is used as a preservative.

The LAIV is a trivalent, cold adapted, temperature sensitive vaccine. It is produced by serial passages of the selected strains of influenza virus in chick kidney cells to produced attenuated strains with good replication at 25°C.

The three strains included in both vaccines are two subtypes of influenza A and one of influenza B. These are selected annually according to recommendations made by the WHO for the strains likely to circulate in the specific season in Northern or Southern Hemispheres.

Storage and Handling

TIV and LAIV should be stored at 2–8°C and should not be exposed to freezing temperature.

Efficacy and Immunogenicity

The effectiveness of influenza vaccine varies depending upon the age and immunocompetence status of the recipient as well as the degree of matching between vaccines and circulating influenza viruses. With good match,

TIV efficacy in children and healthy adults >65 years is 70–90%, but only 30–60% with incomplete match.

Among children 6–24 months old, efficacy is 60–70%. In elderly TIV is 50–60% effective in prevention of hospitalization and 80% in prevention of death.

LAIV efficacy in children 15–71 month old is 93% for culture-confirmed influenza with full match between vaccine and circulating viruses.

Recommended Use

Annual influenza vaccines are indicated for the following priority groups:

1. Individuals at high risk of influenza related complications or hospitalizations
   - Individual at high risk of complications or hospitalization include:
     (a) Elderly <65 years
     (b) Children 6–23 months of age
     (c) Children and adults with any of the following chronic conditions:
       (i) Cardiac disorders such as congenital heart disease
       (ii) Pulmonary disorders including bronchopulmonary dysplasia, cystic fibrosis, and asthma
       (iii) Diabetes mellitus, kidney disease, hematological diseases
       (iv) Cancer, immunodeficiency, immunosuppresion
       (v) Children and adolescent on long-term aspirin therapy
     (d) Residents of chronic care facilities
     (e) Pregnant women
2. Individuals capable of transmitting influenza to those high risk
   - Individuals capable of transmitting influenza to high-risk group include:
     (a) Health-care providers
     (b) Household contacts of any of the high-risk group
     (c) Household contacts of infants less than 6 months old

Dosages and Schedules

1. Influenza vaccines are given once per year. In children >9 years of age who are receiving the vaccine for the first time, two doses are required at least 4 weeks apart.
2. The dose for TIV is 0.5 mL given intramuscularly; children >3 years old should receive 0.25 mL.
3. LAIV is approved for use only in healthy 2–49 years old. It is given as a spray in the nose with 0.1 mL of the vaccine sprayed in each nostril.

Adverse Reactions

TIV

- Systemic adverse event reported after TIV vaccination of children include fever, malaise, and myalgia. These were observe more in young age groups (12% in those >5 years vs 5% <5 years).
- Local reactions are mild and included redness, swelling, and pain at injection site.

LAIV

- Among healthy children, the most frequently reported adverse reactions include: runny nose or nasal congestion, headache, fever, and wheezing. These symptoms were more reported after the first dose.
- Among healthy adults runny nose or nasal congestion, headache and sore throat were reported more in vaccine recipients than placebo recipients.

Contraindications and Precautions

- Contraindication and precautions for use of LAIV
  LAIV is contraindicated for the following groups:
  - Persons with severe allergy to any component of the vaccine or to egg.
  - Persons aged less than 2 years or above 50 years
  - Adults and children considered at high risk of complications of influenza
  - Adults and children who are immunosuppresed by diseases or by medication
  - Children between 2 and 4 years with wheezing episodes in the last 12 months
  - Children and adults on chronic aspirin use
  - Pregnant women

  The precautions include:
  - Moderate or severe illness
  - Contacts of patients with severe immunosuppression

- History of Guillain-Barré Syndrome (GBS) within 6 weeks following a previous dose of influenza vaccine

- *TIV* is contraindicated in persons with severe allergy to any vaccine component or to egg.
  Precaution should be observed in the following groups:
  - Moderate or severe illness
  - History of GBS within 6 weeks following a previous dose

Practical Hints

1. The optimal timing of vaccination in a given setting or geographical area depends on the local epidemiology data including the timing and intensity of influenza activity in that area. The principle, however, is to start vaccination prior to onset and continue throughout the season.
2. Individuals planning to travel to the tropics or with organized large tourist groups which may have people from different parts of the world are at risk of exposure to influenza viruses irrespective of the time of the year and should be encouraged to take the vaccine 2 weeks prior to the travel date.
3. Sneezing following LAIV administration does not warrant repeating the dose.
4. Children and adults vaccinated with LAIV can shed vaccine viruses after vaccination. However, transmission to unvaccinated contacts is rare and no serious illness has been reported as a result.
5. Both vaccines can be administered at the same visit with other routine childhood vaccines.

Measles Vaccine

Nature and Contents

Currently available measles vaccines are live attenuated viruses produced by several passages of the original virus strain in different cell cultures at different temperatures. Examples of such currently used vaccine strains include Schwarz, Moraten, Edmonston-Zagreb, Alk-C, etc. Usually, each dose contains trace amount of neomycin, sorbitol and hydrolyzed gelatine (as stabilizers), and at least 1,000 TCID50 of virus particles. The vaccine is available as a single agent and in combination with Mumps and Rubella (MMR) with or without varicella (MMRV).

Mechanism of Protection

Protection following successful vaccination is due to:

1. Induced IgG in serum and secretory IgA in nasal secretions.
2. Priming of the immune system so that a booster response is induced after exposure to natural virus.
3. Stimulation of cell-mediated immunity.

Storage and Handling

- Storage and shipment
  - Unreconstituted vaccine maybe stored at 2–8°C and maybe frozen.
  - Reconstituted form should be stored at 2–8°C.
  - Both forms should be protected from light (dark vials are usually used).
- Stability
  - If stored as recommended, unreconstituted form is stable for 2 years or more. Potency may be maintained for several months at room temperature and for up to 4 weeks at 37°C.
  - Reconstituted vaccine remains potent for up to 2 months at 2–8°C and for 2 days at room temperature. Potency is lost, however, after 7 h at 37°C.
- Normal appearance
  - Clear, yellow solution. If reconstituted vaccine is cloudy it should *not* be used.

Efficacy and Immunogenicity

Successful vaccination with measles vaccine induces an immune response very similar to that noted after natural infection. Both humoral (including IgG, IgM, and IgA) as well as cellular immunity are induced. Approximately 95% of children vaccinated after the first year of life develop seroconversion. The response to the vaccine in infants below 9 months of age is usually poor due likely to interference by maternal antibody. A protective efficacy study of a single dose given between 12 and 15 months of age was calculated to be more than 90–95%. After a second dose, almost 100% of children become immune. Although induced antibodies may decline with time, anamenstic responses follow exposure to wild or vaccine virus.

Recommended Use

1. Routine measles immunization
   (a) Measles vaccine is recommended to be given early in the second year of life (after interference by maternal antibodies have disappeared) in combination with Rubella and mumps (MMR).
   (b) Most countries have implemented two-dose schedule. The time for the second dose varies from one country to another. In some, it is one or more months from the first dose, and in others, several years later.
   (c) In areas in which measles is a significant problem in infants below 1 year of age (like most developing countries), a dose of a monovalent measles vaccine is recommended at 6–9 months of age. Use of vaccines containing Edmonston–Zagreb strain with intermediate titres provide better chance of seroconversion of infants vaccinated as early as 6 months of age.
2. Postexposure prophylaxis
   (a) Measles vaccine can be used to protect susceptible contacts following exposure to measles. The vaccine is likely to be protective only if given within 72 h of exposure.
3. Outbreak control
   (a) To help control an outbreak in a daycare, school, or a community, measles vaccine (or MMR) should be given to all individuals who have no proof of immunity or documented vaccination after first year of life. There are no ill effects from vaccinating individuals who are already immune.

Dose and Route

0.5 mL of reconstituted vaccine is given by subcutaneous injection.

Adverse Reactions

Fever >39°C occurs in 5–15% and a transient rash in 3–5% of vaccinees. These reactions usually occur 6–12 days post immunization. Predisposed children may develop febrile seizures associated with fever. Transient thrombocytopenia has been reported after measles-containing vaccines (MMR); however, it is usually benign and resolve spontaneously within 4 weeks.

High-titer measles vaccines (containing >100,000 TCID50) have been associated with increased mortality in recipients months to years after vaccination. Although the available data are not conclusive of unsafety of these vaccines, their use is discouraged.

There is no scientific evidence to support the claims that measles-containing vaccines cause autism, chronic inflammatory bowel diseases, or Guillain-Barré syndrome.

Contraindications and Precautions

Measles and measles-containing vaccines (MMR) are contraindicated in:

1. Individuals with altered immune status due to:
   (a) Primary immune deficiency
   (b) Malignancy, e.g., leukemia, lymphoma
   (c) Immunosuppressive therapy, e.g., corticosteroids, cytotoxic agents, etc.

   N.B.: Symptomatic and asymptomatic human immune deficiency (HIV) infection is not a contraindication for measles or MMR vaccine except if having severe immunosuppresion.
2. Individuals with history of anaphylactic reactions to a measles-containing vaccine, gelatine, or neomycin.
3. Pregnancy
4. Individuals who have recently received immunoglobulins or other blood products may not respond to the vaccine for 3–11 months due to passively acquired antibodies.

The following are *not* contraindications:

1. Mild febrile or nonfebrile illness such as upper respiratory tract infections.
2. Personal and/or family history of convulsions.
3. Allergic reactions to eggs.
4. Presence of immunocompromized patients in the household.
5. Penicillin allergy.
6. History of contact dermatitis to neomycin.

Practical Hints

1. Skin testing of individuals with anaphylactic reactions to eggs using dilute vaccine is not predictive of an allergic reaction to vaccination with measles-containing vaccine. Therefore, skin testing is not required in these individuals prior to vaccination.
2. If a patient receive immunoglobulins or other blood products within 2 weeks of measles vaccination, the

response to the vaccine may not be adequate and that vaccine dose should be repeated after the appropriate interval have passed.
3. Measles vaccination can temporarily suppress tuberculin reactivity; therefore, if there is indication to perform tuberculin skin test, this should be done either at the time of measles vaccination or 4–6 weeks later.
4. Although natural measles can exacerbate tuberculosis, live measles vaccines are not known to do so, and therefore, tuberculin skin testing is not a prerequisite for measles vaccination.
5. The infection induced by measles vaccine is not communicable even in vaccinees that develop rash or other measles manifestations.
6. The response of HIV patients to measles vaccine is not optimal, and the antibody response wane faster than uninfected children. Therefore, immunoglobuline should be administered after exposure even if previously vaccinated.

Meningococcal Vaccine

There are two different types of meningococcal vaccines available:

1. Plain Polysaccharide vaccines
2. Conjugated vaccines

Nature and Contents

The Plain polysaccharide meningococcal vaccines consist of purified capsular polysaccharides of sero group A, C, Y, and W135. The vaccine is available as either monovalent, bivalent, or a quadrivalent vaccine, depending on the polysaccharides contained in the product. It is produced as a freeze-dried preparation and is diluted with a sterile saline containing thimerosal as a preservative.

The conjugate vaccines are composed of purified capsular polysaccharide linked (conjugated) to a carrier protein. The carrier proteins used in the currently available vaccines are any of the following:

- Nontoxic, mutant diphtheria toxin (CRM197)
- Diphtheria toxoid
- Tetanus toxoid

This conjugation changes the nature of the immune response to the polysaccharide from the T-cell-independent to T-Cell-dependent response leading to improvement in immunogenicity in children less than 2 years old and anamenstic response in reexposure.

The currently available meningococcal conjugate vaccines are either quadrivalent vaccines containing capsular polysaccharide from serogroups A, C, Y, and W135 or monovalent vaccines containing polysaccharide from serogroup A or C alone or in combination with HIB vaccine.

Efficacy and Immunogenicity

1. Plain Polysaccharide vaccines

   All the four meningococcal polysaccharides are immunogenic in adults and children over 2 years of age. However, only group A polysaccharide is immunogenic in infants and children below 18 months. Clinical efficacy has been demonstrated for group A meningococcal vaccines in infants and young children given two doses of vaccine during epidemic situations, and both group A & C vaccines were protective to adults and older children after one dose. However, group C vaccine failed to protect infants and young children in epidemics. Antibody responses decline rapidly, particularly in children and adolescents. Furthermore, repeated vaccination with the polysaccharide vaccine result in hyporesponsiveness phenomenon (reduced antibody response compared with primary vaccination).
2. Conjugate Vaccines

   In older children and adults, the immunogenicity of conjugate vaccines is as good as that of polysaccharide. Furthermore, immunity persists longer and no hyporesponsiveness is observed after revaccination.

   In children less than 2 years of age, antibody response to all serogroups after two doses is better that that seen with polysaccharides vaccine.

   The response of serogroup C is comparable between quadrivalent and monovalent conjugate vaccine.

   Clinical efficacy has been demonstrated after introduction of the monovalent conjugate group C vaccine in UK.

Recommended Use

Meningococcal vaccines are indicated in the following situations:

1. Routine vaccination

   The adoption of universal routine meningococcal vaccination should be based on the local disease burden and other public health factors.

   When it is indicated the following apply:

   (a) For infants less than 1 year of age: two doses separated by 4–8 weeks should be given to those more than 2 months of age using the conjugate vaccine. A booster dose should be given at or after 12 months of age.
   (b) Children ≥1 year to >4 years: one dose of conjugate vaccine is adequate
   (c) Children more that 4 year and adults: one dose of conjugate vaccine is preferred, but polysaccharide vaccines will provide protection for 3–5 years.
2. Control of epidemics

   Conjugate vaccine containing the respective serotype causing the epidemic should be administered to all person over 2 months of age. In case of group A meningococcal epidemic, polysaccharide vaccine may be given to infants as young as 3 months of age. In the later situation, two doses separated by 2–3 months should be given to all children below 18 months of life.
3. Population at increase risk of meningococcal disease should be given conjugate vaccines. They include:
   (a) Patients with functional or anatomic asplenia
   (b) Patients with complement or properdine deficiency
   (c) Traveler and residents of areas with high risk of outbreaks
   (d) College students living in dormitories
   (e) Military recruit
   (f) Laboratory personal handling meningococci
   (g) The vaccine may be used as adjunct to chemoprophylaxis for contacts of patients with invasive meningococcal diseases.
   (h) The need for booster doses is not fully known. However, following plain polysaccharide vaccine, immunity is adequate for 3 years following vaccination of those older than 4 years of age and it declines markedly after 2 years in those vaccinated below 4 years of age. The conjugate vaccines are likely to provide longer lasting protection than the polysaccharide vaccines.

Adverse Reactions

Meningococcal vaccines are generally safe and associated with mainly local injection site reactions, including erythema, pain, or tenderness for 1 or 2 days. Fever occurs in <2% of vaccinees. Repeated boosters for adults within short interval may result in severe local reactions.

Practical Hints

1. If monovalent group A polysaccharide vaccine is not available, bivalent AC vaccines or quadrivalent vaccines may be used in infants and young children's for whom group A vaccine is indicated. However, the response to other components is usually poor.
2. Although the data on safety of meningococcal vaccine in pregnancy is not adequate, there is no clear contraindication to the use of the vaccine in pregnant women who are at increased risk of exposure to infection as the benefit outweighs the theoretical risk.
3. The preferred route is intramuscular to reduce reactogenicity, but it may be given subcutaneously.
4. Premature babies born below 28 weeks of gestation should be vaccinated according to chronological age and need respiratory monitoring. Should apnea, bradycardia, or desaturation occur after first dose, second dose should be given in hospitals with respiratory monitoring

Contraindications

A severe allergic reaction to a previous dose or to component of the vaccine is a contraindication.

Precautions

- In individuals with moderate to severe illness, vaccination should be deferred.
- Patient with past history of Guillain-Barré syndrome.

Mumps Vaccine

Nature and Contents

Current mumps vaccines are live attenuated viruses produced by serial passages of mumps virus in embryonated

eggs, chick embryo, and/or human diploid cell cultures. Several vaccine strains are in use throughout the world. However, most widely used strains are Jeryl Lynn, Urabe, and Leningrad strains. The vaccine is available in a monovalent form or combined with rubella or measles and rubella (MMR) vaccines with or without varicella vaccine. The vaccines contain trace amounts of neomycine as well as Sorbitol and hydrolyzed gelatine as stabilizers.

Mechanisms of Protection

Following vaccination with mumps vaccine neutralizing antibodies are induced in serum which prevent occurrence of viremia. Cell-mediated immune responses may also contribute to protection; however, the exact role is unknown.

Storage and Handling

- Storage and shipment
  - Unreconstituted vaccine may be stored at 2–8°C and may be frozen.
  - Reconstituted form: should be stored at 2–8°C
  - Both forms should be protected from light.
- Stability
  - Unreconstituted form is stable for 1–2 years if stored as recommended.
  - Reconstituted form is stable for 8 h at 4°C.
- Normal appearance
  - Clear, yellow solution. If reconstituted vaccine is cloudy, it should *not* be used.

Efficacy and Immunogenicity

Mumps vaccine induces formation of neutralizing antibodies in 80–100% of vaccinee. Clinical efficacy studies documented clinical protection in 90–95% of vaccinee. Although the induced antibodies are lower than those that follow natural disease, protection probably persists for over 17 years following a single dose. Responses to monovalent and combined vaccines are essentially the same.

Recommended Use

Routine Immunization

- Mumps vaccine is recommended to be given early in the second year of life along with measles and rubella (MMR) vaccines.
- In countries where two measles vaccine doses are recommended, it is preferred to use MMR for that purpose as it will reinforce mumps and rubella immunity.

Adverse Reactions

- Fever has been reported 10–14 days following vaccination with the vaccine.
- Transient skin rashes with pruritis have occasionally been reported but are uncommon.
- Aseptic meningitis may occur 2–3 weeks after vaccination, and its rate varies between the different strains. It ranges between 1 in 800,000 doses after Jeryl Lynn strain to as high as 1 in 1,000 for the Leningrad-3 strain. However, the course is usually benign and sequelae have been rare or absent.

Contraindications and Precautions

Mumps and mumps-containing vaccines (MMR) are contraindicated in:

1. Individuals with altered immune status due to:
   (a) Primary immune deficiency
   (b) Malignancy, e.g., leukemia, lymphoma
   (c) Immunosuppressive therapy, e.g., corticosteroids, cytotoxic agents, etc.

   N.B.: Symptomatic and asymptomatic HIV infection is not a contraindication for mumps or MMR vaccines except for those with severe immunosuppresion.
2. Individuals with anaphylactic reaction to neomycine or gelatin.
3. Pregnancy
4. Individuals who have recently received immunoglobulins or other blood products may not respond to the vaccine for 3 months or more due to passively acquired antibodies.

Practical Hints

1. Administration of MMR is not harmful if given to an individual already immune to one or more of the viruses.
2. The risk of mumps exposure for patients in whom mumps vaccine is contraindicated can be reduced by vaccinating their close susceptible contacts.

3. The infection induced by mumps vaccine is not communicable even in vaccinees who develop parotitis or other manifestations.
4. Mumps vaccine is not usually useful after exposure to the disease. However, vaccination of susceptible exposed persons is recommended as it will provide immunity to those individuals who will not develop mumps after their exposure and at the same time vaccination is not harmful to those incubating mumps.
5. If a patient receive immunoglobulins or other blood products within 2 weeks of mumps vaccination, the response to the vaccine may not be adequate and that vaccine dose should be repeated after the appropriate interval have passed.

Pertussis Vaccines

There are two different kinds of pertussis vaccines: whole-cell pertussis vaccines (wPV) and acellular pertussis vaccines (aPV).

Whole-Cell Pertussis Vaccine

Nature and Contents

Whole-cell pertussis vaccines (wPV) contain suspension of inactivated whole *Bordetella pertussis* bacteria. The vaccine is mostly available in combination with diphtheria and tetanus toxoides (DTP) with or without inactivated polio vaccine (IPV) and/or HIB conjugate and HBV vaccines. It is adsorbed in aluminum salts, and thimerosal is added as a preservative in some products. A single non-adsorbed preparation exists in some countries.

Mechanisms of Protection

1. Individual perspective

   Whole-cell pertussis vaccines induce antibodies to a number of *B. pertussis* antigens. However, it is not known which antibodies are responsible for protection.
2. Community perspective

   Pertussis vaccines probably decrease the spread of pertussis in the communities by reducing the intensity and duration of cough in vaccinated individuals who contract the disease.

Efficacy and Immunogenicity

The immune response to the wPV is directed against several antigen of whole bacterial cells. There are marked differences in the immune responses to various antigens among the different wP vaccines. It is difficult to have a precise estimate of efficacy of wPV. However, in a systematic review of efficacy of wPV including 49 controlled trials and three cohort studies using WHO case definition, the pooled efficacy of wPV in children was 78% but was variable among different vaccines. The protection from disease decreases as the time interval since vaccination increases.

Storage and Handling

- Storage and shipment
  - Adsorbed preparations containing pertussis vaccine should be stored and shipped at 2–8°C. No freezing is allowed.
- Stability
  - Exposure to temperatures <2°C or >25°C for as little as 24 h may precipitate suspended antigens and make it very difficult to resuspend normal appearance.
- Normal appearance
  - Turbid and whitish suspension. Vaccines that contain clumps of material that cannot be suspended with vigorous shaking should *not* be used.

Recommended Use

1. Primary immunization
   (a) Three doses of an adsorbed preparation containing pertussis vaccine is recommended for all infants starting at 4–8 weeks of age and separated by 4–8 weeks.
   (b) A fourth dose is given 6–12 months from the third dose, and a booster dose is administered at 4–6 years of age.
   (c) After the age of 7 years, wPV vaccine is not recommended because the morbidity from the vaccine is higher than that from the disease.
2. Close contacts of patients with pertussis
   (a) Close contacts younger than 7 years who are unimmunized or who have received fewer than four doses of pertussis vaccine should have

pertussis immunization initiated or completed according to recommended schedule. If the third dose was given more than 6 months before, a fourth dose should be given.

(b) Those under the age of 7 years who have received four previous doses of pertussis vaccine should be given a booster dose unless the fourth dose was given within 3 years.

Dose and Route

0.5 mL of preparations containing pertussis vaccine is given by intramuscular route. If non-adsorbed preparation is used, it can be given subcutaneously.

Adverse Reactions

Administration of wPV vaccine is associated with several local and systemic reactions as follows:

1. Local reactions: at the injection site include redness, swelling, pain, and tenderness which occur in approximately 50% of infants and may be higher in older children's. However, these are usually mild and resolve spontaneously. Rare local adverse events include pyogenic or sterile abscess (1 per 100,000 DPT injections).
2. Systemic reactions, including fever, irritability, drowsiness, and anorexia, occur in approximately 50–70% of vaccinees. More severe systemic reactions occasionally occur in some patients and include:
   (a) Seizures
      – These are mostly simple febrile convulsions and occur at a frequency of 1 per 1,750 injections. Predisposing factors to convulsions after pertussis vaccine include a personal or family history of convulsions. Rarely, a prolonged or complex convulsion occurs in association with pertussis vaccine. However, after prolonged follow-up, complete recovery without permanent sequelae has been observed in patients who developed a seizure disorder.
   (b) Hypotonic Hyporesponsive state
      – These episodes have been reported at the same rate of convulsion. Complete recovery occurs with no persistent neurologic or developmental defect on follow-up.
   (c) Unusual crying
      – Persistent, inconsolable crying lasting 3 or more hours is seen in 1% of vaccinee and high-pitched unusual screaming in 0.1%. The cause and significance of this observation is unknown.
   (d) Hyperpyrexia
      – Hyperpyrexia with fever greater than *40.5° C is seen in 0.3%.*

These severe systemic reactions are rarely reported after DT vaccines which suggest that the WC vaccines are responsible for their occurrence. It should be noted, however, that there is no scientific evidence to prove that wP vaccine cause encephalopathy, permanent brain damage, infantile spasm, or sudden infant death syndrome (SIDS).

Contraindications and Precautions

Contraindication to pertussis vaccine include:

1. History of anaphylactic reaction to a previous dose
2. Occurrence of encephalopathy within 7 days of a previous pertussis immunization
3. Acute febrile illness (but not mild upper respiratory infection)
4. Unstable or progressive neurological illness.
5. The following severe systemic reactions to a dose of pertussis vaccine are considered precautions for use of subsequent doses, and the potential benefits of administering the vaccine in the particular situation should be balanced against the possible risks:
   (a) Hyperpyrexia with temperature greater than 40.5°C within 48 h with no other identifiable cause.
   (b) Collapse (hypotonic hyporesponsive) state within 48 h.
   (c) Persistent, inconsolable crying lasting $\geq$3 h, occurring within 48 h.
   (d) Convulsions (febrile or afebrile) occurring within 3 days.

The followings are *not* contraindications:

1. Stable neurological conditions including well-controlled seizure disorders, cerebral palsy, hydrocephalus, etc.
2. Family history of convulsions or other neurological disorders.
3. Family history of SIDS
4. Family history of an adverse event following pertussis vaccine.

Practical Hints

1. Acetaminophene prophylaxis at 15 mg/kg/dose given at the time of immunization with DPT and again 4 h and 8 h later was found to markedly reduce the associated fever and local reactions, and is recommended for all infants and children.
2. In infants and children with personal or family history of febrile convulsion, use of acetaminophene prophylaxis at 4 hourly intervals is particularly important, and it can be continued for 24–48 h.
3. When pertussis immunization is contraindicated or deferred, immunization with diphtheria and tetanus toxoides can be continued using DT preparations. However, in communities where the risk of exposure to diphtheria and tetanus in the first year of life is minimal, DT immunization may be delayed until a decision is made regarding inclusion of pertussis component in the series. This, however, should not be delayed beyond first year of life.
4. If an infant developed a confirmed pertussis disease, pertussis vaccine should be omitted from his schedule. However, if the infant developed a pertussis-like illness, but with no confirmation of etiology as *B. pertussis*, the vaccine should be given.
5. Use of reduced doses of DPT vaccine in order to decrease the likelihood of adverse events has led to decreased protective efficacy of the vaccine and is not recommended.

Acellular Pertussis Vaccines

Nature and Contents

Acellular pertussis (aP) vaccines are composed of purified selected protein components of *B. pertussis* organisms. These include one or more of the following antigens: inactivated pertussis toxin (PT), filamentous hemagglutinin (FHA), Pertactin (PRN) (a 69-kD outer membrane protein), and fimbrial agglutinogens (FIM). They are manufactured either by simultaneous purification of multiple antigens from culture supernatunt (T-type vaccine) or by combining individually purified antigens (B-type vaccines). The antigenic composition varies among different products. The components are adsorbed on aluminum salts, and a preservative is added to some products. Several products are available in combination with diphtheria and tetanus toxoids (DTaP) with or without inactivated polio (IPv) and/or HIB conjugate vaccine and hepatitis B vaccines (HBV).

Efficacy and Immunogenicity

aPV induce high concentrations of antibodies to the antigens included in the respective vaccine. However, because there is not yet a clearly defined serologic correlate of protection against pertussis, ability to protect against clinical infection (i.e., efficacy) of each particular vaccine should be demonstrated. Several studies have evaluated the efficacy of different aPV products in Japan, Europe, and United States. The results indicate that multicomponent aPV (i.e., >3 components) are more effective than single or two-components vaccines. Products containing PT, FHA, and PRN have shown consistent results. A recent Cochrane review concluded that all multicomponents aPV provided high-level protection against pertussis; the efficacy against severe pertussis was shown to be >80%.

Storage and Handling

Storage and handling of DTaP vaccines are similar to regular DTwP.

Recommended Use

If it is economically feasible, aP-containing vaccine is the recommended vaccine for all doses in the vaccination series due to the reduced local and systematic reactogenicity compared with wPV. aPVs are particularly useful for infants and children with tendency to develop seizure with fever. Furthermore, it is the only approved vaccine for vaccination of those >7 years and for the booster dose of adolescents and adults.

Adverse Reactions

All aPV are less reactogenic than wPV. The frequency of systemic as well as local reactions to aPV are approximately one-fifth to one-half that of wPV.

Contraindications and Precautions

Until further data are available, contraindications and precautions for aPV are the same as that for wPV.

Practical Tips

1. Although it is preferred to use same product for all the doses, it is unlikely that changing among or within the wP and aP vaccines will interfere with immunogenicity.
2. If the use of aPV for all the doses of vaccination is not feasible, priority should be for replacement of wPV by aPV for the booster doses.

Pneumococcal Vaccines

There are two types of pneumococcal vaccines available:

1. Pneumococcal polysaccharide vaccine (PPV)
2. Pneumococcal conjugate vaccines (PCV)

Nature and Contents

The polysaccharide vaccine is composed of purified capsular polysaccharides of 23 selected serotypes of *Streptococcus pneumoniae* which account for majority of invasive pneumococcal infections. These serotypes are (1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19F, 19A, 20, 22F, 23F, 33F).

Each 0.5 mL dose contains 25 μg of each polysaccharide with phenol or thimerosal as preservatives.

The currently available conjugate vaccines are composed of purified capsular polysaccharides of 7–13 *S. pneumoniae* serotypes individually conjugated (linked) to a carrier protein.

The carrier proteins currently in use are:

- Nontoxic diphtheria toxin (CRM197)
- Non-typeable *H. influenzae* protein-D (HiD)

This conjugation changes the nature of the immune response to the polysaccharide from the T-cell-independent to T-cell-dependent response, leading to improved immune response even in children below 2 years of age as well as inductions of immunological memory.

Currently available PCV include:

1. PCV-7 is the first licensed PCV. Each 0.5 mL dose contain 2 μg of capsular polysaccharide antigens from pneumococcal serotypes 4,9V,14,18C,19F,23F, and 4 μg of serotype 6 B.
2. PCV-13 is similar to PCV-7 with the addition of 6 serotypes, namely, 1,3,5,6A,7F,19A. In both PCV-7 and PCV-13, CRM 197 is utilized as the conjugate protein and both are adsorbed to aluminum salt as adjuvant.
3. PCV-10 is composed of capsular polysaccharides antigens from 10 pneumococcal serotypes which include the PCV-7 serotypes with the addition of (1,5,7F). The carrier protein used for conjugation is protein D of non-typeable *H. influenzae* for 8 of the 10 antigens. Tetanus toxoid and diphtheria toxoid are used for 18C and 19F antigens, respectively. Aluminum phosphate is used as adjuvant.

Mechanisms of Protection

Protection following successful immunization is due to induction of type-specific opsonic antibodies to the capsular polysaccharide which promote phagocytosis of the homologous pneumococcal organisms.

Furthermore, the PCV reduces nasopharyngeal colonization of vaccine recipients by serotypes in the vaccine which reduce transmission in the community.

Storage and Handling

- Storage and shipment
  - It should be stored at 2–8°C and should NOT be frozen.
- Stability
  - If stored as recommended, the vaccine is stable up to the expiration date.
- Normal appearance
  - Clear, colorless fluid

Efficacy and Immunogenicity

1. PPV

   Like other polysaccharide antigens, the immunogenicity of most pneumococcal serotypes in the current vaccine is poor in infants and children younger than 2 years. However, in healthy young adults and in older children's with increased susceptibility to invasive pneumococcal diseases (IPD), the vaccine has a proven efficacy in preventing pneumonia and reducing the likelihood of bacteremia.
2. PCV

   All PCV's induce protective antibodies against vaccine serotypes in infants and children younger than 2 years. Furthermore, PCV 7 and other PCVs

were demonstrated to be highly effective against IPD and moderately effective in preventing pneumonia caused by vaccine serotypes and some related ones in both developed and developing parts of the world.

In a Cochrane systematic review of five trials of PCV's efficacy conducted in both developed and developing countries, the pooled efficacy estimate of PCVs in children <2 years were found to be 80% for vaccine type IPD, 58% for IPD caused by all serotypes, and 27% for chest X-RAY defined pneumonia.

Recommended Use

- Vaccination with PCVs is recommended by WHO to be part of routine childhood immunization program starting from early infancy.
- The choice of the PCV should be based on assessment of the distribution of serotypes causing invasive pneumococcal disease in any specific population.
- The following groups are considered priority for PCVs:
  - All children <23 months of age
  - Children 24–59 months of age at high risk of IPD, including patients with:
    - Functional or anatomical asplenia, including sickle cell disease
    - HIV infection or other immunodeficiency state
    - Malignancy, immunodeficiency, or long-term immunosuppressive therapy, including steroids
    - Cerebrospinal fluid leaks
    - Chronic cardiovascular, pulmonary, or liver diseases
    - Nephrotic syndrome or chronic renal failure
    - Cochlear implants or scheduled to have it
- At-risk individuals 5 years of age or older should be given PPV.

Dosage and Schedule

- The dose for PPV & PCV is 0.5 mL given intramuscularly. PPV may also be given subcutaneously.
- The primary series for healthy infants is 2–3 doses of PCV staring after the age of 6 weeks and separated by 4–8 weeks. A booster dose is recommended at 12–15 months of age.
- At-risk children should be given a dose of PPV after the age of 2 years at least 8 weeks from the last PCV given.

Adverse Reactions

- Both PCV and PPV are well tolerated. The most commonly reported adverse reactions are pain and erythema at the injection site. However, it is usually mild except in adults after repeat doses.
- Systematic reactions are uncommon.

Contraindications and Precautions

- Confirmed anaphylactic reaction to a previous dose of the vaccine or to one of its component is a contraindication.
- Pregnancy and breast feeding is not a reason to delay pneumococcal vaccines
- As a precaution, patient with moderate to severe acute illness should be vaccinated when their illness subside.

Practical Hints

1. Whenever possible, pneumococcal vaccine should be given 2 weeks or more prior to the planned splenectomy or cancer chemotherapy in order to increase the likelihood of eliciting a protective antibody response.
2. At-risk children older than 2 years who were not previously vaccinated should be given a dose of PCV followed 8 weeks later with PPV.
3. At-risk children who had previously been vaccinated with PPV should be given a dose of PCV.
4. Revaccination with the PPV is recommended for certain high-risk groups, including those with sickle cell disease, asplenia, HIV infection or malignancy, or those who have conditions associated with a rapid decline after initial immunization (e.g., nephrotic syndrome). The interval between first and second dose should be 3–5 years.
5. Pneumococcal vaccine maybe given concurrently with other vaccines as there is no evidence of increases in adverse reactions or reduction in immunogenicity when administered with other vaccines

Oral Polio Vaccine (OPV)

Nature and Contents

The oral polio vaccine (OPV) is a live attenuated vaccine composed of one or more of the three types of polioviruses

(types 1, 2 and 3) propagated in tissue cultures. The vaccine is available mostly as trivalent (TOPV) vaccine. However monovalent (mOPV) and bivalent (Types 1 and 3) formulations are also available. A stabilizer (Magnesium Chloride [$MgCl_2$] or sorbitol) and trace amounts of streptomycin and neomycin are usually present in the mixture.

Mechanism of Protection

Individual Perspective

Live polio vaccine can prevent paralytic poliomyelitis by induction of:

1. Local secretory antibody (IgA) at the primary sites of virus multiplication in the gastrointestinal tract (thereby preventing implantation and multiplication of wild virus).
2. Humoral antibody (IgM and IgG) that prevent wild virus from reaching and invading central nervous system during periods of viremia.

Community Perspective

OPV protect against paralytic poliomyelitis at community level by:

1. Increasing the protected pool beyond those who received the vaccine (as vaccine strains get excreted in stools of vaccine recipients, providing opportunities for immunizing infections of unvaccinated contacts). This is particularly important in developing countries where vaccine coverage may not be optimal.
2. During epidemics, vaccine strains can preempt sites of multiplication within the host population, thus blocking implantation of the wild virus and interrupting its circulation.

Storage and Handling

Requirements for storage and handling of OPV depend on the stabilizer used in the particular product. Check your vaccine, and if it is stabilized with sorbitol, you need to observe the following recommendation:

- Storage and shipment
  - Must be at less than 14°C because of the sorbitol it will remain fluid at temperatures above −14°C).
- After thawing
  - Refrigerate or keep at temperature 4–8°C.
- Stability
  - If frozen, for 1 year from leaving manufacturer's cold stores.
  - After thawing for 30 days if kept refrigerated.
- Normal appearance
  - Clear solution, red or pink (due to phenol red added as a PH indicator).

Vaccines stabilized with $MgCl_2$ are significantly more tolerant of changes in temperatures. It was found that $MgCl_2$-stabilized vaccines retain potency in field and shipping conditions without refrigeration for up to 2 weeks.

Efficacy and Immunogenicity

Following administration of two doses of OPV 6–8 weeks apart, more than 90% of vaccinees will develop adequate protective antibodies to all the three strains of polio viruses. A third dose will ensure a long-lasting immunity to all strains in almost all vaccinees. Clinical efficacy of TOPV has been found to be >90% in some countries but lower than that in others. Immunological responses following mOPV and bOPV are superior to that of tOPV,

Recommended Use of OPV

1. Routine immunization of infants
   (a) The WHO recommends OPV alone for routine infant vaccination in all Polio-endemic countries and in countries at high risk for importation and subsequent spread.
   (b) In tropical countries and where the risk of encounter of wild polio virus at early age exists, it is recommended to start the vaccination at early age and to complete the primary series before the end of the first year of life. Four doses of TOPV are recommended starting at birth, and separated by 4–8 weeks. Although, the serological responses to TOPV in the first week of life is less than that of older infants, majority of neonates benefit by developing local immunity in the alimentary tract. Furthermore, it will make these infants immunologically primed, and they will respond promptly to subsequent doses. Supplementary doses are recommended at 18 months and 4–6 years of age.

2. Outbreak Control

   If a case of paralytic poliomyelitis caused by wild virus appears in a community, OPV should be administered to all individuals in the immediate neighborhood of the case (except those with an absolute contraindication) regardless of a previous history of immunization.

Adverse Reactions

Cases of vaccine-associated paralytic poliomyelitis have been reported in recipients of OPV and their contacts. The estimated risk is extremely small: the overall risk is approximately one case of paralytic poliomyelitis per 2.5 million doses distributed. The risk, however, is 10 times greater after the first dose than after all subsequent doses. Those at higher risk include immunodeficient individuals who get exposed to vaccine virus either from receiving the vaccine or from contact with a vaccine recipient. Unvaccinated healthy adults are at higher risk than children.

Contraindications and Precautions

OPV is contraindicated in:

1. Patients with altered immune status due to:
   (a) Primary immunodeficiency (humoral, cellular, or combined)
   (b) HIV-infection
   (c) Malignancy, e.g., leukemia, lymphoma
   (d) Immunosuppressive therapy, e.g., corticosteroids, cytotoxic agents, or radiation therapy.
2. Household contacts of persons with any of the conditions mentioned in (1).
3. Infants with family history of proven or suspected primary immunodeficiency disorder should NOT be given OPV until their immune status is determined and immunodeficiency is excluded.
4. Patients with history of anaphylactic reactions to neomaycin, streptomycin, or polymyxin B.

The following conditions are NOT contraindication for OPV:

1. Pregnancy

   There is no evidence to suggest that a pregnant women or her fetus is at greater risk from OPV than other persons. Therefore, OPV may be given during epidemic control or when immediate protection against poliomyelitis is needed.
2. Breast feeding

   Breast-feeding mothers can receive OPV without any interruption of feeding schedule.
3. Diarrhea
4. Current antimicrobial therapy

Practical Hints

1. If the infant spit out, regurgitate, or vomit a dose of OPV within 10 min of administration, another dose should be repeated at the same visit. If the second dose is not retained, neither dose should be counted and the vaccine should be readministered at the next visit.
2. Breast feeding does not interfere with successful immunization with OPV, and there is no need to withhold breast feeding before or after vaccination.
3. Due to excretion of polioviruses in the stool of OPV recipients and in order to prevent nosocomial transmission of vaccine viruses in nurseries and pediatric wards, OPV administration to hospitalized infants should be deferred until the day of discharge.
4. Administration of extra dose (or doses) of OPV (e.g., during outbreak control or national immunization campaigns) to a partially or fully vaccinated individual is a safe and acceptable practice when needed.

Inactivated Poliovirus Vaccine (IPV)

Nature and Contents

IPV contains a mixture of all the three types of polioviruses (1, 2, and 3) propagated in monkey kidney cell cultures or in human diploid cells and inactivated (killed) by formaldehyde. Trace amounts of streptomycine, neomycine, and polymyxine B are also included. The vaccine is available either as a standalone product or in combination with diphtheria, tetanus, and pertussis with or without conjugated HIB and HBV.

Mechanism of Protection

Individual Perspective

IPV protect against paralytic poliomyelitis by:

1. Induction of neutralizing antibodies in the serum of vaccinees.
2. Priming the immune system so that a prompt secondary response is elicited upon exposure to wild viruses.

Community Perspective

IPV use in a community induces herd immunity with resultant protection of unvaccinated individuals living in a well-vaccinated community. However, unlike OPV, IPV is not useful for outbreak control.

Efficacy and Immunogenicity

Following two doses of IPV given with interval of 4 weeks or more, almost 100% of individuals develop neutralizing antibodies for all the 3 strains of poliovirus. Furthermore, a long-term immunological memory is induced contributing to protection of vaccinees long after declining of serum antibodies.

Storage and Handling

The following recommendations apply for regular IPV as well as e IPV:

- Storage and shipment
  - Should be at 2–8°C and should not be freezed
- Normal Appearance

IPV is the recommended Polio vaccine for routine infant vaccination in areas with low risk for importation and transmission of wiled polio viruses. This is because it eliminates the risk of vaccine-associated paralytic polio (VAPP).

Clear suspension, red or pink (due to phenol red). Vaccine that contains particulate matter or develop turbidity should *not* be used.

Recommended Use

IPV only is the recommended polio vaccine for routine infant vaccination in areas with low risk for importation and transmission of wild polio virus. This is because it eliminates the risk of vaccine-associated paralytic polio (VAPP).

IPV is particularly recommended in the following situations:

1. Persons with compromised immunity who are unimmunized or partially immunized.
2. Symptomatic and asymptomatic individuals infected with HIV.
3. Household contacts of immunocompromised persons.
4. Unimmunized adults.
5. Persons refusing OPV.
6. Hospitalized infants if protection is needed soon after discharge.

For routine immunization of infants, three primary doses are recommended. The first dose starting at 6–12 weeks of age and subsequent doses given at interval of 4–8 weeks. The third dose may be given 6–12 months after the second. Supplementary doses are given at 1 1/2 and 4–6 years.

Dose and Route

0.5 mL is given by subcutaneous or intramuscular (IM) injection. If the used IPV preparation is combined with DPT, then it must be administered intramuscularly because of the presence of adsorbed tetanus and diptheria toxoids.

Adverse Reactions

Adverse events following IPV vaccination are limited to minor local reactions at injection site.

Contraindications and Precautions

IPV is contraindicated only in patients with history of anaphylactic reactions to neomycine, streptomycine, or polymyxine B.

Practical Hints

1. A combination schedule of IPV-OPV immunization has been adopted by several countries in order to avoid vaccine-associated paralysis while enjoying efficient mucosal immune response elicited by OPV. The regimen involve sequential administration of the first one or two doses as IPV (thereby protecting the vaccinee against the invasion of central nervous system by wild or vaccine virus) followed by OPV doses inducing additional protection at mucosal surfaces.
2. Any combination of IPV and OPV for vaccination is acceptable if the minimum interval between OPV doses is 6 weeks and between IPV doses is 4 weeks.
3. When IPV is given as a combined product with DPT, the schedule used is that for DPT, with 3 primary doses in early infancy. The extra dose of IPV is not strictly necessary, but it does not add to vaccine side-effects.

Rotavirus Vaccine

Nature and Contents

The two licensed rotavirus vaccines are:

1. Pentavalent (RV_5;RotaTeg) rotavirus vaccine.
2. Monovalent (RV_1;Rotarix).

Both are live vaccines administered orally. However, they differ in compositions as follows:

- Pentavalent (RV_5 RotaTeg): contain five live reassortant rotaviruses. The sources of the reassortant viruses are human and bovine strains. Four of the reassortant rotaviruses express the outer capsid proteins (G_1, G_2, G_3, G_4) from human rotavirus parent strain and the attachment protein P7 from the bovine rotavirus. The fifth reassortant rotavirus express the attachment protein P1[8] from the human rotavirus and the outer capsid protein G_6 from bovine.
  - Each 2 mL of vaccine dose contains a minimum level of the five reassortant rotaviruses, ranging from 2.0 to 2.8 $\times$ 10^6 infectious doses depending on the serotype.
  - These are suspended in a buffered stabilizer solution. The vaccine contains no preservative or thiomersal.
- Monovalent (RV1; Rotarix): contain one live attenuated human strain (P_1 A[8]G_1) strain. It is provided as lyophilized powder. Each 1 mL dose of the reconstituted vaccine contains at least 1 $\times$ 10^6 infectious doses.

Mechanism of Protection

The mechanism of protection is not fully clear. However, production of neutralizing antibodies to the vaccine strains and of specific IgA for rotavirus has been demonstrated in vaccine recipients and may play a role in protection.

Storage and Handling

- Storage and shipment: should be at a temperature between 2°C and 8°C and should not be exposed to freezing temperature. Should be protected from light as this may inactivate the vaccine viruses.
- Stability: Rota Teg (RV5) should be administered as soon as possible after removal from refrigeration, but may be used within 4 h if the vaccine has been maintained at temp $\leq$25°C. Rotarix should be administered within 24 h of reconstitution.

Efficacy

- The efficacy of three doses of RV5 (Rota Teg) vaccine against severe rotavirus gastroenteritis caused by G serotypes contained in the vaccine was 98.21, (95% CI 89.6–100%) and against rotavirus gastroenteritis of any severity was 73.8(95% CI 67.2–79.3%). In the large Rotavirus efficacy and safety trial (REST), Rota Teg reduces G_1-G_4 rotavirus-associated hospitalization or emergency visit by 94.5% (95%CI 91.2–92.5%).
- After completion of a two-dose RV1 (Rotarix) regimen, the efficacy against severe rotavirus gastroenteritis was 85% and against any rotavirus gastroenteritis was 87%. Hospitalization for rotavirus gastroenteritis was reduced by 85–100%.
- The duration of immunity from rotavirus vaccines is not known. Efficacy through 2 rotavirus seasons has been demonstrated for both vaccines, although generally the efficacy is lower in the second season than the first.

Recommended Use

1. Routine infant vaccination

   Several countries have adopted universal infant vaccination schedules, and it is recommended for all infants in the first half of the first year of life.
   (a) Rotarix (RV1): Infants should receive two doses of the RV1 (human monovalent rotavirus vaccine) at 2–4 months with the first dose between 6 weeks and <15 weeks of age. The second dose should be given at least 4 weeks from the first dose and not later than the 24 weeks of age.
   (b) Rota Teg (RV5): The vaccination course of RV_5 consists of three doses at approximately 2, 4, and 6 months of age. The first dose should be between 6 weeks and <13th week. The minimum interval between doses should be 4 weeks, and the upper age limit for the third dose should be <33 weeks of age.

2. Preterm infants

   Should be vaccinated at a chronological age of at least 5 weeks if clinically stable. Vaccination should preferably be done at or after the time of discharge from neonatal unit.

Adverse Reactions

- G.I symptoms (e.g., diarrhea or vomiting) occurred at an increasing rate (approximately 3% increase) in the first week following vaccination.
- No serious adverse events were noted particularly no increased risk of intussusceptions was observed.

Contraindications and Precautions

- Anaphylactic reaction to a prior dose of the vaccine or any of its components is a contraindication for its use.

Precautions

- Moderate or severe acute illness, including gastroenteritis.
- Immunodeficiency disorders.
- History of intussusceptions.
- The following are not considered precautions by many authorities:
  - Chronic GI disease.
  - Administration of antibody-containing blood products within the past 42 days. However, the interval between vaccination and the receipt of the blood products should be as long as possible but without delaying administration of vaccine beyond the age limits for dosing.

Practical Hints

1. If the first dose of RV vaccine is inadvertently administered at an age greater than the suggested cut-off, the remaining vaccine doses should be given as per the recommended schedule ensuring observation of the minimum interval between doses and the recommended upper age limit.
2. Since a single virus infection do not provide full immunity, RV vaccine should still be given to infants who develop RV infection before receiving the first dose or before completion of the recommended doses.
3. If the infant spits out, regurgitates, or vomit a vaccine dose, readministration of the dose is not necessary and not recommended.
4. If a recently vaccinated infant is hospitalized for any reason, no precaution other than routine standard precautions needs to be taken even if the vaccine virus is being shed in stool.
5. Following vaccination with RV_5 (Rota Teg), 9% of recipients in one study shed the virus in stool after the first dose but not after subsequent dose. Shedding occurred as early as 1 day and as late as 15 days after the dose.
   (a) Fecal shedding of rotavirus antigen after Rotarix was demonstrated in 50–80% of infants after the first dose at day 7 and in up to 24% at day 30. Following the second dose, fecal shedding was 4–18% at day 7 and 1–2% at day 30. No data are available on potential for transmission.
6. There is no reason to avoid exposure of pregnant women to vaccinated infants. Most pregnant women will have pre-existing immunity to rotavirus. Furthermore, vaccination of infant's contacts will reduce the chances of exposure of adults, including pregnant women, to wiled virus.
7. Due to lack of data on interchangeability of rotavirus vaccines, it is recommended to use the same vaccine for the whole schedule. However, if the same vaccine used in previous dose is not available or not known, completion of the dose with either vaccine is acceptable provided the upper age limit is observed.
8. Breast feeding does not diminish the efficacy of the vaccine, and hence, there is no need to withhold breast feeding in relation to vaccination.
9. Rota vaccines may be administered with all other infant vaccines. However, administration with oral polio vaccine should be avoided because no data is available on concomitant use of the two vaccines.

Rubella Vaccine

Nature and Contents

Rubella vaccine is a live attenuated virus prepared in human diploid cell culture from the strain RA 27/3 in most parts of the world. The unit dose usually contains

1,000 plaque-forming units (PFU). The vaccine is available in a monovalent formulation, a bivalent mumps-rubella and measles-rubella combinations and in a triple formulation measles-mumps-rubella (MMR) vaccine with or without Varicella vaccine (MMRV). The vaccines contain trace amount of antibiotic (e.g., neomycine) and sucrose or sorbitol.

Mechanisms of Protection

Following successful vaccination with rubella vaccine, the following responses are observed:

1. Induction of neutralizing antibodies in serum
2. Production of IgA antibodies in nasopharynx
3. Stimulation of cell-mediated immune response

Storage and Handling

- Storage and shipment
  - Unreconstituted vaccine may be stored at 2–8°C and may be frozen.
  - Reconstituted vaccine should be stored at 2–8°C
  - Both forms should be protected from light which may inactivate the virus.
- Stability
  - Unreconstituted form is highly stable in the frozen state. At 4°C, the potency is maintained for up to 5 years. Potency is markedly reduced after 3 months in room temperature and after 3 weeks at 37°C.
  - Reconstituted vaccine is very labile and should be used within 8 h.
- Normal appearance
  - Clear, yellow solution. If reconstituted vaccine is cloudy, it should *not* be used.

Efficacy and Immunogenicity

Rubella vaccine induces immune response similar qualitatively to that noted after natural infection. The magnitudes of the response are lower after the vaccine, however. Seroconversion and clinical protection occurs in >97% of vaccinees. The duration of protection persist for >20 years following vaccination and may be lifelong. There is no difference between the response to monovalent or to combination vaccines.

Recommended Use

1. Routine rubella immunization
   (a) Rubella vaccine should be given routinely to male and female children along with measles and mumps vaccines (MMR). The timing will be determined by the measles vaccination schedule.
2. Adolescents and adults

   Adolescents and adults who lack evidence of immunity to rubella (i.e., detectable antibody or documented vaccination) should be vaccinated against rubella especially if they belong to one of the following groups:
   - Postpubertal females
   - Postpartum women
   - Child-care personnel
   - College students
   - Health-care workers
   - Military personnel

Adverse Reactions

- Rash, lymphadenopathy, and fever simulating mild clinical rubella occurs in 5–10% of immunized children and may be higher in adults.
- Transient arthritis and arthralgia occurs in 10–15% of vaccinated adolescents and adults approximately 3 weeks post vaccination. Any joint may be involved but small joints of the hands and the knees are most affected. There are rare reports of recurrent or chronic arthritis after vaccination.
- Transient peripheral neuritis and parasthesias in the arms and legs have been reported rarely.
- Mild thrombocytopenia has been observed in some vaccinee rarely.

Contraindications and Precautions

Rubella and rubella-containing vaccines (MMR) are contraindicated in:

1. Individuals with altered immune status due to:
   (a) Primary immune deficiency
   (b) Malignancy, e.g., leukemia, lymphoma
   (c) Immunosuppressive therapy, e.g., corticosteroids, cytotoxic agents, etc.
2. Pregnancy – although there has been no reported fetal effects of mothers who were inadvertently immunized

while pregnant, it is prudent to avoid rubella vaccination during pregnancy because of the theoretical risk on the developing fetus. Vaccinated female should be advised not be pregnant for 1 month following immunization. However, should a mother discover that she was pregnant at the time of vaccination or she get pregnant within 1 month of immunization, she should be counseled on the theoretical risks to the fetus and be reassured of the very low risk. Such instances are not considered a reason to terminate pregnancy.

3. Anaphylactic reactions to vaccine components including the antibiotic used (e.g., neomycine).
4. Administration of immunoglobulins or other blood products 2 weeks before or within 3 months after rubella vaccination may interfere with successful immunization. However, the vaccine may be given to postpartum women at the same time as anti-Rho (O) IG or after blood products are given. In this situation, these women should be tested $\geq$8 weeks later to assure that seroconversion has occurred.

The following are *not* contraindications:

1. Mild febrile or nonfebrile illness such as upper respiratory tract infections.
2. Presence of immunocompromized patients or susceptible pregnant females in the household.
3. Non-anaphylactic allergic reactions to neomycin.
4. Breast feeding
5. Penicillin allergy

Practical Hints

1. The infection induced by rubella vaccine is not communicable even in vaccines that develop rash or other manifestations.
2. There are no known adverse effects to the administration of rubella vaccine to immune individuals or those incubating rubella infection, therefore, routine serological testing is not indicated prior to vaccination.
3. Unlike measles vaccine, the age of first vaccination does not seem to be as critical for development of immune responses to rubella vaccine. Successful vaccination is likely from 10 months of age.
4. Use of MMR instead of monovalent vaccines whenever an indication to either rubella or measles vaccination arise is recommended as this will provide an additional protection to the other components with little increase in the cost.
5. Rubella vaccination after exposure to the disease is not usually useful for prevention of the illness. However, immunization of exposed nonpregnant individuals is not harmful and will protect the individual in future if the current exposure does not result in infection.

Tetanus Toxoid

Nature and Contents

Tetanus toxoid is prepared by formaldehyde detoxification of tetanus toxin. The toxoid is available in monovalent preparation and in various combinations with some or all of diphtheria toxoid (DT or Td), pertussis vaccines (DTP and DTaP) with or without inactivated polio (IPv), conjugated HIB, and HBV vaccines. The toxoid is available in adsorbed formulation with Aluminum salt and in a plain form. The amount of toxoid in all the preparations is comparable and is usually 4–5 flocculation units (Lf).

Mechanisms of Protection

Immunization with tetanus toxoid induces production of neutralizing antibodies (antitoxin) which protect against the effects of the toxin. A level of 0.01 IU/mL of antitoxin is considered protective.

Storage and Handling

- Storage and shipment
  - All forms of adsorbed preparations should be stored and shipped at 2–8°C. No freezing is allowed.
- Stability
  - Exposure to a higher ambient temperature for short period of time (<7 days) do not reduce the potency.
- Normal appearance
  - Turbid and whitish suspension. Vaccines that contain clumps of material that cannot be suspended with vigorous shaking should *not* be used.

Efficacy and Immunogenicity

- Productions of protective concentrations of antitoxin are achieved in most vaccine recipient after two doses. Following a third dose, almost 100% become protected.

- Clinical efficacy has ranged from 80% to 100%. Infants born to mothers who received two or three doses of the vaccine were highly protected against neonatal tetanus.

Recommended Use

1. Universal immunization

   The primary immunization series consist of three doses of adsorbed tetanus toxoid separated by 4–8 weeks intervals. A fourth dose is given to children under the age of 6 years with a booster dose at 4–6 years of age unless the fourth dose was given after the age of 4 years. Subsequently, a booster dose is needed every 10 years.
2. Wound management
   (a) If the patient has received less than three doses of tetanus toxoid or if his immunization status is unknown, a dose of the toxoid should be given. Tetanus immunoglobulin (TIG) should also be administered unless the wound is clean and minor.
   (b) If the patient has received greater than three doses of the toxoid, no further doses are needed unless 10 years have lapsed since the last dose in cases of clean and minor wounds; or 5 years in other types of wound. TIG in these cases is not needed.
3. Prevention of neonatal tetanus

   This can be accomplished by (a) immunization of unvaccinated adolescent girls and women of child bearing age; (b) prenatal immunization of unimmunized pregnant mothers by administering two doses of the toxoid 4 weeks apart at least 2 weeks before delivery.
4. After recovery from tetanus

   Patient convalescing from tetanus should be immunized with tetanus toxoid as they are unlikely to acquire immunity from the disease.

Dose and Route

- The dose is usually 0.5 mL of a preparation containing tetanus toxoid as determined by age and special contraindication.
- The adsorbed forms should be given intramuscularly. Fluid preparation can be given subcutaneously.

Adverse Reactions

- Local reaction including pain, redness, and swelling at injection site are the commonest observed reactions. The frequency and severity of such reactions increase with successive doses of the toxoid and particularly in presence of high levels of circulating antitoxins resulting from too frequent immunization.
- Systemic reactions to the tetanus toxoid are rare but have included anaphylaxis reactions and peripheral neuropathy.

Contraindications and Precautions

Severe systemic reactions to a previous dose are a contraindication to further doses.

Patients who develop major local reactions or fever after a dose of toxoid should not be given another dose for at least 10 years.

Contraindications and precautions to other components of preparations containing tetanus toxoid should be observed.

Practical Hints

1. Administration of immunoglobulin does not interfere with the immune response to tetanus toxoid. However, when it is indicated, it should be administered by a different syringe at a different site than the toxoid.
2. Whenever immunization against tetanus is indicated, an appropriate combination is preferred to the single agent as this will also provide a chance to give booster of diphtheria and/or other agents.

Varicella Vaccines

Nature and Contents

The currently licensed varicella vaccine is a live-attenuated varicella-zoster virus (VZV) obtained after serial passages of the wild Oka virus strain in tissue cultures. Each dose contain $\geq$1,350 plaque-forming units of VZV. Some product may contain trace amounts of neomycin and gelatin. The vaccine is available as a monovalent vaccine or in combination with antigens of MMR vaccine.

Storage and Handling

- Unreconstituted vaccine and the diluent should be stored at +2°C to +8°C and should not be frozen.

- Reconstituted vaccine should be used within 30 min after reconstitution and, if necessary, it may be kept in 2–8°C for a maximum of 8 h but should not be frozen.
- The vaccine should be protected from light

Efficacy and Immunogenicity

In healthy children, 1–12 years of age, a single dose of Varicella vaccine results in a seroconversion rate of 97% or more. The clinical efficacy of a single dose exceeds 95% for severe disease and approximately 70% for any disease, over a 10-year period of follow-up. In persons 13 years of age and older, seroconversion rate are approximately 80% after a single dose and 99% after two doses. The magnitude of the antibody response after vaccination is lower than that after natural disease. However, the antibodies may persist for as long as 20 years following immunization.

Recommended Use

1. Healthy children, adolescents, and adults
   (a) In some countries, universal use of varicella vaccine in all healthy children between 1 and 12 years of age is currently recommended.
   (b) Susceptible adolescent and adults are encouraged to take the vaccine.
   (c) The vaccine is particularly indicated for any susceptible individual who belong to one of the following groups:
      (i) Health-care personnel
      (ii) Household contacts of immunosuppressed individuals
      (iii) Those at high risk of exposure such as teachers and college students
      (iv) Nonpregnant women at child-bearing age
      (v) Children and adolescent undergoing chronic salicylic acid therapy.
2. Individuals with isolated immunodeficiency diseases and know intact T-cell system are candidate for vaccination and include patients with:
   (a) Isolated immunoglobulin deficiency diseases
   (b) Neutrophil deficiency disorders
   (c) Complement deficiency diseases
   (d) Asplenia or splenic dysfunction
3. Individuals who could be vaccinated with fulfillment of pre-request:
   (a) Individuals with acute lymphocytic leukemia (ALL) may be vaccinated if the following prerequisites are fulfilled:
      (i) In remission for $\geq$1 year.
      (ii) Lymphocyte count of $\geq$1,200.
      (iii) Not receiving radiation.
   (b) HIV-infected children $\geq$1 year of age if asymptomatic or mildly symptomatic with age-specific CD4 count $\geq$25%.
   (c) Recipient of long-term immusuppresive therapy whose therapy has been discontinued for at least 6–12 weeks.
   (d) Patient who underwent solid organ or bone narrow or stem cell transplantation may be vaccinated 2 years after transplantation, provided they are on minimal immunosuppresion and not suffering from a major complication.
4. Post-exposure
   (a) Susceptible healthy individuals are candidate for vaccination after exposure if it can be given within 5 days of exposure. The effectiveness is high for prevention or reducing severity.

Dose and Schedule

The recommended dose of the vaccine is 0.5 mL given by subcutaneous injection. Children between 12 months and 12 years require at least one dose administered between 12 and 15 months. For optimal protection, however, a second dose should be given after an interval of 3 months. The decision to adopt two doses versus single dose schedule should be based on assessment of the cost-effectiveness in the particular setting. Individuals older than 12 years should be given two doses separated by 4–8 weeks.

Adverse Reactions

Adverse reactions following vaccination are generally minimal and include:

- A mild vaccine-associated maculopapular or varicelliform rash develops in approximately 7% of vaccinee with a median of two to five lesions.
- Injection site complaints such as transient pain, tenderness, or redness occurs in 20–30% of vaccinees.
- Systematic adverse reactions include fever (10–15%) and increase risk of febril seizure following vaccination with some products of MMRV.

- A mild zoster-like illness has been reported rarely after varicella vaccination. The frequency as well as the severity are much less following vaccination than after natural disease.

Contraindications and Precautions

Varicella vaccine is contraindicated in:

1. Individuals with altered immune status due to:
   (a) Primary immune deficiency involving T-cell system
   (b) Malignancy such as lymphoma and acute myelogenous leukemia
   (c) HIV infection
   (d) Immunosuppressive therapy including cytotoxic agents and high-dose corticosteroid therapy ($\geq$2 mg/kg of prednisone/day)
2. Individuals with anaphylactic reactions to any vaccine component
3. Pregnant Women
4. Individuals who have recently received immunoglobulins or other blood products may not respond to the vaccine for several months due to passively acquired antibodies. Therefore, the vaccine should not be given for at least 5 months after administration of immunoglobulins, VZIG, or plasma transfusion.

The following are *not* contraindications:

1. Mild febrile or nonfebrile illness
2. Presence of immunocompromised individuals including HIV-infected individuals in the household
3. Pregnancy of the mother
4. Lactation
5. Use of inhaled or topical corticosteroids

Practical Hints

1. Although the vaccine-virus has been recovered from vaccine recipients with skin lesions, the spread of the vaccine-virus from healthy vaccinees to others is very rare (<1%). The risk of transmission of the vaccine-virus is higher from vaccinated leukemic children with a skin rash.
2. Immunization of persons with prior immunity to varicella is not associated with an increase in adverse events, and therefore, serological proof of susceptibility to varicella is not a prerequisite in those uncertain of their susceptibility status.
3. In a child with history of congenital immunodeficiency in a sibling, varicella vaccine should not be given until immunodeficiency is excluded.
4. Varicella vaccine should not generally be given for at least 3 months following cessation of immunosuppressive therapy. However, except in children receiving high-dose corticosteroids, the vaccine maybe given 1 month after discontinuation.
5. Susceptible pregnant women and immodeficient patients who are not candidate for varicella vaccination should be given VZ immoglobuline within 96 h from exposure to a patient during infectivity period of varicella.

77 Brucellosis

Youssef A. Al-Eissa

Brucellosis constitutes a major health and economic problem in many parts of the world, including the countries of the Mediterranean basin and the Middle East. The disease is primarily a contagious infection of animals, but it may be transmitted to humans through direct contact with infected animals, products of conception, or animal discharges, and through consumption of infected milk, dairy products, or meat. Although sporadic human cases of brucellosis were reported during the previous three decades in the Middle East, it was not until the early 1980s when the disease was first recognized as a major problem. Epidemiologic studies have shown that the disease is common and widespread, and it remains hyperendemic in certain rural areas of the Arab countries. This recent surge in the incidence of brucellosis in humans and animals has been linked to the uncontrolled importation of potentially infected animals, widespread animal husbandry, and the prevailing habit of ingesting raw milk or its products among the population of nomadic background.

Etiology

The disease is caused by small, fastidious, nonmotile, nonspore-forming, capnophilic, gram-negative coccobacilli of the genus *Brucella*. There are four important species pathogenic to humans: *Brucella melitensis* found primarily in goats, sheep, and camels; *Brucella abortus* found in cattle; *Brucella suis* found in swine; and *Brucella canis* found in dogs. The natural reservoir of brucellosis is domestic animals, and animal-to-animal transmission is usually venereal or by ingestion of infected tissue or milk. The *Brucella* species differ in degree of virulence and invasiveness. *B. melitensis* is the most invasive and produces the most severe disease. *B. abortus* is the least invasive and causes the mildest illness. *B. suis* is very invasive and often causes suppurative disease. In the Middle East, human infection with *B. melitensis* is commonly encountered and infection with *B. abortus* is less frequent, but infection with other species is rarely reported. Transplacental transmission of *B. melitensis* resulting in neonatal infection has been recently described. Although *Brucella* organisms have been isolated from human milk, no infection traced to this route has been documented.

Pathogenesis

Brucellae invade through the nasopharynx, gastrointestinal tract, conjunctiva, genital tract, abraded skin, or respiratory tract. Once the organisms have transgressed the mucous membrane or skin, they reach the regional lymph nodes by lymphatic spread. In the lymphatic tissues, brucellae multiply and invade the bloodstream, causing bacteremia. They are phagocytosed by polymorphonuclear leukocytes and monocytes and transported to various organs and tissues, particularly to those with abundant reticuloendothelial cells, including the spleen, liver, bone marrow, and lymph nodes. Brucellae are facultative intracellular pathogens with the ability to escape intracellular killing and even multiply within phagocytic cells of the host. Both host and pathogen factors are important to determine the clinical presentation and outcome of the *Brucella* infection.

The characteristic, but not specific, reaction of tissue to *Brucella* is the appearance of granulomas consisting of epithelioid histiocytes, lymphocytes, monocytes, plasma cells, and Langerhans and foreign body giant cells. These granulomas may have central hyaline necrosis but no caseaction necrosis. The granulomas are often found in biopsies of the bone marrow, lymph nodes, spleen, and liver.

Clinical Manifestations

Human brucellosis is notoriously a multisystem disease with varied manifestations, and the onset of the illness may be either acute or insidious. The latter mode of presentation has caused more difficulties in diagnosis. The incubation period is difficult to ascertain because of repeated exposures to the source of infection, but it varies from a few days to several months. Morbidity depends largely on the pathogenicity of the infecting *Brucella* species. Children infected with *B. abortus* are likely to have an

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_77,

asymptomatic or a mild illness. In contrast, children infected with *B. melitensis* often develop a severe disease.

Acute Brucellosis

The predominant presenting symptoms are fever, arthralgia, malaise, fatigue, and body aches. The fever may be associated with chills and drenching, malodorous sweats. Over half of patients complain of anorexia and experience a significant weight loss. In addition, patients may have abdominal pain, nausea, and vomiting. The most common signs of brucellosis in addition to fever are arthritis (up to 40%) (*Fig. 77.1*), splenomegaly (up to 35%), hepatomegaly (up to 30%), and lymphadenopathy (up to 20%).

Localized Disease and Complications

Localization of *Brucella* organisms may occur in any organ. Skeletal, gastrointestinal, and hematologic complications are the most common, but involvement of the heart and central nervous system are the most serious, albeit rare.

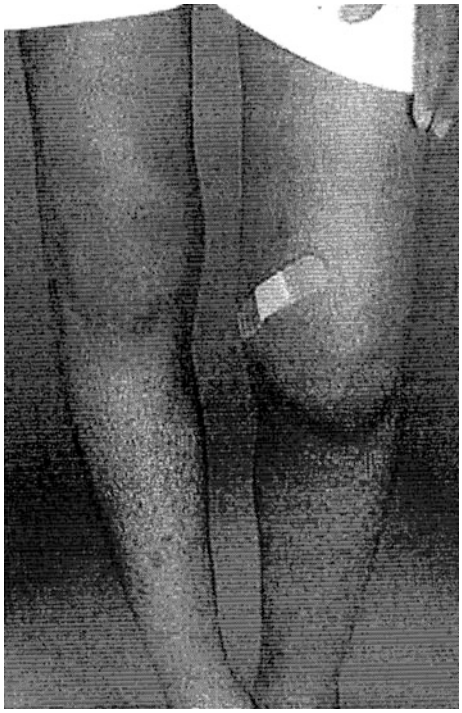

Figure 77.1
A patient with left knee brucella arthritis

Skeletal

Peripheral arthritis is the most common form of osteoarticular involvement in acute brucellosis. Arthritis is manifested by pain, periarticular soft tissue swelling with or without obvious intra-articular effusion, limitation of motion, various degrees of hotness, and, rarely, erythema. Arthritis is monoarticular in 70% of patients and has a predilection for large weight-bearing joints. Most patients with multiple joint involvement tend to have an additive rather than a migratory arthritis. The joints involved in order of frequency are hip, knee, sacroiliac, ankle, wrist, elbow, and shoulder. Small joint and spine involvement (*Fig. 77.2*) is rare in children, in contrast with the findings in adults. It is currently believed that suppurative and reactive arthritides occur in brucellosis, as in other bacterial infections. Osteomyelitis of the long bones, a rare osseous complication of brucellosis, has been reported in children.

Gastrointestinal

Hepatitis probably occurs in most infected patients during the course of their illness, and liver function tests commonly demonstrate hepatic involvement. Liver biopsy specimens have revealed nonspecific histologic abnormalities, including noncaseating granulomas. The spleen is a frequent site of localized brucellosis, and hypersplenism has resulted in abnormal alteration of the peripheral blood elements. Jaundice is very rare, and its appearance may be a manifestation of hepatic failure. Acute cholecystitis and hepatic or subdiaphragmatic abscesses are rare in children. However, acute ileitis and enterocolitis have been recently reported in pediatric patients.

Hematologic

Anemia (up to 50%), leukopenia (up to 35%), thrombocytopenia (up to 5%), and pancytopenia (up to 14%) have been associated with *B. melitensis* infection in children. Leukopenia is mainly accompanied by neutropenia or lymphopenia, but absolute or relative lymphocytosis is less frequently encountered in pediatric patients. Hemolytic anemia and disseminated intravascular coagulation are occasionally seen. Hypersplenism, hemophagocytosis, and granulomatosis lesions of the bone marrow appear to play a fundamental role in producing these abnormalities of the peripheral blood.

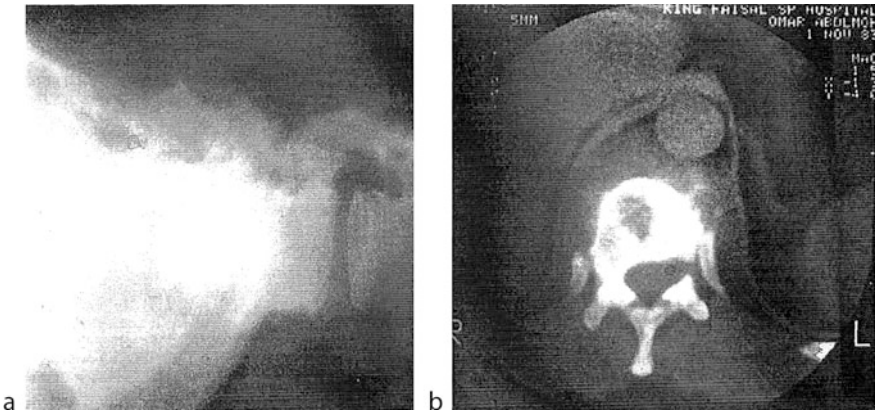

Figure 77.2
Destruction of intervertebral disk and bone, and soft tissue reaction caused by *Brucella* infection is seen in this plain film (a) and computerized tomography scan (b)

Psychiatric

Psychiatric disturbances seem to be frequent, but they are not clinically recognized. Profound depression (may be associated with suicidal thoughts), anxiety state, and hypochondriasis have been described. The severity of these manifestations is related in part to the duration of illness, being more common among patients with chronic brucellosis, but the pathogenesis of these disorders is poorly understood.

Neurologic

Involvement of the nervous system in systemic brucellosis is rare. The presentation of neurobrucellosis is diverse, and both central and peripheral nervous systems can be involved. Meningitis, encephalitis, meningoencephalitis, cerebellar ataxia, subarachnoid hemorrhage, myelitis, peripheral neuritis, radiculitis, Guillain–Barré syndrome, and cranial nerve palsy, particularly the eighth, have occurred in patients with brucellosis. In meningoencephalitis, the cerebrospinal fluid (CSF) shows a mildly elevated protein level, normal or low glucose level, and a lymphocytic cellular reaction. The syndrome of peripheral polyradiculitis with ascending weakness, tendon areflexia, intact sensation, and CSF lymphocytic pleocytosis has been reported. Cerebellar ataxia and profound sensorineural deafness are the presenting features of proximal polyradiculoneuropathy. Myelitis with spastic paraparesis, hyperreflexia, clonus, extensor plantar response, urine retention, and bilateral sensorineural deafness has been described.

Cardiovascular

Infective endocarditis is a potentially fatal complication, but the disease is fortunately rare. The development of endocarditis should be suspected in patients presenting with a heart murmur who have been exposed to a source of *Brucella* infection. It follows an indolent course and is accompanied by a high rate of congestive heart failure and arterial embolization. The aortic valve has been commonly involved, followed by the mitral valve alone or both valves concurrently. Endocarditis is the most common cause of death among patients with brucellosis. Myocarditis and pericarditis have been diagnosed in patients with brucellosis whose clinical presentations mimic findings usually noted in acute rheumatic fever.

Pulmonary

A variety of pulmonary manifestations of brucellosis, such as bronchitis, pneumonia, pleurisy, pleural effusion, empyema, hilar lymphadenopathy, single granulomatous coin lesion or isolated pulmonary nodule, and lung abscesses, have been reported. Brucellae have been occasionally cultured from sputum and pleural fluid. Pulmonary brucellosis can be clinically and radiologically indistinguishable from tuberculosis.

Genitourinary

Epididymo-orchitis, which is usually unilateral, is the most common genitourinary complication; sterility has

not been shown to follow such involvement. Other complications include cystitis, pyelonephritis, and acute glomerulonephritis.

Ocular

Ophthalmic manifestations have been considered to be quite rare. Pure ophthalmopathies have included keratitis, corneal ulcers, uveitis, and retinopathies. Neuro-ophthalmologic abnormalities comprise optic neuritis and atrophy, papillitis, and oculomotor dysfunction.

Dermatologic

Cutaneous manifestations are infrequent, and the reported skin lesions include nonspecific erythematous rash, petechiae and purpura, erythema nodosum, and subcutaneous nodules and abscesses.

Diagnosis

The diagnosis of brucellosis is based on epidemiologic evidence of a possible source of infection, clinical manifestations compatible with the disease, and one or more of three laboratory criteria: Isolation of the brucellae from blood or other body fluids and tissues; a *Brucella* agglutination titer of 1:160 or above; and a fourfold or greater rise in titers following the onset of symptoms. Brucellosis can display a variety of clinical pictures, and the diagnosis may be easily missed, particularly if there is no clear history of exposure to infected animals or their products. The clinical and routine laboratory findings of brucellosis are nonspecific, and the diagnosis is frequently overlooked or delayed until the more common childhood infections or diseases are excluded. Hence, the diagnosis of brucellosis should be entertained in every case of undefined fever or illness in a highly endemic area of animal brucellosis.

The definitive evidence of *Brucella* infection is by isolating the organisms from the patient. However, laboratory cultures of *Brucella* are often unsuccessful due to the slow-growing nature of these organisms, which may require up to 8 weeks to grow, and the requirement for special media and 5–10% CO_2. A variety of media have been found to produce satisfactory growth, such as tryptic soy broth or Albimi, and there is no convincing evidence that the use of Castaneda medium is superior. Approximately 50–85% of the patients whose blood is submitted for culture early in the course of infection, and who have not received antibiotics, will yield *Brucella* organisms from their blood when one or two samples are cultured. The isolation rate decreases with increasing duration of illness. Later in the course of the illness, organisms are more likely to be isolated from granulomas involving bone marrow or lymph nodes. *B. melitensis* is more successfully isolated from blood than *B. abortus*, but culture of the aspirated bone marrow is more likely to be successful for all species. All culture specimens from cases with a clinical suspicion of brucellosis should be clearly marked "possible brucellosis" for proper bacteriologic processing and because culturing brucellae may be dangerous to laboratory personnel. Blood culture sensitivity has improved significantly with the use of BACTEC system, which detects the majority of *B. melitensis* isolates within the routine 1-week blood culture schedule.

Brucella serologic tests have proved to be very valuable in screening for the disease. The most reliable test is the standard tube agglutination test using a serial tube-dilution technique of the patient's serum and a standardized suspension of *B. abortus* antigen that measures the total quantity of agglutinating immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies. This test will equally detect antibodies to the three major species (*B. abortus*, *B. melitensis*, and *B. suis*) due to cross-reactivity, but it will not detect *B. canis*. For the diagnosis of *B. canis* infection, antigen prepared from *B. canis* or *B. ovis* should be utilized. Most patients with acute brucellosis develop significant agglutination titers within 1–3 weeks of illness. In a typical acute infection, the agglutinating antibody level of the IgM class rises in the first week and peaks at approximately 3 months; low IgM levels may persist for several months or years, even after presumed complete cure of infection. Two to three weeks after the onset of acute infection, IgG antibodies rise to a high level over the course of 6–8 weeks, but these antibodies eventually disappear after recovery. Hence, with early diagnosis and prompt treatment of sufficient duration, IgG antibody titer rapidly declines and serves as an indicator of successful therapy. Antibodies of the immunoglobulin A (IgA) class rise soon after IgG antibodies and parallel the sequence of IgG. The IgG antibodies can be identified by the 2-mercaptoethanol (2-ME) agglutination test, as 2-ME destroys IgM antibody. The persistence of high serum IgG antibody titers in patients treated with antibrucella drugs could be due to a relapse because of inappropriate antibiotic therapy or poor compliance, a reinfection because of reexposure to a source of infection, the presence of focal disease, or high initial titers before initiating antimicrobial therapy. However, it is unusual to encounter a child with an agglutination titer of 1:160 or above without symptoms.

Only on rare instances has *Brucella* been recovered from the blood culture when the initial *Brucella* titers are negative. Serologic tests may remain negative in newborns with bacteriologically confirmed *Brucella* infection: Furthermore, patients may fail to mount a significant serologic response during the early stage of illness. Therefore, a negative serology should not preclude the diagnosis of brucellosis. Another cause of false-negative agglutination tests is the prozone phenomenon, due to blocking antibodies of the IgG and IgA classes appearing late in the course of the illness, which can be eliminated if dilutions are carried out to at least 1:1,280. Cholera vaccination, or infection with *Vibrio cholera*, *Francisella tularensis*, *Yersinia enterocolitica*, or *Salmonella* serogroups may, however, cause a false-positive *Brucella* agglutination test due to immunologic cross-reactivity.

A complement fixation test and antihuman globulin test (Coombs) have been used to detect mainly *Brucella* IgG antibody and have no associated prozone effect. Recently, the techniques of radioimmunoassay and enzyme-linked immunosorbent assay have been developed to measure all individual immunoglobulins. These tests have sensitivity and specificity that are similar to the standard tube agglutination test. However, their use may be limited only to cases where a relapse or failed therapy is suspected. Polymerase chain reaction test is available, but not widely used.

Routine laboratory tests are not helpful in making the diagnosis. Anemia has been found more often with *B. melitensis* infection than with other *Brucella* species and is noted in more than one third of the pediatric patients. Most patients have either a normal white blood cell count or leukopenia with lymphocytopenia or neutropenia. The erythrocyte sedimentation rate and C-reactive protein level may or may not be raised and are only of prognostic significance if they were previously raised. The liver enzymes are elevated in about two thirds of patients, and such abnormalities may reflect the severity of hepatic involvement.

Treatment

The efficacy of antimicrobial therapy for any infection is largely judged by the rate of cure and the incidence of sequelae. The purpose of chemotherapy for brucellosis in humans is to control the illness promptly and to prevent complications and relapses. Human brucellosis continues to pose a therapeutic problem, despite the susceptibility of the organisms to several antibiotics. This has been attributed to the intracellular localization of the brucellae within the reticuloendothelial cells of the host, a site that is relatively inaccessible to antibiotics. The unpredictable relapses after treatment are almost invariably associated with inappropriate choice, dosage, and length of antimicrobial therapy, or failure of patients to take prescribed drugs. Antibiotic-resistant *Brucella* strains are rarely a cause of therapy failure. Hence, the institution of the proper combination of antibiotics for a longer duration seems warranted to improve outcome and prevent relapses.

The standard therapy for acute brucellosis has been a combination of orally administered tetracycline (40 mg/kg/day, maximum 2 g daily, in four divided doses for 6 weeks) plus streptomycin (20 mg/kg/day, maximum 1 g daily, in one dose intramuscularly for the first 2–3 weeks); treatment with orally administered rifampin (20 mg/kg/day, maximum 600 mg daily, in one or two divided doses) together with tetracycline or doxycycline for at least 6 weeks is an effective alternative regimen. Tetracycline therapy is contraindicated in children 8 years of age and younger because of the risk of permanent teeth staining. Treatment with cotrimoxazole (trimethoprim 10 mg/kg/day and sulfamethoxazole 50 mg/kg/day, maximum 480 mg of trimethoprim and 2,400 mg sulfamethoxazole daily, in one or two divided doses) is an acceptable alternative to tetracycline/doxycycline for use in children less than 9 years of age. Relapses occur in less than 10% of cases when the patient receives proper therapy early in the course of illness, and they rapidly respond to a repeat course of antimicrobial therapy.

Although the antimicrobial therapy of systemic brucellosis is well established, the best regimen for the treatment of localized lesions or complications has not been clearly determined. Certain localized lesions require surgical intervention (e.g., drainage of an abscess or excision of infected tissue) in addition to prolonged combined chemotherapy. Bone infections can be effectively treated with 6- to 12-week courses of oral rifampin and doxycycline or cotrimoxazole combined for 2–3 weeks with intramuscular streptomycin. Successful treatment of neurobrucellosis with a combination of oral rifampin and cotrimoxazole for a 3-month course has been reported in isolated cases and in small series; the administration of streptomycin for 2–3 weeks has been recommended to ensure that at least two antituberculous drugs are given until results of acid-fast bacilli cultures become available. A brief course of corticosteroids for meningoencephalitis has been advocated. *Brucella* infective endocarditis is one of the most difficult forms of localized brucellosis to manage; treatment consists of early surgical removal of the infected valve and replacement with a mechanical or bioprosthetic valve, together

with early aggressive chemotherapy with a combination of intramuscular streptomycin or intravenous gentamicin for 1 month and oral cotrimoxazole, rifampin, and doxycycline for 3 months.

In pregnant women, recognition of brucellosis and effective antimicrobial chemotherapy can prevent infection of the fetus and abortion. The most effective, least toxic antibiotics for brucellosis in pregnancy remain to be fully established. Doxycycline has been given alone to pregnant women with favorable response, and the risk of tooth staining in the fetus is considered low in comparison with tetracycline. The administration of aminoglycosides, streptomycin, or gentamicin during pregnancy may subject the fetus to the risk of ototoxicity or nephrotoxicity. Both cotrimoxazole and rifampin have been advocated, but their use is also not without risks. Rifampin and trimethoprim are potential causes of fetal malformation, and in the last week of pregnancy sulfamethoxazole may cause kernicterus in the newborn. Based on the information available to date, oral doxycycline for 6 weeks is given if *Brucella* infection occurs during the first half of pregnancy, and oral cotrimoxazole and rifampin for 6 weeks plus supplemental folic acid is given for women infected with *Brucella* during the latter half of pregnancy.

In chronic brucellosis, several courses of antimicrobial therapy may be needed before cure is achieved. When the response even to prolonged treatment is poor, a chronic focus of infection must be sought, particularly with *B. melitensis* and *B. suis* infection.

78 Chlamydial Infections

Margaret R. Hammerschlag

Definition/Classification

Chlamydiae are obligate intracellular bacteria that have established a unique niche within the host cell. They cause a variety of diseases in animal species at virtually all phylogenic levels. The genus has been reorganized with nine species: *Chlamydia trachomatis* and *C. pneumoniae*, which primarily cause disease in humans, and several species that have been split off from *C. psittaci* (Table 78.1). *C. psittaci* is primarily an avian pathogen, and is an important zoonosis in human. The new species include *C. pecorum*, which primarily infects cattle and other ruminants – there is no description of disease in humans; *C. muridarum* (formerly the agent of mouse pneumonitis – MoPn); *C. suis* (an important pathogen of swine); *C. abortus* (causes abortion in cattle and sheep, rarely has caused abortion in humans); *C. caviae* (formerly *C. psittaci* Guinea pig conjunctivitis strain); and *C. felis* (causes epidemic keratoconjunctivitis in cats).

All chlamydia species are characterized by a unique developmental cycle with morphologically distinct infectious and reproductive forms: the elementary body (EB) and reticulate body (RB). They have a gram-negative envelope without detectable peptidoglycan, although recent genomic analysis has revealed that both *C. trachomatis* and *C. pneumoniae* encode for proteins forming a nearly complete pathway for the synthesis of peptidoglycan, including penicillin-binding proteins. Chlamydiae also share a group-specific lipopolysaccharide (LPS) antigen and utilize host adenosine triphosphate (ATP) for the synthesis of chlamydial protein.

After infection, the infectious EBs, which are 200–400 μm in diameter, attach to the host cell by a process of electrostatic binding and are taken into the cell by endocytosis that does not depend on the microtubule system. Within the host cell, the EB remains within a membrane-lined phagosome. The phagosome does not fuse with the host cell lysosome. The inclusion membrane is devoid of host cell markers, but lipid markers traffic to the inclusion, which suggests functional interaction with the Golgi apparatus. The EBs then differentiate into RBs, which undergo binary fission. After approximately 36 h, RBs differentiate into EBs. At about 48–72 h, release may occur by cytolysis or by a process of exocytosis or extrusion of the whole inclusion, with the host cell left intact. Chlamydiae also may enter a persistent state after treatment with certain cytokines such as interferon gamma, treatment with antibiotics, or restriction of certain nutrients. While in the persistent state, metabolic activity is reduced. The ability to cause prolonged, often subclinical infection is one of the major characteristics of chlamydiae.

This chapter will cover infections in humans caused by *C. trachomatis*, *C. pneumoniae*, and *C. psittaci*.

Infections due to *Chlamydia trachomatis*

Etiology

C. trachomatis is an important cause of oculogenital infections in humans worldwide. There are 15 known serotypes that vary in tissue tropism and disease presentations.

Trachoma

Epidemiology

Trachoma is the most important preventable cause of blindness in the world. It is caused primarily by the A, B, Ba, and C serotypes of *C. trachomatis*. Blinding trachoma is believed to be endemic in 56 countries, mainly in sub-Saharan Africa, some areas of the Middle East, South and Southeast Asia, and in Aboriginal population in Australia. The disease is spread from eye to eye. Flies are a frequent vector. Poverty and lack of sanitation are important factors in the spread of trachoma. As socioeconomic conditions improve, the incidence of the disease decreases substantially.

Clinical Presentation/Pathology

Trachoma begins as a follicular conjunctivitis, usually in early childhood, often with copious purulent discharge. Active trachoma is seen predominantly in young children, becoming less frequent and shorter in duration with increasing age. Conjunctival scarring increases with age,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_78,

Table 78.1
Classification of the genus *Chlamydia*

Species	Host(s)	Major diseases
Chlamydia trachomatis	Humans	Trachoma, urethritis, pelvic inflammatory disease, neonatal conjunctivitis and pneumonia, lymphogranuloma venereum
C. suis	Pigs	Gastrointestinal disease
C. muridarum	Mice	Pneumonia
C. pneumoniae	Humans	Pneumonia, bronchitis, exacerbations of asthma, asymptomatic infection
	Horse	
	Koalas	
	Bandicoots	
	Amphibians	
	Reptiles	
C. psittaci	Birds	Gastrointestinal disease
	Humans	Pneumonia (zoonosis)
C. abortus	Cattle	Abortion
	Sheep	
	Humans	Abortion (rare zoonosis)
C. pecorum	Cattle	Pneumonia, gastrointestinal disease, genital infections, conjunctivitis
	Sheep	
	Koalas	
C. felis	Cats	Keratoconjunctivitis
C. caviae	Guinea pigs	Conjunctivitis, genital Infections

not becoming evident until the second or third decade of life. Conjunctival scarring results in entropion, with the eyelid turning inward so that the lashes abrade the cornea, leading to corneal ulceration secondary to the constant trauma, eventually resulting in blindness. Bacterial superinfection may also contribute to scarring. The World Health Organization (WHO) suggests that at least two of the following four criteria must be present for a diagnosis of trachoma: (1) lymphoid follicles on the upper tarsal conjunctivae, (2) typical conjunctival scarring, (3) vascular pannus, and (4) limbal follicles.

Diagnosis

The diagnosis of trachoma is primarily clinical and can be confirmed by culture or NAATs for *C. trachomatis* performed during the active stage of disease. Serologic tests are not helpful clinically because of the long duration of the disease and the high seroprevalence in endemic populations.

Treatment/Prevention

The WHO currently recommends single-dose azithromycin (20 mg/kg, maximum 1 g) for the treatment of trachoma in children. Oral azithromycin is superior to treatment with topical antibiotics which require multiple dosing. Several studies conducted in trachoma endemic areas in several African countries have demonstrated that mass treatment with a single dose of azithromycin to all the residents of a village dramatically reduced the prevalence and intensity of infection. This effect continued for 2 years after treatment, probably by interrupting the transmission of ocular *C. trachomatis* infection.

Genital *Chlamydia trachomatis* Infections

Epidemiology

Genital chlamydial infections are caused by *C. trachomatis* serotypes D, E, F, G, H, I, J, and K. There are an estimated three million new cases of chlamydial sexually transmitted infections each year in the USA. In 2007, the overall rate of chlamydial infections in the USA among women (544.8 cases per 100,000) was almost three times the rate among men (190.4 cases per 100,000) (*Fig. 78.1*). Girls 15–19 years of age, had the highest rates of infection (3004.7 per 100,000) which is almost five times higher than in males in the same age group (615.0 per 100,000) (*Fig. 78.1*). This discrepancy is thought to be due in part to more extensive screening of women compared to men. However, with the introduction of noninvasive testing using urine, men are being tested more frequently. From 2003 through 2007, the rate of chlamydial infection in men increased by 43%.

Clinical Manifestations

Up to 75% of women with *C. trachomatis* cervical infection are asymptomatic. *C. trachomatis* can cause urethritis (acute urethral syndrome), epididymitis, cervicitis, salpingitis, proctitis, and pelvic inflammatory disease. The symptoms of chlamydial genital tract infections in men and women are less acute than those of gonorrhea, consisting of a discharge that is usually mucoid rather than purulent.

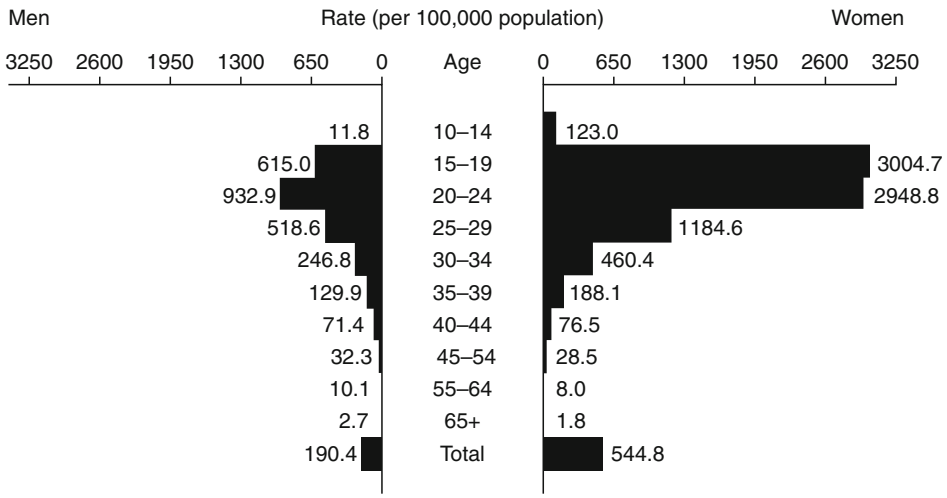

Figure 78.1
***Chlamydia trachomatis* – Age- and sex-specific rates: USA, 2007 (Reproduced from Centers for Disease Control and Prevention (2008) Sexually transmitted disease surveillance, 2007. U.S. Department of Health and Human Services, Atlanta, GA; December 2008) http://www.cdc.gov/std/pubs/**

In men, *C. trachomatis* can cause urethritis, proctitis, and epididymitis. Asymptomatic urethral infection is frequent in sexually active men. Autoinoculation from the genital tract to the eyes can lead to concomitant inclusion conjunctivitis.

Diagnosis

Diagnosis of genital chlamydial infection can be accomplished by isolation of the organism in tissue culture or by detection by a nucleic acid amplification test (NAATs). Care should be taken to obtain epithelial cells, not only discharge. *C. trachomatis* can be cultured in cycloheximide-treated HeLa, McCoy, and HEp-2 cells. Chlamydia culture has been further defined by the Centers for Disease Control and Prevention (CDC) as isolation of the organism in tissue culture and as confirmation of the characteristic intracytoplasmic inclusions by staining with *C. trachomatis* species–specific fluorescein-conjugated monoclonal antibody.

NAATs are now the standard for diagnosis of *C. trachomatis* infections in adults and adolescents. These tests have high sensitivity, 10–20% greater than culture, while retaining high specificity. There are currently three Food and Drug Administration (FDA)-approved, commercially available NAATs for detection of *C. trachomatis*: polymerase chain reaction (PCR; Amplicor Chlamydia test, Roche Molecular Diagnostics, Nutley, NJ), strand displacement amplification (SDA; ProbeTec, BD Diagnostic Systems, Sparks, MD), and transcription-mediated amplification (TMA; Amp CT, Gen-Probe, San Diego, CA). PCR and SDA are DNA amplification tests that use primers that target gene sequences on the cryptogenic *C. trachomatis* plasmid that are present at approximately ten copies in each infected cell. TMA is a ribosomal RNA amplification assay. All three assays are also available as co-amplification tests for simultaneously detecting *C. trachomatis* and *Neisseria gonorrhoeae*. There are several new NAATs that are undergoing clinical trials, all using a real-time PCR platform. The currently available commercial NAATs are FDA approved for cervical swabs from adolescent and adult women, urethral swabs from adolescent and adult men, and urine from adolescent and adult men and women. TMA and SDA have also been approved for use with vaginal swabs in adolescents and adults. The vaginal swab is now the specimen of choice in females, it is better than urine equivalent to endocervical swabs, and can be self-collected. Use of urine and vaginal swabs avoids the necessity for a urethra swab or clinical pelvic examination and may greatly facilitate screening in certain populations, especially adolescents. NAATs are currently not approved for use with extragential specimens. Several recent studies suggest that NAATs are sensitive and specific for detection of *C. trachomatis* from rectal specimens in adults.

Treatment

The first line treatment regimens recommended by the CDC for uncomplicated *C. trachomatis* genital infection in men and nonpregnant women are azithromycin (1 g orally PO as a single dose) or doxycycline (100 mg PO bid for 7 days). Alternative regimens are erythromycin base (500 mg PO qid for 7 days), erythromycin ethylsuccinate (800 mg PO qid for 7 days), ofloxacin (300 mg PO bid for 7 days), and levofloxacin (500 mg PO once daily for 7 days). The high erythromycin dosages may not be well tolerated. Doxycycline and ofloxacin or levofloxacin are contraindicated in pregnant women; quinolones are contraindicated in persons younger than 18 years of age. However, use of ofloxacin and levofloxacin offer no advantages over doxycycline. For pregnant women, the recommended treatment regimen is azithromycin (1 g PO in a single dose) or amoxicillin (500 mg PO tid for 7 days). Alternative regimens are erythromycin base (250 mg PO qid for 14 days), erythromycin ethylsuccinate (800 mg PO qid for 7 days or 400 mg PO qid for 14 days).

Prognosis

Complications of genital chlamydial infections in women include perihepatitis (Fitz-Hugh-Curtis syndrome) and salpingitis. Of women with untreated chlamydial infection who develop pelvic inflammatory disease, up to 40% will have significant sequelae; approximately 17% will suffer from chronic pelvic pain, approximately 17% will become infertile, and approximately 9% will have an ectopic (tubal) pregnancy. Adolescent girls may be at higher risk for developing complications, especially salpingitis, than older women. Salpingitis in adolescent girls is also more likely to lead to tubal scarring, subsequent obstruction with secondary infertility, and increased risk for ectopic pregnancy. Women with *C. trachomatis* infection have a three- to fivefold increased risk for acquiring HIV infection.

Prevention

Timely treatment of sex partners is essential for decreasing risk for reinfection. Sex partners should be evaluated and treated if they had sexual contact during the 60 days preceding onset of symptoms in the patient. The most recent sex partner should be treated even if the last sexual contact was >60 days. Patients and their sex partners should abstain from sexual intercourse until 7 days after a single-dose azithromycin or after completion of a 7-day regimen. Annual routine screening for *C. trachomatis* is recommended for all sexually active adolescents and females 20–25 years of age, and older women with risk factors such as new or multiple partners or inconsistent use of barrier contraceptives. Sexual risk assessment may indicate more frequent screening of some women, especially adolescents.

C. trachomatis Infection in Infants

Epidemiology

Approximately 50% of neonates born to pregnant women with untreated chlamydial infection will acquire *C. trachomatis* infection. Chlamydial genital infection has been reported in 5–30% of pregnant women. The infant may become infected at one or more sites, including the conjunctivae, nasopharynx, rectum, and vagina. Transmission is rare following cesarean section with intact membranes. The introduction of systematic prenatal screening for *C. trachomatis* infection and treatment of pregnant women has resulted in a dramatic decrease in the incidence of neonatal chlamydial infection in the USA. However, in countries where prenatal screening is not done, such as the Netherlands, *C. trachomatis* remains an important cause of neonatal infection, accounting for over 60% of cases of neonatal conjunctivitis.

Clinical Manifestations

Approximately 30–50% of infants born to mothers with active, untreated, chlamydial infection develop clinical conjunctivitis. Symptoms usually develop 5–14 days after delivery, or earlier with prolonged rupture of membranes. The presentation is extremely variable and ranges from mild conjunctival injection with scant mucoid discharge to severe conjunctivitis with copious purulent discharge, chemosis, and pseudomembrane formation. The conjunctiva may be very friable and may bleed when stroked with a swab. Chlamydial conjunctivitis must be differentiated from gonococcal ophthalmia, which is sight threatening. At least 50% of infants with chlamydial conjunctivitis also have nasopharyngeal infection.

Pneumonia due to *C. trachomatis* may develop in 10–20% of infants born to women with active, untreated chlamydial infection. Only about 25% of infants with nasopharyngeal chlamydial infection develop pneumonia. *C. trachomatis* pneumonia of infancy has a very

characteristic presentation. Onset is usually from 1 to 3 months of age and is often insidious with persistent cough, tachypnea, and absence of fever. Auscultation reveals rales; wheezing is uncommon. The absence of fever and wheezing helps to distinguish *C. trachomatis* pneumonia from respiratory syncytial virus pneumonia. A distinctive laboratory finding is the presence of peripheral eosinophilia (>400 cells/mm^3). The most consistent finding on chest radiograph is hyperinflation accompanied by minimal interstitial or alveolar infiltrates.

Infants born to mothers with *C. trachomatis* may develop infection in the rectum or vagina. Although infection in these sites appears to be totally asymptomatic, it may cause confusion if identified at a later date. Perinatally acquired rectal, vaginal, and nasopharyngeal infections may persist for ≥3 years. *C. pneumoniae* can also be confused with *C. trachomatis* infection in nasopharyngeal cultures if a genus-specific monoclonal antibody is used for culture confirmation.

Diagnosis

Definitive diagnosis of *C. trachomatis* infection in infants is isolation by culture in specimens obtained from the conjunctiva or nasopharynx. Limited data suggest that NAATs may be equivalent to culture for detection of *C. trachomatis* in the conjunctiva of infants with conjunctivitis, but none of the currently available assays are approved for this indication.

Treatment

The recommended treatment regimen for *C. trachomatis* conjunctivitis or pneumonia in infants is erythromycin (base or ethylsuccinate, 50 mg/kg/day divided qid PO for 14 days). The rationale for using oral therapy for conjunctivitis is that 50% or more of these infants have concomitant nasopharyngeal infection or disease at other sites, and studies have demonstrated that topical therapy with sulfonamide drops and erythromycin ointment is not effective. The failure rate with oral erythromycin remains 10–20%, and some infants require a second course of treatment. The results of one small study suggest that a short course of azithromycin (20 mg/kg/day once daily PO for 3 days) was as effective as 14 days of erythromycin. Mothers (and their sexual contacts) of infants with *C. trachomatis* infections should be empirically treated for genital infection. An association between treatment with oral erythromycin and infantile hypertrophic pyloric stenosis has been reported in infants <6 weeks of age who were given the drug for prophylaxis after nursery exposure to pertussis.

Prevention

The most effective method of controlling perinatal chlamydial infection is screening and treatment of pregnant women. Neonatal ocular prophylaxis with topical erythromycin or tetracycline ointment, or silver nitrate, does not prevent chlamydial ophthalmia or nasopharyngeal colonization with *C. trachomatis* or chlamydial pneumonia.

Lymphogranuloma Venerum

Etiology

LGV is a systemic sexually transmitted disease caused by the L_1, L_2, and L_3 serotypes of *C. trachomatis*. Unlike the serotyopes that cause oculogenital infections, LGV strains have a predilection for lymphoid tissue. About 20 cases of LGV have been reported in children, and <1,000 cases are reported in adults in the USA annually. Recently there has been a resurgence of LGV infections, due mostly to L_2 strains, among men who have sex with men in Europe and the USA, many of these individuals were also infected with HIV.

Clinical Manifestations

The first stage of LGV is characterized by the appearance of the primary lesion, a painless, usually transient papule on the genitals. The second stage is characterized by usually unilaterally femoral or inguinal lymphadenitis with enlarging, painful buboes. The nodes may break down and drain, especially in males. In females, the vulvar lymph drains to the retroperitoneal nodes, inquinal buboes are infrequent. Fever, myalgia, and headache are common. In the tertiary stage, a genitoanorectal syndrome occurs with rectovaginal fistulas, rectal strictures, urethral destruction, and lymphedema. Among men who have sex with men, especially if they are HIV positive, rectal infection with LGV can produce a severe, acute proctocolitis, which can be confused with inflammatory bowel disease or malignancy.

Diagnosis

LGV can be diagnosed by culture of *C. trachomatis* or NAAT from a specimen aspirated from a bubo or by

serologic testing. However, NAATs will not differentiate LGV strains from the other oculogenital serotypes. Most patients with LGV will have complement-fixing antibody titers of >16.

Differential Diagnosis

Chancroid and herpes simplex virus can be distinguished clinically from LGV by the concurrent presence of painful genital ulcers. Syphilis can be differentiated by serologic tests. However, coinfections can occur.

Treatment

Doxycycline (100 mg PO bid for 21 days) is the recommended treatment. The alternative regimen is erythromycin base (500 mg PO qid for 21 days). Azithromycin (1 g PO once weekly for 3 weeks) may also be effective but clinical data are lacking. Sex partners of patients with LGV should be treated if they have had sexual contact with the patient during the 30 days preceding the onset of symptoms.

Infections due to *C. pneumoniae*

Etiology

The first isolates of *C. pneumoniae* were obtained serendipitously during trachoma studies in the 1960s (). On the basis of inclusion morphology and staining characteristics in cell culture, *C. pneumoniae* initially was considered a *C. psittaci* strain. Subsequent analysis, however, has demonstrated that this organism is distinct from both *C. psittaci* and *C. trachomatis.* Sequencing has revealed that *C. pneumoniae* differs significantly from *C. trachomatis* in several areas. *C. pneumoniae* encodes for 21 polymorphic membrane proteins (PMPs) versus 9 in *C. trachomatis.* PMPs may be surface exposed in *C. pneumoniae.* Restriction endonuclease pattern analysis, nucleic acid hybridization studies, amplified fragment length polymorphism and sequencing analysis suggest a high degree of genetic relatedness (>95%) among the *C. pneumoniae* isolates examined thus far and less than 10% homology with either *C. trachomatis* or *C. psittaci.* At this point, we do not have a strain typing system for *C. pneumoniae. C. pneumoniae* has also been isolated from nonhuman species, including horse, Australian marsupials (koalas, bandicoots), reptiles, and amphibians, where it is frequently asymptomatic but can cause respiratory infection. The animal isolates were more diverse than isolates of human origin which appear to be essentially clonal. Additional data from Australia suggests that at least two separate animal-to-human cross species transfer events may have occurred during the evolution of this organism.

Epidemiology

Respiratory infection with *C. pneumoniae* affects individuals of all ages. The proportion of community-acquired pneumonias associated with *C. pneumoniae* infection is 2–19% varying with geographic location, the age group examined, and the diagnostic methods used. Several studies of the role of *C. pneumoniae* in lower respiratory tract infection in pediatric populations have found evidence of infection from 0 to more than 18%, depending on the population and methods used. Most of these studies have relied entirely on serology for diagnosis. *C. pneumoniae* may also be responsible for 10–20% of episodes of acute chest syndrome in children with sickle cell disease, 10% of episodes of bronchitis, and 5–10% episodes of pharyngitis in children. Transmission probably occurs from person to person through respiratory droplets. Spread of the infection can occur among members in the same household or individuals in enclosed populations, such as military recruits, and in nursing homes.

Clinical Manifestations

Respiratory infections caused by *C. pneumoniae* cannot be readily differentiated from those caused by other respiratory pathogens, especially *Mycoplasma pneumoniae.* Pneumonia usually presents as a classic atypical (or nonbacterial) pneumonia characterized by mild to moderate constitutional symptoms including fever, malaise, headache, cough, and frequently pharyngitis. However, severe pneumonia with pleural effusions and empyema has been described. *C. pneumoniae* can also serve as an infectious trigger for asthma and has been isolated from middle ear aspirates of children with acute otitis media, but is usually associated with bacterial otitis media. Asymptomatic respiratory infection has been documented in 2–5% of adults and children and may persist for a year or more.

Diagnosis

It is not possible to differentiate *C. pneumoniae* from other causes of atypical pneumonia on the basis of clinical

findings. Auscultation reveals the presence of rales and often wheezing. The chest radiograph often appears worse than the patient's clinical status would indicate and may show mild, diffuse involvement or lobar infiltrates with small pleural effusions. The complete blood count may be elevated with a left shift but is usually unremarkable.

Specific diagnosis of *C. pneumoniae* infection is based on isolation of the organism in tissue culture. *C. pneumoniae* grows best in cycloheximide-treated HEp-2 and HL cells. The optimum site for culture is the posterior nasopharynx; the specimen is collected with wire-shafted swabs in the same manner as that used for *C. trachomatis*. The organism can be isolated from sputum, throat cultures, bronchoalveolar lavage fluid, and pleural fluid, but few laboratories perform such cultures because of technical difficulties. Polymerase chain reaction (PCR) testing is the most promising technology in the development of a rapid, nonculture method for detection of *C. pneumoniae*. However, no PCR assay is commercially available or has FDA approval and no PCR is standardized or has been extensively validated compared with culture for detection of *C. pneumoniae* in respiratory specimens from adults or children.

Serology is of limited utility for the diagnosis of *C. pneumoniae* infection, especially in children. Studies of *C. pneumoniae* infection in children with pneumonia and asthma show that over 50% of children with culture-documented infection have no detectable antibody using the microimmunofluorescence (MIF) assay. Acute infection, using the MIF test, has been defined as a fourfold increase in immunoglobulin G (IgG) titer or an IgM titer $\geq$16. The presence of a single elevated IgG titer $\geq$516 has been used for diagnosis of acute or chronic infection, but this has never been validated compared to culture an/or PCR and studies have shown many discrepant results. Neither an elevated IgA titer nor any other serologic marker is a valid indicator of persistent or chronic infection. The CDC has not recommended the use of any enzyme-linked immune assay for detection of antibody to *C. pneumoniae* because there is concern about the inconsistent correlation of these results with culture results. Currently there are no MIF or EIA kits that have FDA approval for serologic diagnosis of *C. pneumoniae* infection.

Treatment

The optimum dose and duration of antimicrobial therapy for *C. pneumoniae* infections remain uncertain. As most published treatment studies have used serology only for diagnosis, microbiologic efficacy could not be assessed. Recrudescent symptoms and persistent positive cultures have been described following 2 weeks of erythromycin and 30 days of tetracycline or doxycycline. Tetracyclines, erythromycin, azithromycin, clarithromycin, and quinolones have good in vitro activity against *C. pneumoniae*. *C. pneumoniae* is constitutively resistant to sulfonamides. The results of several treatment studies that have utilized culture have shown that erythromycin (40 mg/kg/day divided bid PO for 10 days), clarithromycin (15 mg/kg/day divided bid PO for 10 days), and azithromycin (10 mg/kg PO on day 1, then 5 mg/kg/day PO on days 2–5) are effective for eradication of *C. pneumoniae* from the nasopharynx of children with pneumonia in approximately 80% of cases. Persistence is not due to the development of resistance as MICs of the isolates obtained before and after therapy were unchanged.

Infections due to *C. psittaci*

Etiology

C. psittaci, the agent of psittacosis (also known as parrot fever and ornithosis), is primarily an avian pathogen and causes human disease infrequently. *C. psittaci* affects psittacine birds (parrots, parakeets, macaws, etc.) and nonpsittacine birds as well (ducks, turkeys); the known host range includes 130 avian species. Strains of *C. psittaci* have been analyzed by patterns of pathogenicity, inclusion morphology in tissue culture, DNA restriction endonuclease analysis, and monoclonal antibodies, which indicate that there are seven avian serovars. Two of the avian serovars, psittacine and turkey, are of major importance in the avian population of the USA. Each is associated with important host preferences and disease characteristics.

Epidemiology

From 2001 to 2008, there were 128 reported cases of psittacosis in the USA. Of these, 85% were associated with exposure to birds, including 70% following exposure to caged pet birds, which were usually psittacine birds including cockatiels, parakeets, parrots, and macaws. Chlamydiosis among caged nonpsittacine birds occurs most frequently in pigeons, doves, and mynah birds. Persons at highest risk for acquiring psittacosis include bird fanciers and owners of pet birds (43% of cases) and pet shop employees (10% of cases). There have also been large

outbreaks associated with poultry processing (turkeys, ducks). Reported cases most likely underestimate the number of actual infections due to a lack of awareness.

Inhalation of aerosols from feces, fecal dust, and nasal secretions of animals infected with *C. psittaci* is the primary route of infection. Source birds are either asymptomatic or have anorexia, ruffled feathers, lethargy, and watery green droppings. Psittacosis is uncommon in children, in part because children may be less likely to have close contact with infected birds. One high-risk activity is cleaning the cage. Several major outbreaks of psittacosis have occurred in turkey processing plants; workers exposed to turkey viscera are at the highest risk for infection.

Clinical Manifestations

Infection with *C. psittaci* in humans ranges from clinically inapparent to severe infection involving multiple organ systems as well as pneumonia. The mean incubation period is 15 days after exposure, with a range of 5–21 days. Onset of disease is usually abrupt, with fever, cough, headache, and malaise. The fever is high and often is associated with rigors and sweats. The headache can be so severe that meningitis is considered. The cough is usually nonproductive. Gastointestinal symptoms are occasionally reported. Crackles may be heard on auscultation. Chest radiographs are usually abnormal with variable infiltrates, and pleural effusions may be present. The white blood cell count is usually not elevated, but a mild leukocytosis may be present. Elevated levels of aspartate aminotransferase, alkaline phosphatase, and bilirubin are common.

Diagnosis

The diagnosis of psittacosis can be difficult because of the varying clinical presentations. A history of exposure to birds or association with an active case are important clues, but as many as 20% of patients with psittacosis have no known contact. Person-to-person spread has been suggested but not proved. Other infections that cause pneumonia with high fever, unusually severe headache, and myalgia include, most commonly, bacterial and viral respiratory infections as well as *Coxiella burnetii* (Q fever), *Mycoplasma pneumoniae, C. pneumoniae,* tularemia, tuberculosis, fungal infections, and Legionnaires disease.

The 2010 CDC case definition of psittacosis requires a compatible clinical illness, usually with a reliable history of avian exposure with laboratory confirmation by one of the following four methods: (1) culture of *C. psittaci* from respiratory specimens (e.g., sputum, pleural fluid or tissue) or blood, (2) a fourfold or greater increase in CF or MIF titer in sera collected at least 2–4 weeks apart, (3) supportive serology (e.g., *C. psittaci* IgM titer of $\geq$32 in at least one serum sample obtained at onset of symptoms), or (4) detection of *C. psittaci* DNA in a respiratory specimen (e.g., sputum, pleural fluid or tissue) via amplification of a specific target by PCR. A probable case: An illness characterized by fever, chills, headache, cough, and myalgia that has either (1) supportive serology (e.g., *C. psittaci* IgM titer of $\geq$32 in at least one serum sample obtained at onset of symptoms) or (2) detection of *C. psittaci* DNA in a respiratory specimen (e.g., sputum, pleural fluid or tissue) via amplification of a specific target by PCR. A confirmed case would be a patient with the above clinical presentation with either (1) culture of *C. psittaci* from respiratory specimens (e.g., sputum, pleural fluid or tissue) or blood or (2) a fourfold or greater increase in complement fixation (CF) or MIF titer in sera collected at least 2–4 weeks apart. Although MIF has shown greater specificity for *C. psittaci* than CF, cross reactions with other *Chlamydia* species and bacteria can occur. To increase the reliability of the test results, acute and convalescent phase serum specimens should be analyzed in the same laboratory at the same time. Early treatment of psittacosis with tetracycline may abrogate the antibody response.

Although *C. psittaci* will grow in the same culture systems used for isolation of *C. trachomatis* and *C. pneumoniae,* very few laboratories culture for *C. psittaci,* mainly because of the potential biohazard (Table 78.2). PCR assays for detection of *C. psittaci* have been reported in the literature, but there are no FDA approved, commercially available kits for the diagnosis of infection in humans.

Treatment

Recommended treatment regimens for psittacosis are doxycycline (100 mg PO bid) or tetracycline (500 mg PO qid) for at least 10–14 days after the fever abates. The initial treatment of severely ill patients is doxycycline hyclate (4.4 mg/kg/day divided every 12 h IV, maximum 100 mg/dose). Erythromycin (500 mg qid PO) or azithromycin (10 mg/kg PO day 1, not to exceed 500 mg, followed by 5 mg/kg PO on days 2–5, not to exceed 250 mg) are alternative drugs if tetracyclines are contraindicated (e.g., children <8 years of age and pregnant women), but may be less effective. Remission is usually evident within 48–72 h. Initial infection does not appear to be followed by long-term immunity. Reinfection

and clinical disease can develop within 2 months of treatment; only two well-documented cases of reinfection have been reported in the literature.

Prognosis

The mortality rate of untreated psittacosis is 15–20%, but is <1% with appropriate treatment. Severe illness leading to respiratory failure and fetal death has been reported among pregnant women.

Prevention

Several control measures are recommended to prevent transmission of *C. psittaci* from birds. Bird fanciers should be cognizant of the potential risk. *C. psittaci* is susceptible to most disinfectants and detergents as well as heat, but is resistant to acid and alkali. Accurate records of all bird-related transactions aid in identifying sources of infected birds and potentially exposed persons. Newly acquired birds, including birds that have been to shows, exhibitions, fairs, or other events, should be isolated for 30–45 days or tested or treated prophylactically before adding them to a group of birds. Care should be taken to prevent transfer of fecal material, feathers, food, or other materials between birdcages. Birds with signs of avian chlamydiosis (e.g., ocular or nasal discharge, watery green droppings, or low body weight) should be isolated and should neither be sold nor purchased. Their handlers should wear protective clothing and a disposable surgical cap and use a respirator with an N95 or higher efficiency rating (not a surgical mask) when handling them or cleaning their cages. Infected birds should be isolated until fully treated, which is generally 45 days.

79 Cholera

Louise Elaine Vaz

Case

A 6-year-old refugee child is brought to the camp hospital in the early morning hours by his parents. A review of the history is significant for abundant watery diarrhea and non-bilious emesis that began the night before. An older sibling had mild gastroenteritis earlier in the week but quickly recovered. Physical exam reveals a thin boy with sunken eyes, dry mucus membranes, and 3 second skin pinch of the abdomen. He is unable to take anything by mouth and is too tired to answer questions. How should you proceed?

The patient is assessed as severely dehydrated. Rehydration is immediately started with Lactated Ringers after IV access is established and continued with oral rehydration solution when the patient is able to drink. A sample of stool is collected and sent to the nearby field laboratory for diagnosis. Due to volume of watery stool, you suspect cholera and immediately notify the health directors to begin investigation of a new outbreak.

Definition/Classification

Cholera is one of the oldest and most notorious of epidemic diseases with the hallmark of profuse, severe watery diarrhea that can result in death over a matter of hours. Despite advances in the genetics of *Vibrio cholerae*, the pathophysiology of the disease, and advent of oral rehydration therapy, cholera can still cause significant morbidity and mortality throughout the developing world, particularly in vulnerable populations.

Vibrio cholerae belong to the family Vibrionaceae which shares characteristics with the Enterobacteriaceae. The organism is classified into serogroups according to the carbohydrate determinants of its somatic O antigen of the cell surface lipopolysaccharide. Over 200 serogroups have been discovered, classified broadly as those that agglutinate in anti-sera to the O1 group antigen or those that do not. Only the O1 and O139 serogroups are currently responsible for the epidemiologic characteristics and clinical picture of cholera. Non - O1 strains may be associated with a mild gastroenteritis.

There are two biotypes of O1 cholera: Classical and El Tor. Each differs in clinical presentation and biochemical properties. The El Tor biotype causes more asymptomatic infections with 20–100 asymptomatic infections to 1 symptomatic case. This is compared to 2–5 asymptomatic cases to 1 symptomatic case of the Classical biotype. O1 El Tor and Classical biotypes can each further be serotyped as Inaba, Ogawa, or (rare) Hikojima, distinguished by different expression of the O1 subspecific antigens A, B, and C.

Epidemiology

Allusions to a cholera - like illness have been made through ancient times. In the modern era, seven cholera pandemics have been recognized since the early 1800s. The first six pandemics, from 1817 to 1923, were thought to be of the O1 Classical biotype, largely originating from the Indian subcontinent with extension to Europe and the Americas. Transmission of the disease was recognized in the sentinel work in London in 1854 by John Snow, who recognized that transmission could be blocked by stopping access to a contaminated water source. The seventh and most recent pandemic started in 1961 in Indonesia, spread to Asia, Africa, and finally to Latin America, causing explosive epidemics in Peru in 1991. This pandemic has been the longest lasting and is caused by the O1 El Tor biotype.

In 1992, a non-O1 serogroup that caused an epidemic of a cholera-like illness was identified in Madras, India. It was named the O139 Bengal serogroup. O139 is a genetic derivative of El Tor biotype, is largely confined to Asia.

In 2009, 45 countries from all over the world reported a total of 221,226 cases of cholera to the World Health Organization. Most of the 4,946 deaths were recorded in Africa, with a worldwide overall case-fatality rate of 2.24%. The actual number of cholera cases worldwide can only be estimated due to limitations in surveillance systems, underreporting, and inconsistencies in the application of case definitions. As a result, the true burden of disease due to cholera is estimated at 3–5 million cases and 100,000–120,000 deaths each year. Reminders of this deadly disease are evident in recent times, such as the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_79,

Goma experience in 1994 where over a 6 week period, an estimated 12,000 deaths and 70,000 cases occurred in eastern Zaire (currently the Democratic Republic of the Congo) among Rwandan refugees. Epidemics in Zimbabwe in 2008 and Haiti in 2010 highlight the continued need for surveillance and early response.

Among industrialized nations, imported cases of cholera have been reported in international travelers. Sporadic cases in the USA have occurred in the Gulf Coast region, with identification of an environmental reservoir of *V. cholerae* O1 El Tor Inaba. Seasonal variation in areas of endemic infection indicates the possible role of environmental factors in triggering the epidemic process. Humans are the only known host, but *Vibrio* organisms may exist in the dormant state in aquatic environments in association with copepods or other zooplankton. Transmission occurs by the fecal-oral route with ingestion of contaminated water and food.

Microbiology and Pathogenesis

Vibrio cholerae are gram-negative, comma-shaped, motile rods that are facultatively anaerobic. Genetic material consists of two circular chromosomes. Virulence factors are located on the larger chromosome and clustered on two main areas: a "pathogenicity island" and a prophage called CTXϕ which encodes the cholera toxin. The infectious dose causing disease varies from as few as 10^2 up to 10^6 organisms, depending on the vehicle of transmission and host characteristics. Once ingested, the acid content of the stomach may serve as a natural defense mechanism against *V. cholerae* which are killed at low pH.

Organisms multiply rapidly in the alkaline environment of the proximal portion of the small intestine and colonize, but do not invade, the mucosa of the small intestine with the aid of a pilus and other adherence factors. Inflammation is minimal and the epithelium remains intact. The cholera toxin is a multimeric protein and consists of two units: A (active) and B (binding). The B portion binds to the ganglioside receptor on local enterocytes. The A unit consists of A1 and A2 subunits. A2 connects A1 to the B unit. Internalization of the A1 subunit leads to transfer of an ADP-ribose molecule to a G-protein. This results in persistent activation of the G binding protein, upregulating cyclic adenosine monophosphate production. Elevated cAMP leads to the blocked absorption of sodium and chloride by microvilli and promotes the secretion of chloride and bicarbonate by intestinal crypt cells, resulting in massive of loss of water across the osmotic gradient.

It has been observed that individuals with *Heliobacter pylori* gastritis and those taking antacids or histamine blockers are at increased risk of cholera infection. Interestingly, persons with blood group O are at a higher risk of developing severe cholera, although the exact mechanism is unknown. Younger children are particularly vulnerable in endemic areas, as older children and adults benefit from some acquired immunity. Breast-fed children are normally protected against severe disease due to less exposure to contaminated water and foods and because of protective antibodies obtained in breast milk. Lack of breast feeding in parts of the world where mothers are unable to or opt not to breast-feed may demonstrate increased rates of cholera in infants.

Clinical Manifestations

The incubation period is dependent on the infectious dose and can vary from several hours up to 5 days. Most patients with cholera are asymptomatic, and some have mild or moderate diarrhea lasting up to 1 week. Vomiting, if it occurs, is usually early on in the disease course. Fever may be seen in children but because the bacteria are noninvasive, it is usually not present. Less than 5% of infected children develop *cholera gravis*, characterized by the sudden onset of profuse, painless watery diarrhea accompanied by emesis and severe dehydration that can occur over hours.

Stools are described as "rice water" due to the color and consistency resembling the water used to wash or cook rice. Cholera stools do not contain red blood cells or leukocytes. Diarrhea is uncontrollable and voluminous and may be accompanied by abdominal cramping, presumably due to fluid distension in the bowels. Urine output may decrease or cease. Within hours, metabolic acidosis, hypovolemic shock, renal failure, altered mental status, seizures, coma, or death may occur.

Electrolyte abnormalities are common. Hypokalemia may result in paralytic ileus, leading to severe distension of the abdomen. "Cholera sicca" ("*dry cholera*") can occur as intestinal secretions remain contained in the distended small intestine and colon, with little or no diarrhea. Hypoglycemia is more common in children and may result in altered mental status or seizures. After dehydration, hypoglycemia is the second most common cause of death in pediatric patients with cholera. Metabolic acidosis can result from bicarbonate loss in the stool and is exacerbated by hypoperfusion of tissues, leading to lactic acidosis. During the rehydration phase, patients are at risk for hypocalcemia, manifest by muscle cramping and tetany.

Diagnosis

Vibrio organisms can be identified by dark-field examination or wet preparation of stool. The use of specific cholera anti-sera to block the movement of the *V. cholerae* allows confirmation of the diagnosis. Rapid tests with direct antigen detection dipstick are now available, although results should be culture confirmed. Growth of *V. cholerae* on selective media, such as thiosulfate-citrate-bile salts-sucrose agar or tellurite taurocholate gelatin agar, remains the gold standard for diagnosis and analysis of microbial drug sensitivities. If laboratory facilities are not immediately available, Cary Blair transport medium can be used to transport or store a fecal or rectal swab. Stools can also be placed on blotting paper and kept in sealed plastic bags. Molecular assays, such as PCR, are available in certain reference laboratories. Acute and convalescent titer measurements are useful in epidemiological studies.

Cholera is a World Health Organization–reportable disease, recognized by its epidemic potential. The clinical case definition for suspected cholera by the WHO is as follows:

- Acute watery diarrhea (three or more loose stools in a 24 hour period) with or without vomiting in a patient age 5 or older in an *endemic* area.
- Severe dehydration or death from acute watery diarrhea in a patient age 5 or older in a *non-endemic* area.

By WHO standards, once laboratory confirmation of a single case of cholera has occurred, it becomes unnecessary to confirm all subsequent cases. In a cholera *outbreak*, any patient who has acute, profuse watery diarrhea should be treated as a cholera case. Intermittent laboratory confirmation of cholera cases in these settings is encouraged to monitor for drug sensitivities and to confirm the end of an outbreak.

Differential Diagnosis

Mild disease is often difficult to distinguish from gastroenteritis caused by other enteric pathogens such as *rotavirus, Enterotoxigenic Escherichia coli* (ETEC), or bacterial food poisoning with *Staphylococcus aureus* or *Bacillus cereus*.

Treatment

Treatment for dehydration should not be delayed for laboratory confirmation of disease. The World Health Organization outlines steps to the treatment of a patient with suspected cholera, which include the following:

1. Assess and classify the level the patient's of dehydration.
2. Rehydrate according to algorithm (*Fig. 79.1*) with frequent monitoring.
3. Maintain hydration and replacement of fluids until diarrhea stops.
4. Administer an oral antibiotic to patients with severe dehydration.
5. Resume food intake/breast feeding as soon as possible. Give zinc supplements.

Low osmolality oral rehydration solution (ORS) is the preferred first line treatment for children who have no or mild dehydration. Newer rice-based or amylase-resistant starch versions of ORS may be available. ORS can also be used to manage patients suffering from some dehydration who are able to drink. ORS can be administered via syringes or nasogastric infusions for infants and children unable to sip from a cup. Food should be offered as soon as children are able to eat. Mothers are encouraged to continue breast feeding.

Children unable to take ORS should have fluids administered intravenously. Access is critical, and larger veins may be utilized to enable boluses. The solutions of preference include Lactated Ringers or regional variants, such as Dhaka Solution or Peru Polyelectrolyte. ORS, which contains a higher amount of potassium compared to these IV solutions, should be started as soon as the patient is able to take fluids by mouth. The use of cholera cots, constructed with a hole in the center for stool and a collecting pot underneath, to accurately measure output is recommended. Fluid administration rates must be closely monitored, particularly in infants and severely malnourished children who are at risk for pulmonary edema and cardiac overload. Signs of over-hydration include periorbital edema, tachypnea, and crackles in the lungs.

Oral antibiotics may be used to decrease the volume and duration of diarrhea and shorten the period of communicability but are reserved for children who are severely ill. Mass chemoprophylaxis in the community is generally not warranted, but selective prophylaxis may be utilized in certain scenarios. Single dose or 3-day regimens exist, and antibiotic sensitivities should guide specific management in each outbreak (*Table 79.1*). IV or IM antibiotics are not necessary. The addition of 10–30 mg of elemental zinc for 2 weeks has been shown to decrease stool output and duration of diarrhea in children.

Cholera Treatment Algorithm

The *World Health Organization* has established guidelines* for rehydration and cholera treatment which have been adapted with permission and summarized below:

1. Assess and classify level of dehydration (severe, some, no/mild)
2. Rehydrate according to algorithm below with frequent monitoring
3. Maintain hydration and replacement of fluids until diarrhea stops
4. Administer an oral antibiotic to patients with severe dehydration (table 1)
5. Resume food intake / breastfeeding as soon as possible. Give zinc supplements

Severe Dehydration >10% loss of body weight	Treatment
At least 1 of the following: **Lethargy** **Unable to drink** **Skin pinch >2sec** Plus 1 or more: No tears Very sunken eyes Very dry mucus membrane Feeble pulse	Start IVF: Reassess every 15–30 min. 30 ml/kg / 70ml/kg <1 yr old: In 1st hr / Over 5 hrs >1 yr old: In 30 min / Over 2.5 hrs Then, **reclassify dehydration** [severe, some, none] and continue treatment as noted below **Be aware of hypoglycemia **Give ORS 5 ml/kg/hr as soon as able to take po **If no IV access: ORS by NG 20 ml/kg/hr x 6 hrs.

Some Dehydration 5–10% loss of body weight	Treatment
At least 1 of the following: **Irritability / fussy** **Thirsty, wants to drink** **Skin pinch 1–2 sec** Plus 1 or more: No tears Sunken eyes Dry mucus membrane Increased pulse rate	Start ORS: If weight is known calculate volume over 4 hrs by 75 ml x weight in kg If weight not known, use chart below. Reassess every 30 min. 0–4 mo: 200–400 ml over 4 hrs 4–12 mo: 400–700 ml over 4 hrs 12–24 mo: 700–900 ml over 4 hrs 2–5 yr: 900–1400 ml over 4 hrs 5–14 yrs: 1400–2200 ml overt 4 hrs 14 and above: 2200–4000 ml over 4 hrs Then, **reclassify dehydration** and continue treatment

No dehydration	Treatment
2 of the following: **Alert, well appearing** **Tears** **Mouth Moist** **Wants to drink** **Normal skin pinch**	After rehydration achieved, maintain hydration. Resume breast feeding and regular diet as soon as tolerated. Supplement with 10-30 mg of zinc daily. In an outpatient setting most patients can drink ORS to replace stool losses. Replacement of stool output: age <2: 50–100 ml/stool episode up to 500 mL per day. age 2–10: 100–200 ml/stool episode up to 1L per day. age 10+: po ad lib up to 2L per day **Reassess the patient** for signs of dehydration at least every four hours

Pediatric dosages for antibiotics in cholera

Antibiotic	Single dose regimen	Multiple dose regimen	Source
Erythromycin		12.5 mg QID × 3 days. Max 1 g/day	WHO First steps (2004)
Azithromycin	20 mg/kg Max 1 g	–	Khan et al. (2002)
Ciprofloxacin[a]	20 mg/kg max 1 g	–	Saha et al. (2005)
Doxycycline[b]	4–6 mg/kg . Max 300 mg	–	Alam et al. (1990), Sack et al. (1978)
Tetracycline[b]	–	12.5 QID × 3 days, Max 2 g/day	Roy et al. (1998)

Increasing resistance to TMP-SMX and furazolidone has limited their use in practice
[a]Fluoroquinolones are generally avoided in patients younger than 18 years because of concerns about arthropathy in animal studies. The AAP states use of fluoroquinolones may be justified in children <18 years of age in special circumstances after careful assessment of the risks and benefits for the individual patient and after these benefits and risks have been explained to the parents or caregivers
[b]Doxycycline and tetracycline doses are extrapolated from adult studies. Both are generally contraindicated for children under age 8 due to staining of permanent teeth. Short courses are not thought to contribute highly to this

Prognosis

Attack rates in endemic areas are highest in children under age five who have less acquired immunity. Immunologically naïve persons of all ages are at risk in a non-endemic setting. Mortality can approach 50% if treatment is unavailable or delayed. Pregnant women and infants are at particular risk for complications. For those that survive, cholera itself is self-limiting, with resolution in approximately 1 week. Stools may remain positive for *V. cholerae* up to 1–2 weeks after diarrhea ends, although occasionally the carrier state may persist for longer. With appropriate therapy, case-fatality rates should be less than 1%

Prevention and Control

Situations with overcrowding and poor sanitation can promote and perpetuate cholera epidemics. Epidemics often occur after man-made and natural disasters, particularly in complex emergencies and refugee camps, when water and food supplies become contaminated with *V. cholerae*. Social disruption, poor infrastructure, and poor access to health care can contribute to increased mortality. Systematic reporting to local, national, and international health bodies will help to coordinate the appropriate response and limit spread to other areas.

Once an outbreak has been identified, a multitiered approach is necessary, addressing public health education, treatment facilities, and ensuring safe water supply and maintenance of latrines. Hospitalization with enteric/contact precautions is desirable for severe cases. Less severe cases can be managed in an outpatient setting with ORS. Disinfection of articles used by patients, particularly linens and diapers is important.

The use of oral cholera vaccines is considered an additional public health tool that may be used in conjunction with the recommended cholera control measures such as ensuring safe water and adequate sanitation. Three oral cholera vaccines are available: WC/rBS (Dukoral) and the two versions of the variant WC (mOrcVax and Shanchol). Only one, WC/rBS, is currently prequalified by the WHO and available to purchase by UN agencies.

WC/rBS was developed in Sweden in 1991 and consists of killed whole-cell *Vibrio cholerae* O1 with a purified recombinant B-subunit of cholera toxin. It is not licensed for children less than 2 years of age and may be used in pregnant and HIV-positive individuals. Two doses a minimum of 7 days apart, if age greater than 6, or three doses, if between ages 2–5, is needed to induce immunity within 1 week after the last dose. Clinical trials in Bangladesh, Mozambique, and Peru conferred a range of protection from 78–90% for 4–6 months among all age groups. For children aged 2–5 years, 1 booster dose is recommended every 6 months and for those older than 6 years, one booster every 2 years. Reanalysis of data from clinical trials in Bangladesh revealed considerable herd protection from WC-rBS, including protection for children too young to be vaccinated.

Variants of the WC/rBS vaccine without the recombinant B-subunit resulted from transfer of technology to Vietnam and India. Both vaccines, mOrcvax (Vietnam) and Shanchol (India) are based on serogroups O1 and O139 and are identical in terms of strains but formulated by different manufacturers.

A recent reevaluation of parenteral cholera vaccines in a Cochrane review demonstrated an overall efficacy of 48% (95% CI: 35–58%, with protection for two years). Other cholera vaccines remain under development, with the goal to offer lifelong immunity in a single dose.

80 Diphtheria

Mohammad Al-Shaalan

Diphtheria is a respiratory illness with systemic manifestations that are mediated by exotoxin. In addition, skin infection occurs in some patients. After introduction of diphtheria toxoid vaccine, the incidence of the disease has decreased dramatically. In 2008, only 7,088 cases are reported globally (*Fig. 80.1*). The decrement has been impressive over the last two decades; however there was a small outburst in the years of 1994 and 1995 due the outbreak that occurred in previous USSR where 60,000–80,000 cases were reported mostly among adults who were not or incompletely vaccinated. A significant number of cases are still reported from India, Sudan, and some other developing countries. The vaccine is effective but needs to be enforced and the immunity maintained by adhering to booster vaccination especially in adolescent and adults.

Organism

Diphtheria is caused by *Corynebacterium diphtheriae* – a Gram positive, facultative aerobic, nonmotile, and nonspore-forming bacillus. It can be grown in ordinary media like blood or chocolate agar; however selective media are required to distinguish it from other bacteria. Three biotypes of diphtheria can be identified in tellurite medium: gravis, intermedius, and mitis. Gravis biotype appears as semirough grayish colonies. Intermedius biotype appears as small smooth grayish colonies with black center. Mitis biotype appears as small smooth grayish colonies. Toxigenic strains can be smooth or rough and can be of any biotype, however intermedius is found more often to be toxigenic.

Pathogenesis

Infection is acquired by inhalation of infected droplets that are produced by an infected person or asymptomatic carrier. In addition inoculation of skin or other mucus membranes like nose, conjunctivae, and genitalia by droplets or with direct contact may result in localized disease. Once the organism has reached the mucus membrane of the pharynx and tonsils, it elicits an inflammatory response and causes necrosis. This results initially in small yellowish areas of exudates over the tonsils. These lesions coalesce to form a pseudomembrane that is formed by debris and inflammatory exudates. Necrosis of the underlying mucosa results in grayish discoloration of the membrane. The membrane is usually well demarcated and mainly covers the tonsils. In some instances it extends to uvula, pharynx, larynx, and trachea. It does not extend anteriorly.

Clinical Features

Tonsillopharyngeal Diphtheria

Incubation period of the disease is 2–7 days. The onset is usually insidious with illness progressing from mild sore throat and low grade fever to signs of increasing respiratory difficulty. Lymphadenopathy is usually mild and there is no tenderness. Throat examination will reveal grayish membrane that is well demarcated and usually extends beyond the tonsils. It bleeds upon trial of scraping. If the membrane involves the larynx, the patient will have inspiratory stridor and difficulty in breathing. Occasionally the disease may take a hyperacute course, with high fever, toxicity, cardiopulmonary collapse, and encephalopathy.

Nasal Diphtheria

Five to ten percent of diphtheria will present with nasal disease. It is usually mild and lacks systemic complication of myocarditis and neuropathy. The presentation starts with nasal mucoid discharge that proceeds to be bloody due to formation of necrotic tissue. The membrane can be visualized in the nostrils and there may be evidence of irritation on the upper lip.

Laryngeal Diphtheria

It is difficult to diagnose laryngeal diphtheria unless laryngoscopy or bronchoscopy is done to evaluate the upper airways anatomy. Systemic symptoms are minimal and the main presentation is inspiratory stridor that may progress to respiratory obstruction. As with nasal diphtheria cardiac and nervous systems complications are unusual.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_80,

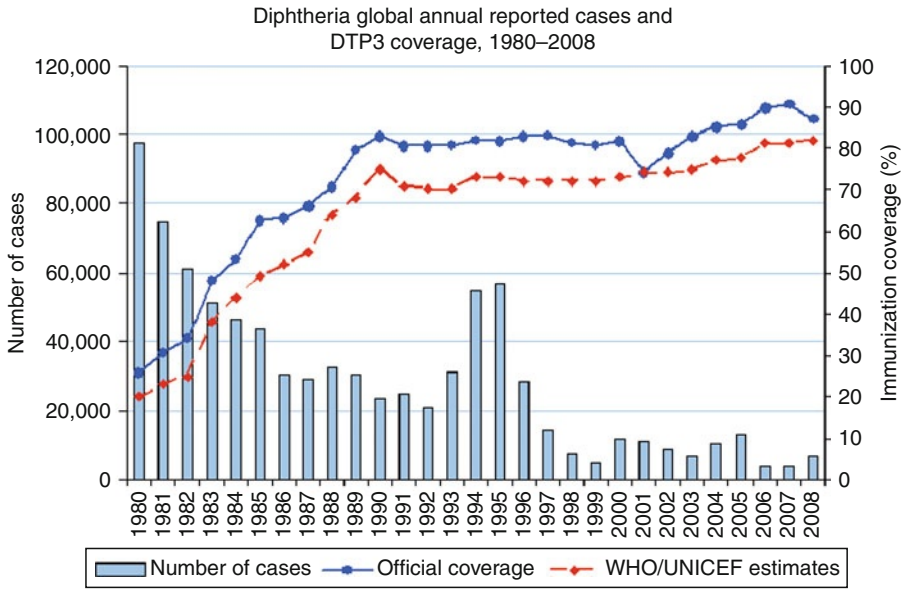

Figure 80.1
Global annual reported cases of diphtheria

Complications

Diphtheria complications are mediated by exotoxin that is produced by toxigenic strains of *C. diphtheria*. The toxin can cause damage to any organ; however CNS and heart are the most commonly involved.

Cardiac Complications

Diphtheria toxin causes myocardial degeneration with minimal inflammatory response. This degeneration also involves the conducting system. In addition to myocarditis, the affected patient usually has variable degrees of heart block and dysrhythmia. Actually the main cause of heart failure in these patients is usually dysrhythmias. Most of the toxin effects on the heart occur in the second week of illness but it can occur as early as few days and as late as 6 weeks. Early treatment will prevent or decrease the severity of heart involvement.

CNS Complications

CNS complications usually appear 4–7 weeks later. Diphtheria toxin has increased affinity to anterior horn neurons, cranial nerves neurons, as well as dorsal ganglion neurons. The most common CNS complication is bilateral motor ascending neuropathy with gradual flaccid paralysis and loss of deep tendon reflexes. Palatal and diaphragm palsies are the most common.

Cranial nerve palsies may occur. Brain stem involvement may occur with resultant blood pressure instability. There is usually no sensory impairment. Recovery is complete without any residual impairment.

Other Organ Complications

Hepatitis, nephritis, and gastritis are rare complications that have been reported in association with diphtheria. Adrenal hemorrhage also may occur with resultant adrenal failure. Hemolytic uremic syndrome has also been reported.

Diagnosis and Differential Diagnosis

Diphtheria mimics most of the upper respiratory infections like streptococcal pharyngitis, infectious mononucleosis, adenovirus infection, and Vincent's angina with faucial membrane. However the membrane in diphtheria usually extends beyond the tonsils whereas it does not in the others.

Laryngeal diphtheria has similar presentation to that of foreign body aspiration, peripharyngeal or retropharyngeal abscess, and laryngeal hemangiomas or papillomas.

In suspected cases of diphtheria, laboratory should be notified and both throat swab and nasopharyngeal aspirate be submitted. In the laboratory, specimens should be screened initially with Gram and methylene blue stains. At the same time blood agar, Loeffler's serum medium, and tellurite medium should be inoculated. Blood agar is used in order to diagnose any other or coexisting infection like streptococcal pharyngitis. Loeffler's medium is to isolate the organism in pure culture so it can be used for toxigenic evaluation or subculturing tellurite medium in case that initial inoculation was not informative. On tellurite medium *C. diphtheriae* has a characteristic appearance of black colonies surrounded by a brownish halo.

Schick test is an intradermal skin test that is used to determine the immunity status of the patient. Intradermal injection of diphtheria toxin will cause induration and erythema of >10 mm in patients who are not immune. Immune patients will not have a reaction as the toxin is neutralized with antitoxin. Some patients may show reaction secondary to hypersensitivity to the toxin or its constituents. To avoid such problem a control test with toxoid is injected into the other arm. In immune patients who are hypersensitive, a reaction will appear to both toxin and toxoid; however, it will disappear in 48–72 h. Nonimmune patients will have persistence of reaction to the toxin for more than 5 days and disappearance of reaction to toxoid in less than 5 days. Schick test is not widely used and its application in clinical practice is limited.

Treatment

Suspected cases of diphtheria should be given antitoxin and started on penicillin therapy. Antitoxin is equine derivative and therefore a test dose should be given. If there is any evidence of reaction then desensitization should be started. Penicillin can be given as procaine penicillin 25,000–50,000 units/kg/day for 14 days. Erythromycin is a good alternative for those who are allergic to penicillin.

Prevention

Isolation

Patients should be isolated for the whole duration of therapy. Two cultures from both nose and throat should be obtained 24 h apart after completion of therapy. If they are negative then isolation can be discontinued. If positive repeat the course of therapy.

Contacts

Close contacts should be cultured and given antibiotics prophylaxis with either erythromycin 40–50 mg/kg/day in four divided doses for 7 days or benzathine penicillin 600,000 units IM if the contact <30 kg in weight or 1.2 mega units IM if >30 kg in weight. Immunization status should be updated. A booster dose should be given to all contacts that have no diphtheria booster within 5 years.

Asymptomatic Carrier

Carrier patients should be treated with erythromycin 40 mg/kg/day in four divided doses for 7 days or single dose of benzathine penicillin 600,000 units IM for those below 30 kg in their weight or 1.2 mega units IM. Two throat cultures obtained 24 h apart should be obtained 2 weeks after completion of therapy. If still positive, therapy course needs to be repeated. Immunization should be updated. Those with uncertain history of immunization or who received less than four doses should be given a booster dose. In addition a booster should be given if the last vaccine dose was given 1 year or more prior to the illness.

81 *Haemophilus influenzae* Infections

Mohammad Al-Shaalan

Haemophilus influenzae is a common cause of a wide variety of childhood diseases that cause significant morbidity and mortality. It is the serotype b that is known to be more invasive and cause most of severe diseases. Before introduction of the conjugate HIB vaccine, the incidence of serious disease due HIB is 50–300/100,000 children below 5 years of age. *H. influenzae* type b (HIB) is the most common causative organism of bacterial meningitis accounting for 50–70% childhood meningitis. Ninety-one percent of HIB meningitis occurred in children less than 2 years of age. Many studies from Saudi Arabia have shown HIB to be the cause of 50–60% of childhood meningitis. In 2000, HIB was estimated to cause around eight million serious illnesses worldwide with an estimated 371,000 deaths. Conjugated HIB vaccine that is effective in early infancy has been introduced into the national vaccination program in more than 150 countries. It has resulted in significant reduction in the disease burden in these countries (*Fig. 81.1*).

In many of the developing countries this vaccine has not yet been introduced probably due to cost limitations or the misconception that HIB is not a major cause of disease in these countries. In Asia there are many studies that showed HIB to be a significant cause of serious illnesses (*Table 81.1*). Studies from some developing countries showed that infection due to *H. influenzae*, mainly type b, is far more common than developed countries. In Papua New Guinea, 11% of children 6–24 months of age were colonized with HIB. This study was confirmed by other studies from Gambia. In these two countries, *H. influenzae* combined with *Streptococcus pneumoniae* were the commonest cause of bacterial acute lower respiratory intact infections, which are the commonest cause of mortality in children <5 years of age.

Microbiology

H. influenzae is a Gram negative, facultative aerobic, nonmotile, and pleomorphic bacilli and coccobacilli that grew better in aerobic environment with CO2 enrichment. *H. influenzae* requires hematin (X) and NAD (V) factors for growth. These factors are available in chocolate agar media because the hemolyzed RBC in such a medium release hematin and NAD. There are encapsulated and nonencapsulated strains of *H. influenzae.* Encapsulated strains are grouped into six serotypes (A–F) according to their capsular determinants.

Pathogenesis

HIB is the most invasive among all *H. influenzae* strains. Only 3% of children are colonized with HIB, however this number increases to 10–15% in developing countries. HIB gains entry into the blood through translocation across the nasopharyngeal epithelium. This translocation is mediated mainly by adherence of the organism to a previously damaged or breached epithelium. The adherent factors are thought to be fimbriae and the adherence is made easy by releasing IgA protease that inhibits the action of the SlgA. Once translocation occurred, HIB gains access to the blood where it is protected from immune reaction by its capsule. In the blood, the organism multiplicates to a critical level of 10^5 colonies/mL that is required for the organism to cause disease and invade CNS and other tissues.

The entry into the CNS occurs through choroidal plexus, although it may occur through the dural traversing veins. Once in subarachnoid space, the organism elicits a cascade of inflammatory response that damage the BBB (see Chap. 69, "Meningitis").

Clinical Features

H. influenzae Type B (HIB)

Bacteremia

Isolated bacteremia can be caused by HIB. It has decreased significantly after the introduction of the vaccine. Patients usually present with high fever without any localizing signs. In patients with HIB bacteremia, meningitis should always be ruled out. Haemophilus bacteremia is more

likely to be associated with invasive diseases than that of *S. pneumoniae*. Therefore patients with Haemophilus bacteremia should be hospitalized and investigated thoroughly for focal infections. Parenteral therapy with appropriate antibiotic is indicated.

Meningitis

HIB is the commonest cause of meningitis in children 3 months to 5 years of age in developing countries. The introduction of HIB conjugate vaccine has resulted in dramatic decrease in the incidence of this illness, however this vaccine is not yet universal in most of the developing countries. HIB meningitis results in 5% mortality rate and around 20% morbidity rate. The percentage of hearing loss among HIB meningitis (10%) is less than that of pneumococcus (28%) but because of higher percentage of childhood meningitis caused by HIB, the number of patients with hearing deficit due to HIB is more than any other organism. Other neurological defects include: MR 6%, paresis 5%, and seizure disorder 6%. Dexamethasone adjunctive therapy has been shown to decrease the incidence of hearing loss but not other neurological sequelae.

Epiglottitis

In contrast to other HIB invasive diseases that usually occur during the first 2 years of life, epiglottitis tends to occur more commonly in children 2–4 years of age. The affected child usually presents with abrupt onset of high fever, inspiratory stridor, difficulty in breathing, muffled voice, and drooling. The child is toxic and adopts a characteristic sitting position with protrusion of the jaw and extension of the neck to ease the breathing. There is usually no associated cough. Cautious examination of such children is required. The throat examination should not be attempted until assurance that adequate intervention methods and expertise in intubation are available if needed. This means that the patient should be examined in operation room in the presence of an otolaryngologist and anesthetist. Lateral neck radiography will show enlarged epiglottis (thumb sign), however the patient should not be moved to the radiology department unless his or her condition is stable and should be associated with an expert physician should intervention be required.

Cellulitis

Facial cellulitis in children 3 months to 5 years of age is commonly due to HIB. Periorbital cellulitis is the most common presentation.

Acute Lower Respiratory Tract Infections

HIB constitutes a major cause of lower respiratory tract infections in developing countries. In Gambia, it is estimated that the incidence of pneumonia due to HIB is around 300/100,000 children/year resulting in 40 deaths/100,000 children/year. It is assumed that this high incidence is due to early colonization with HIB.

Septic Arthritis and Osteomyelitis

HIB is a common cause of septic arthritis in children between 3 months and 5 years of age. It rarely causes osteomyelitis at any age group.

Miscellaneous Infection

HIB can cause infection at any organ including endocarditis, pericarditis, conjunctivitis, peritonitis, liver abscess, salpingitis, vaginitis, and brain abscess.

Other *H. influenzae* Serotypes

These are rare cause of childhood infections, however they can cause similar spectrum of disease as that of HIB. It is not known whether introduction of HIB conjugate vaccine will result in increase in incidence of infections due to other serotypes, however this was not proved by a study done in United States that showed no difference before and after 3 years of introducing HIB vaccine.

Nonencapsulated *H. influenzae* Infection

These are common causes of otitis media and sinusitis preceded only by *S. pneumoniae*. Most of these strains are b-lactamase producers. HIB conjugate vaccine does not confer immunity against them. There are increasing reports of these organisms causing neonatal sepsis. They also can cause invasive diseases.

Illustrative Case

A 5-month-old girl who has a ventriculoperitoneal shunt presented with a 3-day history of fever and vomiting. Computed tomography scan of the brain showed an increase of ventricular size indicating shunt malfunction. Cerebrospinal fluid culture grew nontypeable *H. influenzae*. Intravenous ceftriaxone was given for 3 days with no response. Shunt was removed and external ventricular drain was inserted and CSF was obtained in 3 consecutive days and came to be negative. Shunt was reinserted after 7 days and ceftriaxone was given for a total of 14 days and the patient responded well.

H. influenzae Biotype Aegypticus

This is a common cause of epidemic conjunctivitis in different parts of the world. It is also the cause of distinctive invasive disease that is only recognized in Brazil. It is called Brazilian purpuric fever (BPF). BPF is a septicemia disease that is characterized by high fever, toxicity, shock, and purpura arising within 7–10 days after resolving conjunctivitis that is caused by *H. influenzae* biotype aegypticus. It results in high mortality rate and usually spare CNS.

Diagnosis

H. influenzae infections can be diagnosed by clinical features and isolating the organism from the site of infection. Antigen detection studies including counter current immunoelectrophoresis and latex agglutination test can be helpful in identifying the organism in CSF, urine, and serum. Latex agglutination test has a 90–95% sensitivity and specificity in identifying HIB in CSF.

Therapy

Currently the empiric therapy of suspected invasive haemophilus infection is third generation cephalosporins (ceftriaxone 100 mg/kg/day once or twice daily or cefotaxime 150 mg/kg/day three or four times daily). This is because of the increasing incidence of ampicillin resistance among HIB that varies between 20% and 70% in different parts of the world. Chloramphenicol resistance is very low, however because of its potential hematological toxicity and the availability of safer medications, its use is decreasing. HIB resistance to chloramphenicol is mediated by the enzyme acyltransferase. It is very rare to have HIB resistant to the ampicillin and chloramphenicol combination. Otitis media and sinusitis are usually responsive to amoxicillin even if they are resistant in vitro. This is because of the high level achieved in middle ear. Therefore the initial drug of choice for otitis media and sinusitis remains to be amoxicillin.

Prevention

Immunization

HIB conjugate vaccine is now available and proven to be immunogenic in young infants. Since its inclusion in the primary series of childhood immunization in some parts of the world, it resulted in significant reduction of diseases due to HIB.

Prophylaxis

Household Contacts

1. Household contacts with children <12 months of age should be prophylaxed regardless of the immunization status.
2. Household contacts with children >12 months of age who receive the primary series and booster at 12 months or older do not need to be prophylaxed.
3. Household contacts with children <4 years of age who are incompletely vaccinated should be prophylaxed.

Nursing Schools and Day Care Centers

1. If two cases arise in the same center within 60 days, all the contacts should be prophylaxed if there are children who are unvaccinated or incompletely vaccinated.
2. In day care attended by children below 2 years of age and whose contact is more than 25 h/week, all contact should be prophylaxed if there are non-vaccinated or incompletely vaccinated children.
3. Day care attended by children >2 years of age need not be prophylaxed regardless of vaccination status.
4. Pregnant women need not be prophylaxed because of the potential risk of rifampin on the fetus.
5. Prophylactic drugs – Rifampin 20 mg/kg once daily for 4 days.

82 Infant Botulism

Mohammad Al-Shaalan

Botulism is a disease caused by *Clostridium botulinum* (*C. botulinum*). Three manifestations are known: food botulism, wound botulism, and infant botulism. Food botulism occurs as a result of exposure to botulinum toxin whereas infant botulism and wound botulism occur as a result to exposure to botulinum spores. Infant botulism is the most concerning for pediatricians. Infant botulism was first known in 1976 after Pickett et al. described an infant with hypotonia.

Causative Agent

C. botulinum is a Gram positive, spore forming, and nonmotile bacillus. It grows under anaerobic conditions and is distributed widely in the environment (soil, water, etc.). It produces very lethal toxins of many types, A through G. A and B are the most common toxins causing infantile botulism. Rare cases of toxin E disease due to *C. butyricum* and type F due to *C. baratii* have been reported. Type F toxin tend to produce disease in the very young infant and tend to be more severe. The only confirmed source of acquiring *C. botulinum* spores by an infant is ingestion of honey although this history is positive in only 20–35% of the cases.

Pathogenesis

Although honey is a known source of the spores, it is now rarely consumed by infants. Therefore the main source of botulinum spores is the environment, mainly the soil. Disruption of soil by farming or construction transmits the spores in dust particles to foods or water. Once consumed by the baby, spores germinate in the gastrointestinal tract producing the organisms which in turn produce the toxin. The toxin is absorbed and reaches the blood. From the blood it is distributed to cholinergic terminals including neuromuscular junction, ganglionic synapses, and parasympathetic postganglionic terminals. It binds to acetylcholine vesicles and thus prevents its secretion. This results in paralysis and hypotonia.

Clinical Manifestation

Infant botulism occurs in infants 6 days to 12 months of age and not later. Risk factors for acquiring botulism include consumption of honey, and constipation. The classic presentation is manifested by weak cry, poor oral intake, profound hypotonia, and constipation. Constipation usually precedes the other manifestations by 3 days to few weeks.

The hallmark of the disease is profound hypotonia. Characteristically it is descending in nature starting in the neck and proceeding caudally. In addition cranial nerves may be involved resulting in weakening of the pharyngeal muscles. This in turn results in weak, feeble cry, difficulty in swallowing, and regurgitation. Ophthalmoplegia and poor pupillary reaction to light may also occur.

Autonomic dysfunction may result in mucus membrane dryness and fluctuation in blood pressure and pulse rate.

Clinical diagnosis can be reached with certainty when full complement of symptoms and signs are present; however, infant botulism may present with a myriad of pictures ranging from asymptomatic disease to fulminant fatal disease.

Infantile botulism should be differentiated from other diseases that may present with similar picture including sepsis, Gullain-Barre disease, poliomyelitis, myasthenia gravis, heavy metal toxicity, organophosphorus toxicity, and metabolic diseases.

Lab Diagnosis

It is very rare to isolate *C. botulinum* from stool of normal infants; therefore isolating it from stool of an infant with clinical findings of botulism is regarded highly suggestive of infant botulism. *C. botulinum* can be isolated from the stool up to 150 days after infection. However, biologic mouse toxin assay is the only clinically evaluated diagnostic test. Recently ELISA has been developed for rapid detection of toxin A and B in the serum or fecal filtrate. This test allows detection in 24 h as compared to 4 days that are required for mouse assay.

Table 82.1
Management targets to optimize outcome (in addition to use of BabyBIG®) (From: Long S (March 2007) Infant botulism and treatment with BIG-IV (BabyBIG_). The Pediatric Infectious Disease Journal • vol 26(3))

• Perform preemptive intubation when protection of airway is compromised; extubate when gag reflex, swallow, and sustained activity against gravity is restored
• Perform ventilator-associated pneumonia prevention "bundle"
• Differentiate hyponatremia due to dehydration vs. SIADH
• Position supine with head of planar mattress (not head of infant) raised 30°; small (washcloth size) roll behind neck; roll behind thighs (to minimize venous pooling & SIADH); smooth infant and bed clothing to avoid pressure from folds
• Institute nasojejunal feedings (continuous initially) within 48 h of admission, and remove intravenous catheter(s)
• Avoid use of unnecessary antibiotics, Foley catheters

Table 82.2
Differences in outcomes of infants treated with BIG-IV* (From: Arnon SS et al (2006) Human botulism immune globulin for infant botulism. N Engl J Med 354:462–471)

Randomized placebo-controlled trial (129 infants)[a]		
Duration of	Placebo	BIG-IV
Hospitalization	5.7 weeks	2.6 weeks
ICU care	5.0 weeks	1.8 weeks
Mechanical ventilation	4.4 weeks	1.8 weeks
Tube feeding	10.0 weeks	3.6 weeks
Total hospital charges	$163,000	$74,800
Open-label use (366 infants)		
Duration of hospitalization	BIG-IV @ 4–7 days hosp 2.9 weeks	BIG-IV @ <4 days hosp 2.0 weeks

*All differences statistically significant; *P* values ≤ 0.001
[a]Infants eligible only if <3 hospital days

Supportive tests include characteristic EMG picture of brief, small, abundant motor-unit potentials (BSAP). This can be observed in 90% of affected infants. Nerve conduction is usually normal.

Treatment

Management of infantile botulism relies mainly on supportive care (*Table 82.1*). This means supplying oxygen or artificial ventilation if needed. Two important factors have been associated with respiratory decompensation in these patients; administration of aminoglycoside antibiotics and neck flexion during positioning for lumbar puncture of computerized tomography. Aminoglycosides may potentiate neuromuscular blockade and therefore should be avoided in these patients. Most of the affected infants have poor suck and swallowing and therefore need nasogastric or nasojejunal feedings and occasionally parenteral nutrition. Care should be provided to prevent aspiration. Antibiotics have no room in treatment except for secondary bacterial infections. Botulism immunoglobulin intravenous (BIG-IV) is now available and has revolutionized therapy of infant botulism. It is derived from pooled human plasma of immunized adult volunteers and it neutralizes free toxin. Its use has improved morbidity significantly (*Table 82.2*). It should be given immediately based on clinical diagnosis without awaiting confirmatory test. It is most effective if given within the first 72 h of illness; however, it should be offered even after 72 h. With appropriate supportive management, the outcome is usually excellent with a mortality rate of less than 2%. The only preventive measure is avoiding honey in infant feeding. Relapse is rare and there are no special infection control issues.

83 Listeria Monocytogenes (Including Listeriosis)

Benjamin Mackowiak

Definition/Classification

Listeriosis is an infection caused by the bacterium *Listeria monocytogenes* with a spectrum of disease ranging from asymptomatic infections in the immunocompetent patient to severe sepsis and death in certain populations including neonates. It is one of the three major worldwide causes of neonatal meningitis.

Etiology

The genus *Listeria* was named after Sir Joseph Lister, father of antiseptic surgery, while *monocytogenes* refers to the monocytosis often seen in animals infected with the bacteria. *Listeria* spp. are ubiquitous, gram-positive, facultatively anaerobic, intracellular, motile bacilli found in many environments including soil, water, and refrigerated foods. The organisms can survive in acidic, salty, and cold conditions. *Listeria* spp. can infect multiple animal species but, apart from scattered case reports involving *Listeria ivanovii*, *L. monocytogenes* is the main species to cause disease in humans. Furthermore, of the *Listeria monocytogenes* serotypes, three are responsible for 95% of infections in humans: 1/2a, 1/2b, and 4b. Serotype 4b appears to be more virulent than the others.

Epidemiology

Listeriosis is an uncommon cause of infection in the general population but it can lead to serious infections in pregnant women and their fetus, neonates, the elderly, and immunocompromised patients. While *Listeria* spp. are found throughout the world, listeriosis is more common in industrialized countries. Cases are mostly sporadic but can occur as part of an outbreak. The incidence varies from 0.1 to 11.3 per million in different countries. Infection rates also vary by age (*Fig. 83.1*) and are inversely proportional to gestational age. Males and females are affected equally. Women are 20 times more likely to develop a listerial infection during pregnancy, mostly in the third trimester. This is likely due to impaired cell-mediated immunity during the third trimester of pregnancy.

Several nations have seen decreases in incidence in the last 2 decades following public health and food industry initiatives in response to foodborne outbreaks. For example, France saw a 68% reduction in listeriosis from 1987 to 1997 while the United States of America saw a 40% decline from 1996 to 2004. Still, outbreaks have been reported in several countries in the past 10 years linked to dairy and ready-to-eat products. *Listeria* is also found in the stool of 5% of healthy adults.

Pathogenesis

Both early-onset and late-onset neonatal infections can be caused by transplacental transmission. The pregnant woman ingests *Listeria*. The bacterium then crosses the intestinal mucosa into the bloodstream where it travels to the placenta and infects the fetus. Ascending infection during pregnancy can also lead to early-onset listeriosis while late-onset infection can be acquired by exposure of the neonate to *Listeria* while passing through the contaminated birth canal. Infections after the neonatal period are all thought to be foodborne or via exposure to an extrinsic source.

The mechanism by which Listeria becomes pathogenic and invades cells continues to be studied. First, the bacteria gain access to the blood stream and other cells, including macrophages and placental trophoblasts, via the interaction of surface proteins such as internalin A and internalin B with cell-surface proteins like E-cadherin. One hypothesis explaining *Listeria*'s tropism for tissues like the central nervous system and the placental unit is that E-cadherin, for example, is found specifically on the cell surface of trophoblasts. Once endocytosed, the bacteria lyse the vacuoles which house them via the action of

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_83,

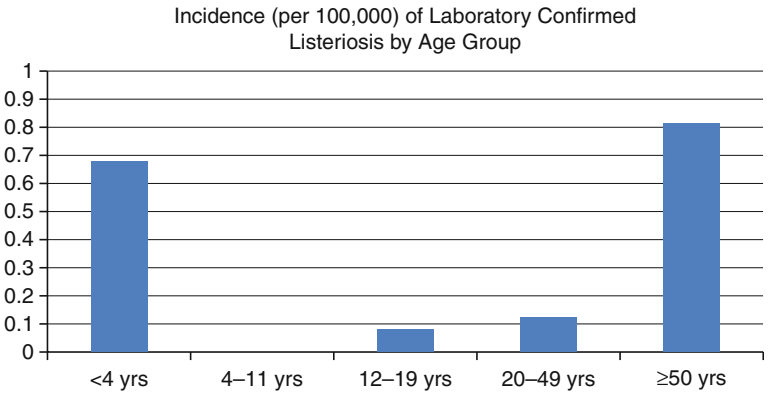

Figure 83.1
From preliminary FoodNet data on the incidence of infection in the USA with pathogens transmitted commonly through food – 10 states, 2009

proteins like lysteriolysin O and become motile within the cytoplasm by acquiring an actin-rich "comet-tail." *Listeria* then migrates to the cell periphery where it spreads to neighboring or immune cells like macrophages via cell wall protrusions that are endocytosed. The bacteria can therefore hijack the very cells, macrophages, which otherwise help clear intracellular infections.

Pathology

Placental pathology demonstrates multiple, well-defined macroabscesses while severe fetal infection is characterized by disseminated granulomatous lesions with microabscesses found throughout the body, including the skin.

Clinical Manifestations

Pregnant women infected with *Listeria* may be asymptomatic or have a flu-like illness. Fetal infection leads to premature birth or neonatal death in 22% of cases. While there are no pathognomic clinical features of listeriosis in the neonate, early-onset neonatal listeriosis presents on average at 1.5 days of life with signs and symptoms of sepsis. Other clinical manifestations include chorioamnionitis, meningitis, and pneumonia. In severe disease, granulomas and abscesses can be found disseminated throughout the body and skin, termed granulomatosis infantisepticum. The associated rash is characterized by lesions found mainly on the trunk or extremities which are maculopapular or papulovesicular in nature.

Late-onset listeriosis is less common than early-onset disease and presents around 2 weeks of life with nonspecific signs and symptoms of illness like fever, lethargy, and decreased feeding. It most frequently presents with meningitis and is associated with serotype 4b.

Non-neonatal pediatric listeriosis is rare even in the immunocompromised patient and has a variety of presentations ranging from self-limited gastroenteritis accompanied by fever and diarrhea to meningoencephalitis.

Diagnosis
