ulcerations secondary to body piercing, venous insufficiency with stasis, inflammatory dermatoses, dermatophyte infections, insect bites, and surgical incisions. Patients with preexisting lymphedema secondary to past surgeries, trauma, thromboses, or congenital vascular malformations are at increased risk for erysipelas and cellulitis. Differential diagnosis includes contact dermatitis, arthropod bite dermatitis, necrotizing fasciitis, and eosinophilic cellulitis.

Treatment includes elevation of the affected area, compresses for ulcerated or necrotic areas, and antibiotics, e.g., penicillin for group A streptococcal infections, first-generation cephalosporin or clindamycin for staphylococcal infections, and in patients with penicillin allergy. Patients with facial or orbital cellulitis require hospitalization and parenteral antibiotics.

Corynebacterium Infections

Pitted Keratolysis (PK)

Pitted keratolysis caused by *Corynebacterium* species *Micrococcus sedentarius* and *Dermatophilus congolensis* is a superficial infection that occurs within the stratum corneum (SC) due to the bacterial production of proteolytic enzymes that digest the outermost layer of the skin. PK is malodorous, 1–2 mm craters, or shallow erosions that coalesce into depressed plaques with moist texture (+/− frank maceration) on the plantar feet and around the toes. It occurs more commonly in males and patients with excessively sweaty feet or exposure to wet environments or boots.

Tinea pedis is the differentiating diagnosis, and KOH prep can confirm or negate, though the distinct pungent odor of PK generally allows the distinction to be made clinically. Treatment includes clindamycin solution, erythromycin solution, mupirocin ointment, or benzoyl peroxide gel for 2–3 weeks. Excessive sweating can be addressed by the use of aluminum chloride preparations or botulinum toxin injections. Patients should avoid wet work and prolonged periods of wearing boots.

Erythrasma

Erythrasma caused by *Corynebacterium minutissimum*, a Gram-positive rod that produces porphyrins, mainly occurs in adults and only occasionally in children. Affected patients have pink to brownish scaling plaques most commonly in the groin and axillae, less so in the inframammary area, abdominal skin folds, gluteal cleft, and interdigital spaces of the toes. Infection is generally asymptomatic, but pruritus may occur, often exacerbated by heat and humidity.

The porphyrins produced by the positive rod cause a coral-pink fluorescence with Wood's light examination, which helps to clinch the diagnosis. Other entities to consider include: tinea infection, Candida or frictional intertrigo (KOH prep for diagnosis), psoriasis, and seborrheic or nonspecific dermatitis. Treatment with topical clindamycin or erythromycin is usually curative or oral antibiotics for extensive disease.

Neisseria meningitidis

Meningococcemia

Meningococcemia is caused by *Neisseria meningitidis*, a Gram-negative diplococcus bacterium spread to asymptomatic carriers via respiratory droplets. Infection is bimodal and typically occurs in children less than 4 years old (neonates <6 months are often protected due to maternal immunoglobulin G antibodies) or adolescents 15–19 years old. Meningococcemia is a viral-like illness with fever, headache, neck stiffness, and photophobia; these signs will often be absent making the diagnosis more difficult in children <2 years old. The infection rapidly evolves into meningitis or septicemia and irreversible shock and death may occur within hours of onset of symptoms.

Most patients (2/3) will initially have blanchable erythematous macules and papules and later small petechiae, usually on the trunk and lower extremities. The petechiae rapidly coalesce into well-demarcated ecchymoses. Extensive purpura with gunmetal gray color occur in fulminant infections, followed by sloughing of the skin, gangrene,

and loss of limbs. Patients with fulminant infections have CNS abnormalities and sepsis.

Patients with suspected infection need hospitalization. The workup should be prompt and includes blood and CSF Gram stain and culture, followed by empiric antibiotic treatment, with broad spectrum and/or multiple IV antibiotics, e.g., benzylpenicillin, cefotaxime, or ceftriaxone. Timely management is crucial since the mortality rate is 5% and 90% if DIC develops. To prevent outbreaks and further spread of infection, household and other close contacts deserve prophylaxis with rifampin, ceftriaxone, or ciprofloxacin.

Pseudomonal Infections

Pseudomonas is a Gram-negative, aerobic rod that produces pyocyanin which causes the notable green color, may be a normal part of the skin flora, especially in the ear canal, groin, and axillae. *Pseudomonas* has a fruity or grape-like aroma associated with infection, and although the odor is not always present or noted, it can be very helpful in making a diagnosis.

The most common cause of *Pseudomonas* infection in normal hosts is hot-tub folliculitis which occurs after exposure to improperly chlorinated hot tubs or spas. Children are particularly susceptible to the infection after bathtub toys or sponges are used in hot tubs and then stored in mesh containers without being rinsed, harboring *Pseudomonas*. Patients may have low-grade fever and malaise but, typically, they are asymptomatic with edematous perifollicular red papules and pustules on the trunk and proximal extremities, although may be pruritic and/or painful. The infection may be associated with otitis externa from the hot-tub exposure and may occur in swimmers secondary to water collection in the external auditory canal.

The differential diagnosis includes *S. aureus* folliculitis, bug bites, and nodular scabies. Culture should be obtained to confirm the diagnosis. Treatment is not necessary since papules resolve spontaneously; however, low-potency corticosteroid may be useful if pruritus is present. As prevention, hot-tub chlorination must be employed or properly adjusted (often necessary to drain hot tub), and toys must be cleaned with bleach, though discarding them would be best. Associated otitis externa deserves treatment with ototopic gentamycin, tobramycin, or ciprofloxacin solution.

Please refer to *Table 149.1* for additional examples of *Pseudomonas* infections.

Table 149.1
Other physical findings secondary to *Pseudomonas*

Condition	Signs/symptoms	Exacerbating factors	Treatment
Pseudomonas nail	Greenish-black discoloration of nails associated with onycholysis	Moist environments/ water work	Gentamycin, tobramycin, or ciprofloxacin solution
Interdigital infections	Macerated, erythematous plaques within toe spaces	Hyperhidrosis, chronic moisture, exposure to wet environments	Acetic acid soaks
			Decrease moisture with aluminum chloride or botulinum toxin injections for hyperhidrosis
Chronic wounds with secondary infection	Associated with wounds of epidermolysis bullosa, thermal burns, neuropathic ulcers, ulcerated hemangiomas of infancy	Uncontrolled/poorly controlled underlying disease	Topical or oral antibiotics depending on severity and distribution of wounds, coupled with treatment of underlying medical condition to prevent future colonization
Ecthyma gangrenosum	Edematous vesicopustule that becomes hemorrhagic and develops into punched-out ulcer with black eschar with surrounding edema	Immunocompromised patients	Hospitalization
			Culture suspected lesions
			Parenteral antibiotic treatment as soon as possible
			Blood cultures and biopsy to confirm diagnosis and rule out bacterial/fungal process, pyoderma gangrenosum, or Sweet's syndrome
	Patients are often bacteremic and septic		Debridement of necrotic tissue

Viral Infections

Viral infections are commonplace in the general pediatrician's office and often exhibit nonspecific skin findings, fever, and malaise. Most viral illnesses are self-limited and rarely warrant dermatologic management and treatment. The most common viral diseases for a dermatologist are molluscum contagiosum and warts.

Classic Exanthems of Childhood

Order	Exanthem
First	Rubeola or measles
Second	Scarlet fever
Third	Rubella or German measles
Fourth	Filatow–Dukes' disease[a]
Fifth	Erythema infectiosum or Parvovirus
Sixth	Roseola or exanthem subitum

[a]Not a separate exanthem, variant of scarlet fever or toxin-producing staphylococcal disease

Measles (Rubeola, First Disease)

Rubeola caused by an RNA morbillivirus, of the Paramyxoviridae family, is a common infectious disease with worldwide distribution and appreciable mortality often related to early age of exposure and poor nutritional status.

Transmission occurs via respiratory spread, 1–2 days before the prodrome until 4 days after the onset of exanthem; the incubation period is 8–12 days. Prodrome lasts 2–4 days, and patients experience high fever, coryza, cough, conjunctivitis, often with white spots on an erythematous base on the buccal mucosa opposite the molars which are Koplik spots and pathognomonic for the disease. The exanthem typically begins 14 days after exposure with red-brown pruritic macules and papules that initially begin along the hairline, behind the ears, and on the neck, which spread to the trunk and become generalized by day 3. The exanthem begins to fade within 5 days (*Fig. 149.5*).

Complications are more likely to occur in young children (<5 years old), young adults (>20 years old), and immunodeficient and malnourished (specifically with low levels of vitamin A) patients, most commonly otitis media and bronchopneumonia, less so encephalitis, myocarditis, pericarditis, and death due to respiratory and neurologic sequelae. The mortality rate in the USA is low, 0.1–0.2%, but worldwide, measles is still a leading cause of death accounting for 197,000 deaths annually.

Figure 149.5
Measles

Patients with measles should be isolated and treated by supportive care measures. Oral rehydration may be all that is required; however, intravenous hydration may be necessary. Dietary supplementation with vitamin A is essential for all kids with measles and reduces mortality by 50% and helps prevent eye damage and blindness. Disease has diminished dramatically, especially in the USA since the advent of the measles vaccine in 1963. However, resurgence has occurred in the last two decades because of parental refusal of about vaccination and home schooling (loss of compulsory vaccination). The measles vaccine is a live attenuated virus and part of the measles, mumps, and rubella (MMR) vaccine. The first dose is given at 12–15 months and the second dose at 4–6 years. Mild exanthem may occur 10–14 days after administration of the vaccine.

Rubella (German Measles, Third Disease)

Rubella caused by Rubivirus, an RNA virus of the Togaviridae family, has worldwide distribution, and transmission occurs via respiratory droplets. The incubation period is 14–21 days, and the infection begins in the nasopharynx followed by a primary and secondary viremia, which causes a generalized systemic infection. Patients are infectious 5–7 days prior to exanthem and for 3–5 days afterward.

Children typically have no prodrome but, occasionally, they have low-grade fever, painful occipital lymphadenopathy, and ocular pain. Adolescents and adults are symptomatic during the prodrome with fever, malaise, sore throat, nausea, and anorexia. Children develop a mild exanthem, but infection is subclinical in 50% of cases. When present, the exanthem begins on the face and neck with pink to erythematous macules and papules that generalize within 24–48 h. An associated enanthem of petechiae on the hard palate, known as Forschheimer spots, may develop.

Arthritis and arthralgias occur with increased age and are more common among women. Within 2–3 days, the exanthem fades, initially on the face and then elsewhere.

In most cases, diagnosis is made clinically and, in more severe cases, serologic testing can be useful to rule out other viral exanthems. Detection of virus-specific immunoglobulin M (IgM) antibody in acute serum and a fourfold rise in antibody titer between acute and convalescent sera is diagnostic of rubella. Affected patients should be isolated and kept at home for 7 days following the onset of disease; given the mild nature, generally no treatment is required. Potential complications include peripheral neuritis, encephalitis, and thrombocytopenia purpura. If rubella is contracted during the first trimester of pregnancy, it can have devastating fetal effects, including intrauterine growth retardation, cataracts, glaucoma, microphthalmia, chorioretinitis, sensorineural deafness, patent ductus arteriosus, atrial and ventricular septal defects, and pulmonary stenosis. Neonates may have violaceous macules/papules secondary to extramedullary hematopoiesis ("blueberry muffin" baby), and 20% of patients will have hematologic abnormalities. The virus can be excreted for 1–2 years.

Introduction of the live vaccine in 1969 reduced the incidence of Rubella by 98%, and the vaccine produces seroconversion in 98% of patients. Today, cases are due to refusal or failure to be vaccinated. Children should receive the measles, mumps, and rubella (MMR) vaccine at 12–15 months and, then, at 4–6 years. Side effects occur in 5–15% of children and include exanthem, fever, and lymphadenopathy. Older children may have arthralgias and arthritis.

Erythema Infectiosum/Parvovirus (Fifth Disease)

Erythema Infectiosum, first recognized and described in 1889, represents infection with Parvovirus B19, a single-stranded DNA virus. The infection, like other viral exanthems, is widespread and typically occurs in young children. It is most common during the winter and spring, and transmission occurs via respiratory droplets, hematogenous spread, and transplacental exchange. The incubation period is 4–14 days and the prodrome is absent or minimal; if symptoms do occur, patients have low-grade fever, headache, sore throat, rhinorrhea, and malaise. The exanthem has two phases, the first, bright red erythematous patches on the cheeks with the characteristic "slapped cheek" appearance; the second, 1–4 days later, lacy, reticulated macules and papules on the proximal extremities, which spread to the trunk. Children, especially adolescents, may have arthralgias and arthritis (knees, ankles, wrists, and elbows most commonly affected). The exanthem is essentially asymptomatic but may be worsened with heat and sun exposure, and fades within a few days to weeks. It is important to counsel parents that the rash may recur with heat (including warm baths), sun exposure, friction, crying, or exercise for up to 4–6 weeks.

Another parvovirus infection is the papular-purpuric gloves and socks syndrome, an entity more commonly seen in adolescents and characterized by the sudden onset of erythema and edema of the palms and soles. Patients develop petechiae in the same distribution, which becomes sharply demarcated confluent purpura. Petechiae may also be found on other areas of the body and oral mucosa. Patients often have pain, burning, or itch, especially on the hands and feet.

The differential diagnosis of erythema infectiosum includes: scarlet fever, rubeola, rubella, roseola, other viral exanthems, erysipelas (face), and drug eruption. In patients with arthralgias and arthritis, lupus erythematosus, Henoch–Schonlein purpura, and juvenile rheumatoid arthritis should also be considered. Children with the papular-purpuric syndrome should be evaluated for Rocky Mountain Spotted Fever or meningococcemia. Parvovirus is a clinical diagnosis, but may be confirmed with elevated levels of IgG and IgM. IgM levels persist for 2–3 months following the infection. Erythema infectiosum may be complicated by anemia in many patients, which may progress to aplastic anemia in patients with sickle-cell disease, other hemoglobinopathies, or those on chemotherapy. Pregnant women with an active infection have a 33% chance of fetal infection, although the vast majority of these infants are born without sequelae. Women in the first and second trimester are at greatest risk. The infection can rarely cause significant anemia leading to hydrops fetalis and death. Children are viremic 1 week prior to exanthem, thus no isolation is recommended at the time of the appearance of the rash.

Children typically recover spontaneously, and no treatment is needed, unless complications arise. Supportive care with rehydration therapy, nonsteroidal anti-inflammatory agents for arthralgias and arthritis, and antipyretics for fever are generally all that is needed.

Herpes Viruses (Herpesviridae)

There are eight human herpes viruses (HHV) with skin manifestations and some with organ involvement. The

Table 149.2
Properties of Herpes viruses

Human Herpes type	Name	Subfamily	Target cell type	Latency	Transmission
1	Herpes simplex-1 (HSV-1)	Alpha	Mucoepithelia	Neuron	Close contact
2	Herpes simplex-2 (HSV-2)	Alpha	Mucoepithelia	Neuron	Close contact, usually sexual
3	Varicella Zoster virus (VZV)	Alpha	Mucoepithelia	Neuron	Contact or respiratory route
4	Epstein–Barr virus (EBV)	Gamma	B lymphocyte, epithelia	B lymphocytes	Saliva
5	Cytomegalovirus (CMV)	Beta	Epithelia, monocytes, lymphocytes	Monocytes, lymphocytes, and possibly others	Contact, blood transfusions, transplantation, congenital
6	Human herpes virus-6 (HHV-6)	Beta	T lymphocytes and others	T lymphocytes and others	Contact, respiratory route
7	Human herpes virus-7 (HHV-7)	Beta	T lymphocytes and others	T lymphocytes and others	Unknown
8	Human herpes virus-8 (HHV-8) Kaposi's sarcoma-associated herpes virus (KSHV)	Gamma	Endothelial cells	Unknown	Possibly exchange of body fluids

viruses have substantial morbidity and mortality in humans and a worldwide distribution. The unifying characteristic of all herpes viruses is the ability to remain latent in various cells (dependent on specific virus) after initial infection. Technological advances allow for earlier diagnosis and treatment. Cell culture and immunospecific or molecular methods are now available for rapid diagnosis of HSV, VZV, CMV, EBV, HHV 6, and HHV 8 (*Table 149.2*).

Herpes Simplex Virus (Human Herpes Virus 1 and 2)

HSV 1 and 2 are double-stranded DNA viruses which were first isolated in the 1960s. Infection is transmitted by direct contact, but viral shedding may occur during asymptomatic periods. HSV1 is usually associated with mucocutaneous disease, i.e., stomatitis, and HSV2 with genital disease. HSV1 remains latent in the trigeminal ganglia and reactivation affects the face and the oropharyngeal and ocular mucosae; HSV2 has a more efficient reactivation in the lumbosacral ganglia, affecting the hips, buttocks, genitalia, and lower extremities. HSV1 has been increasingly cited as the causative agent in genital herpes secondary to orogenital contact.

HSV 1 and 2 can infect people of all ages, causing a wide spectrum of disease, ranging from asymptomatic to severe systemic illness with a high fatality rate. The incubation period is typically 6–8 days but may vary from 1 to 26 days.

Children may be asymptomatic during primary HSV1 infection, usually a gingivostomatitis, or they may have high fever, malaise, irritability, lymphadenopathy, pain with swallowing, and mucosal erythema, ulcerations, exudates, and crusting. Dehydration may occur with oral disease. HSV1 recurrences are typically less severe and are for shorter duration, but secondary infections may occur with a prodrome of pain, tingling, itching, or burning at the affected site. Within 24 h of the prodrome, patients develop small, grouped vesicles on an erythematous base which coalesce into larger vesicles, bullae, pustules, and erosions that may crust. Disease typically occurs at the mucocutaneous junction of the lip and lasts 4–7 days, typically healing without scarring. Triggers and potentially exacerbating factors include sun exposure, illness (especially with fever), stress, and immunosuppression (*Fig. 149.6*).

Primary genital herpes is predominantly a sexually transmitted event, usually in sexually active adolescents or adults; it may occur in young children, raising the question of sexual abuse.

Figure 149.6
HSV1

Differential diagnosis includes impetigo, herpes zoster, hand foot and mouth disease, molluscum contagiosum, and allergic contact dermatitis. Infections may be complicated by erythema multiforme, often indistinguishable from HSV disease, especially with involvement of the oral muscosa. Diagnosis is often clinical, but Tzanck smear of vesicles, culture, direct fluorescent antibody, and PCR can help to confirm.

Patients are contagious until lesions have crusted; as such, parents and patients should be advised to avoid direct contact with other children and pregnant women. Treatment varies depending on the severity of the outbreak. Asymptomatic or mild cases of orolabial herpes simplex can be treated with compresses, bland emollients, and oral analgesics. For more severe or recurrent episodes, antivirals are the treatment of choice. Topical therapy with penciclovir or acyclovir may provide minimal improvement. Oral therapy is far more efficacious, although the dosing and cost may be prohibitive. Acyclovir, valacyclovir (approved in children >12 years old), and famciclovir (recently FDA approved in children) are available for oral use. In patients with frequent mucocutaneous or genital outbreaks or in immunosuppressed patients, prophylactic suppressive treatment may be necessary.

Herpetic Whitlow

Herpetic whitlow is a primary or secondary infection in children and health-care workers caused by HSV1 producing deep, tender vesicles and pustules on the fingers. In children, whitlow occurs when kids put their hands and fingers in the mouth of an infected person. Whitlow may also follow HSV2 infection in sexually active adolescents.

The differential diagnosis includes: blistering distal dactylitis secondary to *S. pyogenes*, orf (sheep pox), and milker's nodules (pseudocowpox). Clinical history will usually help differentiate these entities, but culture may be useful in unclear cases.

Neonatal Herpes

Neonatal herpes infection is acquired during delivery, rarely from intrauterine placental infections, from mothers who are infected with HSV1 or more commonly HSV2 (75% of cases), the latter associated with more severe disease.

The incidence of neonatal herpes is 1 per 3,000–3,200 live births. With an active lesion at the time of delivery, the risk of neonatal infection is 30–50% and women with primary infections are more likely to transmit the disease. With recurrent infections, the rate is significantly lower (2–5%). However, of all cases of neonatal herpes, 60–80% of the mothers have no history of genital infection and no evidence of infection at the time of delivery, thus making prevention difficult. With neonatal infection severe sequelae and death occur in greater than 50% of cases, most often due to rapidly progressive multiple organ failure.

Infants with neonatal herpes typically develop vesicles and bullae within the first 4 weeks of life. The disease can be categorized into three types: skin, eye, or mouth (SEM); CNS; and disseminated disease. SEM type has an excellent prognosis with antiviral therapy, but 75% of cases progress to disseminated disease if not treated. CNS and disseminated disease have a poor prognosis with high morbidity and mortality. If neonatal herpes is suspected, prompt

treatment with antiviral agents is essential to prevent CNS complications and death.

If a pregnant woman has a history of genital herpes, treatment with acyclovir 500 mg daily from 36 weeks until delivery may be attempted, but the efficacy of this approach in preventing transmission to the infant is not clear. If genital disease is present at the time of delivery, Cesarean section should be performed. If vaginal delivery takes place in a woman with HSV disease, neonate deserves careful monitoring. Physicians must be vigilant in regard to detecting and treating neonatal herpes. Acyclovir 20 mg/kg/day every 8 hours for a minimum of 14 days is the recommended treatment for suspected cases. Longer duration of therapy is often required for the treatment of disseminated and CNS infections.

Figure 149.7
Eczema herpeticum

Eczema Herpeticum (Kaposi Varicellifom Eruption)

Eczema herpeticum is an HSV infection in a patient with a primary skin disease, most commonly, atopic dermatitis. The clinical presentation may vary from a few vesicles in areas of dermatitis to fulminating disseminated disease. Patients typically have fever, malaise, and extreme discomfort. Disseminated infection previously had a 20% mortality rate usually due to viremia or secondary bacterial infection, with the advent and use of antiviral treatment; morbidity and mortality have decreased significantly. Mild cases deserve treatment with acyclovir 20–30 mg/kg/day five times daily (up to 200 mg five times daily) or with valacyclovir. Most patients deserve hospitalization for supportive care and intravenous acyclovir. Eczema herpeticum may be complicated by secondary bacterial infection. If suspected, obtain culture and start antibiotic treatment (*Fig. 149.7*).

Varicella Zoster Virus (VZV, Human Herpes Virus 3)

Varicella zoster virus, a double-stranded DNA virus, is the cause of chickenpox, a highly infectious disease common worldwide. The advent of the chickenpox vaccine and the institution of routine immunization in 1995 have drastically reduced the frequency and prevalence of the disease. Chickenpox was primarily a disease of childhood, with more than 90% of cases occurring in children younger than 10 years and with only 2% of cases occurring in adults. Since vaccination began, the epidemiology has shifted; now disease occurs more commonly in adolescents and adults. Complications and more severe disease are also associated with increased age. Overall, the incidence in all ages has decreased with the vaccination.

Transmission occurs via direct skin contact and via respiratory droplets; the virus is commonly isolated from vesicles and is rarely isolated from the respiratory tract. The incubation period is 10–21 days (mean 14 days) and patients are contagious for 7 days, beginning 2 days before the onset of disease. Exclusion from school is routine, but may not prevent transmission. Children have a 2–3-day prodromal period prior to developing the disease and the prodrome varies from asymptomatic to a severe illness with fever, malaise, cough, coryza, and sore throat. Chickenpox begins on the scalp and trunk as erythematous macules that rapidly develop central vesicles on an erythematous base ("dew drop on a rose petal") and evolve into pustules or crusts. New crops of macules and vesicles continue to develop for approximately 7 days, and children may have disease in all stages of development. The polymorphous nature of chickenpox is characteristic. Infections are considered severe if the patient has more than 500 lesions (38% of cases). Crusting occurs within 2–12 days and healing in 16 days, typically without scars, but depressed or hypertrophic scars may occur. Scarring may follow excoriations due to pruritus, which ranges from minimal to intense. Oral disease occurs in 25% of cases. Subsequent attacks are rare clinically; however, serologic evidence of reinfection is common.

Complications in immunocompetent children include secondary bacterial infection (5–10%) and otitis media

(5%). High-risk individuals, i.e., older children, adults, or immunosuppressed patients, require hospitalization and may develop severe complications, including pneumonia, thrombocytopenia, encephalitis, cerebellar ataxia, aseptic meningitis, transverse myelitis, Guillain–Barre syndrome, nephritis, carditis, arthritis, orchitis, uveitis, purpura fulminans, and even death. Reye syndrome was once a complication but is now rare with the avoidance of aspirin in children.

Women in childbearing years without immunity to varicella have a 0.05–0.07% risk of developing chickenpox during pregnancy and potentially infecting the fetus. These women should be vaccinated and titers checked to ensure immunity. If a woman does develop chickenpox during pregnancy, there is a 2–4% chance of fetal infection and development of intrauterine varicella. The risk of fetal abnormalities is greatest if the maternal infection occurs during weeks 8–20 of pregnancy. Neonates with fetal infection have low birth weight, skin disease, and scars in a dermatomal distribution, cataracts, microphthalmia, chorioretinitis, bone and muscle hypoplasia, mental retardation, microcephaly, and dysfunction of bladder and bowel sphincters. If congenital infection occurs after 20 weeks, infants have increased risk of developing herpes zoster in the first few years of life.

Neonates born to a woman who develops chickenpox 5 days before or 2–5 days after delivery are at increased risk of developing disseminated chickenpox, with a 20–30% chance of fetal death usually from pneumonitis and hepatitis. The mortality has decreased considerably with the use of varicella-zoster immune globulin (VZIG) and acyclovir. If a woman develops chickenpox 5 days after delivery, the risk to the neonate is similar to those of older children.

The differential diagnosis of chickenpox includes arthropod bites, eczema herpeticum (patients with atopic dermatitis), herpes simplex infection, impetigo, folliculitis, hand foot and mouth disease, pityriasis lichenoides, scabies, bullous pemphigoid (adults), erythema multiforme, and drug eruption. The diagnosis is usually clinical given the distinct characteristics of chickenpox. A Tzanck smear allows for immediate confirmation, but successful interpretation requires skill and experience. VZV can be isolated from vesicles during the first 3 days of eruption with DFA or PCR. Serologic tests may also be used to determine immune status.

All chickenpox vaccines originate from the live Oka strain developed in Japan in 1970. The vaccine is well tolerated and safe for use in immunocompetent patients. Vaccine complications include erythema at the injection site (25%), and dermatitis within 1 month of vaccination (5%; with leukemic patients, 50%). Children aged 12 months through 18 years should receive two doses of the vaccine given 1 month apart. The vaccine is 70–85% effective in preventing infection and almost 100% effective in preventing severe infection. Breakthrough cases occur more commonly under the previous immunization recommendations (only one dose of the vaccine). Even in breakthrough cases, the number of lesions and length of time to healing were decreased.

In most cases of chickenpox, symptomatic treatment suffices, i.e., antihistamines, oatmeal baths, calamine lotion, Domeboro soaks, menthol-containing lotions, and bland emollients. Secondary infection should be treated with antibiotics. Fever and general discomfort should be treated with acetaminophen.

Varicella-zoster immune globulin (VZIG) is useful in preventing and modifying the development of chickenpox but must be administered within 96 h of exposure. It is recommended for immunocompromised patients and newborns whose mothers developed disease between 5 days before and 2 days after birth. VZIG has been effective in preventing disease in susceptible healthy adults and pregnant women who have had contact with infected individuals. Because VZIG is not currently available, intravenous immune globulin can be substituted when VZIG is indicated.

Acyclovir, a nucleoside analog, is a powerful and selective inhibitor of HSV, and to lesser extent VZV, by blocking viral DNA replication, which must be administered within 24 h of chickenpox lesions. It is not efficaciously used in otherwise healthy children given its expense, marginal effect, and difficulty of delivery within limited window. However, use in adolescents (>12 years of age) and adults, patients with chronic cutaneous or pulmonary disease, those receiving salicylates or corticosteroids, and in immunocompromised patients can reduce morbidity and mortality. The recommended dosage is 20 mg/kg four times per day (up to 800 mg four times per day) in adolescents and adults and 10–20 mg/kg intravenously every 8 h for 10–14 days in sick individuals or immunocompromised patients. If given at the time of exposure, acyclovir may modify or even prevent chickenpox infection. Valacyclovir and famciclovir are reasonable alternatives.

Herpes Zoster (Shingles)

Herpes zoster represents reactivation of latent VZV in the sensory ganglia after previous VZV infection. Zoster most often affects the elderly and children with

immunodeficiency or malignancy; it also occurs in immunocompetent children/adolescents who contacted chickenpox early in life. There have also been an increased number of cases in the last 15 years since the advent of the chickenpox vaccine. Patients generally experience a dull aching sensation, followed by urticarial papules then unilateral, grouped vesicles, and bullae on reddened skin in a dermatomal distribution. The dermatitis is generally accompanied by discomfort, described as a dull constant burning sensation, with intermittent sharp, stabbing pain. The dermatitis lasts for 10–14 days and usually heals without scarring. Involvement of the nasal tip indicates involvement of the nasociliary branch of the trigeminal nerve (V) which may forebode ocular complications, necessitating ophthalmologic consultation (◉ *Fig. 149.8*).

Herpes zoster can be difficult to distinguish from HSV, especially if the HSV infection occurs in a dermatomal distribution. Immunoflourescent microscopy (DFA) can help to confirm the diagnosis.

Zoster is not typically problematic in healthy children, but in immunocompromised patients, ulcerative lesions can occur, disease may involve several dermatomes, and there is increased risk of visceral dissemination causing significant morbidity and mortality. Postherpetic neuralgia may follow zoster and may last for months. Neuralgia is a common and often debilitating complication in elderly patients, less likely in younger patients.

Treatment is not usually required in children. For adolescents and adults, treatment is acyclovir 800 mg five times per day for 7–10 days and for immunocompromised patients 10 mg/kg every 8 h for 7–10 days. Healing is improved and severity of acute pain is diminished if antiviral treatment begins within 48–72 h of the disease onset.

Epstein–Barr Virus (EBV, Human Herpes Virus 4)

Epstein–Barr Virus, first described by Burkitt in 1958 as the causative agent of a lymphoma and the most common tumor in children in East Africa, is the etiologic agent of infectious mononucleosis, a major cause of Gianotti–Crosti syndrome, which is also linked to nasopharyngeal carcinoma. The infection is widespread and humans are the natural host. Primary infection occurs early in life, particularly in tropical climates and lower socioeconomic classes, and is usually asymptomatic.

Infectious Mononucleosis (IM)

IM is a self-limited lymphoproliferative disease characterized by fever, sore throat, lymphadenopathy, fatigue, and splenomegaly. The disease typically lasts for weeks,

Figure 149.8
Zoster

although the fatigue associated with it may last for months. There is no evidence to implicate ongoing viral infection or replication in those with prolonged fatigue following infectious mononucleosis. Patients with infectious mononucleosis treated with ampicillin for suspected streptococcal pharyngitis often develop a hypersensitivity exanthem.

Gianotti–Crosti Syndrome (GCS, Papular Acral Dermatitis of Childhood, Papulovesicular Acrolocated Syndrome)

Gianotti–Crosti, first described in Italy in 1955, is a common exanthem of healthy young children, usually less than 5 years old. The syndrome was initially described in association with hepatitis B infection but has since been associated with parainfluenza virus, echovirus, enteroviruses, hepatitis A and C, cytomegalovirus, human herpesvirus-6, coxsackievirus, rotavirus, parvovirus, molluscum contagiosum virus, respiratory syncytial virus, mumps, human immunodeficiency virus (HIV), *Bartonella henselae*, *Streptococci*, *Borrelia burgdorferi*, *Mycoplasma pneumoniae*, and Epstein–Barr Virus. EBV is the most common etiology worldwide. Vaccinations have been linked to Gianotti–Crosti. GCS typically affects preschool children but may occur in children aged 3 months to 16 years. Prodrome is variable, i.e., upper respiratory or gastrointestinal infection, which leads to the exanthem. Children suddenly develop an asymptomatic exanthem of small pink/red/brown to flesh-colored 2–5 mm monomorphous papules or papulovesicles, symmetrically distributed on the face, buttocks, and extensor surfaces of the extremities. The trunk is usually spared. Patients may have purpura, inguinal or axillary lymphadenopathy, and hepatosplenomegaly (associated with hepatitis B). The exanthem lasts 4–6 weeks and disappears without sequelae.

The differential diagnosis includes: lichen planus, lichenoid drug eruption, papular eczema, Henoch–Schonlein purpura, arthropod reaction, keratosis pilaris, Langerhans cell histiocytosis, urticaria pigmentosa, molluscum contagiosum, erythema multiforme, drug reaction, and id reaction. Generally, the diagnosis is clinically apparent especially with absence of truncal involvement. A biopsy may be necessary for a definitive diagnosis and Epstein–Barr serologies can be obtained in inconclusive cases, along with liver function tests and hepatitis serologies in unimmunized children. Given the self-limited nature of Gianotti–Crosti, no treatment is necessary (◉ *Fig. 149.9*).

◘ Figure 149.9
Gianotti–Crosti

Cytomegalovirus (CMV, *Human Herpes Virus* 5)

CMV species–specific herpesviruses, discovered in the 1950s when human and murine varieties were isolated, are transmitted from person to person via close contact with high incidence in close contact quarters such as day-care centers. Age of infection and prevalence vary worldwide. In the USA and other developed countries, infection tends to occur later in life, while in developing countries children are more prone to infection. Rates of seropositivity are around 50% worldwide, approximating 90% in high-risk groups. Most CMV infections are subclinical, but can be significant in immunosuppressed and immunodeficient patients.

Neonatal CMV is a part of the TORCH infections (toxoplasmosis, other viruses – syphilis, varicella-zoster, parvovirus B19, rubella, CMV, Herpes/HIV). Maternal infection transmitted via the placenta or breast milk is most severe when the virus is contracted during the first half of pregnancy and 0.2–2% of neonates are infected in utero. Of those, only 2–10% will show signs of disease, e.g., intrauterine growth retardation, jaundice, petechiae, hepatosplenomegaly, microcephaly, and "blueberry muffin" skin disease. Even fewer patients develop severe sequelae, such as neurologic complications, mental retardation, and sensorineural deafness. Many infants (10–60%) are infected during the first 6 months of life, and they rarely show any signs of disease.

Most cases of CMV infection do not require treatment; but for severe cases in neonates, immunosuppressed or immunodeficient patients, antiviral treatment is

necessary. Ganciclovir and valganciclovir are the anti-viral agents of choice for the treatment of CMV infections.

Roseola Infantum (Exanthem Subitum, Human Herpes Virus 6 and 7)

HHV6, isolated in 1986 in patients with lymphoproliferative disease infects and replicates in T lymphocytes; two subtypes are known, A and B, and the latter (B) is the causative agent of roseola infantum. Ninety percent of adults have antibodies to HHV6, which is intermittently spread in saliva throughout life. After an incubation period of 9 days, children aged 6 months to 3 years typically develop fever for 3–4 days, but remain otherwise well except for mild, nonspecific upper respiratory or abdominal symptoms. As the fever resolves, the characteristic rose-colored, nonpruritic macules appear on the chest and arms and rapidly generalize. The exanthem fades within 24–48 h. Many children have subclinical cases of infection.

The differential diagnosis includes other causes of viral rashes, Scarlet fever, and drug eruption. The distinct time course of fever and rash helps to make the diagnosis. Isolation of the virus is not usually necessary but can be done by culture, immunohistochemical stains, serology, and polymerase chain reaction. The exanthem is self-limited, but convulsions secondary to high fever and/or direct infection of the meninges have been reported. In one study, one-third of children aged 12–15 months evaluated for febrile seizures had HHV6 infection. In another study, 20% of children with fever of unknown origin had positive IgM antibodies to HHV6. Severe complications, such as permanent neurologic damage following encephalitis, have been reported, but the exact role of HHV6 in these cases is not clear.

In most infants, treatment is supportive and some (13%) will require hospitalization due to febrile seizures. Immunosuppressed patients may require antiviral treatment such as ganciclovir or foscarnet.

HHV7 was isolated in 1990. Primary infection occurs during childhood; over 95% of adults have been infected and 75% were infected before age 6. HHV7 has been associated with roseola infantum and some reports of pityriasis rosea.

Hand–Foot–Mouth Disease (HFMD)

HFMD is a viral exanthem most commonly caused by Coxsackie A16, an Enterovirus, and part of the Picornaviridiae family. Alternative pathogens include other single-stranded RNA viruses such as Coxsackie B, ECHO, and Enterovirus (71). The disease tends to affect children aged 2–10 years old, and sometimes adults. Transmission occurs via the fecal–oral route or respiratory droplets, and the incubation period is 3–6 days. The virus is highly contagious and outbreaks commonly occur in late summer and early fall. Patients usually have a prodrome with low-grade fever (38°C), anorexia, malaise, cough, and sore throat/mouth 1–2 days prior to the development of mucosal and skin disease. Initially, patients have 1–3 mm vesicles on the buccal mucosa and tongue and, in one-third of patients, the palate, uvula, and anterior tonsillar pillars are also involved. The exanthem develops shortly after oral disease with gray-white, oval vesiculopustules that parallel skin lines on the palms and soles or on the dorsal/lateral surfaces of the hands and feet. The vesicles are typically flaccid, thin-walled, and erosions/ulcerations with crust may follow. Another common presentation is a maculopapular exanthem on the buttocks and genitalia. HFMD may be painful or pruritic, but is generally asymptomatic and heals without scarring in approximately 7 days.

The differential diagnosis of oral HFMD includes: HSV infection, aphthous ulcers, Streptococcal or Candida infection; the differential of hand lesions includes varicella, erythema multiforme, dyshidrotic eczema, meningococcemia, Rocky Mountain Spotted Fever, subacute bacterial endocarditis, gonococcemia, disseminated HSV/zoster, and papular acrodermatitis of childhood. Diagnosis is usually based on physical exam, but viral culture, DFA, and/or biopsy can help to clarify/confirm the diagnosis.

The disease is usually self-limited and treatment is not necessary. Though, supportive care may be necessary in some cases. Topical analgesics (viscous lidocaine) can help relieve oral pain, and rehydration may be necessary for some patients. Antipyretics and oral analgesics are also frequently used. In rare cases, due to Enterovirus 71, life-threatening complications such as encephalitis have been reported.

Herpangina

Herpangina is viral exanthem most commonly caused by Coxsackie A9, an Enterovirus, part of the Picornaviridiae family. The infection occurs in young children who exhibit fever and sore throat with a few scattered, discrete vesicles on the soft palate, uvula, tonsils, and tongue. The oral cavity and throat are typically erythematous and

hyperemic. Herpangina is more painful than HFMD but heals without scarring within days.

Mollusca Contagiosum

Molluscum contagiosum is an infection caused by large DNA poxvirus, with transmission through direct skin-to-skin contact, less commonly via fomites. The virus affects patients worldwide, and there is a bimodal distribution; the first in preschool aged children with transmission from nonsexual contact, and the second in early adulthood usually via sexual contact. Adults are rarely affected even with close contact with infected children, most likely due to universal exposure and long-standing immunity. Those at increased risk for developing Molluscum contagiosum include immunocompromised patients and those with atopic dermatitis.

The incubation period is between 2 and 8 weeks, and patients typically develop asymptomatic, flesh colored to erythematous, dome-shaped 1–5 mm papules, often with central umbilication. Papules larger than 5–10 mm are "giant molluscum." Molluscum commonly occur on the face, flanks, abdomen, axillae, thighs, buttocks, and groin, but may be found anywhere on the body. Local inoculation and spread may result in a linear distribution. Pruritic dermatitis may occur in 10% of patients, more so in patients with atopic dermatitis, and often complicates the molluscum treatment. Secondary infection or an inflammatory response to the virus may cause large, painful erythematous papules or pustules. With molluscum near the eye, conjunctivitis may occur (*Fig. 149.10*).

Figure 149.10
Molluscum

The differential diagnosis includes: HSV infection, warts, milia, folliculitis, and skin tags. Giant molluscum may mimic epidermoid cysts. Diagnosis is usually made clinically. A KOH prep and microscopy can assist in making the diagnosis but are not typically necessary. In rare cases, a biopsy may help to confirm the diagnosis, revealing large eosinophilic cytoplasmic inclusions (molluscum bodies). In children with strict genital involvement, child abuse needs to be explored.

Spontaneous regression usually occurs after 6 months to 4 years. Treatment may not be necessary, but per one study, 82% of parents and patients report concern about the lesions and are likely to pursue treatment. Treatment modalities vary depending on patient age and include imiquimod 5% (cost prohibitive), tretinoin 0.025%, salicylic acid, and benzoyl peroxide, with variable efficacy and are generally reserved for treatment of the face. Best results occur with cantharidin 1.5% applied to individual non-facial molluscum. The medication is applied and washed off with soap and water after 3–4 h, bullae may develop within hours to days. In older patients, options include curettage and cryotherapy. Scarring may occur with self-healing or with treatment.

Verrucae (Warts)

Warts are caused by the human papillomavirus (HPV), a subgroup of the Papovaviridae family with over 200 genotypes and 76 different site-specific subtypes. The incubation period for infection varies from months to 3 years. Transmission occurs via direct contact often through damaged skin; spread depends on the patient's immune status. Large warts tend to occur in transplant patients, HIV/AIDS patients, and patients receiving systemic steroids. Warts in immunosuppressed patients tend to be resistant to treatment, and patient comfort is often the mainstay of therapy.

Generally, warts are asymptomatic but may be associated with pain depending on size and where they occur. There are many commonly employed and reasonably effective treatments for warts, but failure rates are appreciable (30%) regardless of treatment modality. Fortunately, warts in healthy patients are self-limited and typically involute within 1–2 years. However, most patients or their parents desire treatment. In general, the goal of treatment is to create inflammation of the wart stimulating natural immunity to attack the wart virus. Several treatments may be

combined and employed at once, and most modalities will require a series of treatments to ensure clearance.

Treatment options include:

- Salicylic acid preparations (various strengths available) applied one to two times daily with or without occlusion
- Topical immunotherapy, i.e., sensitization and treatment with squaric acid solution or diphenylcyclopropenone
- Injected immunotherapy with Candida antigen
- Tretinoin (Retin A 0.1%) applied once to twice daily, often combined with imiquimod
- 5-Fluorouracil solution or cream applied BID
- Cimetidine (oral) 30–40 mg/kg/day for 2–3 months, effective especially in the treatment of genital and perigenital warts
- Cantharidin solution applied to warts and then washed off with soap and water after 8–10 h
- Podophyllin 25%, a metaphase inhibitor, applied to warts (usually genital warts) washed off with soap and water after 4–6 h
- Podophyllotoxin gel 5% (Condylox) used to treat genital warts
- Trichloroacetic acid used to treat genital warts
- Cryotherapy (liquid nitrogen) is often the mainstay of therapy in adolescents and adults, but can be painful and poorly tolerated by young children
- Pulsed dye laser or CO_2 laser treatment for resistant or stubborn warts
- Photodynamic therapy with red light, studies are currently underway and show promising results in the treatment some recalcitrant warts
- Surgical removal may be considered after failure of several other treatment modalities, avoid on the plantar surface due to painful scarring

Verruca Vulgaris (Common Warts)

Common warts, usually caused by HPV types 1, 2, 4, and 7 occur most often on the hands, feet, knees, and elbows but may be found on any body surface. Clinically, warts appear as asymptomatic flesh to white colored callus-like papules that may coalesce into plaques. On the face or mucous membranes, they may have a filiform appearance with a thin stalk. Warts around the fingernails may be large and very difficult to treat especially if the virus has migrated under the nail plate, a complication commonly seen in nail pickers/biters and in immunocompromised patients. The differential

Figure 149.11
Common warts

diagnosis includes calluses, molluscum contagiosum, prurigo nodule, and knuckle pads. Small black dots within the wart are thrombosed superficial capillaries, "wart seeds"; cutting or paring results in pinpoint bleeding – a helpful diagnostic clue. Disruption or disappearance of dermatoglyphs within warts is another diagnostic clue (*Fig. 149.11*).

Verruca Plana (Flat Warts)

Flat warts, associated with HPV 3, 10, and 28, are yellow/white/red/brown to flesh-colored 2–4 mm flat topped papules that may occur in groups or in a linear distribution due to autoinnoculation. Flat warts commonly occur on the face, neck, wrists, and legs, but may be found anywhere on the body. They are often quite subtle and difficult to appreciate, and may be confused with lichen planus, lichen nitidus, mollusca contagiosa, keratosis pilaris, folliculitis, xanthogranulomas, acne, benign cephalic histiocytosis, granuloma annulare, or syringomas. Occasionally, biopsy is needed to confirm the diagnosis (*Fig. 149.12*).

Condyloma Accuminata (Genital Warts)

Condyloma accuminata, caused by HPV types 6 and 11 (90% of cases) and, occasionally, with types 2, 4, 16, 18, 30, 31, 33. Women with genital warts caused by types 16, 18, 31, and 33 have an increased risk of cervical and

Figure 149.12
Flat warts

vulvar dysplasia. The main mode of transmission in infants/children is passage through the birth canal; the younger the child is at the time of presentation, the greater likelihood of transmission at birth. In older children, genital warts may be associated with sexual abuse in 5–10% of cases. The variable incubation period of 1–3 years often makes suspected cases of abuse more difficult to prove.

The appearance of condyloma accuminata is variable, e.g., red/brown/white to flesh-colored, raised or flat, single or grouped papules or plaques. Fusion of the papules can lead to large, moist, vegetative plaques that may fissure and ulcerate. The larger plaques are typically sexually transmitted, and the skin and mucous membranes of the anogenital area are most commonly affected. Other mucous membranes, e.g., the larynx may be affected if exposure occurs during vaginal delivery or in breastfeeding mothers with warts (*Fig. 149.13*).

The differential diagnosis of condyloma accuminata includes molluscum contagiosum, skin tags, anal fissures, and condyloma lata (secondary syphilis). Diagnosis is most often made clinically, but biopsy can help to confirm diagnosis. Treatment options are variable as mentioned above. With the advent of the HPV quadrivalent (HPV 6, 11, 16, 18) and bivalent vaccines, prevention of genital warts and ultimately cervical cancer has become a possibility. The vaccine is approved for use in boys and girls aged 9–26 years old. Vaccination protects against the two types of HPV, 6 and 11, which cause 90% of genital warts and the two types of HPV, 16 and 18, that cause 75% of cervical cancer. The vaccine is given as a series of three injections over 6 months, and the side effect profile is minimal, with injection site reaction being the most common complaint.

Figure 149.13
Condyloma acuminata

Fungal Infections

The two most common causative agents of fungal infections in children are Candida (yeast) and superficial dermatophytes (mold). *Trichophyton* and *Microsporum* species are both acquired through human or animal contact, while *Epidermophyton* is acquired only through human contact; these three species are the dermatophytes most commonly seen in kids. Examples of zoophilic organisms include *Microsporum canis* (cats and dogs) and *T. verrucosum* (cows and horses). Anthropophilic organisms include *Tinea mentagrophytes*, *Trichophyton tonsurans*, *Trichophyton rubrum*, and *E. floccosum*. Organisms produce keratinases which aid in invasion; however, most fungal infections are superficial and affect only the skin, hair, and nails. Less commonly, fungi may cause deep infections when they invade organs. Fungal infections are named using "tinea" (gnawing worm, from Latin) and the area of involvement: tinea capitis – scalp, tinea corporis – body, etc. Immune status dictates susceptibility to infections; the other likely risk factors include excessive moisture and occlusion, which may exacerbate fungal infections.

Tinea Capitis

Tinea capitis affects children worldwide and typically presents in children aged 3–7 years old, rarely in infants and

older children. Transmission occurs person to person, or through fomites, or infected animals. Tinea capitis is caused by a dermatophyte, and the most common causative organisms are *Trichophyton tonsurans* (most common in USA/Canada, most prevalent in black children), *Trichopyton soudanense*, *Trichopyton violaceum*, *Microsporum canis* (most common worldwide), and *M. audouinii*.

T. capitis has four different presentations:

1. Scaly plaques (resembling seborrheic dermatitis) without hair loss, often seen with *T. tonsurans* infection and associated with broken hairs, known as "black dot ringworm"
2. Alopecic patches and scaling with minimal inflammation
3. Scattered papules, pustules, and crusts
4. Kerion formation – an edematous, boggy, tender mass, which occurs as a result of an immunologic inflammatory reaction to the fungal infection (permanent scarring may result) (◉ *Figs. 149.14* and ◉ *149.15*)

Severe forms of tinea capitis may be associated with systemic symptoms such as fever, malaise, and cervical/occipital lymphadenopathy. Disease may be complicated by an id reaction, papulopustules on the face that may be mistaken as resistant disease; however, this reaction resolves with treatment of the tinea infection. If the id reaction is significant, an oral antihistamine and topical corticosteroids will help alleviate symptoms.

◘ Figure 149.14
Tinea capitis

◘ Figure 149.15
Large kerion

The differential diagnosis includes: alopecia areata, trichotillomania, seborrheic dermatitis, psoriasis, discoid lupus, lichenplanopilaris, and bacterial folliculitis. KOH prep helps to confirm diagnosis. Depending on the causative dermatophyte, spores may be within (endothrix) or outside of the infected hair shaft (ectothrix). Other diagnostic modalities include fungal culture (Sabouraud medium) and Wood's light examination. Fungal culture allows determination of the causative agent, especially important in the case of *M. canis* which is indicative of exposure to an animal that needs treatment as well. *M. canis* can be difficult to treat, often requiring longer treatment. Wood's light examination will yield green fluorescence if infection is caused by *Microsporum* (except *M. gypseum*). *Trichophyton* species do not fluoresce. Bacterial culture should be obtained if secondary infection is suspected.

Some individuals may be asymptomatic carriers of the disease, and spores are often difficult to eliminate, especially from fomites (children should avoid sharing helmets/head gear). Tinea capitis deserves treatment with an oral antifungal agent since organisms invade the hair follicle. The treatment of choice is griseofulvin 20–25 mg/kg/day for 6–8 weeks. *M. canis* typically requires extended treatment for 3–5 months or sometimes longer. For younger children, a liquid suspension (125 mg/teaspoon) is available. Parents should be instructed to give the medicine with fatty foods such as whole milk or ice cream to increase absorption. Side effects include headache and upset stomach but, generally, the medication is well tolerated and safe. Laboratory monitoring is not necessary in healthy children for treatment described above (6–8 weeks), but for kids with prolonged treatment or other illnesses/comorbidities, liver function studies and complete blood counts should be obtained. Alternative

regimens include: itraconazole 5 mg/kg/day for 2–3 weeks, fluconazole 6 mg/kg/day for 2–3 weeks, and terbinafine (dosing is weight dependent) <20 kg: 62.5 mg; 20–40 kg: 125 mg; >40 kg: 250 mg for 2–4 weeks. Additionally, topical antifungal shampoos, e.g., ketoconazole, can be used in conjunction with systemic therapy to help decrease scale, shedding, and contagiousness. Secondary bacterial infections should be treated with oral antibiotics.

Tinea Corporis (Ringworm)

Tinea corporis is a superficial fungal infection of the body, most commonly caused by *Trichophyton rubrum*, less so *M. audouinii* and *M. canis*. Transmission occurs by direct contact with those infected, through fomites or when children hold or play with infected cats/dogs (*M. canis*).

Patients develop pruritic, erythematous, circular, or annular plaques with central clearing that expand outward with a peripheral edge of scale/crust and darkening. Vesicles may appear at the periphery of the plaque, and multiple plaques may coalesce and give a polycyclic appearance. Plaques tend to affect the face and arms; however, they can occur at other sites. If the organisms invade the hair follicle or shaft, a deeper infection (Majocchi granuloma) occurs with reddened boggy papules, pustules, plaques, and nodules (*Fig. 149.16*).

Tinea corporis can be difficult to treat and may defy diagnosis. If initially treated with steroids, plaques expand and become more inflamed often with pustules on an erythematous base. If diagnostic clues, i.e., inflammation and scale, are absent, condition is known as tinea incognito. Differential diagnosis includes: psoriasis, granuloma annulare, nummular dermatitis, pityriasis rosea, and erythema annulare centrifugum.

KOH prep establishes diagnosis; culture (Sabouraud medium) confirms the specific causative agent. If a Majocchi granuloma is suspected, biopsy is recommended to confirm a deeper infection. If disease is limited, topical antifungals used twice daily for 2–4 weeks will generally provide clearance. Patients should continue treatment for approximately 1 week after clearance to ensure eradication. For extensive or resistant disease, oral antifungals should be provided, either terbinafine 6 mg/kg/day for 2 weeks or griseofulvin 20 mg/kg/day for 4–6 weeks.

Tinea Pedis

Tinea pedis ("athlete's foot") is more common in adults than in children and tends to develop after puberty. The causative organisms are *Tinea rubrum*, *Tinea mentagrophytes*, *and Epidermophyton floccosum*. Affected patients usually have scaling, erythema and maceration between the third, fourth, and fifth toe spaces (atopic dermatitis favors first and second toe spaces), and/or scaly plaques on the plantar foot. Pruritus and malodor are common and associated onychomycosis may occur.

Figure 149.16
Tinea corporis

There are four recognized types of Tinea pedis:

1. Chronic intertriginous (most common) – erythema and scale of the web spaces and bacterial coinfection which can lead to maceration
2. Chronic hyperkeratotic/moccasin tinea pedis – erythema and scale on the plantar surface; one hand may also be involved (two feet–one hand syndrome)
3. Vesiculobullous – multiloculated, erythematous vesicles and bullae, often on the arch and heel
4. Acute ulcerative (rare in children) – vesicles and pustules that progress rapidly into ulcers and erosions, often with systemic signs of infection and typically seen in immunocompromised and diabetic patients

Many people will develop tinea pedis during their lifetime (70%). Those at increased risk are often exposed to high humidity, wear occlusive footwear, and use communal pools, showers, baths, or locker rooms regularly. Tinea pedis is quite common among athletes.

Secondary bacterial infections and id reactions, manifested as vesicles on the hands/feet or as dermatitis elsewhere on the body, can complicate tinea pedis. Differential diagnosis includes: granuloma annulare, contact dermatitis, psoriasis, juvenile plantar dermatosis, and hereditary keratodermas. KOH prep establishes diagnosis. Chlorazol black E or KOH, in conjunction with dimethylsulfoxide, may enhance visualization of the fungal hyphae. Fungal cultures to determine the causative agent may be helpful, but often not necessary. *M. canis* indicates an infected animal as source and *T. tonsurans* likely means someone in the home has tinea capitis. Bacterial cultures should be obtained if there is concern for secondary infection.

Most small, localized infections will respond to simple measures, including limited use of occlusive footwear, drying powders, and topical antifungal treatment for 4–6 weeks. In resistant or extensive cases, oral antifungal medications: terbinafine 6 mg/kg/day for 2 weeks or griseofulvin 20 mg/kg/day for 4 weeks may be necessary, coupled with topical antibiotics to treat secondary bacterial infections.

Onychomycosis

Onychomycosis is a fungal infection of the nails usually caused by *T. rubrum*. Other causative agents include *Trichophyton mentagrophytes*, *Epidermophyton floccosum*, and *Candida albicans*, typically the cause of onychomycosis in infants and usually acquired intrauterine or via vaginal transmission. Though far more common in adults, onychomycosis can occur in children – prevalence 0.2–2.6%, accounting for 30% of all nail disease. Risk factors include family history of dermatophytosis, Down syndrome, diabetes, and immunosuppression due to HIV infection or medications. The infection is transmitted in shared settings such as swimming pools, baths, and locker rooms.

Clinically patients have dystrophic, hyperkeratotic, yellow-brown discoloration of the nails with onycholysis. The toenails are more commonly affected than the fingernails, generally only some nails are involved, and the infection is usually asymmetrical (*Fig. 149.17* and *Table 149.3*).

Patients often have coinfection with tinea pedis, tinea corporis, or tinea capitis. The differential diagnosis includes psoriasis, lichen planus, traumatic dystrophy, alopecia areata, 20-nail dystrophy (trachyonychia), and pachyonychia congenita. KOH prep establishes the diagnosis, and fungal culture will delineate specific pathogen. When direct microscopy and fungal culture fail to confirm infection, material should be collected from nail clippings, subungual debris, nail bed, or undersurface of the nail plate and sent for histopathology.

Treatment can be difficult, and it is important to weigh the risks and expense of systemic treatment given cure rates (65%) and high rate of recurrence (50%). Parents and children may opt for less invasive measures, such as simply paring and filing of the nail to relieve pressure points causing pain. Patients may also undergo mechanical debridement with total or partial surgical nail avulsion. Topical medications require rigorous compliance and sustained treatment which may not provide clearance. Ciclopirox 8% (Penlac) is a nail lacquer applied daily for 9–12 months (success rate 20%); bifonazole in 40% urea (Mycospor Onycho-Set) and amorolfine 5% with once weekly application are alternatives. Systemic treatment

Figure 149.17
Onychomycosis

Table 149.3
Onychomycosis: Classified by mode and site of invasion

Type	Location	Features	Cause
Distal lateral subungual onychomycosis (DLSO)	Hyponychium	Spreads proximally along the nail bed and lateral nail grooves	Western countries causative agent: *Trichophyton rubrum*
Endonyx onychomycosis (EO)	Distal lateral onychomycosis	Involves nail plate/bed	*T. soudanense* and *T. violaceum*
Superficial onychomycosis (SO)	Dorsal plate		Superficial white onychomycosis-*T. mentagrophytes var interdigitale* and superficial black onychomycosis – *T. rubrum var melanoides* or *Scytalidium dimidiatum*
Proximal subungual onychomycosis (PSO)	Proximal nail fold	Spreads distally on nail plate	*T. rubrum*; PSO with paronychia – *Candida albicans*
Total dystrophic onychomycosis (TDO)		Most severe form Rarely seen in children	May occur as a result of immunodeficiency or culmination of other types of onychomycoses

Table 149.4
Systemic treatment options of onychomycosis

Medication	Properties	Dose	Duration
Itraconazole	Fungistatic against dermatophytes, molds, and yeasts	3–5 mg/kg/day up to 200 mg/day	12 weeks
Terbinafine	Fungistatic against dermatophytes, Aspergillus, Scopulariopsis	Weight dependent:	6–12 weeks for fingernails
		<20 kg: 62.5 mg/day or 125 mg every other day	12 weeks for toenails
		20–40 kg: 125 mg	
		>40 kg: 250 mg	
Fluconazole	Fungistatic against dermatophytes, Candida, nondermatophyte molds	3–6 mg/kg/dose given weekly	12 weeks for fingernails and 26 weeks for toenails
		or	or
		3–6 mg/kg/day (up to 300 mg/day) given daily	2 months for fingernails and 3 months for toenails

deserves confirmation of infection with positive culture (*Table 149.4*).

Tinea Versicolor (Pityriasis Versicolor)

Tinea versicolor (TV) is a common superficial fungal infection of the skin caused by *Malassezia furfur*, which exists in the yeast phase (*Pityrosporum orbiculare*) on normal skin. *M. furfur* produces disease only when substantial numbers of the hyphal form predominate on the skin. The reason for this proliferation of the hyphal form is unknown; however, it is more common in diabetics, patients treated with oral corticosteroids, or patients who have a genetic predisposition to TV. Tinea versicolor is common in tropical climates and areas with high humidity and temperatures.

Typically, adolescents and young adults are most susceptible, but the infection can occur in any age group, including infants. Patients develop scaling, oval-shaped

hyperpigmented (pink/brown) or hypopigmented plaques on the trunk (chest and back), arms and, occasionally, face (more common in infants). The plaques are usually asymptomatic or mildly pruritic and are more prominent during the summer months when patients tan and plaques remain hypopigmented. In the winter, plaques are typically hyperpigmented compared to the unaffected skin. Generally, the patient's concern is mainly cosmetic (*Fig. 149.18*).

The differential diagnosis includes: confluent and reticulated papillomatosis of Gougerot and Carteaud, pityriasis alba, postinflammatory hypo/hyperpigmentation, vitiligo, seborrheic dermatitis, atopic dermatitis, pityriasis rosea, tinea corporis, psoriasis, erythrasma, and secondary syphilis. The diagnosis is often clinical, and stretching of lesional skin helps elucidate fine scale, which is often imperceptible. KOH prep confirms diagnosis exhibiting pseudohyphae and spores ("spaghetti and meatballs"). Wood's lamp examination may be helpful by revealing orange or blue-white fluorescence.

Treatment can be very difficult due to recurrence and relapse. Topical treatment is standard, but compliance and difficulty of application may limit or prevent success. Topical medications include selenium sulfide shampoo 2.5% applied to the body for 10–15 min prior to showering for 7 days, and then weekly to monthly to prevent relapse. Alternative treatment is to apply from the neck down overnight and then wash off the following morning on two consecutive nights. This process is repeated 1 week later. Zinc pyrithione 2% shampoo or soap and ketoconazole shampoo are also effective when used in a similar manner. In patients with persistent infection or who are not amenable to the application of topical medications, oral antifungals may be beneficial and a single dose of fluconazole or ketoconazole 400 mg may be curative. With extensive or recurrent episodes, ketoconazole 200–400 mg daily for 5–10 days, or daily once a month for 6 months should eradicate TV. Itraconazole and fluconazole have also been shown to be effective. It is important to counsel patients that repigmentation may take months to occur, recurrence is common, and prophylactic treatments are usually necessary to prevent relapse.

Figure 149.18
Tinea versicolor

Infestations and Bites

Scabies

Scabies is an infestation with the mite, *Sarcoptes scabiei var. hominis* which affects all age groups; in children, it occurs most commonly under the age of 2. The infestation occurs across all ethnic groups and socioeconomic levels. Outbreaks are typical in overcrowded areas such as daycare centers, elementary schools, and orphanages. Risk factors for scabies include: overcrowding, poverty, poor nutrition, poor hygiene, and homelessness.

Transmission occurs through prolonged skin-to-skin contact, rarely by indirect spread via infected bedding, clothing, etc. After a 3–6 week incubation period, the mite burrows into the stratum corneum and lays eggs that hatch and emerge as larva in 15 days. With recurrence or reinfection, infestation may develop within a few days. The mite is quite efficient and most healthy individuals harbor only 10–15 mites. Most of the resultant dermatitis is the result of an allergic reaction to the body parts of the mite.

Clinical Features

Patients develop a polymorphous pattern of papules, vesicles, pustules, nodules, urticarial plaques, and/or dermatitis. Favored sites are the fingers/hands (flexor wrists), finger and toe web spaces, intertriginous areas, axillae, nipples/areola, umbilicus, and genitalia. The distribution in infants who are crawling differs somewhat; papules and pustules may occur on the palms/soles as well as the head, neck, face (typically spared in older children), axillae, and

diaper area. The classic sign of disease in all age groups is the scabietic burrow, a serpiginous erythematous linear tract with a minute black dot (the mite) at one end. Patients typically develop intense itching, especially at night; with scratching, areas may become lichenified, purulent, or impetiginized. Secondary infection with *Streptococcus* and *Staphylococcus* is common due to excoriations, and id reactions may develop.

Differential Diagnosis

Scabies infestation may mimic atopic dermatitis in infants. Key features to help differentiate the two entities include xerosis and facial/flexural involvement – elements more commonly seen in atopic dermatitis, while burrows, hyperpigmented nodules, extensor involvement, and pruritus in other household members suggest scabies. Other entities to consider include: impetigo, insect bites, viral exanthem, dermatitis herpetiformis, eczema herpecticum, infantile acropustulosis, papular urticaria, tinea corporis, Langerhans cell histiocytosis, and pityriasis rosea.

Evaluation

Skin scraping of burrows or suspicious papules, using mineral oil or KOH for visualization, helps to identify mites, ova, or feces (scybala – only seen with mineral oil). Multiple scrapings from several different sites will increase the yield. Occasionally, dermatoscopy helps to identify mites (*Fig. 149.19*).

Treatment and Prognosis

- Permethrin 5% is the treatment of choice and is approved for infants >2 months old. After bathing, patients (or parents) apply the medication from the neck down, including genitalia (avoiding orifices), leave it on for 8–12 h (may be left on overnight), and shower off the following morning. Complete coverage is essential, parents/caregivers should cover every square centimeter of the body, even if no disease is apparent. Patients should be retreated 1 week later.
- Crotamiton 10% cream. Applied from neck down for 2 consecutive days and then rinsed off 48 h after last application.
- Precipitated sulfur 6–10% is approved for use in children under 2 months old and pregnant women. Applied for 3 consecutive days and then rinsed off 24 h after last application.
- Other reported treatment options: benzyl benzoate, allethrin.

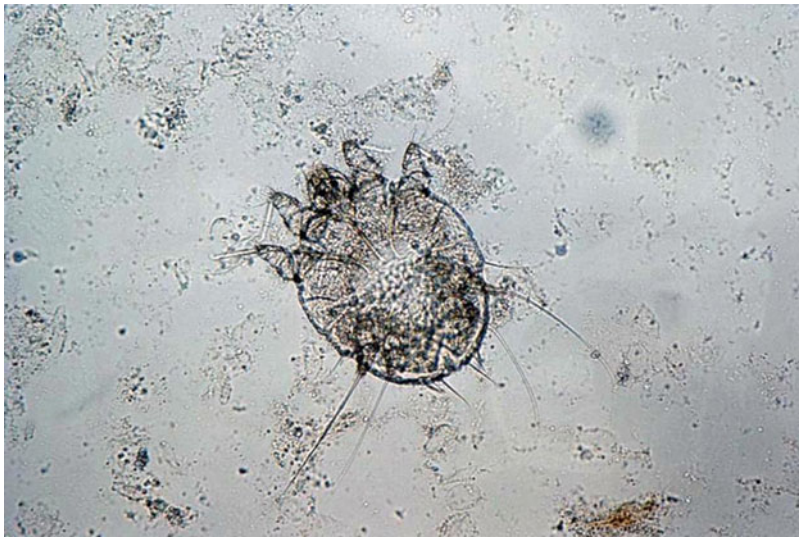

Figure 149.19
Scabies

- Persistent cases, epidemics and Norwegian scabies: treat with ivermectin 200 ug/kg, repeat 1–2 weeks (not to be used in children younger than 5 years or less than 15 kg or pregnant women).

When treating a patient with scabies infestation, all family members and close contacts (i.e., caregivers) should be treated simultaneously, even if asymptomatic. Recurrence rates are high, often related to lack of compliance and not treatment failure/resistant cases. Additional treatments include antihistamines for pruritus, systemic antibiotics for treating secondary infections, and washing linens and clothing in hot water. Mites can persist off the body for up to 2–3 days; any clothes and fomites that cannot be washed should be removed and quarantined for that period of time (at least 1 week). Despite successful treatment, postinflammatory changes and pruritus (a common issue) may persist for weeks to months. Treatment of post-scabietic pruritus with topical corticosteroids should help pruritus and any lingering dermatitis.

Scabies Variants

Nodular scabies is a bug bite like hypersensitivity reaction to the scabies mite. Patients have red-brown edematous papules (5–20 mm in size) and plaques, larger and more prominent than a typical scabies infestation. Nodular scabies affect the axillae, genitalia, buttocks, and groin. Treatment is the same as for traditional scabies, but after eradication of the mites, topical or intralesional steroids are often necessary for the nodules and plaques.

Norwegian scabies is a variant of human scabies that is highly contagious and commonly seen in institutionalized, immunosuppressed and elderly patients; it is uncommon in kids. The infestation is characterized by 1,000 mites, forming hyperkeratotic plaques (pachydermia) on the hands, elbows, knees, and soles, and nail thickening/dystrophy with extremely high elevations of serum IgE and IgG. A single treatment with ivermectin (200 ug/kg) is generally curative, but immunocompromised patients may require a second treatment (not to be used in children younger than 5 years or less than 15 kg or pregnant women). Keratolytics are also useful in removing the thick scale.

Canine scabies is a transient infection in humans caused by *Sarcoptes scabiei var. canis* and acquired after contact with a dog infected with mange. Children develop a pruritic papular dermatitis on the face, arms, chest, and abdomen in the distribution of contact with an infected animal, but patients do not harbor any mites. Skin disease is self-limited and lasts 5–10 days. No specific treatment is required, but topical steroids help to decrease pruritus. The affected animal should be treated by a veterinarian.

Pediculosis

Lice are insects with antennae and three body segments: head, thorax, and abdomen. Each segment has a pair of clawed legs; pubic louse have a small pair of legs and two pairs of legs with large crab like claws. Three types of lice parasitize humans: head lice (*Pediculosis humanis capitis*), pubic or crab lice (*Phthirus pubis*), and body lice (*Pediculosis humanis corporis*). Structurally, body lice and head lice have similar characteristics, both measuring 1–3 mm. The pubic louse is wider and only 1–2 mm in length. Once a female louse has infested a human, she deposits approximately ten eggs daily. These eggs take 7–10 days to hatch and another week to mature.

Pediculosis Capitis

Clinical Features

Pediculosis capitis is a lice infestation on the scalp. Throughout history, epidemics have waxed and waned. Over the past 30 years, incidence has risen and is reaching epidemic proportions in certain countries. Infections are common in elementary-school aged girls (aged 3–11 years old) of all socioeconomic groups and ethnicities, except African American children. Several potential theories have been suggested and include: oiling the scalp, which prevents the louse from adhering or causes suffocation and prevents movement; chemical and heat processing, which impacts the survival of the louse; and basic differences in hair texture and shaft properties.

Transmission occurs by direct contact, but lice may survive for 1–3 days off the infested host; thus, transmission can occur via fomites, e.g., combs, brushes, linens, hats, and clothes. Lice release a poisonous salivary secretion with their mouth parts when piercing the skin. This causes intense pruritus which produces scratching and excoriations, with resultant crusts and perhaps secondary impetiginization, dermatitis of the occipital scalp and postauricular area, and cervical/occipital lymphadenopathy.

Differential Diagnosis

Nits resemble hair casts, fragments of hairspray, and white piedra caused by *Trichosporon ovoides* and *Trichosporon inkin*. The scaling and dermatitis may resemble psoriasis, seborrheic dermatitis, and tinea capitis.

Evaluation

Identification of lice or nits establishes the diagnosis. Though difficult to see given the small, 1–3 mm size and rapid movements, they are most common at the nape of the neck at the hairline and behind the ears. Wetting the hair and combing with a fine-toothed comb may cause lice to fall from the hair and specs of fecal material may also be present on the scalp; well-lit exam rooms with the use of a magnifying glass will help make the diagnosis. The nits (ova) are translucent to opalescent 0.5–1 mm specks and are often detectable sticking to the hair shafts, thus making them difficult to remove (unlike hair casts that slide freely up and down the hair shaft). The nits are laid close to the scalp and grow upward as the hair grows downward. Microscopic exam of nits will show an oblong structure attached to the hair shaft at an acute angle and examination of whether the nit is full or empty may help determine active versus cleared infestation. Larger nits greater than 6 mm imply long-standing infection.

Treatment and Prognosis

Over-the-counter products (*Table 149.5*).
Prescription products (*Table 149.6*).

Other treatment modalities include:

- Single dose of Ivermectin mixed into shampoo, along with vigorous nit removal offers approximately 75% cure rate (not commercially available)
- Applying water/vinegar (4% acetic acid) solution (1:1 ratio) will help remove dead nits by dissolving the chitin in the exoskeleton

Table 149.5
Over-the-counter products (while using OTC products, advise parents/children to stop using cream rinse as it may prevent the medication from working)

Generic name	Trade name	Application	Repeat	Important facts
Permethrin 1%	Nix	Apply to dry hair Rinse after 5–10 min	1–2 weeks later	
Pryrethrins with piperonyl butoxide	RID Pronto	Apply to dry hair Rinse after 5–10 min	1–2 weeks later	Pryrethrins are natural extracts from Chrysanthemums – avoid in patients with contact allergy

Table 149.6
Prescription products

Generic name	Trade name	Application	Repeat	Important facts
Malathion 0.5% lotion	Ovide	Apply to dry hair Rinse after 8–12 h	Repeat 1–2 weeks later	Not for use in kids <6 years old
Permethrin 5%	Elimite	Apply to dry hair Rinse after 8–12 h	Repeat 1–2 weeks later	Not for use in infants <2 months old
Ivermectin 200 ug/kg	Stromectol	One dose	Repeat in 7–10 days	Not for use in children younger than 5 years or less than 15 kg or pregnant women
Trimethoprim-sulfamethoxazole		PO for 2 weeks		Results in clearance due to lice ingesting the antibiotic when obtaining blood meal

- Manual removal with fine tooth combing is possible but requires significant amount of time – unrealistic in most cases
- Suffocation therapy with oils, petrolatum, pomades, mayonnaise to the entire scalp two to three times overnight to kill the lice – somewhat efficacious; however, very messy
- Application and saturation of hair with cetaphil, followed by blow-drying introduced as new treatment modality appears to have similar efficacy rates of previous methods of suffocation, far less messy

In addition to the patient, all family members, close contacts, and caregivers should also be treated. Parents should inform the child's school about the infestation so that classmates may be examined and treated, especially if they are symptomatic. Children can still attend school once treated. Patients should be treated with over-the-counter products initially, and then prescription medications if necessary. Most "resistant" infections are due to improper use of medications.

Pediculosis Corporis and Pubis

Although pediculosis corporis may be spread by close contact among children playing, most cases of corporis and pubis are transmitted during sexual activity. Pediculosis pubis is especially unusual in young children, and if present, consider child abuse as explanation. In sexually active adolescents, pediculosis pubis is often seen in conjunction with other sexually transmitted diseases. The pubic louse is easier to see and may be found grabbing the base of pubic hairs or hairs elsewhere on the body. Nits are similar to those of pediculosis capitis; however, infestation of the eyelashes is common. Nits can be removed from the eyelashes by applying thick coats of petroleum two to three times daily. Any of the treatment modalities described above may be used for pubis, but the treatment of choice is permethrin cream 5% with or without hair removal.

150 Vascular Malformations and Neoplasms in Childhood

Arti Nanda

Vascular malformations are rare disorders representing errors in vascular development. These malformations are often confused with most common vascular tumors, the infantile hemangiomas (IH), and other rare vascular neoplasms. This entry will review the recently adapted classification of various cutaneous vascular anomalies and distinguishing features between vascular malformations and IH as well as the clinical characteristics of significant vascular malformations, vascular neoplasms, and their related syndromes.

Classification of Vascular Anomalies

The recently adapted classification divides vascular anomalies into vascular malformations and vascular neoplasms. Cutaneous vascular birthmarks are rare errors of vascular development and occur in approximately 0.3–0.5% of the population. These lesions are much less common than the infantile hemangiomas but are often confused with them. *Table 150.1* shows the recently adapted classification by the International Society for the Study of Vascular Anomalies (ISSVA). Vascular malformations can be further subdivided into groups based on vessel type and flow characteristics. Capillary, venous, and lymphatic malformations (LM) are slow-flow lesions, and arteriovenous malformations (AVM) and fistulae are fast-flow lesions. Combined lesions may also occur (*Table 150.1*). *Table 150.2* shows distinguishing features between infantile hemangiomas (IH) and various vascular anomalies. Only the significant vascular malformations, vascular tumors, and their related syndromes will be covered in this entry.

Significant Vascular Anomalies and Related Syndromes

Capillary Malformations

Salmon Patch (Synonyms: Angel's Kiss; Stroke Bite)

Salmon patch is a subset of capillary malformation (CM) that is most commonly present on eyelids, glabella (*Fig. 150.1*), and nape of the neck. It is sometimes termed fading capillary stain rather than true CM, because it typically lightens significantly or disappears early in life. Some, often located on the nape of the neck, persist till adulthood without darkening. Salmon patch has no pathological significance, and no treatment is indicated.

Portwine Stain (PS)

Portwine stains (PS), also known as true CM, occur approximately in 3 of 1,000 infants, are present at birth, and have equal sex predisposition. They usually occur sporadically; however, familial cases with associated arteriovenous malformations (AVM) have been described. Portwine stains may arise on any surface of skin but is frequently present on the head and neck area. On the face, distribution usually corresponds to branche(s) of trigeminal nerve (*Fig. 150.2*). Mostly unilateral, occasionally bilateral, single, or multiple lesions may occur. When present on the face, PS may extend to the lips, and gingival or oral mucosa. As the patient matures, PS may become darker, more violaceous, thicker, and develop blebs. It may

Figure 150.2
A child with capillary malformation (portwine stain) affecting right side of the face involving V1, V2, and V3 dermatomes of trigeminal nerve with some spilling on the left side. Child with this distribution has a higher risk of Sturge–Weber syndrome

be associated with underlying soft tissue hypertrophy. On limbs and trunk, PS may appear to be very red at birth and sometimes fades to lighter pink over time. Depending upon its location, PS may occur in association with various congenital malformations, including underlying vascular anomalies, or structural abnormalities of ectodermal origin, including bony or soft tissue hyperplasia or atrophy, neurological defects, eye abnormalities, spinal dysraphism, etc. The treatment options include pulsed dye laser and photodynamic therapy.

Venous Malformations (VM)

Venous malformations (VM) are slow-flow vascular malformations composed of anomalous dilated venous channels. Mucocutaneous VM are uncommon, but when present, they may have significant consequences. These lesions usually arise sporadically, but familial VM can occur and are inherited in an autosomal dominant fashion. Clinically, characteristic VM are usually noted at birth but in some cases may not become evident until the child matures. They typically become more prominent over time. They present as soft blue or purple masses that may be easily compressed with gentle pressure and become more prominent with activity or if the affected area is held in dependent position. Venous malformations do not demonstrate any warmth or thrill on palpation; if these features are present, a mixed arteriovenous malformation should be suspected. Venous malformations may arise on the skin surface or the mucosal surface and may be small focal lesions or larger covering a significant portion of head and neck or extremity. Treatment options include compression modalities, pulsed dye laser, and percutaneous sclerotherapy.

Lymphatic Malformations (LM)

Lymphatic malformations (LM) are developmental anomalies of the lymphatic system that result in abnormalities in lymphatic flow. Lymphatic malformations of the skin and subcutaneous tissue represent a diverse group of disorders that may be primary or secondary, localized or diffuse. A diffuse LM is also known as lymphedema. In this entry, we will briefly review localized LM.

Localized LM present during infancy or childhood and are often called lymphangiomas. They are classified as macrocystic or microcystic LM and arise as isolated or in combination with other vascular malformation. Macrocystic LM of the head and neck area are also called cystic hygromas. Lymphangioma circumscriptum is an older term used to describe microcystic LM with a superficial component. A common presentation of microcystic LM is that of a group of brown to tan papules, which may be mistaken for warts, overlying localized or larger area of the skin (*Fig. 150.3*). The papules may become hemorrhagic or crusted or develop black dots within them (*Fig. 150.3*). Secondary infection, skin erosions, and bleeding are frequently reported complications of microcystic LM. Squamous cell carcinoma has also been reported to arise within a long-standing microcystic LM. Surgical excision with or without grafting, Nd:YAG laser, and CO_2 laser are the treatment modalities reported for these lesions.

Figure 150.3
Microcystic lymphatic malformation on the thigh of a child. *Dark areas* represent hemorrhage in the lymphatic vesicles

Sturge–Weber Syndrome (SWS)

Sturge–Weber syndrome (SWS) is a sporadic congenital disorder characterized by a dermal capillary malformation (port-wine stain) occurring in association with vascular malformations of the leptomeninges and the eye. Since the original description, the syndrome has been variably defined in the literature. The complete syndrome generally includes the triad of facial dermal capillary malformation (PS), ipsilateral central nervous system (CNS) vascular malformation (leptomeningeal angiomatosis), and vascular malformation of the choroid of the eyes associated with glaucoma. Various CNS manifestations include epilepsy, headache, hemiplegia, and mental retardation. Syndrome may manifest with partial involvement. The risk of SWS may be determined by the distribution of PS. Occurrence of SWS is more often seen when PS is present is distribution of first branch (V1) of the trigeminal nerve. The incidence is higher when distribution of PS involves two (V1, V2) or all three divisions (V1, V2, V3), and the incidence of SWS is further higher if the lesions are distributed bilaterally (*Fig. 150.2*). The pathogenesis of SWS is still not clearly elucidated. It has been proposed that the ectomesenchyme for the nasofrontal bud (forehead and upper lid) and piamater (meninges) of the brain share a common progenitor in the anterior neural fold.

Therefore, it has been hypothesized that a common somatic mutation occurring early in embryogenesis in the anterior neural fold results in SWS.

Klippel–Trenaunay Syndrome (KTS)

Klippel–Trenaunay syndrome (KTS) is characterized by a superficial vascular stain (capillary malformation) of the skin in association with soft tissue and bony hypertrophy of the affected limb, and varicose veins with or without deep venous anomalies. The capillary malformation is noticed soon after birth and usually involves the whole limb. It may be accompanied by vascular and/or lymphatic malformation. Varicose veins are present at birth or appear during infancy and are associated with limb hypertrophy. Lower limb involvement is most common, followed by upper limb involvement (*Fig. 150.4a, b*). Involvement of both upper and lower limbs in the same patient may be seen in 10–15% of the cases. Once KTS is diagnosed, regular monitoring of limb length is mandatory. Many cases of KTS can be managed conservatively with elastic support garments. Several radiographic studies are helpful in follow-up and management of these cases. Echo/Doppler and duplex scans are the studies of choice to evaluate for superficial and deep venous anomalies and to rule out arteriovenous shunting. Plain radiographs or ortho-roentenography ("scanograms") can be used to evaluate bony hypertrophy, but in young patients the discrepancy may be subtle radiographic finding. MRI of the limb will help to delineate the extent of soft tissue hypertrophy, bone involvement, and presence of an associated lymphatic anomaly. If there is significant discrepancy in limb length, the orthopedic surgeon should be consulted as surgical correction may be indicated. Capillary malformation can be treated with pulse-dye laser and lymphatic blebs may require surgical excision or destructive laser techniques.

Cutis Marmorata Telangiectatica Congenita (CMTC)

Cutis marmorata telangiectatica congenita (CMTC) is a distinct cutaneous vascular malformation characterized by a fixed reticulated vascular pattern on the skin that resembles physiologic cutis marmorata. It can be differentiated from physiologic cutis marmorata by its persistence when the infant has been warmed. Cutis marmorata telangiectatica congenita may have a female preponderance and cutaneous lesions are usually noted at birth with localized, unilateral, or generalized distribution. The reticulated pattern may be fine or coarse, with broad streaks of discolored skin in a "tram-track-like pattern." Atrophy of the skin and subcutaneous tissue may supervene, resulting in limb hypoplasia (*Fig. 150.5*). Cutis marmorata telangiectatica congenita occurs as an isolated anomaly in the majority of localized cases; however, associated

Figure 150.4
Klippel–Trenaunay syndrome with (a) large geographic vascular stain on the trunk, extending on to the arm and lymphatic malformation in the axilla, and (b) hypertrophy of the hand and forearm

Figure 150.5
Cutis marmorata telangiectatica congenita in an infant affecting right lower limb and trunk with associated ipsilateral limb hypoplasia

congenital anomalies have been reported in 27–50% of cases. Associated abnormalities are more common in generalized cases. The most common associated congenital abnormality is limb hypoplasia. Other rare associations include limb hyperplasia, aplasia cutis congenita, congenital pigmented nevus, widespread dermal melanosis (Mongolian spot), skull asymmetry, syndactyly, scoliosis, hypothyroidism, developmental delay, and anogenital anomalies. Cutis marmorata telangiectatica congenita appears to occur sporadically; however, a genetic basis has been proposed suggesting paradominant inheritance. Cutis marmorata telangiectatica congenita has a tendency to lighten with maturity. In many patients, a marked improvement is often noted in the first 2 years of life. When lightening occurs, it is rarely complete and may have residual reticulate lesions. If lesions persist, they may be treated with pulsed dye laser, although the response is variable.

Significant Vascular Neoplasms and Related Syndromes

Infantile Hemangiomas (IH)

Infantile hemangiomas (IH) also known as hemangiomas of infancy, are the most common vascular tumors seen in childhood. Infantile hemangiomas are not noted at birth and rather become evident in the first few weeks of life as they begin to proliferate. The incidence of IH has been estimated to be 1–5%. Demographic risk factors for IH include female sex, Caucasian ethnicity, premature births, and low-birth-weight babies. Increased maternal age, multiple gestations, preeclampsia, maternal history of infertility, chorionic villus sampling, assisted reproductive technologies, and ovulation promotion have also been proven or suggested as potential risk factors. Although in many instances IH appear as sporadic lesions, recently, a familial tendency was reported in 12% of the patients.

Pathogenesis

The pathogenesis of IH is still not fully understood and is generally believed to be multifactorial. The various suggested pathogenic mechanisms include: (1) developmental theory, (2) placental theory, (3) vasculogenesis, and (4) genetic predisposition.

1. *Developmental Theory:* Developmental basis of IH is suggested due to their common occurrence on the head and neck region; frequent involvement of lines of fusion; and associations of IH with developmental anomalies. It is proposed that some arrest of mesodermal cells occurs during early embryogenesis (between the tenth and twelfth week) that later develop into IH.
2. *Placental Theory*: Frequent appearance of IH in infants with factors associated with placental insufficiency including preterm babies, small for date babies, chorionic villus sampling, etc. suggests a placental link. In addition, IH express GLUT-1 (erythrocyte-type glucose transporter protein), an exclusive marker for IH that is also expressed on chorionic villus cells of the placenta. A relationship to the placenta as the possible source of hemangioma endothelial cells has also been suggested given the presence of overlapping markers in both hemangioma and placental vessels. Infantile hemangiomas probably originate from invading angioblasts that have differentiated toward a placental phenotype or from embolized placental cells. The points against placental origin are lack of villus architecture in histopathology of IH, and IH do not express known placental trophoblastic markers.
3. *Vasculogenesis*: Infantile hemangiomas has long been considered an angiogenic disease because of the tangled disorganized mass of blood vessels in the tumor. The detection of angiogenic factors such as basic fibroblast growth factor (bFGF) and vascular endothelial growth factor-A (VEGF-A) within the tumor has supported this concept. However, an alternative is that IH arises by a process more akin to vasculogenesis, i.e., the de novo formation of vessels from progenitor cells. Children with proliferating IH have increased levels of circulating endothelial progenitor cells and surgical specimens of hemangiomas are positive for co-expression of progenitor specific markers such as CD34, CD133, and VEGF

receptor-2. Thus, VAGF signaling pathway seems to play an important role in the development of hemangiomas.

4. *Genetic Theory*: Familial occurrence of IH favors a genetic basis, and an autosomal dominant mode of inheritance has been proposed. Because of heterogeneity in clinical settings, a polygenic basis has also been proposed. Endothelial cells within the hemangioma lesions (hemEC) exhibit X-chromosome inactivation pattern of clonality with upregulated expression of some markers and downregulation of others. Various upregulating or downregulating mutations within the pathway of angiogenesis/vasculogenesis seem to be responsible for IH.

Clinical Features

Infantile hemangiomas have tremendous clinical heterogeneity in their appearance and behavior. They vary in presentation from small red plaques, nodules, to large and bulky tumors that may result in functional impairment or permanent disfigurement. Infantile hemangiomas often appear as a telangiectatic patch on an area of pallor during the first few weeks of life. Infantile hemangiomas may occur anywhere in the body but the most common location (60%) is the head and neck area. The natural history of IH is characterized by an initial proliferative or growth phase followed by a plateau, and finally the involution phase. Most hemangioma growth occurs in the first 5 months and by this time almost 80% of the final size has been achieved. On an average, IH achieve their maximum size by 9 months, but deep hemangiomas may proliferate little longer. Some IH exhibit minimal proliferation and may remain flat and some may have a network-like or reticulate appearance. Finally, an involutional phase occurs and most IH are involuted by the age 7–9 years. A change in color from bright red to purple or gray often signals transition to involutional phase.

Historically, IH have been classified by their depth into superficial, deep, and mixed types. Superficial hemangiomas involve the superficial dermis and appear as bright red lesions (*Fig. 150.6*). These lesions may be rounded nodules or plaques. Deep hemangiomas involve the deep dermis and subcutis and present as bluish-to-skin-colored nodules. Mixed hemangiomas have both superficial and deep components (*Fig. 150.7*). Another classification of IH is based on morphology and has proven to be more predictive of risk of complications or need for treatment. Under this classification, IH can be described as localized (focal), multifocal, or diffuse cutaneous hemangiomatosis. Localized hemangioma can be further classified as a localized nodule or plaque (*Fig. 150.6*),

Figure 150.6
Localized hemangioma on the dorsum of the hand of an infant

Figure 150.7
Mixed hemangioma with both superficial and deep components on the right flank of an infant

and segmental. Eighty percent of IH are focal and solitary. The term segmental has been used to describe hemangiomas that demonstrate a geographic shape and involve a broad anatomic region or a recognized developmental unit (*Figs. 150.8* and *150.9*). Segmental hemangiomas are at higher risk of complications and associated anomalies. The term multifocal refers to the presence of five or more hemangiomas (*Fig. 150.10*), and these infants are more at risk of visceral involvement. Diffuse cutaneous hemangiomatosis refers to the presence of multiple hemangiomas with a high risk of visceral involvement. They carry a great risk of high output cardiac failure and a high morbidity and mortality. *Table 150.3* enlists hemangiomas of concern and risks associated with them. Ulceration is the most common complication encountered with IH (*Fig. 150.11*). The erythrocyte-type glucose transporter protein 1(GLUT-1) has been shown to be an

Figure 150.8
Segmental hemangioma on the left side of the face of an infant with *PHACE* syndrome

Figure 150.9
Segmental hemangiomas on the right mandibular area of an infant with associated airway hemangiomas

exclusive immunohistochemical marker of IH and is an invaluable tool used to distinguish IH from other vascular neoplasms and vascular malformations.

Congenital Hemangiomas

Unlike IH which arise in early infancy, congenital hemangiomas are rare fully grown solitary lesions that are present at birth. They occur at 1:1 gender ratio and are classified into two different types: noninvoluting congenital hemangioma (NICH), which undergoes proportional growth with the child but no regression; and rapidly involuting

Figure 150.10
Multifocal hemangiomas on the back of an infant

Table 150.3
Infantile hemangiomas (IH) of concern and risks associated with them

IH	Associated risks
Ulcerated hemangioma	Bleeding; infection
Segmental hemangioma	
Ophthalmic	*PHACE/S* syndrome
Maxillary/mandibular	Airways obstruction/*PHACE/S* syndrome
Perineal	*PELVIS* syndrome
Midline lumbosacral	Tethered spinal cord, intraspinal hemangioma, intraspinal lipoma, genitourinary abnormalities
Large hemangioma on/around vital structure/s	
Periorbital	Visual axis occlusion, amblyopia, astigmatism, etc.
Lips/peri-oral	Feeding difficulty, cosmetic disfigurement, ulceration
Nose	Breathing difficulty, scarring, cosmetic disfigurement
Multifocal hemangioma	Visceral hemangiomas (liver, gastrointestinal most important)
Diffuse cutaneous hemangiomatosis	Visceral hemangiomas, high output cardiac failure

Figure 150.11
A large ulcerated hemangioma on the upper limb of an infant

congenital hemangioma (RICH), which regresses within 14–20 months of birth. Clinical appearance and histologically, both NICH and RICH are indistinguishable from infantile hemangiomas, but immunohistochemically neither NICH nor RICH show immunoreactivity for GLUT-1 which is a specific marker of IH.

Table 150.4 includes the syndromes associated with IH and their salient clinical features. Both the syndromes (*PHACE/s* and *PELVIS*) associated with IH are acronyms and are seen in infants with segmental hemangiomas affecting cervicofacial (*Figs. 150.8* and *150.9*) and perineal hemangiomas, respectively.

Table 150.4
Syndromes associated with infantile hemangiomas (IH)

IH	Associated syndrome	Clinical characteristics
Cervicofacial	*PHACE/S* syndrome	*P:* Posterior fossa malformation
		H: Hemangioma
		A: Arterial abnormalities
		C: Cardiac abnormalities/ coarctation of aorta
		E: Eye abnormalities
		S: Sternal clefting/suprapubic raphe
Perineal	*PELVIS* syndrome	*P:* Perineal hemangioma
		E: External genital malformations
		L: Lipomyelomeningocele
		V: Vesicorenal abnormalities
		I: Imperforate anus
		S: Skin tags

Treatment of Infantile Hemangiomas

The clinical heterogeneity and unpredictable and variable course of IH complicate management decisions. Physicians caring for an infant with IH must first determine whether treatment is indicated, as most hemangiomas are self-limited. Up to 38% of hemangiomas referred to tertiary care specialists require treatment due to complications such as ulceration, bleeding, risk of permanent disfigurement, obstruction of vision, airway obstruction, or high-output cardiac failure. Several factors outlined in *Table 150.3* must be considered by physicians managing patients with IH.

1. *Ulceration:* Initial therapy for most ulcerated hemangioma is local wound care. Gentle debridement of crust overlying the ulceration, antiseptic cleaning, and use of antiseptic barrier creams is required in most cases. Topical or systemic antibiotics based on culture and sensitivity are indicated in the presence of secondary infections. If ulceration is recalcitrant to initial topical measures, topical becaplermin gel, a recombinant human platelet-derived growth factor has been shown in a small series to be effective at speeding healing.
2. *Localized hemangiomas of cosmetic concern:* Although most localized IH do not require treatment, in many instances treatment may be indicated due to cosmetic concern, particularly hemangiomas located on the face or other cosmetic sites. Some of the treatment options for such cases include local compression, potent topical or intralesional steroids, cryotherapy, pulsed dye laser, and topical imiquimod (5% cream).
3. *High-risk IH*: High-risk hemangiomas include large, rapidly growing hemangiomas on vital structures, those associated with visceral hemangiomas or systemic anomalies, and diffuse cutaneous hemangiomatosis (*Tables 150.3* and *150.4*). Most cases necessitate a systemic therapy. Various treatment approaches that have been tried in such cases are:
   (a) *Systemic Steroids*: Systemic corticosteroids at a dose of 2–5 mg/kg/day (typically 2–3 mg/kg/day) used up to 6–8 months with slow tapering have historically been the mainstay of therapy. Response to treatment is variable with a reported

regression in one-third, stabilization of growth in another third, and minimal to no response in the final third. Adverse effects are common and include irritability, gastrointestinal upset, sleep disturbance, cushingoid features, adrenal suppression, immunosuppression, hypertension, bone demineralization, cardiomyopathy, and growth retardation.

(b) *Vincristine*: Vincristine has been reported to be effective in the treatment of IH and has historically been reserved for those IH that are resistant to corticosteroids or in patients intolerant to corticosteroids. Single weekly dose of 1–1.5 mg/m^2 has been used. Constipation is the most common side effect, but neuropathy, most commonly presenting as foot drop, is a potentially serious side effect. Administration of vincristine requires placement of central line; therefore, risks associated with it must also be considered.

(c) *Interferon-Alfa*: Recombinant interferon-alfa is an inhibitor of angiogenesis, administered as a subcutaneous injection of three million units per square meter per day, that has also been used successfully for the treatment of IH. Adverse effects include influenza-like symptoms, transient neutropenia, and abnormalities of liver enzymes. The side effect of great concern is spastic diplegia that has been observed more frequently in infants treated at an earlier age thus restricting its use.

(d) *Propanolol*: Propanolol has recently been used in the treatment of IH after growth arrest of an infant's hemangioma was incidentally noted when propanolol was started for obstructive hypertrophic cardiomyopathy. Subsequently, propanolol administered orally at 2–3 mg/kg/day has been shown to have a consistent, rapid, therapeutic effect, leading to considerable shortening of the natural course of IH, with good clinical tolerance. It has been recently proposed to be considered as first-line treatment for high-risk IH due to a better safety profile than other treatment modalities used for such cases. The most common serious side effects of propanolol include bradycardia and hypotension. Other side effects encountered rarely include hypoglycemia, bronchospasm, congestive heart failure, depression, nausea, vomiting, abdominal cramps, sleep disturbance, and night terrors.

(e) *Surgical Excision*: Surgical excision may be an option for function- or life-threatening hemangiomas when medical therapy fails or is not tolerated. Most commonly, surgical therapy is indicated for removal of residual fibrofatty tissue or correction of scarring after involution.

Kaposiform Hemangioendothelioma (KHE)

Kaposiform hemangioendothelioma (KHE) is a rare locally aggressive vascular tumor of the skin, deep soft tissue, and bone in infants and children, characterized by infiltrating nodules and sheets of spindle cells, and is often complicated by the Kassabach–Merritt syndrome. The use of the term "Kaposiform" relates to its unmistakable resemblance to Kaposi's sarcoma and the designation of "hemangioendothelioma" implies the uncertainty regarding the biologic behavior of such tumor, situated somewhere between hemangioma and angiosarcoma. It tends to be locally invasive, but is not known to produce distant metastases. It appears as one or multiple masses, and in most cases is associated with consumptive coagulopathy (Kassabach–Meritt syndrome). Most (75%) cases have skin involvement. Visceral involvement is very uncommon, but several cases with bone, retroperitoneal, or mediastinal involvement have been described. Various factors, including a large tumor, retroperitoneal or visceral involvement, resistance to treatment, presence of lymphangiomatosis, and Kassabach–Meritt syndrome, determine the poor outcome of KHE. Treatment options include surgical excision, systemic steroids, and interferon-alfa.

Figure 150.12
Tufted angioma on the cubital fossa of an infant

Tufted Angioma

Tufted angiomas (TA) are rare vascular tumors, most commonly localized to the skin and subcutaneous tissues and characterized by slow angiomatous proliferation. Tufted angiomas occur most frequently in children and 60–70% of the cases develop before the age of 5 years. Congenital cases are also reported. They are equally prevalent in both sexes and manifest as solitary brown, dull red, or purple patch or plaques (◉ *Fig. 150.12*) that slowly enlarge from 5 months to 10 years. Pain and tenderness are common associated symptoms and may also be accompanied by hyperhidrosis. They usually have a benign course. Rarely, TA may be complicated by the Kassabach–Meritt syndrome. A partial regression may be noticed, but complete regression is not a rule. However, a self-involution has been reported in some congenital TA cases. Surgical excision, cryotherapy, radiotherapy, and pulse-dye laser are the treatment options used for TA.

Surgical Considerations

Preoperative Assessment

In general, most children are healthy and require little specialized evaluation prior to dermatologic procedures. The most important component is a thorough history and physical ensuring proper diagnosis. Any existing conditions affecting surgical risk may require perioperative consultation or have implications for anesthesia. Patient and parents' expectations and goals for the final outcome must be understood prior to undergoing any procedure. The postoperative risks of scarring and possible incomplete resolution of a lesion must be explained by the surgeon. Each patient is unique and a specialized treatment plan must be formulated for their specific diagnosis.

Imaging

An important consideration is when to perform preoperative imaging. Midline lesions, especially on the scalp, are the most concerning for underlying developmental anomalies and can be a harbinger of more serious underlying defects. Nodules on the scalp may communicate with deeper structures and represent a dermoid cyst with a sinus tract, encephalocele, or heterotropic brain tissue. In addition, congenital midline skin lesions such as lipomas, dermal sinuses, acrochordons, or localized hypertrichosis can be the first recognized sign of spinal dysraphism. Most authors agree that magnetic resonance imaging (MRI) provides the best resolution and most accurate information for both superficial and deep structures of the head, neck, and spinal column. A drawback of this modality for infants and young children is the necessity for sedation. Ultrasound is also an effective imaging tool for dermatologic lesions of the midline. It does not require sedation and is far more cost effective, making ultrasound the imaging technique of choice in this age group. MRI or ultrasound is indicated prior to both biopsy and excision of congenital midline cranial masses.

Timing of Surgery

There is no single guideline among dermatologic surgeons about the optimal time to surgically intervene on nonlife-threatening conditions such as hemangiomas, vascular malformations, dermoid cysts, or congenital nevi. The final decision is best made through collaboration of both the surgeon and parents. There is no specific age when local anesthesia can be used over general anesthesia but, if a child is unable to cooperate through the entire procedure, general anesthesia must be used. Some authors feel 8 years in girls and 9 years in boys are the ideal ages, but this is highly variable. An excision performed at a younger age is able to benefit from increased skin mobility but will most likely require general anesthesia. While waiting until preadolescence could allow use of local anesthesia, a large lesion may require a staged excision due to decreased skin mobility. In general, elective procedures should be delayed until preadolescence, so the risk of general anesthesia can be avoided. Exceptions to this rule include certain vascular malformations and hemangiomas, where earlier intervention can prevent development of significant functional and cosmetic problems in the future. Capillary malformations can lead to tissue hypertrophy over time, making treatment more difficult. Venous and arteriovenous malformations are often more extensive than they appear on the surface of the skin, leading to damage of underlying structures with subsequent enlargement. Some proliferative infantile hemangiomas ulcerate or impair important structures. In these circumstances, a more prompt surgical intervention is warranted.

Anesthesia

Techniques to minimize pain during local injection are distractions such as video games or movies, topical anesthetics, lidocaine buffered with sodium bicarbonate, warming the anesthetic and slow infiltration of the anesthetic. Eutectic mixture of local anesthetics (EMLA) cream was the first widely used topical anesthetic used in children. EMLA is generally well tolerated, but there is an increased risk of methemoglobinemia when used in

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_151,

infants younger than 3 months of age. Liposomal lidocaine is a new formulation with similar efficacy to EMLA without the risk of methemoglobinemia. Viscous lidocaine and lidocaine patches are available in a variety of formulations. For pediatric patients, lidocaine 1% (10 mg/ml) is the preferred concentration buffered with 8.4% sodium bicarbonate in a 1:10 ratio. This lessens the injection pain without affecting the onset or duration of anesthesia. The maximum dose of 1% lidocaine without epinephrine is 5 mg/kg and with epinephrine is 7 mg/kg.

Most authorities agree the highest risk period for general anesthesia is within the first year of life. However, the overall risk in a dermatologic setting is low because of the short operation time, the nonemergent elective nature of the procedures, and the majority of patients being healthy. At our institution, general anesthesia is reserved for patients over 6 months of age unless special circumstances necessitate earlier intervention. In a recent multicenter retrospective review of 881 procedures, the most common complication was postoperative nausea seen in 4% of patients. The most common serious complications were hypoxia and aspiration which occurred in 0.1%. Overall, the risk was quite low with over 90% of procedures occurring without complications.

Common Lesions

Verruca Vulgaris

Human papillomavirus (HPV) types 1, 2, 4, 27, and 41 are frequent causes of common warts and infect 20% of school-age children. Warts are most frequently located on the fingers, hands, or feet but can occur anywhere. Numerous medical and surgical modalities are available, though a large percentage of lesions will spontaneously regress within 1–2 years. Conventional medical treatments consist of topical application of podophyllotoxin, cantharidin, salicylic acid, trichloroacetic acid, or lactic acid. Newer immunomodulators such as 5-fluorouracil and imiquimod have also been shown to be effective. In the pediatric population, these options are often difficult because of the frequency and length of application. Locally destructive therapy options include cryosurgery with liquid nitrogen, curettage, electrosurgery, or laser. First-line therapy is cryosurgery with two freeze thaw cycles which can be repeated every 4 weeks until the warts are gone. For recalcitrant lesions, pulsed-dye laser or potassium-titanyl-phosphate (KTP) laser can be used to target the rich supply of dermal capillary vessels present in warts. Combination therapy with a topical and a destructive option often provides the best results (*Fig. 151.1*).

Figure 151.1

Molluscum

Molluscum contagiosum is a member of the poxvirus family and causes common cutaneous lesions in children. Transmission is via direct contact so the virus is often spread between children at daycares and school. The smooth, dome-shaped papules will spontaneously involute in 2–4 years, but treatment is usually requested. Along with numerous medical therapies, cryotherapy and curettage are potential surgical interventions. The limiting factor in the pediatric setting is pain of these procedures, so medical options such as cantharadin or imiquimod cream should be performed first (*Fig. 151.2*).

Congenital Nevi

Congenital nevi are divided into three categories: small, less than 1.5 cm, medium, 1.5–19.9 cm, and giant, 20 cm or greater. All nevi have the potential to develop

Figure 151.2

Figure 151.3

melanoma, but the risk of melanoma is directly related to the size. Most experts agree giant congenital nevi should be excised at a young age because of their increased risk of melanoma. Tissue expansion and staged excision are required in the majority of cases to preserve function and provide adequate cosmesis. For small and medium congenital nevi, careful surveillance is the best option. However, if the lesion begins to change color, shape, or size, it should immediately be evaluated by a dermatologist. Dermabrasion or curettage should not be performed because surgical excision is the only treatment that alleviates the risk of melanoma. Also, these procedures distort both the clinical and histologic architecture, making the diagnosis of a future melanoma far more difficult (*Fig. 151.3*).

Epidermal Nevi

Epidermal nevi are linear hyperpigmented papillomatous lesions distributed along the lines of Blaschko. They occur in 1 in 1,000 live births and are present at birth in 80% of cases. Complete excision to the dermis is required to prevent recurrence but is not always an option based on size or location. Laser ablation, cryosurgery, and medium-to-full-depth chemical peels may decrease symptoms and provide improved cosmesis but will not resolve the lesion (*Fig. 151.4*).

Pyogenic Granuloma

Pyogenic granulomas are solitary friable rapidly growing vascular proliferations usually occurring at sites of trauma. Minor trauma can cause extensive bleeding and be quite alarming to patient and family. These lesions can occur at any age but are more common in children and young adults. Scoop shave excision with electrodesiccation, excision with primary closure, or pulsed-dye laser are effective treatment options (*Fig. 151.5*).

Spider Angioma

Spider angiomas are bright red dilated vessels most commonly seen on the face, forearm, or hands. These lesions respond very well to treatment with pulsed-dye laser or electrofulguration. Multiple treatments maybe required with either method, but electrofulguration carries an increased risk of scarring (*Fig. 151.6*).

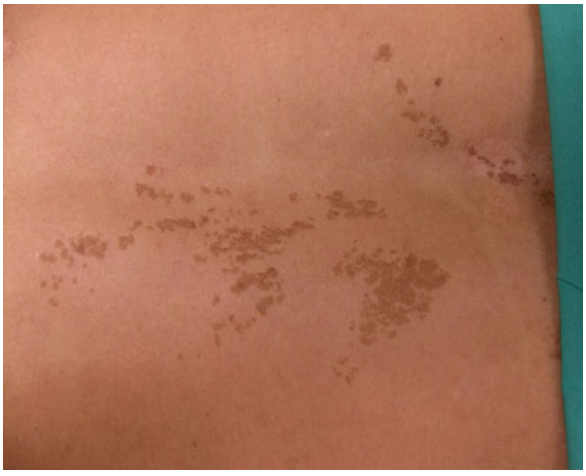

Figure 151.4

Figure 151.5

Figure 151.6

Birthmarks

Hemangiomas

Hemangiomas are benign, congenital vascular proliferations of endothelial cells occurring in 10% of newborns within the first year of life. Most hemangiomas typically undergo a proliferative phase of rapid growth during the first 3–6 months of life followed by a plateau phase and finally an involuting phase after 12 months. Studies have shown 30% of lesions involute when the child is 3 years old, 50% when 5 years old, and 90% when 9 years old. The majority of hemangiomas will involute completely, but 20–30% will leave a residual fibrofatty, atrophic, telangiectatic, hypopigmented, or hyperpigmented scar. These lesions are typically observed if they are limited, do not ulcerate, or do not impair a vital structure. Large segmental facial hemangiomas should raise the suspicion for PHACES syndrome which is an acronym standing for posterior fossa brain malformations, hemangioma, arterial anomalies of the aortic branches, eye anomalies, and sternal defects. Lower facial hemangiomas ("beard" hemangiomas) can be a marker for laryngeal involvement and subsequent airway obstruction. Recent studies support the use of propranolol for extensive hemangiomas that require treatment. Other modalities include intralesional corticosteroids, vascular laser, interferon alfa, and vincristine. After regression, pulsed-dye laser or surgical resection can be used to improve the residual thin skin, malformed vessels, or pigmentary changes.

Vascular Malformations

Nevus flammeus (salmon patch) is a common vascular birthmark located on the glabella, posterior scalp, or nape of neck. The majority of these lesions fade by 2 years of age. Treatment is usually not necessary, but low potency topical corticosteroids can be used with good results.

Port-wine stains are large capillary malformations present at birth in 0.3–0.5% of newborns. They commonly affect the face in the distribution of the trigeminal nerve but can present anywhere on the body. These lesions result in a significant cosmetic problem but can also be part of systemic syndromes. Sturge–Weber syndrome consists of a port-wine stain in the ophthalmic branch of the trigeminal nerve with or without maxillary or mandibular involvement along with glaucoma, seizures, and mental retardation. Klippel–Trénaunay syndrome consists of a port-wine stain usually on an extremity with associated venous malformations and hypertrophy of the affected limb. Proteus syndrome comprises port-wine stains with soft tissue hamartomas, asymmetric overgrowth of bones, and cerebriform connective tissue nevus of palms and soles. The gold standard for treatment of port-wine stains is pulsed-dye laser. Gradual fading will occur over successive treatments with as much as 80% resolution after eight to ten sessions. Best results are obtained when treatment begins prior to 1 year of age. Treatment is painful and requires general anesthesia when performed in young patients. Early laser treatment helps prevent later hypertrophy which is much more difficult to treat (*Fig. 151.7*).

Figure 151.7

Figure 151.8

Café-au-Lait Macules

Café-au-lait macules are light or dark brown macules which can be located anywhere on the body. They are very common and reported in 10–20% of the population. Response to treatment is highly variable and must be explained to the patient and family prior to therapy. Prior to treatment of large or extensive café-au-lait macules, treating small test areas within a lesion is helpful to determine the best laser setting and outcome. This also tests for posttreatment hyper- or hypopigmentation which is an unfortunate side effect. Pigment lasers such as Q-switched ruby, Q-switched Nd:YAG, or Q-switched alexandrite are effective, but multiple treatment sessions are required, and as many as 50% of lesions may recur (*Fig. 151.8*).

Nevus of Ota and Mongolian Spots

Nevus of Ota is a congenital blue-gray hyperpigmentation in the distribution of the first and second branches of the trigeminal nerve seen more commonly in Asians. Mongolian spots are similar lesions located in the lumbar and sacral area but are more likely to regress during childhood. The discoloration is due to melanin-producing melanocytes within the dermis. Given the depth of dermal pigment, pigment lasers with longer wavelengths such as the Q-switched ruby, Q-switched Nd:YAG, or Q-switched alexandrite are effective treatment options. Like other melanocytic lesions, multiple treatments are required for successful removal and may not give total resolution (*Fig. 151.9*).

Figure 151.9

Becker's Nevus

Becker's nevus is an acquired hairy hyperpigmented plaque most commonly on the shoulder and upper arm of males. Malignant transformation has not been reported, so treatment is for improved cosmesis. The hyperpigmented component can be treated with pigmented lasers such as Q-switched ruby or Q-switched Nd:YAG, but recurrence is high. Fractional resurfacing has also been reported to be effective to lighten and improve texture. The hypertrichosis in Becker's nevus can be treated with hair removal lasers such as the long-pulsed

Figure 151.10

Figure 151.11

ruby, long-pulsed alexandrite, long-pulsed diode, long-pulsed Nd:YAG, or intense pulsed light (IPL) (Fig. 151.10).

Malignancies and Rare Tumors

Melanoma

Melanoma is very rare in children with only 2% of all melanomas occurring before the age of 20. In general, pediatric melanomas have thicker primaries than adults because of delayed time to diagnosis. Treatment in children is similar as in adults with wide local excision being the standard of care. The margins for re-excision are based on depth of tumor invasion on initial biopsy. The current recommendations for excision with tumor thickness <0.5 mm is 0.5 cm margins, 0.5–1.0 mm is 1.0 cm margins, 1.0–4.0 mm is 2.0 cm margins, and >4 mm is 2.0–3.0 cm margins.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans is a rare spindle cell tumor occurring in 0.8 per million people, with only 6% of those in children less than 16 years of age. The preferred treatment of these tumors is Mohs micrographic surgery which gives clearance rates of 93–100% (Fig. 151.11).

Hyperhidrosis

First-line treatment for mild hyperhidrosis is topical 20% aluminum chloride hexahydrate or 6.25% aluminum tetrachloride daily for three to five consecutive nights, then once weekly. For more persistent hyperhidrosis, intradermal injection of botulinum toxin type A can produce near anhidrosis for 4–6 months. Oral anticholinergics will decrease sweating in most patients but have significant side effects such as dry eyes, dry mouth, palpitations, mental status changes, changes in vision, urinary retention, and bowel disturbances so should be used with caution. Excision of the sweat glands and sympathectomy are more radical procedures that should only be used in refractory cases.

152 Pediatric Skin Care: Skin Barrier Management and Topical Treatment in Pediatric Dermatology

Zbigniew Ruszczak

Children's skin differs both physically and physiologically from adolescent and adult skin. Newborn skin is the most fragile and permeable, is affected by transepidermal water loss, and is susceptible to penetration by toxic environmental substances or drugs intentionally used to improve pathologic skin conditions. Children's skin is more likely to develop blisters or erosion in response to heat, chemical irritation, and mechanical trauma, including simple friction. Consequently, conditions that may not negatively affect adult skin need to be considered as potentially harmful to children's skin.

One of the most important functions of the human skin is its barrier function. In this respect, an appropriately functioning epidermis is one of the crucial elements. Normally, keratinization of the human epidermis begins at about the 24th week of gestation and is completed shortly before term, so that transepidermal water loss and transepidermal absorption of topically applied substances at birth are similar to those of older children. However, elasticity of young children's skin is much less than older children due to a deceased amount of collagen and elastic fibers. Response to ultraviolet (UV) light differs due to a low number of melanocytes, which still need to proliferate and to mature. Even though the sebaceous glands are fully developed, the numbers of eccrine and sebaceous glands are lower in newborns, children, and young adolescents. This phenomenon has practical clinical implications, i.e., in the development of acne, folliculitis, or pigmentary disorders potentially linked to functioning sebaceous glands (e.g., the so-called "progressive macular hypomelanosis").

In children, skin injuries, hyperemia, and inflammatory processes, as well as acidosis, ischemia, and systemic infections including sepsis, may negatively influence the skin's barrier function.

It is important to realize that in newborn and young children the skin surface:volume ratio is much higher than in older children, adolescents, and adults, and this may result in a higher cutaneous penetration ratio. This phenomenon influences the calculation of the applied dose of topically administered agents and always needs to be considered in therapy planning.

Skin permeability is inversely proportional to gestational age. Even in infants born at term, transcutaneous water loss and percutaneous absorption of topically applied substances, including intentionally given drugs, is two to three times higher than in older children and adults. Substances of low molecular weight and water-soluble substances penetrate very easy. Topically applied antiseptics and antibiotics, salicylates, urea, and alcohol-containing dressings have been associated with neonatal toxicity due to percutaneous absorption, especially in premature infants and newborns.

It is important to realize that the normal barrier function of the skin depends not only on the development of physically intact, cornified epidermis, but also on the quality of epidermal lipid composition. This has important implications in cases of so-called "dry skin" as, for example, in children with atopic dermatitis.

Skin pH is important in the regulation of antimicrobial barrier function and regulation of transepidermal penetration. At birth, the skin pH is usually neutral or slightly alkaline (pH of 6.2–7.5) and decreases rapidly during the first weeks, reaching the range of 5.0–5.5 at the fourth week of life.

Neonatal and newborn skin is more predisposed to heat loss, resulting more from evaporation of water from the skin's surface than from radiative heat loss. The vasoconstrictive response to reduced environmental temperature has practical clinical implications if neonates, newborns, and young children will be examined in cold rooms or left uncovered for a longer period of time before medical examination.

Different body sites have different permeability. Variations in the epidermis, especially in the stratum corneum, and its hydration status, density of hair follicles and sebaceous glands, thickness of the epidermis and dermis, local body temperature, and occlusion influence the penetration of topically applied agents through the epidermis into

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_152,

the dermal skin component, vasculature (and eventual further systemic effect), and subcutaneous fat.

Both long-term, practical experience and clinical experimental data support the simple and practical ranking of body sites from the highest to the potentially lowest permeability and absorption rate – scrotum, face and scalp, trunk and extremities, palms and soles, nails. Hair does not actively absorb or transport substances from the surface into the skin, but the absorption of agents applied to the hair may easily occur through the hair follicle and pilosebaceous units.

Topically applied substances are usually poorly absorbed and only a small portion of the drug penetrates through the stratum corneum. Most of the applied agent remains on the skin surface and is then actively or passively removed from the application area by exfoliation, sweating, wash-out, rub-off, penetration into clothing, or by time, pH, or UV exposure–related degradation.

Therefore, local application of a drug under occlusion (i.e., under polyethylene foils, colloidal, or hydrocolloidal patches) may dramatically increase the penetration and, consequently, local and systemic absorption.

A number of local or environmental factors can increase transepidermal and transdermal penetration of the active substance. Hydration of the skin due to occlusion (moisture retention) in intertriginous areas can increase absorption up to five- to tenfold. Removal of lipid components from the skin surface, for example, by alcohol swab, can also increase transepidermal penetration due to removal of the superficial fat and "opening" of the natural skin barrier. The addition of alcohol or polyethylene glycol to the drug-carrying vehicles also increases penetration of the active substances. This technique has been utilized in the manufacturing of vehicles for super- and high-potent steroids to maximize their bioavailability. On the other hand, extensive use of such substances along with, for example, dimethyl sulfoxide (DMSO), may lead to local adverse skin reactions in the form of burning, stinging, or maceration, especially in eroded skin, and may also lead to irritation or allergic contact dermatitis.

The "opening" or "expansion" of the stratum corneum by DMSO, glycols, water, and other solvents enhances the uptake of the drug and is often used to establish a "superficial skin reservoir" of the applied medication.

Appropriate skin function is best maintained by keeping the skin barrier intact and restoring it as quickly as possible if barrier function is impaired.

Historically, the best way to keep the skin barrier and the skin itself in good shape was to keep skin moist and lubricated. However, this conventional wisdom is not correct. Overwetting and overfatting, especially using semisolid lubricants like vaseline or liquid paraffin may lead to occlusion of the skin surface and retention of heat and fluid under the fat film, negatively influencing skin condition.

Many nondermatologists may be hesitant to use some specific medications in younger patients because of safety concerns. Two groups of topical skin medications are of special interest: corticosteroids and emollients.

Topical Steroids

The selection of a topical corticosteroid in terms of strength and vehicle depends on the nature, location, and extent of the skin lesion(s), the age of the patient, and the duration of treatment.

The vehicle is a crucial factor in topical delivery of active substances. An ointment is generally the most effective vehicle for treating thick, fissured, and lichenified skin lesions. The occlusive nature of the vehicle enhances corticosteroid penetration. In large surface areas it may, however, lead to accumulation of heat and moisture under the almost occlusive layer of the vehicle. Ointments may be considered aesthetically undesirable by some patients.

Creams are generally the vehicle of choice for acute and subacute dermatoses. They may be used on moist skin and in intertriginous areas and are generally aesthetically acceptable to patients. Cream vehicles may occasionally be considered drying, and some patients may benefit from the application of a moisturizer in addition to a corticosteroid cream. Cream formulations usually require the addition of preservatives, which may cause sensitivity.

Solutions, gels, and sprays are the most aesthetically elegant vehicles for use on the scalp. They also may be useful when, for aesthetic or medical reasons, a non-oil-based vehicle is needed. These vehicles frequently contain alcohol and propylene glycol, which may cause irritation or burning if applied to acute dermatoses, erosions, or fissures (see above).

Topical steroids are the most potent anti-inflammatory agents. The introduction of corticosteroids for systemic application in 1951 and topical administration in 1952 revolutionized the daily practice of dermatology.

Development of topical corticosteroids focused on enhancing biological potency and simultaneously minimizing side effects, retaining high activity in the skin and quick metabolism after absorption into inactive metabolites ("soft" corticosteroids). Mometasone and fluticasone propionate (see below) are examples.

Normally, only 1% of an applied corticosteroid dose is therapeutically active. Cutaneous side effects can result from this small percentage or from the transient presence of the initial amount on the skin surface, intended occlusion, large surface area application, or physiologic occlusion in intertriginous or diaper areas.

High-potency topical corticosteroids should be used briefly or intermittently, and potency and frequency should be reduced once partial improvement is achieved. Sudden discontinuation almost always leads to rebound effect and prolonged therapy to tachyphylaxis.

In infants and children the use of topical corticosteroids is influenced by the high ratio of surface area to body weight. Infants, especially premature infants, are less able to rapidly metabolize the quickly absorbed drug through their thin skin.

Topical corticosteroids are divided into seven classes according to their biological potency. Class I represents the most biologically active (potent) drugs, whereas class VII represents the weakest.

The potency of a topical steroid determines its clinical application, maximal surface area treated, duration of application, and potential local and systemic side effects.

It is important to note that a topically applied steroid may change its clinical potency not only due to the concentration, but also depending on the vehicle used, because the type of vehicle determines the bioavailability, penetration, and the length of time the drug stays on the skin surface, and therefore the vasoactive properties.

Some steroids have been chemically modified so that they retain their biological potency in all forms of vehicles used for application to the skin. This complicates the understanding of the biology of topical steroids.

To make this "science" simpler, the following classifications do not include the weight percentages of the particular steroid or the grams of vehicle, but focus on the chemical form of the vehicle itself (petrolatum-based ointment, cream, or lotion).

Class I (ultrapotent) steroids are clobetasol propionate, betamethasone dipropionate, diflorasone diacetate, and halobetasol propionate, all in an ointment vehicle. Clobetasol is also considered ultra-potent as a cream or lotion.

Class II (potent) steroids include betamethasone dipropionate (in a cream or lotion vehicle), mometasone furoate (in all forms – ointment, cream, gel, and lotion) diflorasone diacetate (ointment), halcinonide (ointment), triamcinolone acetonide (ointment), fluocinonide (ointment, cream, and gel), and desoximetasone (in all forms – ointment, cream, and gel).

Class III (high-mid strength) steroids include triamcinolone acetonide (ointment), fluticasone propionate (ointment), amcinonide (cream or lotion), diflorasone diacetate (ointment), halcinonide (in all forms – cream, ointment, and lotion), fluocinonide (ointment, cream, and gel), desoximetasone (ointment and cream), and betamethasone valerate (ointment).

Class IV (middle-mid strength) includes triamcinolone acetonide (cream), flurandrenolide (ointment, gel, and cream), prednicarbate (ointment), mometasone furoate (cream and lotion), triamcinolone acetonide (ointment), betamethasone valerate (foam or cream), fluocinolone acetonide (ointment), and hydrocortisone valerate (ointment).

Class V (low-mid strength) includes alclometasone dipropionate (ointment), flurandrenolide fluticasone propionate (lotion and cream), prednicarbate (cream), triamcinolone acetonide (lotion), hydrocortisone butyrate (ointment, cream, and solution), fluocinolone acetonide (cream), and hydrocortisone valerate (cream), and prednicarbate (cream).

Class VI (low strength) steroids, including alclometasone dipropionate (ointment, cream, and lotion), desonide (ointment and cream), and fluocinolone acetonide (solution).

Class VII (very low strength) steroids include hydrocortisone as a cream in all available concentrations: 0.5%, 1%, and 2.5%.

Structural modifications influence the efficacy of topical corticosteroids. Betamethasone dipropionate and clobetasol propionate, known as fifth-generation corticosteroids, are typical examples of super-potent molecules that can control specific dermatoses very rapidly, but that are associated with a high risk of topical and systemic adverse effects.

Recently, steroid components have been synthesized that aim to have adequate anti-inflammatory effects and minimal adverse effects. The topical corticosteroids widely used nowadays for the treatment of different dermatoses and allergic reactions of the respiratory tract (in particular asthma) are budesonide, mometasone furoate, prednicarbate, the di-esters 17,21-hydrocortisone aceponate and hydrocortisone-17-butyrate-21-propionate, methylprednisolone aceponate, alclometasone dipropionate, and carbothioates such as fluticasone propionate. These new formulations have higher anti-inflammatory effects and good compliance among patients (often only a once-daily application is needed), compared with well-known and established corticosteroids. They rarely induce cross-sensitivity reactions and have weak atrophogenicity.

Minimally infiltrate, acute, inflammatory skin lesions frequently respond to low- to medium-strength topical corticosteroids. Chronic, hyperkeratotic, lichenified, or indurated lesions may better respond to high- or very high-strength topical corticosteroid preparations.

Treatment of the face and intertriginous areas (axilla, groin, perineum, and inframammary area) needs special consideration. Because of the thin stratum corneum and possibly because of the nature of the pilosebaceous structures in the area, the face is particularly susceptible to local side effects. In intertriginous areas, heat, moisture, a thin stratum corneum, and self-occlusion enhance the penetration of topical corticosteroids that can cause both local side effects and potential systemic effects from the enhanced absorption. The occlusive effects of diapers enhance penetration in the groin area to an even greater extent.

For these reasons, low-strength preparations are preferred for the face and intertriginous areas. In some patients, especially if the lesions are indurated, lichenified, or impetiginized, short-term (generally for a week or 2 weeks) use of more potent agents is occasionally required. These agents should rarely, if ever, be used in the diaper area of infants.

Recalcitrant lesions of the face or intertriginous areas such as those of discoid lupus erythematosus and lichen sclerosus may require more potent corticosteroids or a longer duration of treatment.

Lesions on skin with a thick stratum corneum, such as the palms and soles, frequently require treatment with high- or very high-strength topical corticosteroids to achieve significant improvement.

The amount of body surface area to which the corticosteroid is to be applied will help determine the specific class of drug that should be used. Because of the likelihood of systemic absorption, corticosteroids of low to medium strength are preferred when large areas are to be treated.

It is important to make treatment simple for patients, parents, and physicians. Parents should be instructed on how to apply medications. It is important to prescribe the appropriate amount of the drug – too little leads to too quick an end to medication, provoking rebound effects after abrupt interruption; too much may lead parents to apply more than appropriate.

Thin application is desirable for most medicines except emollients, where thicker or multiple daily applications may be preferred. Moisturizers may be applied in the "steroid free intervals" to damp skin to retain hydration.

Estimates of coverage of the skin can be made by using the "rule of nines," in which the body surface is divided into 11 equal parts, each constituting ~9% of the total body surface area. Based on this, the following estimation can be made: 2 g of cream or ointment should be enough to cover each of the following body surface areas (thin application!): head, one arm, chest (anterior), back, abdomen, buttocks, lumbar area, one half of each leg.

Another practical way to measure the amount of topical steroids needed per application is the fingertip unit (FTU) and the rule of hand. An FTU is the amount of cream or ointment that can be pressed out onto the medial surface of the second finger of the adult hand. Two "mean" adult hand surfaces correspond to one FTU, which is approximately 0.5 g of the topically applied agent.

Unfortunately, both the opening of the tube (tube-size-dependent) and the adult finger are not standardized, so the rule has been established for practical demonstration to the patient/parent how much cream or ointment should be applied per surface area.

Factors that increase percutaneous absorption of a medication include inflammation, fresh skin hydration (after a bath), any type of occlusion (especially with plastic foils, films, or wraps or the use of diapers), epidermal breakage or injury, heat and hot, humid environment (climate should be considered), and type of vehicle (see above).

Age is a consideration in the selection of both the class of the steroid used and the vehicle, particularly in children and elderly patients, because of the body surface area to weight ratio in infants and the thinness and fragility of the skin of premature infants and the elderly.

In children, the duration of daily use of very-high-strength topical corticosteroids should not exceed 1–2 weeks and should be restricted only to the most affected areas and areas of concomitant lichenification. Recalcitrant lesions on small body surface areas may be eventually treated for a longer duration of time.

Higher to medium-strength corticosteroids should not be used in intertriginous areas, including diaper areas. Medium- and high-strength topical corticosteroids rarely cause side effects when used with caution for 3 months or less. Exceptions include use on the face and in intertriginous areas. For treatment of longer duration, intermittent therapy may be preferable to long-term continuous therapy.

Side effects are rare with the use of low-strength topical corticosteroids. However, even with these agents, intermittent therapy may be preferable to continuous therapy for long-term management of chronic skin diseases, particularly if large surface areas are being treated.

Allergic reactions should be considered in cases of persistence or worsening of the inflammatory dermatosis despite topical corticosteroid application (bacterial and/or fungal infections should be ruled out up-front).

Potential contact sensitizers in topical corticosteroids are vehicle components such as parabene, propylene glycol, benzyl alcohol, chlorocresol, ethylenediamine hydrochloride, isopropyl palmitate, polysorbate, stearyl alcohol, or the corticosteroid itself. Prevalence of corticosteroid-dependent sensitization is 0.2–6% and depends on the frequency, duration, and type of drug used.

Topical corticosteroids should be discontinued when the skin disease has resolved. Long-term therapy with topical corticosteroids may be used for a chronic skin disease that is responding to treatment with the medication. If continuous long-term treatment is needed, patients should be monitored for the development of side effects and tachyphylaxis (loss of clinical effect over time).

The recommended frequency of application varies depending on the topical corticosteroid selected and the site to be treated.

Once- or twice-daily applications are usually recommended for most preparations. Occasionally, more frequent application is necessary. Skin with a thick stratum corneum and from which the medication is easily removed during normal activity, such as the palms and soles, may require more frequent application. Other regimens, such as every-other-day therapy or weekend-only (pulse therapy) application, may be effective for chronic conditions in selected cases.

Generally, the lowest potency corticosteroid that is effective, especially in infants and children, should be used. Occlusion under polyurethane or polyethylene foils, tight-fitting clothing, or diapers increases absorption several-fold.

Prolonged use should be avoided in the periorbital area, face, and intertriginous areas.

Topical corticosteroids used in large amounts, for long time periods, and under occlusive conditions may cause different abnormalities. Reported side effects of topical corticosteroid use include cutaneous and/or local effects such as acneiform eruption, folliculitis, rosacea, periocular and perioral dermatitis, atrophy of the epidermis and dermis, skin fragility (young or sun-damaged skin, intertriginous areas, and the face are most susceptible), delayed wound healing, granulomas, purpura, telangiectasia and erythema, striae, hypopigmentation, and hypertrichosis. Use of topical steroids can mask or aggravate dermatophyte or bacterial infection or promote secondary infection.

Systemic side effects of appropriately administered topical steroids are rare. They are seen most frequently with prolonged and extensive use in infants and children of very-high-strength topical corticosteroid compounds. Such adverse reactions may lead to cataracts, glaucoma with periorbital use, adrenal suppression (hypothalamic-pituitary-adrenal axis), growth retardation (infants and young children), hypertension, and Cushing's syndrome.

In summary, topical corticosteroids, if used appropriately, are safe and effective.

Current advice to patients to apply topical corticosteroid preparations "sparingly" or "thinly" contributes to "steroid phobia," increasing the risk of poor clinical response and treatment failure.

In the patient's mind, the current advanced groups are mixed together with the old-generation steroids, regardless of their potential for adverse effects. The advice also tends to reinforce an erroneous concern that the risks from topical corticosteroids may be similar to those from systemic corticosteroids.

Recently, a change in the pharmacy labeling of topical corticosteroids has been proposed to more accurately reflect the low risk of harm from corticosteroids of low to moderate potency and the importance of applying sufficient medication to achieve a satisfactory clinical response. Patients are informed that treatment should not exceed prescribed quantities, and if used for a prolonged period of time careful medical supervision is required. The current recommendation of the European Dermatology Working Group stresses that topical corticosteroid product information should include clear "fingertip unit" instructions, preferably with images of an FTU and a chart to show the number of units required for specific areas of the body (see above for details).

The fear of use of topical steroids resulted in the development of products having steroid-like biological effect without steroid-like adverse reactions. Recently, two new topical immunosuppressive treatments, pimecrolimus and tacrolimus, were marketed to provide alternatives to topical corticosteroids without the associated long-term side effects. They both work by inhibiting calcineurin in the skin, which regulates the activity of several transcription factors that control cell division and trigger the early stages of T cell activation.

Tacrolimus 0.1% is as effective as potent corticosteroids for treating atopic dermatitis and more effective than mild preparations such as hydrocortisone acetate 1%.

Pimecrolimus is less effective than potent corticosteroids; it has not been compared with mild corticosteroids.

Both agents caused more burning of the skin than topical corticosteroids, but no differences were observed in rates of skin infections.

Both products would be interesting alternatives to topical corticosteroids, but they cannot be seen as a corticosteroid replacement, especially in the management of an acute phase of an inflammatory skin disease.

Moisturizers and Emollients

As mentioned previously, emollients (moisturizers) are essential not only to maintain the function of skin barrier but also to support hydration and integrity of the skin. Moisturizers are a group of cosmetic products designed for skin care and hygiene. They make the skin surface (stratum corneum) softer and more pliant by increasing its hydration. Among many moisturizing skin products on the market, some are marketed as so-called cosmetic and therapeutic adjuvants.

The beneficial effects of emollients include support of skin barrier functions and protection against transepidermal water loss and negative effect of exogenous or endogenous offenders that result in dry and/or scaly skin. Moisturizers are possibly the most prescribed products in dermatology, and, until recently, even dermatologists received little or no training regarding their ingredients, pharmacokinetics, benefits, and toxicities.

Naturally occurring skin lipids and sterols are often added to moisturizers. In the correct proportion, these agents can help promote repair of cutaneous barrier function. In the wrong proportion, they can delay repair or may have opposite effect.

The term "moisturizer" is often used synonymously for humectant, emollient, lubricant, oil, or grease, which is not fully correct since each term has a specific definition. A moisturizer is a substance that imparts or restores moisture. A humectant is a substance, such as glycerin, that absorbs or helps another substance retain moisture. The term "emollient" describes a substance that makes something soft or supple. Grease is rendered animal fat or a thick lubricant, usually oily matter. "Lubricant" is a term for a substance, such as grease, that is capable of reducing friction, heat, and wear when introduced as a film between solid surfaces; something that lessens or prevents destruction by rubbing.

Moisturizers claim to heal and prevent the dryness of the skin. Dry skin is not a unique, well-defined condition, but represents a medley of totally unrelated changes in the structure of the stratum corneum associated with environmental and systemic conditions that influence the properties of the skin surface.

Information about moisturizers has exponentially increased in recent years. Their structure and function are becoming very complex and sophisticated; many are equidistant between cosmetics and drugs. Modern moisturizers include agents that mimic natural ingredients and function as botanicals, including vitamins, hydroxy acids, and retinoids. Other common ingredients are metabolites of collagen, elastin, deoxyribonucleic acid, ribonucleic acid, lecithin, sodium hyaluronate, sodium passive cutaneous anaphylaxis, and ceramides.

Moisturizers impart a temporary barrier to the damaged stratum corneum, which allows time for repairing this layer. Two concepts have been proposed to explain water passage through the skin. First, the solubility-diffusion model postulates that water has a finite solubility in lipids; therefore, it can permeate through lipids. In this model, the water molecules are moving through the lipid barrier as individual entities, or one molecule at a time. This model is probably the best description of transepidermal water loss through the stratum corneum. The second model postulates that water passes through lipids through transient pores or water-filled channels. The evidence for the existence of such channels or pores is inconclusive in the case of most biomembranes and especially for the stratum corneum.

Emollients fill the spaces between the corneocytes, thus providing therapeutic improvement to defects in desquamation. Emollients function is to smoothen the roughened skin, changing its appearance, supplementing or replacing natural skin lipids, and providing occlusion. Emollients are usually composed of water in oil emulsions; thus, oil is the largest component, ranging from 3% to 25%. The concentration of oil in emollients is important for easier spreading and for the degree of occlusion that is desired.

Negative effects of the use of moisturizers are rare. Dermatitis is seldom observed with the application of moisturizers. When dermatitis occurs, the ingredients that are most frequently liable are fragrances, preservatives, lanolin, vehicles, and sunscreens. The most common offenders in fragrances are cinnamic alcohol, hydroxycitronella, and isoeugenol along with often reported and well-known potential sensitizers such as formaldehyde-releasing preservative systems, notably quaternium-15, imidazolidinyl urea, and bronopol.

The most important inflammatory skin disease in which moisturizers and emollients play a crucial role is atopic dermatitis. Therapy for atopic dermatitis still remains a challenge for the physician and patients and their parents. The success of any therapeutic concept is based on a broad and early diagnostic approach, which allows relevant provocation factors and allergens to be ruled out. During remission periods, the regular use of a topical basic therapy that consists of a drug-free, water-in-oil moisturizer has been shown to decrease relapses and severity.

The increasing prevalence, patient morbidity, health care costs, and potential toxicities of current therapies make the development of disease prevention strategies for atopic dermatitis an important goal. The development of new atopic dermatitis prevention strategies was one of

the six "urgent calls" for research in a systematic review of atopic dermatitis recently published in Europe. Despite decades of extensive research, primarily focusing on allergen avoidance, no accepted strategies exist for prevention of the disease. Most recently, probiotic supplementation and extensively hydrolyzed infant formulas have shown some promising results.

Skin barrier dysfunction plays a prominent role in the development of atopic dermatitis. Although advances have been made in understanding the genetic and biochemical basis for skin barrier defects seen in atopic dermatitis, there have been no primary prevention strategies that target the skin barrier.

Recently, an interesting and very promising concept of prevention of or, if prevention is not possible, significant delaying of the onset of atopic dermatitis in children of highly genetically predisposed families has been described.

This novel approach begins by "restoring" or "supporting" the skin barrier function from birth. It was found that an intervention with an oil-in-water, cream, used widely to treat dry skin and often recommended for the management of atopic dermatitis, dramatically decreases the symptoms up to achieving a clinical "normality" of the skin barrier. The therapy was particularly effective when the parents were encouraged to use the emollient immediately (within 3 min) after bathing.

Targeting the skin barrier for atopic dermatitis prevention is a novel concept which reveals the importance of the skin barrier in the development of this disease and possibly also of food allergy and asthma. Correcting skin barrier defects from birth may prevent atopic dermatitis onset or moderate disease severity.

Practical Approaches to the Use of Moisturizers and Emollients in Children

As mentioned above, emollients generally contain moisturizers. Water employed as an integral part of an emollient on the stratum corneum can be stabilized through the use of substances reducing dehydration. However, such substances usually have an occlusive effect and create a film resulting in a decrease or blocking of transepidermal water loss. These products can contain hydrocarbons (petrolatum derivates such as Vaseline or solid or liquid paraffin), cetyl or stearyl alcohol, waxes, lanolin or oils (mostly of plant origin), and ceramides.

Emollients having occlusive effect should never be used alone, in an extensive manner, or in areas of physiological moisture retention because their cosmetic and medical qualities are inadequate and their occlusive properties are too great.

The optimal emollient allows a sufficient quantity of water to remain in the stratum corneum but has no or only minimal occlusive effect. In this respect, oil-in-water emulsions and creams seem to be a good choice.

In areas of extensive keratinization, hyperceratosis, or thick seborrheic plaques, the short-term use of fatty emollients with or without combination with urea (in children not more than 5–10%) may increase the desquamative effect of the treatment.

In many countries, a simple formula utilizing natural olive oil and water has been used for generations as an adequate, simple, cheap, and satisfactory moisturizing emollient.

In daily practice a freshly prepared mixture or 50% olive oil with 50% lukewarm water is shaken ex tempore into dispersion and applied to the skin directly after bathing and gives excellent results in both "just dry" skin as well as in already damaged atopic dermatitis skin in children of all age groups.

Protective creams are usually used to reduce the risk of skin irritation, particularly in intertriginous areas (e.g., diaper areas). Such creams can be, however, paradoxically too occlusive if used in thick layers. Parents should be aware that "too much" is in this case really too much and that butter-like layers of cream (with or without zinc oxide) may harm and not help.

Powders are still widely used to prevent erythema or to "smooth" the skin, especially in newborns and neonates. The traditionally understood role of powders is to absorb moisture, especially in skin folds. However, after contact with water, powder often aggregates and forms clumps, which mechanically irritate the sensitive and fragile skin resulting in erosions, secondary infections, and contact dermatitis.

Antiseptics and antibiotics are widely used in pediatric skin care. However, it needs to be stressed that antiseptic baths, rubbing of children's skin with antiseptic solution (in many cases containing alcohol), or preventive use of antibiotic-containing creams is not recommended. These may increase skin dryness and irritation, promote paradoxical development of secondary infections, lead to increased sensitization, and, consequently, to the development of allergies and contact dermatitis.

In addition, saprophytic bacterial colonization is necessary for normal development of a functioning skin barrier, and destruction of this environment may contribute to development of skin diseases caused by a disrupted barrier.

Rheumatology

Alberto Martini

153 Clinical Approach to a Child with Suspected Rheumatic Diseases

Alberto Martini

Rheumatic disorders are systemic diseases in which joints are frequently involved. Arthritis may represent the main clinical feature, as in juvenile idiopathic arthritis (JIA), or a minor symptom as in systemic lupus erythematosus (SLE) where other features are much more important for the diagnosis as well as for long-term prognosis.

The pathogenesis of rheumatic diseases is still poorly understood but it is thought to be, depending on the disorder, autoimmune or/and autoinflammatory. Autoimmune means that abnormalities in adaptive immunity lead to an immune response against the "self." Autoinflammatory means that abnormalities in the regulation of the inflammatory process result in chronic inflammation: in recent years, several monogenic disorders (called autoinflammatory diseases) have been identified in which genetic defects affecting the innate immune response mechanisms lead to persistent or recurrent inflammation. Most of the rheumatic diseases are considered multigenic and multifactorial. Multifactorial means that not only genetic but also environmental factors are involved in the etiopathogenesis and multigenic that many different predisposing genes, each of which with a modest role, have to be present in the same patient.

Diagnostic Approach

There is no single sign, symptom, or laboratory examination that is specific for any of the rheumatic diseases which moreover may show symptoms that overlap with those seen in diseases belonging to almost every medical subspecialty. The diagnosis implies the exclusion of other conditions than can be responsible for the same symptoms. A typical example of the large variety of sign and symptoms that can characterize a rheumatic disease is given by SLE which can affect any organ and therefore mimic many different disorders.

The diagnosis of rheumatic diseases is therefore clinical; history, symptoms, laboratory examinations, and imaging, if indicated, should be consistent with the suspected disease and fit each other like the tesserae of a mosaic. The more they are and the better they fit, the clearer the image will appear.

The differential diagnosis of rheumatic disorders is very broad. Here we will take into consideration principally those aspects related to the assessment of a child presenting with arthritis. Arthralgia is just pain referred to a joint that appears normal and has a full range of motion; it is very common and, especially if transient, has low clinical significance. Arthritis implies the objective presence of signs of joint inflammation; its definition requires the presence of swelling and/or of joint pain with limitation of motion. Arthritis is an important symptom and mandates a careful diagnostic workup.

Many diseases, other than rheumatic, can cause joint involvement. They include trauma, infections, postinfectious, inflammatory or genetic diseases, malignancy, benign tumors, and orthopedic disorders. Moreover, a sizable proportion of children, especially adolescents, presenting with joint complains is affected by diseases of psychological origin including pain amplification syndrome.

Medical History and Physical Examination

Medical history and physical examination are of paramount importance in establishing the correct diagnosis.

Swelling of a single joint is frequently erroneously ascribed to a previous trauma which is often present in the medical history of any child. A false diagnosis of traumatic arthritis should be avoided since joint immobilization, in case of an inflammatory arthritis such as JIA, is contraindicated. An arthritis following after 1–3 weeks a gastrointestinal infection especially in an HLA-B27-positive patient may suggest post-dysenteric (reactive) arthritis. Morning stiffness or stiffness after long period of immobility with improvement of pain with subsequent activities is consistent with an inflammatory arthropathy. On the contrary, mechanical pain is not associated with stiffness and is usually worsened by movements that load the joint. Aching pain especially pronounced at nighttime

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_153,

may suggest malignancy (chiefly acute leukemias or metastatic neuroblastoma) or osteoid osteoma. In malignancy, pain is usually localized to the bone and especially to the metaphyseal region and is often out of proportion with respect to the objective findings. In plant thorns synovitis often weeks or months elapse between the entry of the fragment and its dissection into the joint; a careful search of the injury in the medical history should therefore be performed. A history of abdominal pain, diarrhea, weight loss, and blood in the stools can lead to suspect an inflammatory bowel disease. A history of tick exposure and of the typical annular rash (erythema migrans) is strongly suggestive for Lyme disease. Effusions in the large joints are observed in the camptodactyly – arthropathy-coxa vara-pericarditis syndrome (CAPS), a disease due to mutation in the gene of lubricin, a major joint lubrificant; the presence, since the first few months of life, of camptodactyly is very helpful to address the correct diagnosis. In relapsing polychondritis, arthritis is associated with a history of cartilage inflammation of ears, nose, and larynx.

The characteristics of arthritis could be helpful in addressing the correct diagnosis. An extremely painful monoarthritis with refusal to move the joint in a febrile child strongly suggests septic arthritis. Arthritis is fixed and persistent in JIA, while it is migratory in rheumatic fever; in migratory arthritis, the involvement of one or few joints is followed by the involvement of other joints while the previously affected joints improve. Moreover, arthritis in JIA is characterized more by swelling than by pain and is slowly sensitive to nonsteroidal antiinflammatory drugs (NSAIDs); the opposite is true for rheumatic fever in which arthritis is painful but with limited swelling and is extremely sensitive to NSAIDs. The inflammation of the enthesis (insertion of tendon or ligaments on the bone) is called enthesitis and is suggestive of a spondyloarthropathy; the most common sites are on the calcaneous at the insertion of the Achilles' tendon or of the plantar fascia. Joint contractures and limitation of motion in the small joints of the hand can be a feature of systemic scleroderma; the coexistence of a tightened skin, Raynaud phenomenon, and other features can address the diagnosis. Focal tenderness over a long bone in a febrile child is suggestive of osteomyelitis. If the metaphysis is intra-articulars, as is the case for the hip, osteomyelitis and septic arthritis coexist; if, as in the knee, it is extra-articular it can cause a reactive, sterile effusion in the joint. In an adolescent with a febrile polyarthritis involving the large joints and erytematous/vescicular/pustular cutaneous lesions, gonococcal arthritis should be suspected.

Disk space infection (diskitis) can be suspected in a child that does not want to move the legs, pelvis, or low back and has pain when standing or sitting. Musculoskeletal pain and dactylitis are common in sickle-cell disease. Several autoimmune manifestations including chronic arthritis can be observed in immunodeficiencies. In Scheie disease, a mucopolisaccharidosis, and in mucolipidose type III the disease can first present with progressive contractures of the joints of the hands. Another metabolic disease, lysinuric protein intolerance, may show features consistent with a rheumatic disease such as vasculitis, glomerulonephritis, autoimmune hemolytic anemia, circulating ANA, and low complement levels. Muscle weakness, joint contractures, and enlargement of the bone end of the interphalangeal joints (pseudorheumatoid arthritis) may represent the presenting features of a bone dysplasia, spondyloepiphyseal dysplasia tarda. Pain along the long bones with periostitis and polyarthritis (secondary hypertrophic osteoarthropathy) can be observed in patients with digital hippocratism and severe pulmonary impairment.

A marked joint laxity such as that observed in Ehlers–Danlos, Marfan, and Larsen syndromes can lead to joint swelling secondary to recurrent dislocations. Normal children with mild joint hypermobility can experience transient joint pain and, occasionally, small, transient joint effusions. Growing pains are often localized in the calf, over the anterior thigh or behind the knee, and are of short duration; physical examination as well as laboratory tests are normal.

Multisystemic involvement, usually in an inflammatory context, is suggestive for a rheumatic disease. Recurrent, self-limiting episodes of fever and arthritis are characteristic of autoinflammatory diseases. A high-spiking fever with an evanescent, nonfixed, erythematous rash that occurs with fever peaks suggests systemic JIA. New or changing heart murmurs in a febrile child are consistent with infective endocarditis. Involvement of specific organs can be of help in addressing the diagnosis. Kidney and/or central nervous system involvement is common in SLE and in systemic vasculitis. The involvement of coronary arteries and of heart valves is typical, respectively, of Kawasaki disease and of rheumatic fever. The lung is characteristically involved in antineutrophil cytoplasmic antibodies (ANCA)-associated vasculitis and in systemic scleroderma. Recurrent, painful, shallow oral (and genital) ulcers are a feature of Behçet disease. Muscle weakness associated with typical cutaneous features characterizes juvenile dermatomyositis. Raynaud phenomenon in children is often associated with systemic scleroderma. Uveitis is mainly observed in oligoarticular antinuclear antibody (ANA)-positive JIA, spondyloarthropathies, Behçet disease, Blau syndrome, and sarcoidosis.

Laboratory Investigations

Laboratory tests can be diagnostic for diseases that mimic a rheumatic disorder (bone marrow aspiration for leukemias, genetic tests for genetic diseases, serology, blood and synovial cultures for infectious diseases, etc.). In rheumatic diseases they can be supportive for the diagnosis but not diagnostic and should be always interpreted according to the clinical findings.

Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) can help to differentiate inflammatory and infectious diseases and malignancy from other conditions (such as genetic or orthopedic diseases). However, in some rheumatic diseases, such as oligoarticular JIA, Henoch–Schöenlein purpura, and juvenile dermatomyositis, they can be normal. In SLE, ESR is elevated while CRP is usually only moderately increased or even normal.

Low white blood cell and/or platelet count is seen in viral infections, SLE, and infiltrative processes in the bone marrow. Urinalysis is of course essential to identify kidney involvement. Muscle-related enzymes, creatine kinase, transaminases, aldolases, and dehydrogenase, are useful if myositis is suspected. A Mantoux tuberculin skin test should be performed especially in case of monoarticular knee arthritis since tuberculous arthritis at onset can mimic monoarticular JIA.

Low complement values are characteristic of SLE and of hypocomplementemic urticarial vasculitis but can also be observed in some primary glomerulopathies (membranoprolipherative, post-streptococcal).

The diagnostic value of autoantibodies depends on their titers and on the clinical features they associate with. ANA may be positive in many rheumatic diseases but also in other non-rheumatic diseases and, in low titers, in a small percentage of normal children. In JIA, they identify a subset of patients at particular risk of developing chronic anterior uveitis. Some particular ANA specificities have been strongly associated with a particular disease: this is for instance the case for anti-double-stranded DNA or anti-Sm antibodies with SLE. Rheumatoid factor (RF) is useful for the diagnosis of RF-positive polyarticular JIA; it can be also positive in other rheumatic diseases, in some chronic infections, and in a very small percentage of normal children. Anticardiolipin antibodies and lupus anticoagulant are antiphospholipid antibodies that can be observed especially in SLE and are associated with predisposition to develop venous or arterial thrombosis. Antineutrophil cytoplasmic antibodies (ANCA) although nonspecific are especially associated with three types of vasculitis: Wegener's granulomatosis, Churg–Strauss syndrome, and microscopic polyangiitis.

Joint aspiration is mandatory in febrile children with extremely painful monoarthritis in which septic arthritis is suspected; in general, white blood cell count (WBC) is higher than 50,000/μL and >90% of leukocytes are neutrophils. Blood is recovered from joint fluid aspiration in case of hemophilia or synovial hemangioma. A chocolate-brown synovial fluid is characteristic of pigmented villonodular synovitis. Crystal-induced arthritis, common in adults, is very rare in children and therefore joint aspiration is almost never performed with this indication.

Synovial biopsy is rarely useful for diagnostic purposes. It is indicated in tuberculous arthritis, sarcoidosis, and a few other rare conditions.

Imaging

X-rays as well as the sophisticated imaging technique available nowadays can be very useful in the follow-up of patients with rheumatic diseases, but their role is more limited in the initial diagnostic workup of a child presenting with arthritis.

Plain-film radiographs are mainly useful in the diagnosis of malignancies and of bone and cartilage disorders, such as fractures, bone tumors, avascular necrosis, osteochondritis dissecans, slipped capital femoral epiphysis, and bone dysplasias. Multiple chronic lesions with osteolysis and encircling sclerosis are suggestive of chronic recurrent multifocal osteomyelitis (CRMO) once infections and malignancy have been excluded. Computed tomography is precious to image bone details in selected circumstances. Ultrasound is a very useful noninvasive technique to assess joints and tendons. Magnetic resonance imaging (MRI) using contrast enhancement can accurately visualize synovium, joint fluid, peri- and intra-articular structures, bone edema, and bone erosions. Technetium bone scanning is useful particularly for the early diagnosis of infections and malignancies.

Follow-up

An accurate follow-up is often an essential component of the diagnostic approach to rheumatic diseases. For instance, viral arthritis can often mimic different types of rheumatic disorders. It is however transient and symptoms disappear in the space of a few weeks and do not recur. For this reason, in the diagnostic criteria of JIA it is mentioned that the arthritis should last for at least 6 weeks. Transient monoarticular synovitis of the hip is one of the more common form of arthritis observed in

children. It often follows by 1 or 2 weeks an upper respiratory tract infection and resolves spontaneously in a few days or weeks; ESR is normal or only slightly elevated. The diagnosis of osteolysis or spondyloepiphyseal dysplasia tarda can be made only when the characteristic radiological features appear.

An adequate follow-up is also important because the clinical spectrum of rheumatic diseases may evolve over a period of months or years. It may be therefore necessary to follow the disease course before making a definite diagnosis. For instance in systemic JIA, the arthritis, which is of course essential for the diagnosis, may appear weeks or months after the beginning of systemic symptoms.

Some conditions should always been considered when assessing a child with rheumatic complaints since they all require a prompt diagnosis. They include septic arthritis, which is a real emergency since it can lead very rapidly to joint destruction, malignancies, Kawasaki disease, rheumatic fever, renal and cerebral involvement associated with SLE or vasculitis.

A web site with information for families of children with rheumatic diseases is available in 50 languages (http://www.printo.it/pediatric-rheumatology).

154 Juvenile Idiopathic Arthritis

Alberto Martini

Definition

Juvenile idiopathic arthritis (JIA) is not a single disease but a term which includes all forms of arthritis beginning before the 16th birthday, persisting for more than 6 weeks, and for which no cause is known. Therefore, there is no clinical or laboratory feature that is pathognomonic of JIA which represents an exclusion diagnosis that gather together all forms of childhood chronic arthritis of unknown cause.

This heterogeneous material has been analyzed in order to identify discrete clinical subsets that could correspond to different diseases. More than 30 years ago two classification systems were created one in USA and one in Europe. The condition was named juvenile rheumatoid arthritis (JRA) in USA and juvenile chronic arthritis (JCA) in Europe. Although similar in many respects, these two classifications had also some important differences that have prevented interchangeable use and comparative research. About 10 years ago the International League of Associations for Rheumatology (ILAR) proposed a new classification system to be shared between the two sides of the Atlantic. This classification, in which the term JIA has replaced JRA or JCA, has unified classification criteria and terminology and since then has represented a useful tool for international research. However, it has the limits inherent to any classification based on clinical criteria, and probably will be modified as new information on pathogenesis becomes available.

Epidemiology

JIA is the most common chronic rheumatic disease in childhood and an important cause of short- and long-term disability. Studies in American and Northern European countries have reported an incidence and a prevalence of JIA varying from 2 to 20 and from 16 to 150 per 100,000, respectively. Differences have been found in the incidence of the various JIA subtypes according to geographical areas or ethnicity. While in western countries the most common subtype is represented by oligoarthritis, this same subtype is rare in countries such as Costa Rica, India, New Zealand, and South Africa where polyarthritis predominates.

The JIA Subtypes

According to the current (ILAR) classification the various JIA subtypes or categories (*Table 154.1*) are identified by a definition and several exclusion items on the basis of the features presented in the first 6 months of disease. Seven different subtypes have been identified, many of which appear to represent different diseases. The seventh subtype however do not represent a definite entity but group together all the forms that according to the definitions and the exclusion criteria do not fit in any of the other categories.

Systemic Arthritis

Systemic arthritis is characterized with respect to the other JIA subtypes by prominent systemic manifestations. The disease occurs as often in boys as in girls, does not show a preferential age at onset, and represents about 10–15% of all JIA cases. It is observed also in adults where it is of rare occurrence and is known as "adult onset Still disease."

The characteristic of the disease is a high spiking daily fever greater than 39°C. Myalgias and abdominal pain may be intense during fever peaks. Another frequent feature is an evanescent, non-fixed, erythematous rash that typically occurs with fever peaks (*Fig. 154.1*); sometimes it can be urticaria-like and pruritic. Hepatomegaly, splenomegaly, and generalized lymph node enlargement, if present, are usually mild. Pericarditis or pleuritis are not rare but are more often mild and asymptomatic. Cardiorespiratory distress due to myocarditis or cardiac tamponade is very unusual. Arthritis is more often symmetrical and polyarticular. It may be absent at onset in about 30% of cases and develops during disease course, weeks or months after the onset of fever.

Laboratory examinations show leukocytosis (with neutrophilia), very high erythrocyte sedimentation rate

Onset type	% of all JIA	Onset age	Sex ratio
Systemic arthritis	10–15%	Any	M = F
Oligoarthritis	40–50%	<6 years	F >>> M
RF-positive polyarthritis	<5%	>10–12 years	F >>> M
RF-negative polyarthritis	15–20%	Variable	F >> M
Enthesitis-related arthritis	5–10%	>7 years	M >> F
Psoriatic arthritis	<5%	Variable	F > M
Undifferentiated arthritis	10–20%		

Figure 154.1

Rash associated with systemic JIA. Evanescent, non-fixed, salmon-colored rash that occurs with fever peaks

(ESR), and marked thrombocytosis. Anemia, sometimes profound, is common and is microcytic. For unknown reasons about 5–8% of patients with systemic arthritis may develop a life threatening complication called macrophage activation syndrome (MAS). It is a form of hemophagocytic lymphohistiocytosis and may follow an intercurrent viral illness or a change in medication. The syndrome includes a non-remitting (instead of a spiking) high fever, pancytopenia with marked neutropenia, hepatomegaly, a coagulopathy with hemorrhagic manifestations, and neurologic symptoms such as lethargy, disorientation, seizures, or coma. Laboratory features include elevated serum liver enzymes and triglycerides, low sodium levels, and markedly increased ferritin concentrations; the abnormal coagulation profile is characterized by the prolongation of prothrombin and partial thromboplastin time, hypofibrinogenemia (which causes a drop in ESR values), and detectable fibrin degradation products. The demonstration of active phagocytosis of hematopoietic cells by macrophage in the bone marrow is common. The syndrome is a life threatening complication that should be promptly recognized and treated.

Both disease characteristics and sensitivity to treatment with biological agents (see later) suggest that systemic JIA is a heterogeneous condition and that at least some forms are autoinflammatory in nature.

Oligoarthritis

It is characterized by the presence of an arthritis affecting 1–4 joints during the first 6 months of disease. Although oligoarthritis as a whole is probably heterogeneous, the large majority of patients belong to a quite well characterized type of disease. This form, which is typical of children and is not observed in adults, is characterized by an asymmetric arthritis, an early onset (before 6 years of age), a female predilection, a high frequency of positive antinuclear antibodies (ANA), and a high risk for developing a chronic iridocyclitis. In Europe and USA, oligoarthritis represents up to 50% of all forms of JIA while in other countries such as Costa Rica, India, New Zealand, and South Africa it is more seldom observed.

The disease affects predominantly the joints of the lower limbs; the knee is the most commonly affected joint followed by the ankle. In about 30–50% of cases a single joint is involved at presentation. Joints are obviously swollen but in general not particularly painful although joint contractures are frequent.

Acute phase reactants may be normal or moderately increased although in some instances ESR may be quite high. Antinuclear antibodies are detected in significant titers in about 70–80% of patients and represent a risk factor for the development of chronic iridocyclitis.

The ILAR classification distinguishes two categories in the oligoarthritis subtype based on the number of joints that are involved after the first 6 months of disease: *persistent oligoarthritis* in which the disease remains confined to 4 or less joints and *extended oligoarthritis* in which arthritis extend to more than 4 joints. However, the clinical characteristics of ANA positive patients belonging to these two categories are the same with respect to age at onset, sex ratio, asymmetry of articular involvement, and frequency of uveitis. This suggests that extended oligoarthritis is the same disease as persistent oligoarthritis and that the difference is only in the spread of arthritis. The involvement of an upper limb joint and a higher sedimentation rate at onset have been suggested to predict the evolution to the extended phenotype (which may occur in up to 50% of patients).

A chronic, asymptomatic, nongranulomatous, anterior, mono or bilateral uveitis affecting the iris and the ciliary body (iridocyclitis) and that can cause severe visual impairment is a characteristic feature of the disease and affects about one third of patients. The onset is insidious and very often entirely asymptomatic in contrast with the painful, acute uveitis that can be observed in enthesitis-related arthritis. In less than 10% of patients uveitis is detected before the onset of arthritis and in about half of patients it occurs at the time of JIA diagnosis or shortly thereafter. Most children who develop iridocyclitis do it within 5–7 years from the onset of arthritis. The onset before arthritis is unfortunate since, being the iridocyclitis initially asymptomatic, it is in this case usually diagnosed when damage is already established. ANA positive patients present a higher risk of developing uveitis. If left untreated or in most severe cases iridocyclitis can cause severe ocular damage.

Iridocyclitis can occur in other JIA subtypes such as RF-negative polyarthritis or psoriatic arthritis especially if ANA are positive. As discussed later there is evidence suggesting that ANA positive patients represent a single disease entity currently classified into different categories. Since uveitis is asymptomatic, children with JIA should be screened periodically by slit-lamp examination; the advised frequency of the examination reflects the anticipated frequency of the ocular complication. Any patient with oligoarthritis or polyarthritis of early-onset or, more in general, with ANA positive, RF-negative JIA should undergo slit-lamp examination at least every 3 months.

Rheumatoid Factor Positive Polyarthritis

It is defined as an arthritis that affects five or more joints during the first 6 months of disease and on the presence of high and persistent titers of the IgM rheumatoid factor (RF). It is the same disease as RF-positive rheumatoid arthritis (RA) in adults; however, while in adults it is the most common form of chronic arthritis, in children it represents a small minority (<5%) of all cases of JIA. Antibodies to cyclic citrullinated peptides (anti-CCP), as in adults, are often positive while they are not detected in the other forms of JIA.

The disease is much more frequent in females, is usually observed in adolescents, and is very rare before 8 years of age. It is characterized by a symmetrical polyarthritis with the early involvement of wrist, metacarpophalangeal and proximal interphalangeal joints, and a subsequent rapid spread with involvement of many joints. Low-grade fever may be present. It is practically only in this form that rheumatoid nodules are observed. They are firm, usually mobile and non-tender, and are usually located below the olecranon or at other pressure points.

Rheumatoid Factor Negative Polyarthritis

It is defined as an arthritis that affects five or more joints during the first 6 months of disease in the absence of IgM RF. It accounts for about 15–20% of all JIA cases and is the less defined and probably the most heterogeneous JIA subtype. This heterogeneity has also been supported by recent studies on peripheral blood gene expression profiles.

At least 3 distinct subsets can be identified from a clinical point of view.

Early-Onset, ANA Positive Polyarthritis

This form resembles in all respects, except for the number of joints affected in the first 6 months of disease, ANA positive oligoarticular JIA. It is indeed characterized, as the latter, by an asymmetric arthritis, an early onset (before 6 years of age), a female predominance, ANA positivity and an elevated risk to develop a chronic iridocyclitis. The hypothesis that ANA-positive RF-negative polyarthritis and ANA-positive oligoarthritis are the same disease, the former representing a rapid arthritis spread in the latter, is also strongly supported by studies on the frequency of the various JIA subsets in different

ethnic populations. Indeed, in those countries in which ANA positive, early onset, iridocyclitis-associated, oligoarthritis is rare, ANA positive, early onset, iridocyclitis-associated RF-negative polyarthritis is also seldom observed.

Prolific Symmetric Synovitis

This is the more classic form of RF-negative polyarthritis. Joint involvement is symmetric and affects large joints as well as the small joints of hands and feet. ESR is often elevated and ANA are usually negative. Age at onset is about 7–9 years. The relation between this form of arthritis and the RF-negative form that represent 25% of all forms of adult RA is unknown since no reliable markers exist for both conditions.

Dry Sinovitis

A small subgroup of patients with polyarticular RF-negative arthritis show little palpable synovial thickening but gradually contract up leading to marked loss of function. These children tend to be about 7 or 8 at presentation. There is usually little pain in the affected joints. ESR in these patients is often normal or only modestly raised and ANA are negative.

Enthesitis-Related Arthritis

It accounts for about 5–10% of JIA cases and mainly affects males after the age of 6 years. It is characterized by the association of enthesitis and arthritis. Enthesitis represent the inflammation of enthesis, which are the insertion of ligaments and tendons to the bone. The most common sites are the calcaneal insertions of the Achilles tendon or plantar fascia and the plantar fascia attachments to the metatarsal heads. Most patients are HLA-B27 positive. Arthritis commonly affects the joint of the lower extremities. At variance with the other JIA subtypes, hip involvement is common at disease presentation. The disease is often remitting and may be mild. A variable percentage progressively develops the involvement of the joints of the axial skeleton. Indeed, enthesitis-related arthritis is a spondyloarthropathy, a disease which is treated in detail in another chapter of this section (Chap.155, "Juvenile Ankylosing Spondylitis"). It overlaps with the previously defined seronegative enthesopathy and arthropathy (SEA) syndrome.

Psoriatic Arthritis

Represents less than 5% of all cases of JIA, although estimates of its prevalence are very variable. It is defined by the presence of arthritis plus a typical psoriatic rash or, if the latter is absent, the presence of any two of the following: family history of psoriasis in a first-degree relative; dactylitis (swelling of one or more digits that extend beyond the joint margins); and nail pitting. There is evidence that this subtype does not represent a clearly defined entity. In adults, psoriatic arthritis is a form of spondyloarthropathy. Many patients that meet the ILAR criteria for psoriatic arthritis, in which patients with enthesitis are by definition excluded, have features very similar to those observed in oligoarthritis: early onset, asymmetric arthritis, female predominance, risk for the development of iridocyclitis and ANA positivity. The main difference is that these patients have a higher frequency of the involvement of both small and large joints. In previous studies on children with psoriasis and arthritis in which patients with enthesitis were not excluded, a proportion of patients presented with arthritis and enthesitis and some developed sacroiliitis during follow-up similar to adult patient with psoriatic arthritis. So it appears that the association of psoriasis with arthritis does not define a unique entity.

Undifferentiated Arthritis

It does not represent a separate subset, but a category in which by definition patients that do not fulfill inclusion criteria for any category or that fulfill criteria for more than one are included.

Etiology and Pathogenesis

The etiopathogenesis of JIA is still poorly understood. Moreover, the heterogeneity of JIA implies that very probably multiple etiopathogenetic factors are involved. As for many other rheumatic diseases the etiopathogenesis appears to depend from alteration in innate and/or in adaptive immune response and is considered multigenic and multifactorial. Multifactorial means that both genetic and environmental factors are needed and multigenic that there are many different predisposing genes, each of which with a modest role, that have to be present in the same patient.

Data on disease concordance in identical twins are scanty. A concordance rate of 25% has been found in some studies. Several studies on disease concordance in

nontwins have suggested that genetic components are important especially for oligoarticular JIA. Oligoarticular JIA has also been consistently associated with some HLA antigens, in particular HLA-DRB1*08. As the other spondyloarthritides, enthesitis-related arthritis is strongly associated with HLA-B27. Rheumatoid factor positive polyarthritis is associated, as in adults, with the HLA-DRB1 alleles that share a particular epitope sequence (the shared epitope). The hypothesis that an infection triggers the disease in genetically susceptible individuals, although attractive, remains unproven.

The inflammatory synovitis in JIA is similar to that observed in adult RA and does not appear to differ significantly among the different JIA subtypes. The synovium shows marked hyperplasia of the lining layer and an exuberant infiltration of the sub-lining layer with mononuclear cells including T cells, B cells, macrophages, dendritic cells, and plasma cells. The T cell aggregates are composed predominantly of CD4+ cells. The inflammatory process leads to pannus formation with cartilage and bone erosions mediated by degradative enzymes such as metallo-proteinases. As for adult RA, the observed potent therapeutic effect of anti-tumor necrosis factor (TNF) agents in many patients supports an important pathogenic role for this cytokine.

Systemic JIA has some peculiar pathogenetic aspects. The driving cytokines here are represented by interleukin-1 and interleukin-6. The excellent response observed in some patients with anti-IL-1 therapy has lead to the suggestion that at least some forms of systemic JIA belong to autoinflammatory diseases. Another peculiar aspect of systemic JIA is the predisposition to develop MAS. The reasons of this predisposition are unknown but the pathogenesis of MAS seems to depend, as in the other forms of hemophagocytic lymphohistiocytosis, on the excessive expansion and activation of cytotoxic cells with hypersecretion of pro-inflammatory cytokines that in turn induce macrophage activation, further cytokine production and tissue infiltration.

Diagnosis

As previously mentioned JIA is defined as any arthritis of unknown origin, lasting for more than 6 weeks and with onset before 16 years of age. It is therefore an exclusion diagnosis and, by definition, any other cause of chronic arthritis has to be ruled out. As outlined in another chapter of this section (Clinical Approach to a Child with Suspected Rheumatic Diseases) many other diseases can indeed cause arthritis (*Table 154.2*).

Table 154.2
Main diseases that cause arthritis

Infectious
Septic arthritis
Gonococcal arthritis
Endocarditis
Mycobacterial arthritis
Lyme disease
Viral arthritis
Post-infectious (reactive)
Rheumatic fever
Post-dysenteric arthritis
Viral infections
Serum sickness
Rheumatic and inflammatory diseases
Juvenile idiopathic arthritis
Juvenile ankylosing spondylitis
Systemic lupus erythematosus
Juvenile dermatomyositis
Scleroderma
Overlap syndromes
Systemic vasculitis
Behcet disease
Autoinflammatory diseases
Chronic recurrent multifocal osteomyelitis
Sarcoidosis
Inflammatory bowel diseases
Neoplastic diseases
Leukemia
Lymphoma
Neuroblastoma
Malignant bone tumors
Osteoid osteoma
Synovial tumors
Bone and cartilage disorders
Trauma
Patellofemoral syndrome
Avascular necrosis
Osteochondritis dissecans
Slipped capital femoral epiphysis
Other diseases
Immunodeficiencies
Histiocytic syndromes
Hemophilia
Sickle cell disease
Mucopolysaccaridoses
Mucolipidoses
Spondyloepiphyseal dysplasia tarda

Hypertrophic osteoarthropathy
Plant-torn synovitis
Joint hyperlaxity

In systemic JIA malignacies (in particular leukemia and lymphomas) and infections must be always considered and ruled out. In endemic areas, leishmaniosis and brucellosis should be excluded since, although in general associated with leucopenia, both diseases can mimic the systemic features of systemic JIA (sJIA) and moreover be a cause of MAS. Inflammatory bowel diseases, rheumatic fever, Kawasaki disease as well as other rheumatic diseases such as systemic lupus erythematosus and systemic vasculitis should also be ruled out. The differential diagnosis of systemic JIA can be particularly difficult at presentation in patients in whom systemic features precede the development of overt arthritis; a definite diagnosis cannot be made until the appearance of arthritis.

In a febrile child with a very painful monoarthritis septic arthritis has to be excluded. Tuberculous arthritis may cause a monoarticular arthritis usually of the knee that can initially mimic monoarticular JIA. For more details on the differential diagnosis of arthritis see Chap. 76 (Clinical Approach to a Child with Suspected Rheumatic Diseases).

Some characteristics of articular involvement in JIA may be helpful. With the exception of enthesitis-related arthritis, in which joint involvement can be quite painful or transient and recurrent, the arthritis of JIA is characterized by persistent joint swelling which is often not particularly painful especially in the oligoarticular subtype. Joint contractures are however frequent. Since joint involvement is not very painful physical examination can detect the involvement of joints that were not initially referred as affected. Morning stiffness or stiffness after long period of immobility with improvement of pain with subsequent activities is characteristic and its duration is proportional to disease activity.

Treatment

A treatment able to "cure" the disease is not available. However, the prognosis of JIA has improved very much in the last decade, thanks to substantial progresses in disease management. Since JIA is not a single disease the therapeutic strategy varies also according to the different JIA subtypes. It is often problematic to anticipate what strategy will be needed to control the disease since it is difficult to predict at onset, even within a definite subtype, which children will recover and which children will go on to have unremitting disease. Treatment therefore follows a step by step approach according to the severity of the disease and its sensitivity to therapies. The goal of treatment is to reach the complete control of the disease, to preserve the physical and psychological integrity of the child and to prevent any long-term consequence related to the disease or its therapy. This requires a careful long-term follow-up in which monitoring of treatment, disease activity and disease damage is critical. Periodic X-ray examinations of the affected joints are needed to document disease evolution.

Optimal management of JIA requires a multidisciplinary approach that involves pediatric rheumatologists, nurses, physical and occupational therapists, social workers and, when indicated, psychologists, orthopedic surgeons, and ophthalmologists.

Medical Treatment

Oligoarthritis and Polyarthritis

Nonsteroidal anti-inflammatory drugs (NSAIDs). NSIADs have been the mainstay of JIA treatment for decades. Their role remains important and most children with JIA are started on an NSAIDs. These drugs work primarily by inhibiting the enzyme cyclo-oxygenase (COX) that converts arachidonic acid to prostaglandin, a family of substances involved in inflammation. There are two COX, COX-1 which is considered a constitutive enzyme found in most mammalian cells and COX-2 which is undetectable in most normal tissues and is induced in activated macrophages and other cells at sites of inflammation.

Just a few NSAIDs are approved for use in children; the most commonly used include naproxen, ibuprofen, and indomethacin; acetylsalicylic acid is much less used than in the past because of the less favorable safety profile. They are all COX-1 inhibitors; experience with COX-2 inhibitors in children is very limited.

The anti-inflammatory effect of NSAIDs in JIA is slow and is usually achieved after several weeks of continuous administration. NSAIDs are usually quite well tolerated and side effects are less common than in adults. They include nausea, abdominal pain, mood changes, tinnitus, elevated liver enzymes, hematuria; gastric or duodenal ulcerations are less frequent than in adults.

Intra-articular steroid injections. Intra-articular steroid injections with triamcinolone hexacetonide are frequently

needed at disease onset or during disease course. In mono or oligoarticular arthritis they are used often in association with or in substitution for NSAIDs. They are specifically indicated in the presence of persistent joint contractures, susceptible to cause deformity. Indeed, they are rapidly effective and, most importantly, they break the vicious circle that leads to deformity, such as valgus deviation due to flexion contracture of the knee (*Fig. 154.2*). Although they are not curative, their effect may last for long periods.

Methotrexate. In those children in which the disease is not well controlled by NSAIDs and steroid injections, a second line agent is often needed. These patients have usually an arthritis with a polyarticular onset or course, and second line therapy should be introduced quite early in order to try to prevent disease progression. The second line agent of first choice in JIA is methotrexate (MTX). The effect of MTX on inflammation depends on the inhibition of purine synthesis. A controlled study has shown its efficacy at a dose of 10 mg/m^2/week. A further study has shown that the plateau of efficacy is reached at 15 mg/m^2/week and that higher doses are not accompanied by a better effect. At doses >10 mg/m^2/week parenteral administration is advisable. The effect is usually detectable within 6–12 weeks. MTX is usually well tolerated especially if associated with the administration of folic or folinic acid. The most common side effects are gastrointestinal toxicity and an increase in liver enzymes.

Figure 154.2
Severe valgus deformity secondary to long standing flexion contracture of the knee

Anti-TNF agents. In those patients that have an unsatisfactory response to MTX and in whom the disease remains active, treatment with anti-TNF agents is indicated. Usually the anti-TNF agent is added to MTX. The first anti-TNF agent used and registered both in Europe and in USA for JIA has been etanercept, a fusion protein consisting of two identical chains of the recombinant extracellular tumor necrosis factor monomer fused with the Fc domain of human IgG1. A controlled study has shown the efficacy of etanercept, at a dose of 0.4 mg/kg s.c. twice a week, in patients with JIA who were resistant or intolerant to MTX. Subsequently, other studies have confirmed the remarkable and rapid efficacy and, so far, the good safety profile of the drug in JIA. Since cases of reactivated tuberculosis have been reported during treatment with TNF inhibitors, all children should have a documented negative TB test before starting therapy. The overall safety of anti-TNF agents, including the potential of inducing malignancy, will be best assessed in the future with long-term studies.

Controlled trials with other anti-TNF agents such as Infliximab and Adalimubab have also been performed and have shown a similar profile of safety and efficacy with respect to etanercept. Both are monoclonal antibodies directed against TNF; Infliximab is a chimeric antibody (it has a mouse component) while Adalimumab is a fully human antibody. The Infliximab study has shown that although the dosages of 3 and 6 mg/kg (i.v. every 8 weeks) were both effective, children treated with 3 mg/kg developed in a higher percentage antibodies against Infliximab with a similar higher rate of infusion reactions. Adalimumab has been registered in USA for use in JIA at a dose of 20 mg (s.c. every other week) in children weighing 15–30 kg and of 40 mg for those weighing >30 kg; in Europe it has been so far registered only for children >30 kg. Indirect evidence suggests that, as in adults, anti-TNF agents are more effective if combined with MTX.

Other Drugs A controlled trial has recently shown the efficacy of Abatacept, an inhibitor of lymphocyte activation, in the treatment of MTX-resistant JIA. The percentage of response was similar to that observed with anti-TNF agents and the safety profile was good. Moreover, treatment showed an effect also in a discrete proportion of patients who had previously failed also anti-TNF agents. Abatacept is fully human fusion protein that consists of the

extracellular domain of the cytotoxic T-lymphocyte-associated antigen (CTLA)-4, linked to the constant portion of human immunoglobin. Activation of T cells requires 2 signals from the antigen-presenting cell (APC). One is the presentation of the antigen to the T-cell receptor in the context of a major histocompatibility complex molecule, the other is a costimulatory signal. One of the best characterized costimulatory signals is delivered by the APC molecules CD80 or CD86 to the T cell's CD28 molecule. CTLA-4 is a protein naturally expressed on the activated lymphocyte surface that avidly binds to CD80/86. Abatacept, therefore, by binding to costimulatory molecules on the surface of APC prevents their binding to CD28 and interferes with lymphocyte activation. Abatacept has been registered for use in JIA in Europe and in USA.

Studies are ongoing to assess the efficacy of anti-IL-6 therapies in polyarticular course JIA.

Studies performed many years ago have shown that hydroxychloroquine and D-penicillamine are not more effective than placebo in RF-negative JIA. Sulfasalazine is used in some center as a second line agent in patients with polyarticular JIA and in enthesitis-related arthritis. It should not be used in systemic JIA, for the increased risk of toxicity, in patients with porphyria or with glucose-6-phosphate dehydrogenase deficiency. A recent trial has shown the efficacy of leflonomide in JIA but the experience with this drug is still limited. In general the use of second line agents other than MTX has declined over the years with the introduction of the more efficacious anti-TNF agents.

In polyarticular JIA systemic steroids (prednisone) are used only as a bridge drug when the disease is very active and time is required before second line agents (as MTX) can show their efficacy.

Systemic Arthritis

Systemic arthritis frequently does not respond to NSAIDs alone. In this case, once infectious and neoplastic disorders have been excluded and the diagnosis is established, prednisone therapy is often indicated. Once disease control is reached, steroid therapy has to be progressively tapered. Indeed, the use of steroids should be limited as much as possible because of their severe, well-known side effects. Vitamin D and calcium supplements to try to prevent osteoporosis as well as dietary counseling to prevent fat increase secondary to increased appetite are indicated. Treatment of MAS relies on prompt recognition of this complication and the use of high dose steroids and cyclosporine which is usually highly and rapidly effective in this specific indication. In children characterized by a polycyclic course, steroids and NSAIDs may be sufficient to control episodes of disease activity. In unremitting disease, steroid tapering is often accompanied by recurrence of systemic symptoms and arthritis. While systemic symptoms often, but not always, fade during disease course, arthritis persists and often represents the main determinant for disease outcome. MTX is less effective in systemic arthritis than in other JIA subtypes. Anti-TNF agents also are less effective in systemic arthritis than in other JIA subtypes. The use of thalidomide has been proposed for resistant systemic arthritis. In patients with very severe unremitting disease autologous bone marrow transplantation has been performed. In the very rare cases that develop amyloidosis alkylating agents are indicated.

As mentioned above, the pathogenesis of systemic JIA seems to differ from that of the other JIA subtypes, and IL-6 as well as IL-1 appear to play a prominent role. Indeed, a controlled trial with Tocilizumab (an anti-IL-6 receptor humanized monoclonal antibody) has shown very promising results. Another confirmatory controlled trial is ongoing. Moreover, several noncontrolled studies with Anakinra (a recombinant form of the natural IL-1 receptor antagonist) have shown also the efficacy of IL-1 inhibition in the treatment of systemic JIA. In some patients, usually characterized by a lower number of joints involved, anti-IL-1 therapy has been shown to have a spectacular effect similar to that observed in some autoinflammatory diseases. This has suggested, as previously mentioned, that at least some form of systemic JIA could indeed represent autoinflammatory diseases. A controlled trial is ongoing using Canakinumab, a monoclonal fully human antibody which is a more potent inhibitor of IL-1 than Anakinra. It appears therefore that treatment with IL-6 and IL-1 inhibitors, if their safety will be confirmed, will represent a major advance in the treatment of systemic JIA and an opportunity to unravel the clinical heterogeneity of this disease.

Chronic Iridocyclitis

Early diagnosis is very important for the success of therapy. The initial approach consists of glucocorticoid eye drops associated with mydriatics to dilate the pupil and prevent the occurrence of posterior sinechiae. Concurrent therapy with NSAIDs is often used. In patients with disease resistance to topical therapy, systemic steroid administration and/or subtenon injection of corticosteroids are required. In disease not controlled by the above measures several drugs have been claimed to be effective including MTX, cyclosporine, and alkylating agents. However no controlled trials exist. The efficacy of etanercept is

controversial while Infliximab and Adalimumab have been anecdotally reported to be of benefit.

Other Therapeutic Aspects

Physiotherapy and occupational therapy are important components of the therapeutic approach to any patients with JIA. In general, children limit by themselves their activities and should not be restricted. Swimming and bicycle riding that do not put significant weight on the joints should be encouraged. An orthodontic approach is often indicated in case of temporomandibular joint involvement.

Arthroscopic synovectomy may be indicated in a few cases to debulk proliferative synovitis resistant to other treatments. Soft tissue release may be useful in selected cases but the intervention as well as the following postoperative rehabilitation have to be performed by experienced personnel. Total arthroplasty, in particular of the hip and knee, represents a successful option in the presence of severe functional impairment and is generally delayed until growth has stopped. It presents special problems and has to be performed by orthopedic surgeons with specific experience.

JIA has a great psychological impact on the child and his family. Children should be encouraged to normally attend school as well as all the activities that are appropriate for their age. Parents may tend to excessively protect the child and limit his activities; this can affect the proper development of the child personality and prevent him from acquiring adequate self-confidence and self-esteem. When indicated a psychological support can be required.

Course and Prognosis

A part from polyarticular RF-positive JIA that, like in adults, tends to run a progressive and aggressive course, the prognosis of the other JIA subsets differ greatly even among patients belonging to the same subset. Moreover, while in many cases of JIA the disease spontaneously remits with time, a sizable proportion of patients enter adult life still with an active disease. No reliable markers are available to predict early in the disease course the ultimate outcome in order to tailor treatment to the risk of disability.

Oligoarticular JIA

Patients with oligoarticular JIA have in general the best outcome. The early use of intra-articular steroids is very effective in preventing the deformities secondary to joint contractures such as valgus deformity in case of flexion contracture of the knee (*Fig. 154.2*) or leg-length inequality secondary to asymmetric knee involvement (*Fig. 154.3*). In the majority of children the disease tends to remit spontaneously with time although some series have reported that the rate of remission after 6–10 years from disease onset ranges only from 23% to 47%. The percent of patients that develop extended oligoarthritis has been reported to vary between 20% and 50%. Joint damage is more frequent in patients with a polyarticular course.

The outcome of uveitis depends very much on early diagnosis and treatment. Prior to careful monitoring for uveitis with periodic slit-lamp examinations, a severe outcome was observed in more than one third of patients. Now only a minority of patients suffer complications which can however be significant and include keratic precipitate, posterior synechiae between the iris and the anterior surface of the lens resulting in an irregular and poorly reactive pupil, band keratopathy, secondary cataracts, and glaucoma. A small minority of patient may experience a progressive disease that can lead to blindness despite adequate monitoring and treatment. The course of iridocyclitis may be relapsing or chronic and does not parallel the clinical course of arthritis.

Figure 154.3
Leg-length inequality secondary to asymmetric knee involvement

Systemic Arthritis

Systemic arthritis has a variable course. In about half of patients the disease is characterized by a monocyclic or an intermittent course with relapses followed by intervals of remission; in these patients the arthritis accompanies the episodes of fever but remits when systemic features are controlled. The long-term prognosis of these patients is usually good since the disease tends to disappear with time without causing articular damage. In the other half of patients the disease follows an unremitting course. In many, but not all, cases systemic symptoms eventually resolve, leaving chronic arthritis as the major long-term problem. This second group of patients with an unremitting disease course is probably the most severe among all JIA subtypes with a high risk of severe joint destruction. Death were once principally related to the development of amyloidosis that now appears to be a very uncommon complication. Nowadays, MAS remains the most serious and potentially fatal threat and has to be promptly recognized and treated.

Other Subtypes

RF-positive polyarthritis is a chronic and aggressive disease and has the same poor long-term outcome as RF-positive adult RA. RF-negative polyarthritis has a variable outcome reflecting the heterogeneity of the subtype: the percent of patients with bad outcome varies widely among series probably reflecting different patient selection. The prognosis of psoriatic arthritis as defined by the current ILAR criteria is not yet defined; in general, in comparison with oligoarticular JIA, patients have a more frequent involvement of small joints and a higher number of affected joints.

A variable percentage of patients with enthesitis-related arthritis progressively develops a full blown picture of ankylosing spondylitis with involvement of the joints of the axial skeleton.

Growth Anomalies

A characteristic feature of chronic arthritis in children is the effect it may have on bone and joint development. Nowadays, thanks to intra-articular steroid injections and the use of more potent drugs such as anti-TNF agents these complications are observed much less frequently.

Local growth disturbances occur at sites of inflammation resulting in either overgrowth or undergrowth of the iuxta-articular bone extremities. Overgrowth is due to accelerated development of ossification centers, possibly related to increased vascularization and growth factor release secondary to inflammation. As previously mentioned flexion contracture of the knee can cause valgus deformity and asymmetric knee involvement can result in lengthening of the affected leg with leg-length inequality; both, if not very pronounced, tend to resolve with growth if arthritis is controlled.

Undergrowth is secondary to growth center damage or premature fusion of epiphyseal plates. When extremities are involved, it may be symmetric resulting in small hands or feet, or it may be isolated with selective brachydactyly. Arthritis of the wrist may cause growth failure of the ulnar head with shortened ulna and ulnar deviation of the carpus. Unilateral involvement of the temporomandibular joint may result in mandibular asymmetry, and bilateral involvement may cause marked micrognatia. The involvement of the temporomandibular joint is rather frequent and has to be carefully sought in order to start in time an adequate orthodontic treatment. Similarly, involvement of the cervical spine, which is frequent in patients with JIA, may cause undergrowth of the vertebral bodies resulting ultimately in a short neck. Involvement of the neck may make difficult intubation in case of general anesthesia. Atlantoaxial instability is rare in JIA but can be observed.

Anomalies in growth and morphogenesis of skeletal segments result also from anomalous tractions, on growing structures, secondary to muscular spasm and periarticular fibrosis. They are more marked in children with precocious onset of arthritis and very active disease. A characteristic developmental anomaly of the hip is often observed in children with early onset of arthritis. It includes enlargement and flattening of the femoral head, incompletely covered by an underdeveloped acetabulum, and a short, squat, valgus, and anteverted femoral neck.

General growth abnormalities may be secondary to the treatment with steroids as well as to the inflammatory process particularly in patients with severe, persistently active, systemic JIA.

In the affected joints periarticular osteoporosis is common. The use of corticosteroids may lead to generalized osteoporosis.

155 Juvenile Ankylosing Spondylitis

Rubén Burgos-Vargas · Raúl Gutiérrez-Suárez

Definition

The term juvenile-onset ankylosing spondylitis (AS) refers to a disease, which onset of symptoms occurs before the age of 16 years and its main features are familial aggregation, strong association with HLA-B27, as well as peripheral arthritis and enthesitis at onset and sacroiliitis and spondylitis throughout the course of the disease. Juvenile-onset AS is the counterpart of adult-onset AS, the prototype of the group of disease and syndromes known as spondyloarthritis (SpA). Either in children or adults, the SpA group includes undifferentiated forms, psoriatic arthritis (PsA), reactive arthritis (ReA), ulcerative colitis, and Chron's disease.

Diagnosis

Juvenile-onset AS is diagnosed according to the modified New York criteria for AS (*Table 155.1*). The fulfillment of such criteria requires clinical and radiographic evidence of spinal and sacroiliac joint involvement, particularly structural radiographic changes of the sacroiliac joints. (*Fig. 155.1*). Since AS in children and adolescents usually presents with peripheral rather than axial arthritis and enthesitis, the diagnosis of AS is rarely made; in fact, most patients fulfill the modified New York criteria 5–10 years after the onset of peripheral symptoms.

Besides the diagnosis of AS reflects a considerable delay, the structural changes that had taken place throughout the course of the disease are certainly irreversible and represent the end of a disease spectrum, which starts with undifferentiated symptoms. It is therefore that the recognition of children with peripheral arthritis and/or enthesitis and the identification of bad prognostic factors (i.e., HLA-B27, polyarthritis, back or sacroiliac joint pain) are essential to provide the best available treatment in the earliest phase of the disease and attempt to halter disease progression.

The earliest form of juvenile-onset AS is equivalent to undifferentiated SpA according to the European SpA Study Group (ESSG) or enthesitis-related arthritis (ERA) according to the International League for Associations of Rheumatology (ILAR) classification criteria for juvenile idiopathic arthritis (JIA). Rarely, the diagnosis of AS is made in children with less than 3 years of disease duration.

Epidemiology

The incidence and prevalence of juvenile-onset AS in pediatric rheumatology clinics vary according to diagnostic criteria. The proportion of patients with juvenile-onset SpA whose final diagnosis was juvenile-onset AS varied between 13.1% and 25.4% in mid-1990s registries from Canada, the USA, and the UK. In a recent study, 2.5% of 3,269 patients seen throughout 23 years in specialized Canadian clinic had juvenile-onset AS. Finally, the percentage of HLA-B27 children with arthritis that actually have AS may be close to 75%. The proportion of juvenile-onset AS among patients with AS ranges from less than 21% in caucasian populations to 30–50% in Mexicans, Indians, North Africans, and Asians.

As mentioned before, the diagnosis of AS requires of axial symptoms and structural changes in the sacroiliac joints not present in the initial years of the disease. Therefore, epidemiological data only reflect the end of the spectrum. The earliest stage of AS corresponds to most epidemiological data on undifferentiated SpA, including the seronegative enthesopathy and arthropathy (SEA) syndrome.

The age of onset of juvenile-onset AS occurs between the ages of 6 and 12 years, but they may commence at any age below 16 years and is much more frequent in boys than in girls in the prepubescent years, but the proportion of affected girls increases with age.

Pathogenesis

The etiology of AS, including juvenile-onset AS is still unknown. Genetically determined susceptibility is a major factor, but the role of bacterial infections and perhaps mechanical, growth, and developmental factors needs to be investigated.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_155,

Table 155.1
The modified New York classification criteria for ankylosing spondylitis

Clinical criteria
Low back pain and stiffness for at least 3 months, which improves with exercise, but is not relieved by rest
Limited lumbar spinal motion in sagittal (sideways) and frontal (forward and backward) planes
Chest expansion decreased relative to normal values corrected for age and sex
Radiologic criteria
Bilateral sacroiliitis grade 2 to 4
Unilateral sacroiliitis grade 3 or 4
Definite AS, if one radiologic criterion is associated with at least one clinical criterion
Probable AS, if three clinical criteria are present or one radiologic criterion is present without any clinical criterion

Figure 155.1
Grade 3 bilateral sacroiliitis in a 14-year-old boy with 6 years disease duration. There is subchondral sclerosis of the iliac bone, joint surface irregularities, which include some erosions on both sides, and joint space narrowing of the hips (From Burgos-Vargas R (2006) The juvenile-onset spondyloarthritides. In: Weisman MH, van der Heijde D, Reveille JD (eds) Ankylosing spondylitis and the Spondyloarthropathies. Mosby, Philadelphia, pp 94–106)

AS, including juvenile-onset AS, are strongly linked to HLA-B27, particularly B*2705. HLA-B27 association determines the prevalence of AS in the general population and familial aggregation of the disease. Four major hypotheses have been postulated to explain the role of HLA-B27 in the pathogenesis of AS. The arthritogenic peptide hypothesis suggests that the HLA-B27 molecule is able to bind a unique bacterial or self-antigenic peptide, which is then presented to a HLA-B27-restricted cytotoxic (CD8+) T cell. Such hypothesis assumes that a bacterial product and a self-tissue constituent share an aminoacid sequence that elicits an autoimmune response through molecular mimicry. The B27 misfolding hypothesis refers to the abnormally slow folding and accumulation of the B27 heavy chain as covalent homodimers and multimers in the endoplasmic reticulum (ER), ER stress, activation of the unfolded protein in macrophages, activation of the nuclear factor-kB, and cytokines production. The β2m hypothesis refers to the deposition of β2m in the synovium and perhaps other tissues. Finally, the surface homodimer hypothesis postulates that HLA-B27 heavy chain homodimers expressed at the cell surface are recognized by leukocyte receptors and upset the normal development of HLA class I–mediated responses; tissue-specific adaptation to stress at sites of tension may be modulated by a cytokine-mediated mechanism, but unusual signaling leads to excessive proinflammatory cytokine release.

Around 90% of the overall susceptibility to the development of AS is determined genetically. An autosomal dominant trait with 20% penetrance has been demonstrated in some studies. AS occurs 10–20 times more frequently in relatives of patients with AS and 50–80 in their siblings.

Nearly one-half of the genetic contribution to AS is attributed to HLA-B27 and other major histocompatibility complex (MHC) genes, including ERAP1 and IL23R. Thus, B27-postive individuals with a family history of AS have a tenfold greater risk of developing AS than those without familial aggregation.

Different MHC gene polymorphism associations have been described in AS and juvenile-onset AS in several populations including: HLA-DPB1*0301; HLA-DRB1*01, *04 *08, and LMP2 alleles; tumor necrosis factor (TNF); heat shock protein (HSP) and low molecular weight protein (LMP) polymorphism; and outside the MHC region with CYP2D6, ANKH, and IL-1 and IL-1RA.

Currently, three different genome-wide linkage scans and a formal meta-analysis with the whole genotype combination have confirmed the linkage between the MHC region and AS and nominal or suggestive linkage with 2q, 3p, 5q, 9q, 10q, 11q, 16q, 17p, and 19q. Derived from

multiplex case family studies, the best-fitting model involved in the AS genetics ranges from three to nine genes. ARTS1 and IL23R, which are responsible for 26% and 9% of population-attributable risk of AS are two of the three most important genes associated with AS.

Despite no clear triggers of AS and juvenile-onset AS have been found some data suggest a role for bacterial infections in the pathogenesis of the disease. Since killing of bacteria in B27-expressing cells is impaired, infective organisms persist within the host. On the other hand, HLA-B27 can modulate the production of cytokines, favor bacterial cell invasion, and delay bacterial killing. Further evidence include the presence of antibodies against bacterial peptidoglycan in children with juvenile-onset AS, creased T-cell responses to enteric bacteria and heat shock protein 65 in peripheral blood and synovial in HLA-B27 positive pauciarticular JCA, and cases of AS triggered by different microorganisms such as *Mycoplasma pneumoniae*. The synovial fluid of patients with juvenile-onset undifferentiated SpA or AS may contain *Salmonella*, *Shigella*, *Chlamydia*, *Campylobacter*, and *Mycobacterium tuberculosis* DNA.

Pathology

SpA and juvenile-onset SpA synovitis is milder and cartilage erosion less severe than in rheumatoid arthritis (RA). There is hyperplasia of the lining cell with CD68 expression and CD163+ macrophages in the sublining layer and marked neo-vascularity with increased numbers of CD146+ endothelial cells. TNF-α is prominently expressed in the synovium of peripheral joints and high levels of CD8-activated cells, TNF-β, γ interferon, and interleukins 2, 4, and 6. Most cells express TNF receptor p55 and p75 are expressed in most cells, but the former predominates in the vascular endothelium.

Enthesitis consists of a nonspecific inflammation accompanied by granulation tissue, lymphocytes, and plasma cells in the bone marrow, the fibrocartilage, and the interface between calcified fibrocartilage and subchondral bone. There is localized osteitis with marked bone proliferation and mucopolysaccharide deposits also found in tarsal soft tissues. Overall, the inflammatory infiltrates are mainly composed by CD3+, CD4+, and CD8+ T cells. Interestingly, osteocartilaginous proliferation and enthesophytosis may also occur in noninflammatory situations such as bone growth and development, particularly under the effect of trauma or mechanical stress. Cross-reactive humoral and T-cell immune responses to aggrecan G1 domain, a normal constituent of the enthesis, would explain the peculiar localization of the disease.

Clinical Manifestations

The clinical picture of AS in children in the early stages corresponds to undifferentiated SpA or SEA syndrome.

Arthritis. The commonest clinical presentation of juvenile-onset AS is lower-limb oligoarthritis. The joints most frequently affected are the knees and then the ankles and tarsus. Slight and mild cases may enter into sustained remission or have recurrent symptoms. Most patients attending specialized clinics have an increasing number of joints involved throughout the years. The second most frequent type of onset is the combination of arthritis and enthesitis; in such a case, the latter involves the plantar fascia and Achilles tendon's attachments as well as tarsal entheses. Rarely, AS starts with a combination of peripheral and axial symptoms, including back pain and sacroiliitis.

The severity, duration, and consequences of arthritis and enthesitis may not parallel each other and may differ between sites. The distinction between arthritis and enthesitis may be difficult in some sites, for example the sacroiliac joints and the feet. The long-term consequences of arthritis and enthesitis in certain regions, for example, the feet, may lead to ankylosing tarsitis, a peculiar form of disease accompanying AS and other juvenile SpA or a clinical situation presenting without symptoms of other SpA.

The course of arthritis is variable. Some patients have few episodes of mono or oligoarthritis for 3–6 months; others develop recurrent episodes of oligo or polyarthritis for longer periods followed by partial remission, and few develop severe and persistent bilateral polyarthritis; but generally by the end of the first year the majority has polyarthritis and some involvement of the upper extremity joints. The involvement of the hips, MTP, and foot IP joints as well as some of the upper extremities, particularly the shoulder increases during the course of the disease. Permanent joint damage, including joint contractures and limited mobility, muscle atrophy, and distorted bone alignment occur in some patients on the long term.

Enthesitis. Enthesitis and its consequences – osteocartilaginous proliferation and enthesophytosis – may occur within the joints (i.e., the sacroiliac joints) and in extra-articular sites (i.e., Achilles tendon and plantar fascia attachments to the calcaneus). Apart from the plantar fascia and Achilles tendon entheses, the functional entheses of the longitudinal apposition of the

peroneal and tibialis anterior and posterior, as well as extensor hallucis longus tendons to the tarsal bones), those of the knees (tibial anterior tuberosity), hips (greater trochanter), and pelvis (iliac crest and ischion) may be involved. Involvement of the upper-limb entheses is rare. Enthesitis presents with pain, swelling, and reduced mobility of the joints even in cases with no synovitis. The bursae and synovial sheaths of the feet may be swollen (◉ *Fig. 155.2*).

Axial involvement. By definition, all patients with juvenile-onset AS have spinal and sacroiliac joint involvement. In the Mexican and Canadian populations, 70–90% of patients with SEA syndrome fulfill adult-onset criteria for AS within 10 years of symptoms. Shorter follow-ups yield lower figures. Axial symptoms may accompany disease activity at peripheral sites, particularly in patients with severe polyarthritis and enthesitis. Spinal symptoms include pain, stiffness, and reduced mobility and in some patients correspond to typical signs of inflammatory back pain. The diagnosis of inflammatory back pain is the most characteristic symptom of axial disease in juvenile-onset AS – and other SpA – and relies on the following criteria: onset of pain or awakening because of pain in the second half of the night, spinal morning stiffness >30 min, and improvement with exercise, but not with rest. Some children and adolescents clearly fulfill such criteria, but the characteristics of spinal disease in other patients are different. Alternating gluteal – sacroiliac – and costosternal pain are uncommon at onset. All three segments of the spine may be involved, but the thoracolumbar junction and the cervical spine seem most frequently affected. Compared with healthy controls the anterior and lateral spinal flexion and less frequently chest expansion are reduced in parallel with axial symptoms. The involvement of the hips or knees may interfere with the assessment of the spinal mobility.

Extra-articular manifestations. During episodes of disease activity, 5–10% of patients have high-grade fever, weight loss, muscle weakness, fatigue, lymph node enlargement, leukocytosis, or anemia. Up to 27% have non-granulomatous acute uveitis, usually unilateral, frequently recurrent and rarely precedes the onset of the

◉ **Figure 155.2**

Composite images of ankylosing tarsitis in a 16-year-old boy with AS of 9 year's disease duration and complete ankylosis of the tarsal bones and grade 2 bilateral sacroiliitis. (a and b) Flat foot and swelling around the ankle. (c, d, e, and f) T2-weighted-fat suppressed MR imaging showing edema in various tarsal bones, joint spaces (c and d), and soft tissues (e and f) surrounding the tendons of the posterior aspect of the foot on the coronal view (arrows) fat. (g) Complete ankylosis of the tarsal bones and an enthesophyte at the plantar fascia attachment (Modified from Burgos-Vargas R (2009) A case of childhood-onset ankylosing spondylitis: diagnosis and treatment. Nat Clin Pract Rheumatol 5:52–57)

musculoskeletal manifestations. Uveitis seldom leaves ocular sequelae. At least between 40 to 60% of patients have nonspecific IBD. Rare manifestations in the initial years of disease are aortic valve lesion and nonspecific conduction disturbances, and other fewer miscellaneous findings. Pulmonary function test abnormalities, amyloidosis, and atlantoaxial subluxation may also occur.

Juvenile-onset and adult-onset AS. Most differences between juvenile and adult-onset AS consist in symptoms at onset. Children and adolescents with AS have peripheral arthritis and enthesitis in the initial years and axial symptoms 5–10 years later. In contrast, most adult patients complain of spinal and sacroiliac pain and stiffness. Peripheral joint disease is more common in juvenile-onset AS and persistent hip disease is associated with a poor functional outcome. Also, the severity of AS is greater in juveniles than in adults since more juvenile-onset AS patients require hip replacements, more patients are in functional classes III and IV, and Bath ankylosing spondylitis functional index (BASFI) mean scores are higher. However, the severity of spinal involvement seems lower than in adults.

Imaging Studies

Radiographic examination. The presence of bilateral grade 2 or unilateral grade 3 sacroiliitis is mandatory to establish the diagnosis of AS in patients with symptoms of axial disease (Fig. 155.1). These changes are usually not seen before 5–10 years after onset. Peripheral joints may show osteopenia, space narrowing, and even ankylosis; erosions and destructive changes are rare; when present, they are usually seen on the margins or the articular surface of some small joints of the feet or the hips. Collectively, osteopenia, joint space narrowing, bone ankylosis, and enthesophytes characterize ankylosing tarsitis, a radiographic event that may be present in juvenile-onset AS (Fig. 155.2). Generally, spinal radiographic changes occur much later than sacroiliac joints and are rarely seen in childhood or adolescence. Radiographic findings of enthesopathy include bone overgrowth, enthesophytosis, bone bridging, and ankylosis; less frequently, subcortical bone cysts and erosions at tendon attachments.

MR imaging. MR is the most sensitive indicator of inflammation in both the sacroiliac joints and the spine. The best MR sequences are T1-weighted and T2-weighted-fat suppressed or Short Tau (t) (inversion time) Inversion Recovery (STIR). Hyperintense signals in MR are interpreted as edema and inflammation in the bone, synovium, peritendineous tissue, and bursae (Fig. 155.3). Structural changes, specifically erosions, bone destruction, enthesophytosis, and ankylosis may also be seen on MR. Interestingly, MR studies may reveal inflammatory changes of the sacroiliac joints in asymptomatic children.

Other studies. Joint and entheses ultrasonography may provide useful information in active disease. Computed tomography may show structural changes. Finally, radionuclide imaging does not appear to be useful because the growing plates might show augmented periarticular radionuclide activity.

Differential Diagnosis

Early on the course of juvenile-onset AS, its recognition and differential diagnosis represent an important problem, particularly when some children present with nonspecific complaints (i.e., fatigue, tiredness, and ill-defined aches and pains), which are often related to growth, sexual maturation, and development. The involvement of joints and entheses are frequently attributed to injuries and overuse as consequence of games and sports; the diagnosis in such cases range from ankle sprain, meniscus rupture, to Leg–Calve–Perthes and Osgood–Schlatter diseases. Patients with monoarticular

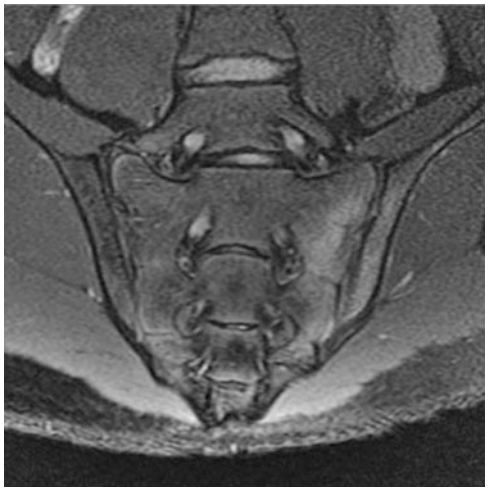

Figure 155.3
Short Tau (t) (inversion time) Inversion Recovery (STIR) MR imaging of the sacroiliac joints of a 16-year-old boy a 3-month history of gluteal pain and a 3-year history of peripheral arthritis and enthesitis. There is ample edema of the iliac bone and sacrum (line) and part of the sacrum inferior quadrant on the opposite side

involvement of the hips are often diagnosed as toxic synovitis of the hip or even tuberculosis and other types of septic arthritis. These circumstances yield mistreatment in early disease and late referral of patients to specialized departments.

Treatment

Currently, the main therapeutic goal in patients with juvenile-onset AS is to reduce the intensity and duration of signs and symptoms of disease, particularly of those related to inflammation (◉ *Table 155.2*). Ideally, therapy should also reduce the structural consequences of the disease, yet there is no evidence that any treatment may do so thus far and on the other by the time the diagnosis of AS is made, patients have structural changes already.

The multidisciplinary health team approach may provide education and relief of medical and nonmedical manifestations. Juvenile-onset AS patients require continuous care and treatment. Patients with juvenile-onset SpA should be enrolled in physical and occupational therapy programs to prevent the consequences of the disease, particularly, hip, foot, and spinal problems. Rest, dynamic splints, and exercise programs should be individualized. Juvenile-onset AS may profoundly harm the quality of life of children and adolescents, and, therefore, their transition to adulthood. Therefore, it is important to consider a number of issues including the psychological, educational, and socioeconomic aspects of life. Disease activity and later, disease damage, may affect these individuals' social life, including personal and family activities, education, and jobs.

Despite there are no guidelines or recommendations for the treatment of juvenile-AS, those issued for adult patients may be adapted at some extent. Treatment, particularly pharmacologic therapy should be individualized according to specific problems. Patients with high-level disease activity with involvement of peripheral and axial joints and entheses should be treated in a different way than children with mild involvement of few joints or entheses. Nonsteroidal anti-inflammatory drugs (NSAIDS) provide symptomatic relief for most patients with mild symptoms. The use of oral prednisone and deflazacort or intra-articular preparations of glucocorticoids may be beneficial in patients with moderate and severe disease activity not responding to NSAIDS or persistent swollen joints. Sulfasalazine might be useful in some patients with peripheral arthritis. Methotrexate is also frequently used to treat juvenile-onset SpA, but there is no clear evidence of improving disease activity in these patients. In adults with AS, the efficacy of sulfasalazine has also been questioned and there is no clear indication of methotrexate in such condition. In contrast, sulfasalazine or methotrexate may improve extra-articular manifestations such as anterior uveitis.

◘ Table 155.2
Medications used in the treatment of juvenile-onset SpA

Drug category	Major indication	Effect
NSAIDS	Pain and swelling	Symptomatic relief
	Peripheral and axial arthritis and enthesitis	
Sulfasalazine	Pain and swelling	Symptomatic relief
	Peripheral arthritis and enthesitis	
	Psoriasis, uveitis, intestinal bowel disease	
Glucocorticoids	Pain and swelling	Symptomatic relief
	Peripheral and axial arthritis and enthesitis	
	Uveitis, psoriasis	
Methotrexate	Pain and swelling	Symptomatic relief
	Peripheral arthritis	
	Uveitis, psoriasis	
Etanercept	Pain and swelling	Symptomatic relief Remission, probably
	Peripheral and axial arthritis and enthesitis	
Infliximab	Pain and swelling	Symptomatic relief
	Peripheral and axial arthritis and enthesitis	Remission, probably

The most significant advance in the therapy of adult and indeed juvenile SpA is the use of tumor necrosis factor alpha (TNF-α) blockers. The anti-inflammatory effect of etanercept and inflixmab in patients with juvenile-onset SpA, including juvenile-onset AS is clearly noticed within few weeks of treatment and their long-term administration provides sustained response. TNF-α blockers reduce the number of active joints, tender entheses, pain intensity, and acute phase reactants and improve functioning. MR imaging of peripheral and sacroiliac joints may also show significant changes with TNF-α blockers. Until now, TNF-α have been safety and well tolerated.

Surgical modalities such as soft tissue release, synovectomy, tendon repair, arthroplasty, and joint replacement may be indicated in some forms of hip, knee, and MTP disease.

Prognosis

Currently, accurate data on long-term prognosis are very limited and there are no validated measures of outcome for juvenile SpA or juvenile-onset AS. Disease activity and structural damage result in diverse degrees of pain, stiffness, loss of movement, functional impairment, and harm to quality of life. Information on juvenile-onset SpA, not exclusively juvenile-onset AS indicate that the probability of remission 5 years after onset only reaches 17% of patients with juvenile-onset SpA; by 10 years of disease less than 50% are in remission; and by 17 years after onset more than 50% of the patients still have active disease. Sixty percent of the patients have moderate to severe functional limitations 10 years after onset, particularly those with disease activity for more than 5 years; however, low-level disability has also been found after 27 years of disease. Compared with other subgroups of JIA, patients with juvenile-onset SpA have higher bodily pain and childhood health assessment questionnaire (C-HAQ) scores, poorer physical health and lower physical functioning and health-related quality of life.

156 Post-infectious Arthritis and Related Conditions

Alberto Martini

In some instances, arthritis is not due to the direct invasion of the joint by the pathogen but rather to the immune response against the infectious agents. In this case, the eliciting infection precedes by a few weeks the onset of symptoms.

Post-streptococcal Arthritis

Acute rheumatic fever (ARF) is a classical post-infectious disease and arthritis is an integral part of its clinical picture (see Chap. 153, "Clinical Approach to a Child with Suspected Rheumatic Diseases"). Arthritis in ARF affects the large joints, is migratory, is characterized by pain, limitation of motion and limited joint swelling and is very sensitive to the treatment with non-steroidal anti-inflammatory drugs.

Post-streptococcal arthritis refers to a post-streptococcal syndrome characterized by an arthritis that is persistent rather than migratory, is less responsive to non-steroidal anti-inflammatory drugs, and occurs in patients whose illness does not fulfil the Jones criteria for the diagnosis of ARF. Usually, the latent period between the streptococcal pharyngitis and the onset of arthritis is shorter (<10 days) with respect to that usually observed in ARF. The course of arthritis is variable; it may last for a few or for several weeks and occasionally even for months. The treatment is based on the administration of non-steroidal anti-inflammatory drugs.

A small proportion of these patients develop valvular heart disease in the follow-up. It is still debated if post-streptococcal arthritis is a defined entity or a manifestation of ARF. This debate involves also the need and the duration of secondary penicillin prophylaxis. The more conservative approach is to follow a prophylactic regimen similar to that proposed for ARF patients who have arthritis but not carditis, that is, to continue prophylaxis until the patient reaches the age of 21 years and for a minimum of at least 5 years.

Reactive Arthritis

Reactive arthritis is a term that identifies an inflammatory arthritis that arises after certain types of gastrointestinal or genitourinary infections. It occurs most frequently in HLA-B27 positive individuals and is therefore considered to belong to the group of spondyloarthropathies (see Chaps. 154, "Juvenile Idiopathic Arthritis" and 155, "Juvenile Ankylosing Spondylitis"). The microorganisms most frequently involved are *Chlamydia trachomatis, Salmonella, Shigella, Campylobacter,* and *Yersinia*. The etiopathogenesis of reactive arthritis is unknown. One theory postulates a CD8-positive cross-reactive T cell response against peptides presented in the context of HLA-B27; this response would cross-react with bacterial epitopes.

The diagnosis associates the presence of an arthritis (usually asymmetric and involving predominantly the lower limbs) with the evidence of an infection, within the preceding 1–4 weeks, with one of the above mentioned microorganisms. Such evidence can be supported either by a history of diarrhea or urethritis or, in the absence of symptoms, by laboratory analysis.

The arthritis, which may be accompanied by fever, is similar to that observed in enthesitis-related arthritis (see Chap. 154, "Juvenile Idiopathic Arthritis"). It is usually asymmetric, predominantly affects the lower limbs, and is often associated with enthesitis and tenosynovitis. The simultaneous presence of arthritis, conjunctivitis, and urethritis constitutes the so-called Reiter's syndrome. Acute phase reactants may be elevated usually in proportion to the severity of clinical symptoms.

The course as well as the severity of arthritis are variable. After a period of weeks or months the arthritis can either go into permanent remission or follow a recurrent pattern which may evolve in a full blown picture of ankylosing spondylitis (see Chap. 155, "Juvenile Ankylosing Spondylitis").

Treatment depends from the severity and the duration of symptoms and is similar to that described in the chapters devoted to enthesitis-related arthritis (see Chap. 154, "Juvenile Idiopathic Arthritis").

Transient (Toxic) Synovitis of the Hip

Although it is often considered secondary to a viral illness its true etiology remains uncertain. It is a common cause

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_156,

of limping in children and is most prevalent between 3 and 10 years of age. In the majority of children it is preceded by 1 or 2 weeks by an upper respiratory tract infection.

The clinical picture is that of a monoarticular synovitis of the hip lasting for a few days and causing a limping gait; pain can be referred to the hip, thigh, or knee. Physical examination shows a limitation of the internal rotation of the affected hip. Children are often afebrile or have low grade fever. Acute phase reactants are normal or occasionally mildly elevated. Ultrasonography of the hip shows a joint effusion. The condition resolves spontaneously within 2 or 3 weeks; non-steroidal anti-inflammatory drugs are indicated.

The condition is usually easily differentiated from septic arthritis, which is characterized by a very painful arthritis accompanied by high fever and a marked elevation of acute phase reactants. If there are doubts, a joint aspiration has to be performed.

Viral Arthritis

Articular symptoms in viral infections are thought to be mainly secondary to the immune response against the virus. Several viruses cause post-infectious arthritis (*Table 156.1*). The clinical course of arthritis is typically self-limiting, usually lasting no longer than a few weeks. The diagnosis is usually made on clinical and serologic grounds and on the transient nature of arthritis.

Joint symptoms in the acute phase of alphavirus infection may be severe and consist of a migratory polyarthralgia or an arthritis affecting mainly the small joints of the hands, feet, wrists, and ankles. Diffuse myalgia and back or shoulder pains may also be present.

Parvovirus B19 associated joint symptoms are more frequent in adults where they usually present as a self-limited, acute symmetric polyarthritis affecting the small joints of the hands, wrists, and knees. In children, they often consist of an asymmetrical and oligoarticular arthritis, often involving the knee. Articular symptoms are usually preceded or accompanied by the classic manifestation of acute parvovirus B19 infection, the "slapped cheek" rash of the fifth disease (erythema infectiosum). In some patients, during the acute infection, autoantibodies can be transiently positive in low to moderate titers.

The arthritis associated with rubella usually follows natural infection or, more rarely, rubella vaccination. Uncommon in males and in prepubertal girls, it affects mainly adult females and appears soon after the onset of rash. Arthritis is frequently symmetrical and polyarticular.

Arthritis, although infrequent especially nowadays with the current available therapies, can occur at any stage of human immunodeficiency (HIV) virus infection, although it is more common in the advanced phases of the disease. Rarely it can be the presenting feature. The arthritis more often affects the large joints of the lower limbs. The defective immune response makes of course these children also at risk for infectious arthritis.

Arthritis may occasionally occur during cytomegalovirus or Epstein-Barr virus infection.

During the preicteric phase of acute hepatitis B infection a small proportion of patients develop a symmetric polyarthritis. Hepatitis C–related arthritis is rare in adults and even more in children.

In mumps, arthritis is unusual and predominantly affects young adult males; it may occur before, after, or even in the absence of parotitis.

Varicella-associated arthritis is uncommon in children. It usually occurs after or coincident with the onset of the disease and tends to affect large joints, especially the knees. Suppurative arthritis has also been reported as a complication of varicella.

Table 156.1
Viruses more frequently associated with arthritis

Alphaviruses
Human parvovirus B19
Rubella virus
HIV
Cytomegalovirus
Hepatitis B virus
Mumps

157 Miscellaneous Conditions Associated with Arthritis

Alexandre Belot · Pierre Quartier dit Maire

Relapsing Polychondritis

Relapsing polychondritis (RP) is a rare multisystem disorder characterized by widespread, destructive, inflammatory lesions of the cartilage. The peak incidence is between the fourth and the sixth decades and less than 5% of the published cases concern children. The disease includes cartilage inflammation of ears, nose, and larynx. Recurrent flares may lead to floppy ears, saddle nose, and laryngotracheal stenosis. Ear inflammation involves the cartilaginous portion of the pinna and spares the non-cartilaginous lobe. Arthritis is common and non-erosive. Most of the children present with conjunctivitis or episcleritis during the follow-up. Hearing impairment occurs in less than 10% of cases. Histology is not mandatory for the diagnosis and may show granular deposits of immunoglobulins and C3, as well as CD4+ lymphocytes and plasma cells associated to a loss of basophilic staining of the cartilage matrix. Erythrocyte sedimentation rate (ESR) is usually elevated but normality, a normal ESR, does not exclude the diagnosis of RP. Autoantibodies against collagen or matrilin-1 have been reported in some cases but with lack of specificity; therefore, the diagnosis remains mainly clinical and the Michet criteria can be used to diagnose childhood onset RP (*Table 157.1*). An association to other autoimmune disorders is less common than in adults (less than 15% of reported pediatric cases); when present, it may include hematologic diseases, inflammatory diseases (Goodpasture, Henloch-Shönlein purpura), and an overlapping syndrome with Behçet disease called MAGIC syndrome (Mouth And Genital ulcers with Inflammed Cartilage syndrome). Differential diagnoses in pediatric practice also include rare inherited degenerative chondropathies, Chronic Infantile Neurologic Cutaneous and Articular (CINCA) syndrome/Neonatal Onset Multisystem Inflammatory Disease (NOMID), Wegener's granulomatosis, and congenital syphilis. Silverman syndrome can be discussed in the presence of saddle nose and ear destruction, but normal X-rays usually rule out this diagnosis. Indeed, some pediatric RP cases have been first diagnosed as Silverman syndrome. Prognosis depends on associated vasculitis and laryngotracheal lesions which can lead to fatal aortic aneurysm and valvulopathy or laryngeal collapses and pulmonary infection, respectively. Treatment consists in nonsteroidal anti-inflammatory drugs in the mildest forms of the disease or steroids and immunosuppressants in the cases with systemic involvement. Few reports also suggest an efficacy of biologics.

Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy (HOA) is a rare syndrome characterized by an excessive proliferation of skin and bone at the distal parts of the extremities and is closely associated with severe chronic disease such as cystic fibrosis, malignancies, and biliary atresia.

The hallmark of the disease is a unique bulbous deformity of the tips of the digits so-called finger clubbing and pain along the long bones with periostitis. Most patients have symmetric polyarthritis with pain and effusions in the knees, wrists, and ankles. Synovitis of the hand joints is far less common. Digital hippocratism is not rare and more often related to cystic fibrosis. Radiographs may also show a symmetrical periosteal new bone formation at the distal ends of the tibiae, radii, fibulae and ulnae and occasionally joint effusions that may be large. Correction of the underlying etiology leads to a quick regression of HOA. Several isolated reports suggest that biphosphonates are effective in relieving bone pain. Octreotide treatment was also associated with clinical improvement in a few case reports.

Vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) may be involved in the pathogenesis of HOA. These growth factors represent potent stimuli for angiogenesis or osteoblast differentiation and are induced by hypoxia. Immunohistochemistry studies have shown increased VEGF and PDGF deposition in the stroma of clubbed digits. Recently, primary form of HOA has been demonstrated to be secondary to a mutation in the gene encoding for hydroxyprostaglandin

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_157,

Table 157.1
Diagnostic criteria for relapsing polychondritis

Michet et al. criteria (1 of 2 conditions necessary for diagnosis)
– Proven inflammation in 2 of 3 of the auricular, nasal, or laryngotracheal cartilages or – Proven inflammation in 1 of 3 of the auricular, nasal, or laryngotracheal cartilages plus 2 other signs including ocular inflammation, vestibular dysfunction, seronegative inflammatory arthritis, and hearing loss

dehydrogenase (HPGD). In this form starting early in the youth, features include skin thickening and excessive sweating ("pachydermoperiostosis"), delayed closure of the cranial sutures ("cranio-osteoarthropathy"), and congenital heart disease, especially patent ductus arteriosus. These symptoms may be related to a defect of prostaglandin E2 (PGE2) catabolism. Consequently, PGE2 and its inactive, HPGD-derived metabolite, 11a-hydroxy-9, 15-dioxo-2,3,4,5-tetranor-prostane-1,20-dioic acid (PGE-M) urine measurements may be useful to evocate the diagnosis, showing an increase of PGE2 and a reduction of PGE-M. Then HPGD mutation analysis is mandatory for the diagnosis.

Mucha-Habermann Disease

Pityriasis lichenoides et varioliformis acuta (PLEVA), also known as Mucha-Habermann disease, is a rare dermatosis characterized by erythematous, scaly papules often accompanied by hemorrhagic lesions. Febrile ulceronecrotic variant of PLEVA, also termed febrile ulceronecrotic Mucha-Habermann disease (FUMHD), is characterized by the acute onset of extensive ulceronecrotic skin lesions associated with high fever (up to 40°C), malaise, myalgia, arthralgia, gastrointestinal and central nervous system symptoms, interstitial pneumonitis, lymphocytic myocarditis, and death. Notably, there is a prognostic difference between adult and children for the FUMHD because all cases resulting in fatality are of the adult type, whereas no fatal cases have been reported among children. T cell clonality in FUMHD is a bad prognostic factor, mainly found in adult patients. Treatments of FUMHD are not standardized and are mainly related to single case reports in the literature. According to Yang, the initial combination use of high-dose corticosteroids rapidly brings down the inflammatory component of the FUMHD, and prolonged treatment with erythromycin can maintain the therapeutic effect. This sequence was successful for the treatment of a 14-year-old patient. Immunosuppressive drugs, phototherapy, antibiotics, or skin grafting may be of interest to treat pediatric FUMHD.

Plant-Thorn Synovitis

Plant-thorn synovitis, a severe foreign-body granulomatous inflammation induced by plant material, is an uncommon cause of arthritis. Injuries of rose thorn or date palm are frequent in the USA whereas, black thorn is the principal cause of thorn synovitis, in Europe. It frequently occurs incidentally when in contact with thorny plants and children are more often affected. The initial symptoms are usually transient and represented by a mild synovitis. Then, local arthritis or soft tissue swelling may develop. At a later stage, chronic or relapsing arthritis represent misleading symptoms for the clinician and can be reminiscent with a chronic inflammatory disease. Symptoms may occur long after the thorn injury has been forgotten, and the diagnosis is usually established at the time of the synovectomy. Histological findings show a sterile granulomatous synovitis. Plant thorns are usually not radiopaque and X-rays are useless. Recently, it has been shown that magnetic resonance imaging and sonography can be helpful for the diagnosis. Removal of the plant thorn with synovectomy is the only curative treatment.

Autoimmune Manifestations of Immunodeficiency

In the last decades, substantial progress led to a precise understanding of primary immunodeficiencies (PID) with the identification of more than 120 genes accounting for more than 150 distinct diseases. Notably, several PID are associated with autoimmunity and give rise to a better understanding of tolerance breakdown.

Autoimmune Manifestations Associated to B and/or T Cell Defects

Bruton's agammaglobulinemia, is an X-linked immune disease due to mutations in Bruton's tyrosine kinase (BTK), a signal transduction molecule essential for B-cell maturation. BTK-deficient B cells do not differentiate into antibody-producing plasma cells, and patients present

with pan-hypogammaglobulinema responsible for recurrent bacterial infections. Juvenile rheumatoid arthritis, dermatomyositis, aseptic polyarthritis, cytopenia, and chronic diarrhea mimicking inflammatory bowel disease have been reported. In some cases, chronic viral infection may explain the symptoms and careful screening for infection is mandatory.

IgA deficiency (IgAD) is the most common primary antibody deficiency and can be diagnosed in children older than 4 years. The most common infections associated with IgAD are sinopulmonary and gastrointestinal infections, especially with *Giardia lamblia*. The prevalence of autoimmune disorders in IgAD patients varies from 7% to 36%. It mainly consists in hematologic disorders, celiac disease and rheumatic disease such as systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). Autoimmune thyroiditis is the most common manifestation of autoimmunity in these patients. The association between IgAD and primary antiphospholipid syndrome has been reported recently.

Hyper-IgM syndromes (HIGM) are primary immunodeficiencies secondary to mutations of various genes, including the genes including CD40 ligand (X-linked HIGM), CD40, NF-κB essential modulator (NEMO), activation induced cytidine deaminase (AID) or uracil DNA glycosylase (UNG). HIGM patients display low levels of IgG and IgA with normal or elevated IgM levels. These patients are prone to recurrent sinopulmonary and gastrointestinal infections. Patients with CD40 ligand mutations may also develop opportunistic infections, mainly *Pneumocystis carinii* infections and cryptosporidiosis. Autoimmunity has also been described in HIGM patient series including immune thrombocytopenia, Coombs positive hemolytic anemia and nephritis, suggesting that tolerance is breached in these patients. Several autoantibodies have been identified in the plasma of HIGM patients. Other autoimmune manifestations seen in these patients include inflammatory bowel disease, autoimmune hepatitis, seronegative arthritis, hypothyroidism, and discoid lupus erythematosus. In two cohorts of patients with X-linked HIGM, chronic neutropenia was found in 44–60% of the patients, anemia, or thrombocytopenia in 15% and 4%, respectively. Seronegative arthritis was seen in 11% and inflammatory bowel disease in 6% of the patients. Other HIGM also demonstrate autoimmunity with a large spectrum of symptoms including cytopenia, autoimmune hepatitis, SLE, diabetes mellitus, inflammatory bowel disease mimicking Crohn's disease and bilateral chronic uveitis. Lymph node, spleen, and liver hyperplasia is a common feature in patients with AID mutations and may also be seen in other HIGM syndromes.

Common variable immunodeficiency (CVID) usually appears later in life. In many cases, the underlying genetic defect is unknown. Some patients disclose mutations in genes encoding the inducible costimulator (ICOS), CD19, the transmembrane activator, calcium-modulator and cyclophilin ligand interactor (TACI) or B-cell activating factor of the tumor necrosis factor family receptor (BAFF-R). Autoimmune manifestations occur in about 22% of CVID patients and are organ specific in most of the cases, consisting in autoimmune cytopenias, pernicious anemia, Hashimoto's thyroiditis, rheumatoid arthritis, and/or vitiligo. In patients with CVID, idiopathic thrombopenia frequently precedes other clinical manifestations. However, cytopenias may also occur later in the disease course.

IgG subclass deficiency can be associated to autoimmune manifestations such as vasculitis, cytopenia, and arthritis. IgG2 is the most prevalent IgG subclass deficiency in childhood. The hallmark of IgG2 deficiency is a defect in anti-polysaccharidic antibody response with severe infections to *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*.

Some patients with severe combined immunodeficiencies (SCID) and a high proportion of the patients with combined immunodeficiencies (CID) are prone to develop autoimmune manifestations. The paradox wherein severe T cell defect can be associated to severe self reactivity of the immune system can be explained, at least in part, by the rupture of central and peripheric tolerance in SCIDs and CIDs. Indeed central tolerance, which is in charge of elimination of autoreactive T cell clones, is impaired in SCID because of markedly reduced expression of Aire, a transcriptional regulator for the expression of tissue-specific antigens in the thymus. Peripheral tolerance is also markedly decreased in SCID because of several factors including the expansion of T cell clones as a consequence of the lymphopenia observed in these conditions as well as a diminished number of regulatory (FOXP3+) T cells, allowing autoreactive T cells to proliferate and infiltrate various organs in the body of SCID. Autoimmunity may also be observed in patients with DiGeorge syndrome (22q11.2 deletion syndrome), where it is more common among patients with a partial yet relatively pronounced deficiency of T cell development. Autoimmune manifestations of DiGeorge syndrome are found in about 10% of patients and consist in autoimmune cytopenias, juvenile arthritis, vitiligo, autoimmune endocrinopathy, or inflammatory bowel diseases. Haemolytic anemia, thrombocytopenia, insulin-dependent diabetes mellitus, asthma, and skin rash has also been reported in patients with SCIDs/CIDs due to

adenosine deaminase deficiency or purine phosphorylase deficiency. Wiskott–Aldrich syndrome (WAS) is a single-gene primary immunodeficiency associated with a remarkably high prevalence of autoimmunity, as high as 70% in retrospective cohorts, which is likely explained by a defect in T regulator differentiation. Omenn syndrome secondary to hypomorphic mutation of RAG1, RAG2, or ARTEMIS can develop autoimmune complications including lymphadenopathy, splenomegaly, erythroderma, and autoimmune hepatic dysfunction. These complications are associated with eosinophilia and elevated IgE, suggesting the involvement of the Th2 subset of T cells that produces IL-4, IL-6, and other cytokines that drive plasma cell differentiation and IgE production by B cells. Patients with these complications have been treated with high-dose steroids, antithymocyte globulin, and cyclosporin A, but bone marrow transplantation remains the only definitive treatment. Class I deficiency (TAP1 or TAP2 deficiency) can present as a granulomatous disease mimicking Wegener disease and recurrent infection in the context of a granulomatous disease should alert the clinicians. Class II deficiency starts earlier in life and is usually revealed by severe or recurrent infections.

Primary Immunodeficiencies Defined by Autoimmune Manifestations

Several monogenic primary immune deficiencies are defined by the occurrence of autoimmune manifestations. Among them are the Autoimmune lymphoproliferative syndromes (ALPS), the Immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX), the Autoimmune-Polyendocrinopathy-Candidiasis-Ectodermal Dystrophy (APECED) syndrome, CD25 deficiency, and the recently described syndrome of immunodeficiency and autoimmunity associated with mutations in the gene encoding the Stromal Interaction Molecule 1 (SIM1). The extended analysis of these diseases widely increases the understanding of human immune tolerance regulation. ALPS is secondary to a mutation of the death domain Fas or Fas-Ligand responsible for an uncontrolled proliferation of double negative CD4-CD8- T cells, with lymphadenopathy, splenomegaly, and polyclonal hypergammaglobulinemia. The diagnosis is often made before the age of 2. These patients may develop autoantibodies usually associated with systemic lupus erythematosus (SLE) without evidence of clinical manifestations of SLE. Autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, and autoimmune neutropenia occur in 29–38%, 23–34%, and 19–27% of the cases, respectively. Glomerulonephritis, optic neuritis, Guillain–Barré syndrome, arthritis, cutaneous vasculitis, primary biliary cirrhosis, autoimmune hepatitis, blistering dermatosis, or acquired factor VIII deficiency have been reported in a few case reports.

IPEX is the consequence of mutation in Foxp3 transcriptional factor leading to a defective development of CD4+ CD25+ regulatory T cells. As a consequence, T cell activation and cytokine production are increased. Autoimmune manifestations are characterized by autoimmune enteritis, type 1 diabetes mellitus occurring during the first months of life, eczema, hypothyroidism, AIHA, membranous nephropathy, recurrent infections, and high titer of IgE. Patients presenting with IPEX syndrome usually die before the age of 2.

APECED (Autoimmune Polyendocrinopathy-Candidiasis-Ectodermal Dystrophy) syndrome is a recessive autosomal disease secondary to a defect of the autoimmune regulator gene (AIRE). Symptoms include chronic mucocutaneous candidiasis, polyendocrinopathy and/or hepatitis, and dystrophy of dental enamel and nails. Candidiasis is usually the first clinical manifestation of the disease, occurring around the age of 5, followed in most cases by hypoparathyroidism before the age of 10 and adrenocortical failure before the age of 15. Other organ-specific autoimmune manifestations encountered in this condition include hypothyroidism, hypogonadism, type 1 diabetes mellitus, pernicious anemia, vitiligo, alopecia, and primary biliary cirrhosis.

Autoimmune Manifestations Associated to Hereditary Complement Deficiency

Primary complement defect, especially in early components of the classical pathway, leads to an increased susceptibility to SLE. C1q, C1s, and C1r complete deficiencies are rare and associated with a high risk to develop pediatric SLE. One of the mechanisms may be an impaired clearance of immune complexes and apoptotic cell debris. More than 90% of homozygous C1q deficient patients present with SLE-like syndrome, whereas SLE occurs in more than 50% of patients with C1s and/or C1r deficiencies. Homozygous C2 deficiency, which is the most frequent hereditary deficiency in classical pathway complement components (1/10,000 to 1/30,000 among Caucasian people), is associated with SLE in 10–30% of the cases.

Table 157.2

Autoimmune manifestation of primary immunodeficiencies (Modified from Goyal R, Bulua AC, Nikolov NP, Schwartzberg PL, Siegel RM (Jan 2009) Rheumatologic and autoimmune manifestations of primary immunodeficiency disorders. Curr Opin Rheumatol 21(1):78–84)

Disease or Syndrome	Mutant gene	Immunologic defect	Manifestations	Autoimmune manifestations
Bruton agammaglobulinemia	Bruton's tyrosine kinase	X-linked agammaglobulinemia	Recurrent bacterial infections and enteroviral infections	Recurrent arthritis, including aseptic arthritis, dermatomyositis-like syndrome, meningoencephalitis (enteroviral infection)
Hyper IgM syndrome (HIGM)	CD40 ligand	Ig class switching defect leading to decreased IgG with normal to elevated IgM	Sinopulmonary and gastrointestinal infections with encapsulated bacteria and lymphoid hyperplasia	Diabetes mellitus, autoimmune hepatitis, rheumatoid arthritis, inflammatory bowel disease, and uveitis
Common variable immunodeficiency (CVID)	TACI (TNFRSF13B)	Hypogammaglobulinemia, humoral and T-lymphocyte dysfunction	Recurrent chronic infections particularly respiratory	Inflammatory bowel disease, autoimmune hemolytic anemia, thrombocytopenia, rheumatoid arthritis pernicious anemia
Severe combined immunodeficiency	Multiple	Lymphocyte development	Failure to thrive, chronic mucocutaneous fungal infections or opportunistic infections, or both	Alopecia, autoimmune thrombocytopenia
Wiskott–Aldrich syndrome (WAS)	WASP	CD4 T-lymphocytes, regulatory T cells, NK cells	Micro-thrombocytopenia with bleeding diathesis, eczema, recurrent infections	Autoimmune hemolytic anemia, arthritis, vasculitis, inflammatory bowel disease, glomerulonephritis
Omenn syndrome	RAG1, RAG2, ARTEMIS	T-B-NK+	Exudative skin rash, lymphadenopathy, hepatosplenomegaly, eosinophilia, and hyper-IgE levels	Part of primary syndrome
Autoimmune polyendocrinopathy candidiasis-ectodermal dystrophy (APECED)	AIRE	Negative selection defect of autoreactive T cells in the thymus	Hypoparathyroidism, chronic mucocutaneous candidiasis, adrenal insufficiency, primary hypogonadism, alopecia, vitiligo, pernicious anemia	Part of primary syndrome

Table 157.2 (Continued)

Disease or Syndrome	Mutant gene	Immunologic defect	Manifestations	Autoimmune manifestations
Immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX)	Foxp3	Regulatory T cell defects	Autoimmune thyroid disease, excema, type I diabetes, eosinophilia, hyper IgE	Part of primary syndrome
Leukocyte adhesion deficiency (LAD1)	CD18, ITGB2	Monocytes and neutrophils adhesion defect	Recurrent bacterial infections	Inflammatory bowel disease
Chronic granulomatous disease (CGD)	CYBB and other components of the NOX2 NADPH oxidase complex	NADPH oxidase	Recurrent suppurative microbial infections, granuloma formation	Chronic inflammation with granuloma formation, inflammatory bowel disease

Autoimmune Manifestations Associated to Phagocytic Cell Defect

Chronic Granulomatous disease (CGD) is a genetic immunodeficiency secondary to a defect of NADPH oxydase complex in phagocytes enabling generation of superoxide and other reactive oxygen species (ROS). Systemic lupus erythematous, mouth ulcers and discoid lupus have been reported in many CGD patients; discoid lupus is also a common feature among X-linked CGD female carriers. Inflammatory bowel disease is the frequent inflammatory condition associated to CGD with symptoms mimicking Crohn's disease. Lung, urogenital tract, and eyes can also demonstrate germ-free granulomatous lesions. Steroids are helpful to resolve the symptoms but do not prevent relapses. Other autoimmune manifestations are represented by idiopathic thrombocytopenic purpura, myasthenia gravis, and juvenile rheumatoid arthritis in a few case reports. In some patients, the severity of autoimmune or inflammatory manifestations, usually associated with recurrent infections, may be part of the symptoms leading to the indication of allogeneic hematopoietic stem cell transplantation.

In conclusion, primary immunodeficiencies shed new lights into the pathogenesis of autoimmune diseases. Molecular identification of mechanisms involved in tolerance maintenance is crucial to develop new treatment as specific as possible of the underlying defect.

As primary immunodeficiencies can present with symptoms suggesting a rheumatic disease (*Table 157.2*), a careful assessment is mandatory in pediatric rheumatology practice to avoid, in particular, an inappropriate use of immunosuppressive drugs in these patients.

158 Pain Amplification Syndromes

Lisa F. Imundo · Simona Nativ

Introduction

Pain is a common presenting complaint in the pediatrician's office. As many as 30% of children and adolescents experience significant muscular fatigue and chronic or recurrent musculoskeletal pain. The symptoms have many causes and the differential in children includes infectious and metabolic conditions, growing pains, overuse injuries, hyperextensibility, orthopedic problems, arthritis, and genetic syndromes.

Pain Amplification Syndromes are rarely recognized or diagnosed in a timely fashion by the primary care physician. These syndromes are characterized by a lack of physical or laboratory findings. Typically the child describes the pain as maximal (on a pain scale of 10/10). There is disability out of proportion to the physical findings, a sensation of pain to non-painful stimuli, psychological distress, an inappropriate indifferent affect (La Belle indifference), a significant family history of disability or chronic pain, and the presence of multiple somatic complaints. Indeed, the degree of pain and disability in these groups is strikingly high compared to children with Juvenile Idiopathic Arthritis or other classical rheumatic conditions where joint disease is readily demonstrable.

Given the lack of a diagnostic test and variability of presentation, as well as a large number of potential etiologies, Pain Amplification Syndromes have been called by many synonyms, despite the possibility that they all represent variations of a common process. Generalized pain syndromes include fibromyalgia, fibrositis, myofascial pain syndrome, pain amplification syndrome, and diffuse wide spread myofascial pain, while localized pain syndromes have been called reflex sympathetic dystrophy, reflex neurovascular dystrophy, causalgia, and Sudeck's atrophy.

Some authors suggest that the precise classification in children with pain and fatigue is not necessary because overlap in clinical presentation is frequent and all children with pain syndromes respond to a similar treatment programs.

Pathogenesis of Pain Amplification Syndromes

An understanding of the pathophysiology and pathogenesis of chronic central pain syndromes has evolved over recent years and is now known to involve multiple interrelated systems including genetic factors, environmental triggers, as well as the neuroendocrine and autonomic nervous system which are simultaneously involved in disordered pain regulation.

Genetic Factors

Studies among patients with central pain syndromes have noted a familial component. First degree relatives of individuals with a pain syndrome have an increased risk of developing a similar disorder, as well as being diagnosed with other concomitant pain disorders such as irritable bowel syndrome and temporomandibular disorders.

Recent studies have identified polymorphisms in genes encoding catechol-*O*-methyltransferase, an enzyme that inactivates catecholamines, as well as the serotonin 5-HT2A receptor and a dopamine D4 receptor. In all of these instances, monoamine metabolism or transport is affected. Monoamines appear to be key factors in the human stress response and these polymorphisms may contribute to abnormalities in pain and sensory processing.

Environmental Factors

Multiple environmental factors have been investigated as possible triggers in the development of central pain syndromes. Physical trauma especially truncal injury, infections (Hepatitis C, Lyme disease, Epstein-Barr Virus, Parvovirus, HIV), catastrophic events such as war, emotional/psychological stress, and the diagnosis of autoimmune diseases have been implicated as playing a role in triggering the onset of pain syndromes. Recent studies of patients with fibromyalgia and other related pain

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_158,

syndromes have noted that approximately 5–23% of patients have an identifiable precipitating event, such as a prolonged or painful episode early in life, prior to the onset of diagnosis. However, an overwhelming majority of patients diagnosed as having a pain syndrome have no known trigger at the onset of symptoms and diagnosis.

Behavioral and Psychologic Factors

Between 7% and 22% of patients with fibromyalgia and other central pain disorders suffer from comorbid psychiatric conditions such as depression. These conditions may also contribute to the symptomatology noted in central pain disorders. Depression is a frequent comorbid condition in pain amplification syndromes and may predate the pain syndrome or be a result of having chronic pain. Patients with depression or anxiety will not have improvement in their pain without proper evaluation and treatment of the underlying psychiatric problems. Therefore, it is imperative that a psychiatric evaluation be required as part of an initial work up for pain amplification syndromes.

Pathophysiology of Enhanced Pain Perception

There appears to be central augmentation of sensory input and altered pain inhibitory function in patients who suffer from central pain. This may be due to both neuroendocrine and autonomic nervous system dysregulation. The concept involves a stimulus being applied to a tissue resulting in sensory inputs from nerve receptors in the tissue being transmitted along primary afferent fibers in the dorsal horn of the spinal cord. Second order spinal neurons then transmit this information to the brain. Neurotransmitters such as Substance P and excitatory amino acids such as glutamate are released in this process and activate postsynaptic receptors which are thought to produce pain perception. Once the sensory input is eliminated, there is reduction of pain sensitivity. When there is a strong or prolonged sensory input there is an exaggerated release of neurotransmitters and excitatory amino acids which cause a hyper-excitable state. There is a positive feedback phenomenon which leads to prolongation of the hyper-excitable state. This model is felt to be responsible for central augmentation and for the low pain thresholds, and high pain intensity described in central pain syndromes. Notably, the source of the exaggerated or prolonged input is unknown in central pain syndromes. In favor of this theory are recent studies showing elevated levels of Substance P and excitatory amino acids glutamate and aspartate, in the cerebrospinal fluid of patients with central pain syndromes. This indicates that the pain is both real and inappropriate.

Is the Brain Responsible for All the Peripheral Pain?

There also appears to be a deficiency in serotonergic and noradrenergic transmission in the central nervous system, shown by a reduction in the levels of primary metabolites of both 5-HT and norepinephrine, but normal levels in the opioidergic system. 5-HT is involved in the inhibition of neurotransmitters and excitatory amino acids, as well as in mood, sleep, and pain regulation all of which are dysregulated in central pain syndromes. Decreased levels of 5-HT may lead to increased levels of Substance P and glutamate and further prolongation of a hyper-excitable state.

There appears to be dysregulation within the hypothalamic-pituitary-adrenal (HPA) axis and sympathetic nervous systems in patients with central pain syndromes. The dysregulation does not appear to occur at the pituitary or primary endocrine level. Rather, it implicates central nervous system dysregulation. Recent studies have shown elevated levels of adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), and decreased levels of insulin growth factor-1 (IGF-1), growth hormone, and estrogen. IGF-1 deficiency has been postulated as a possible cause for sleep impairment commonly noted in central pain syndromes. It has been speculated that many of these hormonal abnormalities are secondary to the observed deficiencies in the serotonergic pathway which influences the HPA axis.

While great strides have been made in the understanding of central pain syndromes and their associated disordered pain regulation, much work is still needed to fully understand these abnormalities. It is unclear if the above processes are causal or secondary phenomena, and there is, as of yet, no identifiable sensory input which triggers these syndromes.

Clinical Characteristics

Overall, children with pain amplification syndromes have disturbed sleep patterns and poorer stress and pain coping mechanisms than age matched controls. This leads to nonrestorative sleep, poor school performance, inability to concentrate, and, oftentimes, withdrawal from school

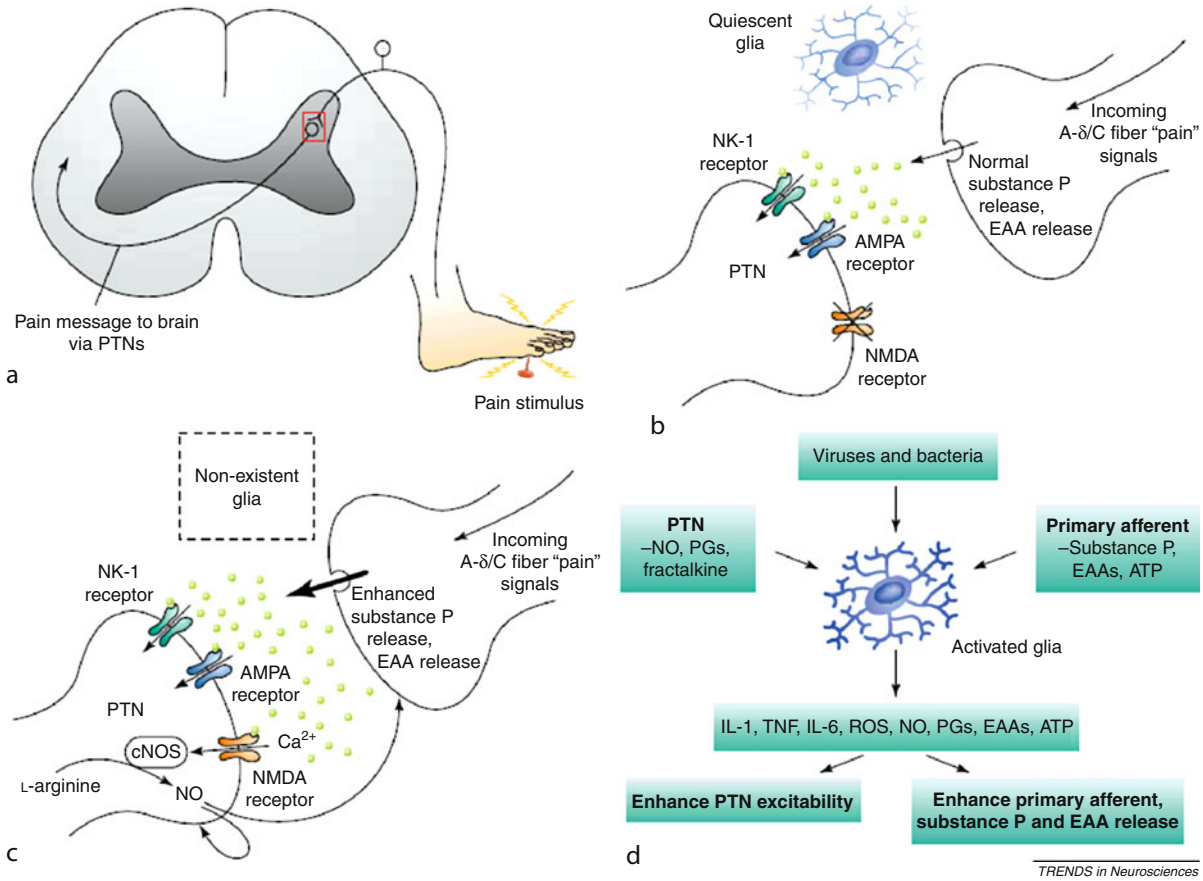

Figure 158.1

(a) Sensory input, (b) transmission within the dorsal horn, (c) neurotransmitters released that promote sensory transmission, and (d) Schematic of pain amplification neural pathway

altogether. Headaches, usually frontal, are common and often occur for hours each day. Some patients complain of numbness and paresthesias or vertigo but no underlying physiologic pathology can be demonstrated. Most patients have widespread musculoskeletal complaints of achiness, arthralgias, and myalgias often concentrated in the neck and upper back. Most patients feel worse after any type of exertion, exercise, or massage and prefer not to be touched. These symptoms respond poorly to over-the-counter medications.

Testing

Reasonable diagnostic studies are often unavoidable except in very early cases and they help to reassure both physician and family. Repeated investigations by inexperienced physicians may prolong the time to diagnosis and treatment. In these cases, x-rays will show patchy demineralization (Sudeck's atrophy), while Doppler studies, technetium, and gallium scans may reflect the excessive autonomic activity and increased or decreased blood flow. MRI evaluation may show dermal enhancement and edema. It is important not to misinterpret these findings as indicative of other disorders (*Fig. 158.1*).

Major Syndromes

Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy (RSD) (neurovascular dystrophy) is not rare in childhood but is difficult to diagnose. The important diagnostic clue is that the child suddenly assumes an immobile posture of a hand or foot that is soon accompanied by diffuse juxta-articular swelling and continuous burning pain (causalgia) that is greatly intensified by light touch (allodynia). The swelling is often

accompanied by color and temperature (trophic) autonomic changes often with coolness and sweating. RSD usually occurs distally involving one hand or foot. These children invariably refuse to bear weight on the foot or even wear shoes or socks. When the hand is involved the child protects the hand by curling it against the chest and the child refuses to use the hand for self care, eating, or writing. Even the lightest touch can cause excruciating pain.

Uniquely, the child refuses to move the hand or foot or holds it in an uncomfortable or bizarre posture. This disease occurs predominantly in teenage girls.

Fibromyalgia Syndrome

Fibromyalgia syndrome (FMS) is a descriptive syndrome that includes widespread musculoskeletal pain, fatigue, and multiple discrete tender points. Diagnostic guidelines for adults were published by the ACR in 1990 (add a link). The classification criteria dictate a history of chronic, diffuse pain with greater than 11 tender points on examination. There is limited published data in children and teenagers with FMS. Children tend to have fewer discrete tender points than adults, but usually develop the requisite number if they are followed over time. Many experts feel that the trigger point tenderness is not required to make the diagnosis of FMS in children.

At least 6% of children seen in pediatric rheumatology centers have this diagnosis, making it the third most common diagnosis in some clinics. The mean age of onset is 12.6 years and it is more common in teenage girls. It appears to be less prevalent in minority and urban populations.

Risk Factors. Primary fibromyalgia occurs without underlying illness. Teenage girls appear to be at higher risk with an increased prevalence of concomitant depression. Prolonged pain and trauma have been proposed as risk factors and have been studied in adult patients with a history of childhood physical or sexual abuse, PTSD, and other traumas. When compared with adult FMS patients, pediatric FMS patients have a higher percentage of secondary fibromyalgia with an underlying rheumatologic condition such as JIA, spondyloarthritis, or SLE.

Treatment Modalities of Pain Amplification Syndromes

The complex nature and unclear pathophysiology of pain amplification syndromes have led to difficulty in both the creation of pharmacologic and non-pharmacologic treatments and their testing in clinical trials. Most of the data and studies involve adult populations and to date there are few pediatric trials designed to examine the efficacy of different treatments. Management of pediatric pain amplification syndromes is similar to that used for adults, with modifications based on age and developmental level and there are fewer medications that are generally prescribed in children. In the initial stages of evaluation and diagnosis, it is of vital importance to establish a therapeutic relationship in which the pain symptoms of the child are validated and noted to be real. The general pediatrician must be sensitive to the diagnosis of a pain amplification syndrome and make an appropriate referral, to avoid misdiagnosis. Once an appropriate diagnosis is made, a multidisciplinary approach should be utilized in order to promote education, exercise, cognitive behavioral therapy, and medications when indicated.

The main goal of treatment should be complete return to school and normal activities. The family should be educated about the role of stress, sleep, pain, and exercise and its role in pediatric pain amplification syndromes. They must be supported in their successful reentry to school by providing whatever accommodations are needed, such as an extra set of school books, modified physical education program or beginning classes later in the morning. No treatment protocol has been completely successful, but incorporating psychological support and exercise reduces disability.

Non-pharmacologic Therapies

There are a plethora of non-pharmacologic therapies available which have been evaluated in the adult literature. Of note, cognitive behavioral therapy (CBT) and aerobic exercise have been used with the strongest evidence of success in treatment in the adult population and in the pediatric population.

Cognitive Behavioral Therapy

Management of psychological factors may play a role in decreasing the perception of chronic pain in these patients. Cognitive behavioral therapy helps patients control pain via guided imagery and distraction in order to help the patient cope with behavioral and cognitive responses to pain. By decreasing their daily stress levels through cognitive behavioral therapy, patients can improve physical functioning. There have been several small pediatric studies documenting the effectiveness of cognitive behavioral therapy in the context of juvenile primary fibromyalgia syndrome. Psychological support

should be provided with evaluation for coexisting conditions such as depression, anxiety and school phobia.

Exercise Interventions: Exercise has been shown to be effective in improving quality of life in pediatric patients with central pain syndromes. Chronic deconditioning secondary to pain leads to decreased physical activity and decreased functioning which becomes a cycle of inactivity. Aerobic programs have been found to have positive effects both on mood and physical functioning in patients. Cardiovascular exercise routines have had greater evidence of benefit then strength training or stretching. During the initiation of aerobic exercise, there may be increased reports of pain, followed by gradual improvement and an increase in energy level. There are also reports of improved sleep and mood with exercise initiation. A pilot study that examined a 12 week exercise intervention in children and adolescents with juvenile fibromyalgia and compared intense aerobic exercise with a light intensity program known as Qigong found improvements in both groups of patients with better response in several measures in the intense aerobic exercise group.

Physical and occupational therapy is an integral component of the treatment of RSD in an effort to reverse immobility and preserve function. Intensive daily desensitization with an experienced physical therapist and a home program is usually extremely successful in relieving and resolving the pain. The rehabilitation must begin immediately when the child is diagnosed. We generally begin with massage while examining the patient and direct them to bear weight or use their hand despite the pain. Once parents are educated about these mysterious symptoms and accept there is no harm in moving the painful limb they can carry out the program at home. Other therapeutic interventions that have had some success in treatment of RSD include nerve stimulation, lidocaine patches, and sympathetic blocks. Prolonged immobility will create symptoms that are more difficult to treat.

Sleep Hygiene: As children with central pain syndromes, most notably the juvenile primary fibromyalgia syndrome have disturbed sleep cycles, reinforcement of sleep hygiene should be an integral component of the multidisciplinary approach to treatment. Regular sleep schedules, avoidance of day time napping, and limitation of caffeine intake are important in establishing sleep-wake cycles.

Pharmacologic Therapies

Many classes of medications have been evaluated in adult literature in the treatment of pain amplification syndromes. The use of medication should be an adjunct to promote better sleep and tolerance to physical therapy. Medications are not curative by themselves. Drug treatment of pain amplification in children is off-label and the risk to benefit ratio should be evaluated prior to onset. Medications such as tricyclic antidepressants, SSRIs, Serotonin and Norepinephrine Dual Reuptake Inhibitors, and CNS acting medications (Pregabalin and Gabapentin), and analgesics have been evaluated in the adult population with variable efficacy. Currently, Duloxetine, Milnacipran, and Pregalbin are FDA approved in the treatment of adult pain amplification syndromes. The use of tramadol, an opioid and serotonin/norepinephrine reuptake inhibitor, has had some efficacy in treatment of fibromyalgia.

Prognosis

There are only limited studies that have examined follow up in pediatric pain amplification syndromes and the results vary between institutions. Overall, it appears that the prognosis is better for children than their adult counterparts. The majority of these children do not develop any other rheumatic diseases but they are prone to developing chronic pain in other organ systems especially headaches, abdominal pain, as well as other psychiatric disorders. Neither the rate of relapse nor long term functional outcome is known. Patients and their families must understand these syndromes are difficult to treat. A multidisciplinary approach appears to be the most comprehensive and successful treatment modality.

159 Systemic Lupus Erythematosus

Bianca Lattanzi · Angelo Ravelli

Definition and Classification

Systemic lupus erythematosus (SLE) is a multisystem, inflammatory, autoimmune disease that can affect any organ system and is characterized by the presence of circulating antinuclear antibodies, especially antibodies to native (double-stranded) DNA. Its clinical manifestations are widely variable, and its course is unpredictable. If left untreated, SLE is often progressive and has a significant fatality rate. It is estimated that 15–20% of patients with SLE have their onset before 16 years of age. Although clinical and laboratory features in juvenile SLE are similar to those that are seen in adults, SLE that begins in childhood has been considered more severe than SLE with onset during adulthood. Furthermore, children diagnosed with SLE may need high-dose corticosteroids and immunosuppressive agents for disease control more often than do their adult counterpart.

In 1971, the American College of Rheumatology (formerly American Rheumatism Association) developed a set of criteria for the classification of SLE, which were revised in 1982 and modified in 1997 (◗ *Table 159.1*). SLE is established when a patient fulfills at least 4 of the 11 criteria. The criteria can be present simultaneously or occur with time along the disease course. The 1982 criteria have been determined to have a sensitivity of 96% and a specificity of 100% in juvenile SLE.

Etiology and Pathogenesis

The etiopathogenesis of SLE remains unknown. The disease is characterized by a dysregulation of the immune system with polyclonal B-cell activation, which appears to drive the production of self-reactive autoantibodies. The production of autoantibodies may represent the sentinel event in the pathogenesis of SLE as it has been found to antedate the onset of clinical symptoms by years. Production of autoantibodies leads to formation of immune complexes, with subsequent tissue deposition and complement activation. The mechanism for polyclonal activation and autoantibody production is not understood. Possible causes include nonspecific responses to antigenic stimuli, such as viral antigens, or loss of either B-cell immune tolerance to self-antigens or suppressor T-cell function. The role of interferon-α in the pathogenesis of SLE has received increasing attention in recent years. This cytokine has been found to be elevated in the serum of SLE patients, and its therapeutic administration in patients with hepatitis has been linked with the development of autoantibodies and lupus-like syndromes. It is hypothesized that interferon-α promotes B-cell responses and immunoglobulin class switching, which may in turn increase autoantibody production. Recent studies have implicated defective apoptosis in the pathogenesis of SLE. Failure of apoptosis may lead to the persistence of self-reactive lymphocytes that normally undergo programmed cell death. In addition to INF-α, other cytokines, such as interleukins-6, 10, 12, and 18, may be involved in the induction of the inflammatory process.

Other mechanisms may play a role in amplifying the manifestations of SLE. Defects in macrophage phagocytosis and processing immune complexes have been reported. The effects of sex hormones, namely estrogens, may account for the disease predominance in females. However, estrogen-containing contraceptives do not produce exacerbations of SLE. Furthermore, that female predilection is also seen among patients with prepubertal onset argues against a prominent responsibility of estrogens. Exposure to ultraviolet rays in sunlight is known to trigger lupus flares, perhaps through damage to skin cells, resulting in release of nuclear debris, such as DNA, which complexes with circulating anti-DNA antibodies. The administration of some drugs can lead to lupus-like serologic and clinical manifestations. However, their discontinuation is usually associated with complete remission.

Reports of clusters of SLE in some families suggests common genetic and/or environmental predisposition. Furthermore, a high concordance rate for monozygotic twins has been described. However, the inheritance of a predisposition to SLE is most likely multifactorial, and multiple genetic factors probably play an important role. The development of SLE has been associated with several HLA aplotypes, Fcγ receptor polymorphisms, and complement abnormalities, such as deficiencies in early components of the complement pathways, namely, C1q, C2,

and C4, high incidence of C4 null alleles and abnormal complement receptors. The genetic factors predisposing to juvenile SLE may differ across ethnic groups. Caucasians patients have a two-fold increase in the frequency of DR-B1 alleles, DR2, and DR3, but this association is not seen in non-Caucasians. Ethnic differences have been reported for Fcγ receptor polymorphisms as well.

Epidemiology

The median age at diagnosis in juvenile SLE ranges from 11–12 years, with disease onset under the age of 8 years occurring in <20% of cases. Although the disease is more common in females than males, the female:male ratio in juvenile SLE (4–5:1) is lower than that seen in adult-onset SLE (9:1). Similar to adult-onset SLE, juvenile SLE is more common and diagnosed at a younger age in non-Caucasian than in Caucasian patients. Incidence and prevalence rates of juvenile SLE have been reported to be 0.3–0.9 per 100,000 children/year and 3.3–8.8 per 100,000 children/year, respectively. The disease frequency differs between ethnic groups. Overall, it is more common in nonwhite populations, particularly in Hispanics, Afro-Americans, Afro-Caribbean, Native Americans, and Asians.

Clinical Manifestations

Children and adolescent with SLE often present with nonspecific constitutional symptoms, such as fever,

fatigue, malaise, and weight loss. Signs and symptoms related to involvement of visceral organs may be already detectable at disease onset or develop throughout the disease course.

Mucocutaneous manifestations. Skin disease is common in juvenile SLE, both at disease onset and during disease exacerbations, and is very heterogeneous (Table 159.2). The most characteristic manifestation is the classic "butterfly" or malar rash (Fig. 159.1), which is observed at onset in 30–50% of patients. It is characterized by symmetrical erythema and edema that are typically centered over the malar eminences and over the bridge of the nose, and sometimes extend to the forehead and the V area of the neck; the nasolabial folds are typically spared. The rash is usually confluent and well demarcated, and may be slightly raised. The malar rash may be precipitated by exposure to sunlight (photosensitivity) but is non-scarring.

A number of other dermatologic manifestations can occur in juvenile SLE. Maculopapular rashes resulting from vasculitis or perivasculitis may be seen anywhere in the body, particularly on sun-exposed areas, such as the face and the upper-anterior chest (Fig. 159.2). These lesions, that are sometimes painful, may also involve the palms and soles. More rarely, cutaneous disease may present as a more widespread morbilliform or exanthematous eruption, or in an extremely acute form that can simulate toxic epidermal necrolysis. Petechial and purpuric eruptions may be related to perivasculitis or be secondary to thrombocytopenia. Raynaud phenomenon is seen in some patients.

Discoid lupus occurs rarely in pediatric patients. The discoid lesions consist of areas of flat or slightly elevated, sharply demarcated, red–purple, papulosquamous patches with adherent scales and follicular plugging, which most commonly occur in sun-exposed areas, such as the scalp and the limbs, in an asymmetric distribution.

Alopecia is a common feature of juvenile SLE. It is associated with disease activity and is usually characterized by diffuse hair thinning, which initially affects frontal hairs. The hairs become brittle and kinky, and are prone to breaking off. This phenomenon is generally referred by the child or the parents as an excessive hair falling on the pillow, in the comb, or after shampooing. This alopecia is usually non-scarring and more often causes limited

upset. In contrast, irreversible scarring alopecia from permanent follicular destruction is rare.

Other uncommon cutaneous manifestations of juvenile SLE are urticarial and bullous (pemphigoid-like) lesions. Fingers, toes, or face red–purple patches and plaques that are precipitated by cold exposure and are reminiscent of simple chilblains or pernio lesions are occasionally observed in children. Diffuse hyperpigmentation, usually most prominent on the light-exposed and extensor surfaces of the body, is another important, though rare, dermatologic feature of juvenile SLE. Shallow, painful ulcers of the lips, gums, palate, and nasal mucosa occur in 10–15% of patients and frequently occur during disease exacerbations. Similar lesions are seen occasionally on the vulvar surface.

A number of skin changes that may develop in patients with lupus have been associated with the presence of circulating antiphospholipid antibodies. They include leg ulcers, livedo reticularis, cutaneous necrosis, gangrene of the digits or extremities, thrombophlebitis, necrotizing purpura, and nailfold infarcts. Leg ulcers, which occur more often in the lower limbs, are painful and sharply marginated; they have a necrotic center or base and leave a white atrophic scar on healing. Livedo reticularis has been related to the stagnation of blood in dilated superficial capillaries and venules, and affects primarily the skin of the tights, shins, and forearms.

Musculoskeletal disease. Most patients with juvenile SLE have musculoskeletal involvement, mainly arthritis or arthralgia, with or without associated tenosynovitis. Arthritis is typically symmetric and nonerosive and affects large and small joints. Joint involvement is usually marked by only mild to moderate effusion; however, tenderness and pain on passive motion with reduced range of movements may be present. Deforming arthritis is uncommon, although hand arthritis can lead to ligament damage and significant joint laxity. Although myalgia is frequent, true myositis with muscle weakness is seen in less than 10% of patients. When present, myositis can be difficult to distinguish form steroid-related myopathy. Avascular necrosis is a known complication of corticosteroid therapy (*Fig. 159.3*). It is seen in 10% of cases and may be more common in children than in adults. The juxtaarticular regions of the large, weight-bearing joints, particularly hips and knees, are typically affected. Osteoporosis and vertebral fractures may occur in patients on long-term corticosteroid treatment and are often asymptomatic. Inflammatory musculoskeletal pain should be distinguished from noninflammatory pain than results from a pain amplification syndrome secondary to mood or emotional disturbance.

Renal disease. Overall, 60–80% of children with SLE have urinary or renal function abnormalities early in the disease course. Kidney involvement becomes manifest most frequently in the first 2 years from disease onset. However, lupus nephritis may also occur later in the disease course. Treating physicians should routinely screen for hematuria and proteinuria, as well as for laboratory

Figure 159.3
MRI of the right ankle showing avascular necrosis of the distal tibia, astragalus, and calcaneus

parameters of renal function and hypertension. A high index of suspicion should be maintained, and symptoms such as headache, weight gain, and swelling of the extremities should raise the alarm for possible renal involvement. Typically, microscopic hematuria and proteinuria precede more overt signs of nephritis. Although it may be easy to predict the histologic lesion in patients who present with severe renal failure and significant hypertension, in less severe cases, it is difficult to predict the morphologic pattern based on clinical and laboratory parameters, including urine sediment and the amount of proteinuria. For this reason and because treatment differs for diverse forms of SLE nephritis, it is suggested that renal biopsy be always performed at the time of initial presentation in patients who have significant abnormalities on urinalysis or abnormal renal function. It is common view that early diagnosis may improve the long-term outcome of patients with proliferative lupus nephritis.

The World Health Organization (WHO) has defined a morphologic classification of kidney biopsies in SLE, which was revised in 2003 by the International Society of Nephrology and the Renal Pathology Society (*Table 159.3*). The spectrum of lupus nephritis ranges from mild mesangial proliferation (class II) to diffuse proliferative glomerulonephritis (class IV) to membranous nephritis (class V). Patients with advanced glomerular sclerosis are classified in class VI. Among patients with

Table 159.3
Abbreviated International Society of Nephrology/Renal Pathology Society Working Group (ISN/RPS) classification of lupus nephritis 2003

Class I	Minimal mesangial lupus nephritis
Class II	Mesangial proliferative lupus nephritis
Class III	Focal lupus nephritis
Class IV	Diffuse segmental (IV-S) or global (IV-G) lupus nephritis
Class V	Membranous lupus nephritis
Class VI	Advanced sclerosing lupus nephritis

Source: Adapted from Weening JJ, D'Agati VD, Schwartz MM et al. (2004) The classification of glomerulonephritis in systemic lupus erythematosus revisited. Kidney Int 65:521–530

active nephritis, those who have class III or class IV lupus nephritis carry the greatest risk of developing end-stage renal disease. Recently, definition of the degree of active inflammation and cumulative damage with activity and chronicity scores, respectively, has been proposed. However, the prognostic value of these scores is still uncertain.

Neuropsychiatric disease. Involvement of the CNS and peripheral nervous system is another major cause of morbidity and mortality in juvenile SLE. Overt neuropsychiatric disease may be seen in approximately one third of patients. However, a greater proportion of cases may have subtle manifestations, particularly cognitive dysfunction, when examined with specific neuropsychiatric testing. Patients with lupus may develop a wide variety of neuropsychiatric manifestations. In 1999, the American College of Rheumatology provided a classification of neuropsychiatric lupus into 19 separate disease entities (*Table 159.4*). However, patients with neuropsychiatric lupus may meet criteria for more than one of these entities. Although neuropsychiatric disease is seen more often in the first year after disease presentation, it can also occur later in the disease course in around one quarter of patients.

Headache is the most common neuropsychiatric manifestation. However, a mild isolated headache may be due to causes unrelated to SLE. A true lupus headache is refractory to standard analgesic treatment. When the headache is severe or unremitting, then investigations are warranted because it is often due to an organic cause, such as vasculitis, cerebral vein thrombosis, or raised intracranial pressure caused by CNS infection or pseudotumor cerebri.

Psychiatric manifestations occur in up to 40% of pediatric patients with SLE, and they are mostly characterized by psychosis, depression, cognitive dysfunction, or

Table 159.4
1999 ACR nomenclature and case definitions for neuropsychiatric SLE

Central nervous system	Peripheral nervous system
Aseptic meningitis	Guillan–Barrè syndrome
Cerebrovascular disease	Autonomic disorder

confusion. Psychiatric symptoms are frequently associated with headache. Laboratory markers of lupus activity can be negative, and brain parenchymal imaging studies, including MRI and CT scan, are frequently normal. The diagnosis is, therefore, solely based on clinical features. The differential diagnosis between lupus psychosis and steroid-induced psychosis is often difficult. The usefulness of single-emission computed tomography (SPECT) has been advocated by some authors but denied by others. It has been suggested that the presence of mania, head banging, and excessive crying (uncommon in neuropsychiatric lupus) are useful to differentiate lupus from steroid-induced psychosis.

Cognitive dysfunction occurs in about 30% of patients and may range from concentration and attention defect, memory loss, and decreased school performance, to frank confusion, and coma. Cerebrovascular disease is seen in up 25% of pediatric patients. It may be secondary to small vessel inflammation or to the presence of lupus anticoagulant and anticardiolipin antibodies (antiphospholipid syndrome). Seizures are frequent at disease presentation and are often associated with other CNS manifestation, but can also occur in isolation. Generalized seizures are more frequent that localized seizures. Seizures may also be secondary to uremia, hypertension, or CNS infection. Chorea is more common in juvenile than in adult-onset SLE. It is generally accompanied by the presence of antiphospholipid antibodies and may occur in isolation or together with other manifestations of the antiphospholipid syndrome.

Cranial and peripheral neuropathies are rare in juvenile SLE. Cranial nerve involvement is most common and may present with optic neuropathy, oculomotor palsy, facial palsy, or trigeminal neuropathy. Transverse myelitis may present with acute paraplegia or quadriplegia, and may be associated with antiphospholipid antibodies. Other clinical manifestations are polyneuropathy, mononeuritis, miastenia gravis-like syndrome, demyelinating disease, and Guillan–Barrè syndrome.

Cardiac involvement. The most common form of cardiac involvement is pericarditis with pericardial effusion. Myocarditis and valvular disease are less frequent, and ischemic heart disease secondary to coronary artery vasculitis is rare. Symptomatic pericarditis occurs in 15–25% of patients, whereas up to 68% of patients have echocardiographic abnormalities consistent with pericarditis. In case of severe pericardial effusion, constriction or tamponade may ensue. Valvular heart disease may be associated with the presence of antiphospholipis antibodies or Libman–Sacks endocarditis. Myocarditis can occur in about 15% of children and may lead to congestive heart failure, cardiomegaly, and arhitmias. For this reason, tachycardia without fever in lupus patients should be always investigated.

The major source of cardiac morbidity associated with juvenile SLE is premature artherosclerosis. A number of traditional and nontraditional atherosclerotic risk factors, including lipid abnormalities, abnormal endothelial function, nephritis, and heavy proteinuria, have been linked to the development of early atherosclerosis in juvenile SLE. Recent studies have shown that children and adolescents with lupus have myocardial perfusion defects, abnormal vascular reactivity, and increased carotid intima-media thickness, suggesting that pediatric patients are exposed to an increased risk for myocardial infarction and cerebral vascular events early in life. It is believed that the chronic inflammatory process of lupus is the leading risk factor for premature atherosclerosis. The responsibility of corticosteroids is less clear.

Pulmonary involvement. Pleuritis and pleural effusions are frequently seen in patients with juvenile SLE. Less common forms of pulmonary disease include lupus pneumonitis, pulmonary hemorrhage, pulmonary hypertension, pulmonary embolism, and pneumothorax. Symptoms suggesting lung disease include persistent dry cough, chest pain, dyspnea, and orthopnea, but the course can be occasionally subclinical. Acute lupus pneumonitis is characterized by bibasilar pulmonary infiltrates and atelectasia. It usually responds to corticosteroid therapy.

However, an infectious etiology for the pulmonary infiltrate should be always searched for. Pulmonary hemorrhage is rare but should be considered in children who develop sudden pallor, tachycardia, and falling hematocrit, even if hemoptysis is absent. Chronic interstitial lung disease is not described in children with lupus.

Hematologic manifestations. Leukopenia, anemia, and thrombocytopenia are commonly seen in pediatric patients with SLE. Cytopenia affecting one or more cell lines is frequent in poorly controlled disease and may be a marker of disease activity. Anemia is usually microcytic and hypocromic as related to chronic disease. Thrombocytopenia may be the presenting symptom of SLE in children and adolescents, and may predate the development of other signs and symptoms of SLE by many years. In general, isolated hematologic involvement at disease onset is observed more frequently in juvenile SLE than in adult-onset SLE. All children who have chronic autoimmune thrombocytopenic purpura should have antinuclear antibodies determined because, if positive, they are at high risk of developing SLE. The Coombs' test is positive in approximately 30–40% of patients, but less than 10% of patients have overt hemolysis. When present, autoimmune hemolytic anemia may be severe enough to require transfusion.

Leukopenia occurs in 20–40% of cases of juvenile SLE. It may consist of either lymphopenia or granolocytopenia, although lymphopenia is more common. Lymphopenia is a reliable indicator of general disease activity but does not require a specific therapy. A profound lymphopenia may herald a significant risk for serious infection. Neutropenia may be due to central depression of granulopoiesis, antigranulocyte antibodies, or splenic sequestration.

The most common coagulation abnormalities seen in juvenile SLE are related to the presence of lupus anticoagulant, which is observed in 20–30% of cases. Patients with lupus anticoagulant and other antiphospholipid antibodies, namely, anticardiolipin antibodies and anti-β2 glycoprotein I antibodies, have an increased incidence of venous and arterial thrombosis and other clinical manifestations, such as chorea, livedo reticularis, thrombocytopenia, Coombs' positive hemolytic anemia, cardiac-valve abnormalities, and skin ulcers (so-called antiphospholipid syndrome). Occasionally, patients with these antibodies may develop a catastrophic antiphospholipid syndrome, which is characterized by widespread microangiopathic changes and thrombosis in multiple organs. Because antiphospholid antibodies react with cardiolipin used in the serologic test for syphilis, their presence may result in a false-positive test.

Patients with juvenile SLE may develop macrophage activation syndrome, a severe, potentially life-threatening complication characterized clinically by nonremitting high fever, pancytopenia, hepatosplenomegaly, hepatic dysfunction, encephalopathy, coagulation abnormalities, and sharply increased levels of ferritin. The pathognomonic feature of the syndrome is seen on bone marrow examination, which reveals numerous morphologically benign macrophages actively phagocytosing hematopoietic cells. This syndrome is associated with an excessive activation and proliferation of T lymphocytes and macrophages with massive hypersecretion of proinflammatory cytokines. Macrophage activation syndrome may occur spontaneously, as a complication of active underlying disease, or may be triggered by an infection or a change in drug therapy.

Gastrointestinal and liver disease. The most common gastrointestinal complaint is abdominal pain, which can be related to peritoneal inflammation due to serositis, vasculitis, pancreatitis, pseudo-obstruction, or paralytic ileus. Lupus enteropathy may present as acute ischemic gut inflammation or protein-losing entheropathy. This condition is suggested by the occurrence of cramping abdominal pain and diarrhea. The same symptoms may also be secondary to mesenteric vasculitis or thrombosis, however. Gastrointestinal vasculitis carries a high risk for perforation, whose symptoms may be masked by ongoing high-dose corticosteroid therapy. Pancreatitis may occur in less than 5% of patients and may be secondary to active inflammation, infection, or corticosteroid or azathioprine therapy. Splenomegaly may reflect the generalized inflammatory state or, occasionally, macrophage activation syndrome. Hepatomegaly is frequent, as is the abnormality of liver function tests. Liver involvement may be due to lupoid hepatitis, Budd–Chiari syndrome, macrophage activation syndrome, or, more rarely, intrahepatic necrotizing arteritis with nodular regenerative hyperplasia. Mild liver function test increase may be secondary to fatty liver in patients who have received prolonged corticosteroid therapy.

Autoantibodies. The hallmark of SLE is the production of a wide array of autoantibodies directed against several antigens. The most common are the antinuclear antibodies, which are found in up to 100% of patients. ANA represent an excellent screening tool but lack specificity because they can be found in apparently healthy individuals and in patients with different rheumatic diseases or other conditions. Anti-double-stranded anti-DNA antibodies are more specific for lupus and often reflect the degree of serologic disease activity. Other autoantibodies seen in patients with

juvenile SLE include anti-RNP, anti-Sm, anti-Ro, anti-La, and antiphospholipid antibodies. Anti-ribosomal P antibodies have been linked to the development of psychosis.

Diagnosis

The diagnosis of juvenile SLE is based on the typical constellation of clinical and laboratory features. Although the American College of Rheumatology criteria (*Table 159.1*) were designed as classification criteria, they are widely used for diagnosis. However, not all patients have at least 4 criteria at the time of disease presentation. Indeed, the clinical spectrum of SLE is protean, and early identification can be challenging when the disease occurs in monosymptomatic or oligosymptomatic form, or presents with atypical clinical manifestations. Thus, patients suspected to have lupus who demonstrate fewer than four criteria should receive appropriate medical treatment

Differential Diagnosis

Because of the multisystem nature of SLE, lupus must be considered in the differential diagnosis of many conditions, ranging from fevers of unknown origin, to arthritis, anemia, thrombocytopenia, nephritis, and neurologic dysfunction. The differential diagnosis includes other rheumatic diseases, including rheumatic fever, post-streptococcal glomerulonephritis, hematologic malignancies, immune thrombocytopenic purpura, and idiopathic hemolytic anemia. In general, lupus should be considered in patients with a systemic inflammatory illness and multiorgan symptoms, especially if there are hematologic or urinalysis abnormalities, or if autoantibodies are found.

Drug-Induced Lupus

Exposure to some drugs, including anticonvulsivants, sulfonamides, and antiarrhythmic agents, may induce a lupus-like disease. Many of these patients have antihistone antibodies. The typical symptoms of fever, rash, and pleuro-pericardial disease usually abate with discontinuation of the inciting drug. Serum complement levels generally remain normal, and visceral organ involvement, namely renal disease, are rare.

Treatment

General Aspects of Management

The therapeutic management of juvenile SLE is driven by the affected target organs and disease severity. Early disease control and a comprehensive approach to care are crucial to reduce long-term morbidity and mortality. Meticulous and frequent reevaluation of clinical signs and laboratory tests is fundamental, especially for monitoring of renal disease and detection of disease flares. Prompt recognition and treatment of disease flare may improve patient outcome.

In all patients with hypertension, blood pressure should be tightly controlled with the use of antihypertensive agents. Because lupus patients are known to have an increased risk of early atherosclerosis, cardiac risk factors should be minimized with diet, exercise, and maintenance of a healthy life-style. In patients on long-term corticosteroid therapy, osteoporosis prevention with calcium and vitamin D supplementation is advocated. Sun exposure should be minimized and include use of a sunscreen, particularly in patients with photosensitive rash. Patients with antiphospholipid antibodies should be advised about the need of minimizing exposure to other pro-thrombotic factors, such as smoke, alcohol, and use of estrogen contraceptive pills. In case of development of antihospholipid antibody-related thrombotic complications, long-term anticoagulation is prescribed.

Pharmacologic Therapy

Nonsteroidal anti-inflammatory agents are used to treat arthralgia and arthritis. However, these medications should be used with caution because patients with lupus are more susceptible to hepatotoxicity. Ibuprofen is generally avoided because of reports of ibuprofen-related aseptic meningitis in SLE patients.

Hydroxychloroquine is often used to treat skin lesions and musculoskeletal manifestations. Because its major side effects are retinal maculopathy, ophthalmologic evaluation is required every 6 months. However, ocular toxicity is rare if the dose is kept to less than 6.5 mg/kg/day. Hydroxychloroquine may also reduce the risk of thromboembolic disease and lowers lipid levels. It might have a general effect on prevention of lupus flares as well.

The mainstay of pharmacological therapy of juvenile SLE is represented by corticosteroids, which can be administered orally or intravenously, depending on clinical manifestations and personal physician's experience.

Prednisone or prednisolone (1–2 mg/kg/day) are started at disease onset in order to attain remission. Initial dose may be divided into 2 or 3 daily doses, on the basis of disease severity. Administration of high-dose pulse intravenous methylprednisolone (30 mg/Kg/day to a maximum of 1 g/day for 1–3 consecutive days) is frequently used with the aim of achieving prompt control of active disease or disease exacerbation, particularly in the presence or severe renal, CNS, or hematologic involvement, and of preventing adverse effects of daily corticosteroid administration. Lower doses of prednisone (e.g., 0.5 mg/kg/day) may be used in patients with mild disease severity or for the treatment of skin rash or musculoskeletal manifestations. Once a satisfactory control of disease manifestations is obtained, corticosteroid dose is gradually reduced until the minimal dose that is sufficient to maintain remission over the long-term.

Patients with severe disease or major visceral organ involvement may require cytotoxic therapy. Pulse intravenous cyclophosphamide has been found to maintain renal function and prevent progression in patients with proliferative glomerulonephritis. However, the optimal therapeutic regimen and length of therapy remain controversial. Cyclophosphamide is also used to treat vasculitis, pulmonary hemorrhage, CNS involvement, and life-threatening hemolytic anemia. Adverse effects include secondary infections, gonadal dysfunction, and increased risk of later malignancies.

Azathioprine has been used to prevent renal progression, but nowadays its main indication is long-term maintenance therapy after induction with cyclophosphamide. This drug may have a steroid-sparing role in the treatment of other disease manifestations, namely, autoimmune cytopenia. Mycophenolate mophetil is an alternative to cyclophosphamide for some type of lupus nephritis, particularly membranous nephritis, and has an efficacy comparable to azathioprine as maintenance therapy in proliferative nephritis. This drug has been recently proposed as a less toxic and equally efficacious alternative to cyclophosphamide in the induction therapy of proliferative lupus nephritis. However, this indication is still controversial. Methotrexate and cyclosporine are also used as steroid-sparing agents for some specific disease manifestations, such as arthritis or cytopenia.

In recent years, there has been increasing interest for the use of biologic medications in SLE. The anti-CD20 monoclonal antibody rituximab has been tried, alone or in combination with cyclophosphamide, with encouraging results in the treatment of severe and refractory cases of proliferative glomerulonephritis, CNS disease, or cytopenia. Use of rituximab in the management of lupus nephritis is currently being explored with the aim of designing therapeutic protocols that allow for a lower cumulative cyclophosphamide dose. Side effects of rituximab include infusion reactions, increased risk for infection, and demyelinating syndromes. Autologous stem cell and allogeneic bone marrow transplantation have been proposed for patients with very severe, resistant disease.

Outcome and Prognosis

The natural history of juvenile SLE is widely variable, ranging from acute, life-threatening disease to long-lasting, smoldering disease. The prognosis is worse in patients with involvement of major visceral organs, particularly the kidney and the CNS. The major causes of death in patients with juvenile SLE currently include infection, nephritis, CNS disease, and pulmonary hemorrhage. However, over the past two decades there has been a marked improvement in survival among patients with juvenile SLE. In some recent reports, the 5-year survival rate approaches 100% and the 10-year survival rate is close to 90%.

Figure 159.4
Typical cutaneous rash of neonatal lupus

As a result of the prolonged life expectancy, children and adolescents with SLE are now exposed to an increased risk of morbidity related to the sequelae of disease activity, side effects of medications, and comorbid conditions, such as recurrent infections, accelerated atherosclerosis, osteoporosis, and hypertension. The development of cumulative organ damage has been observed in 50–60% of patients, with the musculoskeletal, renal, and neuropsychiatric systems being most frequently affected. Furthermore, children and adolescents with SLE have been found to have poorer HRQL, particularly in the physical domain, and lower socioeconomic achievements than their healthy peers. These issues emphasize the need of continuing a careful long-term follow-up of currently treated patients in order to understand the overall impact of the disease and its therapy. Furthermore, future treatments and treatment strategies should be aimed not only at better controlling disease activity but also at reducing the development of nonreversible organ damage.

Neonatal Lupus

Newborns of mothers affected with SLE or Sjogren's syndrome, who possess anti-Ro/SSA or anti-La/SSB antibodies, may develop lupus manifestations. The disease results from transplacental transfer of these autoantibodies between the twelfth and sixteenth weeks of gestation. Symptoms include congenital heart block, cutaneous rashes, hepatitis, thrombocytopenia, neutropenia, and pulmonary and neurologic disease. The rash occurs most frequently on the face and scalp (◉ *Fig. 159.4*) and may leave scars in 25% of cases. Treatment is supportive in most cases, although a course of steroids may be required in patients with severe manifestations. Severe thrombocytopenia may require corticosteroid or intravenous immunoglobulin therapy. Most manifestations resolve spontaneously, although congenital heart block is permanent and often requires cardiac pacemaker, either after birth or, when detected and sever, antenatally. Corticosteroid treatment of the pregnant mother after heart block is detected early in utero, and postnatal corticosteroids may be effective.

160 Antiphospholipid Antibody Syndrome

Tadej Avčin

Definition/Classification

The antiphospholipid antibody syndrome (APS) is a multisystemic autoimmune disease characterized by thromboembolic events, pregnancy morbidity, hematologic, dermatologic, neurologic, and other manifestations in the presence of elevated titers of antiphospholipid antibodies (aPL). Antiphospholipid antibodies are a heterogeneous group of autoantibodies directed against negatively charged phospholipids or phospholipid-binding plasma proteins. The most relevant aPL for identifying patients at risk for immune-mediated thrombosis are anticardiolipin antibodies (aCL), antibodies against β_2 glycoprotein I (anti-β_2GPI) and lupus anticoagulant (LA).

The classification criteria for APS were developed by consensus and designate patients who suffered from vascular thrombosis or pregnancy morbidity associated with the presence of aPL, detected on two or more occasions at least 12 weeks apart (*Table 160.1*). These criteria were developed for classification of adult patients with APS and include pregnancy morbidity as a clinical criterion, which is not applicable for the pediatric population. A classification of "probable APS" has been given to patients with aPL that have non-criteria clinical features associated with APS such as livedo reticularis, thrombocytopenia, nephropathy, and neurologic manifestations. Catastrophic antiphospholipid antibody syndrome (CAPS) is a rare, life-threatening variant of APS, characterized by acute microvascular occlusive disease involving at least three organ systems in less than a week.

Etiology

The cause of APS remains unknown. It may occur as an isolated clinical entity (primary APS) or in association with autoimmune diseases, infections and malignancies. Primary, isolated APS accounts for approximately half of all pediatric patients with APS. The majority of cases associated with underlying autoimmune disease occur in patients with systemic lupus erythematosus (SLE) and lupus-like disease. Preceding or concomitant infections were found in approximately 10% of children with primary APS or APS associated with autoimmune disease. APS associated with malignancies is exceedingly rare in childhood and accounts for less than 1% of all pediatric APS cases.

Epidemiology

APS is considered the most common acquired hypercoagulation state of autoimmune etiology, and aPL were reported in up to 25% of unselected children with thrombosis. The average age of onset in 121 pediatric APS patients included in an international registry was 10.7 years with the female-to-male ratio 1.2:1. Children of all ethnic background have been affected with APS.

Antiphospholipid antibodies can be found in a high percentage of children that do not experience thrombosis. SLE is the autoimmune disease in which aPL occurs in highest percentage, with the reported mean frequencies of 44% for aCL, 40% for anti-β_2GPI, and 22% for LA, respectively. The estimated incidence of thromboembolic events in pediatric SLE patients with positive LA was 54% and with positive aCL 22%.

Low levels of aPL can be found in children without any underlying disorder. These naturally occurring aPL are usually transient and could be the result of previous infections or vaccinations that are common in the pediatric population. LA can be rarely found in apparently healthy children as an incidental finding of prolonged activated partial thromboplastin time (aPTT) in pre-operative coagulation screening. The risk of future thrombosis is exceedingly low in otherwise healthy children who were incidentally found to have positive aPL.

Pathogenesis

There is an accumulating experimental evidence that aPL may directly contribute to disease pathogenesis and are not just a simple serological marker of APS. The dominant antigenic targets in APS are β_2GPI and prothrombin.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_160,

Table 160.1
2006 revised classification criteria for the antiphospholipid antibody syndrome (APS)

Clinical criteria	1. Vascular thrombosis One or more clinical episodes of arterial, venous, or small-vessel thrombosis, in any tissue or organ. Thrombosis must be confirmed by objective validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
	2. Pregnancy morbidity One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus. One or more premature births of a morphologically normal neonate before the 34th week of gestation because of: (i) eclampsia or severe preeclampsia defined according to standard definitions, or (ii) recognized features of placental insufficiency. Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.
Laboratory criteria	1. Lupus anticoagulant (LA) present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis. 2. Anticardiolipin antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titer, on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA. 3. Anti-β_2 glycoprotein I antibody of IgG and/or IgM isotype in serum or plasma, present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA.

APS is present if at least one of the clinical criteria and one of the laboratory criteria are met

Multiple pathogenic mechanisms have been proposed by which aPL may predispose to thrombosis including interaction between aPL and endothelial cells, platelets, monocytes, activation of the complement system, and interaction with the proteins involved in the regulation of the coagulation cascade. At present, it cannot be discerned whether one dominant mechanism is responsible for venous, arterial, or small-vessel thrombosis.

Genetic associations in APS are suggested by the frequent findings of aPL in first-degree relatives of people with APS or with SLE. Family studies support that APS and aPL can occur in family clusters, but this is so only in a minority of patients. Some HLA-DR and -DQ types (e.g., B1, B8, and DR3) may occur with increased frequency among patients with APS, depending on the racial and ethnic backgrounds of patients studied. Experimental animal models as well as preliminary studies on the polymorphisms of candidate genes of inflammatory mediators suggest the association between inflammatory gene single nucleotide polymorphisms and thrombosis in APS.

Pathology

The histopathologic alterations in APS have been described as thrombotic, microangiopathic, ischemic, or coincidental with underlying disease–related pathology. Thrombotic vaso-occlusive lesions in APS may involve any organ or system and, histopathologically, do not differ from those seen in other prothrombotic conditions. Thrombotic lesions are mainly non-inflammatory and may occur in large or small vessels. Some patients with APS can develop true vasculitis, which is in general causally not related to aPL but to the coexisting underlying disease, most commonly SLE.

Microangiopathic lesions can be characteristic of APS and appears to be significantly underestimated. A major role in the initiation and development of acute microangiopathic lesions is that of endothelial cells of the small blood vessels that are activated and injured by aPL.

Clinical Manifestations

Children with aPL can present with various thrombotic (*Table 160.2*) or nonthrombotic clinical manifestations (*Table 160.3*). The presence of vascular occlusive event is required for the diagnosis of definite APS, but children with aPL more frequently present with nonthrombotic clinical manifestations. At the time of the initial thrombotic event in children with definite APS, the estimated frequencies of associated nonthrombotic manifestations

Table 160.2
Venous and arterial thromboses manifestations of pediatric antiphospholipid syndrome

Vessel involved	Clinical manifestations
Venous sites	
Limbs	Deep vein thrombosis
Skin	Livedo reticularis, chronic leg ulcers, superficial thrombophlebitis
Large veins	Superior or inferior vena cava thrombosis
Lungs	Pulmonary thromboembolism, pulmonary hypertension
Brain	Cerebral venous sinus thrombosis
Eyes	Retinal vein thrombosis
Liver	Budd-Chiari syndrome, enzyme elevations
Adrenal glands	Hypoadrenalism, Addison's disease
Arterial sites	
Limbs	Ischemia, gangrene
Brain	Stroke, transient ischemic attack, acute ischemic encephalopathy
Eyes	Retinal artery thrombosis
Kidney	Renal artery thrombosis, renal thrombotic microangiopathy
Heart	Myocardial infarction, cardiomyopathy
Liver	Hepatic infarction
Gut	Mesenteric artery thrombosis
Bone	Infarction

Table 160.3
Nonthrombotic clinical manifestations associated with antiphospholipid antibodies in pediatric population

Organ system	Clinical manifestations
Hematologic	Thrombocytopenia
	Autoimmune hemolytic anemia
	Leucopenia
	Lupus anticoagulant-hypoprothrombinemia syndrome
Skin	Livedo reticularis
	Raynaud's phenomenon
	Subungual splinter hemorrhages
	Skin ulcers
	Cutaneous necrosis
Central nervous system	Chorea
	Epilepsy
	Migraine headache
	Transverse myelitis
	Multiple sclerosis-like disorders
	Sensorineural hearing loss
	Cognitive defects
	Psychosis
	Guillain–Barré syndrome
Heart	Libman–Sacks endocarditis

are 38% for hematologic manifestations, 18% for dermatologic manifestations, and 16% for nonthrombotic neurologic manifestations. All children with aPL presenting either with thrombotic or nonthrombotic manifestations require thorough assessment for evidence of underlying systemic disease, since APS may develop as an initial manifestation of SLE.

Thromboses

Vascular occlusive events in APS may involve arteries, veins, or small vessels in all organs (*Table 160.2*). Venous thrombosis is the most common thrombotic event occurring in up to 60% of pediatric APS patients. The most frequently reported site of venous thrombotic event is deep vein thrombosis in the lower extremities, followed by cerebral sinus vein thrombosis, portal vein thrombosis, deep vein thrombosis in the upper extremities, and superficial vein thrombosis. Venous thrombotic events are particularly common in APS associated with pediatric SLE, and the strongest predictor of thrombosis risk in these patients is persistent LA positivity. Arterial thrombosis occurs in approximately 30% of pediatric APS patients. The most frequently reported site of arterial thrombotic event is ischemic stroke, followed by peripheral arterial thrombosis.

Small-vessel thrombosis occurs in less than 10% of pediatric APS patients and may present as localized small-vessel thrombosis or an aggressive microvascular occlusive disease (*Fig. 160.1*). Localized small-vessel thrombosis most commonly appears as isolated thrombosis of digital vessels or renal thrombotic microangiopathy. Aggressive microvascular occlusive disease is characteristic of catastrophic APS, which is a potential life-threatening variant of APS leading to multiorgan failure. The most commonly affected organ systems include the kidney, lung, central nervous system, heart, and skin. Catastrophic APS in children is most frequently triggered by preceding infections, SLE flares, or in association with underlying malignancy.

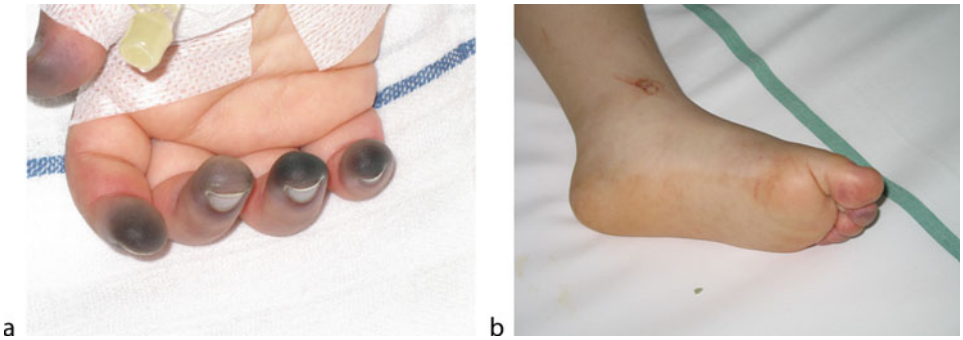

Figure 160.1
Necrotic changes on the fingertips (a) and toes (b) in a child with atypical hemolytic uremic syndrome complicated by thrombotic microangiopathy associated with antiphospholipid antibodies

Hematologic Manifestations

The characteristic hematologic manifestations associated with aPL in children are thrombocytopenia, autoimmune hemolytic anemia, and leucopenia. Thrombocytopenia is usually mild, with platelet counts greater than 50×10^9/L and is rarely associated with hemorrhagic phenomena. Thrombocytopenia may appear as an isolated clinical manifestation, associated with Coombs-positive hemolytic anemia (Evans syndrome) or along with other APS manifestations.

The acquired LA-hypoprothrombinemia syndrome is a rare hematologic complication consisting of a severe bleeding diathesis associated with the presence of a certain subtype of LA, namely the antiprothrombin antibodies that cause rapid depletion of plasma prothrombin.

Neurologic Manifestations

Typical neurologic manifestations are ischemic stroke and cerebral sinus vein thrombosis, both caused by thrombotic occlusion of cerebral vessels. Several other neurologic manifestations have been associated with the presence of aPL, including various movement disorders Video epilepsy, migraine, transverse myelitis, multiple sclerosis-like disorders, sensorineural hearing loss, cognitive defects, psychiatric diseases, and Guillain–Barré syndrome. These manifestations are not fully explained by the ischemic pathophysiologic mechanism, and primary immunologic effects of aPL have been suggested such as direct interaction with neuronal tissue or immune complex deposition in the cerebral blood vessels wall.

Other Manifestations

Dermatologic manifestations are frequently present in patients with APS, ranging from minor signs to life-threatening conditions such as widespread cutaneous necrosis. The most common findings are livedo reticularis, Raynaud's phenomenon, digital necrosis, subungual splinter hemorrhages, and skin ulcers. Livedo reticularis and especially the coarser variant called livedo racemosa are considered a major clinical feature of APS, strongly associated with cerebral and ocular ischemic arterial events.

Cardiac involvement may affect all tissues and include valvular disease (Libman–Sacks endocarditis), occlusive coronary artery disease, cardiomyopathy (due to multiple small vascular occlusions), and intracardiac thrombosis. Pulmonary manifestations include pulmonary embolism, infarction, and pulmonary hypertension. Antiphospholipid antibodies are also associated with renal, hepatic, digestive, and adrenal manifestations resulting from occlusive vascular disease of intra-abdominal vessels.

Osteoarticular manifestations such as avascular necrosis of bone, non-traumatic fractures, and bone marrow necrosis are rarely seen in APS patients. Association between aPL and Perthes disease has been suggested in pediatric population.

Perinatal Complications Associated with Antiphospholipid Antibodies

The presence of maternal aPL during pregnancy is associated with a number of serious obstetric and fetal

Figure 160.2
Magnetic resonance imaging of the head showing ischemic changes in the left hemisphere in a neonate with transplacentaly transferred IgG anticardiolipin antibodies and heterozygous methylenetetrahydrofolate reductase C677T and prothrombin G20210A gene mutations

complications including preeclampsia, utero-placental insufficiency, intra-uterine growth restriction, fetal distress, and premature birth. The prematurity rate in babies born to mothers with APS is 10–15% and the incidence of growth restriction is 15–20%.

Perinatal thrombotic events are exceedingly rare complication due to transplacental passage of maternal aPL (*Fig. 160.2*). Arterial thromboses were reported in 80% of the aPL-related perinatal thrombotic events and were frequently associated with additional thrombophilic risk factors such as arterial or venous catheters, sepsis, asphyxia, and/or congenital thrombophilia.

Children born to mothers with APS have increased risk of developing learning disabilities at a later stage in life and regular neuropsychological assessments are recommended for long-term follow-up.

Diagnosis

Classification criteria for the diagnosis of APS require the presence of at least one of the clinical criteria and one of the laboratory criteria (*Table 160.1*). Patients that have non-criteria clinical features associated with aPL are classified as probable APS. In clinical practice, testing for aPL should be performed in every child presenting with thrombosis or clinical features that are suggestive of APS, such as unexplained thrombocytopenia, hemolytic anemia, livedo reticularis, Raynaud phenomenon, and chorea.

Antiphospholipid antibodies can be detected by a variety of laboratory tests. The most sensitive test is the aCL test, which uses enzyme-linked immunosorbent assay (ELISA) to determine antibody binding to solid plates coated with cardiolipin. The specificity of aCL for APS increases with titer, and is higher for the IgG than for the IgM isotype. The anti-β_2GPI ELISA has improved specificities over the aCL test. The LA test is a functional assay measuring the ability of aPL to prolong in vitro phospholipid-dependent clotting reactions such as the aPTT, the Russell viper venom time, or the kaolin clotting time. The LA assay correlates better with the occurrence of thromboembolic events than the aCL or the anti-β_2GPI assays and is regarded as a less sensitive but more specific test for detection of aPL.

Persistent positivity of aPL is of major importance for diagnosing APS, and all abnormal aPL values should be verified on at least two occasions at least 12 weeks apart to demonstrate persistence. In a cohort of children included in the pediatric APS registry, the presence of aCL was detected in 81%, anti-β_2GPI in 67%, and LA in 72% of cases.

Imaging studies are aimed to detect thrombosis in target organs with the use of color-flow and pulsed Doppler ultrasound, echocardiography, computerized tomography plus angiography, and magnetic resonance imaging with or without angiography. Except during interventional procedures, venography and angiography are rarely used in children, because of technical difficulties, the requirement for iodinated contrast, and the possibility of extending thrombus. A tissue biopsy is required for definitive histopathologic confirmation of small-vessel occlusions in the target organ.

Differential Diagnosis

Because of its possible manifestations, APS must be considered in the differential diagnosis of many problems, ranging from thrombosis to unexplained thrombocytopenia, hemolytic anemia, livedo reticularis, Raynaud phenomenon, and various neurologic manifestations.

All children presenting with aPL-related thrombotic event should receive a broad investigation for additional congenital and acquired prothrombotic risk factors, and thorough evaluation for evidence of underlying SLE

or other systemic disease. The main congenital prothrombotic states to be considered include factor V Leiden, prothrombin G20210A mutation, deficiencies of antithrombin, protein C and protein S, total cholesterol, triglycerides, lipoprotein (a), fasting homocysteine concentration, and T677T polymorphism of the methylenetetrahydrofolate reductase (MTHFR) gene (297, 298). The most common acquired factors that may contribute to the risk of thrombosis are infection, malignancy, congenital heart disease, nephrotic syndrome, systemic vasculitis, central venous lines, surgery, and immobilization.

The differential diagnosis of nonthrombotic aPL-related clinical manifestations includes a variety of hematologic, dermatologic, neurologic, and other diseases. Catastrophic APS should be distinguished from severe SLE vasculitis, sepsis, thrombotic thrombocytopenic purpura, macrophage activation syndrome, and disseminated intravascular coagulation.

Treatment

Treatment strategies for children with APS are based on a few pediatric observational cohort studies and modified recommendations for adult patients with APS. General therapeutic measures in all children with APS include avoidance of additional risk factors for thrombosis such as smoking, hypertension, obesity, hypercholesterolemia, and use of estrogen-containing oral contraceptives in adolescent girls.

Treatment of the acute thrombotic event in children with APS is no different from that of thrombosis arising from other causes. Most patients receive anticoagulation therapy with unfractionated heparin as a loading bolus injection followed by continuous infusion. Low-molecular-weight heparins (LMWHs) are being used increasingly for initial therapy of acute thrombosis in children due to their subcutaneous administration, more predictable dose response, and reduced requirement for monitoring. The target therapeutic anti-Xa activity for children treated with LMWH ranges between 0.5 and 1.0 U/mL. Systemic or local thrombolytic therapy should be considered in difficult cases with high-risk clots.

Patients with persistently positive aPL, in particular those with LA, have a high risk for recurrent thrombosis and should receive long-term anticoagulation with warfarin. In the absence of controlled trials, the optimal intensity and duration of anticoagulation therapy in pediatric APS patients are still controversial. The standard treatment in adult APS patients with venous or non-cerebral arterial thromboembolism consists of oral anticoagulation at a target INR of 2.0–3.0, and in patients with ischemic stroke, either low-dose aspirin or moderate intensity warfarin with INR between 1.4 and 2.8. This recommendation has been challenged by a systematic review that included observational cohort studies and advised life-long anticoagulation at a target INR of 2.0–3.0 in patients with first venous events and above 3.0 for those with recurrent and/or arterial events. The major fear of high-intensity anticoagulation in children with APS is that secondary bleeding complications will exceed its beneficial effects. During the mean follow-up period of around 6 years, 20% of pediatric patients included in the international APS registry developed recurrent thrombotic events, which is significantly higher than recurrence rates reported in adult APS patients (3–11%). Given the higher recurrence rate of thrombosis, it seems reasonable to consider anticoagulation in all pediatric patients with definite APS at least at a target INR suggested for adult population. Moreover, it is essential to individualize treatment according to the presence of additional thrombophilic risk factors and the aPL profile (multiple aPL antibodies, high titers of aCL and/or anti-β_2GPI, presence of LA).

Patients with catastrophic APS require immediate aggressive treatment of the ongoing thrombotic events, suppression of the excessive cytokine storm, and elimination of possible precipitating factors such as infection or necrotic tissue. The highest recovery rate in catastrophic APS was achieved by the combination therapy of anticoagulants, corticosteroids, and plasma exchange.

In recurrent thrombosis, despite optimal anticoagulation, the first approach is usually adding low-dose aspirin and increasing the warfarin dose to achieve a higher INR. Additionally, an improved understanding of the pathogenic mechanisms by which aPL induce thrombosis has suggested some innovative treatments such as new anticoagulant and antiplatelet drugs, hydroxychloroquine, statins, complement inhibitors, rituximab, and other targeted therapies.

Prognosis

Pediatric APS is a serious and potentially life-threatening disease. During a 6-year follow-up period, 20% of children with APS develop recurrent thrombosis and the estimated mortality rate is 7%. Major causes of death in patients with APS are thrombotic events, SLE complications, and hemophagocytic syndrome.

Approximately 20% of children who initially present with primary APS may progress over time to develop

clear-cut SLE or a lupus-like disease. Therefore, all these patients need closer follow-up with regular clinical and immunological assessments for an underlying systemic connective tissue disease. The presence of aPL has also a negative impact on the global disease outcome in patients with SLE.

Prevention

The risk of future thrombosis is very low in asymptomatic children who are incidentally found to have positive aPL, high among those in whom thrombosis already occurred, and extremely high in patients with catastrophic APS. Primary prevention involves thromboprophylaxis in aPL positive asymptomatic children and patients with SLE but without previous thrombotic events.

Because of the increased risk of bleeding during play and sports, it is generally recommended that asymptomatic children with aPL do not need any long-term prophylactic treatment. The final decision on the use of specific prophylactic therapy such as low-dose aspirin (3–5 mg/kg/day) or warfarin should be individualized and based on the presence of additional congenital or acquired prothrombotic risk factors and the aPL profile. Prophylaxis with LMWH is generally recommended during high-risk situations, such as prolonged immobilization or surgery.

The coexistence of an underlying autoimmune disease, particularly SLE, significantly increases the thrombosis risk. Low-dose aspirin has been recommended as thromboprophylaxis in all pediatric SLE patients with persistently positive aPL. An additional protection may be provided by hydroxychloroquine, which has protective role against the development of both venous and arterial thromboses in SLE patients.

161 Juvenile Dermatomyositis

Lucy R. Wedderburn

Definition and Classification of Juvenile Dermatomyositis (JDM)

The idiopathic inflammatory myopathies (IIM) of childhood are rare, multi-system serious conditions, characterized by inflammatory changes of muscle and other tissues with associated dysfunction, of which juvenile dermatomyositis (JDM) is the most common. JDM typically affects skin and muscle but can also affect other systems including gut, lungs, joints, and central nervous system. The current classification criteria for JDM remain those of Bohan and Peter, defined over 30 years ago. Efforts to generate new criteria which would more closely align with modern clinical diagnostic tests, such as magnetic resonance imaging (MRI), are underway. The Bohan and Peter criteria for definite JDM require the presence of characteristic rash, combined with three of: symmetric proximal muscle weakness, raised serum muscle enzymes (which may include creatine kinase (CK), transaminases, lactate dehydrogenase (LDH), and aldolase), and abnormal findings on muscle biopsy or electromyography (EMG). The presence of rash and any two of these features make a diagnosis of "probable" JDM. Since many centers no longer perform EMG, while some do not perform muscle biopsy except in atypical or difficult cases, many clinically typical cases of JDM may be classified as "probable" under this system. In addition to this need for more appropriate modern diagnostic criteria, evidence from serological studies suggests that a classification which incorporates autoantibody specificity would be clinically useful.

Epidemiology of JDM

The incidence of JDM is between two and four per million children under the age of 16 per year, while juvenile polymyositis (JPM) is very rare, (about 20 times less common than JDM). There have been few large epidemiological studies of JDM in different ethnic groups but some data suggest ethnic differences. JDM is more common in girls than boys (F:M ratio approximately 2.3:1) and has a mean age of onset of just over 7 years, although it can present at as young as 2 years and throughout childhood.

Etiology and Pathogenesis of JDM

The etiology of JDM remains unknown. As for other autoimmune conditions, a working hypothesis is that it is caused by interactions between environmental triggers, immune dysfunction, and specific tissue responses in genetically susceptible individuals. Some studies suggest a seasonal pattern to onset, or that infections may commonly precede the onset of JDM. Proposed infectious triggers include parvovirus or enteroviruses but definitive evidence for specific triggers of JDM remains lacking. Many genes influence susceptibility to myositis of which the best understood are the human leukocyte antigen (HLA) loci. The alleles HLA-B*08, DRB1*0301, and DQA1*0501 confer risk of myositis in both adults and children. HLA-DPB1*0101 also confers risk of myositis (adult and pediatric) especially in particular serological subgroups, and the DQA1*0301 allele is an additional risk factor for JDM. Many other genes likely contribute to susceptibility or subtype in JDM: to pursue these, large numbers of cases are required; the results of ongoing genome-wide studies in myositis are awaited.

Autoantibodies are common in JDM and can be divided into two categories: myositis specific antibodies (MSA), which are relatively specific for myositis or subtypes of disease; and myositis associated antibodies (MAA) which are also found in other autoimmune conditions. Between 60% and 75% of children with JDM are ANA positive and approximately 70% of children with JDM have one or more detectable MSA or MAA if full serological testing is used. Several novel autoantibodies have been identified in JDM including an antibody known as anti-p155/140, present in ~25% of JDM cases and associated with extensive skin involvement, and a novel antibody known as anti-p140, present in 23% of JDM patients and associated with risk of calcinosis. It is possible that in the future autoantibodies may provide

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_161,

valuable prognostic tools. The pathological role of autoantibodies in myositis remains unknown, but it is of interest that muscle tissue from adults with DM or PM has increased expression of several of the target antigens of such antibodies, and evidence suggests that immune complexes containing anti-Jo-1 or anti–Ro 52/anti–Ro60 autoantibodies induces type I interferon production.

Muscle biopsy from children with JDM may show small vessel endothelium abnormalities, including thickened endothelial cells, deposition of complement or immune complexes, and loss of capillary density, leading some researchers to propose that endothelium is the target of damage in JDM. Other changes on biopsy include inflammation, muscle fiber MHC class I protein overexpression, muscle fiber regeneration, and fiber atrophy (*Fig. 161.1*). Four "domains" of typical change have been defined in a proposed scoring system with which to assess JDM biopsy material. Recent studies suggest that type I interferons, made predominantly by dendritic cells, may induce this pathology, and that muscle from JDM patients shows a "signature" typical of a type I interferon-driven process, on gene expression profiling. Other cytokines thought to play a role in muscle damage in JDM include TNF and IL-1. These cytokines can upregulate MHC proteins on muscle fibers, which is increased in myositis including JDM. MHC over-expression is thought to cause muscle damage through a process called ER Stress in human myositis, and which in model systems is more severe in juvenile than adult muscle.

Clinical Manifestations of JDM

The onset of JDM may be gradual and insidious, which may lead to misdiagnosis for many months; alternatively children may progress from full health to being severely weak and unwell, in only a few weeks. The classical rash of JDM typically manifests as a periorbital "heliotrope" rash, and/or Gottron's papules over the extensor surfaces, commonly over metacarpophalangeal and interphalangeal joints. Less typical rashes, which may lead to a delay to diagnosis, can occur anywhere on the body, including other extensor surfaces but also ears, axillae, or trunk (*Fig. 161.2*).

Other skin features may include vasculitic rash, ulcerative change, and intradermal or subcutaneous calcification (calcinosis), all of which indicate a poor prognosis. Calcinosis can take the form of subcutaneous plaques or nodules, or extensive sheets of calcium which may encase a whole limb or the body. Severe cases may also present with severe widespread oedema which may cause diagnostic difficulty. Several skin scoring systems have been proposed, to ensure comprehensive assessment of skin involvement in JDM. The examination of nailfolds is simple and informative and may reveal periungual erythema or dilated capillary loops, associated with ongoing active disease, prolonged course, and poor prognosis. The skin rashes of JDM are often photosensitive, therefore history of exacerbation after sun exposure is important. With time, and in severe cases, serious complications of skin disease are ulceration of skin lesions (which can be in other sites such as axillae, eye lids, or pressure points) and calcinosis, and both should be examined for with great care, both on presentation and at every assessment.

The second cardinal feature of JDM is muscle weakness, which can be easily missed in a sick child especially if muscle strength is not formally tested. Weakness typically starts in proximal muscles, and again may be insidious or rapidly progressive. Proximal weakness leads to difficulty with stairs, dressing, or walking, and is frequently combined with tiredness or lethargy. Children may be mistakenly thought to be uncooperative when in fact weakness prevents them from performing tasks. On examination, the child may be unable to sit up from lying, or to hold the head off the bed, or to squat, and may also demonstrate Gower's sign, where the child uses his/her arms placed upon the legs to help themselves to stand up from the floor. Weakness in a sick child is easily missed; however, the Childhood Myositis Assessment Scale (CMAS) and manual muscle testing of a standard group of 8 muscles (MMT8) are available as validated tools for muscle assessment and can be performed in a few minutes. Weakness of the muscles of the palate or pharyngeal muscles can lead to dysphagia or dysphonia; therefore a history of altered speech (sometimes described as "Donald Duck") or trouble with swallowing should be asked about.

Children with JDM can have a wide range of other symptoms including irritability, fevers, anorexia, arthritis, myalgia, Raynaud's phenomenon, lethargy, dyspnoea, mood changes, headaches, and abdominal symptoms. More rare but also ominous signs include generalized peripheral oedema, which appears to be more common in younger children, and also lipodystrophy, where there is a marked atrophy of subcutaneous tissue.

Assessment, Diagnosis, and Differential Diagnosis in JDM

In specialist centers, the assessment and diagnostic workup for children suspected of having JDM will include careful clinical and functional assessment, blood testing,

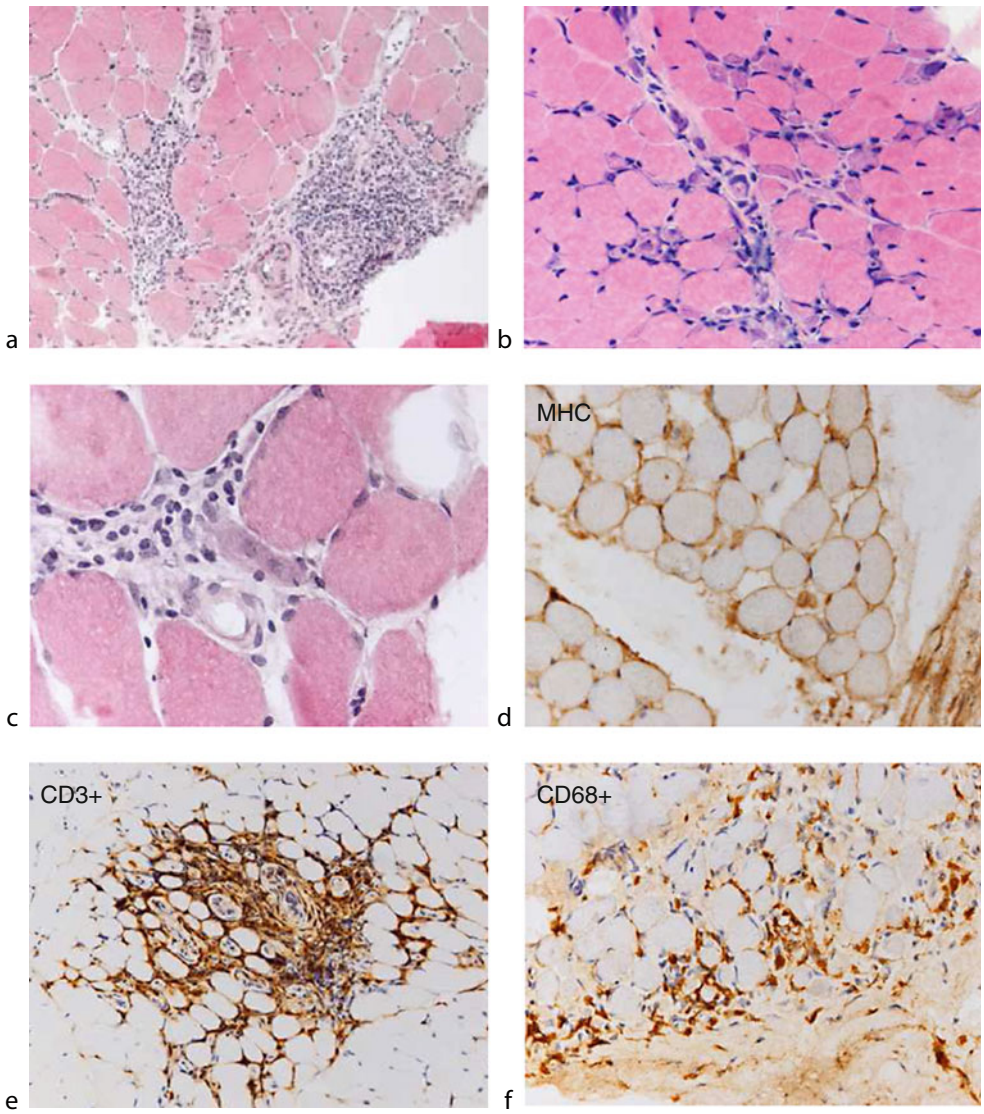

Figure 161.1

Histological features seen on muscle biopsy tissue from juvenile dermatomyositis patients. (a–c) Sections stained with haematoxylin and eosin, (d–f) immuno histochemistry for markers as shown. (a) Shows inflammatory infiltrate, largely preivascular, and variable muscle fiber size; (b) shows marked inflammation, as well as muscle fiber atrophy, and internal myonuclei; (c) shows variable muscle fiber size, regenerating basophilic fiber with central nuclei; (d) shows increased sarcolemmal expression of MHC class I (also known as HLA) on muscle fibers; (e) shows infiltrating T lymphocytes (CD3+) in a perivascular pattern; and (f) shows diffuse infiltration of myeloid cells (CD68+)

imaging (most commonly MRI), and, in many centers, muscle biopsy. Laboratory tests should include full blood count, ESR, muscle enzymes, renal and hepatic function, as well as analysis of autoantibody status (see above, pathogenesis section). Formal muscle testing and documentation of skin and nail fold changes is critical. Calcinosis should be looked for whenever it is suspected and can be confirmed by plain radiography. Inflammatory changes seen in muscle by MRI (typically assessed in T2 weighted images of quadriceps muscles) can be quantified and have been shown to correlate with disease activity. Although the Bohan and Peter criteria for

(b) Periungual erythema and nail fold capillary loops. (c) Scaly erythematous rash over knee in a child with JDM, which may be mistaken for other diagnoses such as psoriasis. (d) Scarring lesions in a child with JDM with ulcerative skin disease. (e) Ulcerative lesion behind pinna in child with JDM

diagnosis of JDM include changes on EMG, many centers no longer routinely perform this test in children. Muscle biopsy is performed in many centers, but until recently the lack of a standardized system for analysis and assessment of histopathological features led to variable diagnostic or prognostic yield from this test. An International Consensus Group has recently proposed a formal system for analysis of changes on JDM muscle biopsy and assessment of severity. In addition to these tests, specific features may require further investigation such as high resolution pulmonary CT with lung involvement, or videofluroscopy in the presence of suspected pharyngeal involvement.

Although modern criteria for the diagnosis of juvenile inflammatory myositis are not yet agreed, tools for assessment of disease activity and damage have been proposed by two International collaborative groups, the Paediatric Rheumatology International Trials Organization (PRINTO) and the International Myositis Assessment and Clinical Studies Group (IMACS). Both proposed core sets include a parent/patient assessment, the physicians overall assessment, muscle strength measurement, functional assessment (e.g., Child Health Assessment Questionnaire), and assessment of extra-muscular disease and damage. The PRINTO set also includes a measure of quality of life, the Child Health Questionnaire (CHQ). Regular serial measurements and assessments are vital in order to monitor disease course and response to treatment. The PRINTO collaboration has tested the validity and consistency of the proposed set of tools in measuring response to treatment in JDM. It is important to be vigilant in monitoring for complications or signs of active disease including ongoing rash, nail fold abnormalities, new lesions of calcinosis, respiratory or gut involvement, or lipoatrophy.

The differential diagnosis of JDM includes other inflammatory myositis such as JPM, post infectious myositis, focal myositis, eosinophilic myositis, genetic dystrophies, and myositis, which is part of another connective tissue disease such as SLE or scleroderma. Pediatric myositis shows a higher rate of such "overlap" than seen in adults: for example, in a cohort of over 100 cases of JDM, almost a quarter had features suggestive of overlap with scleroderma. In JDM cases with minimal or no apparent muscle involvement, the differential diagnosis may include alternative causes of the rash such as psoriasis. Amyopathic dermatomyositis presents with classical rash but no muscle involvement; this is a rare but well-recognized entity, which still requires immunosuppressive therapy; muscle biopsy confirms lack of pathological change in these cases.

Treatment of JDM

The care of children with JDM is ideally delivered by a mutlidisciplinary team of specialists, including pediatric rheumatologists, specialist physiotherapists and nurses, speech/language therapists, and others. Modern management involves active early drug treatment, with the aim of rapid control of disease activity, combined with physiotherapy to maintain and regain muscle strength. There is a severe lack of evidence base for the drug management of JDM, but international efforts are now facilitating adequately powered drug trials. The mainstay of treatment of JDM remains corticosteroids, usually combined with disease modifying agents, most commonly methotrexate (MTX) or cyclosporin A. In most centers steroids are initially given as intravenous methylprednisolone (MP), with a total of six pulses given in two sets of three, a dose 30 mg/kg/day for 3 days, (maximum dose 1 g), repeated after a week, and oral steroids (1–2 mg/kg) between pulses and in weaning doses thereafter. Bioavailability of ivMP is thought to be higher than that of oral prednisone, particularly in children with vasculopathy and gut involvement. Methotrexate is given at a dose of 15 mg/m^2, preferably subcutaneously, with folic acid (typically 1 mg/day). Evidence suggests that early use of MTX with corticosteroid reduces overall steroid dose and long-term side effects, while providing equally good disease control as steroid alone. Other DMARD used for active JDM include Azathioprine 3–5 mg/kg/day, Hydroxychloroquine 3–6 mg/kg/day (especially for rash), and Ciclosporin (total of 4–10 mg/kg/day in two doses, aiming for trough level of 75–100 ng/mL). A recent large consensus study found that a majority of North American pediatric rheumatologists advise use of steroids with MTX for moderate to severe cases of JDM as first line of management. A multinational trail comparing steroids alone, to steroids with MTX or steroids with cyclosporin is underway. Intravenous immunoglobulin has been shown to be effective in adult DM and in small series of JDM cases, and is in use in some countries, in place of MTX of cyclosporin.

Concurrent with drug management, exercise under the supervision of a physiotherapist is very important in maintaining and restoring muscle strength and there is evidence that it is safe to muscles. Other measures required include strict sun protection advice, good dietary advice, and protection against osteoporosis. Specific management will depend on organ involvement, such as NG feeding for children with dysphagia and risk of aspiration pneumonia, specialist skin care for those with ulcerative disease, and speech and language therapy for children who have dysphonia.

Many cases of JDM respond well to combined treatment of steroid plus first DMARD such as MTX. However a proportion of children continue to show active disease, in particular rash, development of ulceration or calcinosis, or involvement of other organs such as pulmonary, GI, or CNS systems. For these severe or refractory cases the current choice of therapy is largely led by local experience. Cyclophosphamide, given IV monthly at 0.5–1 g/m^2 has been shown to be beneficial in a series of cases with severe features including severe weakness, dysphagia, skin or gastrointestinal ulceration, or CNS disease. A small number of severe cases have been successfully treated with anti-TNFα therapy (Infliximab). Anecdotal reports of treatment using Etanercept suggest that this may be less effective than Infliximab. The B cell depleting monoclonal antibody (anti-CD20) Rituximab has been found to be effective in a small case series, and children are currently included in a large international trial of Rituximab in myositis. A few severe cases of JDM have been successfully treated by autologous stem cell transplantation (ASCT); experience from other autoimmune conditions suggests that it may be important to consider ASCT before irreversible damage has taken place. The complication of calcinosis is difficult to treat but some centers advocate use of pamidronate and diltiazem. Comorbidities including those due to side effects of drugs need to be considered; in particular, cumulative doses of both steroids and cyclophosphamide should be monitored, and treatment to prevent osteoporosis, such as calcium supplementation or bisphosphonates, considered. Where multiple or high doses of cyclophosphamide are planned, gamete storage may be offered to teenage patients, in particular for boys.

Prognosis and Outcome in JDM

Before the use of steroids and more recently DMARDS, mortality associated with JDM was roughly 30% of children; recent data suggest that in the modern era mortality is much reduced, with one study involving 1,353 patient years estimating mortality at just under 1%. There is evidence that early aggressive treatment reduces time to remission and reduces morbidity in JDM. However despite this improved situation, the functional outcomes of JDM remain poor. It is estimated that 15–20% of cases continue to have active disease despite early treatment and run either a chronic, or a polyphasic, relapsing course; one study of 490 patients with mean follow-up of 7.7 years found that 69% had cumulative damage. Early persistence of rash and nailfold changes appears to predict a longer time to remission. Clinical features which indicate severe disease include ongoing rash or severe weakness despite treatment, ulcerative skin disease, calcinosis, dysphagia that is unresponsive to treatment, and other major organ involvement (gut, CNS, pulmonary). Recent reported deaths due to JDM have been due to respiratory failure, pancreatitis, cadiovascular failure or catastrophic gut vasculopathy.

The recent availability of internationally agreed measures of disease outcome and response to treatment, which are being prospectively validated, will make the assessment of outcome in JDM more amenable to robust analysis in the near future; in addition the existence of several large national and international collaborative cohort studies will facilitate collection of outcome data from large numbers of children. While it is now clear that with early and aggressive management a proportion of children with JDM can reach full remission, off medication, and can recover full muscle strength, predictors for complications, or response to treatment are still much needed. Long-term side effects of treatments include osteoporosis from steroids, and the as yet unknown risks of chronic immune blockade from treatment with biological agents. In addition, as for other pediatric chronic autoimmune disorders such as JSLE, there is preliminary evidence that children with JDM may have metabolic changes (such as alterations in lipid metabolism) which could lead to long-term increased risk of cardiovascular disease. In the future, improved outcomes for children with JDM will be driven by a combination of international research efforts, the use of modern treatments, an increasing opportunity to include children in international drug trials to generate a robust evidence base for this treatment, and improved access for children to specialized centers for care.

Acknowledgments

This work on is supported by generous grants from the Wellcome trust, Action Medical Research, The Henry Smith Charity and the Myositis Support Group UK. I would like to thank Ms. H. Varsani and Dr. J. Holton for help in preparing figures.

162 Juvenile Scleroderma

Francesco Zulian

Juvenile scleroderma syndromes, although rare, represent the third most frequent chronic rheumatic conditions in pediatric rheumatology practice after juvenile idiopathic arthritis and systemic lupus erythematosus. They essentially include two varieties, juvenile systemic sclerosis (JSSc) and juvenile localized scleroderma (JLS).

Juvenile systemic sclerosis is quite rare and involves both skin and internal organs. Unlike adults, children with JSSc show a significantly less-frequent involvement of the internal organs and a slightly better outcome as far as mortality and morbidity are concerned.

Juvenile localized scleroderma, also known as morphea, is the more frequent subtype of scleroderma in childhood. It comprises a group of distinct conditions which involve the skin and subcutaneous tissues. They range from very small plaques of fibrosis involving only the skin, to diseases which may cause significant functional and cosmetic deformity.

Etiology and Pathogenesis

Although the cause of scleroderma, potential pathogenetic mechanisms include a tripartite process in which dysfunction of the *immune system, endothelium,* and *fibroblasts* gives rise to a heterogeneous phenotype that is characterized prominently by fibrosis.

Autoimmunity is evident by the elaboration of circulating disease-specific autoantibodies and multiple abnormalities of the inflammatory cell function. These include the presence of mononuclear cell (MNC) infiltrates in early lesions, altered function of helper T and NK cells, and release of cytokines, chemokines, and growth factors. Raynaud's phenomenon, capillary dropout, and abnormalities in vascular tone are manifestations of endothelial cell dysfunction, particularly evident in JSSc. Fibroblast dysfunction is represented by fibrosis as the result of increased synthesis and deposition of extracellular matrix proteins. These three areas of abnormal function, although apparently unassociated with each other, are closely linked by several immunologic alterations.

Juvenile Systemic Sclerosis

Definition/Classification

Juvenile systemic sclerosis (JSSc) is a chronic connective tissue disease characterized by symmetrical thickening and hardening of the skin, associated with fibrous changes in internal organs.

Although rare in children, it represents one of the most severe rheumatic conditions in pediatric rheumatology practice.

Very recently, an update of the Classification Criteria for JSSc has been proposed. On the basis of this new classification, a patient, aged less than 16 years, shall be classified as having JSSc if the one major, presence of proximal skin sclerosis/induration, and at least two of 20 minor criteria, grouped in nine main categories, are present (*Table 162.1*).

Epidemiology

The onset of JSSc in childhood is very uncommon: children under 16 years of age account for less than 5% of all cases. The onset occurs at a mean age of 8.1 years and the peak age is between 10 and 16 years. The disease is almost fourfold more frequent in female and there is no clear evidence for a racial predilection.

Clinical Manifestations

The onset is often insidious. The mean time between the first sign of the disease and the diagnosis of JSSc is between 1.9 and 2.8 years with a range between 0 and 12.2 years. Overlap syndromes, most frequently with polymyositis-dermatomyositis account for almost one third of all cases.

Raynaud's phenomenon (RP) is the first sign of the disease in 70% of the patients and in 10% it is complicated by digital infarcts. Proximal skin induration is the second

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_162,

Table 162.1
Classification criteria for juvenile systemic sclerosis

Major criterion	Proximal sclerosis/induration of the skin
Minor criteria	
– *Skin*	Sclerodactyly
– *Vascular*	Raynaud's phenomenon
	Nailfold capillary abnormalities
	Digital tip ulcers
– *Gastrointestinal*	Dysphagia
	Gastroesophageal reflux
– *Renal*	Renal crisis
	New onset arterial hypertension
– *Cardiac*	Arrhythmias
	Heart failure
– *Respiratory*	Pulmon fibrosis (HRCT/X-ray)
	Decreased DLCO
	Pulmonary hypertension
– *Muskulo Skeletal*	Tendon friction rubs
	Arthritis
	Myositis
– *Neurological*	Neuropathy
	Carpal tunnel syndrome
– *Serology*	Antinuclear antibodies
	SSc selective autoantibodies (anticentromere, antitopoisomerase I, antifibrillarin, anti-PM-Scl, anti-fibrillin or anti-RNA polymerase I or III)

A patient, aged less than 16 years, shall be classified as having juvenile systemic sclerosis if the one major and at least two of the 20 minor criteria are present. This set of classification criteria has a sensitivity of 90%, a specificity of 96%, and kappa statistic value of 0.86

most frequent symptom, being present in 40% of cases (Fig. 162.1). As expected, the association of RP and skin changes, eventually with some signs of internal organ involvement, are the key diagnostic features.

During the overall course of the disease, RP and skin induration are far the most frequent symptoms (84%), followed by the respiratory involvement with pulmonary fibrosis and hypertension, gastrointestinal symptoms (malabsorption and gastroesophageal reflux), arthritis, and cardiac involvement (arrhythmia, heart failure). Rarely reported are scleroderma renal crisis, renal failure, and central nervous system involvement.

Figure 162.1
Sclerodactyly and flexion contracture of the fingers in a 10-year-old Hispanic girl with systemic sclerosis

Distinctive Features from the Adult Form

In general, a comparison with adult series is difficult because in children the limited cutaneous form, which is the far most frequent in adults, is rare. Children, at the time of diagnosis, show a significantly less frequent visceral involvement compared to adults. The exception is for the prevalence of arthritis seen early in JSSc. Differences with adults become less evident during the follow-up with the exception of interstitial lung involvement, gastroesophageal dysmotility, renal involvement, arterial hypertension which are significantly much more common in adults. Other differences during the course of the disease include the prevalence of arthritis and myositis, which are slightly more common in children than adults; while Raynaud's phenomenon and skin sclerosis are fairly less frequent in the pediatric age.

Similarly to adults, children with JSSc are commonly found to have antinuclear antibodies (ANA) with a frequency of 81–97%. Antitopoisomerase I autoantibodies are present in 28–34% of patients while the prevalence of anticentromere antibodies is lower in children (7–8%) as compared to adults (21–23%). The frequency of occurrence of rheumatoid factor (RF) and antiphospholipid antibodies (APL) is similar in adults and children with SSc.

Treatment

The pharmacologic management of patients with JSSc is challenging since no drug has been shown to be of unequivocal benefit in either children or adults with systemic sclerosis.

Recently, an EULAR task force, including pediatric rheumatologists, has proposed some recommendations for the management of SSc.

For Raynaud phenomenon, calcium channel blockers (CCB), oral nifedipine or nicardipine, should be considered as first-line therapy, and iloprost, or other available intravenously delivered prostanoids, would be used for severe SSc-related RP and digital ulcers. In fact, a recent study in children with JSSc and other connective tissue diseases reported that intermittent infusions of iloprost were safe and effective in treatment of refractory RP and ischemic digits.

For the treatment of interstitial lung disease, cyclophosphamide should be considered. According to the experience in juvenile SLE, cyclophosphamide should be administered as i.v. pulse therapy at a dosage of 0.5–1 g/m^2 every 4 weeks for at least 6 months. To prevent cystitis, adequate hydration and frequent voiding must be emphasized. Indeed, prophylactic MESNA should be considered to minimize contact of acrolein with the bladder mucosa.

Glucocorticoids, preferably prednisone at a dosage of 0.3–0.5 mg/kg per day, should be reserved for the treatment of myositis, arthritis, and tenosynovitis. Since several studies suggest that steroids are associated with a higher risk of scleroderma renal crisis patients should be carefully monitored for blood pressure and renal function.

Methotrexate, which is widely used for the treatment of many rheumatic conditions in children, has been shown to improve skin score in early diffuse SSc in adults. Accordingly, methotrexate could be the treatment of choice for the skin manifestations also for children with JSSc, especially in the early phase. Angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril, losartan) are unanimously considered effective for the long-term control of blood pressure and stabilization of renal function of scleroderma renal crisis. Symptomatic treatments are essentially based on the principle of good clinical practice and include the use of proton pump inhibitors, such as omeprazole and lansoprazole, for prevention of gastroesophageal reflux disease and esophageal ulcers; the use of prokinetic drugs, such as domperidone, for the management of symptomatic motility disturbances; and rotating antibiotics, such as metronidazole, ciprofloxacin, and doxycycline, to treat malabsorption due to bacterial overgrowth.

As far as new experimental drugs (i.e., bosentan, sitaxsentan, and sildenafil for pulmonary arterial hypertension and digital ulcers), there is not enough experience, at present, to recommend their use.

Prognosis

The ultimate prognosis of the child with JSSc depends primarily on the extent of visceral involvement. Skin tightness and joint contractures inevitably lead to severe disability in some patients. Progressive gastrointestinal involvement is typical, however, starting with the esophagus and proceeding distally. Although the disease may stabilize in some patients for long periods, gastrointestinal complications and inanition may become severe. Cardiac arrhythmias may result from myocardial fibrosis and congestive heart failure is often a terminal event. Pulmonary interstitial disease and vascular lesions are probably universal, even if not clinically evident. Renal failure or acute hypertensive encephalopathy supervenes as a potentially fatal outcome in a few children and this event seems more likely to occur early in the course of the disease.

Recent studies showed that the prognosis of SSc in children appears better than in adults. The survival of childhood onset SSc at 5, 10, 15, and 20 years after diagnosis resulted to be 89%, 80–87.4%, 74–87.4%, and 69–82.5%, respectively, so significantly higher than in adult onset disease.

The commonest causes of death in children are related to the involvement of cardiac, renal, and pulmonary systems. Indeed, cardiomyopathy is a leading cause of early death, especially in children. This complication is rare and usually associated with diffuse cutaneous disease and features of polymyositis. An aggressive immunosuppressive treatment has been shown to be effective on muscle, skin, and lung involvement but does not impair progression of myocardial dysfunction.

In children with poor prognosis, diagnosis is made earlier as probably clinical manifestations are clear since the onset of the disease and severe enough to lead rapidly to death. This is confirmed by the fact that most of the deaths occurs in the first 5 years after diagnosis. Therefore, in children, SSc may have two possible evolutions: few children have a rapid development of internal organ failure leading to severe disability and eventually to death, while other patients experience a slow insidious course of the disease with lower mortality and disability.

Juvenile Localized Scleroderma

Definition/Classification

Juvenile localized scleroderma (JLS), also known as morphea, comprises a group of conditions in which the

process of fibrosis involves essentially the skin and subcutaneous tissues. They may range from very small plaques to extensive indurate lesions which cause significant functional and cosmetic deformity.

The most widely used classification divides JLS into five general types: plaque morphea, generalized morphea, bullous morphea, linear scleroderma, and deep morphea. Some conditions, such as atrophoderma of Pasini Pierini, eosinophilic fasciitis or lichen sclerosus et atrophicus, are sometimes classified among the subtypes of JLS but this aspect is still controversial. This classification does not include the mixed forms of JLS where different types of lesions occur in the same individual. This subtype is more common than previously recognized, accounting for 15% of the whole group.

A proposal for a new classification includes five subtypes: circumscribed morphea (CM), linear scleroderma, generalized morphea (GM), pansclerotic morphea, and the new mixed subtype where a combination of two or more of the previous subtypes is present.

Figure 162.2
Circumscribed morphea of the lower left eyelid, characterized by an area of induration with waxy consistence and ivory color, surrounded by an inflammatory edge

Epidemiology

Although JLS is relatively uncommon, it is far more common than systemic sclerosis in childhood, by a ratio of at least 10:1. There is a mild female predilection with the female to male ratio being 2.4:1. The mean age at disease onset is 7.3 years and a few cases with onset at birth, so-called congenital localized scleroderma, have been also described.

Clinical Manifestations

Circumscribed morphea (CM) is characterized by oval or round circumscribed areas of induration surrounded by a violaceous halo (*Fig. 162.2*). It is confined to the dermis with only occasional involvement of the superficial panniculus.

When there are four or more individual plaques larger than 3 cm and involving at least two out of seven anatomic sites (head-neck, right upper extremity, left upper extremity, right lower extremity, left lower extremity, anterior trunk, posterior trunk) we have the so called *generalized morphea* (GM) (*Fig. 162.3*).

Linear scleroderma, the most common subtype in children and adolescents, is characterized by one or more linear streaks that can extend through the dermis, subcutaneous tissue, and muscle to the underlying bone,

Figure 162.3
Generalized morphea involving, symmetrically, the lower limbs in an 8-year-old girl. Note the bluish halo of the active lesions, named lilac ring

causing significant deformities (Fig. 162.4). The upper or lower extremities can be affected but also the face or scalp, as in the *en coup de sabre* variety (ECDS). The Parry Romberg syndrome (PRS), characterized by hemifacial atrophy is considered the severe end of the spectrum of ECDS and for this reason is included in subtype of linear scleroderma. Evidence for this close relationship is the presence of associated disorders, including seizures, CNS abnormalities, and dental and ocular abnormalities, reported with similar prevalence in both conditions.

Pansclerotic morphea, an extremely rare but severe subtype, is characterized by generalized full-thickness involvement of the skin of the trunk, extremities, face, and scalp, with sparing of the fingertips and toes. It is more common in children than adults. Recent reports raised the attention on the possible evolution of chronic ulcers, frequently complicating pansclerotic morphea, to squamous cell carcinoma, a threatening complication already reported in LS.

Conversely to what has been reported for many years, JLS is not exclusively confined to the skin but can present many extracutaneous features. A recent multinational study reported that almost one fourth of the patients present extra-cutaneous manifestations. The overall distribution of these manifestations includes arthritis 19%, neurological findings 4%, associated autoimmune conditions 3%, vascular changes (i.e., Raynaud's phenomenon) 2%, and ocular or gastrointestinal abnormalities 2%.

Figure 162.4
Linear scleroderma of the right upper limb involving the forearm and the first and second fingers

Articular involvement is the most frequent finding, especially in linear scleroderma. Children who develop arthritis often have a positive rheumatoid factor (RF), and sometimes an elevated erythrocyte sedimentation rate (ESR) and circulating autoantibodies. The most frequent neurological conditions are seizures and headaches, although behavioral changes and learning disabilities have also been described. Abnormalities on magnetic resonance imaging (MRI), such as calcifications, white matter changes, vascular malformations, and vasculitis, also have been reported.

Gastroesophageal reflux (GER) is the only gastrointestinal complication reported so far in JLS.

Autoantibodies

Antinuclear antibodies (ANA) are present in more than 40% of patients with JLS. This frequency is lower than in adult with LS but is higher than in normal population. In children there is no correlation between the presence of ANA and a particular subtype or disease course.

Of interest, antitopoisomerase I antibodies (anti-Scl 70), a marker of SSc in adults, were found to be positive in 2–3% of children with JLS but not in adults with LS. Conversely, anticentromere antibodies (ACA) were found in 12% of adults with LS but only in 1.7% of children. Whether these antibodies are markers that reflect the immunological component of the disease process or can have a prognostic significance is unclear. It should be noted that none of SCL-70-or ACA-positive patients in a series of 750 JLS patients presented signs or symptoms of internal organ involvement after a mean follow-up of 3.4 years.

Rheumatoid factor (RF) has been detected, at low titer, in 16% of the patients with JLS, and significantly correlated with the presence of arthritis.

One of the major autoantigens for ANA in JLS is nuclear histone. Anti-histone antibodies (AHA) have been detected in 47% of patients with JLS with a different prevalence in the various subtypes, higher in GM, lower in circumscribed morphea.

Diagnosis and Disease Assessment

The management of JLS is challenging and the detection of disease activity and progression remains a fundamental

problem. Clinical examination is subjective – classical skin scoring methods utilized in the assessment of systemic sclerosis cannot be applied. Among the new tools which have been proposed for the assessment of the skin lesions, infrared thermography (IRT), computerized skin score (CSS), ultrasound (US), and magnetic resonance imaging (MRI) are those most frequently used.

Infrared thermography (IRT) is able to detect areas of increased temperature caused by the inflammatory process, revealing, in this way, active lesions. This technique has shown to have a very high reproducibility but yields false-positive results in the assessment of old lesions characterized by marked atrophy of the skin and subcutaneous tissues. In these cases, an accurate clinical examination can help differentiate these lesions from the active ones.

The computerized skin score (CSS) consists in the demarcation of hyperemic and indurate borders of the lesions on an adhesive transparent film with different colors. The film, transferred over a cardboard, is scanned and recorded in a computer. Calculation of the affected area is performed by computer software.

Ultrasonography (USG) is another technique that has been proposed for monitoring JLS. USG can detect several abnormalities such as increased blood flow, increased echogenicity due to fibrosis, and loss of subcutaneous fat. The first two parameters appear to be signs of active lesions, which disappear in the remission phase. Loss of subcutaneous tissue was found in both active and stable patients. The two main limits of USG are represented by its operator-dependent value and the lack of validation as outcome measure in prospective studies.

MRI is also an important tool in the clinical management of JLS. MRI is clearly most useful when CNS involvement is suspected but is also able to demonstrate the true depth of soft tissue lesions and the degree to which different tissues are involved in other sites.

In comparison to USG, MRI has two main disadvantages: the need for sedation in younger patients and the presence of possible artifacts.

Treatment

Over the years, many treatments have tried for localized scleroderma.

Circumscribed morphea generally is of cosmetic concern only, and therefore systemic treatments with potentially significant toxicity are not justified. In general, these lesions will spontaneously remit with residual pigmentation as the only abnormality. Therefore, treatment should

Table 162.2
Treatment with phototherapy in localized scleroderma

Author	Treatment	Regimen	No. patients (children)	Follow-up	Result	Assessment
Kersher	UVA1	UVA1 20 J/cm^2 for 12 weeks (total number of treatments: 30; cumulative UVA1 dose: 600 J/cm^2	20 (0)	12 weeks	Effective (90%)	Clinical judgment, 20 Mhz USG, histopathology

MTX methotrexate, *USG* ultrasonography

be directed mainly at topical therapies such as moisturizing agents, topical glucocorticoids, or calcipotriene.

Phototherapy with ultraviolet (UV) represents another possible therapeutic choice for localized scleroderma. Treatment with UVA1 at low, medium, and high doses, with or without psoralens (PUVA) all seem to be effective clinically, although high doses seem somewhat better. This approach seems to be much more effective for localized or superficial lesions than for the subtypes with deeper involvement such as linear or generalized scleroderma (◉ *Table 162.2*).

Since the rate of relapse after UV phototherapy discontinuation is not known, the need for prolonged maintenance therapy, leading to a high cumulative dosage of irradiation, and the increased risk for potential long-term effects such as skin aging and carcinogenesis are clear limitations for its use in the pediatric age group.

When there is a significant risk for disability, such as in linear and deep subtypes, systemic treatment methotrexate (MTX) in combination with corticosteroids should be considered (◉ *Table 162.3*). The treatment protocol usually consists in a combination of oral prednisone (0.5–1 mg/kg/day) or intravenous methylprednisolone (20–30 mg/kg/day for 3 days) and MTX (10–15 mg/m^2/week). Most patients show a response within 2–4 months and the side effects are usually mild and associated more with corticosteroid use rather than with the MTX treatment. Only one study has recently proven MTX efficacy and safety in a double-blinded randomized controlled trial (◉ *Table 162.3*).

Prognosis

Information on the long-term outcome of children with JLS is very less and based on small series of patients. However, it is common experience that adults with childhood-onset localized scleroderma suffer from long-term disease sequelae that significantly impact quality of life, including permanent functional and cosmetic impairment. In addition, some continue to have episodes of active disease throughout life.

163 Sjogren Syndrome, Raynaud's Phenomenon, Overlap Syndromes

Fabrizio de Benedetti

Sjogren Syndrome

Definition/Classification

Sjogren syndrome (SS) is a chronic autoimmune disease, of unknown etiology, whose main characteristic is lymphocytic infiltration of exocrine glands. SS may occur as an isolated disorder (primary) or, more commonly, in association with systemic lupus erythematosus or other connective tissue diseases. SS is characterized by a wide clinical spectrum ranging from isolated involvement of salivary and lacrimal glands to a systemic disease that may involve lungs, kidneys, muscles, and the central nervous system.

Epidemiology

Primary SS appears to be very rare in children, while secondary SS is more common. SS is more frequent in females and usually occurs in adolescence, although it has been observed in children as young as 5 years.

Pathology

The common finding in affected organs is lymphocytic infiltration. In salivary glands, infiltrating lymphocytes progressively replace the salivary epithelium. Germinal centers formation may occur. A typical finding is the proliferation of ductal lining cells leading to the formation of epimyoepithelial islands, with keratin-containing epithelial cells. Labial (usually lower lip) salivary gland biopsy is a practical and easy way to access the main target tissue of SS. Focal aggregates adjacent to ducts and acini are typical. Epimyoepithelial islands, which are a characteristic feature in major salivary glands, are very uncommon in labial salivary glands.

Clinical Manifestations

Differently from adults, recurrent parotid swelling is the most frequent symptom at onset, occurring in 70–90% of children with SS. It is more often painless. At presentation, xerostomia and xerophthalmia are relatively rare in children, but occur in up to 50% during the course of the disease. As a consequence of saliva deficiency, patients complain of difficulties in chewing and in initiating swallowing, burning sensation, abnormalities of taste, and dental caries. The oral mucosa may appear dry, erythematous, and sticky. Infection with Candida may be observed. Decreased tear secretion progressively damages the conjunctival and chorneal epithelia causing eye irritation (burning, foreign body sensation, and photophobia). Dryness of other mucosae may occur. Extraglandular manifestations appear to be rare at onset in children. Fever, arthritis and arthralgia, and fatigue are the most common ones both at the onset and during the course. Involvement of the lungs (with interstitial disease), kidneys (interstitial nephritis, renal tubular acidosis), and the central nervous system is relatively uncommon, but may represent significant challenges. Vasculitic and hematological (thrombocytopenia) features have also been described.

Diagnosis and Differential Diagnosis

The disease course in children may be very insidious, with a long time between initial symptoms and development of full-blown sicca syndrome. As a consequence, diagnostic criteria for adult SS are not sensitive enough in children. As mentioned above, recurrent parotid swelling, which is not included in adult criteria, is by far the most frequent presentation in children.

Polyclonal hypergammaglobulinemia, rheumatoid factor at high-titer antinuclear antibodies, and anti-Ro/SSA and anti-La/SSB antibodies are present in the large

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_163,

majority of patients. Increased ESR is common. Leukopenia, anemia, and thrombocytopenia may also be observed. The Shirmer's test is used to evaluate tear's secretion (<5 mm wetting of a filter paper strip in 5 min is considered positive). Traditional radiocontrast sialography provides evidence of ectasia of the salivary ducts. Recent data, yet to be confirmed in children, showed that ultrasonography revealed parenchymal inhomogeneity in major glands and decreased echogenicity and volume of submandibular glands in patients with SS. Demonstration of periductal and/or periacinal lymphocytic infiltrates in the minor salivary glands of the lower lip is the best single criterion for establishing a definitive diagnosis. Differential diagnosis includes juvenile recurrent parotitis, which is characterized by intermittent swelling of one or both parotid glands, associated with fever, pain, and skin erythema. Autoantibodies and lymphocytic infiltration are absent. It is usually responsive to antibiotics. Diffuse lymphocytosis syndrome, a well-known entity in HIV infected children, may cause parotid enlargement. HCV infection may be associated with chronic sialadenitis. Malignancy and sarcoidosis should also be considered in the diagnosis.

Treatment and Prognosis

The outcome of children with SS is usually good. However, since SS is potentially a multisystem disease, patients with SS should be followed regularly. Treatment of symptoms secondary to xerostomia is based on the use of sugar-free lemon drops or chewing gum to stimulate salivation. Frequent ingestion of fluid is often the best solution. Careful oral hygiene is important to prevent dental disease. Xerophthalmia is treated with artificial tears (as frequently as every 30 min); attention to environmental humidity is also important. Oral pilocarpine has been suggested for sicca syndrome (both eye and oral). Systemic and organ manifestations are managed usually with corticosteroids and immunosuppressants. Hydroxychloroquine has been reported to be useful in the long-term treatment.

Raynaud's Phenomenon

Definition

The characteristic triphasic color change sequence (blanching, cyanosis, erythema) originally described by Raynaud in 1862 is still the definition of Raynaud's phenomenon. The term "primary Raynaud's phenomenon" (RP) is applied to patients in which no underlying disorder can be identified. In contrast to adults, in children primary RP is rather rare (probably less than 10%). Secondary RP in children is usually associated with autoimmune connective tissue diseases. The association with other underlying diseases that have been reported in adults (i.e., mechanical obstruction, polycythemia, cryoglobulinemia) is rare, if not exceptional in children.

Clinical Manifestations

RP is usually suspected in a child who presents with the characteristic triphasic color change of distal body parts on exposure to cold or stress: white to blue to red. The blanching phase is clearly demarcated and uniformly white. It begins at the distal end of digits. More often ends abruptly at the distal interphalangeal joints, but it may involve the whole digit up to the metacarpophalangeal joints. RP invariably involves fingers, usually more than one, and the thumb is usually spared. Toes, and more rarely, ears, nose tip, and lips may be involved. Paresthesias, numbness, or pain (particularly during the red phase) may accompany the changes in color.

Diagnosis and Differential Diagnosis

The diagnosis of RP is based on the presence of the triphasic color changes. Isolated RP may be the first sign of systemic scleroderma, and in some children may precede other manifestations by years. The presence of positive antinuclear antibody, nailfold capillary abnormalities, or, more rarely, esophageal dismobility, is a hint that the child may evolve to scleroderma. RP must be distinguished from normal vascular instability which is rather common particularly in adolescents, more often girls. The skin becomes reddish, but the triphasis color changes are not present and nailfold capillaroscopy is normal. Acrocyanosis should also be considered: it is a rare vasospastic disorder characterized by bluish color and coldness of the hands (not limited to the distal part of the fingers), often associated with excessive perspiration and edema. Minor abnormalities in nailfold capillaries have been described (dilated loops, decrease in number).

Treatment

Precipitating circumstances, such as exposure to cold and stress, should be avoided as much as possible. A number of

drugs have been used for the specific treatment of RP, but they have not been specifically investigated in children. Nifedipine should probably be considered the drug of choice (starting dose 0.2 mg/Kg at bedtime to avoid hypotension and up to the same dose for 2–4 times per day). Intravenous prostanoids and, particularly, iloprost are efficacious in RP and healing digital ulcers, but the experience in children is very limited. Other vasodilators, including ACE inhibitors and bosentan, have not shown significant benefit in adult trials.

Overlap Syndromes

Definition

Some children present with clinical and laboratory features that are characteristics of the major classic rheumatic diseases, such as juvenile idiopathic arthritis (JIA), systemic lupus erythematosus (SLE), juvenile dermatomyositis (JDM), and systemic scleroderma (SS). The terms "overlap syndrome" and "undifferentiated CTD" are used to define these children. Based on the presence of diagnostic criteria and characteristic serologic features, the best defined entity is mixed connective tissue disease (MCTD). MCTD is defined by the presence of features of SLE, JIA, JDM, and SS, associated with high-titer antinuclear antibody (speckled pattern) and with autoantibodies directed against one of the extractable nuclear antigens, namely U1RNP.

Epidemiology

MCTD is very rare representing less than 1% of CTDs in children. It is more common in adolescence with a 5:1 female-to-male ratio. Young children affected with MCTD have been reported

Clinical Manifestations

Most often, the initial presentation is characterized by edema and swelling of the hands, Raynaud's phenomenon, and arthralgias and/or polyarthritis. The subsequent course is defined by which component of the overlap syndrome plays the major role. Polyarthritis is very common; it may be erosive or nonerosive. Joint contractures may develop and skin involvement may contribute. Indeed, scleroderma-like skin disease is frequent and may become the prominent feature in several patients. Raynaud's phenomenon usually persists throughout the course of the disease. Pulmonary involvement is rather common and may progress with time to overt interstitial lung disease. Also esophageal manifestations of scleroderma, such as reflux and dysphagia, develop rather commonly. Renal disease occurs in less than one fourth of the patients; it is usually less severe than in SLE. Other manifestations may occur: skin signs of JDM such as heliotropic rash and Gottron's sign; myositis is frequent but rarely severe. Serositis are occasional.

Diagnosis

The diagnosis is based on the association of signs and symptoms of various CTDs with the high-titer ANA with speckled pattern and autoantibodies to U1RNP. Other ANA specificities are usually not present at high titer. Rheumatoid factor is often present. Several sets of criteria for MCTD have been developed in adults, but have not been validated in children. The most frequently used criteria in childhood are the Kasukawa's criteria (*Table 163.1*).

Treatment and Prognosis

There is no specific treatment for MCTD. Therapy is aimed at addressing the predominant problem of a given child, according to the principles of the treatment of each CTDs. The long-term outcome is variable and unpredictable, although two third of the patients have a favorable outcome. Significant morbidity and mortality are more often associated with pulmonary involvement. Deaths associated with myocarditis and renal involvement have also been reported.

Table 163.1
Diagnostic criteria for MCTD (Kasukawa's criteria)

I. Raynaud's phenomenon or swollen finger or hands
II. Anti-RNP antibody positivity
III. At least one abnormal finding from two or more of the following categories
1. Signs or symptoms of SLE (polyarthritis, facial rash, serositis, lymphadenopathy, leukopenia, thrombocytopenia)
2. Signs or symptoms of scleroderma (sclerodactyly, pulmonary fibrosis, vital capacity <80%, carbon monoxide diffusion <70%, decreased esophageal motility)
3. Signs or symptoms of dermatomyositis (muscle weakness, elevated creatine kinase, EMG abnormalities)

164 Henoch–Schöenlein Purpura

Nicolino Ruperto

Definition/Classification

Henoch–Schönlein purpura (HSP) is an acute small-vessel leucocytoclastic vasculitis which was first reported in the nineteenth century by Heberden and later by Schönlein and Henoch who described the typical rash, joint manifestation, and gastrointestinal and renal involvement.

Etiology

The disease presents in most patients from autumn to spring often following an infection. A wide variety of pathogens, drugs, and other environmental exposures have been associated with HSP. Antistreptolysin O titers are raised in 20–50% of patients, but most cases have no direct link to streptococcal infection.

Epidemiology

Henoch–Schönlein purpura is the most frequent systemic vasculitis of childhood with an estimated annual incidence of 20.4 per 100,000 for all children, and 22.1 per 100,000 in children younger than age 14. The mean reported age of onset is 6.4 years. Black children seem to have a significantly lower annual incidence of HSP than white or Asian children. The reported boys to girls sex ratio is 1.2:1. It is much more frequent in children than in adults.

Pathogenesis

The cause of HSP is unknown, but it is likely that IgA has a fundamental role in the pathogenesis of the disease. Skin or renal biopsies demonstrate the deposition of IgA (IgA1) in the wall of skin capillaries and in the glomeruli. Diminished glycosylation of the hinge region of IgA1 has been reported in patients with HSP and IgA1 molecules with diminished hinge-region glycosylation are prone to aggregate into macromolecular complexes that can activate the alternative pathway of complement.

In regard to host susceptibility, several genetic polymorphisms relating to HSP and in particular to severity and/or risk of renal involvement have been described.

Clinical Manifestations

The onset is usually that of an acute purpura associated with other signs and symptoms with malaise and fever present in about one third of the children.

Purpura is present to different degree in all children with most of them typically showing the characteristic palpable purpura, 2–10 mm in diameter, commonly in crops, with lower limb predominance (*Fig. 164.1*). The lesion usually appears on the lower extremities and buttocks and in the region of frictions (e.g., socks or slip). The lesions begin as erythematous maculopapules that later became petechial or purpuric. Similar to ecchymoses, they change in color from red to purple and then vanish. Damage to vessels can also result in local angioedema.

Arthritis occurs in most cases, is painful, mainly affects the large joints of the lower limbs, and disappears spontaneously after few days.

Diffuse abdominal colicky pain with acute onset is present in the majority of HSP children. Many patients have occult heme-positive stools, but massive hemorrhage only occurs occasionally. Intussusception (usually ileoileal) is a severe but rare complication. Pancreatitis, hydrops of the gallbladder, and protein-losing enteropathy have been occasionally reported. Sometimes, gastrointestinal complaints can precede the appearance of the classic purpuric lesions.

Renal involvement is reported in around 35% of children and may manifest as proteinuria and/or hematuria, nephritis, nephrosis, or acute renal failure. In most cases, renal involvement is mild (microscopic hematuria with or without low-grade proteinuria). More rarely, renal involvement is severe and can progress to chronic renal failure. Renal manifestations usually occur within 4 weeks from disease onset. Urinalysis should be done each week while the disease is active, then each month for 3 months

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_164,

Figure 164.1
The figure showed the characteristics palpable purpura, 2–10 mm in diameter, commonly in crops, with lower limb predominance. The lesion usually appears on the lower extremities and buttocks and in the region of frictions (e.g., socks or slip)

thereafter. If all analyses are normal, nephritis is unlikely to occur. An uncommon manifestation is ureteritis which can cause obstruction and renal colic.

Other less common complications include central nervous system involvement, orchitis, epididymitis, carditis, pulmonary hemorrhages, neuropathies, and ocular involvement.

Laboratory findings are unspecific. Erythrocyte sedimentation rate as well as acute phase reactants may be normal or elevated. Serum IgA are elevated in about half of patients. Other laboratory studies are useful only to exclude other forms of vasculitis that can mimic HSP.

Diagnosis

Diagnosis is usually established on the presence of recurrent crops of palpable purpuric lesions predominantly affecting the skin of lower limbs and buttocks often associated with arthritis/arthralgia, colicky abdominal pain, and abnormalities in the urinalysis. In doubtful cases, a punch skin biopsy will show leukocytoclastic vasculitis with IgA and C3 deposition.

Acute hemorrhagic edema is a benign form of leukocytoclastic vasculitis that can be confused with HSP. It is characterized by the triad of fever, purpura, and edema, and affects children of less than 2 years of age. Purpuric lesions, usually larger than those seen in HSP, are localized on the face and extremities, while the trunk is spared. Edema, which is nonpitting, usually also affects the face and the limbs. It is a benign and self-limiting disease that usually resolves spontaneously without sequelae.

Treatment

Most patients require only supportive treatment. Nonsteroidal anti-inflammatory drugs (NSAIDs) are indicated to control joint pain. The efficacy of corticosteroid therapy is controversial. However, in general, prednisone is used in case of severe complications and its administration is often associated with prompt improvement of severe abdominal pain. There is no evidence that corticosteroid therapy is effective in treating the purpura, shortening the duration of the disease, or preventing recurrences or the development of nephritis.

Similarly, there is a lack of randomized controlled trial to establish the benefit of treatment in case of severe renal involvement. Uncontrolled studies suggest the potential efficacy of high-dose corticosteroids associated with cyclophosphamide or azathioprine in patients with severe HSP nephritis (nephrotic syndrome, diminished renal function, and diffuse extra-capillary nephritis on renal biopsy). Therefore, it is acknowledged that, even in the absence of controlled evidence, early aggressive therapy is warranted in patients with severe nephritis.

Prognosis

In the vast majority of cases, HSP is a self-remitting disease that disappears in few days or weeks. Although symptoms might recur, they generally totally disappear within 4–6 months. Prognosis mainly depends on the extent and severity of renal involvement. Patients with nephritis may show persistent urinary abnormalities for months or even years, but only 1–3% of patients are at risk to progress to end-stage renal disease. At renal biopsy, the presence of crescent formation in more than 50% of the glomeruli is associated with a poor prognosis.

165 Kawasaki Disease

Rae S. M. Yeung

Disease Definition

Kawasaki Disease (KD) is one of the most common causes of vasculitis affecting children. Although the inflammatory response is found in medium and small vessels throughout the body, the most common site of damage is the coronary arteries, making KD the leading cause of acquired heart disease in children from the developed world. KD continues to be a diagnostic challenge. There is no single diagnostic test or unique clinical finding to distinguish KD from other acute febrile exanthems of childhood. Although called a disease, KD is truly a syndrome complex characterized by multi-system inflammation. KD presents clinically as prolonged fever, usually greater than 5 days in duration, a polymorphous skin rash, nonexudative bilateral conjunctival injection, oral mucosal inflammation with erythema of the lips and a strawberry tongue, extremity changes which include redness of the palms and soles and swelling of the dorsum of the hands and feet, as well as cervical lymphadenopathy, typically unilateral and greater than 1.5 cm in diameter. Presence of fever plus at least four out of five of these principal features constitutes the diagnosis of typical KD (◉ *Table 165.1*). The absence of a specific diagnostic test for the disease continues to hinder identification of affected children and a lack of predictive markers of this clinically heterogeneous clinical syndrome is an obstacle to the improvement of therapy for affected children.

Epidemiology

The most common age of occurrence is between 12 months and 5 years although younger children and adults can be affected. Since the initial clinical descriptions in Japan and Hawaii, the number of cases of KD has increased dramatically and is currently recognized worldwide. KD is seen in all ethnic groups and in all regions of the world, but the incidence of disease varies dramatically from region to region and between different ethnic groups suggesting a major role for genetics in KD risk and outcome. The annual incidence, reported as number per 1,000,000 children under 5 years of age, ranges from 5 in Denmark, 8 in New Zealand, 26 in Canada, 39 in Hong Kong, 55 in China, 105 in Korea to over 180 in Japan. Siblings of affected children are at tenfold higher risk for KD compared to the general population, and incidence of KD is twofold higher than normal in children of affected individuals.

In Asia and North America, KD is more common during the winter and early spring months and boys outnumber girls by 1.5–1.7 to 1 with greater than three quarters of affected children under the age of 5. The case fatality rate of KD in Japan is about 0.08%. This number appears to be decreasing in the most recent nationwide surveys done in countries that have active surveillance programs for KD. Virtually all deaths of patients with KD result from its cardiac sequelae. The peak mortality has been reported to occur between 15 and 45 days after the onset of fever. During this subacute phase of illness, inflammation continues and is coupled with marked elevation in the platelet count and a hypercoagulable state. Sudden death from myocardial infarctions may also occur years after the acute KD episode in children who had coronary artery aneurysms and stenosis.

Etiology

Despite numerous studies, the etiology of KD remains elusive. KD has been linked with many different etiologic agents ranging from bacteria such as *Staphylococcus*, *Streptococcus*, *Proprionibacterium*, and *Chalmydia* to viruses such as Epstein–Barr virus, parvovirus, coronavirus, and retroviruses, but no one causative agent has been consistently demonstrated. KD fits nicely in the spectrum between an infectious disease, an inflammatory syndrome, and a true autoimmune disease, with an infectious trigger leading to a prolonged self-directed immune response in a genetically susceptible host. The etiology debate has centered around the mechanism of immune activation: conventional antigen versus superantigen. Evidence supporting both hypotheses continues to accumulate. Some investigators have focused their work on identifying

Table 165.1
Diagnostic features of KD

Prolonged fever (at least 5 days in duration) plus the presence of at least four of the following five principal features:
1. Polymorphous skin rash
2. Bilateral nonexudative conjunctival injection
3. Oral–mucosal changes including:
• Erythema
• Cracked lips
• Strawberry tongue
• Injection of the oral and pharyngeal mucosa
4. Extremity changes including:
• Erythema of the palms and/or soles
• Swelling of the hands and/or feet
• Periungual peeling of the fingers and/or toes in the subacute phase
5. Cervical lymphadenopathy (>1.5 cm in diameter), usually unilateral

one specific pathogen or family of pathogens responsible for disease. One group has identified oligoclonal IgA antibodies present in arterial tissue from fatal cases of KD. Recent interest and debate has centered on a novel human coronavirus found by a group of investigators in the respiratory secretions of some children with KD. Others investigators have not been able to confirm these data, echoing the outbreak-dependent nature of this syndrome.

The longer the search for a single infectious agent, the longer the list of diverse infectious organisms found. The presence of a shared property, common to multiple infectious agents, resulting in the same pathogenic process leading to the clinical syndrome of KD is another explanation. One such common feature of many infectious organisms is the presence of superantigenic activity. Superantigens are a group of proteins which share the ability to stimulate a large proportion of T cells (up to 30% of the T cell repertoire compared to one in a million T cells for conventional antigens) by binding to a portion of the T-cell receptor β chain (TCRVβ) in association with the major histocompatibility complex (MHC) class II molecules with no requirement for antigen processing. Superantigens have been identified in a variety of microorganisms including bacteria (*Staphylococci*, *Streptococci*, *Mycobacterium*, *Mycoplasma*, *Yersinia*), and viruses (rabies, EBV). Evidence from a number of KD outbreaks point to the classic footprint for superantigens specifically TCRVβ skewing in the peripheral blood and in affected cardiac tissue.

Although the debate continues regarding the mechanism of initial immune activation, the more likely scenario is that there is cooperation between different mechanisms and a final common pathway of immune activation responsible for this clinical syndrome. One of the unifying features of KD is a prolonged inflammatory response. It is possible that in many cases the infectious trigger, which started the inflammatory process, has been eliminated, and in those children who develop KD the persistent inflammatory response has become the problem. Containing the inflammatory response is one of the objectives of therapy in acute KD. Inflammation in itself is not worrisome, but prolonged inflammation leads to activation of downstream effectors, which can lead to coronary artery damage.

Pathogenesis

Systemic inflammation is the most striking finding in KD. This is evidenced clinically and biochemically during the acute phase of illness. Like other syndromes characterized by systemic inflammation, TNF-α is markedly elevated in children during the acute phase of KD. TNF-α is a pleiotropic cytokine critical in the regulation of immune cells and plays a critical role in inflammation. The link between the systemic immune response seen in the acute phase of KD and subsequent damage to the coronary arteries is not clearly understood. There is now emerging evidence that TNF-α is critical in the pathogenesis of KD, specifically at the level of the target tissue- the coronary artery. Key downstream effects of TNF-α signaling include leukocyte recruitment to the coronary artery and up-regulation of matrix degrading enzymes and pro-inflammatory cytokines. TNF-α up-regulates expression and activity of many members of the matrix metalloproteinase (MMP) family of enzymes. MMPs are a family of zinc-dependent matrix-degrading proteases that share the ability to degrade molecules of the extracellular matrix. Elastin is an important extracellular matrix component in arterial vessel walls. Breakdown of elastin leads to the loss of structural integrity of the vessel wall and ballooning, the hallmark of aneurysm formation. MMPs play an important role in the degradation of elastin leading to aneurysm formation. Two MMPs in particular, MMP-2 and MMP-9, have been localized to areas of inflammation and internal elastic lamina degradation in aneurysms. In fatal cases of human KD, MMP-9 was expressed in coronary artery aneurysms but not in non-KD control coronary vessels suggesting a role in the development of aneurysms.

Clinical Manifestations

KD has many features suggestive of an infectious trigger. The illness is endemic with seasonal fluctuations and is punctuated with epidemic outbreaks. Many of the clinical features of KD are outbreak dependent with a different spectrum of clinical findings found from one mini outbreak to another, and cases having similar clinical phenotypes clustering temporally. KD can be divided into three phases: acute, subacute, and convalescent. The acute phase is characterized by a multi-system vasculitis, evidenced by the classic signs of inflammation including redness, heat, and swelling. The five principal features plus fever are the distinctive inflammatory changes seen in this illness. There are many associated clinical features, all attributed to the underlying vasculitis. The effects of KD on multiple systems of the body are well recognized. These include: aseptic meningitis, anterior uveitis, myositis, and hydrops of the gall bladder. The pattern of manifestations of many of these associated features has evolved over the past 2 decades mainly due to the changing pattern of clinical treatment. Arthritis can also be a common finding in KD, seen in 7% of children at diagnosis of KD. Which compares favorably to a much higher incidence in the pre-intravenous immunoglobulin (IVIG) treatment era. The arthritis of acute KD is effusive and often noted to be intensely painful, affecting ambulation in many instances. A predominance of large joints are affected regardless of the pattern of joint involvement. The clinical course of symptomatic arthritis is short-lived in the majority of affected children. Most affected children have a dramatic and rapid resolution of their arthritis following combined treatment with IVIG and high dose aspirin, regardless of the number of joints involved or distribution of disease. Despite evidence of increased systemic inflammation in children with arthritis, their response to treatment and coronary outcome are unchanged compared to children without arthritis.

The subacute phase of illness is characterized by resolution of fever, as well as the associated systemic symptoms associated with inflammation. There is often a classic peeling of the skin starting at the periungual region of the fingers and toes. During this phase, coronary artery lesions are most commonly detected. Despite early treatment with high dose IVIG and aspirin, aneurysms continue to develop in approximately 5% of children who are appropriately treated. When adjusted for body surface area, this number increases to 20–30% of affected children who develop coronary artery lesions (CAL). KD is now recognized as the number one cause of acquired heart disease in children in the developed world.

There has been increasing recognition of typical KD (see *Table 165.2* – differential diagnosis). The challenge clinically is recognition of children who present with incomplete or atypical disease. Incomplete KD is the more appropriate term as these children do not present with atypical features but rather they simply do not present with the full clinical picture typical of the disease and have fever with less than four out of five of the principal clinical features of KD. The diagnosis of KD is strictly based on clinical criteria. Having said this, many physicians and experts in the area have recognized that there are supportive criteria which aid in the identification of this group of children at increased risk for development of CAL. The American Heart Association (AHA) has proposed an algorithm to aid in the evaluation and management of children who do not fulfill full diagnostic criteria for KD (*Fig. 165.1*). The proposed supportive criteria include laboratory findings which reflect the underlying multi-system inflammation. These include elevated C-reactive protein (CRP), raised erythrocyte sedimentation rate (ESR), hypoalbuminemia, anemia, elevated serum transaminases, thrombocytosis, and leukocytosis (*Table 165.3*). Incomplete KD presents clinicians with the challenge of correctly identifying and treating patients to prevent the development of coronary artery lesions. The studies investigating the contribution of clinical phenotype to coronary outcome have identified duration of

Table 165.3
Supplemental laboratory criteria in the evaluation of suspected incomplete KD[a]

1.	Hypoalbuminemia (Albumin ≤ 3.0 g/dL)
2.	Anemia for age
3.	Liver inflammation (elevated alanine aminotransferase)
4.	Thrombocytosis (platelets ≥ 450,000/mm after day 7)
5.	White blood cell count ≥ 15 000/mm
6.	Sterile pyuria (urine ≥ 10 white blood cells/high-power field)

[a]AHA algorithm 2004

fever as the most powerful predictor of poor coronary outcome. Duration of fever may be an indirect measure of the severity of the underlying vasculitis. Other surrogate markers of inflammation include the platelet count, serum albumin level, and failure to respond to IVIG therapy, all of which are related to fever duration. These clinical and laboratory features have all been identified as high-risk factors for development of coronary artery aneurysms.

The take home message for the evaluation and management of the child with suspected KD is a high index of suspicion for KD in children presenting with prolonged fever. Every young child with prolonged fever and signs or symptoms consistent with KD, with no other disease accounting for these clinical findings, needs close clinical follow-up and appropriate laboratory investigations (*Fig. 165.1*). The AHA algorithm aims to improve identification of at risk children and to initiate appropriate treatment in affected children.

Pathology

The basic pathologic lesion in KD is a necrotizing vasculitis with fibrinoid necrosis of medium-sized muscular arteries (predominantly coronary arteries), but venous involvement is also documented. The initial lesion begins

in the microcirculation in the adventitia. Inflammatory cells are detected by 7–9 days after fever onset with neutrophils rapidly giving way to lymphocytes and large mononuclear cells. Destruction of the external elastic lamina and all layers of the artery accompany this cellular infiltrate resulting in aneurysm formation.

Coronary Artery Lesions

The major long-term sequelae of KD is damage to the coronary vasculature; thus, cardiac imaging is an integral component of the management of children with KD. Two-dimensional echocardiography is the imaging modality of choice due to the noninvasive nature and the high sensitivity and specificity for detection of abnormalities in the proximal segments of the coronary arteries. Echocardiographic evaluation of the coronary anatomy should include assessment of the internal coronary artery diameters. The numbers and locations of aneurysms and the absence or presence of intraluminal thrombus should also be assessed. The criteria used to define coronary artery abnormalities in KD were first proposed by the Japanese Ministry of Health in 1984. These criteria were applicable to either angiographic or echocardiographic measurements, and defined coronary arteries as abnormal if the internal lumen diameter is greater than 3.0 mm in children less than 5 years of age or greater than 4.0 mm in children above 5 years of age, if the internal diameter of a segment measures at least 1.5 times that of an adjacent segment, or if the coronary artery lumen is clearly irregular (◉ *Table 165.4*). The AHA classified aneurysms as small (<5 mm), medium (5–8 mm), or giant (>8 mm). Coronary artery dimensions in normal children increase linearly with body size, as measured by body surface area (BSA). Thus more recently, investigators have recognized the need to correct for BSA and have classified coronary artery lesions as measurements greater than 2.5 standard deviations above the expected mean. Using this corrected BSA definition (Z-scores), there is approximately a 20% incidence of CALs despite appropriate treatment. Although the coronary anatomy is the focus of the attention in KD, cardiac function should be included in the imaging evaluation, as depressed ventricular contractility is common early in acute KD and histologic studies suggests the myocarditis is universal during the acute phase.

Although imaging protocols may vary, most agree that in uncomplicated cases, echocardiographic evaluations are needed at time of diagnosis and in the subacute phase (6–8 weeks). Additional echos between these time points may be needed to guide management of high-risk patients. Some advocate repeat imaging 6 months to 1 year post acute KD, but recent studies have suggested that normal coronary outcome at the subacute echo is unlikely to change at 1 year. There remain limitations to echocardiography, including detection of thrombi and coronary artery stenosis. In addition, the visualization of coronary arteries becomes more difficult as a child grows and body size increases. Angiography, intravascular ultrasound, transesophageal echocardiography, magnetic resonance angiography, and ultrafast computed tomography may be of benefit in the management of certain cases.

The initial size of the aneurysm is an important contributor to the likelihood of resolution/regression of that lesion, with smaller aneurysm more likely to regress. Coronary aneurysms that do not regress may progress to stenosis or occlusion or abnormal tortuosity or show continued aneurysmal morphology. Aneurysmal dilatation can also progress to rupture, but fortunately is extremely rare in KD.

◘ Table 165.4
Echocardiographic results (Echo +) supportive of KD diagnosis[a]

Any of the following three conditions:
1. BSA normalized z-score of ≥ 2.5 for the LAD or RCA
2. Japanese Ministry of Health definitions of coronary artery aneurysm which include:
• Coronary artery internal diameter > 4 mm in those ≥ 5 years old
• Coronary artery internal diameter > 3 mm in those < 5 years old
• Coronary artery internal diameter ≥ 1.5 times that of the adjacent segment
• Coronary artery lumen is clearly irregular
3. ≥3 other suggestive features including:
• Perivascular brightness
• Lack of tapering
• Decreased LV function
• Mitral regurgitation
• Pericardial effusion
• z-scores in LAD or RCA of 2–2.5

[a]AHA guidelines 2004

Treatment of Acute KD

IVIG

High dose IVIG is the accepted therapy in acute KD. Its efficacy in reducing the prevalence of coronary artery

lesions is well documented. Many different doses and administration schedules have been used in North America, Europe, and Japan. The general consensus is that higher doses given in a single infusion have the greatest efficacy. Several meta-analysis have confirmed this dose effect. Dose comparison studies showed a significant reduction of aneurysms with increasing dose, with those receiving 2 g/kg in a single dose showing both a reduction in the number of aneurysms as well as a reduction in the duration of fever compared to those receiving lower doses. Different predictive instruments have been developed to model risk for poor coronary outcome. In Japan, the Harada score was developed to aid in the rational allocation of a limited IVIG supply to those at highest risk for aneurysm formation. In addition to the clinical factors already described, male sex and the very young (<12 months old) were added as demographic features of those at risk.

The AHA recommends that IVIG be administered in a single infusion at a dose of 2 g/kg. Most infusion protocols start with a very slow rate with stepwise increases in infusion rate. The total duration of the IVIG infusion is typically 8–12 h depending on the concentration of IVIG. Multi-system inflammation involving the heart can potentially compromise the heart's ability to handle the fluid challenge associated with the IVIG infusion, thus necessitating the long duration of infusion. IVIG therapy should be instituted during the acute phase of illness, typically within the first 10 days of fever, but IVIG treatment is indicated anytime during the acute phase of illness even in those presenting after day 10 of illness. Early treatment with IVIG before day 5 of illness does not affect coronary outcome, but may increase the need for IVIG retreatment. This observation may be biased for a more severe phenotype in those treated early. When analyzed separately, those treated early ($\leq$ 4 days of fever) had higher risk scores than those treated later suggesting that those treated early in their disease course had more dramatic clinical features implying more intense inflammation and severe vasculitis.

IVIG is made from pooled donor plasma. As such, manufacturing and product differences are present. There are ongoing and conflicting investigations into potential differences in efficacy and side-effect profile between different IVIG preparations. Nonetheless, prescribing practices vary from institution to institution and the use of many different products and concentrations (5% or 10% solutions) of IVIG are employed in the acute therapy of KD and may be dictated by product availability. Although the mechanism of action of IVIG in the treatment of KD is not clearly understood, IVIG does have general immunomodulatory effects. Possible mechanisms of action include general immunosuppression via the modulation of pro-inflammatory cytokine production, and regulation of expression and function of Fc receptors, inhibiting activation of complement, neutralization of bacterial superantigens or other infectious agents, anti-idiotypic antibody effects, and effects on the activation, differentiation, and effector functions of both T cells and B cells and other antigen presenting cells.

Due to the protective effects of receiving pooled immunoglobulin and the general immunomodulatory effects, immunizations may not generate an effective or protective immune response for months after IVIG administration. Although harmless to receive immunizations, both live or killed vaccines, they may not be effective and the child may need to be re-immunized 9–11 months after IVIG administration if there is an inadequate immune response. Typically, live vaccinations are deferred for 9–11 months after a child receives high dose IVIG unless the risk of infectious exposure is high.

Aspirin

A widely debated issue in the acute therapy of KD is the dose of aspirin – high versus low dose. At high doses, aspirin has important anti-inflammatory properties and at low doses, it has anti-platelet activity. At high doses, salicylates inhibit the activity of IKK, thereby preventing NF-κB nuclear translocation. At lower doses, salicylates inhibit the cyclooxygenase enzymes leading to a reduction in prostaglandin and thromboxane synthesis. Despite high dose aspirin having an additional mechanism of immunomodulation compared to low dose aspirin, with inhibition of nuclear translocation of NFκB affecting transcriptional regulation of important pro-inflammatory cytokines as well as inhibition of TNFα signal transduction, administration of aspirin during the acute phase of KD does not appear to alter coronary outcome. During the acute phase of KD, the anti-inflammatory dose of aspirin, 80–100 mg/kg/day given in four divided doses, is typically prescribed in North America. Circulating total salicylate levels have been shown to vary tremendously despite consistent oral dosing at 80–100 mg/kg/day, with serum concentrations ranging from 0.1–0.25 mg/mL.

The duration of high dose aspirin therapy varies from institution to institution. Many centers reduce the aspirin dose to anti-platelet levels (3–5 mg/kg/day) after the affected child has been afebrile for 24–72 h. Others continue anti-inflammatory doses of aspirin until day 14 of illness or longer. In Japan, the dose of aspirin used is lower

(20 mg/kg) and may reflect the different pharmacokinetics of aspirin metabolism in the Oriental population. A Cochrane review of aspirin in the therapeutic management of acute phase of KD concluded that there is insufficient evidence to support or refute the use of aspirin as part of the treatment regimen due to lack of good quality randomized clinical trials. Low dose aspirin is administered for its anti-platelet effect and typically continued until the child shows no evidence of coronary artery damage at 6–8 weeks after fever onset and laboratory measures of inflammation have returned to normal. Children with coronary artery lesions may continue aspirin or other anti-platelet agents indefinitely.

Refractory Disease

One of the major challenges in the current management of KD is the treatment of patients who fail to respond to initial therapy with IVIG. Ten to twenty percent of children will not respond to a single dose of IVIG. The definition of refractory disease or treatment failure varies, but in general is defined as persistent or recrudescent fever $\geq$ 36 h after initial IVIG therapy. Persistent fever is more common than recrudescent fever. Although debate continues regarding the optimal therapy for refractory disease, most investigators agree on a second dose of IVIG. The second dose of IVIG continues to be high dose therapy at 2 g/kg. Treatment of this subgroup of patients with refractory KD has included additional IVIG, corticosteroids, and much less commonly various immunosuppressive agents including cyclophosphamide and cyclosporin, as well as plasma exchange, inhibition of elastase activity (ulinastatin), and more recently the biologic therapy against tumor necrosis factor-alpha (*Fig. 165.2*). The goal of all these therapies is to ameliorate the immune response thus decreasing the chance of ongoing inflammation and damage to the coronary arteries. The order of these therapeutic interventions continues to be controversial.

Although steroids are efficacious and widely used in other forms of vasculitis, their use in KD is very limited.

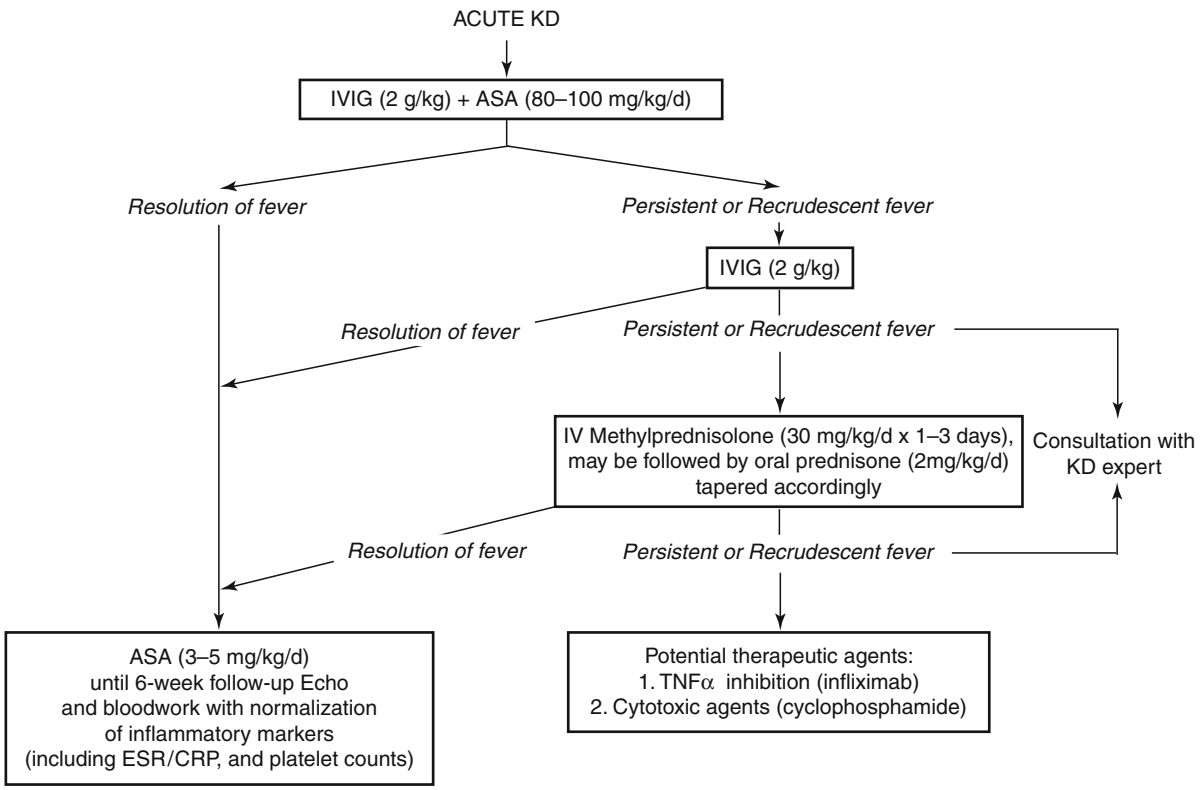

Figure 165.2
Proposed algorithm for the management of acute Kawasaki disease

Use of steroids in acute KD has been controversial, but more recent studies have shown their usefulness in both the acute phase as well as in refractory disease. KD refractory to IVIG was the most common indication for corticosteroid use in patients with KD, and this treatment was found to be effective, with rapid resolution of fever in the majority of patients. The most common dosing regimen of steroids is high dose pulse steroids given as intravenous methylprednisolone 30 mg/kg up to a maximum of 1 g. This is given once per day over 1–3 days. Dosing regimens vary from center to center and little evidence is available to support the dose or schedule of steroid administration. At our institution, high dose IV dosing may be followed by oral prednisone at 2 mg/kg/day which is then rapidly tapered to 0 over the course of 1 to 2 weeks unless resistant fever or fever recrudescence requires a longer taper or alternate therapy (◉ *Fig. 165.2*).

Therapeutic Options in Children with Coronary Artery Aneurysms

No prospective studies are available to guide treatment decisions in children with coronary artery lesions, thus recommendations are based on knowledge of the pathophysiology and lessons learned from adults with coronary disease. The basis of these therapeutic guidelines is prevention of thrombosis, and specific management is dependent on the extent and severity of coronary artery disease. As such, anti-platelet therapy alone or in combination with anti-coagulation is an integral component of the management plan. Thrombocytosis together with platelet activation is a key finding in KD, thus necessitating the use of anti-platelet agents. Low dose aspirin is used even in those with no evidence of coronary damage until the 6-week follow-up echocardiogram and may be continued indefinitely in those with coronary artery damage. In the presence of more severe coronary disease, the addition of another anti-platelet agent targeting non-ASA-dependent pathways of platelet activation (dipyridamole and clopidogrel) may be included. In the presence of large or giant aneurysms, which pose a significant thrombotic risk, anti-coagulation is added. In the acute phase, the usual choice is heparin. Long-term anti-coagulation can be achieved by either warfarin or low-molecular weight heparin in combination with an anti-platelet agent. Little data is available to guide interventions in the presence of intravascular thrombi, but recent trials have targeted the platelet glycoprotein IIb/IIIa receptor involved in the final common pathway of platelet aggregation. Abciximab, a platelet glycoprotein IIb/IIIa receptor inhibitor, has been used acutely in children with intraluminal thrombus to reestablish vessel patency and salvage the myocardium.

Conclusion

In summary, KD is an important cause of acquired heart disease in childhood. There is increasing recognition of typical KD. The challenge clinically is recognition of children who present with an incomplete clinical presentation. A high index of suspicion in every child with prolonged fever and signs or symptoms consistent with KD, coupled with close clinical follow-up and appropriate laboratory investigations and imaging is warranted. Prolonged inflammation leading to coronary artery damage is the underlying pathology in KD. Early identification and treatment of affected children to suppress the inflammatory response is one of the objectives of therapy. High dose IVIG together with aspirin is the mainstay of therapy in acute KD. Disease modeling continues to be imperfect and future studies will need to identify novel biomarkers to enhance the traditional clinical and laboratory measures of inflammation. The ultimate goal for identification of this high-risk phenotype is to guide clinical decisions involving use of therapeutic interventions to improve coronary outcome in affected children.

166 Childhood Polyarteritis Nodosa

Fatih Ozaltin · Seza Ozen

Definition/Classification

Polyarteritis nodosa (PAN) is a clinical syndrome with a wide variety of signs and symptoms, which are caused by fibrinoid necrosis of small and/or medium-sized arteries. Two disease entities are defined: classical PAN and cutaneous PAN. Microscopic PAN will be discussed in another section. Patients are often classified as PAN based on existing criteria. The recent EULAR/PRINTO/PRES (Ankara) criteria propose the need for a biopsy showing characteristic histological features of PAN or angiography reflecting the mid-size arteritis, as mandatory criteria for the classification of a child as PAN (*Table 166.1*).

Epidemiology

PAN is a rare disease in both children and adults. The disease is seen worldwide. In a large international multicenter study, where 110 patients with PAN were included, it has been reported that mean age at diagnosis was 9.05 ± 3.57 years and that the girl to boy ratio was 56:54.

Etiology, Pathogenesis, and Genetic Background

In most cases, the etiology remains unknown; however, infectious agents have been considered as etiologic or contributing factors. A relationship between hepatitis B infection and PAN has been well described and probably represents an immune complex disease. Streptococcal infections could also be a contributing factor especially in patients with cutaneous PAN.

There is no substantial evidence on genetic predisposition for PAN. Familial occurrence is rare. Recent studies have suggested that PAN is more frequent in patients with familial Mediterranean fever (FMF). It has been suggested that mutations in the gene for FMF provide a susceptibility factor for the development of PAN by forming a proinflammatory state.

Clinical Manifestations

PAN is typically a multisystem disease resulting from vascular inflammation predominantly in skin, abdominal viscera, kidneys, central nervous system (CNS), and muscles. Symptoms may be subtle. However, PAN should be considered in any child with unexplained fever, palpable purpura, myalgia, arthritis, mononeuritis multiplex, or unexplained pulmonary, cardiovascular, or renal disease. Children usually have constitutional symptoms such as fever, malaise, and weight loss. Skin lesions include petechia/purpura, splinter hemorrhages, infarction and ulceration, papules, livedo reticularis, and painful nodules.

Nonspecific abdominal pain occurs in two thirds of patients, usually due to mesenteric and other ischemia caused by vasculitis. Infarction of the gut, gallbladder, or pancreas may develop. Aneurysms of abdominal mid-size arteries have been reported.

Renal involvement (proteinuria, hypertension) has been reported as 45–80%. Renal involvement is classically limited up to the level of spiral arteries, and glomerulonephritis is not seen in this type of PAN.

Clinical findings regarding central nervous system involvement may vary from organic brain syndrome to seizures and hemiparesis. Sensorimotor peripheral neuropathy (mononeuritis multiplex) is quite characteristic.

Cardiovascular involvement including mitral and/or tricuspid valve regurgitation, and impaired left ventricular function may rarely occur.

Testicular or epididymal swelling and tenderness are again rare but important findings for diagnosis in males.

Laboratory Findings

Mild anemia, leukocytosis, thrombocytosis, and elevated acute phase reactants are characteristic features. Autoantibodies are negative and ANCA is frequently negative in this type of PAN.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_166,

Table 166.1
Classification of PAN (Ozen et al. (2010))

Typical histopathology or angiographic abnormality (mandatory) plus one out of five of the following criteria:
1. Skin involvement
2. Myalgia or muscle tenderness
3. Hypertension
4. Peripheral neuropathy
5. Renal involvement

Treatment

Corticosteroids and cyclophosphamide are the mainstay of treatment of systemic necrotizing vasculitides. Oral or intravenous cyclophosphamide is indicated in severe organ involvement. The cumulative dose of cyclophosphamide is a major concern. A number of large studies have shown that a cumulative dose up to 200–250 mg/kg is safe in terms of gonadal toxicity. Azathioprine is used for maintenance treatment.

Prognosis

The prognosis of childhood PAN was guarded in initial series. However, with the judicious use of immunosuppresants, the prognosis, even in children with definite systemic involvement, is better than adults, with reported survival rates.

Cutaneous PAN

Cutaneous PAN (CutPAN) is designated for polyarteritis nodosa limited fundamentally to the skin. It has been described as a distinct clinical entity with benign but relapsing course without systemic involvement. However, there has been much debate on whether or not it can progress to systemic form.

A history of a preceding upper respiratory tract infection, often with streptococcus, is usually present. CutPAN is characterized by purpura, multiple painful subcutaneous nodules, livedo reticularis, and sometimes nonspecific musculoskeletal findings such as myalgia and arthralgia. Constitutional symptoms are not expected to be present and the acute phase reactants are often normal. Nonsteroid antiinflammatory drugs are used in most cases. CutPAN usually responds to short courses of prednisone (0.5–1 mg/kg/day) therapy. Prolonged course and relapses are frequent. Penicillin prophylaxis may be needed if streptococcal infection is implicated as triggering agent. Prognosis is generally good; however, relapses and the chronic course are of concern.

167 Antineutrophil Cytoplasmic Antibody (ANCA)-Associated Small-Vessel Vasculitides

Fatih Ozaltin · Seza Ozen

Definition

The antineutrophil cytoplasmic antibody (ANCA)-associated small-vessel vasculitides (AAV) comprise a group of disorders characterized by necrotizing vasculitis with a paucity of immune deposits associated with antibodies against cytoplasmic constituents of neutrophils, particularly proteinase 3 (PR3) and myeloperoxidase (MPO). In this group, three major clinical entities are present: *Wegener's granulomatosis* (*WG*), *Churg–Strauss syndrome* (*CSS*), and *microscopic polyangiitis* (*MPA*). It should be emphasized that most but not all patients show a positive ANCA by serology.

Wegener's Grantulomatosis

Wegener's granulomatosis (WG) is a necrotizing vasculitis affecting small to medium-sized vessels. The disease is characterized by granulomatous inflammation involving respiratory tracts, including sinuses, nasal passages, pharynx, and lungs, and pauci-immune necrotizing crescentic glomerulonephritis, and in most patients the presence of ANCA.

Epidemiology

WG is rare in childhood. This has resulted in descriptions in the pediatric population that have been based on smaller numbers of patients, most often in the form of case reports, case series, and literature reviews. The two largest single-center pediatric series to date have reported on a combined total of only 40 patients. In a recent report of 60 patients, the mean age of diagnosis was 11.7 years.

Etiology and Pathogenesis

The etiology of WG remains unknown. Both genetic and environmental factors seem to be involved. Familial occurrence is extremely rare. Use of cocaine and exposure to silica have been indicated as environmental factors. As carriage of *Staphylococcus aureus* is strongly associated with PR3–ANCA positive Wegener's granulomatosis, the bacterium might be involved in the PR3-specific autoimmune response. However, it has not been possible yet to produce the disease associated with PR3 ANCA in animals.

Pathology

The characteristic pathologic finding is granulomatous involvement in arteries. Kidney biopsy is indicated in children with kidney involvement. Characteristic finding is pauci-immune necrotizing crescentic glomerulonephritis (◉ *Fig. 167.1*). Granuloma formation is rarely observed in kidney tissue unlike to the lung or sinus biopsy.

Clinical Manifestations

Clinical manifestations are nonspecific and virtually any organ can be involved. However, presenting and diagnostic symptoms are usually confined to the respiratory tract and the kidneys. The classical triad of the disease is paranasal sinus involvement, pulmonary infiltration, and kidney involvement (◉ *Table 167.1*). Constitutional symptoms, including fever, malaise, and weight loss, are common at presentation. In different pediatric series, upper respiratory tract involvement (sinusitis, epistaxis, otitis media, etc.) has been reported in 84–100% of the patients, while lower respiratory tract involvement in 80–87%. Since subglottic stenosis is common in the pediatric practice, the presence of upper airway involvement (subglottic, tracheal, and endobronchial stenosis) has been added as a criterion to the revised classification criteria in childhood WG.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_167,

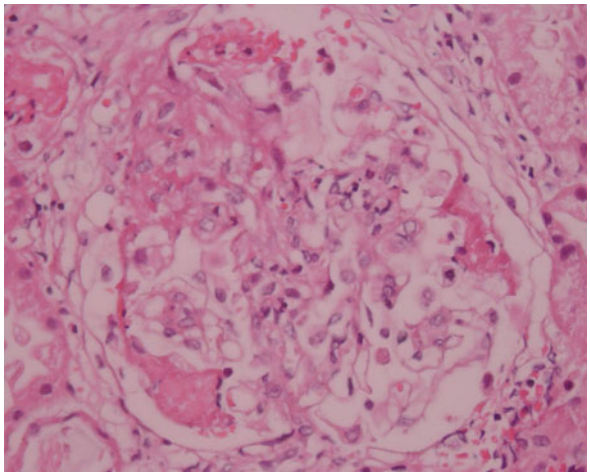

Figure 167.1
Necrotizing crescentic glomerulonephritis in a child with ANCA-associated vasculitis

Renal involvement, which is characterized by necrotizing pauci-immune glomerulonephritis in biopsy, is frequently seen and often causes renal failure requiring dialysis. Skin lesions including purpura and panniculitis/nodules may be seen in one third of the patients. Conjunctivitis, scleritis, and proptosis have also been reported as frequent symptoms at onset or during the course of the disease. Arthritis/arthralgia, hypertension, gastrointestinal involvement venous thrombotic events and CNS involvement occur less frequently. The disease may also present in a limited form.

Diagnosis and Laboratory Findings

Many of the "classic" features of the disease may be lacking early in the course. Although diagnostic criteria do not exist, for diagnosis the child should have (1) small-vessel vasculitis; (2) granulomatous inflammation of the airways; (3) nodules, infiltrations on chest radiographs; and (4) renal involvement. According to recently proposed classification criteria, three out of six criteria should be present for WG (*Table 167.1*).

There is usually mild anemia and thrombocytosis. Marked elevation of acute phase reactants are usually present. Urinalysis may show microscopic hematuria, proteinuria, and casts in case of renal involvement. Renal impairment may be present.

ANCA is highly associated with WG (*Table 167.1*). ANCA may be either cytoplasmic (c-ANCA), which is related to proteinase 3 (PR3) or more rarely related to myeloperoxidase (MPO). Sensitivities of PR3-ANCA and MPO-ANCA for WG are 70–80% and 10%, respectively. A few patients with WG are ANCA-negative.

Table 167.1
EULAR/PRINTO/PRES (Ankara, 2008) classification criteria for Wegener's granulomatosis (From Ozen et al. (2010))

Three of the following six should be present:
1. Abnormal urinalysis[a]
2. Granulomatous inflammation on biopsy
3. Nasal and/or sinus and/or oral inflammation
4. Subglottic, tracheal, or endobronchial stenosis
5. Abnormal chest X-ray or computed tomography
6. Any ANCA positivity

[a] If kidney biopsy is performed, it characteristically shows necrotizing pauci-immune glomerulonephritis

Radiologic Findings

Chest radiographs or CT are abnormal in up to two thirds of the patients and include nodules, cavitation and infiltrates, and pleural effusions. Sinus radiographs will reflect the sinusal involvement.

Treatment

Since there are few data relating to treatment of children with WG evidence-based treatment, recommendations come from studies performed in adult population.

Localized disease defined by the European Vasculitis Study (EUVAS) group refers to patients with symptoms restricted to the upper and/or lower airways, without constitutional symptoms or systemic vasculitis. In this group, Methotrexate may be used to induce remission.

EUVAS approaches the treatment of (systemic) WG and MPA in a similar fashion, and thus the treatment of these two diseases will be reviewed together. Conventional treatment is to induce remission with cyclophosphamide and corticosteroids in these two ANCA-associated vasculitides, WG, or MPA. Patients should be started with oral prednisone plus pulse intravenous cyclophosphamide or oral cyclophosphamide to induce remission. In this study of adults, prednisone was tapered to 10 mg by 6 months. Cyclophosphamide doses should be adjusted to age, renal function (level of evidence 1b; recommendation A).

In the CYCAZAREM study, azathioprine has proven to be effective for maintenance therapy after 3–6 months of remission induction therapy with prednisolone and oral cyclophosphamide. Leflunomide, methotrexate, and

mycophenolate mofetil may be alternative therapies to maintain remission.

In severe renal vasculitis and immediately life-threatening disease, plasma exchange should be started to improve renal prognosis (level of evidence 1b; recommendation A). In refractory disease, there are no randomized trials providing evidence for the best therapy. Rituximab has been proven to be effective in recent trials of ANCA-associated vasculitides in adults.

Prognosis

The use of immunosuppressives has resulted in much lower mortality rates than those published in early studies of WG. Lack of ear, nose, and throat involvement has also been shown to be a significant indicator of increased risk of mortality. Treatment may result in significant morbidity and mortality.

Churg–Strauss Syndrome (Allergic Granulomatosis)

Churg–Strauss syndrome (CSS) is a disease characterized by pulmonary and systemic small-vessel necrotizing vasculitis, vascular and/or extravascular granulomas, eosinophilia and tissue infiltration by eosinophils, occurring in individuals with asthma, and often allergic rhinitis or sinusal polyposis. Asthma and severe eosinophilia in combination with vasculitic organ manifestations are key features of this unique disease.

Epidemiology

Reports of CSS occurring in children are limited and generally consist of single case reports. In a recent systematic review, where 33 children with CSS have been included, mean age at onset has been found as 12 years with a male-to-female ratio of 0.74.

Etiology and Pathogenesis

Etiology and pathogenesis remain unknown. Inhaled allergens, infections, drugs have been implicated as triggers. A possible contribution of leukotriene receptor antagonists to the development of CSS has been suggested.

The pathogenic role of anti-MPO autoantibodies is now well established both in vitro and in vivo. However, the mechanisms leading to vasculitis in CSS are yet to be elucidated, particularly in ANCA-negative patients.

Pathology

Histological signs of CSS include eosinophilia, vasculitis, or granuloma. Small-vessel vasculitis is found in most of the patients, extravascular eosinophils are histologically evident in 80% of the patients, while granulomas are seen in 45% of them.

Clinical Manifestations

History of asthma has been reported in 91% of the patients while sinusitis in 77% at the time of clinical presentation. Pulmonary infiltrates are also a common finding (85%), whereas pleural effusions are rarely seen (12%). Other organs such as the skin (66%), peripheral nerves (39%), and the gastrointestinal tract (40%) are also involved. Renal and musculoskeletal symptoms occur rarely. Cardiac involvement is frequently seen and is characterized by granulomatous pericardial disease (27%) and eosinophilic cardiomyopathy (42%). Severe mitral valve regurgitation has also been reported. Other organs are rarely affected.

Diagnosis

According to the American College of Rheumatology criteria for classification of the CSS, a patient is considered to have CSS in the presence of at least four of the following criteria with a sensitivity of 85% and a specificity of 99.7%: (1) asthma, (2) eosinophilia, (3) history of allergy, (4) mono/polyneuropathy, (5) pulmonary infiltrates, (6) paranasal sinus abnormality, (7) extravascular eosinophils in biopsy.

Laboratory Findings and Pathology

The most striking laboratory features are significant eosinophilia ($\geq$10% of the peripheral leukocytes) and elevation of serum IgE level. Acute phase reactants are increased in active disease. ANCA positivity is not a consistent finding however the usual association is with MPO-ANCA.

Chest X-Ray may reveal diffuse pulmonary infiltrates with impaired pulmonary function tests.

Treatment and Prognosis

Strict and aggressive therapy is indicated in patients with CSS. Most children respond well to initial steroid therapy. However, those patients with vital organ involvement immunosuppressive agents such as cyclophosphamide, azathioprine, or metotrexate are often needed.

Mortality is significantly higher (19%) in children than adults (5%). This is partly explained by the more severe cardiac involvement, which has major impact on mortality.

Microscopic Polyangiitis

Microscopic polyangiitis (MPA) is defined as non-granulomatous small-vessel vasculitis with few or no immune deposits affecting small vessels. Necrotizing glomerulonephritis is very common and necrotizing arteries of medium-sized arteries may also be present. Pulmonary capillaritis without upper respiratory tract involvement often accompanies to glomerulonephritis. It can mimic classical PAN histologically, as both diseases produce necrotizing arteritis. The key distinction between them is in the involved vessel size since MPA is predominantly small-vessel vasculitis, while PAN is confined to mid-sized arteries. In addition, MPA is often associated with a high titer of MPO-ANCA.

Epidemiology

Microscopic polyangiitis is rare in children. The annual prevalence of MPA has been reported as 25.1 per million adults in France. In two pediatric series, the mean age at diagnosis was 12 years.

Etiology, Pathogenesis and Genetic Background

Infections may have an initiating role, although a specific antigen has not been indicated. MPO-ANCA has been implicated in the pathogenesis. There are several in vitro data supporting the observation that ANCA are capable of endothelial damage. In two elegant animal models, anti-MPO antibodies in mice and in rats induced necrotizing and crescentic glomerulonephritis with widespread vasculitis in the lung and other organ systems.

Genetic factors may be operative in the pathogenesis. MPO levels are influenced by two single nucleotide polymorphisms in the gene, MPO463 and MPO129. The MPO 463 polymorphism has been associated with an increased risk of development of MPO-ANCA associated disease.

Clinical Manifestations

The constitutional features of MPA are similar to those of classical PAN. However, the predominant feature is progressive (often rapidly) glomerulonephritis with or without pulmonary involvement. It is one of the leading causes of pulmonary-renal disease in children. Renal disease manifests as nephritis and renal functions may be acutely impaired. Myalgia, skin lesions, joint disease, gastrointestinal symptoms, and central and peripheral nervous system involvement have all been defined in MPA. In some series, end stage renal disease has been reported as high as 40%.

Diagnosis and Laboratory Findings

Diagnosis depends on characteristic renal biopsy findings in the presence of typical clinical manifestations and a positive p-ANCA staining with high MPO-ANCA level by ELISA. Classical PAN, Henoch Schonlein purpura, Wegener's granulomatosis, Churg–Strauss syndrome, and systemic lupus erythematosus should be considered in differential diagnosis.

Leukocytosis, thrombocytosis, and elevation of erythrocyte sedimentation rate and C-reactive protein level are consistently present. Urinalysis shows proteinuria and hematuria. Renal functions may be impaired.

MPO-ANCA is important in diagnosis and follow-up of the disease. In childhood, those patients with necrotizing glomerulonephritis and pulmonary involvement seem to have the highest MPO-ANCA levels.

Treatment and Prognosis

Guidelines for treatment of Wegener's Granulomatosis (WG) are applicable for MPA as well.

Five-year survival rates vary between 45% and 74% in different adult series. Renal involvement is a significant factor in predicting poor prognosis, either in the form of proteinuria (>1 g/day) or raised creatinine levels. Overall relapses seem to be less frequent as compared to WG.

168 Takayasu Arteritis

Fatih Ozaltin · Seza Ozen

Definition

Takayasu arteritis (TA) is a chronic, idiopathic vasculitis of the large arteries. It primarily affects the aorta, its proximal branches, and occasionally the pulmonary arteries, which result in luminal stenosis, occlusion, or aneurysms.

Epidemiology

In children, the mean age of onset is 12 years. The female: male ratio is about 2:1. There are geographic variations in the presentation of TA. While obstructive lesions are frequent in the United States, Europe, and Japan, aneurysms are more common in Africa and India.

Etiology, Pathogenesis, and Genetic Background

Although many studies have proposed microorganisms such as bacteria and viruses as causative agents in TA, no specific infectious agents have been confirmed so far.

Circulating antiaortic endothelial cell antibodies (AAECAs), increased expression of E-selectin and vascular cell adhesion molecule-1, and increased production of interleukin (IL)-4, IL-6, and IL-8 have been reported in patients with TA.

Rare familial cases may suggest the role of genetic factors. Genes of certain activation molecules are upregulated in patients with TA.

Clinical Manifestations

Clinical manifestations are symptoms secondary to ischemia of organs supplied by stenotic vessels and constitutional symptoms such as fever, weight loss. The ischemic symptoms include stroke, visual aberration, angina, and renovascular hypertension, and claudication of extremities. Hypertension is one of the most frequent presenting symptoms in childhood. Headache is also a frequent complaint. Absent pulses and bruits over the stenotic vessel may be detected. Classically, TA follows a number of courses. The monophasic course is limited to 20% of cases. Some patients exhibit progressive or relapsing/remitting course.

Diagnosis and Laboratory Findings

To demonstrate angiographic abnormalitie(s) is mandatory for the diagnosis. Recent proposed classification criteria for TA is given in *Table 168.1*.

Acute phase reactants are elevated in about 2/3 of the patients. Autoantibodies, rhematoid factor, and ANCA are negative; however, anti-endothelial antibodies are frequently present. Electrocardiography may show findings of left ventricular hypertrophy suggesting chronic hypertension.

Radiologic Findings

Since TA involves aorta and its main branches, MR angiogram will be adequate to show the vascular lesions (*Fig. 168.1*). PET scan can be performed in selected cases, especially for differential diagnosis; however, the high cost is of concern.

Four types of involvement have been described in angiography. These include (1) aortic arch only; aortic arch and descending thoracic aorta; aortic arch, thoracic and abdominal aorta; aortic arch and abdominal aorta, (2) descending thoracic aorta only; descending thoracic and abdominal aorta, (3) diffuse aortic involvement, and (4) diffuse aortic and pulmonary artery involvement.

Treatment

Corticosteroids, methotrexate (MTX), azathioprine, mycophenolate mofetil, and cyclophosphamide (CYC) have all been used in the treatment of TA. A high (50%)

Table 168.1
Classification criteria for Takayasu Arteritis, Ankara 2008 (Ozen S, Pistorio A, Iusan SM et al. (2010) The EULAR/PRINTO/PRES criteria for Henoch-Schönlein Purpura, Wegener Granulomatosis, Takayasu Arteritis and Childhood Polyarteritis Nodosa: ANKARA, 2008. Ann Rheum Dis 69:798–806)

Angiographic abnormalities (mandatory criterion) and 1 out of 5 of the following criteria:
1. Pulse deficit or claudication
2. Four limbs blood pressure discrepancy
3. Bruits
4. Hypertension
5. Increased acute phase reactants

relapse rate is observed in adults treated with corticosteroids only. There is no consensus on follow-up and no A-level evidence-based data on the treatment of childhood patients. In a recent study, patients were allocated to receive (1) oral steroids and MTX if they had disease limited to one side of the diaphragm only, and without pulmonary disease; and (2) oral steroids and oral CYC followed by oral MTX as above if the disease was more widespread. This single-center experience suggests that cyclophosphamide and corticosteroid induction followed by methotrexate is an effective and safe treatment for childhood TA and may prevent relapses. Angiotensin-converting enzyme inhibitors and angiotensin1 receptor blockers should be avoided in the presence of renal artery involvement. In resistant cases, anti-TNF treatment has been successful in case series.

Angioplasty or bypass grafting can successfully be performed when needed. However, this procedure should be done when the patient is in remission.

Prognosis

There is an absence of prospective and randomized controlled trial data in TA in childhood. However, from adult studies, it is estimated that TA has an overall 10-year survival rate of approximately 90%. This rate is reduced by the presence of complications. Optimal management of these factors could reduce the mortality.

169 Other Forms of Vasculitis

Fatih Ozaltin · Seza Ozen

Hypocomplementemic Urticarial Vasculitis Syndrome

Definition

Hypocomplementemic urticarial vasculitis syndrome (HUVS) is a rare vasculitic disorder characterized by recurrent attacks of erythematous, urticarial, and hemorrhagic skin lesions associated with arthritis and sometimes abdominal distress. HUVS can also be distinguished by the presence of angioedema, urticaria, uveitis, and chronic obstructive pulmonary disease.

Etiology and Pathogenesis

Exact etiology of the diseases is unknown. HUVS is an immune complex disease characterized by the presence of anti-C1q antibodies at a high titer in all patients. Anti-C1q is thought to contribute to the formation of circulating or locally formed immune complexes. Furthermore anti-C1q may be pathogenic by disturbing the clearance of apoptotic cells, resulting in induction of autoimmunity or aggravating the autoimmune inflammatory state.

Clinical Manifestations, Laboratory Findings, and Pathology

Although rare, HUVS must be considered in the differential diagnosis for all patients with urticarial rash (*Fig. 169.1*). Renal disease affects up to 50% of patients and usually occurs within 4 years of onset of the rash. The laboratory hallmark of HUVS is hypocomplementemia involving the early components of the classical complement pathway. Urinalysis may be normal or can demonstrate hematuria and/or proteinuria.

The skin biopsy shows leukocytoclastic vasculitis whereas the kidney involvement may vary from crescentic glomerulonephritis to membranoproliferative or membranous lesions.

Differential Diagnosis

Systemic lupus erythematosus (SLE), cryopyrin associated periodic fever syndromes and other hypocomplementemic diseases should be considered in the differential diagnosis. A certain portion of the patients may progress to SLE as well.

Treatment and Prognosis

No specific therapy is currently available for HUVS. Skin lesions appear to be poorly responsive to antihistamines. Prednisone, hydroxychloroquine, or dapsone has been used successfully in anectodal reports. Pulmonary disease associated with HUVS can be life threatening, and no therapies have been shown to be consistently effective. Some patients with progressive renal deterioration have responded to high-dose prednisone, with or without cyclophosphamide. Prognosis depends on the extent of systemic involvement.

Cogan Syndrome

Definition

Cogan syndrome (CS) is a systemic vasculitis characterized by sensory neural hearing loss and nonsyphilitic interstitial keratitis.

Etiology and Pathogenesis

Etiology and pathogenesis remain unknown although association with some particular infections has been suggested. Organ-specific autoimmune processes have been implicated.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_169,

Figure 169.1
Typical urticarial lesions in hypocomplementic urticarial vasculitis in a girl

Clinical Manifestations and Laboratory Findings

Clinical manifestations include inflammatory eye disease (i.e., interstitial keratitis, conjunctivitis, scleritis, retinitis, retinal vasculitis) and vestibuloauditory dysfunction. Systemic vasculitis affecting aorta or small-/medium-sized arteries and aortic valve insufficiency and constitutional symptoms may be observed. Acute phase reactants are elevated and antinuclear antibody may be positive.

Differential Diagnosis

In differential diagnosis, one should consider Takayasu arteritis, Wegener's granulomatosis, and polyarteritis nodosa.

Treatment and Prognosis

Early diagnosis and treatment are mandatory to avoid ophthalmologic and otologic sequelae. A combination of corticosteroids and corticosteroid-sparing immunosuppressive drugs such as cyclophosphamide and methotrexate have been advocated. Disease course may be characterized by flares and remissions over years. A significant proportion of the patients become deaf.

Central Nervous System Vasculitis

Definition

Primary vasculitis (or angiitis) of the central nervous system (CNS) is inflammatory vasculitis affecting the CNS vessels alone. Diagnostic criteria have been suggested for adults including (1) a newly acquired neurologic deficit, (2) angiographic and or histologic features of CNS vasculitis, and (3) no evidence of systemic condition. CNS vasculitis can also be secondary to a number of infectious diseases or systemic lupus erythematosis.

Etiology and specific pathogenesis of the primary CNS vasculitis are unclear.

Clinical Manifestation, Laboratory Findings, and Pathology

Headache, transient ischemic attacks, paresis and plegia, seizures, encephalopathy, and neurocognitive impairment may all occur. The diagnosis may be considered in any child with sudden onset neurologic deficit.

Acute phase reactants and cerebrospinal fluid examination may be completely normal. There may be an increased protein and mild pleocytosis in the cerebrospinal fluid. An angiography is indicated for the assessment of CNS vasculitis. In large/medium vessel vasculitis, a magnetic resonance (MR) angiography may suffice. However, for small-vessel involvement a conventional angiogram has higher sensitivity and should be considered in the presence of typical MR changes. Angiography may be negative in small-vessel CNS vasculitis where only a brain biopsy will provide the definite diagnosis.

The histopathology reveals infiltration of mainly mononuclear cells around the vessel and sometimes granuloma formation.

Differential Diagnosis

Differential diagnosis includes systemic rheumatological diseases with CNS involvement including: SLE, Behcet's disease, polyarteritis nodosa, Kawasaki disease, Henoch–Schonlein purpura, and ANCA-associated vasculitides. Bacterial infections due to streptococcus, mycobacteria; viral infecations such as *Varicella zoster*, *Ebstein-Barr virus*; spirochetal infections such as *Borelia burgdorferi* and fungal infections such as aspergillus should also be considered. Finally, the differential diagnosis also includes neoplasms of the brain.

Treatment and Prognosis

There are no established treatment protocols but it is suggested to treat children with CNS vasculitis with corticosteroids and cyclophosphamide. Long-term follow-up is necessary to define the neurological, cognitive, and behavioral outcome. Distal artery involvement is associated with poorer outcome. Permanent neurologic deficit may occur.

Hypersensitivity Vasculitis

Definition, Etiology, and Pathogenesis

Hypersensitivity vasculitis (HV) is an inflammatory vascular disease characterized by prominent skin involvement with the existence of a trigger (usually a drug or vaccine). ACR defines HV as palpable purpura, precipitated by a medication or other agent with characteristic biopsy. It has been described after treatment with heterologous antiserum.

Pathology

Pathology is characterized by the perivascular or extravascular infiltration of the small vessels with polymorphonuclear leukocytes and the presence of leukocytoclasia.

Clinical Manifestations and Laboratory Findings

Skin lesions (i.e., purpura, urticaria, and palpable nodules) are predominantly located on the legs, although the upper limbs and trunk may also be affected. Generally the disease lasts few weeks with a self-limiting course. Relapsing and chronic course has been defined.

Leukocytosis usually occurs and is sometimes accompanied by eosinophilia and circulating immune complexes. The erythrocyte sedimentation rate is often normal.

Differential Diagnosis

Other causes of leukocytoclastic vasculitis should be considered in the differential diagnosis.

Treatment

Management is usually symptomatic consisting of antihistamines and NSAIDs. If systemic symptoms are present, corticosteroid therapy is indicated.

170 The Autoinflammatory Diseases

Marco Gattorno

Introduction

Under the term of autoinflammatory diseases are gathered a number of inherited disorders secondary to mutations of genes coding for proteins that play a pivotal role in the regulation of the inflammatory response. Most of these disorders have generally an early onset, ranging from the first hours to the first decade of life. The clinical spectrum of these disorders is extremely variable (*Table 170.1*).

Some of them are characterized by recurrent flares of systemic inflammation presenting as sudden fever episodes associated with a dramatic elevation of acute phase reactants, and with a number of clinical manifestations, such as rash, serositis (peritonitis, pleuritis), lymphadenopathy, arthritis. Disease flares are usually separated by symptom-free intervals of variable duration, characterized by a complete well-being, normal growth, and complete normalization of acute phase reactants. Familial Mediterranean Fever (FMF), Mevalonate kinase deficiency (MKD), and tumor necrosis factor (TNF)-receptor-associated periodic syndrome (TRAPS) are the three monogenic disorders gathered under the term of *Periodic fevers.*

In other disorders, systemic inflammation is dominated by a characteristic urticarial rash associated with a number of other clinical manifestations. Familial Cold Autoinflammatory Syndrome (FCAS), Muckle–Wells Syndrome (MWS), and Chronic Infantile Neurological Cutaneous and Articular Syndrome (CINCA) represent the clinical spectrum associated to different mutations of a gene named *NALP3* (or *CIAS1*, cold-induced autoinflammatory syndrome 1) coding for a protein called Cryopyrin. These three disorders are also gathered under the term of Cryopyrinopathies or Cryopyrin-related periodic syndromes (CAPS). Mutations of another member of the NALP family, the *NALP12* gene, have been recently associated with a new autoinflammatory disease.

Other diseases are characterized by typical granulomatous formations (*Granulomatous disorders*). Blau's syndrome is characterized by noncaseating granulomatous inflammation affecting the joint, skin, and uveal tract and is associated with mutations of the *CARD15* (or *NOD2*) gene.

A further group of diseases are dominated by the presence of sterile pyogen abscesses affecting skin, joints, and bones (*Pyogenic disorders*). These include the Pyogenic Sterile Arthritis, Pyoderma Gangrenosum and Acne (PAPA) syndrome secondary to mutations of the CD2-binding protein 1 (*CD2BP1*) gene, and the Majeed syndrome, characterized by chronic recurrent multifocal osteomyelitis, congenital dyserythropoietic anemia, and neutrophilic dermatosis caused by mutations of the *LPIN2* gene. Finally, a recently identified autosomal recessive autoinflammatory syndrome, due to the deficiency of the interleukin-1-receptor antagonist (DIRA), is characterized by a neonatal-onset multifocal osteomyelitis, periostitis, and skin pustulosis.

The Cryopyrinopathies

FCAS, MWS, and CINCA are autosomal-dominant disorders related to different mutations of a single gene: *NALP-3* (or *CIAS1* or *PYPAF1*), encoding a protein called cryopyrin. So far, more than 80 different missense mutations have been described (http://fmf.igh.cnrs.fr/infevers/). However, 30% to 40% of patients with a phenotype consistent with a cryopyrinopathy do not display any mutation of the *NALP3* gene.

Pathogenesis

Interleukin-1β (IL-1β) is one of the major proinflammatory cytokines. Unlike most cytokines, IL-1β lacks a secretory signal peptide and is externalized by monocytic cells through a nonclassical pathway, arranged in two steps, as shown in *Fig. 170.1* (ref). A crucial role in IL-1β processing is played by the Inflammasome, a multi-protein complex responsible for activation of the IL-1 converting enzyme (ICE) (or Caspase-1). NALP3 is a key protein of the Inflammasome that, in the presence of adequate stimuli, oligomerizes becoming available for the binding of the adaptor protein ASC (Apoptosis associated Speck-like protein containing

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_170,

Table 170.1
The autoinflammatory diseases

	Diseases	Gene chromosome	Protein	Transmission	Clinical features
Periodic/ recurrent fevers	Familial Mediterranean fever	*MEVF* 16p13.3	Pyrin	AR	Short duration of fever episodes: 24–48 h
					Abdominal and chest pain. Erysipelas-like erythema
					High incidence of renal amyloidosis in untreated patients
					Good response to Colchicine
					Possible response to IL-1 blockade
	Mevalonate kinase deficiency	*MVK* 12q24	Mevalonate kinase	AR	Early onset (usually <12 months)
					Mean duration of fever episodes: 4–5 days
					Poor conditions during fever episodes. Abdominal pain, vomiting, and diarrhea. Splenomegaly
					Good response to steroids. High rate of self-resolution during adulthood. Amyloidosis is rare
	TNF-receptor-associated periodic syndrome	*TNFRSF1A* 12p13	p55 TNF receptor	AD	Prolonged fever episodes: 1–3 weeks
					Periorbital edema, monocytic fasciitis
					Incidence of renal amyloidosis: 15–25%
					Response to TNF- and IL-1 blockade
NALPs-related diseases	FCAS, MWS, CINCA	*CIAS1/NALP3* 1q44	Cryopyrin	AD	FCAS: rash, fever, and arthralgia after cold exposure
					MWS: recurrent or sub-chronic urticaria-like lesions, sensorineural hearing loss, amyloidosis
					CINCA: as above + mental retardation, chronic aseptic meningitis, and bone deformities
					Good response to IL-1 blockade
	NALP12-associated periodic fever	*NALP12 19p13*	NALP12	AD	Periodic fever after cold exposure, hearing loss
Granulomatous disorders	Blau's syndrome	*CARD15/ NOD2* 16q12	CARD15	AD	Early onset (<5 years)
					Polyarticular granulomatous arthritis, uveitis, skin rash
					Good response to anti-TNF monoclonal antibodies
Pyogenic disorders	PAPA syndrome	*PSTPIP1* 15q24–q25.1	PSTPIP1	AD	Pyogenic sterile arthritis, pyogenic gangrenosum, Cystic acne. Good response to IL-1 blockade
	Majeed's syndrome	*LPIN2* 18p	LPIN2	AR	Multifocal osteomyelitis, congenital dyserythropoietic anemia, inflammatory dermatosis
	DIRA	*IL1RN* 2q	IL1 receptor antagonist	AR	Neonatal-onset multifocal osteomyelitis, periostitis, and pustulosis. Dramatic response to Anakinra

FCAS familiar cold autoinflammatory syndrome, *MWS* Muckle–Wells syndrome, *CINCA* chronic infantile neurological cutaneous and articular syndrome, *PAPA* pyogenic sterile arthritis, pyoderma gangrenosum and acne (PAPA) syndrome, *CRMO* chronic recurrent multifocal osteomyelitis, *DIRA* deficiency of the interleukin-1-receptor antagonist, *AR* autosomal recessive, *AD* autosomal dominant

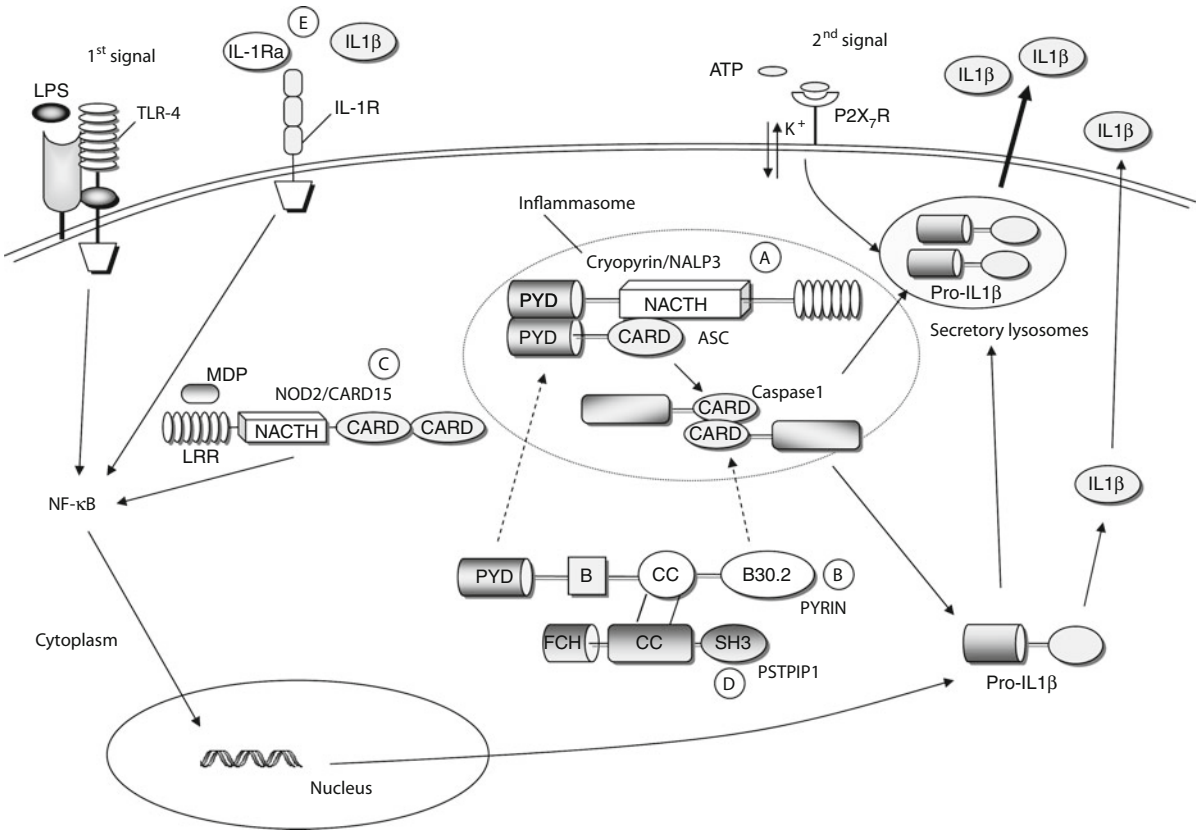

Figure 170.1

Schematic representation of the functional role of genes involved in autoinflammatory diseases in the control of NF-kB activation and IL1β secretion. (a) Role of Cryopyrin (NALP3) in the activation of Inflammasome and induction of IL-1β secretion. Toll-like receptor ligands, such as LPS, are the first signal for gene expression and synthesis of the inactive IL-1βprecursor (pro-IL-1β). A second stimulus, such as exogenous ATP, strongly enhances proteolytic maturation and secretion of IL-1β. After stimulation, NALP3 oligomerizes becoming available for the binding of the adaptor protein ASC (Apoptosis associated Speck-like protein containing a CARD). This association activates directly two molecules of Caspase-1 which, in turn converts pro-IL-1β to the mature, active 17 kDa form. (b) Role of Pyrin in the regulation of Inflammasome activation. Marenostrin/pyrin modulates the inflammasome by interacting with both ASC and Caspase-1 with the pyrin and SPRY domains, respectively (see also text). (c) CARD15/NOD2 is an intracellular sensor for pathogen-associated molecular patterns, such as MDP (muramyl dipeptide). After stimulation NOD2/CARD15 is able to induce both NF-κB activation and the release of bioactive IL-1β in a Caspase 1 dependent-manner. (d) PSTPIP1 binds to pyrin. Disease-associated mutations in PSTPIP1 enhance pyrin binding forming a trimolecular complex with ASC. (e) The binding of IL-1β with type I IL-1 receptor (IL-1R1) lead to a proinflammatory response via the activation of NF-kB pathway. The IL-1 receptor antagonist (IL-1ra) acts as a natural inhibitor of IL-1β activity by competing for binding to IL-1R1

a CARD). This association activates directly two molecules of Caspase-1 which, in turn converts pro-IL-1β to the mature, active 17 kDa form (*Fig. 170.1*). Mutations in the *cryopyrin* gene in humans are associated with its gain of function that lead to an excessive production of IL-1β even in absence of a second signal, such as extracellular ATP.

Clinical Picture

FCAS is characterized by urticarial rash and fever spikes of short duration (usually <24 h) induced by cold exposition. Arthralgia and conjunctivitis are also common. Muckle–Wells syndrome is characterized by recurrent episodes of urticaria and fever that may develop in the early

infancy. The fever episodes can be associated with arthralgia, conjunctivitis, and drowsiness and are not strictly evoked by cold exposure. Acute phase reactants are elevated during fever episodes and may persist slightly increased also during free intervals. During the course of the disease, neurosensorial deafness may develop. Amyloid A (AA) amyloidosis is a complication of the late stage of the disease.

CINCA represents the more severe phenotype associated with mutations of *NALP3* gene. An urticaria-like rash may develop during the first weeks of life (Fig. 170.2a). Many affected individuals present typical "facies" characterized by frontal bossing, saddle back nose, and midface hypoplasia, causing a sibling-like resemblance (Fig. 170.2b). Bone involvement is another characteristic hallmark of the disease. The most characteristic features are represented by bony overgrowth that predominantly involves the knees (including the patella) and the distal extremities of hands and feet. A chronic inflammatory polyarthritis may be also present, sometime leading to bone erosions. Central nervous system (CNS) manifestations include chronic aseptic meningitis, increased intracranial pressure, cerebral atrophy, ventriculomegaly (Fig. 170.2c), sensorineural hearing loss, and chronic papilledema, with associated optic-nerve atrophy and loss of vision. Mental retardation and seizures have also been reported. Patients display a persistent elevation of acute phase reactants, leukocytosis, and chronic anemia.

Treatment

The pivotal role of Cryopyrin in the control of Caspase 1 activation and the massive secretion of active IL-1β observed in cryopyrin-mutated individuals, suggested that anti-IL-1 treatment could represent an effective therapy. Initial isolated case reports suggested that the recombinant IL-1 receptor antagonist (Anakinra) has a dramatic effect on the control of rash and constitutional symptoms in FCAS and Muckle–Wells patients. These findings have been confirmed in different studies on CINCA patients.

Anakinra is given at a starting dosage of 1 mg/kg/day s.c. Soon after the first injections, patients displayed a prompt normalization of acute phase reactants with a dramatic improvement of urticarial rash, arthritis, headache, and fever with a complete resolution within 1 week from the beginning of the treatment. Improvement of hearing loss after Anakinra treatment has been described in up to 30% of CINCA patients. Recently, the use of other IL-1 blockers characterized by a longer half-life, such as IL-1 trap (Rilonacept) and IL-1 monoclonal antibody (Canakinumab), has shown the same preliminary excellent results at least in FCAS and MWS patients.

NALP12-Associated Periodic Fever Syndrome

This new disorder was firstly described in two families originating from Guadeloupe presenting a clinical phenotype characterized by recurrent fever episodes associated with arthralgias, myalgias, and abdominal pain. A particular sensitivity to cold as a trigger factor for the clinical manifestations has been reported in most of the cases so far described. Urticarial rash, recurrent oral ulcers, and neuronal hearing loss have been also reported. Little information is so far available on the response to treatment.

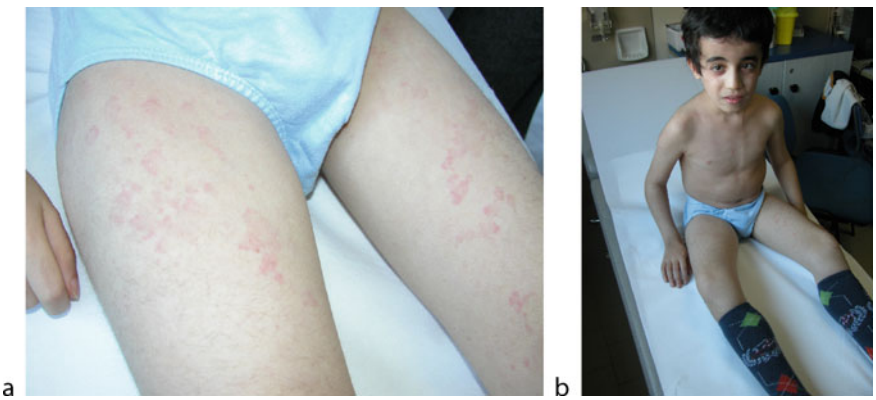

Figure 170.2
Clinical manifestations in CINCA patients: (a) urticarial rash; (b) typical facies characterized by frontal bossing and midface hypoplasia

The NALP12 protein has been identified as an important regulator of the inflammatory response, in particular, it acts as a negative regulator by suppressing both canonical and noncanonical NF-kB activation and subsequent production of proinflammatory cytokines and chemokines.

Mutations in *NALP12* gene have been associated with a defective regulatory function of the protein. However, further studies are needed to better clarify the actual pathogenic impact of mutations of this protein in affected patients.

The Periodic Fevers

Familial Mediterranean Fever (FMF)

Familial Mediterranean fever is the most frequent among hereditary recurrent inflammatory disorders. This disease mainly affects populations originating from the eastern part of the Mediterranean basin: Armenians, Turks, Non-Ashkenazi and other Jews, Arabs. A much lower prevalence is observed in Greece, Southern Italy, and even in Japan. Among Armenians, non-Ashkenazi Jews, and Turks, the frequency of heterozygotes in the general population is greater than one fifth. In 1997, the gene associated with FMF was cloned by two parallel International consortia and called *MEFV* (for MEditerranean FeVer) coding for a protein called pyrin or marenostrin. To date, more than 70 MEFV mutations have been recorded (http://fmf.igh.cnrs.fr/infevers/). In the ethnic groups in which FMF is endemic, 80–90% of the mutations are localized in exon 10. In particular, five founder molecular alterations, V726A, M694V, M694I, M608I in exon 10, and E148Q in exon 2, account for 70–80% of cases.

Pathogenesis

The Pyrin protein is made by a number domains that play an important role in its function. The pyrin domain is a specific domain of 90 amino acids located in the N-terminal region and is able in interact with the ASC protein involved in the Inflammasome by homotypic pyrin domain binding. A second pivotal domain is called B30.2 (or SPRY) and is located in the C-terminal region of the protein, where the most frequent mutations associated with FMF are located. The B30.2 interacts directly with Caspase-1 modulating the IL-1β production. Recent works suggest that marenostrin/pyrin modulates the inflammasome by interacting with both ASC and Caspase-1 with the pyrin and SPRY domains (*Fig. 170.1b*).

Clinical Picture

Even if a disease onset in adulthood can be observed, most patients begin to suffer of fever attacks since during childhood. Fever episodes have a short duration (1–3 days) and often associated with acute inflammation of the serosa with severe abdominal pain due to aseptic peritonitis and/or chest pain due to pleuritic involvement. Joint involvement is frequent and characterized by an asymmetrical and nondestructive oligo- or mono-arthritis, that most commonly involves hip, knee, or ankle. An erysipelas-like erythema on the lower part of the legs (ankle and the dorsum of the foot) is not frequent, but is highly suggestive for the disease. Myalgia may be observed during fever episodes. Neutrophilia and elevated erythrocyte sedimentation rate are typically associated with fever attacks.

Amyloid A (AA) type amyloidosis is the most severe long-term complication of FMF. The most common clinical manifestation of amyloidosis is the development of proteinuria and may lead to renal failure. Renal involvement is usually observed after a variable time from disease onset (phenotype-I). In some rare patients (less than 1%), renal amyloidosis may represent the first manifestation of the diseases (phenotype-II).

Treatment

Colchicine is the treatment of choice for FMF. The adult dose is 1 mg/day and, in nonresponsive patients, it can be increased to 2 mg. In children, the starting dose should be $\leq$0.5 mg/day for children below 5 years of age, 1 mg/day (5–10 years) and 1.5 mg/day (>10 years). Dosage can be increased in a stepwise fashion up to a maximum of 2 mg/day. The use of colchicine has dramatically reduced the incidence of amyloidosis. However, poor compliance to treatment (mainly due to gastrointestinal side effects, such as nausea and diarrhea) is one of the major causes of treatment failure.

Periodic Fever Associated with Mevalonate Kinase Deficiency

Periodic fever associated with mevalonate kinase deficiency (MKD) was originally identified in 1984 in six patients of Dutch ancestry with a long history of recurrent attacks of fever of unknown cause and a high serum IgD level. High IgD plasma levels have been used as a diagnostic hallmark until mutations in the mevalonate kinase (*MVK*) gene, encoded on chromosome 12q24, were

identified as the cause of the disease. The complete deficiency of this enzyme causes a distinct syndrome called mevalonic aciduria (MA), which is clinically characterized by severe mental retardation, ataxia, failure to thrive, myopathy, and cataracts; notably, these patients also suffer from recurrent fever attacks.

Pathogenesis

MVK is an essential enzyme in the isoprenoid biosynthesis pathway which produces several biomolecules involved in different cellular processes. Although the dysregulation of this biochemical pathway seems to play a pivotal role in the developing of fever, at present the pathogenetic mechanisms leading to the autoinflammatory disease remain still poorly understood. Cells from patients with the MKD phenotype still contain residual MVK enzyme activities (from 1% to 8% of the activities of control cells), while in cells from patients with the MA phenotype the MVK enzyme activity is below the detection level (approximately 0.1% of normal individuals). Recent in vitro studies have shown that shortage of non-sterol isoprenoid end products, mainly the geranylgeranyl groups, lead to an increased activation of Caspase 1 in circulating monocytes with a consequent hypersecretion of the 17 kDa active form of IL-1β.

Clinical Picture

Disease onset occurs very early in life. Fever attacks have an abrupt onset and last 4–6 days. Severe abdominal pain often accompanied by vomiting and/or diarrhea is frequently associated with fever attacks. Cervical lymphadenopathy is common. Splenomegaly is observed during fever attacks in about half of patients. Mucocutaneous manifestations are frequent and include erythematous macules, urticaria-like lesions and, less commonly, oral aphthous lesions. Articular involvement occurs in the majority of patients as arthralgia or as an oligoarticular arthritis.

The symptoms of MKD persist for years, but usually tend to become less prominent with time. However, in some patients, the disease may progress toward adulthood. Even if amyloidosis was not considered as a possible long-term complication of MKD, it has been recently described in rare patients.

Increased plasma levels of IgD (>100 UI/ml) during fever episodes and in basal conditions have been considered in the past as a hallmark of the disease. However, the specificity of this finding is low. An increased urine excretion of mevalonic acid is observed during fever spikes and decreased MVK activity may also orientate toward the diagnosis.

Treatment

Fever attacks usually respond dramatically to the administration of steroids (prednisone: 1 mg/kg/day in a single dose). However, due to the high frequency of the fever episodes, some patients may need almost continuous treatment. The use of biologic treatments is largely anecdotal and sometimes controversial. Anti-TNF therapy has been found to reduce the frequency and intensity of fever attacks in some patients, but not in others. Recently, the use of the IL-1 receptor antagonist (Anakinra) was found to be effective in sporadic patients.

The TNF-Receptor-Associated Periodic Syndrome (TRAPS)

The name TRAPS refers to the protein affected by the mutation in this disease: TNF receptor superfamily type 1A (*TNFRSF1A*). Even though TRAPS has been initially described in subjects of Nordic origin, as emphasized by the name of Familial Hibernian Fever, mutations in *TNFRSF1A* have now been found in many populations, including Black Americans, Japanese, and also along the Mediterranean basin.

Pathogenesis

In most of the patients, plasma concentrations of the soluble form of the receptor are low or paradoxically normal during attacks. This suggests a quantitative or qualitative abnormality of the soluble form of the receptor. In fact, the shedding of free TNFRs from the membrane produces a pool of soluble receptors that may scavenge circulating TNF by competing with membrane bound receptors (*Fig. 170.3*). This latter phenomenon represents an important strategy for the regulation of the effect of circulating free TNF during acute inflammation. At variance with the other, p75 receptor, p55 TNFR is also able to induce cell apoptosis, via activation of the caspases cascade trough the induction of the so-called Complex II (*Fig. 170.3*). It has been shown that neutrophils from TRAPS display a clear defect in the activation of Complex II and, therefore, a resistance of TNF-induced

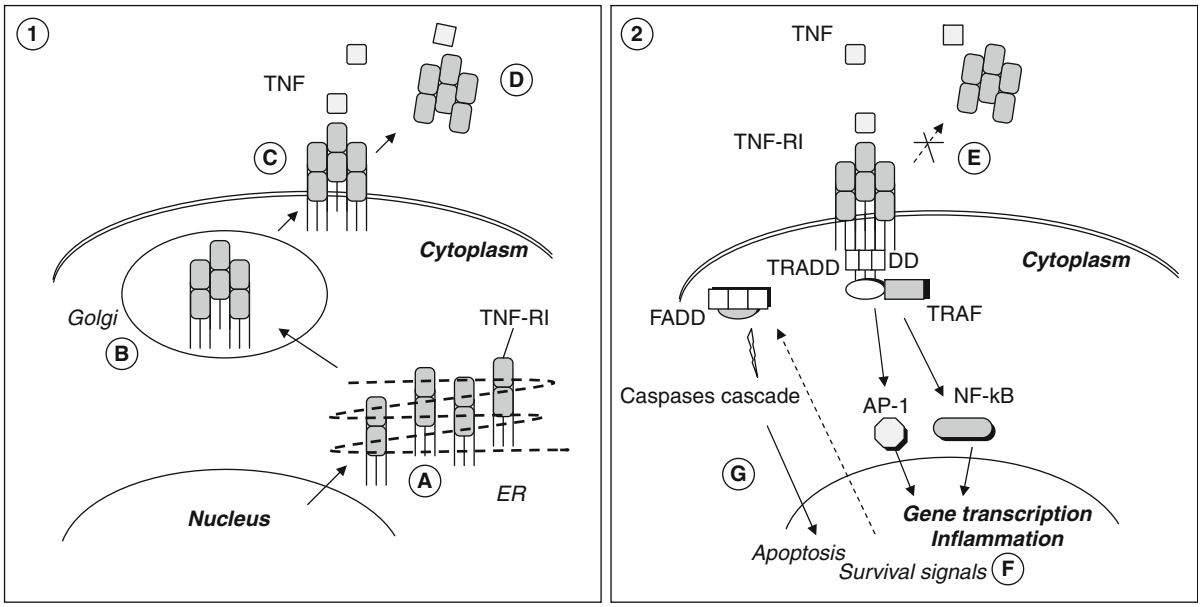

Figure 170.3

Physiopathology of TRAPS syndrome Panel (1). The TNFR1 molecules are transported from endoplamic reticulum (ER) (a) to the Golgi, where they are pooled, (b) before going on to the surface as a trimer (c). When TNF binds to the cell surface TNFR1 trimer, intracellular signalling results in NF-κB activation (Complex I). A defect of trafficking of mutated TNFR1 has been postulated. Upon activation, cell surface receptors are cleaved off by metalloproteinase to buffer the circulating TNF (d). Panel (2) Some TNFRSF1A mutations may interfere with the process of shedding, leading to a lack of appropriate TNF inhibition and therefore to uncontrolled inflammation (e). TNFRSF1A is also able to induce cell apoptosis, via activation of the caspases cascade (Complex II). During cell activation, Complex II is inhibited by the expression of anti-apoptotic factors produced through the activation of the NF-kB pathway (f). When the NF-κB activity subsides, the pro-apoptotic signals inducible by the intracellular p55 TNFR complex lead to cell death (g). Neutrophils from TRAPS display a clear defect in the activation of Complex II and, therefore a resistance of TNF-induced apoptosis

apoptosis. This defect may represent an additional mechanism explaining the sustained activation of inflammatory cells during fever episodes. Additional insights came from the study of transfected cells with the mutant form of the TNFRI protein, showing a defect of trafficking of the mutated TNFRI to the cell membrane with an accumulation of the protein in the endoplasmic reticulum (*Fig. 170.3*). The possible pathogenic consequences of ER retention of mutated TNFR1 are matter of intensive investigations by several groups.

Clinical Picture

TRAPS attacks last longer than in FMF, generally more than 5 days and up to 3 weeks, even though attacks shorter than 5 days have been reported. Abdominal pain can simulate a surgical event. Skin manifestations are present in more than three fourths of the cases. A wide spectrum of rashes can be observed: urticaria-like, plaques, and patches. The most distinctive lesion is an erythematous, swollen, warm, and tender plaque of various sizes with hazy edges (*Fig. 170.4*). It rather involves the upper and lower limbs, but can be observed at the chest. Usually, the rash has a migratory course from the root to the extremity of the limbs. This pseudo-cellulitis is often accompanied by painful myalgias and constitutes the other most distinctive manifestation of TRAPS attacks. Thoracic, scrotal pain, arthritis, orbital edema, and conjunctivitis are also observed in TRAPS attacks.

Treatment

Corticosteroids, when given at the onset of an attack, can attenuate the length and the severity of it. In the most

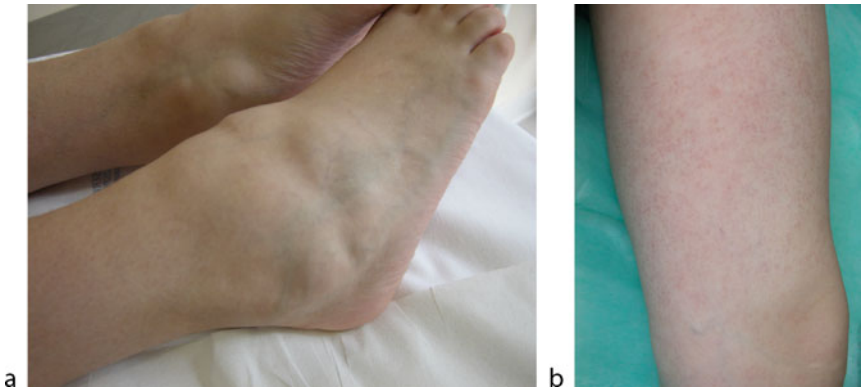

Figure 170.4
Clinical manifestations in a Blau's patient. Typical "boggy" synovitis (a) and tan-colored, scaly, ichthyosiform rash (b) in a 5-year-old girl

severe forms of the disease, clinical signs of inflammation are almost permanent and require daily use of corticosteroids, and may lead to dependency, requiring the use of other anti-inflammatory drugs. TNF inhibitors seem designed as treatment of TRAPS. Etanercept and other TNF inhibitors have provided various degrees of clinical improvement and allowed to spare steroids. Notably, a paradoxal reaction with exacerbation of the inflammatory signs has been observed after the administration of anti-TNF monoclonal antibody (Infliximab) in some TRAPS patients. A persistent response to IL-1 blockade (Anakinra) has also been recently observed.

The PFAPA (Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis) Syndrome

PFAPA was first described by Marshall et al. in 1987. The disease usually develops before 5 years of age. It is characterized by fever spikes of abrupt onset lasting 3–6 days; fever recurs regularly (sometime with a clockwise periodicity) every 2–6 weeks. Children with PFAPA syndrome appear often in good conditions also during the fever spikes. The aphthous lesions observed in PFAPA are small and localized to labial gingival and are rapidly self-remitting. Cervical lymph node enlargement is frequent (and may be relevant); enlarged lymph nodes are tender and normalize with the resolution of the fever attack. Typically, fever attacks dramatically respond to a single dose of steroids (betamethasone: 0.1 mg/kg). The disease has a benign course and tends to spontaneously remit with time. Although some anecdotal familial cases of PFAPA have been reported, no documented genetic basis has been so far identified.

Granulomatous Disorders

Blau Syndrome

Blau syndrome (see also ❯ Chap. 172, "Sarcoidosis"), or familial juvenile systemic granulomatosis, is an autosomal-dominant disease characterized by a noncaseating granulomatous inflammation affecting the joint, the skin, and the uveal tract (the triad of arthritis, dermatitis, and uveitis). The gene responsible for Blau syndrome, *NOD2/CARD15*, encodes a protein containing a NACHT domain. NOD2/CARD15 recognizes muramyl dipeptide (MDP), the minimal motif of peptidoglycan of both Gram-positive and Gram-negative bacteria. After stimulation with MDP, NOD2/CARD15 is able to induce both NF-kB activation and the release of bioactive IL-1β in a Caspase 1 dependent-manner (❯ *Fig. 170.4*). Notably, mutations of the LRR domain of the same gene are associated with another chronic granulomatous disease, such as Crohn's Disease.

Disease onset is usually observed during the first years of life. A symmetrical polyarticular arthritis with a typical pattern of boggy synovitis is the typical joint manifestation. A typical tan-colored, scaly, ichthyosiform rash is seen in almost 90% of the affected individuals (❯ *Fig. 170.4*). Eye involvement is characterized by intermediate uveitis or panuveitis. Fifty percent of the patients with ocular involvement develop cataracts, and approximately one third may undergo into secondary glaucoma.

Patients are treated with oral steroids and immunosuppressive drugs (methotrexate, cyclosporin A) with variable results. Recent anecdotal reports suggest a beneficial effect of anti-TNF (Infliximab) and anti-IL-1 treatment.

Pyogenic Disorders

PAPA Syndrome

Pyogenic Sterile Arthritis, Pyoderma Gangrenosum, and Acne syndrome (PAPA, MIM 604416) is a disorder caused by mutations of gene coding for the CD2-binding protein 1 (*CD2BP1*), or *PSTPIP1*. PSTPIP1 protein has been shown to bind pyrin (Fig. 170.1), and it is postulated that the increased pyrin binding seen with the PAPA mutations may alter inflammatory susceptibility. The manifestations of this disorder are pyogenic gangrenosum, cystic acne, and pyogenic sterile arthritis which represents the most common symptom of the disease. An oligoarticular arthritis has its onset in early childhood and is characterized by recurring inflammatory episodes that resembles septic arthritis leading to accumulation of sterile pyogenic, neutrophil-rich material within the affected joints, which ultimately results in significant synovial and cartilage destruction. Dermatologic manifestations are also episodic and recurrent and are characterized by debilitating, aggressive, ulcerative skin lesions, usually of the lower extremities, undistinguishable from pyogenic gangrenosum. Sterile abscesses at injection sites may also be observed. PAPA syndrome has been reported to be generally responsive to oral glucocorticoids. Anecdotal reports have shown the possible efficacy of anti-TNF and anti-IL-1 treatment.

The Majeed's Syndrome

In 1989, three related Arab children presenting an association of chronic recurrent multifocal osteomyelitis (CRMO), congenital dyserythropoietic anemia, and inflammatory dermatosis were described by Majeed and coworkers.

Unlike isolated CRMO, bone manifestations has an earlier age at onset, more frequent episodes, shorter and less frequent remissions, and is probably lifelong. Congenital dyserythropoietic anemia is characterized by microcytosis both peripherally and in the bone marrow, which may need repeated blood transfusions. Inflammatory dermatosis may vary from a Sweet syndrome to chronic pustulosis. In 2005, a linkage analysis was performed on two Jordan families allowing the identification of the *LPIN2* gene mapped on chromosome 18p.

DIRA (Deficiency of the Interleukin-1-Receptor Antagonist)

DIRA is a recently identified autosomal recessive autoinflammatory syndrome, due to the deficiency of the interleukin-1-receptor antagonist secondary to truncating mutations of the *IL1RN* gene. As a result of these mutations, no interleukin-1-receptor antagonist protein is secreted, which inhibits the proinflammatory cytokines interleukin-1 and interleukin-1β. The disease begins around birth with multifocal osteomyelitis, periostitis, and pustulosis. Persistent elevation of acute phase reactants (ESR and CRP) is observed since birth. The skin manifestations range from groupings of small pustules to a generalized pustulosis. The bone manifestations include osteolytic lesion with a sclerotic rim, epiphyseal ballooning of multiple distal and proximal long bones, widening of ribs and clavicles, heterotopic ossification or periosteal cloaking of the proximal femoral metaphysis, and periosteal elevation of the diaphysis. The patients show a dramatic response to the substitutive treatment with recombinant IL-1 receptor antagonist (Anakinra).

171 Behçet's Disease

Isabelle Koné-Paut · Tu-Anh Tran

Definition, Classification

Behçet's disease (BD) is a multisystem recurrent inflammatory disorder usually grouped into vasculitic syndromes, and initially reported in 1931 by Adamantiades in the French literature as one case of relapsing hypopion, then by Huluci Behçet in 1937 under the association of bipolar aphthous lesions plus uveitis. Involvement of medium- and great-sized vessels leads to serious neurological and ocular damage and also to patient's death by pulmonary or cardiac complications. BD encompasses a number of clinical manifestations classically distinguished between major and minor in accordance to their severity and frequency (*Table 171.1*). Most of them are self-limited, but some of them like genital ulcers and eye lesions may cause permanent tissue damage. Most commonly used diagnostic criteria have been proposed by an International Study Group in 1990, but they are not applicable for every patient especially pediatric ones.

Etiology/Pathogenesis

BD appears as a polyfactorial disease where the participation of the innate immunity, environmental factors, as well as inflammatory responses abnormalities could play a pivotal role. Ubiquitous microbial pathogen and heat-shock proteins may stimulate the innate immune system of BD patients through Toll-like receptors, especially TLR2 and TLR4. The involvement of pathogens in individuals with genetic susceptibility is widely believed in BD, especially in those carrying the HLAB51 tissue antigen. The association of the HLAB51 with BD reaches 40–80%, in countries where the disease is prevalent. The genetic hypothesis is for a long time suspected because of the peculiar geographic distribution of BD and the occurrence of familial cases (2–10%), and increased in pediatric BD. Several susceptibility loci were identified by genome-wide studies in BD multicase Turkish families. Several autoinflammatory genes could also influence the phenotype of BD.

Epidemiology

BD is reported elsewhere; however most cases cluster from Japan to Mediterranean basin along the former Silk Route. The usual age for the disease is 30–40 years but the disease may start and may be completed before the age of 16 years. BD affects more frequently males in Mediterranean countries but more frequently females in Japan and Korea.

Pathology

BD lesions evidence a mixed immunologic pattern, that is, increased and deregulated nonspecific inflammatory responses with organ mononuclear cell infiltration suggesting an autoinflammatory mechanism as well as specific antigen-driven responses with oligoclonal T-cells expansion running in parallel with disease exacerbation which more likely is associated with autoimmune mechanisms. Activated mononuclear cells secrete pro-inflammatory cytokines: IL-1, IL-6, TNF-α, GMCSF, and IL-8 activating and attracting granulocytes in skin lesions. Neutrophils express activation receptors, adhesion molecules, and chimiokines receptors (CXCR2) producing an excess of free radicals and having increased phagocytosis. T lymphocytes from BD patients secrete TH1-polarized cytokines spontaneously. Activated NK cells, CD8+ lymphocytes, and $\gamma\delta$ T are increased in patient's sera but also infiltrate the inflamed sites. Circulating endothelial cells and elevated markers of endothelial activation reflect vascular injury, also one major trait of BD. Both endothelial alteration and hypercoagubility state contribute to vasculitis and vascular occlusion

Clinical Manifestations

Recurrent oral aphthosis (ROA) is the initial manifestation of 70–90% of pediatric BD. Lesions may involve any part of the oral mucosa including lips and usually disappear without scarring. Genital lesions are generally painful, and located on the vulva or scrotum. Other locations

Retinal vasculitis		Arterial/venous thrombosis	
Skin lesions	(80)	Gastrointestinal lesions	(0–25)
Erythema nodosum	(45)	Cardiovascular lesions	
Folliculitis/acne	(70)	Pleuropulmonary lesions	
Pathergy test		Epididymitis	(8)

on penis and in the perianal area occur more likely in childhood than in adult BD. The presence of scar is remarkable and is a useful clue for eventual retrospective evaluation. Other causes of ROA are common in childhood and must be ruled out as possible. Children with ROA alone that increases in severity with time justify careful follow-up, while other BD symptoms may appear secondarily. Acneform, folliculitis-like, and papulopustular lesions onto the lower extremities are the most common skin lesions often occurring in combination. Sweet's syndrome like lesions, pyoderma gangrenosum, and necroziting vasculitis are more exceptional. The hyperreactivity of skin to intracutaneous injection or needle prick, known as pathergy, considered as a key feature BD, is less commonly observed in pediatric BD than adult BD. Posterior or total uveitis, frequently bilateral accompanied with retinal vasculitis, macular edema, and papillitis are the most typical of BD. The course may be very severe, especially in male patients, with definite impairment of visual acuity secondary to optic atrophy. Anterior uveitis with hypopion is classical but rarely observed. Neuro-BD includes encephalomyelitis, aseptic meningitis, benign intracranial hypertension, and organic psychiatric disturbances. Cerebellar signs, pyramidal and extrapyramidal syndrome, spinal cord involvement, pseudobulbar syndrome, and epilepsy reveal encephalomyelitis. These features are not specific and look like multiple sclerosis especially if they are the first manifestation of BD (5% of cases). Joint problems in BD are usually minor, limited to few joints (knees, ankles, elbows, and wrists), and run acute and recurrent course. Venous thrombosis is a predominant feature of BD even if not part of the international criteria. Involvement of the lower extremities: tibial, femoral, and iliac vessels are the most common. Vasculitis of pulmonary arteries leads to aneurysm and thrombus formation and frequently to the patient death.

Diagnosis, International Criteria

In the absence of pathognomonic feature, the diagnosis is made according to the international criteria (Lancet 1990). Recurrent oral ulceration (at least three times a year and observed by a physician) is mandatory. This criterion must be associated with two signs among genital ulceration, skin lesions – erythema nodosum, papulopustular lesions, pseudo folliculitis, eye lesions – posterior or total uveitis, retinal vasculitis, and positive pathergy test (pustula with surrounding erythema at 24–48 h following intradermal 24-gauge needle prick or saline injection).

Treatment

Steroids and immunosuppressive drugs are still currently used for treatment of serious manifestations. Azathioprine is convenient for use in children with good tolerance. A daily dose of 2 mg/kg is effective to control and prevent eye disease, genital ulcers, and thrombophlebitis. Severe aphthosis may be responsive to thalidomide but side effects are frequent as well as the development of polyneuropathy. Daily colchicine (1–2 mg/day) is commonly used as disease-modifying drug; however only two placebo-controlled studies have shown its efficacy in preventing oro/genital ulcers, skins lesions, and arthritis. Interferon α may improve steroid-dependant uveitis with few experience in children. They also control mucous and

papulopustular lesions. More specifically targeted biologic therapies against TNF and IL-1 will progressively overstep immunosuppressive treatments. Treatment of thromboses with anticoagulants is controversial, while BD-thrombus is adherent with no risk for embolism. Moreover, the use of anticoagulants could favor bleeding into vascular aneurysm.

Prognosis

The disease course is unpredictable but more severe in males than females. The eye and brain involvement are responsible for chronic morbidity and severe disability (blindness, dementia, and pseudobulbar syndrome). The mortality is related to vascular complications.

Prevention

Daily colchicine may prevent mucous/skin lesions and eye disease and low dose aspirin may prevent BD thromboses.

172 Sarcoidosis

Carlos D. Rose · Carine H. Wouters

Definition and Classification

The term Pediatric Sarcoidosis encompasses a spectrum of granulomatous inflammatory conditions of childhood of which the pathologic hallmark is the presence of non-caseating epithelioid and giant cell granulomas in a variety of tissues and organ systems.

Blau Syndrome (BS) and *Early Onset Sarcoidosis* (EOS) constitute, respectively, the familial and sporadic forms of a pediatric autoinflammatory disease characterized by a clinical triad of polyarthritis, uveitis, rash, and a unique association with mutations of the *NOD2* gene. The term *Pediatric Granulomatous Arthritis* (PGA) has been proposed to refer to both.

A large number of children with sarcoidosis are *NOD2* mutation negative and tend to exhibit systemic and visceral manifestations at presentation. Within this group, a distinct entity named *Infantile Onset Panniculitis with Uveitis and Systemic Granulomatosis* has been identified recently.

The adult form of sarcoidosis, characterized mainly by pulmonary involvement and hilar adenopathy, can rarely be seen at the pediatric age, especially in older children; for this subset the authors have proposed the term "*Childhood Onset Adult Sarcoidosis*."

Etiopathogenesis

BS and EOS are part of the hereditary autoinflammatory diseases, characterized by an autosomal dominant inheritance pattern, and strongly associated with mutations in the central NOD/NACHT domain of the *NOD2* protein. These mutations are not found, however, in other forms of pediatric sarcoidosis which display a more heterogeneous phenotype, nor are they found in adult sarcoidosis.

The NOD2 protein is a member of a family of NOD-like receptor cytosolic proteins comprising different functional domains and implicated in pathways of inflammation and apoptosis. The two amino-terminal CARD domains of NOD2 have a role in the mediation of NF-κB activation and secretion of pro-inflammatory cytokines. The central NOD domain mediates self-oligomerisation of NOD2 proteins and activation of downstream effector molecules. The LRR region is important in the "sensing" of molecular motifs specific to pathogens, such as lipopolysaccharide.

The pathologic hallmark of sarcoidosis is the presence of non-caseating epithelioid granulomas in affected tissues/organs. The granulomas consist of a central cluster of monocytes/macrophages, epithelioid cells, and multinucleated giant cells, surrounded by a corona of lymphocytes.

Epidemiology

An overall incidence of sarcoidosis in children of 0.29/100,000/year, ranging from 0.06/100,000/year for children below 5 years to 1.02/100.000/year for children 14–15 years, has been estimated.

Clinical Manifestations

Sarcoidosis Associated with *NOD2* Mutation (BS/EOS)

BS/EOS most often presents during the first years of life with a characteristic tan-colored, scaly, fine papular rash. A symmetrical polyarthritis involving large and small joints with exuberant "boggy" synovial and tenosynovial swelling and relatively preserved range of motion is typical; clinodactyly results from contractures of the flexor tendons of the digits. Ocular involvement consists of an insidious granulomatous iridocyclitis and posterior uveitis and can evolve into a severe destructive panuveitis see (*Fig. 172.1*).

More recently, a myriad of clinical manifestations beyond the clinical triad, including prolonged fever, granulomatous and interstitial nephritis, vasculitis, severe hypertension, interstitial pneumonitis, peripheral and mediastinal lymphadenitis, pericarditis, cranial neuropathy, and parotitis have been documented.

Sarcoidosis Without *NOD2* Mutation

Sarcoidosis with wild-type *NOD2* constitutes a heterogeneous group of granulomatous inflammatory disorders, in which some distinct subsets can be identified.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_172,

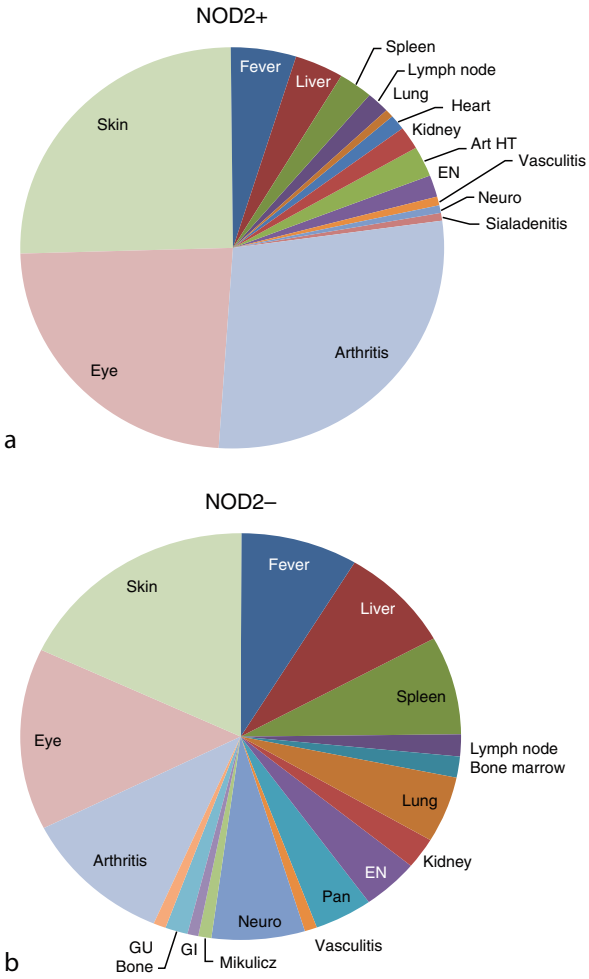

Figure 172.1
Cumulative clinical manifestations in 75 patients with pediatric sarcoidosis recruited through the International PGA Registry. (a) The large majority of patients with *NOD2* associated sarcoidosis display a clinical triad with skin, joint, and eye involvement, although incomplete forms and extended manifestations exist. (b) A large heterogeneity of clinical manifestations is typical of sarcoidosis with wild-type *NOD2*

Infantile onset Panniculitis with Systemic Granulomatosis is characterized by severe systemic inflammation with lobular panniculitis from infancy, progressive widespread granulomatous infiltration affecting joints, eyes, internal organs and central nervous system, and a potentially fatal course.

A review of published clinical manifestations of *Childhood onset Adult Sarcoidosis* reveals a relatively high frequency of systemic features (malaise, fever, weight loss), lung involvement, hilar and peripheral lymphadenopathies at presentation compared to adults. Hepatomegaly and splenomegaly are often seen; mild elevation of liver enzymes is common. Cutaneous manifestations include erythema nodosum, erythematous macules, papules, and plaques (Fig. 172.2) left. Uveitis is the most common ocular manifestation. Neurological manifestations mostly indicate central nervous system involvement (seizures, hypothalamic dysfunction). Renal involvement, mainly a tubulo-interstitial nephritis, most commonly manifests with decreased creatinine clearance and hypercalciuria. Some particular presentations rarely observed in older children include Löfgren's syndrome (arthritis, erythema nodosum and hilar adenopathy) and Mickulicz syndrome (parotid and lacrimal gland involvement) (Fig. 172.2) right.

Diagnosis

There is no laboratory test diagnostic of sarcoidosis. The ESR and acute phase reactants may reflect disease activity. Peripheral blood cell counts may show mild anemia, leucopenia, or lymphopenia. Hypergammaglobulinemia is often present, but autoantibodies are absent. Elevation of angiotensin converting enzyme (ACE) is not consistent and the value of serum ACE levels in sarcoidosis remains controversial. Hypercalciuria and hypercalcemia can lead to nephrocalcinosis and nephrolithiasis.

The diagnosis is confirmed by the finding of characteristic non-caseating epithelioid and giant cell granulomas which can be documented in biopsies of any involved organ/tissue.

The frequencies of *NOD2* mutation among sarcoidosis patients exhibiting the clinical triad of dermatitis, arthritis, and uveitis vary between 50% and 98%.

Differential Diagnosis

The diagnosis of sarcoidosis in a child requires the exclusion of other causes of granulomatous inflammation including primarily chronic infections by mycobacteria and fungi, but equally primary immunodeficiency disorders (Chronic Granulomatous Disease, Common Variable Immune Deficiency), and systemic inflammatory diseases such as granulomatous vasculitides (Wegener's Granulomatosis, Churg-Strauss syndrome) and Crohn's disease.

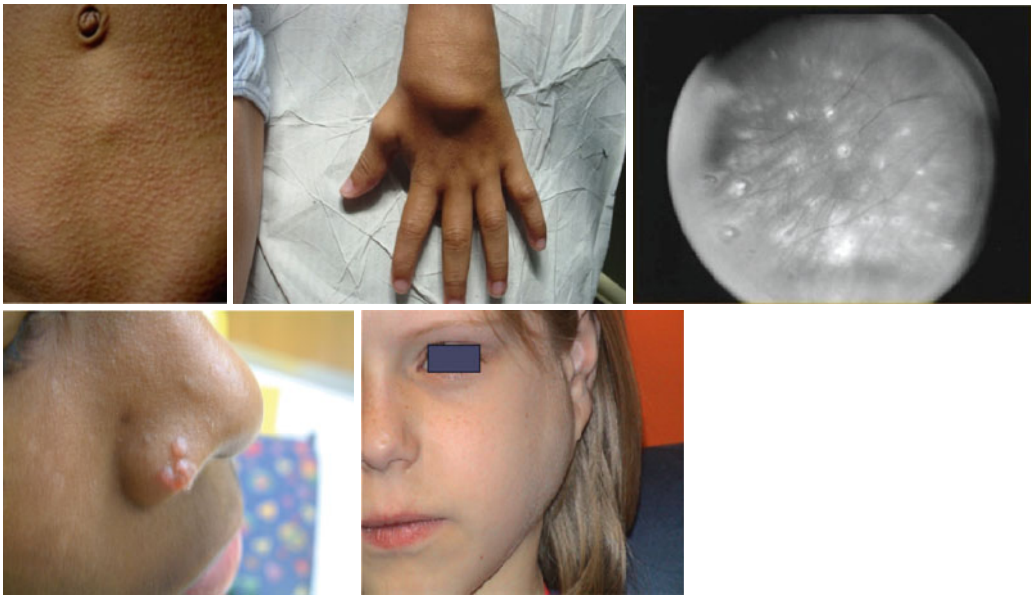

Figure 172.2
***Upper row*: clinical triad typical of *NOD2* associated Pediatric Saroidosis. *Left*: Fine maculopapular erythematous/tan eruption. *Middle*: Typical "boggy" synovitis with cyst-like synovial swelling. *Right*: Multifocal choroiditis characteristic of granulomatous panuveitis. *Lower row*: Pediatric sarcoidosis with wild-type *NOD2*. *Left*: Typical maculopapular lesion consisting of multiple non-caseating granulomas on nose. *Right*: Mikulicz syndrome with parotid and lacrimal gland involvement in a girl presenting with sicca symptoms**

Treatment

Evidence-based data on the optimal treatment of pediatric sarcoidosis are scarce. Moderate to low-dose daily corticosteroid therapy is effective to control uveitis and joint disease. Methotrexate at a dosage of 10–15 mg/m^2 once weekly was found to be effective in suppressing disease activity and allowing corticosteroid tapering. Anti-TNF monoclonal antibody agents (Infliximab, Adalimumab) may constitute a major therapeutic advance in the treatment of arthritis and visceral manifestations of pediatric sarcoidosis; the effect on uveitis activity is less convincing. Experience with IL-1 antagonists is minimal and associated with variable results.

Prognosis

There are limited data on the outcome of *NOD2* mutation-associated sarcoidosis in children. Ocular disease can be relentless and causes visual loss in more than one third of patients. Dissemination of granulomatous inflammation and vital organ involvement can occur at a later stage, indicating the necessity of thorough systemic surveillance throughout the disease course.

The outcome of pediatric sarcoidosis forms with wild-type *NOD2* is variable. The large majority of patients with adult-type sarcoidosis enter into remission within 2–5 years after disease onset. Conversely, chronic inflammation and organ damage involving lung, eye, CNS, and/or kidney have been noted in up to one fifth of patients. The outcome is worse in patients with severe lung/organ involvement at presentation, in case of multiorgan involvement, CNS, or eye disease.

173 Amyloidosis

Tekin Akpolat · Seza Ozen

The amyloidoses constitute a group of diseases characterized by extracellular tissue deposition of fibrils composed of low molecular weight subunits of a variety of proteins. At least 25 different precursors of amyloid fibrils are now known. In pediatrics, the most common form of amyloidosis is reactive AA amyloidosis due to chronic inflammatory diseases and will be the subject of this chapter. AA amyloidosis was described secondary to chronic infections as well, in the early twentieth century. AL amyloidosis, which is seen generally in the elderly, is the most common type of amyloidosis in the developed countries today. Other forms of amyloidosis such as AFib, AL, and ACys have rarely been reported in children.

AA Type Amyloidosis

Familial Mediterranean fever (FMF) and juvenile rheumatoid arthritis are the two most common causes of AA type amyloidosis in the childhood. Recent developments in the diagnosis and treatment of these two diseases have led to a decrease of AA type amyloidosis. Sickle cell anemia, chronic granulomatous disease associated aspergillosis, Hodgkin's disease, and Behçet disease are other diseases that have been associated with AA type of amyloidosis in children in the medical literature.

Pathogenesis

The pathogenesis of amyloidosis depends on the underlying cause and the type of fibrils deposited. In the case of reactive (secondary) amyloidosis, serum amyloid A (SAA) which is the precursor protein for the AA fibrils is an acute phase reactant. Classically, secondary or reactive amyloidosis was associated with any chronic inflammatory disease. The persistence of inflammation subsequently is thought to result in the deposition of AA fibrils. In recent years it has become clear that secondary amyloidosis is mainly the complication of autoinflammatory diseases which is a new chapter in medicine that flourished with the definition of the gene for FMF. The most important complication of inadequately treated monogenic autoinflammatory diseases is the development of secondary amyloidosis. In the case of FMF, the contribution of genetic modifiers such as SAA genotype or M694V mutation and environmental factors (e.g., country) have also been implicated in the pathogenesis.

Clinical Manifestations

The child will often have a medical history covering the features of the autoinflammatory disease that is the primary cause of reactive amyloidosis. The reader is referred to the chapter on autoinflammatory diseases for the review of clinical features of these diseases. Secondary amyloidosis can be seen in autoinflammatory diseases that do not have a monogenic inheritance such as Behçet disease and inadequately treated systemic juvenile idiopathic arthritis (JIA) as well. The clinical manifestations of amyloidosis vary widely and depend on the involved organ(s) and the amount of amyloid fibrils deposited. Amyloid fibrils are most commonly deposited in kidneys, but may also attack the heart, peripheral nerves, thyroid, gastrointestinal system, and bone marrow. Although more than one organ is affected generally, localized forms also can occur.

Proteinuria, nephrotic syndrome, and progressive kidney failure are the main presenting features of AA amyloidosis. Involvement of heart and kidneys are the most important predictors affecting survival. On the other had gastrointestinal amyloidosis may also have devastating complications.

Diagnosis

Amyloidosis should be suspected typically in a patient who presents with proteinuria and who has one of the autoinflammatory syndromes. However, organs other than kidney may be affected as well. In fact in patients who are candidates for this complication, amyloidosis should also be considered in the differential diagnosis of cardiomyopathy, peripheral neuropathy, hepatomegaly, or in the presence of symptoms related to gastrointestinal tract.

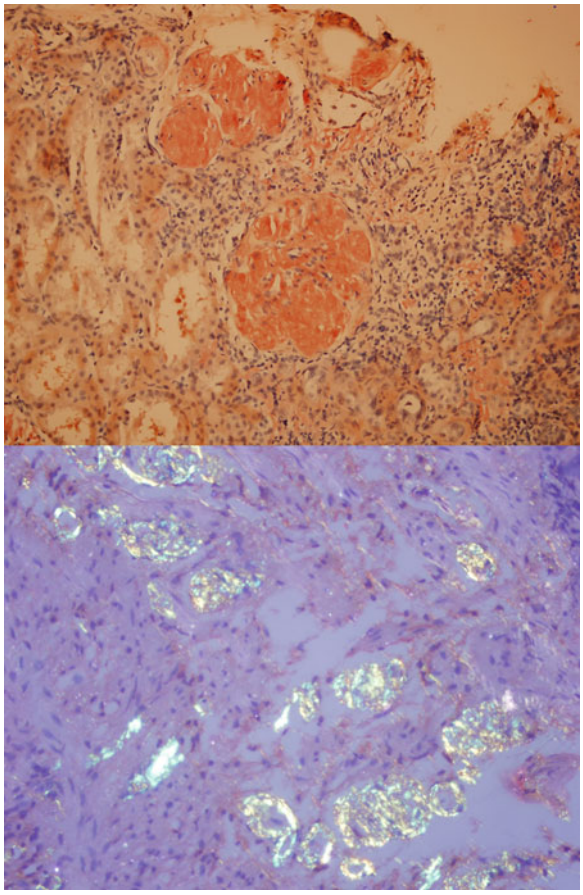

Figure 173.1
Congo red staining on kidney (*upper*, light microscopy, ×200) and rectum (*lower*, polarized light, ×400) biopsies

The diagnosis of amyloidosis is based on the demonstration of amyloid fibrils in the biopsy of the involved tissue (*Fig. 173.1*). Rectal or abdominal fat biopsies may also reveal amyloid deposition. The deposited amyloid fibrils are extracellular, eosinophilic, and metachromatic on light microscopy. Congo red staining is necessary for diagnosis. Amyloid fibrils appear faintly on Congo red staining and show the characteristic apple-green birefringence under polarized light. Specific investigation is needed for detection of types of amyloid fibrils.

Treatment

Specific treatment of the underlying disorder, aiming to suppress the inflammatory activity is the major strategy. Colchicine suppresses the inflammatory activity, decreases the severity and frequency of attacks, and prevents amyloidosis in patients with FMF. Clinical remission may occur at the stage of proteinuria in a few number of FMF patients after colchicine treatment. In the other autoinflammatory syndromes, specific therapy for the suppression of inflammation is often achieved with anti-IL-1 treatment. Biologic treatment such as anti-TNF, anti-IL-1 therapy may have a beneficial effect on amyloidosis per se. However, many patients continue to progress to end-stage renal failure, albeit with a longer renal survival, even with these agents. New treatment options directed to affect the amyloid structure or to prevent fibrillogenesis or to weaken their structural stability are being investigated.

Symptomatic Treatment is Required for Affected Organs

Once end-stage renal failure develops, renal replacement therapy is required. Renal transplantation is one of the options, but the decision should be based on other involved organs, especially the heart. New agents are needed to change the poor outcome of patients with amyloidosis and trials are under way. Since there is no excellent therapy for amyloidosis, the physician should concentrate on the prevention of the disease.

Oral and Craniofacial Disorders

J. Burton Douglass

174 The Oral Cavity

J. Burton Douglass · Christer Ullbro

The primary function of the oral cavity, as part of the gastrointestinal tract, is to start the digestion process by mastication and the breakdown of carbohydrates through enzymes in the saliva. These functions require a well-functioning oral cavity with healthy teeth, intact and healthy oral mucosa, and normal salivary production. Several diseases and medical conditions threaten the preservation of the health of the oral cavity. On the other hand, bad oral conditions might be a complicating factor to, and a diagnostic aid for, several diseases.

The Teeth

Development

All teeth develop from a band of ectodermal tissue, the dental lamina, formed from the oral epithelium and mesodermal connective tissue. The formation of the lamina starts around the fifth week of intrauterine life. The lamina will develop a number of swellings. They will gradually develop into germs for the deciduous teeth. The permanent teeth will later develop from the same dental lamina.

The tooth germ consists of the enamel organ, derived from the ectoderm, which produces the enamel. It also consists of the dental papilla and the dental sac, derived from the mesenchyme, producing dentine, pulp, and the cementum on the root. The mineralization of the tooth germ is a two-step procedure, in which the initial mineralization provides one third of the minerals and the second mineralization provides the remaining two thirds. The initial mineralization takes place when the tooth is forming, while the second mineralization takes place from the time when the formation of the crown is finished and up to 1 year prior to eruption.

During the time of development, there are many disorders that may interfere with different stages of the tooth formation. The tooth's developmental stage at the time of disturbance will affect the type of defect that will emerge more than the nature of the disorder. Disturbances range from the total destruction of the tooth bud (due to infection or radiation in an early stage of tooth development) to a mild disturbance of the mineralization of enamel (due to trauma or infection late during the secondary mineralization). The enamel will not be changed once it has been formed. It is, therefore, possible to estimate when the disorder happened through the nature and the location of the disturbance.

The *enamel* may develop *hypoplasia* if an early disorder interferes with the formation of the enamel matrix, or *hypomineralization* if the disorder affects the secondary mineralization. The etiology varies and includes genetic as well as acquired and idiopathic factors (*Table 174.1*).

The *dentin* can be affected by *dentinogenesis imperfecta*, a hereditary disorder in which the dentin is composed of irregular tubules, often with large areas of poorly calcified matrix. Both the primary and the permanent dentitions are affected. The teeth have a gray-yellow to yellow-brown appearance. The enamel is normal but as the dentin is soft, the enamel will often be lost due to stress fractures. Dental radiographs on affected teeth show pulp obliteration and short, blunted roots. Dentinogenesis imperfecta is a specific condition or a clinical feature of *osteogenesis imperfecta type III* and *IV*.

The dentin also shows deficiencies with poorly mineralized hard tissue and porosities in *vitamin D-resistant rickets*. Dental abnormalities include normal but thin enamel, interglobular dentin, and enlarged pulp chambers where the pulp horns reach to or beyond the dentoenamel junction. Clinically healthy teeth might show abscesses emerging from pulpal infection, caused by bacteria penetrating to the pulp through cracks in the enamel and the poorly formed dentin (*Fig. 174.1*).

Dentin dysplasia is a rare hereditary anomaly. The dentin is atypical with pulpal obliteration, defective root formation, and a tendency for periapical infection. Both the primary and the permanent dentitions are affected. The enamel is normal.

Shell teeth is a condition where the enamel is of normal thickness but the dentin is thin, giving the appearance of a thin shell of hard tissue surrounding a large pulp chamber and large pulp canals. Shell teeth are sometimes seen as the result of early childhood osteomyelitis or radiation therapy.

Both *enamel* and *dentin* are affected in *odontodysplasia*, a developmental anomaly involving

both mesodermal and ectodermal components in a group of teeth. The affected teeth are discolored, hypoplastic, and hypomineralized. The teeth are smaller with short roots, open apices, and wide pulp chambers. They often fail to erupt completely. The anomaly affects the primary as well as the permanent dentition. The condition is unilateral and, generally, only affects one arch. The term *ghost teeth* has been used for teeth with this condition. The etiology is unknown.

The *cement* is affected in *hypophosphatasia*. In this condition, hypoplasis or aplasia of the cementum causes premature loss of primary and sometimes permanent teeth. In *cleidocranial dysostosis*, there is no deposition of cellular cement. It has been suggested that the cement is deficient in *juvenile periodontitis* and that the premature tooth loss in this disease might be the result of this defect.

Chemotherapy and *radiation* used in pediatric oncology patients often cause dental developmental anomalies. Defects noted include tooth and root agenesis, root thinning and shortening, and enamel defects. Odontogenic cell sensitivity is dependent on the position on the cell cycle and the mitotic activity of the developing tooth at the time of chemoradiation therapy.

Eruption

The eruption of the *primary dentition* usually starts with the eruption of the lower incisors, at the age of 6–8 months. The primary dentition is fully erupted by the age of 3. The approximate number of teeth erupted at different ages is given in *Table 174.2*. The eruption time for primary teeth has a wide normal range.

Premature eruption of primary teeth is uncommon, but might happen with *natal* or *neonatal teeth*. It might cause soft tissue ulceration or interfere with feeding. Due to poor root formation there is also a risk of inhalation of the tooth. Natal or neonatal teeth are in most cases extracted to avoid these complications. Premature eruption of primary molars might occur in Letterer-Siwe disease or other histiocytoses, Ellis-van Creveld syndrome, hyperplasia of the adrenal cortex, diabetes mellitus, and hemifacial hyperplasia.

Delayed eruption of primary teeth may be the result of lack of space, fibrous gingiva, or other local factors disturbing the eruption. Children with obvious delayed or premature eruption should be dentally and medically investigated.

The eruption of the *permanent dentition* starts with the eruption of the central mandibular incisor at the age of 6–7 years and ends with the eruption of the second permanent molar at the age of 12–14 years (with the exception of the third molars). Eruption time for permanent

Table 174.2
Eruption of primary teeth

Age (mo)	Total number of erupted teeth	Latest erupted teeth
8	2	Lower central incisors
10	4	Upper central incisors
13	8	Lateral incisors
16	12	First molars
20	16	Cuspids
30	20	Second molars

	Lack of space
	Malnutrition
	Fibrotic mucosa

teeth has a wide normal range. Systemic, inherited, or local factors may cause anomalies in the eruption of teeth (*Table 174.3*).

An *eruption cyst* is a follicular cyst sometimes seen in connection with normal tooth eruption. If there is bleeding in the cyst it is classified as *eruption hematoma*. Usually there is a small, smooth swelling in the soft tissue at the site for tooth eruption. If treatment is needed, puncturing of the cyst is usually the treatment of choice.

Age Determination

Developing teeth can be used as indicators of chronologic age, and have been regarded as superior to other developing organs or structures for age determination of children with unknown birth dates. Different methods, based on comparison of radiographic development of teeth, are used.

Figure 174.2
Lingual eruption of permanent incisors with persisting primary mandibulary and maxillary incisors

Exfoliation

The reason for normal exfoliation of the primary tooth is the resorption of the root. Resorption is slow up until 1 year prior to exfoliation, when the process is accelerated. The resorption is thought to be initiated by the pressure of the erupting permanent tooth and is caused by osteoclasts resorbing the root and surrounding tooth structure.

The shedding of the primary tooth is usually bloodless, through proliferation of the gingival epithelium below the exfoliating tooth. The permanent tooth will normally erupt without rupture of the soft tissue.

The permanent successor may sometimes have a position that allows the permanent tooth to erupt without any, or only partial, resorption of the primary tooth in the area. This is especially common in the mandibular incisor region (*Fig. 174.2*). The treatment is extraction of the primary tooth.

Premature exfoliation may be seen in patients with hypophosphatasia, acatalasia, Papillon-Lefèvre syndrome, and prepubertal periodontitis. It can also be seen in patients with acute leukemia, neutropenia, Chédiak-Higashi syndrome, and acrodynia.

Divergence in Number

Hypo- and hyperdontia in the *primary dentition* are usually found in the incisor region. None of these numerical variations will normally need any treatment. The prevalence of hypodontia is 1–7 per 1,000 and can be seen in children with ectodermal dysplasia, Down syndrome, and cleft lip and palate.

Hyperdontia has a prevalence of 3–6 per 1,000 and can be seen in children with cleidocranial dysostosis.

Numerical variations in the primary dentition should always be investigated by radiographic examination. With hypodontia in the primary dentition, there is a 75% risk that the corresponding tooth in the permanent dentition will be missing. In hyperdontia there is a 25% risk that there will be an extra tooth in the permanent dentition.

Hypodontia in the *permanent dentition* is not uncommon in healthy individuals. The lower second premolar is missing in about 3%, and the upper second premolar and lateral incisor in about 1.5% of the population. Severe hypodontia may be seen in *hypohidrotic ectodermal dysplasia*, *orofacial-digital syndrome*, *Ellis-van Creveld syndrome*, and *cleidocranial dysostosis*. Anodontia, complete absence of primary and permanent teeth, is a rare condition usually associated with a systemic disorder.

Hyperdontia is usually seen as an upper, midline supernumerary tooth (mesiodens) and has a prevalence of 1–36 per 1,000. Supernumeraries are often seen in *cleft-palate syndrome*, *cleidocranial dysostosis*, and *orofacial-digital syndrome*. Supernumeraries affecting eruption of permanent teeth should be surgically removed.

Divergence in Shape

Variation of tooth shape is predominantly determined by genetic factors. It is uncommon in the primary dentition, except for double formation. This formation can be due to a fusion of two or more teeth or a division of a single tooth germ.

In the permanent dentition, variation in shape is most often seen on third molars and upper lateral incisors. The most common malformation is invaginated odontome. This occurs mostly in the upper lateral incisor.

Local macrodontia can be seen in hemifacial hypertrophy. Other disorders affecting tooth morphology are trauma, radiation, and chemotherapy during the time for tooth development. Microdontia can be seen in pituitary dwarfism.

Discoloration

Primary teeth are naturally whiter than permanent teeth. Depending on the thickness of the enamel and dentin, the natural color of permanent teeth might differ. Extrinsic discoloration with staining from food, drinks, or medication may affect the teeth. Intrinsic discoloration is often the result of hypomineralization (e.g., fluorosis), medication (tetracycline), or the incorporation of different metabolites (porphyria, cholestasis). Extrinsic discoloration can easily be removed with professional tooth cleaning. Intrinsic discoloration can sometimes be affected by bleaching of the enamel, but the result of such a treatment is unpredictable.

Dental Caries

Dental caries is the most common disorder of the dental hard tissue. Although the prevalence of caries among children has decreased in most Western countries, epidemiologic studies have shown that dental caries is still a considerable problem in the Middle East, with high incidence of dental decay at a young age.

Dental caries is a demineralization and disintegration of the dental hard tissue. Caries is caused by acids produced from bacterial fermentation of carbohydrates, preferably sugar. A normal salivary production is important to alter the effect of the acid achieved through the saliva's diluting and buffering capacity.

The keys to avoid dental caries are to reduce the number of cariogenic bacteria in the mouth, to reduce the amount of fermentable carbohydrates consumed, and to increase the resistance of the tooth surface with frequent supply of fluoride.

The cariogenic bacteria, *Streptococcus mutans* and lactobacilli, are reduced by proper oral hygiene. Basic oral hygiene is performed by mechanical cleaning, which should be initiated as soon as the first primary tooth erupts. Children with severe caries problems and conditions making cleaning difficult may benefit from chemical cleaning with chlorhexidine. The numbers of cariogenic bacteria will also be reduced by decreasing the amount and the frequency of sugar intake. A well-balanced diet, with not more than five to six intakes per day, is a good basis for maintained dental health. The protective action of fluoride against the development of caries is well established. The fluoride will be present in the fluid interacting with the enamel, thereby increasing the resistance to acid. Fluoridation of the water supply, naturally or artificially, is an effective means of preventing dental caries.

The recommended dose is 1 ppm. Most toothpastes contain fluoride, and cleaning two times daily will provide a basic fluoride protection. More intensified fluoride treatment by means of fluoride tablets, varnishes, or topical solutions should be used as per individual needs.

Young children with short exposure to fluoride, inefficient oral hygiene, and a high frequency of sugar intake through a feeding bottle or on a pacifier have a high risk of developing rampant caries, usually affecting the upper incisors and primary molars (nursing bottle caries).

Children treated with radiation to the head and neck region because of malignant neoplasms or with total body radiation prior to bone marrow transplantation will have a reduced salivary secretion. It has been shown that the buffer capacity of the saliva is reduced in children treated for malignancies. With reduction of salivary flow, there will be an increase of the *Streptococcus mutans* and an increased risk of developing caries. Fluoride and chlorhexidine are efficient in preventing decay and should be used, together with other preventive measures, for children treated with radiation and chemotherapy.

Dental decay in primary and permanent teeth should be removed to prevent the decay from causing complications in the form of pulp infections or abscesses with infections in surrounding bone tissue and, ultimately, loss of teeth. It is important to retain primary molars to obtain a functional occlusion. The fact that primary teeth will be shed and replaced with permanent teeth does not justify not treating decay, even in young children. Regular annual visits to the dentist from the age of 3 are important in making the patient and the family dentally aware.

Trauma

Trauma is a common reason for dental injuries in young children. Epidemiologic studies have shown that one fourth of all children have had traumatic injuries to their permanent teeth and one fifth of the children under the age of 7 have had injuries to their primary teeth. All children with trauma to their teeth should be examined by a dentist. Prompt and correct treatment of the injury will reduce the number of complications and improve the prognosis for the traumatized tooth.

Trauma to the oral tissues in the form of tooth fractures, soft tissue lacerations, bruises, and bone fractures are common symptoms of physically abused children. Studies have revealed that 50% of physically abused children suffer from trauma to the head and neighboring areas.

Gingiva

The gingiva, together with alveolar bone and the periodontal ligament, form the periodontium. Several diseases and medical conditions involve the gingiva and the periodontium. The role of dental bacteria, accumulated on the teeth (plaque), as a factor in the development of gingivitis and periodontitis has been clearly recognized. The inflammatory response of the gingiva usually reflects the amount of dental plaque accumulated on the teeth, but can also be influenced by the state of general health.

Gingivitis

Gingivitis is a nonspecific term used to indicate an inflammatory condition of the gingiva, regardless of the etiology. Plaque-associated gingivitis is an inflammation, with redness, swelling, and bleeding. It includes the interdental as well as the marginal gingiva. The inflammation can be controlled or prevented by removal of, or inhibiting, the plaque accumulation.

In cases where the inflammatory response does not correspond to the level of plaque accumulation or to improved oral hygiene, other conditions should be considered. Examples of such conditions are acute leukemia, diabetes mellitus, neutropenia, thrombocytopenia, and hormonal changes associated with puberty.

Gingivitis, as such, is a harmless disease and will most likely not proceed into periodontitis, except in specific cases where the immunologic defense system is weakened or the microorganisms of the plaque are aggressive. Dental plaque consists normally of gram-positive bacteria, but the amount of gram-negative bacteria increases in aging plaque. Two-week-old plaque consists of up to 50% gram-negative bacteria. The plaque initially accumulates above the gingival margin but, if not removed, will accumulate in the periodontal pocket. The aging plaque consists of more than 300 different species, among them bacteria with considerable pathogenic potential.

Mouth breathing, due to deficient lip closure or impaired ability to breathe through the nose, may cause frequent drying out of the gingiva in upper anterior areas. This is thought to cause vasoconstriction and decreased resistance to microbial attack.

Acute necrotizing gingivitis (ANG) is a rare periodontal condition primarily seen in young adults and adolescents. It rarely affects healthy children in developed countries, but can frequently be seen among malnourished children in developing countries. It is also seen as a frequent symptom among young human immunodeficiency syndrome

(HIV)-infected adults. The disease is characterized by a necrosis at the top of the interdental papilla that later spreads along the marginal gingiva. The lesions are covered with a grayish yellow membrane which, when removed, exposes a bleeding surface. Patients usually exhibit severe pain and a characteristic oral fetor and may also suffer from regional lymphadenopathy, increased salivation, and elevated temperature. The exact etiology of ANG is unknown but affected sites usually harbor high levels of spirochetes and *Prevotella intermedia*. Local treatment, by removal of plaque, will usually produce rapid healing. In cases with severe gingival necrosis, antibiotics should be used.

Acute streptococcal gingivostomatitis is caused by streptococci and is usually preceded by tonsillitis. The gingiva becomes inflamed, red, and swollen, with an increased tendency to bleed. The submandibular lymph nodes are sometimes enlarged and tender.

Herpetic gingivostomatitis is an acute gingivitis normally caused by herpes simplex virus type 1. In recent years, type 2 virus has been increasingly found in oral infections. The disease is usually seen in children between the ages of 2 and 4 years. Often, the symptoms proceed unnoticed and subclinically but occasionally the disease manifests clinically and is characterized by a sudden onset of fever, general malaise, regional lymphadenopathy, crusts on the lips, oral lesions with acute gingivitis, and small vesicles in the and swollen and often covered by a serofibrinous exudate. This disease is not associated with destruction of the gingiva, and the oral lesions will usually heal in 10–14 days. Treatment is medication against fever and sufficient hydration. Topical anesthetics may be used if the lesions are too painful to permit eating. Antibacterial mouthwashes may be used to reduce secondary infection. In immunologically compromised patients, systemic antiviral treatment may be necessary.

Gingival hyperplasia may be caused by the use of antiepileptic drugs, or it may be inherited as an autosomal dominant trait. In the inherited type, the gingiva usually enlarges in infancy. The teeth are usually covered by thick, firm to soft, pink or red gingiva. Surgical intervention may sometimes be necessary to ensure the eruption of primary molars and permanent teeth, and also for cosmetic purposes and the enhancement of oral hygiene.

Medication with antiepileptic drugs of phenytoin type produces gingival hyperplasia in approximately 50% of patients. The drug induces an increased synthesis or retarded breakdown in drug-sensitive fibroblasts. In areas with chronic irritation, for example in areas with gingivitis, there will be subepithelial fibrosis. Poor oral hygiene with marginal plaque accumulation is a factor favoring gingival enlargement in patients treated with drugs of this type.

Figure 174.3
Gingival overgrowth on a renal transplant patient on cyclosporine medication (see Color, Figure 175-3)

Cyclosporine induced gingival overgrowth is frequently seen in patients taking cyclosporine after organ transplantation (*Fig. 174.3*). Studies have shown that there is no correlation between blood levels, or oral dosage of the drug, and the occurrence or severity of gingival overgrowth. An oral hygiene regimen initiated after the treatment with cyclosporine has been induced will reduce the gingival inflammation, but not the overgrowth. The gingival changes occur most rapidly during the first 2–6 months, reaching a plateau at about 12 months. Treatment of gingival overgrowth will be surgical reduction of the gingiva for cosmetic or functional purposes.

Periodontitis

Periodontitis is a chronic inflammatory condition preceded by gingivitis. It culminates in the loss of tooth attachment and even loss of the tooth. Periodontitis is rare in healthy children. The incidence increases during adolescence and among children with impaired immune systems.

The organism in the subgingival plaque, consisting mostly of anaerobic and motile bacteria, will destroy the periodontal tissue through the release of toxins, enzymes, and other harmful substances. The immunologic answer to this attack will contribute to the destruction of the connective tissue. The final result is the loss of the tooth due to lack of periodontal support. The periodontal destruction is initiated by bacterial mechanisms. Both the humoral and the cellular immune systems will participate in the defense toward the bacterial antigens.

Periodontal destruction might be severe due to disturbances in these systems (e.g., neutropenia or acute forms of leukemia).

Prepubertal Periodontitis

This is a rare condition affecting the primary dentition in young children. There is one generalized and one localized form of the disease, probably with a genetic basis. *The generalized form shows* acute inflammation and gingival hyperplasia with rapid destruction of the alveolar bone. Children with this condition have functional defects in neutrophils and monocytes, and are frequently affected by other infections (e.g., respiratory infections and otitis media). The permanent dentition may or may not be affected. In the *localized form*, the inflammation is mild and the bone loss is less rapid, affecting only a few teeth. In this form, there is no functional defect of the neutrophils or monocytes. Diseases in which prepubertal periodontitis has been reported include acrodynia, Chédiak-Higashi syndrome, cyclic neutropenia, Ehlers-Danlos syndrome, histiocytosis X, hypophosphatasia, lazy leukocyte syndrome, leukemia, neutropenia, Papillon-Lefèvre syndrome, and scleroderma.

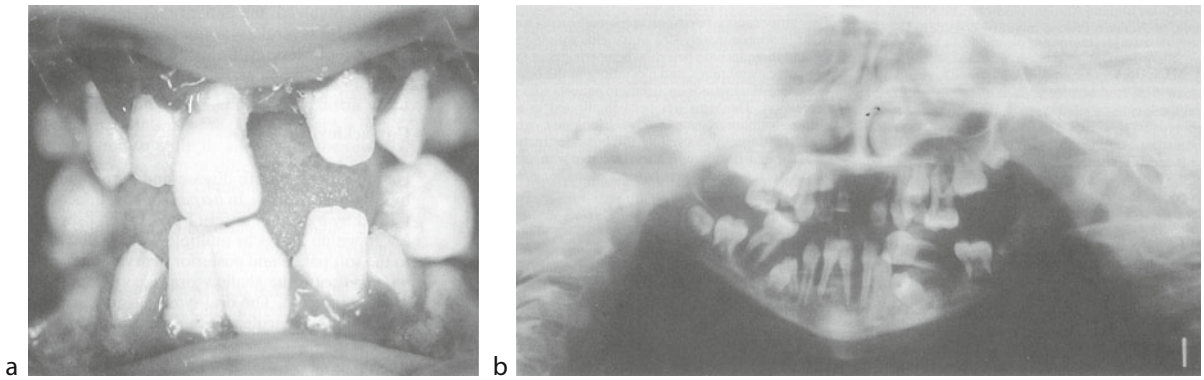
Juvenile Periodontitis

Juvenile periodontitis affects less than 1% of all teenagers. It has its onset around puberty and there is a familial distribution. The oral tissue appears normal, but usually bleeds severely on gentle touch. Radiographic and clinical examinations show deep pockets with severe bone loss, predominantly around first permanent molars and incisors. The amount of plaque does not correspond to the degree of periodontal destruction. Functional defects in neutrophils or monocytes, local disturbances in the root cement, and the presence of *Actinobacillus actinomycetem comitans*, possibly together with Bacteroides-like species, have been discussed as possible factors causing the disease.

Treatment of periodontal lesions in the primary dentition is usually extraction of affected teeth, with the goal being to prevent the infection from involving the permanent dentition. In the permanent dentition the treatment includes professional tooth cleaning and periodontal treatment, sometimes including surgical intervention. If bacteria samples show involvement of specific bacteria involved in periodontitis, treatment with broad-spectrum antibiotics may be justified. It is important to use the antibiotics for a period of at least 3 months because the periodontal bone is affected.

Papillon-Lefèvre Syndrome

Papillon-Lefèvre syndrome is an autosomal recessive disease characterized by palmar-plantar hyperkeratosis and severe periodontal destruction (◉ *Fig. 174.4*). The cutaneous lesions of the palms and soles are usually manifested during the first year of life. The oral symptoms start immediately upon eruption of the primary teeth and cease after the premature loss of the first dentition, only to start again after eruption of the permanent teeth. Patients with Papillon-Lefèvre syndrome are in most cases edentulous in the early teens.



◉ Figure 174.4
(a) Patient with Papillon-Lefèvre syndrome. (b) Radiograph from the same girl showing total bone loss around molars and incisors in the mandible

The treatment is a combination of measures to improve the oral hygiene and to extract teeth with periodontal disease before the loss of alveolar bone is extensive. In the event of gingival infection and the presence of gram-negative anaerobic bacteria, the use of antibiotics has been successful in preventing destructive periodontal infection.

There are reports that treatment with retinoids reduces the periodontal breakdown. Long-term follow-up of this treatment does not support this opinion. Studies to find the etiology behind the severe periodontitis and the optimal treatment for affected children are ongoing.

Hypophosphatasia

Hypophosphatasia is an autosomal recessive disorder defined by low serum alkaline phosphatase activity. Children with this disorder may show skeletal abnormalities (that resemble rickets) and loss of alveolar bone on radiographs. Loosening and premature exfoliation of primary teeth without evidence of any gingival or periodontal infection are classic features of hypophosphatasia. Histology of exfoliated primary teeth exhibits aplasia and hypoplasia of root cementum, large pulp chambers, and interglobular dentin formation. Supplements of vitamin D, phosphate, or a combination of vitamin D and fluoride are used as treatment for bone abnormalities. None of these approaches have been shown to be consistently successful.

Histiocytosis X

Histiocytosis X is a group of diseases with varied clinical manifestations, but sharing the common histologic feature of an infiltrating histocytosis. *Letterer-Siwe disease* occurs in infants with oral ulcerations, gingival hyperplasia, and diffuse bony destructions of the jaw. *Hand-Schüller-Christian disease* occurs mainly in young children diagnosed with multifocal bone defects and sometimes progressive loosening of teeth. *Eosinophilic granuloma* is a unifocal cystic lesion in bone, most often in the mandible. Patients with histiocytosis X are treated with corticosteroids, radiation, and chemotherapy.

Primary Hyperoxaluria

Dental and periodontal findings in primary hyperoxaluria include extensive infiltration of oxalate crystals in the pulp of developing teeth, in the marrow spaces of the alveolar bone, in the gingival corium, and in the periodontal ligament. Crystalline calcium oxalate deposits within the periodontal ligament provoke a granulomatous foreign-body reaction that results in external root resorption, pulp exposure, and tooth mobility.

Pigmentation of the Gingiva

All people except albinos have a certain degree of melanin pigmentation, distributed throughout the epidermis of the skin. There is a great variation in the degree of pigmentation of the skin and of the mucosa between races and also between individuals of the same race. Light-skinned individuals normally have a relatively even coloration throughout the oral cavity, while dark-skinned people frequently have macules of pigmentation of various configuration and sizes on their oral mucosa. The gingiva are frequent sites of this pigmentation (*Fig. 174.5*).

If the pigmentation has a sudden onset, differential diagnosis including melanoma, junctional nevus, hemosiderin deposition after trauma, Albright syndrome, Peutz-Jeghers syndrome, or Addison disease might be considered.

Oral Mucosa

The oral mucosa has a special appearance and is of three different types. The keratoid fixed mucosa covers the hard palate and the alveolar process. The keratoid movable

Figure 174.5
Pigmentation of the gingiva on an 8-year-old girl (see color Figure 175-5)

mucosa is located inside the lips and cheeks, soft palate, floor of the mouth, and bottom of the tongue. Specialized mucosa covers the tongue.

Herpes Labialis

Studies have shown that 40–90% of individuals have antibodies to herpes simplex virus type 1. Many only suffer infection subclinically. In individuals with low antibody titer, reinfection in the oral mucosa is possible. Recurrent herpes simplex infections develop in about 30–40% of patients who have had primary herpetic stomatitis. The disorder originates from reactivation of the virus, which remains latent in the nerve tissue in between periods of excitation. Recurrent infection usually appears as small vesicles around the mucocutaneous junction of the lips, often called herpes labialis, while recurrent intraoral herpetic infections are rare. Use of systemic acyclovir is useful in many patients who suffer frequent recurrences of either herpes labialis or intraoral lesions.

Varicella-Zoster Virus

Varicella-zoster virus causes chickenpox and herpes zoster. Oral symptoms in *chickenpox* are vesicles in the palate and throat, sometimes preceding the onset of the typical skin rash. The *herpes zoster* infection is a reactivation of these viruses persisting permanently in the sensory nerves or root ganglia. The reinfection is usually unilateral, appearing in the distribution of the corresponding nerve. If the maxillary or mandibular division of the trigeminal nerve is involved, the patient may experience toothache-like pain for several days prior to onset of more characteristic cutaneous lesions. Relief of pain can be accomplished with the use of analgesics and systemic acyclovir therapy.

Coxsackievirus

Hand-foot-and-mouth disease and herpangina are caused by Coxsackievirus A. In *herpangina* the infection is characterized by a sudden onset of pyrexia and sore throat, followed within 2 days by multiple vesicles that are restricted to the soft palate and posterior pharynx. In *hand-foot-and-mouth disease* the shallow oral ulcers are usually spread over the mucosa. The oral symptoms are accompanied by erythematous macules on the hands and feet.

Epstein-Barr Virus

This virus causes *infectious mononucleosis*. Oral lesions occur in approximately 30% of patients with mononucleosis, and these include petechial hemorrhages in the palate, exudative membranes, and ulcerations in the oral mucosa.

Epstein-Barr virus is oncogenic in patients with immunodepression. The virus has been implicated in a type of diffuse lymphosarcoma, *Burkitt lymphoma*, which may present intraorally as swelling and bone destruction of the jaws. Epstein-Barr virus is also associated with *hairy leukoplakia*, seen on the lateral borders of the tongue in HIV-infected persons.

Cytomegalovirus

Cytomegalovirus can cause sialadenitis with salivary gland swelling. This condition is uncommon and is limited to immunosuppressed patients or newborns.

Bacterial Infections

Scarlet fever is caused by an infection of streptococci. Oral symptoms include a congested oral mucosa and a tongue coated with red, protruding papillae (strawberry tongue) or bright red, swollen, hyperemic papillae (raspberry tongue).

Primary tuberculous infections are rarely manifested by oral signs and symptoms. However, with advanced pulmonary tuberculosis, painful intraoral ulcers can be seen. The most common place is the dorsum of the tongue, and the shape is irregular with overhanging edges.

Actinomycosis is a chronic suppurative and granulomatous disease caused by *Actinomyces israelii*. Other actinomycetes may contribute. The actinomyces gain entrance to the soft tissues through open necrotic pulps, radicular cysts, wounds, or impacted teeth. The infection is usually localized in the submandibular area, around the jaw angle, and is spread, forming abscesses and sinuses with subsequent fibrosis. Treatment is usually excision and, due to a strong tendency to relapse, prolonged antibiotic therapy for 4–6 weeks.

Fungal Infection

Oral candidiasis is an infection caused by *Candida albicans*, a microorganism normally found in the oral

flora in 30–50% of the population. A local or systemic disturbance of the resistance mechanisms or the environment is necessary if the organism is to multiply and invade the mucosa. Oral candidiasis may be seen in different clinical forms.

Acute pseudomembranous candidiasis (thrush) is the most common fungal infection in children. It is seen as raised, pearly white patches covering the tongue, cheek, or soft palate. It can be rubbed off, leaving an erythematous surface.

Acute atrophic candidiasis is seen as red, painful, edematous mucosa. *Chronic atrophic candidiasis* is seen in angular chelitis in children.

Mucocutaneous candidiasis can be seen in children with hypoparathyroidism or Addison disease, in children taking long-term broad-spectrum antibiotics, and in children with iron deficiency and diseases or medical treatment associated with immunodeficiency. The oral changes are similar to those seen in acute pseudomembranous candidosis. The nails and skin may also be affected. Children with congenital immunoglobulin A (IgA) deficiency or cellular immunodeficiency reveal increased prevalence of fungal infections.

Median rhomboid glossitis is sometimes regarded as a chronic candida infection. It usually presents as a rhomboid patch without papillae on the dorsum of the tongue. Histologically, there is a lack of filiform papillae, and varying degrees of hyperkeratosis in which fungal hyphae is demonstrated. Treatment with antifungal agents can be successful. Spontaneous regression may also be seen of this innocent lesion.

HIV infection in children is characterized by oral candidiasis. This is usually manifested as pseudomembranous *Candida* infections, but gingivitis and angular cheilitis, superinfected with *Candida*, is not uncommon.

Treatment of Oral Candidiasis

Good oral hygiene is an important part of managing oral candidiasis, along with the support of chemical agents such as chlorhexidine. Local and systemic predisposing factors should also be addressed. If a specimen from the mucosa or clinical signs confirms candidiasis, treatment with topical antifungal drugs such as nystatin lozenges or amphotericin B lozenges are the first drugs of choice. The lozenges should dissolve slowly in the mouth, four times daily for at least 4 weeks. If lozenges are difficult for the patient to use, nystatin mixture is available. In severe cases of oral candidiasis, ketoconazole, fluconazole, or clotrimazole have been shown to be efficient.

Aphthous Ulcer

Aphthous ulcer is probably caused by an immunologic reaction causing deterioration of the epithelium. The ulcers are oval and have a crateriform base with elevated, reddened margins. The central part of the ulcer is covered with a gray-yellow coating. These painful ulcers are usually situated on the tongue and the buccal and lingual mucosa. The ulcers will heal without any scar formation. Antibacterial mouth rinses might be used to reduce secondary infection. Patients with Crohn disease sometimes reveal ulcerated oral lesions with a clinical appearance similar to aphtous ulcer.

Periadenitis mucosa necrotica recurrens or Sutton aphthae is a severe form of recurrent aphthous ulcers. These ulcers are deeply extended and extremely painful. They usually heal slowly and with scar formation. Topical treatment with corticosteroids, ointment or spray, is sometimes efficient. Rinsing with a solution of chlortetracycline three times a day for 4 days has shown to be efficient in 50–75% of patients.

Erythema Multiforme

Erythema multiforme is a dermatologic disease of unknown etiology. The skin reacts with asymptomatic erythematous macules or papules. The oral lesions can involve the mucosa anywhere in the mouth. Most commonly the lips are affected, with vesicles or bullae rapidly bursting into ulcers. The oral findings might be the only symptoms of the disease. The lesions usually heal in 2 weeks, but recurrent attacks are common. Treatment is mainly with corticosteroids and sometimes with antibiotics to prevent secondary infection. In mild cases, topical anesthesia may be the only treatment needed.

Epidermolysis Bullosa

Epidermolysis bullosa is a diverse group of disorders, with blister formation as a common feature. Tissue separation occurs at variable depths in the skin and/or mucosa depending on the specific type of epidermolysis bullosa. The disorder may involve the eyes, teeth, oral mucosa,

esophagus, intestinal tract, anus, genitourinary tract, and musculo-skeletal system.

The character and extent of oral involvement vary greatly from one type to the other. In the milder forms, the oral mucosa may suffer only occasional blistering, with vesicles that heal rapidly without scarring. In more severe cases, the entire mucosa is affected with severe intraoral blistering with subsequent scar formation, microstomia, obliteration of the oral vestibula, and ankyloglossia. Depending on the type of epidermolysis bullosa, the dentition may be severely affected by enamel defects similar to defects appearing in amelogenesis imperfecta.

Children with epidermolysis bullosa have an extremely cariogenic diet and have difficulty performing routine dental prophylaxis. Preventing dental caries is therefore challenging. Oral hygiene instructions using a soft-bristled, small-headed toothbrush and administration of fluoride are important. Routine dental treatment with local anesthesia is possible in patients with minimal soft tissue involvement or limited treatment needs. Individuals with severe soft tissue involvement, requiring multiple restorative and surgical procedures, are best managed with general anesthesia, often with a modified anesthesiologic approach.

Lichen Planus

Lichen planus is a chronic, inflammatory condition with unknown etiology involving the skin and the oral mucosa. Children are occasionally affected. Oral lesions usually are found on the posterior part of the buccal mucosa, but can also be seen on the tongue or anywhere in the mucosa.

Oral lichen planus exhibits six different clinical appearances: three white (papular, reticular, plaque-like) and three red (atrophic, ulcerative, and bullous). The red lesions are sometimes painful and often infected with *Candida albicans*. All red lesions should be treated by the elimination of trauma, antifungal therapy, and usually corticosteroids for anti-inflammatory treatment. Surgical excision or cryosurgery may be used for ulcerations if pharmacologic treatment is ineffective.

Leukoplakia

Leukoplakia or hyperkeratotic lesions are rare in children. They are often the result of long-standing trauma to the mucosa from dental appliances or as a result of the use of snuff. Most of these changes are reversible after elimination of the trauma. If they persist, they have to be observed because of their precancerous potential.

Oral Mucosa Manifestations of Systemic Diseases

Crohn Disease

Crohn disease is a chronic relapsing inflammatory granulomatous disorder of unknown etiology. The disorder may affect the gut, from the mouth to the anus. In the mouth, the gingiva in the vestibulum may demonstrate linear, hyperplastic folds, occasionally ulcerated.

Kawasaki Syndrome

Kawasaki syndrome usually occurs in children under the age of 5 years. The etiology is unknown. Oral manifestations, occurring within 1–3 days of onset of the disease, consist of erythema, fissuring and crusting of the lips, oropharyngeal erythema, and increased prominence of the lingual papilla ("strawberry" tongue). Other symptoms are fever, generalized nonvesicular rash, swelling and erythema of the hands and feet, and cervical lymphadenopathy. The overall prognosis is good, but cardiac disorders can arise.

Lupus Erythematosus

Lupus erythematosus is a chronic autoimmune disorder of unknown etiology. It is usually divided into chronic discoid lupus erythematosus and the acute systemic type. Oral lesions occur in patients with the discoid and also in patients with the systemic type of the disease. Oral discoid lesions are often found on the buccal mucosa, gingiva, and vermilion border. A typical lesion presents with a central erythematous lesion and peripheral radiating striae. In systemic lupus erythematosus discoid lesions, erythematous lesions and, rarely, ulcerations have been described. In severe cases, oral mucositis superinfected with *Candida albicans* can be seen. Systemic corticosteroids and immuno-suppressants are the treatments of choice for systemic lupus erythematosus. Oral lesions may be treated with topical steroids combined with antifungal treatment if necessary.

The Tongue

Several diseases and disorders affect the tongue with lesions in the mucosa. Some changes in the texture are, however, normal anatomic features. An example is anomalous thyroid tissue in the tongue, usually located around the foramen cecum.

Geographic tongue is a benign, inflammatory condition characterized by round areas with atrophy of papilla filiformis. The lesions are red areas with irregular circinate patterns on the tongue. The areas are outlined by a thin white or yellowish line (*Fig. 174.6*). The pattern and the locality of the red areas may change from time to time. Histologically, the lesions resemble those seen in psoriasis and have been suggested as oral manifestations of psoriasis. Most lesions are asymptomatic, but some patients may complain of soreness or a burning sensation. Treatment with etching solution has been reported to be effective.

Scarlet fever may be diagnosed early in the course through its oral manifestations. The tongue is heavily coated and grayish, and becomes fiery red with large fungiform papillae. This is called "raspberry tongue." By the fourth to fifth day, there is a complete desquamation of the tongue with multiple papillary elevations, sometimes called "strawberry tongue."

Hairy leukoplakia is a lesion usually seen in people with late-stage HIV or acquired immunodeficiency syndrome (AIDS). The lesion is a white patch, usually on the lateral margin of the tongue. The surface is irregular and may show corrugations or flat papules. The lesion is usually asymptomatic, but may be painful if superinfected with *Candida*. Immunohistochemical studies have demonstrated the presence of Epstein-Barr virus in the nuclei of epithelium from hairy leukoplakia.

Figure 174.6
Geographic tongue on a young patient (see color Figure 175-6)

Salivary Glands

Xerostomia is a condition usually seen in children with fever, but is also a complication of drugs with anticholinergic activity. It is also found in chronic graft-versus-host disease, rheumatoid disorders affecting the salivary glands, and after high-dose irradiation involving the salivary glands.

Mumps is a viral disease affecting the parotid glands with painful swelling of one or both glands. The swelling usually appears between the posterior border of the mandible and the mastoid and then extends downward and forward. The swelling usually disappears after 3–7 days.

Recurrent parotitis is a recurrent, idiopathic swelling of the parotid gland of otherwise healthy children. One or both parotid glands are involved. The swelling might appear several times every year and will usually last for 2–3 weeks. Sialography will often reveal sialectasis in both glands, even though each episode of infection tends to affect only one side. It is generally accepted that recurrent parotitis resolves around puberty and that sialographic features can return to normal as the patient becomes older. Treatment options are to provide antibiotic therapy when each episode occurs or to provide long-term prophylactic antibiotics.

Suppurative parotitis is a swelling, usually unilateral, that is caused by *Staphylococcus aureus*. The swelling is followed by pain and fever and, once treated with antibiotics, is not recurrent.

Mucocele is a soft, painless, fluctuant, well-defined swelling often with a bluish color. The mucocele usually originates from the small salivary glands in the oral cavity. The cause for the mucocele is trauma, causing mucous to extravasate into the tissue and eventually be enclosed with granulation tissue. It might also be caused by an obstruction of the excretory duct creating a mucous retention cyst. Treatment for mucoceles is surgical removal.

Ranula is the term for a mucocele localized in the floor of the mouth. It may originate from minor salivary glands, in which case it is located superficially. If it originates from one of the sublingual glands, it is larger and more deeply located. Most sublingual mucoceles are extravasation cysts. Marsupialization with packing is the treatment of choice.

Salivary calculus may develop in any of the salivary glands and produce transient episodes of gland swelling, particularly at mealtimes. Approximately 20% of salivary calculi are radiopaque. If not detected in routine radiographs, salivary calculus should be apparent on sialographic views. The treatment is surgical removal.

Tumors seen in the salivary glands of children are usually of the vascular type. Both minor and major glands may be affected, and the palate is the most frequent involved site.

Pleomorphic salivary adenoma accounts for the majority of tumors in the parotid gland. In the submandibular gland, a high proportion of lesions are either *adenoid cystic carcinoma*, *mucoepidermoid tumor*, or *adenocarcinoma*. Neoplasms of the sublingual salivary gland are virtually all malignant, while in the minor salivary glands, around 50% of lesions are malignant.

Cysts

Most of the cysts in the mouth are of epithelial origin.

Odontogenic Development Cyst

Follicular cysts develop around the crown of an unerupted tooth. The cyst is developed by fluid accumulation in the dental follicle. Treatment is enucleation or occasionally marsupialization.

Primordial cysts and *keratocysts* are thought to develop from the dental lamina, or the tooth germ, before mineralization starts. The epithelium of the cyst is often keratinized. These cysts are often found in the lower jaw, and may reach considerable size without causing any pain or swelling of the jaw. The treatment is enucleation, and the surgery must be done with good margin to avoid recurrence. Keratocysts are one of the diagnostic features seen in the basal cell nevus syndrome.

Gingival cysts of the newborn occur with high frequency up to the age of 3 months. These cysts are called *Bohn nodules* when they are located on the buccal or lingual side of the alveolar ridge and *Epstein pearls* when they are located at the midpalatine raphe, the borderline between the hard and the soft palate. The cysts are whitish and 2–3 mm, and will quickly disintegrate. They develop from epithelial remnants of the dental lamina or epithelial inclusions at fusion lines. No treatment is necessary.

Lateral periodontal cysts arise in the periodontal ligament of a vital tooth. The cyst often develops in the lower jaw in combination with erupting molars. The mechanism by which the cyst arises is thought to be from a follicular cyst that is displaced laterally as the tooth erupts. Symptoms are often swelling of the jaw and pain, due to secondary infection. Treatment is surgical enucleation.

Odontogenic Inflammatory Cyst

Radicular cysts are caused by an inflammatory process from a nonvital tooth and develop from epithelial remnants in the periodontium. These cysts are often asymptomatic and grow slowly. They appear radiographically as round or ovoid radiolucencies around the tooth apex. They are treated by enucleation, and the nonvital tooth is extracted or treated endodontically.

Developmental Nonodontogenic Cysts

Nasopalatine duct cysts and globulomaxillary cysts are developed from epithelial remnants in the fusion lines of the embryonic process. The nasopalatine duct cyst is situated in the midline, and the globulomaxillary cyst is between the upper lateral incisor and the maxillary canine. The treatment is surgical excision.

Nonepithelial Cysts

Simple bone cysts are also called hemorrhagic or traumatic cysts. The etiology is unknown, and the cyst is without epithelial lining. It is most commonly found in the lower jaw, and does not involve the teeth in the area. The cyst is usually asymptomatic. Surgical curettage is recommended, but spontaneous healing has been reported.

Odontogenic Tumors

Ameloblastoma is a slowly growing, destructive tumor that is asymptomatic at its early stage. Most of these tumors are located in the molar area of the lower jaw. Radiographically, they resemble expanding uni- or multilocular cysts. Histologically, there is a fibrous stroma with proliferating odontogenic epithelium. Treatment is excision with good margin, as these tumors have a strong tendency to recur.

Adenoameloblastoma is surrounded by a capsule and is usually located in the anterior region of the maxilla.

Ameloblastic odontoma is a tumor consisting of both ameloblastic tissue and mineralized dental tissue. The tumor is encapsulated, and the treatment is excision.

Ameloblastic fibroma is a rare, benign, and slowly expanding tumor. It is predominantly found in children in the maxilla. The tumor is encapsulated and can easily be removed surgically. There is no risk of recurrence.

Odontoma is a tumor that contains both enamel and dentin. Most odontomas are found in the mandible, and they are often asymptomatic.

Odontogenic myxoma is a benign, locally aggressive, nonmetastasizing neoplasm arising from the primitive mesenchymal structure of a developing tooth. The tumor is often clinically asymptomatic. The main symptom is usually bone expansion, but mobility and displacement of teeth may also occur. Radiographically, the tumor usually appears as a multilocular radiolucent lesion. Treatment is surgical resection, but the recurrence rate is high.

Nonodontogenic Lesions

Central giant cell tumor is a benign tumor consisting of osteoclast-like giant cells. Symptoms are swelling and expansion of the cortical plate of the jaw, together with tooth mobility. The tumor has the capacity to destroy bone. The tumor appears as a radiolucency on the radiograph, revealing resorption and tooth displacement. Giant cell tumors are often associated with *hyperparathyroidism.*

Fibrous dysplasia is a condition with a painless bony swelling during childhood. The lesion consists of proliferating fibrous tissue, replacing bone. The tissue contains foci of giant cells and may involve multiple bones or a single bone. It is a self-limiting disease, and the lesions become inactive over the years. Surgical treatment is necessary only when the swelling is disfiguring or interferes with function.

Eosinophilic granuloma is a lesion that is primarily an inflammatory reaction involving the reticuloendothelial structures of bone. The lesions are clinically without symptoms but pain, swelling, and tenderness may occur. The lesions are destructive and are well demarcated. The area destroyed by the lesion is replaced by soft tissue. The treatment is curettage and sometimes radiation. The prognosis of most cases is good.

Osteomyelitis is an inflammation of bone marrow and can present in acute or chronic forms. *Acute suppurative osteomyelitis* of the jaw is most often due to the spread of infection into the medullary space after a periapical tooth abscess. The infection presents with pain, swelling, and pus formation. Cortical expansion and bony swelling occur due to appositional bone growth in the periosteum. Radiographs reveal radiolucent bone areas due to necrotic and sclerotic conditions. Long-term antibiotic treatments, sometimes together with surgical intervention, have been shown to be successful in some cases, but recurrences are frequent. Short-term treatment with corticosteroids, at the time of recurrence, has also been shown to be successful.

Soft Tissue Tumors

Hemangiomas are hamartomas and often congenital. Most hemangiomas are present at birth or arise at an early age. Hemangiomas frequently occur in the head and neck region in children, with lips, tongue, buccal mucosa, and palate as common sites of location. Many congenital hemangiomas undergo spontaneous regression at a relatively early age. Cases that do not show remission have been treated in a variety of ways, including surgery, radiation therapy, sclerosing agents, or cryotherapy. Hemangiomas do not become malignant or recur after adequate removal or destruction.

Lymphangiomas are most often seen in the tongue, but are occasionally found on the lips, gingiva, and buccal mucosa. Most cases are present at birth. If the tongue is affected, considerable enlargement may occur. Spontaneous regression of lymphangioma is rare. Surgical excision is the treatment of choice in cases with functional or extensive disturbances. Lesions show a tendency to recur after removal.

Cystic lymphangioma (hygroma) occurs as a large, deep, diffuse swelling. It is usually located in the neck but can also be found in the mouth (◉ *Fig. 174.7*).

Neurofibromatoma is a benign tumor originating from nerve tissue. The tongue is the most common site in the

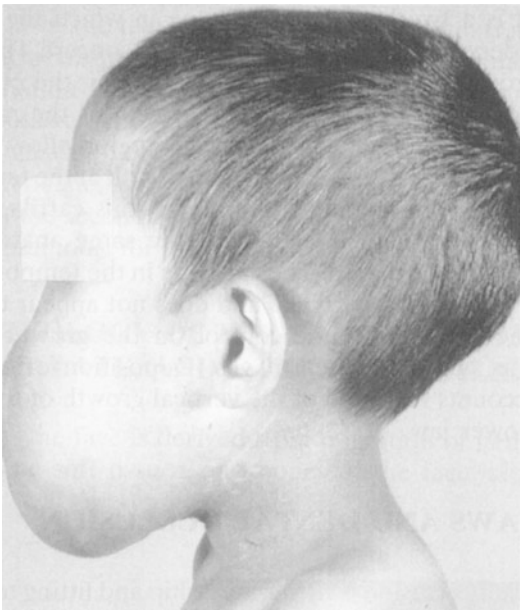


Figure 174.7
Disfiguration of the mandible due to a cystic hygroma on a 6-year-old boy

oral tissue but other locations in the mouth and the pharyngomaxillary space may be involved. Intrabony mandibular neurofibromas have been reported.

Malignant Tumors

Malignant lymphomas are classified into Hodgkin and non-Hodgkin lymphomas. Hodgkin disease frequently affects the lymph nodes in the neck; this is often the presenting symptom. The lymphoid tissue in the oral cavity and the soft tissue of the mouth and jaws may be involved later. *Burkitt lymphoma* is an undifferentiated non-Hodgkin lymphoma. It is worldwide in distribution and occurs mainly in children between 2 and 14 years of age. It has the highest proliferation rate of any human neoplasm, and when the tumor involves jaw lesions it can cause toothache, tooth mobility, and displacement, as well as intraoral and extraoral swelling.

Rhabdomyosarcoma is a malignant tumor originating from striated muscle masses. The lesions are often located on the tongue or soft palate.

Craniofacial Growth and Development

The bony growth and development of the head is best described by dividing the complex into four different areas: the cranial vault, the cranial base, the nasomaxillary complex, and the mandible. Basically, the head matures from the top down (i.e., the cranial vault attains its adult growth, then the base, the nasomaxillary complex, and finally the mandible). There are exceptions in this scheme, but overall it assists in understanding how the head grows and develops and is critical to understanding the morphogenesis of some craniofacial anomalies.

Some basic concepts pertaining to growth of the craniofacial skeleton are essential in the understanding of the development of the head. Bone growth can occur by deposition of new bone on a surface (e.g., the periosteal surface of the posterior ramus of the mandible) and concomitant resorption on the endosteal surface. This produces bone growth known as drift. The apposition of new bone and resorption of preexisting bone is called remodeling and is a fundamental bony growth process. As a result of growth, the bones of the face are relocated relative to each other. This is known as displacement or translation of the bones. Primary displacement occurs when the bones move in response to direct forces and secondary displacement occurs when the bones are repositioned by the growth of adjacent bones. For example, the maxilla grows downward and forward partially in response to growth of soft tissues in the midface (primary displacement). The maxilla is also affected by the expansion of the cranial vault and the growth of the cranial base. As these structures grow, the maxilla is translated in space relative to its preexisting position (secondary displacement).

There are 32 bones in the skull. Some of the bones have cartilage precursors (endochondral bones); others have connective tissues precursors (membranous bones). Some bones develop from both membranous and endochondral sites. The overall mechanisms controlling the growth of the bones in the head are unknown. Genetic control is the most powerful, but how the genetic control is expressed and how other factors (i.e., the environment) affect normal growth and development is only partially known or theorized.

There are three major theories that attempt to explain the bony growth and development of the head. The first states that the bones, like many other tissues and organs, are the primary determinants of their own growth and development. The second theory states that cartilage is the primary determinant of growth and that bone responds secondarily and passively to the growth of these structures. The third theory holds that all skeletal growth is a result of the bones being imbedded in a soft tissue functional matrix and it is the growth of the soft tissues that determine the growth and development of the bones and cartilages. The major difference in these theories is the location where the genetic control is expressed: directly at the level of the bone (therefore, the periosteum), directly on the cartilage (therefore, bone responds secondarily, an example of epigenetic control), or housed in the investing soft tissues (epigenetic control). The more growth is controlled indirectly, the greater the opportunity for environmental influences to affect it. The exact mechanisms are not known, but the face appears to grow in response to the growth of the cartilages and the investing soft tissues (i.e., combination of the second and third theories of growth).

For example, the cranial base is essentially endochondral bone, and the growth control for these structures appears to reside in the endochondral cartilages. Therefore, these cartilages are growth centers. That is, they have intrinsic forces responsible for the growth of the bone. Remodeling at the posterior ramus of the mandible accounts for a tremendous amount of the overall growth of this bone, but this area grows not in response to an expanding cartilage but passively in response to other forces, probably the development of the muscles of mastication (the pterygoids, masseter, and temporalis).

This passive growth in the area makes the posterior ramus a growth site. All growth centers are growth sites, but not all sites are growth centers. The growth of the orbit is an example of another response of the facial bones to extrinsic forces. As the globe expands and develops, the bony socket surrounding the eye develops in response to this soft tissue growth.

The Cranial Vault

The cranial vault is composed of a series of flat membranous bones interconnected in the fetus and infant by connective tissue sutures and six "soft spots," the fontanelles. The bones of the vault grow in response to the rapidly expanding infant brain. This growth of bone in response to growth of soft tissue is an excellent example of growth controlled by the soft tissue functional matrix. The brain case is approximately 65% complete at birth and is 90% complete by age 5. Premature closure of one or more sutures is called craniosynostosis. This can lead to a number of developmental complications, including mental retardation, abnormal facies, and lopsidedness of the skull (e.g., plagiocephaly).

Cranial Base

The cranial base grows as a result of remodeling and endochondral growth. The posterior cranial base continues to grow interstitially at the speno-occipital synchondrosis until approximately age 20, having started the fusion process in the early teens. This growth contributes to the posterior lengthening of the maxilla. This is important for the late eruption of the third molars and aids in the growth of the nasopharynx. The other cranial base synchondroses fuse considerably earlier, and much of the apparent increase in length of the anterior cranial base is remodeling and expansion of the frontonasal sinuses. The cranial base cartilages have traditionally been thought to be growth centers and as such they house the genetic control for the growth of the cranial base. Growth of the cranial base – by secondary displacement – affects the downward and forward movement of the middle and lower face.

Nasomaxillary Complex

The maxilla grows downward and forward by primary displacement from growth at the sutures, by surface remodeling, by expansion of the nasal airway, and by secondary displacement from growth of the brain and the cranial base. In many craniofacial anomalies the cranial vault and cranial base are malformed, and as a partial consequence of this, maxillary hypoplasia is seen (because of lack of secondary displacement). The role of the nasal cartilage in "pulling" the maxilla is not completely known, but it appears to play a role in the forward development of the complex. The investing soft tissues of the face play a role in the development of the bony midface. The maxilla appears to grow in response to other forces, as it has no cartilages directly affecting it. The tongue plays a role in molding the maxilla and alveolus in the early development years. Abnormal tongue position (e.g., glossoptosis) can contribute to abnormal maxillary dental arch form (a narrow V-shaped palate).

Mandible

The mandible develops as a single bone, unique in the skeleton because of its horseshoe-shaped anatomy and because it is a two-hinged single bone in which the hinges work independently of each other but in concert. The mandible grows primarily at the posterior rami, the coronoid processes, and the condyles. The growth at the ramus is membranous, and the changes in this region allow for the eruption of the posterior teeth. The growth at the temporomandibular joint is endochondral, but this cartilage does not behave like, nor does it have the same anatomy as, other skeletal cartilages. The cartilage in the temporomandibular joint is fibrocartilage and does not appear to exert the same type of genetic control on the growth of the mandible as do other cartilages. Deposition of alveolar bone accounts for some of the vertical growth of the body of the lower jaw.

The Jaws and Dental Occlusion

The dental occlusion is the relationship and fitting together of the maxillary teeth with the mandibular teeth and therefore is the interface of the independent, movable lower jaw with the upper jaw that is fixed to the skull. The development of the occlusion accounts for the vertical alveolar growth of the jaws. The teeth and their position relative to each other and subsequently the position of the jaws play three major roles in the growth and development of the child:

1. They are essential in the change from a soft to a hard diet, and after a more diverse diet is achieved, the teeth

have a major role in *digestion*, namely, *mastication* of food.
2. The teeth are essential in *proper speech development.*
3. The appearance and position of the teeth – especially in combination with functioning, normal muscles of facial expression – have a role in the development of the child's *positive self-image.*

In order for the lower face to function properly and to be pleasing esthetically, the jaws must have a reasonable relationship to each other in all three planes of space (sagittal, vertical, and transverse). In the sagittal plane, three basic types of jaw relationship exist. An orthognathic relationship implies that the jaws are well related. Prognathism implies that the lower jaw is anterior to the upper jaw. Retrognathia implies that the lower jaw is posterior or behind the upper jaw. This is implied because jaw relationship is a function of the position of both jaws; consequently, what on first observation may appear to be a mandibular prognathism may in fact be a maxillary retrusion. The vertical plane of space can again yield three basic types of jaw relationship: normal, apertognathia, and closed bite. Normal is self-explanatory; apertognathia is commonly called open bite. In open bite, the anterior teeth are disarticulated vertically; persons with apertognathia often have long, narrow, tapering faces, and the lips are open at rest. In closed bite or deep bite, the upper incisors cover the lower incisors vertically, and persons with this type of skeletal and dental relationship typically have short, square faces, and often have excessive lower lip curl. In the transverse plane, most of the problems reside in the maxilla, and are expressed by unilateral or bilateral dental crossbites. There are a myriad of combinations of relationships of the jaws, the teeth, and the planes of space. It is normal for the newborn and infant to present with mandibular retrognathia. However, if a newborn is examined and shows an excessive degree of retrognathia (i.e., micrognathia or brachygnathia), the palate should be thoroughly examined for cleft palate, as children born with micrognathia can have cleft of the secondary palate and glossoptosis. This triad is pathognomonic for the Robin sequence.

Embryology of the Face, Cleft Lip and Palate, and Other Anomalies

Most of the face is derived from migration of neural crest cells. The soft tissues, and bones of the face, along with the teeth, are derivatives of this tissue, and disturbances with the migration of the cells can account for some of the phenotypes observed in many craniofacial anomalies. The migration is completed by the fourth week of intrauterine life. The face then develops from the fusion of various processes. Interference with this fusion accounts for a variety of the facial clefts. Clefting of the lip and/or palate is a common congenital deformity, but club foot and syndactyly are the most common. Cleft lip and/or palate is, by far, the most common craniofacial deformity (*Fig. 174.8*).

At approximately the fourth week, the neural crest cells give rise to the facial processes: the frontonasal, maxillary, and mandibular processes. The maxillary and mandibular are both derived from the first branchial arch, the skeleton of this arch being the Meckel cartilage. The bilateral frontonasal processes give rise (at approximately 31 days) to lateral and medial nasal processes and an intervening nasal pit. At approximately 36 days in the human, the median nasal, lateral nasal, and maxillary processes fuse to form the upper lip and primary palate.

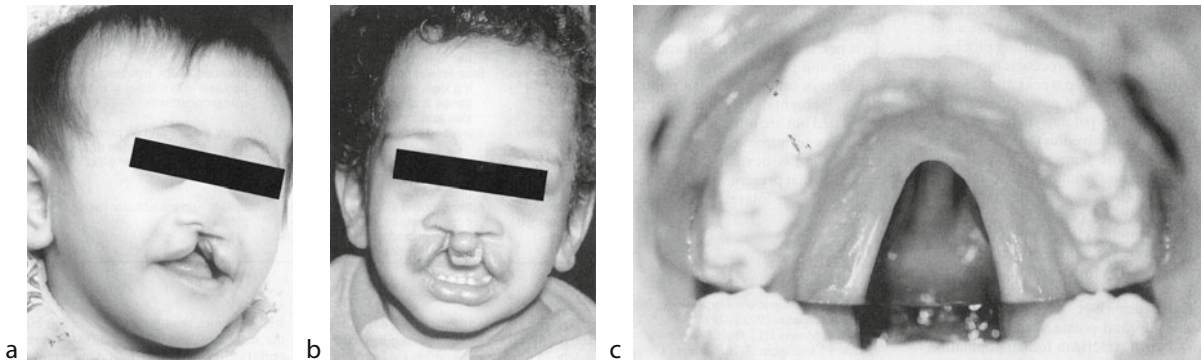

Figure 174.8
(a) Unrepaired unilateral cleft lip. (b) Unrepaired bilateral cleft lip. (c) Unrepaired cleft palate

The maxillary and mandibular processes fuse at the corners and establish the width of the mouth. The depression between the fusing processes of the upper face and the mandibular process is the stomodeum or the primitive oral cavity. Two weeks after closure of the primary palate, the secondary palate closes. This occurs by the elevation of the palatal shelves. Consequently, clefting of the lip (and alveolus) and clefting of the secondary palate are not the same embryologic phenomenon. Clefting of the lip and primary palate can lead to the subsequent clefting of the secondary palate, but not vice versa. Approximately 60% of people born with cleft lip also have cleft palate. Isolated cleft palate occurs well after lip closure and in many cases represents a mechanical deformation rather than a true malformation (i.e., the tongue prevents the shelves from closing properly and, therefore, inhibits proper fusion).

The incidence of cleft lip and palate varies, from 2.79 per 1,000 reported in a North American Indian population to 0.24 per 1,000 in an African-American population. In a study of more than 400,000 Caucasian births in England, the incidence was 0.95 per 1,000. There are conflicting reports from the Middle East. One report from Saudi Arabia puts the incidence at 2.19 per 1,000, while another report from Saudi Arabia places the incidence at 0.3 per 1,000. A report from Kuwait places the incidence at 1.48 clefts per 1,000 live births. It appears that the incidence of cleft lip and palate in Arab populations is consistent with that seen in other Caucasian populations.

Developmental disturbances of the face and mouth can be isolated but are often associated with other organ system anomalies (syndromes). The list of these problems is exhaustive and is beyond the scope of this chapter.

Table 174.4
Some anomalies that have orofacial components

Diagnosis	General findings	Orofacial findings	Etiology and frequency
Achondroplasia	Generalized skeletal dysplasia with short stature	Facial dysmorphism	Autosomal dominant
Apert syndrome	Acrocephaly, hypertelorism with exophthalmos, syndactyly of the fingers, antimongoloid slant of the palpebral fissures, low-set ears	Maxillary hypoplasia, often cleft palate	Autosomal dominant
Cleidocranial dysostosis (dysplasia)	Upper thorax narrow with a hypo or dysplasia of the clavicles, large, broad, short cranium	Delayed dental development	Autosomal dominant
Crouzon syndrome	Oxycephaly (turricephaly), exophthalmos, hypertelorism	Maxillary hypoplasia, malocclusion	Autosomal dominant
Cutis laxa, recessive type II	Loose skin, dislocated hips	Maxillary hypoplasias, relative prognathism, dental crowding	Autosomal recessive
Hemifacial microsomia (Goldenhar syndrome, oculoauriculovertebral spectrum)	Marked facial asymmetry with underdeveloped mandible on the affected side, microtia or ear tags, deviated chin	Canted occlusal plane, malocclusion	Sporadic occurrence
Osteogenesis imperfecta (generalization of all types)	Blue sclera, bone fragility, hearing loss, deformities of long bones and spine, hearing loss and joint hyperflexibility	Opalescent teeth, maxillary hypoplasia with relative mandibular prognathism	Autosomal dominant
Osteopetrosis (Albers-Schönberg disease)	Increased bone density	Primary molars and all permanent teeth are distorted and remain, or partially erupted	Autosomal dominant
Robin sequence	Cleft palate, micrognathia, glossoptosis	See general findings	Sporadic occurrence
Treacher-Collins syndrome (mandibulofacial dysostosis)	Antimongoloid slant of the palpebral fissures, malar hypoplasia, microtia with frequent conductive hearing loss	Maxillary and mandibular hypoplasia	Autosomal dominant

Some anomalies that present with orofacial disturbances that may be of particular interest are presented in *Table 174.4*.

Gastrointestinal and Liver Disorders

Hisham M. Nazer

175 Major Symptoms and Signs of Gastrointestinal Disorders

Abdel-Hai Hammo · AbdulWahab M. A. Telmesani · Hisham M. Nazer

Introduction

This chapter is intended to address in some details the major symptoms and signs of gastrointestinal, as well as, some other hepatic disorders.

The chapter is a new addition to second edition of ***"Textbook of Clinical Pediatrics"*** to enrich the knowledge and modify the clinical approach in dealing with such a wide spectrum of clinical manifestations with practical approach and clinical applications of varied spectrum of symptoms and signs pertinent to gastrointestinal and liver disorders.

The chapter is to be looked as complementary to other chapters covering various relevant symptoms and signs with practical clinical application. It does reflects real recognition for the needs of such added information to the classically set and written chapters.

This chapter will focus on four major topics:

1- Dysphagia	2- Diarrhea
3- Constipation	4- Abdominal pain

Other chapters of relevance to cover the remaining varied spectrum of gastrointestinal and hepatic disorders that the reader is advised to refer to for completion include:

1. Approach to a child with failure to thrive (Chap. 183, "Approach to a Child with Failure to Thrive")
2. Approach to a child with malabsorption (Chap. 184, "Approach to a Child with Malabsorption")
3. Cyclical vomiting syndrome (Chap. 176, "Cyclical Vomiting Syndrome")
4. Functional gastrointestinal disorders (Chap. 185, "Functional Gastrointestinal Disorders")
5. Intractable diarrhea of infancy (Chap. 188, "Intractable Diarrhea of Infancy")
6. Chronic diarrhea (Chap. 190, "Chronic Diarrhea")
7. Practical approach to children with hepatobiliary disorders (Chap. 203, "Practical Approach to a Child with Hepatobiliary Disorder")
8. Cirrhosis and Ascites (Chap. 212, "Cirrhosis and Ascites")

Dysphagia

Dysphagia is the medical term for the symptom of difficulty in swallowing. It is derived from the Greek *dys* meaning bad or disordered, and *phago* meaning "eat". It is a sensation that suggests difficulty in the passage of solids and/or liquids from the mouth to the stomach. http://en.wikipedia.org/wiki/Dysphagia - cite_note-isbn0721600107-9#cite_note-isbn0721600107-9

Dysphagia is distinguished from other symptoms including odynophagia, which is defined as painful swallowing, and phagophobia which is a psychogenic dysphagia.

Dysphagia either refers to the difficulty with initiating a swallow (usually referred to as oropharyngeal dysphagia) or the sensation that foods and or liquids are somehow hindered in their passage from the mouth to the stomach (usually referred to as esophageal dysphagia). Dysphagia therefore is the "perception" that there is an impediment to the normal passage of swallowed material.

There are two main types of dysphagia, each categorized by the part of the body that is affected. The two types have different symptoms.

Oropharyngeal Dysphagia

Oropharyngeal Dysphagia is a swallowing problem that originates from a problem or abnormality affecting the throat or mouth. The process of moving a food bolus, in particular liquids, from the mouth to the esophagus, while coming in close proximity to the airway, requires a fine coordination of events happening at a very rapid rate.

Some signs and symptoms of oropharyngeal dysphagia include difficulty controlling food in the mouth, inability to control food or saliva in the mouth, difficulty initiating a swallow, coughing, choking, frequent pneumonia, unexplained weight loss, gurgly or wet voice after swallowing, nasal regurgitation, and dysphagia which are usually related to a disruption of this phase of swallowing

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_175,

that be caused by either structural defects or more commonly neuromuscular dysfunction. Both sensory and motor injury may result in an inability to accomplish the transfer of a bolus of food or liquids from the mouth to the esophagus.

Structural abnormalities that may be encountered in the hypopharynx include: hypopharyngeal diverticulum (Zenker diverticulum), head and neck tumors, irradiation, or postcricoid webs.

Causes

- Myasthenia gravis
- Bell's palsy
- Bulbar palsy and pseudobulbar palsy
- Xerostomia
- Radiation
- Neck malignancies
- Neurotoxins (e.g., snake venom)
- Eosinophilic esophagitis
- Poliomyelitis
- Tardive dyskinesia

In these settings, patients may note that a solid bolus presents difficulty leaving the mouth and entering the tubular esophagus. The actual site of obstruction is always at or below the level at which the level of obstruction is perceived. This may occur as a result of poor motor control of the tongue, jaw, or other oral structures or may be due to an abnormality of the swallowing reflex.

Some patients have limited awareness of their dysphagia, so lack of the symptom does not exclude an underlying disease. When dysphagia goes undiagnosed or untreated, patients are at a high risk of aspiration and subsequent aspiration pneumonia. Some patients present with "*silent aspiration*" and do not cough or show outward signs of aspiration. Dysphagia within 1 s after swallowing suggests oropharyngeal dysphagia.

Signs and symptoms may include:

Low interest in feeding or meals
Tension in the body while feeding
Refusal to eat foods that have certain textures
Lengthy feeding or eating times (30 min or longer)
Food or liquid leaking from the mouth
Coughing or gagging when eating or nursing
Spitting up or vomiting during feeding
Poor weight gain

Inspection of oral cavity should alert for oral ulceration, masses, and lesions.

Neurologic testing of the cranial nerves involved in swallowing, both sensory and motor

Skin exams for scleroderma, and limbs for neuromuscular disorders

Esophageal Dysphagia

Once the food bolus enters the esophagus, passage may be hindered by structural abnormalities or alterations in esophageal motility. These alterations range from congenital abnormalities to acquired conditions.

Solid food dysphagia is the hallmark symptom of esophageal dysphagia, although both solid and liquid dysphagia are typically encountered in achalasia.

The most common symptom of esophageal dysphagia is the inability to swallow solid food, which the patient will describe as "becoming stuck" or "held up" before it either passes into the stomach or is regurgitated.

Esophageal dysphagia may be caused by two general mechanisms:

1. Structural or mechanical process impairing movement of a food bolus through the lumen, including structural abnormalities in the esophagus or extrinsically impinging upon the esophagus
2. Functional disorder

Etiologies may be differentiated by several historical points:

1. Solid versus liquid dysphagia: Dysphagia to solids alone suggests a mechanical or structural abnormalities, while dysphagia to both solids and liquids suggests a neuromuscular disorder.
2. Intermittent versus progressive symptoms: Intermittent dysphagia suggests a fixed esophageal ring or web which has not changed in size. In contrast, progressive one suggests a peptic stricture or achalasia.
3. Associated symptoms: History of heartburn or acid reflux suggests a peptic stricture. Chest pain with intermittent dysphagia indicates diffuse esophageal spasm.

Achalasia is a major exception to usual pattern of dysphagia in that swallowing of fluid tends to cause more difficulty than swallowing solids. In achalasia, there is idiopathic destruction of parasympathetic ganglia of the auerbach submucosal plexus of the entire esophagus, which results in functional narrowing of the lower esophagus, and peristaltic failure throughout its length

Signs and symptoms of esophageal dysphagia may include:

- Trouble in swallowing
- Constant feeling of a lump in the throat
- Pain with swallowing
- Drooling
- Coughing or choking with eating or drinking
- Recurrent pneumonia
- Nasal sounding voice
- Sensation of food sticking in the chest
- Weight loss
- Signs of malnutrition and dehydration
- Taking a long time to chew food
- Moving the head or neck in a strange motion while swallowing

Causes

- ***Functional causes include***
  - Achalasia
  - Myasthenia gravis
  - Bulbar or pseudobulbar palsy
- ***Mechanical causes include***
  - Peptic esophagitis
  - Carcinoma of the esophagus or gastric cardia
  - External compression of the esophagus, such as obstruction by lymph node and left atrial dilatation in mitral stenosis
  - Candida esophagitis
  - Pharyngeal pouch
  - Esophageal web
  - Esophageal leiomyoma
  - Systemic sclerosis
- ***Others***
  - Muscle disorders (dermatomyositis, myotonic dystrophy)
  - Nervous system problems
  - Obstructive lesions in the throat or esophagus, such as tumors
  - Vitamin B12 deficiency
  - Head injury, stroke
  - Cerebral palsy
  - Huntington's disease
  - Myasthenia gravis
  - Amyotrophic lateral sclerosis
  - Scleroderma
  - Infection with herpes simplex virus or yeast
  - Narrowing of the esophagus after infection or irritation
  - Injury to the swallowing muscles from chemotherapy and radiation for cancer

Differential Diagnoses of Dysphagia in Pediatric Patients

Congenital Anomalies

- Prematurity
- Nasal and nasopharyngeal
- Nasal and sinus infections
- Septal deflections
- Tumors
- Defects of lips and alveolar processes
- Hypopharyngeal stenosis and webs
- Craniofacial syndromes (e.g., Pierre Robin, Crouzon, Treacher Collins)
- Laryngeal stenosis, cleft, paralysis, and webs
- Laryngomalacia, laryngotracheoesophageal cleft
- Tracheoesophageal fistula/esophageal atresia
- Esophageal strictures and webs
- Vascular anomalies:
- Aberrant right subclavian artery (dysphagia lusorum)
- Double aortic arch, right aortic arch with left ligamentum

Acquired Anatomic Defects

- Trauma
- Intubation and endoscopy
- Central nervous system disease, anomalies, infections, hypoxia
- Head trauma
- Peripheral nervous system disease
- Neuromuscular disease
- Myotonic muscular dystrophy
- Myasthenia gravis
- Guillain–Barré syndrome
- Poliomyelitis (bulbar paralysis)

Diagnostic Tests

- Nasopharyngoscopy
- Blood tests – to check for infection and thyroid function

- Esophagram with barium swallow – is favored as the initial step because it provides information about both the structural lesions as (web, strictures, rings, or neoplasm) and esophageal motility
- Endoscopy – to assess for strictures, web, and ring, but poor for motility assessment
- Videoradiographic studies
- Ultrasound
- Manometry – for achalasia and motility study
- pH studies for gastroesophageal reflux disease
- CT scan – for neck and chest
- Chest X-ray

Treatment of Dysphagia

Symptomatic

A thorough investigation of dysphagia reveals a diagnosis in a large proportion of cases, and therapy is directed at the specific diagnosis. In some instances, empiric interventions are employed for both diagnosis and treatment. Corrective swallowing strategies and dietary manipulations are the principal empiric interventions, aimed at reducing aspiration risk and avoiding nonoral feeding. Balloon catheter or Savary dilation of the cricopharyngeus has been reported for patients with primary cricopharyngeal dysfunction, with good success.

For esophageal dysphagia, empiric strategies include dilation, antireflux therapy, and treatments aimed at sensorimotor dysfunction. Although the risk of perforation or significant bleeding approximates 1% when standard dilation is performed for a variety of benign indications, Antireflux therapy is offered to many patients with esophageal dysphagia, but a real estimate of its efficacy is unknown. Esophageal *prokinetics*, such as the 5-HT_4 agonist cisapride, increase midesophageal contraction pressures and could conceivably benefit patients with unexplained esophageal dysphagia.

Glucagon inhibits LES contraction and has been used acutely in patients with idiopathic food bolus impactions. The limited benefits of this approach may be related to the negative effects of glucagon on esophageal body motility. *Smooth muscle relaxants*, such as nitrates, calcium channel blockers, and peppermint oil, effectively decrease LES pressure or reduce distal esophageal contraction amplitudes and improve transit symptoms in achalasia. These agents have been tried in patients with spastic disorders with limited benefit.

Symptoms

Symptoms include:

- Trouble swallowing
- Constant feeling of a lump in the throat
- Pain with swallowing
- Drooling
- Coughing or choking with eating or drinking
- Recurrent pneumonia
- Nasal sounding voice
- Sensation of food sticking in the chest
- Weight loss

Diagnosis

The doctor will ask about your symptoms and medical history, and perform a physical exam. The exam will focus on the nervous system. The doctor will also watch you chewing and swallowing.

Tests may include:

- Nasopharyngoscopy – using a scope to view the throat
- Blood tests – to check for infection and thyroid function
- Esophagram with Barium Swallow – X-ray test of the esophagus
- Endoscopy – a thin, lighted tube inserted down the throat to examine the esophagus
- Videoradiographic studies – X-rays during which swallowing is filmed on video
- Ultrasound – a test that uses sound waves to examine structures inside the body
- Manometry – tests the amount of pressure generated in various parts of the esophagus
- pH studies – tests the degree of acidity in the esophagus
- CT scan – a type of X-ray that uses computers to make pictures of the neck and chest
- Chest X-ray – to check for pneumonia

Swallowing Techniques and Exercises

A speech-language pathologist can teach

- Techniques to help you swallow more easily
- Exercises that strengthen the muscles needed for swallowing

Diet Changes

In severe cases, high-nutrition liquid drinks and thickener powder may be added. If a problem persists with feeding liquids, gastric tube will be placed.

Surgery

In severe cases, surgery may be needed to:

- Release an overly tight muscle
- Remove a stricture or web that is blocking the esophagus
- Place a stent to hold the esophagus open
- Place a gastric feeding tube

Diarrhea in Children

Definition

Diarrhea implies an increase in stool volume and diminished stool consistency. It is a common cause of death in *developing countries* and the second most common cause of infant deaths worldwide. The loss of fluids through diarrhea can cause dehydration and electrolyte imbalances. It has been defined in infants and young children as daily stools with a volume greater than 10 ml/kg and in older children as daily stools with a weight greater than 200 g. This situation typically implies an increased frequency of bowel movements, which can range from 4 to 5 times to more than 20 times per day.

Diarrheal episodes are classically distinguished into acute and chronic based on their duration. *Acute diarrhea* is thus defined as an episode that has an acute onset and lasts no longer than 14 days*; chronic or persistent diarrhea* is defined as an episode that lasts longer than 14 days. The distinction often has a different set of causes, presentation, complications, management, and a different prognosis.

Pathophysiology of Diarrhea

Normally, the small intestine and colon absorb 99% of both oral intake and endogenous secretions from the salivary glands, stomach, liver, and pancreas. Diarrhea results from a disruption of this normal mechanism and as a result, the net absorptive status of water and electrolytes will be disturbed, resulting in excess losses and dehydration. The small intestine is the prime absorptive surface and the colon then absorbs additional fluid, transforming a relatively liquid fecal stream in the caecum to well-formed solid stool in the rectosigmoid part. Either a decrease in absorption or an increase in secretion leads to additional fluid within the lumen and diarrhea.

Diarrheal illnesses may be classified as follows:

- Osmotic, due to an increase in the osmotic load presented to the intestinal lumen, either through excessive intake or diminished absorption
- Secretory, when increased secretory activity occurs
- Inflammatory (or mucosal), when the mucosal lining of the intestine is inflamed
- Motile, caused by intestinal motility disorders

In osmotic diarrhea, stool output is proportional to the intake of the unabsorbable substrate; osmotically active substance (e.g., magnesium ion, lactulose) that osmotically retains fluid within the lumen, thereby reducing water absorption. Diarrheal stools promptly regress with discontinuation of the offending nutrient, and the stool ion gap is high, exceeding 100 mOsm/kg. Because neither the small intestine nor colon can maintain an osmotic gradient, unabsorbed ions remaining in the intestinal lumen obligate retention of water to maintain an intraluminal osmolality equal to that of body fluids (about 290 mOsm/kg). The most common cause is related to poorly absorbed sugar and the most common clinical syndrome related to excess sugar malabsorption is of disaccharidase enzyme deficiency such as *lactase deficiency,* which accounts for lactose intolerance. javascript:top.left.goRef('r_chap09.htm','r11')

Lactase is present in the brush border of the small intestine and if the enzyme level transiently or permanently disappears, then lactose malabsorption forms and diarrhea develops. Congenital deficiency of lactase is quite rare and seems to be due to a mutation in a gene distinct from that for lactase-phlorizin hydrolase. Other disaccharidase enzyme deficiency is quiet rare.

The essential characteristic of osmotic diarrhea is that it disappears with fasting or cessation of ingestion of the offending substance. This characteristic has been used clinically to differentiate other causes of diarrhea. Electrolyte absorption is not impaired and low in the stool.

In secretory diarrhea, the driving force for this type of diarrhea is always either net secretion of chloride or bicarbonate or inhibition of net sodium absorption. There is little-to-no structural damage. The epithelial cells' ion transport processes are turned into a state of active secretion.

The most common cause of acute-onset secretory diarrhea is a bacterial infection of the gut. They may trigger release of cytokines attracting inflammatory cells, which, in turn, contribute to the activated secretion by

inducing the release of agents such as prostaglandins or platelet-activating factor.

Features of secretory diarrhea include that the intestinal fluid secretion is isotonic, continues even when there is no oral food intake, a lack of response to fasting, and a normal stool ion gap (i.e., 100 mOsm/kg or less), indicating that nutrient absorption is intact.

The absence or disruption of a specific absorptive pathway may cause diarrhea. For example, there are congenital syndromes due to absence of a specific transport molecule, such as *congenital chloridorrhea* and *congenital sodium diarrhea*.

In chloridorrhea, cl-HCO3 exchange in the ileum and colon is defective, transforming chloride into a poorly absorbed ion. Diarrhea due to chloridorrhea can be reduced by limiting chloride intake or inhibiting chloride secretion by reducing gastric acid secretion with a proton-pump inhibitor.

In inflammatory diarrhea, there is damage to the mucosal lining or brush border, which leads to a passive loss of protein-rich fluids, and a decreased ability to absorb these lost fluids. It can be caused by bacterial infections, viral infections, parasitic infections, or autoimmune problems such as inflammatory bowel diseases. Some of these are usually temporary, because over time the intestine may improve its capacity for absorption by the process of *adaptation.*

In motility-related diarrhea, diarrhea is caused by the rapid movement of food through the intestines (hypermotility). For fluid and electrolyte absorption to be complete, the contact time between luminal contents and the epithelium must be sufficient to permit absorption. There is not enough time for sufficient nutrients and water to be absorbed.

This can be due to a vagotomy, diabetic neuropathy, or hyperthyroidism that can produce hypermotility and lead to pseudodiarrhea and occasionally real diarrhea. Diarrhea can be treated with antimotility agents. Hypermotility can be observed in people who have had portions of their bowel removed, allowing less total time for absorption of nutrients.

Common Causes of Chronic Diarrhea

- **Infectious diseases.** There are a few infectious diseases that can cause chronic diarrhea. Although most bacteria causing diarrhea are cleared spontaneously within 4 weeks, some organisms, such as *Aeromonas* and *Pleisiomonas*, and *Giardia lamblia*, may cause chronic diarrhea. Patients with AIDS often have chronic infections of their intestines that cause diarrhea.
- **Postinfectious.** Following acute viral, bacterial, or parasitic infections, some children develop chronic diarrhea. The cause of this type of diarrhea is not clear, but some of the individuals have bacterial overgrowth of the small intestine. This condition also is referred to as postinfectious diarrhea.
- **Bacterial overgrowth of the small intestine.** Because of small intestinal problems, normal colonic bacteria may spread from the colon and into the small intestine. The diarrhea is presumably due to toxins, as well as fatty diarrhea, due to bile salt deconjugation.
- **Inflammatory bowel disease (IBD).** Crohn's disease and ulcerative colitis, diseases causing inflammation of the small intestine and/or colon, commonly cause chronic diarrhea. Stools are characterized by the presence of mucus and pus and are usually associated with ulceration of the mucosa.
- **Carbohydrate (sugar) malabsorption.** Carbohydrate or sugar malabsorption due to deficiency in diasaccharidase enzymes will result in malabsorption of sugar as with lactase deficiency in which milk products containing lactose, leading to diarrhea. The undigested lactose reaches the colon and pulls water (by osmosis) into the colon. This leads to diarrhea. Although lactose is the most common form of sugar malabsorption, other sugars in the diet also may cause diarrhea, including fructose and sorbitol.
- **Fat malabsorption.** Fat malabsorption may occur because of reduced pancreatic secretions that are necessary for normal digestion of fat (e.g., pancreatitis) or by diseases of the lining of the small intestine that prevent the absorption of digested fat (e.g., celiac disease). Passage through the small intestine and colon also may be more rapid when there is malabsorption of fat.
- **Irritable bowel syndrome.** The irritable bowel syndrome (IBS) is a functional cause of diarrhea or constipation. Inflammation does not typically exist in the affected bowel. It may be caused by several different underlying problems, but it is believed that the most common cause is rapid passage of the intestinal contents through the colon.
- **Endocrine diseases.** Several endocrine diseases (imbalances of hormones) may cause diarrhea, for example, (hyperthyroidism) and (Addison's disease).
- **Laxative abuse.** Can be an occasional cause of chronic diarrhea.

Clinical Presentation

History

- *Acute diarrhea* is a benign, self-limited condition, subsiding within a few days. The clinical presentation and course of illness depend on the etiology of the diarrhea; for example, rotavirus is more commonly associated with vomiting, dehydration, and diarrhea. Diet history should include the amount and type of fluids, solid foods, and formula ingested. The volume intake and hydration status determine the amount of fluids that is lost.
- The proper amount of fluid for most young children is around 100 ml/kg/day. Fluid intake that exceeds this amount may result in looser stools. Fat intake of less than 3 g/kg/day may contribute to toddler's diarrhea, especially in the setting of excessive free fluid and carbohydrate intake (e.g., as occurs with large amounts of fruit juice intake). Apple and pear juice contain a high fructose-to-glucose ratio, and consumption of these juices can result in fructose malabsorption and diarrhea.

Stool Characteristics

- Patients with toddler's diarrhea often have loose stools with undigested food particles.
- Frequent loose watery stools may indicate carbohydrate intolerance.
- Pasty or loose foul-smelling stools indicate fat malabsorption. This symptom is commonly seen in *Giardia* infections, enterokinase deficiency, hepatic and pancreatic dysfunctions, and protein sensitivity syndromes.
- Bloody stools are seen in patients with protein sensitivity but not in disaccharidase and pancreatic enzyme deficiencies or in patients with giardiasis.

Other Symptoms

- Systemic symptoms, including weakness, fatigue, and failure to thrive, are systemic consequences of chronically poor nutrient absorption. Malabsorption of carbohydrates, fats, or proteins can cause failure to thrive.
- Flatulence associated with foul-smelling stools that float suggests fat malabsorption, which can be observed with infection with *Giardia lamblia*.
- Stool characteristics such as consistency, color, volume, and frequency can be helpful in determining whether the source is from the small or large bowel.
- Food history can be helpful.
  - Ingestion of contaminated food is a common cause.
  - Organisms that cause food poisoning include the following:
    - Dairy food – *Salmonella* species
    - Eggs – *Salmonella* species
    - Meats – *C. perfringens* and *Aeromonas, Campylobacter*, and *Salmonella*
    - Ground beef – Enterohemorrhagic *E. coli*
    - Poultry – *Campylobacter* species
    - Vegetables – *Aeromonas* species and *C. perfringens*
- Water exposure can contribute to diarrhea.
  - Swimming pools have been associated with outbreaks of infection with *Shigella* species; *Aeromonas* organisms are associated with exposure to the marine environment.
- *Giardia, Cryptosporidium,* and *Entamoeba* organisms are resistant to water chlorination; therefore, exposure to contaminated water should raise index of suspicion for these parasites.
- A history of camping suggests exposure to water sources contaminated with *Giardia* organisms.

Physical Examination

- Dehydration
  - Dehydration is the principal cause of morbidity and mortality
  - Signs, symptoms, and severity
  - Lethargy, level of consciousness, sunken anterior fontanel, dry mucous membranes, sunken eyes, lack of tears, poor skin turgor, and delayed capillary refill are signs of dehydration
- Failure to thrive and malnutrition
  - Reduced muscle and fat mass or peripheral edema secondary to carbohydrate, fat, and/or protein malabsorption.

    Giardia organisms can cause intermittent diarrhea and fat malabsorption.
- Abdominal pain
  - Nonspecific abdominal pain and cramping are common with some organisms.
  - Pain usually does not increase with palpation.

Laboratory Studies

- In patients with diarrhea, a stool pH level of 5.5 or less or presence of reducing substances indicates carbohydrate malabsorption, which is usually secondary to viral illness and transient in nature.

- Enteroinvasive infections of the large bowel cause leukocytes. Absence of fecal leukocytes does not eliminate the possibility of enteroinvasive organisms. However, presence of fecal leukocytes eliminates consideration of enterotoxigenic *E. coli, Vibrio* species, and viruses.
- Exudates found in stool highly suggest colitis. Colitis can be infectious, allergic, or part of inflammatory bowel disease.
- Always culture stool for *Salmonella, Shigella,* and *Campylobacter* organisms and *Y. enterocolitica* in the presence of clinical signs of colitis or if fecal leucocytes are found.
- Look for *C. difficile* in persons with episodes of diarrhea characterized by colitis and/or blood in the stools. *C. difficile* may also occur without a history of antibiotic use.
- Bloody diarrhea with a history of ground beef ingestion must raise suspicion for enterohemorrhagic *E. coli.* If *E. coli* is found in the stool, determine if the type of *E. coli* is O157:H7.
- Rotavirus antigen can be identified by enzyme immunoassay and latex agglutination assay of the stool.
- Adenovirus antigens can be detected by enzyme immunoassay. Only serotypes 40 and 41 are able to induce diarrhea.
- Examination of stools for ova and parasites is best for finding parasites. Perform stool examination every 3 days or every other day.
- The leukocyte count is usually not elevated in viral-mediated and toxin-mediated diarrhea. Leukocytosis is often but not constantly observed with enteroinvasive bacteria. *Shigella* organisms cause a marked bandemia with a variable total white blood cell count.
- At times, a protein-losing enteropathy can be found in patients with extensive inflammation in the course of enteroinvasive intestinal infections (e.g., *Salmonella* species, enteroinvasive *E. coli*). In these circumstances, low serum albumin levels and high fecal alpha-1-antitrypsin levels can be found.

Procedures

Endoscopy for intestinal biopsies for others ill-defined causes as: celiac disease, enzyme assays, duodenal aspirates for Giardia, inflammatory bowel disease, congenital lymphangiectasia, and other rare conditions.

Management

- In many cases of diarrhea, replacing lost fluid and salts is the only treatment needed. It should be started as soon as possible mainly in infants before it progresses to dehydration that warrants hospitalization. This is usually by mouth – oral rehydration therapy – or, in severe cases, intravenously.
- Research does not support the limiting of milk to children as no effect on duration of diarrhea. Certain food and drinks are better to be avoided during the course of the illness that may increase the intestinal load and worsen the diarrhea. Examples of these foods are: whole grain breads and cereals, fresh or frozen fruits (except banana), dried fruits, fruit juices with pulp and prune juice, fatty foods, rich desserts, spicy foods and fried foods.
- However, certain foods are encouraged during the course of the disease to be consumed that will lower the frequency and volume of stool as: bananas, applesauce, boiled white rice, potatoes (without skin; mashed or baked), and plain pasta.
- The use of probiotics in treating diarrhea showed some effectiveness. The probiotic lactobacillus can help prevent antibiotic-associated diarrhea and in those who had lactose intolerance, taking digestive enzymes containing lactase when consuming dairy products has helped in alleviating sign and symptoms of lactose intolerance and diarrhea-related symptoms.

Medications

Medications may be beneficial; however, you need to be cautious when prescribed or it could be contraindicated in certain situations and would worsen the diarrhea or mask the underlying disease.

- Antibiotics: While antibiotics are beneficial in certain type of acute diarrhea, they are usually not used in most of them. There are concerns that antibiotic may increase the risk of hemolytic uremic syndrome in people infected with Escherichia coli O157:H7. However, some bacteria are developing antibiotic resistance, particularly *Shigella.*
- Antimotility agents: Antimotility agents like loperamide are effective at reducing the duration of diarrhea.

- Bismuth compounds: While bismuth compounds (Pepto-Bismol) decreased the number of bowel movements in those with travelers' diarrhea, it does not decrease the length of illness.
- Codeine phosphate: Codeine phosphate is used in the treatment of diarrhea to slow down the peristalsis and the passage of fecal material through the bowels, which gives a firmer stool, and also means that feces is passed less frequently.

Abdominal Pain

Abdominal pain is a common pediatric problem seen frequently in the outpatient clinics and emergency departments. It constitutes around 5% of the unscheduled visits and presents as an acute or chronic abdominal pain. It can be such a difficult problem to resolve especially in the young infant. Involvement of most, if not all systems of the body, may be associated with abdominal pain as part of its clinical presentation. The viscera are full of pain receptors. Two types and locations of pain receptors in the bowel have been identified. The first type is located in the serosa and the submucosa of the intestine and responsible for painful stimuli caused by distention, torsion, compression, and traction. The second type of receptors located on the surface of the mucosa induce pain through chemical stimuli of histamine, bradykinin, prostaglandins, and serotonin released in response to inflammation and ischemia. Pain arising from the bowel is usually felt in the midline because of the bilateral innervations, while pain arising from solid organs like liver, kidneys, ureter, ovaries, etc., usually lateralizes because they are unilaterally innervated. The central, peripheral, sympathetic, and parasympathetic innervations of the gastrointestinal tract make the intestine a very sensitive organ to many of the hormones released in the body that can easily be provoked by psychological stresses. Hence, it acts like a mirror to our psychological and emotional states. In this chapter, abdominal pain will be addressed as a problem rather than specific etiologies.

Epidemiology

Up to 17% of the schoolchildren complain of abdominal pain at some time of their life. The prevalence of acute abdominal pain in childhood is around 5.1%. Upper respiratory tract infections and gastroenteritis account for 35% and 11% of causes of acute abdominal pain, respectively. Approximately 1% of children with abdominal pain require surgical intervention. It is the acute pain that usually warrants quick comprehensive coverage of history, physical examination, and investigations to reach the diagnosis as soon as possible and to save the child from the risk of delayed diagnosis and improper management. The incidence of chronic abdominal pain is around 15%. Functional or nonorganic causes of chronic abdominal pain account for more than 90% of the chronic abdominal pain in the pediatric age group. Chronic abdominal pain is more common in girls than boys with two peaks: an early one from 4 to 6 years and a later one at early adolescence life.

Acute Abdominal Pain

Acute abdominal pain is a frequent, nonspecific, symptom for many of the childhood viral illnesses like upper respiratory tract infection, gastroenteritis, constipation, in addition to nonorganic conditions. Nonsurgical but serious diseases can present with abdominal pain and need immediate attention and intervention like diabetic ketoacidosis (DKA), peritonitis, bacterial gastroenteritis, pneumonia, and urinary tract infections (UTI). Life-threatening conditions like upper respiratory tract infection cause diffuse abdominal pain secondary to mesenteric lymphadenitis. Diffuse pain is also found in gastroenteritis. Pain at the epigastria is usually due to gastritis, peptic ulcer disease, and pancreatitis, while pain at the right upper abdomen is due to hepatitis and cholecystitis. Pain at the umbilicus that migrates to right lower quadrant is typical for appendicitis. Epigastric pain that refers to the back is characteristic of pancreatitis. Intermittent colic with intervals of well-being is characteristic of intussusceptions. Pain associated with peritonitis is aggravated by movement. History of trauma raises the possibility of solid organ injury, while past history of surgery is usually associated with adhesions and bowel obstruction. History should include bowel habit to rule out constipation. History of abdominal pain in adolescent girls should include regularity of the menstrual periods and sexual activity to include or exclude the possibility of pelvic inflammatory disease and ectopic pregnancy. Pain precipitated by hunger is associated with peptic ulcer which is not common in children. Family history of peptic ulcer is positive in about 70% of children with peptic ulcer disease. Associated symptoms with abdominal pain give additional clues toward the diagnosis. Fever is a sign of infections as with gastroenteritis, pharyngitis, urinary tract infections, peritonitis, and occasionally appendicitis. Pneumonia is also recognized cause of abdominal pain

usually associated with cough and fever. Vomiting is a nonspecific but frequent association of acute abdomen. Abdominal pain and vomiting are common initial presentation of gastroenteritis; on the other hand, they can also be signs of intestinal obstruction secondary to volvulus, adhesions, malrotation, and intussusception. Bilious vomiting indicates obstruction below the ampulla of Vater and should be taken seriously. Nausea and vomiting are among the common symptoms of appendicitis. Vomiting and abdominal pain is a common presentation of DKA. Diarrhea is a manifestation of gastroenteritis but also an uncommon manifestation of UTI, pneumonia, and appendicitis. Bloody diarrhea and abdominal pain should raise the suspicions of hemorrhagic colitis, hemolytic uremic syndrome, intussusception, and inflammatory bowel disease. Hemolytic anemia and recurrent bouts of hemolysis induce gall stone formation leading to abdominal pain secondary to cholecystitis, common bile duct obstruction, or pancreatitis. In the neonates, feeding history, amount, and frequency can be diagnostic of GER, colic, and/or cow's milk allergy. Constipation in neonates can be a manifestation of Hirschsprung's disease which per se can cause abdominal pain or secondary to its serious complication of enterocolitis.

The physical examination of a child with abdominal pain should be thorough and may have to be repeated more than once. An ill-looking child with abdominal pain should be carefully evaluated for peritonitis or perforated appendix. Poor perfusion and signs of hypovolemia result from trauma (solid organ injury) and sepsis secondary to perforated appendix or peritonitis. A common presentation of diabetic ketoacidosis is deep breathing (Kussmaul breathing), abdominal pain, and decreased level of consciousness. Congested and inflamed large tonsils covered with exudates support the diagnosis of streptococcal infection. Chest crepitations and decreased air entry to parts of the lung points toward pneumonia. A soft abdomen in a comfortable well-looking child is unlikely to be seen in serious illnesses or acute abdomen. Abdominal distention is commonly due to gas, stool, organomegaly, bowel obstruction, or the presence of a mass. The child can be asked to use his or her finger to point to the site of the pain. Children with acute abdomen usually have tenderness and sometimes guarding. Consistent tenderness at the same site and abdominal guarding are signs of intra-abdominal inflammation or inflamed peritoneum. Organomegaly in a child with abdominal trauma can be due to hemorrhage in the solid organ that warrants prompt action toward stabilizing the patient with possible surgical intervention. Tenderness on percussion indicates inflamed peritoneum as seen in acute appendicitis. Bowel sounds are exaggerated in gastroenteritis as well as in intestinal obstruction. In male patients, examination of the scrotum is essential. A swollen tender scrotum is a sign of testicular torsion. Rectal examination is uncomfortable for young children. Recent studies showed that rectal exam is of little help even in case of appendicitis. Although historically seen as an important item in assessing abdominal pain, if it is to be done, it should be done by pediatric gastroenterologists or pediatric surgeons. Abdominal pain and typical purpuric rash over the lower limp extensor surfaces is likely caused by intestinal submucosal hemorrhage associated with Henoch–Schonlein purpura. Important causes of acute abdominal pain in childhood are summarized in *Table 175.1*.

Investigation

The investigations required in most cases after completing history and thorough examination are usually limited. According to the specific suspected entity/entities, laboratory tests should be directed. The habit of ordering a set battery of investigations for every patient with acute abdominal pain is a malpractice and should be avoided. High WBC is an acute phase reactant of infections particularly bacterial. High WBC among other criteria is a supportive evidence of appendicitis although normal

Table 175.1
Causes of acute abdominal pain in childhood

– Infantile colic	– Mesenteric lymphadenitis
– Volvulus	– Henoch–Scholein purpura
– Appendicitis	– Pyelonephritis
– Gastroenteritis	– Diabetic ketoacidosis
– Constipation	– Inflammatory bowel disease
– Urinary tract infection	– Peptic ulcer disease
– Dietary protein allergy	– Cholecystitis
– Viral illness	– Urolithiasis
– Foreign body ingestion	– Adhesions
– Trauma	– Incarcerated hernia
– Renal colic	– Tumors
– Pneumonia	– Hemolytic uremic syndrome
– Pancreatitis	– Meckel's diverticulum
– Poisons	– Hepatitis
– Porphyria	– Child abuse
– Sickle cell crisis	– Intussusception
– Testicular torsion	

WBC does not rule out appendicitis. Blood chemistry, random blood sugar, and blood gases are important when DKA is suspected. Urine dipstick can be an indicator for the presence of WBC, nitrate, ketones, and sugar and is valuable in the diagnosis of dehydration, UTI, and DKA. Serum amylase and lipase are usually elevated in case of pancreatitis. Throat swab and culture should be ordered when streptococcal infection is suspected. Barium contrast studies may be also helpful in identifying the cause of abdominal pain, especially when it is vague and nonspecific (*Fig. 175.1*). Abdominal ultrasonography may confirm the presence of gallstones in the gall bladder (*Fig. 175.2*) or the biliary ducts. Cholestatic liver disease is associated with bile plug and bile sludge formation in the biliary duct with increased incidence of stone formation. Hepatic ultrasonography may also identify other causes of chronic vague abdominal pain as in hydatid disease (*Fig. 175.3*) The treatment of abdominal pain due to hepatobiliary disorders depends mainly on treatment of the underlying cause.

Abdominal ultrasound is very useful to assess organomegaly, stones, cyst, and abscess formation. Moreover, it can be diagnostic for intussusceptions and occasionally appendicitis. Plain abdominal X-ray is helpful in the diagnosis of intestinal obstruction and perforation by showing air-fluid levels or free air in the peritoneum. Upper GI contrast X-ray series can be used to diagnose obstruction in case of volvulus, and barium enema as a diagnostic and sometimes therapeutic in suspected intussusceptions. Contrast computed tomography has been utilized in the diagnosis of appendicitis with high sensitivity and specificity as well as in the confirmation of pancreatitis. In some instances, magnetic resonance cholangio pancreatography (MRCP) examination may be required.

Cholelithiasis: abdominal sonography in an 11-month-old male infant with abdominal pain, renal tubular acidosis, and gallbladder stone (*arrow*)

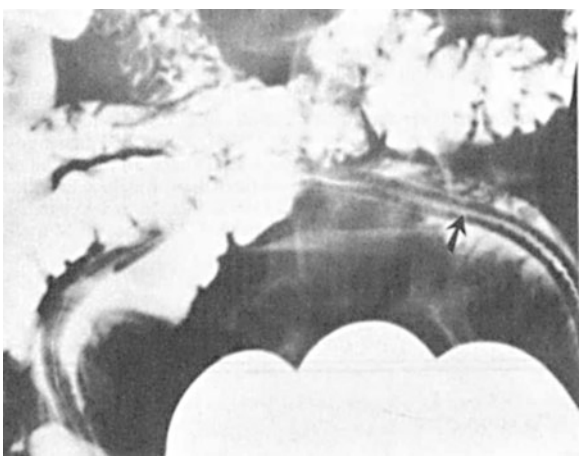

Figure 175.1
Barium contrast study in 10-year-old boy with vague abdominal pain. The follow-up study has revealed an elongated defect of *Ascaris* worm (*arrow*) in the contrast

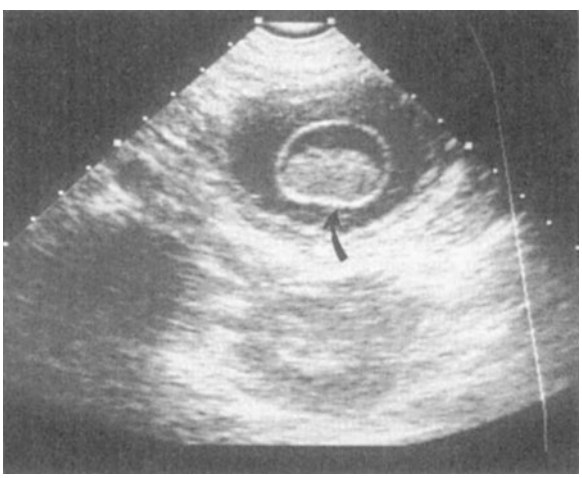

Figure 175.3
Hydatid cyst: abdominal sonography in a 12-year-old girl with vague abdominal pain. Note the round mass (hydatid cyst) in the left lobe of the liver *(arrow)*

Management

Once the diagnosis is reached, proper treatment can be instituted. Appropriate resuscitation measures while maintaining homeostasis should be applied to any patient who is morbid, ill looking with signs of hypovolemia and pending shock. While obtaining history, a good intravenous line should be established and, if needed, blood for cross-match and transfusion should be sent to the laboratory. Child trauma management is a team task of nurses, pediatricians, and surgeons. Traditionally, analgesia is contraindicated for patients with acute abdomen, but this concept seems to be changing. A double-blind study concluded that intravenous morphine provides significant pain reduction to children with acute abdominal pain without adversely affecting the examination. Moreover, morphine does not affect significantly the ability to identify children with surgical conditions.

Chronic "Recurrent" Abdominal Pain (RAP)

Chronic abdominal pain and recurrent abdominal pain (RAP) are two terms used interchangeably. Recurrent abdominal pain is defined as at least three episodes of abdominal pain, over a period of 3 months, severe enough to interfere with activity. Pain lasting more than 1 month is considered chronic. Recurrent abdominal pain is one of the most frequent complaints in the childhood and the most common episodic pain in pediatric age group. The incidence of childhood RAP has been found to be up to 15% and the prevalence between 4% and 12% in children aged 2–6 years. Girls are affected more than boys. The peak incidence of RAP is 5–6 years for boys and girls, and second peak for girls is, in early adolescence, 9–10 years of age. There are two categories of RAP: organic and functional (nonorganic) causes (Table 175.2). The list is incomplete but is intended to give some guidance on the spectrum of causes of RAP in childhood. The clinical details of these conditions are discussed in their relevant chapters. However, the nonorganic RAP is the most common as it accounts for more than 90% of the cases.

Functional (Nonorganic) Abdominal Pain

Functional disorders are those without any evidence of organ pathology. Children with nonorganic RAP have lower pain threshold than their peers particularly gastrointestinal pain. The child stresses and worries start to be projected and expressed through the digestive system in the form of abdominal pain. Hence, psychosocial evaluation and verifying family dynamics are essential for the diagnosis, treatment, and counseling.

Table 175.2
Alarming symptoms and signs in chronic "recurrent" abdominal pain

Symptoms	Signs
– Young age < 5 years	– Flank tenderness
– Constant site of pain	– Organomegaly
– Pain awaking child while asleep	– Abdominal mass
– Vomiting and/or diarrhea	– Anal fissures and ulceration
– Blood in stool or urine	– Anal skin tags
– Fever	– Oral ulcers
– Weight loss	– Joint swelling and redness
– Failure to thrive	– Anemia
– Delayed puberty	– High ESR
– Dysphagia	– Abnormal liver function test
– Respiratory symptoms	– High urine WBC or bacteria
– Arthralgia	
– Hematuria, dysuria	

Clinical Evaluation

Until recently, nonorganic RAP was collectively called functional abdominal pain. Rome group came up with Rome I and II criteria that shaped the diagnosis, but it was adult oriented. Rome III criteria described four different presentations of childhood functional RAP which started to be adopted by pediatricians and pediatric gastroenterologists. The four recognizable types of functional RAP are:

1. Functional dyspepsia: The pain is felt mostly in the upper abdomen. The pain is peptic ulcer–like in its location and is associated with symptoms of recurring nausea and vomiting. Additional symptoms are dysmotility or delayed gastric emptying causing bloating and upper abdomen fullness.
2. Irritable bowel syndrome (IBS): The pain is in the lower abdomen or takes the course of the colon. Some of the patients have rectal pain or spasms. Like adult IBS, the child often has alternating bowel habit of diarrhea and constipation.

3. Abdominal migraine: This is a rare type of RAP. It is characterized by episodic bouts of severe non-colicky abdominal pain that lasts for hours and is associated with pallor, nausea, and vomiting. Family history of migraine is commonly positive.
4. Functional abdominal pain: When the pain does not fit the above categories and no organic cause is found, the diagnosis of functional abdominal pain comes to play.

Although there are four different types of nonorganic chronic recurrent abdominal pain, yet all are precipitated by either anxiety or depression. The anxiety and depression are secondary to psychosocial or family dynamic disturbances.

Four circles need to be explored for children when functional RAP is suspected (Fig. 175.4). These are the family and the child personality, the schooling, peers, and physical or sexual abuse.

The fist circle is the child personality and family dynamics. A chaotic family, parental dispute and fights, abusive parents, and a passive dependent personality all can lead to stressful environment for the child and eventually appear in the form of abdominal pain. Similarly, hospitalization, loss of a family member, or even moving to another neighborhood can be stressful for the child.

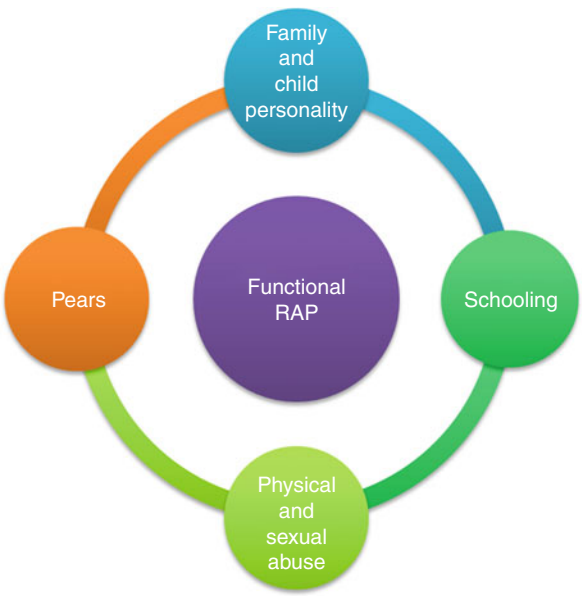

Figure 175.4
Functional RAP in childhood: recognized four interrelated circles

The second circle is schooling and, in particular, school performance. Poor school performance can lead to depression; on the other hand, the perfectionist, competitive, and excellent students are prone to develop anxiety. Both depression and anxiety can lead to RAP.

The third circle is the peers, and bullying has been reported to be a major cause of RAP.

The fourth and last circle is the area of child abuse, in particular, sexual abuse which is an area of marked stress, anxiety, and/or depression. The treating physician needs to explore all the four circles carefully and tactfully. The child and the parents need to be interviewed together and sometimes separately as some important information may not be obtained in the presence of the parents.

History and interviews may be done over two or three sessions. Repeated visits promote the child–physician trust and help the child to volunteer difficult and sensitive information. In most of patients, functional RAP is associated with other symptoms like headache, bone or muscle pain, commonly leg pain, and varied spectrum of psychosomatic manifestations.

The physical examination of a child with functional RAP should be thorough to assure no organic pathology is present. The child growth has to be plotted to make sure he or she is growing normal. Similarly, sexual growth and the Tanner stage are to be determined. Typically, abdominal examination frequently shows inconsistent and changing pain location. Tenderness may be found but may disappear when the child is distracted. The pain is usually localized at or around the umbilicus and is not related to meals. The abdomen is otherwise soft, with no guarding or organomegaly. The rest of the body exam is usually unremarkable.

Organic Chronic Abdominal Pain

The organic causes of chronic recurrent abdominal pain constitute less than 10%. Certain signs and symptoms (red flags) associated with chronic abdominal pain should be alarming for possible organic etiology (Table 175.3). In such situations, the child deserves attention and proper investigations. Pain that awakens the child from sleep is unlikely to be functional and could be secondary to inflammatory bowel disease (IBD) or peptic ulcer disease. Family history of IBD and peptic ulcer disease raises such possibility even further. History of recurrent mouth ulcers, weight loss, joints pain, and hematochezia are manifestations of Crohn's disease. Respiratory symptoms, dysphasia, and chronic abdominal pain are found in gastroesophageal reflux or chest infection. Dysuria is

Table 175.3
Organic causes of chronic "recurrent" abdominal pain

– Constipation	– Heavy metal poisoning (Lead. . .)
– Urinary tract infection	– Familial mediterranian fever (FMF)
– Hiatal hernia	– Pelvic inflammatory disease
– Lactose intolerance	– Tumors (ovarian, etc.)
– Gastritis	– Tuberculosis
– Parasitic infestations	– Dysmenorrhea
– Intestinal malrotation	– Nephrolithiasis
– Subacute intestinal obstruction	– Porphyria
– Hernia	– Hydronephrosis
– Cholecystitis and cholelithiasis	– Cystic fibrosis
– Cholydocal cyst	– Pancreatitis
– Celiac disease	– Peptic ulcer disease
– Eosinophilic gastroenteritis	– Meckel's diverticulum
– Inflammatory bowel disease	

a sign of urinary tract infection. Vomiting after meals and family history of pancreatitis are a call to pursue the diagnosis of pancreatitis, particularly hereditary pancreatitis, while vomiting blood could be due to peptic ulcer or esophagitis. Bilious vomiting is a sign of bowel obstruction below the ampulla of Vater and can be intermittent as in intestinal malrotation, superior mesenteric artery syndrome (SMS), and intussusception. Fever is always a sign of organic disorders either an infection or chronic diseases like juvenile rheumatic arthritis. Chronic diarrhea and weight loss might be secondary to celiac disease or cystic fibrosis. Tenderness that is severe and persistent in the same location should be considered organic until proven otherwise as well as organomegaly and masses. Familial Mediterranean fever (FMF) is a rare autosomal recessive disease that presents with recurrent episodes of severe abdominal pain.

Investigations

In the era of evidence-based medical practice, ordering full investigation to rule out everything is not acceptable and is a waste of resources. Thorough history, clear psychosocial stressful event, normal growth, physical examination, and no alarming signs or symptoms should be sufficient to diagnose functional abdominal pain; hence, no additional investigations are needed. Occasionally, anxious parents are not convinced of the diagnosis of functional disorders. In such situation, basic laboratory workup of CBC, ESR stool, and urinalysis can be assuring and convincing.

When alarming sign or symptoms are found in history or physical examination, proper investigations should be done. Full chemistry, liver function test, lipase and amylase can be done in case of possible hepatobiliary and pancreatic disorders, and urinalysis and culture when UTI is suspected. A urea breath test or stool antigen is done to rule in or out *Helicobacter pylori* infection for patients with peptic disease. Although *Helicobacter pylori*, per se, as a cause for functional RAP have been postulated by some studies; yet, the general consensus is that there is no relation between *H. pylori* infection and functional abdominal pain. Abdominal ultrasound can help to show abnormal pancreas, cysts, gall bladder, and urinary tract stones. Endoscopy is the proper tool for investigating peptic diseases, IBD, and obtaining biopsy for celiac disease.

Management

Once a specific diagnosis is reached, appropriate treatment should be instituted accordingly. Nonorganic, functional RAP in childhood is a cry for help, and the child is usually under psychological pressure. It is important to make sure that the parents are aware of the fact that the pain is real and the child is not malingering. The pediatrician should explore the four circles, explained earlier, and look for the triggering situation. The child should be referred to the psychologist for counseling to resolve the problem and /or provide the child with strategies to cope with his or her stresses. A one-to-one, family, or group therapy may be needed and beneficial. Additionally, relaxation techniques can help the child to release the pressure. Psychologist, social services, and child abuse team need to be involved in case of child abuse. If schooling is the problem, the pediatrician, as the child advocate, may communicate with the school principal or the child teacher and explain the child's problem as well as suggesting solutions. Alternative therapy and dietary manipulation has been suggested and used with some help. Peppermint oil, high-fiber, low-lactose, and low-oxalate diet has been used in children with abdominal migraine, and some cases provided relief. The most important factor that helps the treatment of functional RAP is the insight of the child and the parent of the problem and its causes. The family should be patient as it takes time for the therapy to give effect, and their cooperation is essential.

Constipation

Definition

The North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) defined constipation as delay or difficulty in defecation for 2 or more weeks. Constipation is also defined as a stool frequency of less than three times per week, hard painful defecation, or palpable abdominal or rectal mass on examination. Constipation definitions can be summarized as the change from the normal habit of stool frequency and/or consistency.

Etiology

According to the etiology, constipation can be classified into two categories: functional and organic. The functional type is also called idiopathic as there is no identified pathology and/or organic etiology. In the organic type, constipation is part of the symptoms of an underlying pathology or diseases like Hirshsprun's disease, hypothyroidism, etc.

Epidemiology

Constipation is a common problem in childhood with prevalence that ranges from 0.3% to 30%. It constitutes up to 3% of the general pediatrics visits and 25% of the pediatric gastroenterology consultations. Constipation is four times higher in monozygotic twins than in the dizygotic ones and 6–12 times higher when parents have constipation. There is no gender difference in the prevalence of constipation. Constipated children have higher rate of functional urinary incontinence than nonconstipated. The most common cause of constipation is the functional, while organic causes constitute a small percentage of the causes. The incidence of encopresis and fecal soiling (involuntary passage of stool) in children less than 7 years of age is 1–3%.

Pathogenesis

The child who is engaged in playing or activities of interest will not respond to the urge of defecation. He or she will resist the urge until it resolves. As the child keeps resisting defecation, stool accumulates, the rectum will dilate, and eventually the child will lose the feeling of the stool in the rectum. The rectum is efficient in absorbing the stool fluids turning the stool into a hard bulk that is difficult to pass. Passing hard stool causes anal fissures resulting in considerable pain on defecation. Children respond to fissures pain by stopping defecation to avoid the unpleasant feeling, hence worsening constipation. Similarly, the stubborn and defiant toddlers react to parental pressure and forceful toilet training by avoiding bowel movements with consequent accumulation of hard stool in the rectum and finally constipation. Rectal dilatation and spontaneous relaxation of anal sphincter will allow the soft stool to seep around the hard stool causing fecal soiling, i.e., encopresis. Encopresis is a term used for involuntary passage of stool "fecal soiling" in children who have usually already been toilet trained. Other situations and events that can cause stool withholding and functional constipation are: unavailability of toilets, dirty school toilets, change of environment, intercurrent illness, psychosocial stresses due to parental fights or loss of one of the parents, schooling or peer problems, and finally, physical or sexual abuse.

In case of secondary or organic causes, constipation will be part of the symptoms of the causative disease

Clinical Manifestations

Constipation in newborns and infants should be alarming to rule out pathologies like anal atresia and Hirschsprung's disease. Constipation is more common in babies who are formula fed and frequently starts toward the end of the first month of life. Cow's milk allergy (CMA) has been found to cause constipation, and infants may improve when taken off cow's milk. Positive allergy and immunological studies were found in constipated children secondary to CMA. Although newborns have frequent bowel movement, constipation in exclusively breast-fed babies is normal, harmless and affected babies show no discomfort, feeding well and thriving. It is normal for exclusively breast-fed babies to go for several days to a week without a bowel movement. Older children with constipation may complain of abdominal pain, decreased appetite, and urinary frequency secondary to pressure by the full rectum on the bladder. Painful defecation and anal itching are signs of anal fissure. The time when the child tries to avoid defecation in an attempt to withhold stool, he or she will stand on toes, cross legs, contract the anus and the gluteal muscles, and start rocking back and forth until defecation urge resolves. This action is usually performed while hiding behind furniture or in a corner. The position and facial features adopted by the child can be mistaken for seizure disorder. Chronic dilatation of the rectum with large and hard stool

makes the anus dilated with decreased sensation. The soft and liquid stool can pass around the hard stool down the underwear causing fecal soiling (encopresis). Delayed walking may be a sign of spinal cord abnormalities like tethered cord that can present with constipation. Constipation rarely can be secondary to diabetes insipidus (DI) where the rectum absorbs the stool fluids, resulting in constipation. History should include inquiry about polydipsia, polyurea, and signs of hypothyroidism.

Physical examination of children with functional constipation is generally unremarkable. Stool mass occasionally can be felt on abdominal examination. Anus should be examined, under good and bright light, for fissures, signs of abuse, and anal position. Ectopic anus is usually displaced interiorly and associated with constipation. Rectal examination is important to assess the tone of anal sphincter and stool in the rectum. In some children, the anus is dilated and stool can be visualized without the need for rectal examination. In Hirschsprung's disease, the anal sphincter is very tight and the rectum is empty contrary to functional constipation. The back of the child should be inspected for the presence of hair tuft and/or lumbosacral deformity which can be associated with tethered cord. For the children with chronic and refractory constipation, neurological assessment of the lower limbs reflexes and anal wink needs to be part of the physical examination. Short stature and course facial features can be signs of hypothyroidism with resulting constipation.

Diagnosis

Functional constipation in a healthy child with normal growth and physical exam requires no investigations. Plane abdominal radiography can be done when it is difficult to assess fecal content of the colon or in case of child's refusal of rectal exam. Investigations are reserved to rule in or out suspected diseases or pathologies causing the constipation. When Hirschsprung's disease is suspected, rectal manometry, rectal biopsy, and rarely barium enema are required for confirmation. Blood work is reserved to investigate hypothyroidism, hypercalcemia, diabetes insipidus, and cow's milk allergy. MRI is a valuable tool to investigate spinal cord dysraphism like spina bifida, lipoma, and tethered cord.

Treatment

Specific organic causes of constipation require specific management according to the etiology. For functional constipation, the following are the steps of management.

Education

The first step in the treatment of constipation is good explanation and education of the parents and older patients. Education gives good insight and magnitude of the problem and helps in achieving therapeutic goals. The use of drawings and illustrations gives visual clarification and supports in understanding the problem and the rationale behind long-term treatment. The purpose of long-term treatment of chronic constipation is to get the dilated colon and rectum return to the normal caliber. The steps of the treatment should be written on a paper and handed to the patient and family.

Disimpaction

Newborns and infants do not need disimpaction, and at most need stool softeners such as lactulose. In older children for maintenance therapy to work it is important to clear the hard stool occupying the colon and rectum. Disimpaction can be done rectally or orally. Rectal disimpaction is done by one or two phosphate enema which is widely used and is effective. Repeated phosphate enemas carry the risk of electrolyte disturbance particularly infants and young children. Glycerin suppository can be used, and it is a safe one. Agents used for oral disimpaction are: (1) Mineral oil (liquid paraffin oil) at 15–30 ml/year up to 240 ml daily until disimpaction is achieved but should not be used for young children because of risk of aspiration and lipoid pneumonia. (2) Polyethylene glycol (PEG) at dose of 1.5 g/k/day for 3 days. (3) Senna and bisacodyl in appropriate dosage also can be used.

Maintenance Therapy

The goal of the maintenance therapy is to have at least one to two bowel movements a day. In chronic constipation, treatment should continue for at least 3–6 months to allow the colon to return to normal caliber and withdrawal of medication should be slow. The once-a-day-treatment regime should be the target to ensure compliance. Treatment may be frequent initially to ensure good effect but eventually to come to once a day. Choices of maintenance therapy are: (1) Lactulose 1–3 ml/kg/day initially twice daily then once a day. The dose can be increased or decreased according to the response with the aim of soft bowel movement daily. (2) PEG 1 gm/kg/day dissolved in water or juice. The pediatric PEG 3350 contains minimal electrolytes to

avoid sodium overload, and it is more palatable for kids. (3) Mineral oil (liquid paraffin oil) at a dose of 1–3 ml/kg/day, best to be given 2–3 h after meals to avoid malabsorption of fat-soluble vitamins. Mineral oil still holds as one of the good and effective stool softeners but should not be used in infants. Other maintenance medications less used are Magnesium hydroxide/citrate and sorbitol.

The maintenance therapy can be given at bedtime, while, during daytime, high-fiber diet, natural stool laxatives like prune juice, and hydration should be encouraged.

Treatment of anal fissure helps resolve the pain and allows easier defecation and toilet training. Anal fissure can be treated by sitz baths and frequent application of petroleum gel or 0.2% nitroglycerin cream.

Behavioral Modification

Toilet training is an important part of treatment. The child should have regular toilet time. He or she should take enough time especially after meals. The use of rewards and calendar with stickers will enforce good and regular toilet habit. Psychologist's help may be needed to prepare the child for the behavioral modification. Sitting on the toilet regularly and having a bowel movement twice or at least once daily is the target of the management.

Failure of therapy and/or the possibility of organic causes should be an indication for referral to pediatric gastroenterologist for further workup and management.

Prognosis

Response to therapy is good initially; however, there is high rate of relapse particularly in chronic constipation. Long-term maintenance therapy is important for good outcome. Maintenance therapy may need to continue for 6 months to 1 year coupled with slow withdrawals of stool softeners. Failure of treatment despite good stool softener dosage and therapy adherence is an indication for possible nonfunctional (organic) cause for which the child should be well investigated. It has been found that one-fourth of children with functional constipation continued to experience symptoms at adult age particularly when constipation starts at older age and there is a delay in seeking medical treatment. Studies have found a statistical link between constipation and colon cancer among middle-aged adults.

Prevention

Early treatment of anal fissures and constipation prevents progression to chronic constipation and fecal soiling. Healthy dietary habits and natural dietary fibers are important for good bowel function and prevention of constipation. Hydration and exercise are supportive factors in preventing constipation.

176 Cyclical Vomiting Syndrome

Sonny K. F. Chong · Dinesh Banur

Historical Perspective

Samuel Jones Gee (1839–1911) a physician at St Bartholomew's Hospital, London first described in 1882 a group of children with a poorly understood condition, in the hospital reports:

- These cases seem to be all of the same kind, their characteristics being fits of vomiting which occur after intervals of uncertain length. . ..free from signs of disease. The vomiting continues for a few hours or a few days. . .. Patients are left exhausted

The periodic disorders in children were first published in the British Journal of Children's diseases in 1933 by Willye WB and Schlesinger D. They described 80 cases, in a detailed study of children with nervous instability and a relationship between migranous attacks and epilepsy. JJ Kempton further described the *Periodic Syndrome* in 1956 in the British Medical Journal. Five main symptoms were discussed – *pallor, headache, abdominal pain, vomiting, and pyrexia.*

Any combination of these, in any order, make up this periodic illness, with intervals of certain regularity or sometimes with irregular intervals.

Definition

The most recent revised diagnostic criteria of CVS (cyclic vomiting syndrome) in both children and adults is best described by Rome III criteria (2006)

- Stereotypical episodes of vomiting regarding onset (acute) and duration (<1 week)
- Three or more discrete episodes in the prior year
- Absence of nausea and vomiting in between episodes
- No metabolic, gastrointestinal, or CNS structural disorders
- Supportive criteria: Past or family history of migraine

Clinical Features

CVS was initially thought to be rare, but now it is seen relatively common in pediatric populations. Abu Arafeh and Russell's study (1995) of schoolchildren in Scotland found that 1.9% fulfilled the diagnostic criteria for CVS. Chong and Bartlett carried out a CVS Audit in the UK (2003) and found a higher proportion of female to male (ratio 2:1), with a mean age of onset of 6.5 years and age at diagnosis of 9 years, although other studies have reported much younger or older ages of onset.

Although there are a large number of differential diagnoses, CVS is characterized by stereotypic, self-limiting episodes of intractable nausea and vomiting which is seen in childhood and less frequently in adults. The child is free from symptoms between episodes which can last from weeks to months. There may be associated symptoms of lethargy, pallor, pyrexia, headache, abdominal pain, and excess salivation. Physical examination is usually normal.

Typical attack of CVS progress through four phases:

Phase 1 – No symptoms. Trigger factors have been reported in 73% of the children during this period. Infection 41%, stress 34%, diet 26%, motion 9%, menses 13%.

Phase 2 – Prodrome characterized by nausea (93%), disturbed gastric antral myoelectric activity, and associated autonomic components (salivation, tachycardia, vasoconstriction).

Phase 3 – Episodes are frequently characterized by retching, vomiting (94%) usually in the morning; nausea, tiredness (91%) (at times so severe that it can result in a "conscious coma"); vomiting bile (88.7%), abdominal pain (67%), fever (37%), headache (36%), prostration, encephalopathy, posturing dystonia, hypertension, retention of urine.

Phase 4 – Recovery. Each episode lasts for few hours to few days.

The average number of episodes reported varies from 8 to 12 per year. Over 60% had onset of an episode in the early morning and over 10% in the evenings.

A very high percentage, over 65%, have a family history of migraine in first-degree relatives in the national UK audit of Bartlett and Chong, with a family history of CVS in 11% of children.

In summary, it is important to establish in the diagnosis that the episodes are discrete (93% have this), that the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_176,

patient is well in between episodes (64%), the episodes are stereotypical (98%), and the family has a history of migraine (66%).

Pathophysiology

The etiology and pathogenesis of CVS remains elusive. Several hypotheses in vogue include a disorder of the brain-gut axis, migraine variant, corticotrophin-releasing factor in excess in response to stress which induces a hypercortisolemia resulting in inhibition of GTP cyclohydrolase and reduction in BH4 and Nitric oxide. This could result in hypertension in severe case as seen in Sato's syndrome. Autonomic dysfunction, gastric dysmotility, and a mitochodriopathy has also been hypothesized, with mitochondrial energy depletion due to a mitochondrial mutation has been suggested. Genetic association including A3243G mitochondrial DNA mutation have been seen in some cases with a resultant metabolic encephalopathy occurring as a result of hyperphenylalaninaemia, reduced dopamine, and serotonin turnover.

Recent advances in the understanding of the electric rhythms of the stomach, which control gastric motility and emptying, have been made with the mapping of the stomach. Preliminary studies have shown more detailed electrical differences between different regions of the stomach. This has lead to the use of gastric electrical stimulation devices in treating nausea and vomiting in adults and new targets for therapy.

Making the Diagnosis

Diagnosis requires taking an accurate clinical history, identifying key clinical features, and excluding other disorders. It is important to differentiate between chronic and cyclical vomiting. Chronic vomiting persists regularly with vomiting for a short time every day. Cyclical vomiting occurs on a regular pattern with intense vomiting for a few days and then a gap of several weeks.

Essential features are recurrent episodes of severe vomiting lasting hours to days, separated by symptom-free periods in the absence of any identified pathology. Supportive features include a clear pattern with regard to onset, frequency, intensity, and duration of self-limiting episodes.

A history of associated signs and symptoms such as fever, pallor, social withdrawal, abdominal pain, and migraine-like symptoms (headache, photophobia, phonophobia) may be seen and help to clinch the diagnosis. Nevertheless, it is important to exclude meningitis.

Triggering Factors

It is important to identify triggering factors. The most common are unpleasant emotional factors. Factors reported to trigger an episode included 41% infection, 34% psychological, 26% dietary, 18% exhaustion, 13% menses, 13% atopic, and 9% motion. Some reported foods that may trigger an episode include tomatoes, chocolate, cola, caffeine, artificial sweeteners, soy foodstuffs, dairy products, nuts, and eggs.

Investigations

- Urine MC&S
- FBC, liver function test, Ca, Lipase, amylase
- Urine for metabolic screen to exclude mitochondriopathy and fatty acid oxidation defects
- Radiological investigations include abdominal ultrasound, barium meal, and follow through to exclude life-threatening conditions such as small bowel obstruction and malrotation
- Sinus X-rays and renal ultrasound scan
- CT or MRI if raised intracranial pressure is suspected
- EEG to rule out abdominal epilepsy, which is rare
- Vestibular function test and autonomic nervous function testing (tilt testing and R-R interval on ECG)

Differential Diagnoses

- Malrotation with volvulus (or intermittent small bowel obstruction)
- Gastroesophageal reflux disease (chronic esophagitis)
- Renal disease
- Raised intracranial pressure (brain tumor)
- Chronic sinusitis
- Chronic pancreatitis (hereditary pancreatitis)
- Addison's disease
- Disorders of fatty acid oxidation
- Urea cycle defects
- Abdominal migraine/epilepsy

There are some *GI etiologies* that have a similar pattern to CVS and have to be checked for and ruled out, before the confirmed diagnosis of CVS. These are anatomic – malrotation, dysmotility of the GI tract – gastric dysrhythmia, mucosal injury, infections, or chronic appendicitis, gall bladder and pancreatic disease.

Non-GI etiologies that also mirror CVS are neurological conditions – migraine, epilepsy, neoplasm, metabolic,

endocrine, e.g., Addison's disease, renal conditions – acute hydronephrosis due to pelvi-ureteric junction stricture (Dietls crisis), kidney stones, and psychological – stress, parental anxiety, and Munchausen by proxy.

General therapy includes:

Supportive measures – IV fluids, analgesia, and sedation
Prophylactic treatment for patients with episodes more than once a month
Abortive treatment for patients with episodes of less than once a month
Identification and avoidance of triggers
Parental support – CVSA support group

Management involves identifying the stage of cyclical vomiting and initiating appropriate treatment. It is obviously best to abort the episode whenever possible or to start prophylactic treatment soon afterward. Some of the strategies used as abortive treatments for patients as an episode begins include antimigraine drugs – sumatriptan or ketorolac inhibitor, and antiemetic drugs – ondansetron, lorazepam, stemetil, and chlorpromazine.

1. To identify and treat any triggering factors
   - Antimigraine prophalaxis
   - Prophylaxis for motion sickness
   - Hormone preparation or low-dose fluoxetine for menses triggered CVS
   - Anticonvulsants

   Prophylactic therapy reduces the number and severity of attacks, and is most appropriate for patients who have frequent attacks of more than three to four episodes per year or of long duration. There is no definitive prophylaxis, but several classes of drug work with varying degrees of success.
2. Treatment of well-defined prodrome
   - Prochlorperazine (Buccastem) 3 mg sublingual 6–8 hourly before full-blown episode begins.
   - Intravenous 5–HT3 antagonist, Ondansetron 0.1–0.2 mg/kg/dose, 8 hourly, maximum 8 mg (rectal administration may be appropriate), or Granisetron 20 mcg/kg up to 1 mg can be used alone or in combination.
   - Lorazepam 0.05 mg/kg IV given with Ondansetron is both an anxiolytic and antemetic.
   - If the above fails, Ondansetron plus Aprepitant can be used. Low or a test dose of Aprepitant should be tried initially using 80 mg every other day as bradycardia and hyperglycemia are infrequent possible side effects.
   - If the above fails, rarely Dexamethasone could be given in addition to the above.

   If a patient can recognize symptoms of a forthcoming attack and can retain oral medication, an attack can be aborted. Some patients experience anticipatory nausea and vomiting as a prodromal anxiety or abdominal pain, which can be treated with an anxiolytic or pain relief.
3. Treatment of established emetic phase
   - Antiemesis with Ondansetron 0.1–0.2 mg/Kg/dose, maximum 8 mg, 8–12 hourly
   - Anxiolysis with Lorazepam (as above)
   - IV fluids and electrolyte balance
   - IM Chlorpromazine, 1 mg/kg, maximum dose of 40 mg for children <5 years and 75 mg for 6–12 years
   - Blood pressure control with IV labetolol or clonidine in CVS with hypertension (Sato's syndrome)

   Start antiemetics (e.g., IV Ondansetron, Granisetron) early and introduce benzodiazepines such as Lorazepam, which have antiemetic, anxiolytic, and sedating actions, as antiemetics alone may not relieve nausea and vomiting.

Prophylaxis or Long-Term Treatment

There are a wide range of treatments for CVS but no large-scale trials have been performed. Treatment remains empirical, and on a patient-by-patient basis. There is an increasingly extensive body of clinical experience in treating CVS leading to a developing consensus view of treatment protocols.

The use of antimigraine prophylaxis should be started as soon as the abortive treatment has controlled symptoms acutely. The following medications below are used in the following order in our unit at Queen Mary's Hospital for children, Carshalton, Surrey.

A metabolic cocktail of carnitine, and coenzyme Q, and Riboflavin are considered in younger children less than 4 years of age if the CVS is resistant to the above standard treatment.

Propranolol 1–3 mg/kg/day in three divided doses (not to be used in asthma patients)
Cryproheptadine 0.3 mg/kg/day in three divided doses
Amytriptyline 25–50 mg/day, starting with 10 mg daily and increase slowly (0.5–1 mg/kg/day)
Pizotifen 500 μg bd, increasing to 1.5 mg daily
Metabolic cocktail – carnitine 500 mg bd and Coenzyme Q10 30 mg daily. (In older children, dose can be increased carnitine 50–100 mg/kg/day in 2 divided doses Coenzyme Q10 10 mg/kg/day in 2 divided doses)

Complications

Prolonged vomiting can cause dehydration, electrolyte imbalance, ketosis, gastritis, esophagitis, dental disease, poor growth, and psychosocial problems. IV infusion of saline or glucose solution with additional potassium, combined with ranitidine, can help prevent most of these complications. However, caution is needed because the syndrome of inappropriate antidiuretic hormone (SIADH) has been noted in some patients, in whom fluids should be limited.

Continuing with intravenous or oral sedation until an episode has resolved may be necessary for 48–72 h or until the episodes of CVS has run its course.

Psychiatric assessment and counseling is important in the further management of the CVS child. Stress management is important for those with stress as a trigger. These episodes can be aborted or shortened with early management.

Complications such as dehydration, electrolyte disturbances, and peptic oesophagitis, can prolong recovery time, but this can be lessened or avoided if IV fluids and H2-receptor antagonists such as ranitidine are used early.

Occasionally, upper GI endoscopy may be necessary to exclude severe gastroesophageal reflux disease or peptic ulcer diathesis, *H pylori* gastritis, or eosinophilic esophagitis which has been shown to masquerade as CVS.

Prognosis

Prognosis is generally good to be guarded as the episodes improve or become less frequent, or cease as children grow older. In long-term studies, Hammond (1974) found an increased likelihood of migraine and psychological difficulties in those diagnosed with severe cyclical vomiting presenting in childhood [3]. In addition, in a study of adults diagnosed with CVS in childhood, Dignan et al. (2001) found 31% continued to experience attacks as teenagers. This suggests that CVS develops into migraine at a later stage in some patients. It should not be viewed simply as a pediatric illness that resolves with the onset of puberty.

Links to Other Conditions

The belief that CVS is psychosomatic is not widely accepted, but many accept it may be triggered by psychological stress. Although psychiatric or psychological disorders may need to be suspected or implicated in children with CVS, more frequently than not, the psychological stressors are secondary. Nevertheless, it is important to exclude an organic pathology first, before counseling is considered.

Current research focuses on the hypothesis that CVS is a disorder of the brain-gut axis that is triggered by physiological or behavioral reactions. An exaggeration of our normal emetic reflex might be one such dysfunction.

CVS, *migraine headache, and abdominal migraine* were described as "manifestations of the migraine diasthesis" as they are "functional, self-limited episodic disorders" that all have symptom-free intervals.

In all three disorders, patients might complain of nausea, vomiting, abdominal pain, headache, photophobia, and phonophobia. The similar features of CVS and migraine, coupled with the widely held belief that these conditions are associated, led to the proposal that antimigraine therapy should be used for managing CVS.

One study found that 91% and 83% of patients given prophylactic Amitriptyline or Cyproheptadine, respectively, had a partial or complete response to therapy. Sumatriptan was effective for aborting episodes. A trial of L-carnitine prophylaxis has recently been shown to reduce frequency of attacks.

Another study investigating gut electrical activity (cutaneous electrogastrogram) found half of CVS patients had accelerated gastric rhythms following food, and during episodes of CVS, but no significant abnormalities in controls. Some suggest abnormal gastric myoelectric activity or dysrhythmias might be responsible for feelings of nausea and vomiting. Vomiting is a nonspecific yet common clinical feature of many inherited metabolic disorders. It has been suggested that mutations or rearrangement in mitochondrial DNA are responsible for metabolic disorders, which can in turn lead to cyclical vomiting.

Conclusion

CVS is a disease of severe episodic vomiting, sudden in onset and associated with continuous nausea and lethargy. The symptoms often start in childhood and can continue on to early adulthood, but adult onset is also possible. CVS is often missed in the early stages of the disease. CVS is more commonly seen in girls than in boys in the UK. A family history of migraine is present in a significant number of first-degree relatives. Contrary to other studies, more than one-third of patients were not symptom free between episodes, suggesting a different etiology.

The condition is frequently missed or undiagnosed until late in the illness, but this is gradually changing as awareness increases.

177 The Esophagus

Mark A. Gilger · Hisham M. Nazer

Achalasia

Achalasia is a motor disorder of the esophagus characterized by functional obstruction, aperistalsis, and incomplete relaxation of the lower esophageal sphincter in response to swallowing and increased lower esophageal sphincter (LES) pressure. The disease manifests itself usually in late childhood and early adult life. However, achalasia has been recognized in all ages including infancy.

Esophageal achalasia is a well-known pathology described in families with more than one affected siblings. The exact cause of achalasia remains unknown. Genetic factors were suggested to play a role in the pathogenesis, and some authors considered it an autosomal recessive character. Other report suggested that the defect could be neurogenic, myogenic, or hormonal in origin.

Clinical Features

Difficulty in swallowing, dysphagia, and regurgitation of retained food in the esophagus during or after meal are the main complaints. Achalasia is usually presented with dysphagia (usually to solids) and vomiting. Affected patients are therefore slow eaters and slow swallowers. Vomiting of food remnants with inability to eat and failure to thrive are other well-recognized findings. Aspiration pneumonia, regurgitation, respiratory difficulties, choking, and sudden death have also been reported in achalasia.

The onset is insidious with fluctuation of symptoms especially during the early stages of the disease. At a later age, the child may complain of a choking sensation of food sticking in the region of the lower sternum. The child will at a later stage get the habits of drinking water or adopting certain maneuvers to facilitate the passage of food bolus and ease his symptoms. Vomiting which may occur hours after meal is usually associated with the presence of undigested food eaten several hours ago. Aspiration pneumonia and repeated chest infections may complicate recurrent episodes of vomiting. Later recognized complications include malnutrition and failure to thrive.

Diagnosis

Clinical history contributes greatly to the suspicion of achalasia in an index case. Plain chest radiograph may show dilated food-filled esophagus with an air-fluid level. Radiologic signs of recurrent aspiration pneumonia further support the diagnosis, which is usually confirmed on barium swallow and fluoroscopy. The esophagus is dilated and sometimes tortuous, with absence of stripping waves, uncoordinated contraction, and obstruction at the gastroesophageal junction with prolonged retention of the barium in the esophagus (*Fig. 177.1*). The classic *rat-tail* deformity of funneling and narrowing of the distal esophagus is a result of failure of relaxation of the lower esophageal sphincter (LES). Manometric intraluminal pressure studies, when available, should be performed to confirm the diagnosis. Esophagoscopy is performed to exclude any other associated anomalies.

Differential Diagnosis

It is important to distinguish achalasia from other causes of esophageal dysphagia especially esophageal stenosis and partial thoracic stomach. Recurrent or chronic pulmonary infections may dominate the clinical picture to the extent that esophageal dysfunction may be overlooked. Achalasia should therefore be included in the differential diagnosis of a child with recurrent respiratory infections.

Treatment

There is no specific medication that ensures recovery. Pneumatic dilatation is performed to disrupt the muscle fibers of the LES. Pneumatic as well as hydrostatic dilatation have proved ineffective except in mild cases. Relief of symptoms is usually temporary.

Anticholinergic drugs have been found to be of no value though some studies have shown that nifedipine therapy does decrease the lower esophageal pressure and improve esophageal emptying. However, such studies in

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_177,

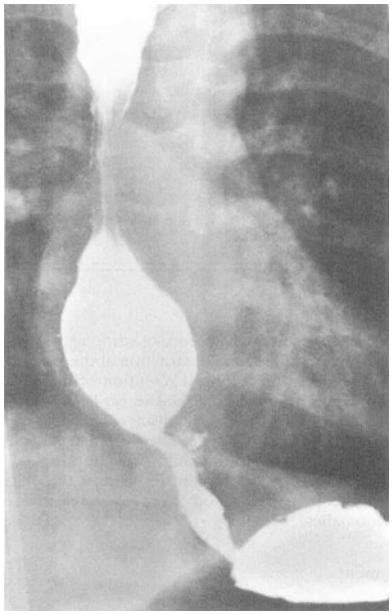

Figure 177.1
Achalasia of the esophagus. Esophagogram in a 3-year-old boy with a history of difficulty in swallowing. Notice the narrowing of the distal esophagus with prestenotic dilatation (Courtesy: Dr. Hisham Nazer)

children are rather limited and mostly resorted to in patients with whom pneumatic dilatation or myotomy is contraindicated to achieve some weight gain before more aggressive therapy is resorted to.

The results of pneumatic dilatation in children have been variable and are difficult to compare because of different techniques used. Recognized complications include bleeding and gastroesophageal reflux. If pneumatic dilatation fails to relieve symptoms, surgical approach in resorted to.

Surgery is resorted to rather early for those babies with severe achalasia, evidence of malnutrition, and lack of response to medications or dilatations. Modified Heller esophago-myotomy via a laparoscopic approach is the operation of choice. The results of myotomy have been quite satisfactory. Studies have concluded that the laparoscopic extended Heller myotomy with fundoplication is a safe and effective method for the treatment for achalasia in the pediatric population even in advanced cases.

Recognized complications of surgical procedures include gastroesophageal reflux, dysphagia, mediastinitis, and recurrence of symptoms. Diet has no role in the primary treatment of the disease. Elevation of the head of the bed helps prevent nocturnal regurgitation.

Esophageal Atresia

This congenital anomaly of the esophagus with or without a fistula to the trachea is discussed in a separate chapter on gastro-surgical emergencies of the newborn.

Esophagitis

Esophagitis is a common problem associated with gastroesophageal reflux disease (GERD). Esophagitis is attributed to abnormal acid secretion. However, recent reports have revealed that reflux esophagitis is not associated with increased acid secretion.

Eosinophilic Esophagitis

Eosinophilic esophagitis (EE) is an inflammatory gastrointestinal disorder that is increasingly diagnosed in pediatric patients. It is a chronic and relapsing condition associated with atopy and infiltration of the esophageal mucosa by eosinophils typically in a density exceeding 15 per high power field, where gastroesophageal reflux disease has been ruled out by negative pH probe study or clinical failure of a proton pump inhibitor trial. Eosinophilic esophagitis (EE) is a disease based on a clinicopathologic diagnosis that involves a localized eosinophilic inflammation of the esophagus. The systematic exclusion of gastroesophageal reflux disease is critical.

Eosinophilic esophagitis (EE) is a condition of esophageal inflammation that occurs in the absence of acidification and is characterized by mucosal eosinophilia and epithelial proliferative changes. Depending on the patient's age, EE may present as a feeding disorder, vomiting, abdominal pain, dysphagia, or food impaction. EE progresses in some individuals to esophageal fibrosis and then presumably to irreversible esophageal dysfunction. The specific mechanism of fibrosis in EE remains unknown, but it may be related to multiple potentially fibrogenic products secreted by eosinophils.

EE in adults typically presents with dysphagia and esophageal food impaction in an episodic manner. The pediatric presentation however varies, and it can mimic other conditions such as gastroesophageal reflux disease. As patients get older, EE manifests as abdominal pain and subsequently may present with dysphagia and food impactions.

Presenting symptoms include vomiting, chest or epigastric pain, and dysphagia with occasional food impaction or strictures. Most patients are males with atopy

associated with food allergens, peripheral esoinophilia, and elevatged immunoglobulin IgE levels.

Endoscopically the esophagus presents a granular furrowed or ring appearance. Esophageal biopsies reveal eosinophilia on histopathology.

Treatment

Elimination diet is prescribed for patients with EE and proven allergens. Inhaled and systemic corticosteroids have also been used successfully for nonallergic or nonresponders to elimination diet. . . .

EE, like most allergic diseases, responds to glucocorticoids. Systemic steroids have proved an efficacious short-term option for the disease. Equally effective are glucocorticoids formulated for inhalation, and fluticasone propionate, which when swallowed from a metered-dose inhaler is as effective as prednisolone.

More recently therapy under investigation and assessment among affected children include leukotriene inhibitors (Montelukast) and anti-interleukin 5 (anti-IL-5) antibody (Mepolizumab). If left untreated, patients with EE may progress to develop stricture formation.

Montelukast has minimal risk of adverse reactions compared with steroid therapy and may offer clinical relief in a small subset of children with eosinophilic esophagitis.

Reslizumab is a humanized monoclonal antibody with potent IL-5 neutralizing effects that represents a potential treatment for eosinophilic diseases. Although the exact mechanism of EE is unknown, food allergens are thought to have an important role. Effective treatment options include dietary restrictions and various steroid formulations.

EE should be considered in the course of evaluating pediatric patients with chronic gastrointestinal symptoms particularly in young white male patients with atopy. Esophageal subepithelial fibrosis is prevalent among children with EE and is considered as a specific marker for the disease. Eosinophilic esophagitis (EE) is caused by immunologic reactions to ingested/inhaled allergens.

Oral viscous budesonide (OVB) is an effective treatment of pan-esophageal disease in children with EE. OVB improves symptoms, endoscopic and histologic features. However, Proton pump inhibitor single therapy did not significantly improve esophageal eosinophilia or symptoms of EE.

Barrett Esophagus

Barrett esophagus (BE) is an acquired defect, the result of chronic mucosal injury, usually from acid reflux, but also possibly from bile, alkali, and other physiochemical causes. GERD is an accepted risk factor for the development of Barrett Esophagus BE occurs in about 10% of patients with GERD, which implies that other factors, genetic or environmental, play an undetermined role. Familial BE has also been reported.

Barrett esophagus is defined as an extension of columnar epithelium into the esophagus and/or as the presence of islets of columnar mucosa in the distal esophagus. BE is a rare condition in the pediatric age group and is known to be associated with reduced lower esophageal sphincter pressure and abnormal esophageal peristalsis. It is frequently associated with hiatal hernia.

Barrett patients have also defective esophageal acid clearance as demonstrated during 24 h pH monitoring. The severity of the disease is correlated with reduced lower esophageal pressure.

Clinical Features

Patients with BE present with a history of regurgitation, epigastric pain, and abdominal pain. Dysphagia (especially to solid), esophagitis, and ulceration are also recognized features.

BE is grossly apparent at endoscopy as velvety red tongues extending up the esophagus from the proximal gastric fold at the gastroesophageal junction. There may be islands of residual white squamous mucosa within an area of Barrett esophagus. There is definite recognized increased risk of adenocarcinoma of the esophagus up to around 100 folds in patients with BE. Other recognized endoscopic findings include ulceration and nodularity or friability. However, the endoscopic appearance of BE in childhood may not be classic.

The diagnosis is confirmed by histology of the lower esophagus being lined with columnar epithelium instead of squamous epithelium. Barrett esophagus is associated with esophagitis, ulceration, and stricture formation. Symptoms usually subside on completion of therapy for gastroesophageal reflux. Surgery is occasionally indicated in the course of therapy to improve outcome.

Corrosive Esophageal Injury

Background

Ingestion of caustic materials remains a concern in children, although severe injury is uncommon. In 2004, the US Toxic Exposure Surveillance System of the American Association

of Poison Control Centers reported 2,438,644 poison exposures for children under age 6. About 10% (124,962) were exposures to cleaning substances. The majority of caustic ingestions occur in children under 6 years and most are minor, only rarely leading to serious caustic injury.

Historically, severe caustic burns in children were increasing during the late 1960s correlated with the commercial availability of highly concentrated (>30%) alkaline liquid drain cleaners. Recognition of this led to legislation in the USA entitled the *Poison Prevention Packaging Act of 1970.* This required child-resistant containers and limited concentrations of caustic material to 10% for hazardous substances routinely stored at home, such as bleach and cleansers. This law has contributed to a decrease in serious caustic injuries in young children, and deaths due to ingestion are now very rare (.011% of all ingestions). Unfortunately, severe caustic ingestions have not stopped as accessibility to industrial-strength caustic agents remains a risk for serious burn injuries in children.

When pediatric ingestions do occur, they are usually minor, being limited to "lick or taste" scenarios. In contrast, ingestions by adolescents and adults are frequently intentional (suicide attempts) with larger volume ingested and greater potential for serious injury.

Corrosive Agents

Alkalis are odorless, colorless substances that are frequent causes of caustic ingestion. Cleaning products, such as oven cleaners and drain cleaners often contain lye, which is a strong alkali such as sodium or potassium hydroxide. Bleaches are the most commonly ingested alkali, but are weak alkali and tend to have a benign clinical course. Acids are generally bitter tasting and subsequently are much less commonly ingested. These include products such as toilet bowel cleaners (sodium bisulfate, sulfuric acid, and hydrochloric acid); metal cleaners (hydrochloric acid); battery fluids (sulfuric acid); and swimming pool products (hydrochloric acid). Acids account for only about 10% of ingestions seen in children.

Pathogenesis

The extent and severity of the corrosive injury is determined by the form (liquid vs. solid), concentration, and amount of material ingested. Lye-containing products are the most common cause of serious burns and strictures following caustic ingestion in children and can injure the esophagus, stomach, and duodenum. Ingestion of alkali causes liquefaction necrosis, which results in rapid destruction of the superficial mucosa, allowing deeper invasion of the caustic substance.

Sites of injury in the esophagus are initially red, progressing to brown within 30 min due to tissue necrosis. Within 24 h shallow ulceration appears, followed by sloughing of the necrotic layer within 2–4 days after ingestion. Tissue repair occurs 1–3 weeks after the initial injury, at which time the esophageal wall is at its weakest. This is important when considering the timing of diagnostic evaluation such as upper endoscopy. Stricture formation is seen 3–6 weeks after ingestion, depending on the extent of the initial lesion.

Acid ingestions result in coagulation necrosis in which a coagulum forms a tissue barrier over the surface mucosa, limiting deeper absorption of the corrosive substance. Acid ingestions are more commonly associated with gastric injury including perforation, stricture, pyloric stenosis, and gastric outlet obstruction.

Solid caustic agents in the form of granules, pellets, and powers tend to adhere to the oral mucosa causing immediate pain and are often expectorated, limiting burn injury to the oropharynx and upper esophagus. Historically, only 10–15% of patients with granular lye ingestions sustain serious injury.

Clinical Presentation

Symptoms such as drooling, dysphagia, vomiting, abdominal pain, and hoarseness indicate the presence of a significant caustic ingestion. These symptoms, however, cannot adequately predict the presence or severity of esophageal mucosal damage. Indeed, the absence of oropharyngeal lesions does not exclude the presence of gastroesophageal injury. A review of nine studies that included 489 patients with caustic ingestions showed that 76% of patients sustained oral burns and 63% incurred esophageal injury. In those patients with oral burns, 54% had concomitant esophageal burns, whereas 45% of patients without oral burns sustained esophageal injury.

Notification of the Poison Control Center is always recommended when evaluating a child with a history of exposure to a caustic substance. The Poison Control Center staff can help identify and categorize the ingested substance and make specific treatment recommendations.

Evaluation

Although a detailed history is helpful, most pediatric ingestions are accidental and occur during times when

a child is unsupervised. The physical examination should include a close inspection of the cheeks, lips, buccal mucosa, and posterior pharynx. Auscultation of the chest can identify evidence of bronchospasm or stridor, suggesting airway involvement. The family should be instructed to bring the container of the ingested material to the hospital to aid in identifying the ingested substance.

After the patient is stabilized, chest and abdominal radiographs should be obtained to assess for free air, suggesting possible perforation. If the findings are equivocal, a CT scan with oral, water-soluble contrast can assist in determining early perforation and need for surgical exploration. Barium studies are useful for verifying perforation and detecting stricture formation 3–6 weeks after ingestion, but are not recommended in the acute burn injury. Corrosive esophagitis is associated with irregular esophageal narrowing and stricture formation, which may be well demonstrated on barium contrast studies (◗ *Figs. 177.2* and ◗ *177.3*).

Endoscopy is the most effective and reliable method to determine the location, extent, and severity of gastroesophageal injury. The timing of the endoscopy is important. Endoscopy should be performed between 6 and 48 h after ingestion, as too early endoscopy (<6 h after the ingestion) may underestimate the extent of injury and late endoscopy (5–15 days after the ingestion) may predispose to perforation. Caustic injuries are graded similarly to skin burns (◗ *Table 177.1*).

Treatment

If the history and physical examination are consistent with an accidental ingestion of a small amount of dilute acid or base and the patient is asymptomatic after observation and able to drink fluids, then the patient can be sent home without an endoscopic evaluation and with instructions to return if symptoms develop. If respiratory symptoms are present, laryngoscopy should be performed to evaluate the presence of an upper airway injury. Intentional vomiting should be avoided to prevent further injury of the esophagus and upper airway.

Administration of a mild acid or base as a neutralizing solution, such as vinegar or bicarbonate, is not recommended because an exothermic chemical reaction may cause thermal injury at the site of mucosal damage. Likewise, the administration of oral fluid (even water) to a child with symptomatic gastroesophageal injury is not

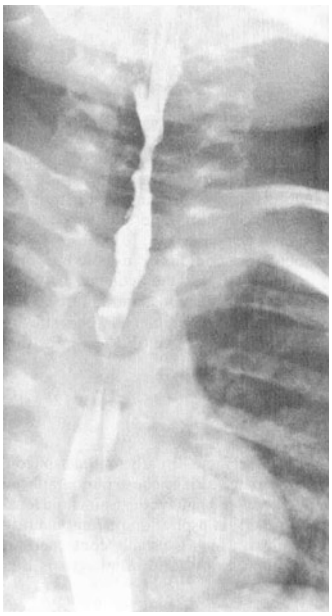

Figure 177.2
Esophageal stricture in a 2-year-old boy as a result of corrosive ingestion 2 months previously. Esophagogram reveals long stricture in the proximal esophagus (Courtesy: Dr. Hisham Nazer)

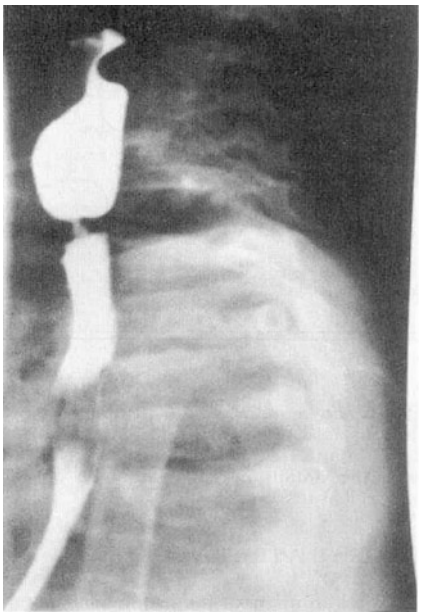

Figure 177.3
Esophageal stricture after acid ingestion. Esophagogram reveals a well-defined narrow stricture in the proximal esophagus with prestenotic dilatation. (Courtesy: Dr. Hisham Nazer)

Table 177.1
Caustic esophageal injury in children

Injury	Type	Endosopic findings	Outcome
Grade 0	Normal	Normal Mucosa	Normal/No Sequelae
Grade 1	First Degree Burn	Superficial Erythema & Edema	Normal/No Sequelae
Grade 2A	Second Degree Burn	Bleeding, erosions, blisters and exudates of mucosa/submucosa	Normal/No Sequelae
Grade 2B	Second Degree Burn	Circumferential Burn	Stricture likely
Grade 3	Third Degree Burn	Full thickness burn with deep ulcers, eschar, necrosis	Stricture + possible perforation

recommended as it may predispose the child to vomit and increase the risk of aspiration.

Children with grade 1 or 2A burns (*Table 177.1*) may be started on clear liquids after 24 h of observation and may be discharged home when tolerating a regular diet without difficulty. Children with grade 2B or grade 3 lesions experience the highest risk of complications and should have a nasogastric tube placed under direct visualization (during endoscopy) to provide nutritional supplementation and prevent complete obstruction of the lumen.

Those children with evidence of extensive transmural necrosis may benefit from early surgical exploration with gastrostomy, intraluminal esophageal stent placement, and radical resection if serosal discoloration of the stomach is present. Children with severe esophageal injury may eventually require colonic interposition surgery.

Treatment to prevent stricture formation is controversial. Systemic corticosteroids have been used since animal studies showed that cortisone prevents stricture formation. Studies in children and adults, however, have not demonstrated such favorable results. Conversely, if corticosteroids are used, a broad spectrum antibiotic should be used simultaneously to prevent local infection. It has been suggested that the depth and severity of the initial burn, rather than the treatment, may be the most important factors in determining risk of stricture formation.

Complications

Early complications of caustic injury are more often seen in children with severe injury and include perforation, mediastinitis, peritonitis, pneumonia, tracheoesophageal fistula, bleeding, sepsis, and even death.

Esophageal stricture formation is the most common late complication of caustic ingestion and can be diagnosed as early as 3 weeks following ingestion. After an esophageal stricture is found, conservative therapy with esophageal dilation is begun to maintain the child's ability to swallow. Gastric ulceration, perforation, and pyloric stenosis with distal outlet obstruction also can occur with alkaline ingestions but are seen more commonly after severe acid ingestions. It has been estimated that lye ingestion patients have a markedly increased risk of esophageal squamous cell carcinoma, with an average onset over 45 years following the initial injury, and hence routine endoscopic screening is recommended later in life.

Foreign Body Ingestion in Children

Foreign body ingestion is primarily a pediatric problem. In the year 2000, there were more than 107,000 cases of foreign body ingestion reported by the American Association of Poison Control Centers and 80% occurred in children. Most ingestions occur in young children 6 months to 3 years of age. The vast majority of ingested foreign bodies pass spontaneously and are symptom-free; however, about 10–20% require endoscopic removal and less than 1% require surgical intervention. Fortunately, mortality from foreign body ingestion is rare.

Coins are the most common gastrointestinal foreign bodies in children. However, young children ingest just about anything, including toys, magnets, batteries, pins, screws, marbles, and bones (*Fig. 177.4*). Multiple foreign body ingestion usually occurs in children with developmental delay. Most ingestions in young children are accidental, as compared to adolescents and adults where ingestions are often intentional.

Clinical Features

Most foreign body ingestions are asymptomatic and often observed by family members. Even in the emergency room

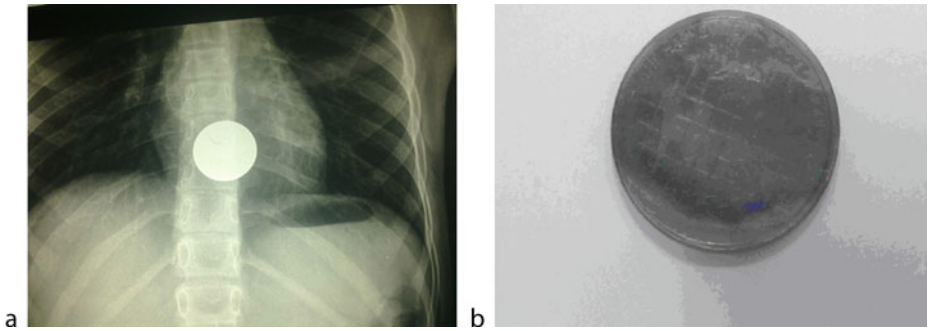

Figure 177.4
(a) Antero-posterior Plain X-ray Chest showing foreign body in the esophagus. (b) Endoscopic removal of the object (Coin) (Courtesy Dr. Hisham Nazer)

setting, only half of children with an ingested foreign body displayed symptoms at the time of the ingestion. Symptoms usually occur related to the location of the foreign body. For example, older children note the sensation of something "stuck" in the throat, suggesting an upper esophageal foreign body. A common symptom is refusal of feeds in infants and toddlers. Drooling suggests a complete esophageal obstruction. If the foreign body has remained in place greater than 24 h, symptoms of respiratory compromise may occur such as wheezing, stridor, or choking.

Foreign bodies tend to stick in areas of anatomic or physiologic narrowing. In the esophagus, these include the upper esophageal sphincter, the aortic arch impingement, and the lower esophageal sphincter. If a foreign body or food bolus lodges in the mid esophagus, esophageal pathology such as a stricture or esophagitis should be suspected. Children with previous esophageal surgery, such as tracheoesophageal fistula repair, are at high risk for foreign body obstruction.

Management

History and Physical Examination

Every child with suspected foreign body ingestion must undergo an initial evaluation of the airway and breathing, making special note of the neck exam for swelling, erythema, or crepitus. Crepitus suggests free mediastinal air from esophageal perforation. Chest exam should focus on inspiratory stridor and expiratory wheezing. For example, wheezing may indicate tracheal compression do to a lodged esophageal foreign body. Examination of the abdomen may indicate small bowel obstruction or perforation. Neck crepitus and possible small bowel obstruction require immediate surgical consultation and abdominal imaging should be obtained.

Diagnostic Examination

The initial diagnostic test should be radiographs (anteroposterior and lateral) of the neck, chest, and abdomen. Coins or disk batteries usually orient in the coronal plane and appear as a round object on an anteroposterior radiograph (*Fig. 177.4a*). Objects lodged in the trachea tend to orient in the saggital plane and are best seen in lateral projection. The lateral projection radiograph may help to identify the object or establish if more than one foreign body is present.

Some objects, such as toys made of plastic or wood, are not visible on plain radiographs. For example, Arana et al. in a study of 325 children found only about two thirds of the ingested objects were radiopaque. When the foreign body is not detected on plain film and a radiolucent foreign body is suspected, computed tomography is useful.

In general, gastrointestinal contrast studies should be avoided as the contrast material may obscure visualization on subsequent endoscopy. In addition, aspiration has been reported after oral contrast administration in cases of unsuspected high esophageal obstruction.

Management

Rapid Intervention

If any of the following warning signs are present, urgent endoscopic intervention is required.

Long (>5 cm) or sharp objects in the esophagus or stomach
Button battery (ies) in the esophagus
Multiple batteries in the esophagus or stomach
Signs of airway compromise
Drooling (patient cannot swallow secretions)
Evidence of intestinal obstruction or infection (fever, abdominal pain, or vomiting)

Routine Intervention

In the asymptomatic patient, most esophageal foreign bodies can be observed for 12–24 h, as spontaneous passage may occur. For example, coins lodged in the esophagus passed spontaneously into the stomach in about one third of asymptomatic children without warning signs.

Esophageal foreign bodies lodged for an unknown duration (or greater that 24 h) should be removed. Failure to spontaneously pass suggests possible esophageal pathology (e.g., stricture, abnormal motility). In addition, delayed passage of the foreign body may predispose to complications such as transmural erosion, perforation, and fistulae formation. In several case series, duration of lodgement for more than 24 h was the strongest predictor of complications.

Coins that reach the stomach can be observed and most will pass within 1–4 weeks. Practitioners can check the location of the coin with a plain radiograph about once a week. Coins that do not pass by 4 weeks should be removed endoscopically. If the child develops signs or symptoms of obstruction, such as abdominal pain, vomiting, or fever, the child should be reevaluated.

Techniques of Foreign Body Removal

The method of removal of an esophageal or gastric foreign body depends upon the expertise and experience of the practitioner. Many techniques exist, including rigid and flexible endoscopy, bougienage, Foley catheter, and the "penny pincher" technique.

Flexible Endoscopy

Flexible endoscopy is generally accepted as the preferred method in most circumstances because it allows the operator to directly visualize the foreign body and gastrointestinal tract. The endoscopist should have a variety of instruments to grasp the foreign body. Specific instruments such as the rat-tooth and alligator forceps, polyp snare, retrieval net, and helical baskets should be available. Removal of a sharp or pointed object generally requires a foreign body protector hood or overtube to avoid injury.

Rigid Endoscopy

Rigid endoscopy is a surgical technique using a rigid, channeled device that is introduced into the esophagus under general anesthesia. It is useful for objects in the proximal esophagus. The technique requires considerable skill and may cause complications such as esophageal abrasion and perforation.

Magill Forceps

Magill forceps are useful to remove foreign bodies in the oropharynx or uppermost esophagus. In cases done under general anesthesia, the anesthesiologist often can remove the object in the upper esophageal sphincter at the time of tracheal intubation, without the need for intubation. Most cases, however, require intubation and a laryngoscope is used to visualize the foreign body and remove it.

Alternative Approaches

Bougienage (passage of a dilator) has been used by some to push esophageal objects into the stomach. This approach is generally not recommended as it does not allow visualization of the esophagus and does not remove the foreign object. It may have a limited role in selected patients with witnessed, short-term (less than 24 h) coin ingestion. The Foley catheter technique has also been advocated. This approach does not permit visualization of the esophagus and carries the risk of balloon inflation below an unsuspected stricture and subsequent esophageal perforation as well as the potential of causing aspiration of the foreign body if it is inadvertently dragged into the trachea. Another published approach is the penny pincher technique in which an endoscopic grasping forceps is inserted through a nasogastric tube, under fluoroscopic guidance (usually without anesthesia or endotracheal intubation). This approach is an improvement over the Foley catheter method because it permits direct control of the object, but does not allow inspection of the esophagus. This method requires considerable experience and operator time.

Special Circumstances

Disk Batteries

Button batteries in the esophagus are an emergency and must be urgently removed. The esophagus is flat and a lodged disk battery will conduct electricity between the anode and cathode (positive and negative poles), which can result in liquefaction necrosis and perforation. Retained batteries can also leak caustic material (e.g., mercury, silver, lithium and sodium, or potassium hydroxide) causing additional mucosal injury. Disk batteries generally pass uneventfully from the stomach. However, because of the potential for leakage and toxicity, batteries should be removed if they are within reach of the endoscope.

Sharp or Pointed Objects

Sharp or pointed objects lodged in the esophagus are a medical emergency and require urgent removal. Many sharp or pointed objects (e.g., straight pins, needles) are not readily visible by X-ray; hence, if there is high suspicion of ingestion, endoscopy should be performed. The risk of mucosal injury during removal of a sharp object can be reduced by using a protector hood on the end of the endoscope or an overtube. If the object is in the stomach or proximal duodenum, it should also be removed promptly, using a flexible endoscope. If the object has passed the stomach and the patient is asymptomatic, it should be followed with serial radiographs. Surgical intervention should be considered for objects that fail to progress for 3 days or if symptoms occur.

Food Impaction

Impacted food bolus is the most common esophageal foreign body in adults, but is unusual in children. This usually occurs while eating. Children who do present with a food impaction suggests underlying esophageal pathology (strictures, achalasia, esophagitis, or esophageal motility disorders). As mentioned, children who are in acute distress or drooling require urgent removal of the impaction. Proteolytic enzymes, such as papain, are not recommended because their use may cause erosion and perforation. The use of glucagon to promote spontaneous passage of an impacted food bolus by relaxing the esophagus can be tried if the patient is stable as it appears generally safe, but it may not be effective and should not delay endoscopic removal.

Magnets

A solitary, smooth ingested magnet is of little risk, but two or more magnets may attract across layers of bowel leading to injury such as fistula, volvulus, perforation, or obstruction. As such, it is important to determine the location and number of magnets as ingestion of multiple magnets requires removal.

Long Objects

Objects longer than 5 cm generally do not pass the stomach and should be removed.

Summary

Many children with esophageal foreign bodies are asymptomatic and the objects pass uneventfully. When symptoms occur, such as a sensation of something stuck in the chest, feeding refusal, drooling, or respiratory symptoms, intervention and foreign body removal are indicated. Flexible endoscopy is the preferred approach in most cases. Objects that have passed beyond the stomach usually pass without complications.

178 Gastroesophageal Reflux Disease

Mohammad I. El Mouzan

Gastroesophageal reflux disease (GERD) is a common cause of morbidity worldwide. The estimated incidence of 1 in 300 live births and 60% preponderance have been reported. This incidence however is increased in certain conditions such as cerebral palsy, mental retardation, and operated tracheoesophageal fistula.

Pathogenesis

Although the mechanism of GERD remains unclear, several anatomic and functional factors prevent reflux. The phrenoesophageal ligament, the acute esophageal angle, and the lower esophageal sphincter (LES) are the most important "antireflux barriers."

Dysfunction of the LES resulting in inappropriate relaxation of the sphincter in response to increased intra-abdominal pressure (associated with physiologic activity such as crying, cough, sneezing, defecation, etc.) is the commonest mechanism. Other forms of LES dysfunctions such as spontaneous intermittent relaxation or continuous reduction in basal pressure are less common. Reflux of gastric content in the esophagus causes most of the symptoms such as regurgitation and vomiting, chronic bronchitis, recurrent aspiration pneumonia, apnea and bradycardia, and bronchospasm. Failure to thrive results from loss of calories, and esophagitis results from the effects of gastric contents (mostly acid) on the esophageal mucosa. In addition, certain manifestations such as stridor, bronchospasm, and apnea may be related to the presence of acid in the esophagus through a reflex mechanism without aspiration.

Clinical Presentation

Gastroesophageal reflux is a normal phenomenon both in children and adults. The distinction between physiologic reflux and disease (GERD) is a matter of quantity. Regurgitation and vomiting are the commonest manifestations in infants and resolve spontaneously. A minority of infants however develop GERD with recurrent vomiting, hematemesis, odynophagea (pain on swallowing), dysphagea, irritability resembling infant colics, arching of the back during feeding, and failure to thrive. In addition, GERD has been implicated as one of the causes of chronic respiratory diseases such as recurrent bronchospasm, stridor, chronic cough, and recurrent pneumonia. In infants, GERD has been associated with apparent life-threatening events (ALTE). In older children, GERD presents most commonly with recurrent vomiting, hematemesis, heartburns, and dysphagea. Rarely, stereotypical stretching and arching of the back (Sandifer syndrome) is caused by esophageal pain may be confused with seizures or dystonia. Chronic untreated peptic esophagitis leads to chronic blood loss with iron deficiency anemia, esophageal stricture, and replacement of the normal esophageal mucosa of the distal esophagus with a potentially malignant metaplastic epithelium called Barrett's mucosa. Finally GERD has been linked to chronic laryngitis, sinusitis, and otitis media.

Diagnostic Methods

There is no test that can distinguish physiologic reflux from GERD. In infants with uncomplicated reflux (vomiting and regurgitation only), history and physical examination are usually sufficient for the diagnosis of reflux. In complicated cases, however, usually more than one investigation is needed.

Barium Meal

Barium meal (and not swallow) is usually the first investigation. It is inexpensive, readily available, and allows identification of structural anomalies such as hiatal hernia, esophageal stricture, gastric volvulus, malrotation, and pyloric stenosis. However, low sensitivity (31–86%) and specificity (21–86%) suggest high false-negative and false-positive results, indicating that barium meal alone should not be used to diagnose or exclude reflux.

Esophageal pH Monitoring

This test, also called pH probe, detects acid reflux in the lower esophagus. A probe placed in the lower esophagus

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_178,

Time pH < 4 (min)	253	218	33	1	9	199
Percent time pH < 4 (%)	17.6	19.1	18.6	1.1	6.9	22.5

Figure 178.1
A 24-h esophageal pH monitoring in an infant. Abnormal study with an abnormal percent time pH < 4 score of 17.6%. On follow-up, the patient developed peptic esophagitis grade III

through the nose measures the pH which is transmitted to a recorder. More recently, a wireless capsule, attached to the esophageal mucosa, transmits pH to the recorder eliminating the nasoesophageal tube and discomfort. The recording lasts for about 24 h during which the patient performs his usual activities. Data collected during this period is analyzed by computer and results are expressed in a graph and table. Parameters include number of reflux episodes, number of prolonged episodes, duration of the longest reflux episode, and percentage of time pH was less than 4. The latter is called the reflux index. Advantages include ability to quantify reflux, allowing the distinction between physiologic and pathologic reflux (GERD). Another important advantage is to clarify the relation between reflux episodes and symptoms by calculating the symptom index score (the number of symptoms occurring during reflux episodes). A causal relationship is suggested when the score is more than 0.50. However, esophageal pH studies do not detect nonacid reflux which occurs in the postprandial period which may cause chronic respiratory disease (*Fig. 178.1*).

The Multichannel Intraluminal Impedance

This recently described technique measures the conductance potential (electrical impedance) of refluxed material and identifies its physical characteristics (liquid, gas, or mixed). It is combined with pH monitoring in the same probe to determine whether these reflux episodes are acid or nonacid. Studies have shown that combined impedance with pH identified more reflux episodes with better identification of weakly acid GERD not detectable by

conventional pH probe alone and yet responsible of symptoms of GERD. At present, the main disadvantages of this technique are lack of normal values for nonacid episodes, poor reproducibility, and high cost.

Endoscopy and Biopsy

Visualization of the esophageal mucosa detects signs of inflammation which is confirmed by histopathology. Thus, this procedure is important in the detection of peptic esophagitis, a complication of GERD and not a diagnostic test of GERD per se. The degree and extent of esophageal lesions (erythema, erosions, and ulcerations) have been used in the grading of esophagitis. Endoscopy and biopsy also detect strictures and Barrett's esophagus. Endoscopy and biopsy also help in the differential diagnosis of peptic esophagitis which include Crohn's disease, webs, and eosinophilic or infectious esophagitis. Because of poor correlation between endoscopic appearance and histology, biopsy is commonly recommended whenever endoscopy is performed.

Scintigraphy

This technique is performed by oral ingestion or instillation of technetium-labeled formula or food into the stomach. The areas of interest, the stomach, esophagus, and lungs, are scanned by a gamma camera for evidence of reflux and aspiration. Main advantages are the ability to demonstrate reflux of nonacidic gastric contents and study of gastric emptying, which may be delayed in children with GERD. Disadvantages include lack of standardization, high cost in terms of equipments, and expertise.

Other Techniques

Ultrasonography: Monitoring of the gastroesophageal region after a meal for reflux has been introduced as a noninvasive technique for the identification of reflux. However, the test requires dedication and expertise which are not commonly available. Therefore, although attractive, this test is not widely performed. *Esophageal manometry*: Manometry is not a diagnostic test for reflux per se. It is frequently performed in adults to detect motility disorders associated with GERD, but rarely indicated in children. *The Bilitec 2000*: This is a fiber optic spectrophotometric probe that detects bilirubin in the refluxate, which may be helpful in the diagnosis of nonacid reflux caused by duodenogastric reflux disease.

Therapeutic Measures

Three modalities are described: medical therapy consisting of dietary, positional, and drug therapies. Nonresponse to an adequate trial of medical therapy or dependence on drug therapy is an indication for surgery. However, endoscopic methods may be considered as an alternative to surgery.

Dietary Measures: Thickening of infant feeds is widely used. Milk-thickening agents decrease the number of episodes of vomiting but do not improve reflux index scores. Thickening may be achieved with the addition of rice cereal to formula or addition of thickening agents to formula. The advantage of thickening with rice cereals is the increase of caloric intake. Newer formulas that contain carob flour or locust bean gum as thickening agents are now available. These formulas have been reported to decrease vomiting and esophageal acid exposure when compared with unthickened formulas and formula thickened with rice cereal.

The usefulness of small volume and more frequent feeds remains controversial.

For older children and adolescents, dietary advice includes cessation of smoking and avoidance of spicy food, chocolate, and caffeine. In overweight and obese patients, weight reduction was associated with improvement of reflux.

Postural therapy: The recommended positioning of infants with GERD has evolved over the last two decades. The prone positioning recommended in the past for the treatment and prevention of GER in infants is now changed to supine positioning. This change in recommendation was based on the recognition that prone positioning was associated with a higher rate of sudden infant death syndrome (SIDS) and on the reduction in SIDS rate and mortality in infants in the non-prone position compared to those in the prone position. Older children and adolescents may benefit from elevation of the head of the bed.

Drug Therapy

Prokinetic therapy: Prokinetic therapy enhances esophageal peristalsis and accelerates gastric emptying. Bethanecol, metoclopramide, domperidone, and cisapride have been used with controversial or marginal effectiveness. Cisapride, widely used in the past, has been withdrawn from the market because of serious cardiac side effects. At present, although domperidone and metoclopramide are used on empirical basis, no prokinetic agent can be recommended on scientific grounds.

Acid-controlling drugs: A wide range of acid-controlling agents is available. *Antacids* neutralize gastric acidity. However, in order to be effective, large doses must be given frequently. *Antihistamine-2 receptor antagonists* (*H-2 blockers*) decrease acid secretion by inhibiting the histamine-2 receptors on the gastric parietal cell. Representatives of this category include cimetidine, ranitidine, and famotidine. Ranitidine is probably the most commonly used in children. *Proton pump inhibitors* (*PPI*) are the most potent acid suppressors. They deactivate the H^+, K^+ – ATPase pumps so that virtually no acid is pumped in the gastric lumen. Optimal effectiveness is achieved when the PPI is administered one-half hour before meals so that peak plasma concentrations coincide with the mealtime. The main indication is the treatment of esophagitis. However, since these agents reduce esophageal acid exposure, they may be useful in the treatment of GER-related respiratory disorders.

Surface Agents (Sucralfate) are represented by sodium alginate forms a surface gel that decreases the regurgitation of gastric contents into the esophagus and protects the esophageal mucosa. Sucralfate gel acts by adhering to peptic lesions and protects the esophageal mucosal surface. Information on the doses and side effects are available in the references given at the end of the article.

Surgical therapy: Although many surgical techniques have been described, Nissen fundoplication is the most commonly used. Surgery is indicated in children unresponsive to an adequate trial of medical therapy. Laparoscopic fundoplication is currently more frequently performed than the open technique. The success rate varies with the degree of selection of cases and the experience of the centers but usually reaches 90%.

Endoscopic therapy: Endoscopic therapeutic techniques have been described recently: endoscopic polymer implantation, delivery of radiofrequency to the cardia (Stretta system), and endoscopic gastroplication (EndoCinch system).The latter appears to be the most popular and has been reported to be safe and effective in adults. Experience in children is limited but encouraging and may become an alternative to surgery in children dependent on antireflux medications.

Approach to the Diagnosis and Therapy

It is well recognized that the majority of uncomplicated GER in infants, the so-called "happy spitters," are self-limited and therefore do not require investigation or medications and supportive measures such as thickening of feeds, and supine positioning may be helpful. An overlap of symptoms between GER and cow's milk protein allergy has been reported, and a trial of hypoallergenic formula for 1–2 weeks may be considered. Regular follow-up is recommended to document recovery or persistence of symptoms and complications. Complicated GERD presenting with recurrent vomiting, weight loss or poor weight gain, irritability in infants, heartburn, chest pain, hematemesis, dysphagia or feeding refusal, apnea or ALTE, wheezing, stridor, hoarseness, cough, abnormal neck posturing (Sandifer syndrome), all require consultation with pediatric gastroenterologist for further evaluation and investigations. An adequate trial (at least 2 months duration) of medical therapy is recommended as soon as the diagnosis of GERD is established. Nonresponse to medical therapy is an indication for surgery.

179 The Stomach

Jumana Shammout · Hisham M. Nazer

The gastric wall is composed of three layers: the mucosa, the muscularis mucosae, and the serosa. The gastric mucosa is lined by a single layer of mucus-secreting columnar epithelium punctuated by pits where the gastric glands are situated. The stomach can be divided histologically into three areas according to the predominant gland type: cardiac, fundus or oxyntic, and antral.

The cardiac region is the area just distal to the gastro-esophageal junction; it contains mainly mucus-secreting glands and endocrine cells. The fundus/oxyntic region extends from the cardia to the dome-shaped fundus and the body of the stomach to the level of the incisura angularis. It contains parietal cells that secrete HCL and intrinsic factor, chief cells that secrete pepsinogen, G cells that secrete gastrin, and enterochromaffin cells that secrete histamine and serotonin.

The antral/pyloric region is located distal to the incisura angularis, and contains D cells that secrete somatostatin, G cells, and enterochromaffin cells.

Gastropathies, Gastritis and Peptic Ulcer Diseases

Gastritis is defined as inflammation of the gastric mucosa. The lesion is usually superficial, though cases may be associated with deeper involvement of the gastric mucosa. There is partial or complete loss of the gastric gland cells. This entity of gastritis is referred to as *nonerosive gastritis*. There may also be some intestinal metaplasia with replacement of the gastric mucosa by an intestinal mucosa. An immunologic mechanism may play a role. Affected patients are prone to suffer from pernicious anemia that requires treatment with intramuscular vitamin B12 injection.

Gastritis may, however, be severe enough to progress into severe erosions and hemorrhages (*erosive gastritis*). The lesion may progress even deeper to the submucosa and muscularis mucosa with secondary ulceration. The mucosal barrier of the stomach is disrupted secondary to decreased mucosal blood flow.

Pathophysiology

Normally, the gastric mucosa is protected from acid and pepsin attack by a viscous gel layer formed of mucus, phospholipids, and bicarbonate which are secreted by the gastric epithelial cells under prostaglandin stimulation. Peptic disease results from an imbalance between the gastric mucosal aggressive and protective mechanisms.

Gastritis and ulcers are classified as *primary or secondary* based on the underlying etiology. *Primary ulcers* are usually chronic, duodenal, and in the majority of cases caused by infection with *Helicobacter pylori*, whereas *secondary ulcers* are usually acute and gastric. Secondary gastritis and ulceration occur in association with severe stress such as systemic illnesses, burns, and head injuries. They may also be induced by the ingestion of drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs).

Peptic disorders are far less prevalent in the pediatric age group than in adults, accounting for only about 10–20% of cases of abdominal pain seen in outpatient gastroenterology clinic settings.

Clinical Presentation

In children, the symptoms caused by gastritis and gastric ulcers are highly variable. Young children with peptic disorders may present with irritability, vomiting, and poor appetite. Older children may present with epigastric pain, nausea, early satiety, vomiting, anemia, and weight loss. Epigastric tenderness may be elicited on physical examination.

Gastritis and gastropathies are classified by their endoscopic appearance into *erosive and hemorrhagic* or *nonerosive* types (Table 179.1) based on the most common presenting picture.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_179,

Table 179.1
Classification of gastritis and gastropathy in children

Erosive and/or hemorrhagic gastritis or gastropathy	Nonerosive gastritis or gastropathy
Stress gastropathy	Nonspecific gastritis
	Helicobacter pylori gastritis
Neonatal gastropathy	Crohn's gastritis
Traumatic gastropathy	Allergic gastritis
Aspirin and other nonsteroidal anti-inflammatory drugs	Proton pump inhibitor gastropathy
Portal hypertensive gastropathy	Gastritis of chronic granulomatous disease
Uremic gastropathy	Cytomegalovirus gastritis
Chronic varioliform gastritis	Eosinophilic gastritis
Bile gastropathy	Collagenous gastritis
Henoch–Schönlein gastropathy	Graft-versus-host disease
Corrosive gastropathy	Ménétrier's disease
Exercise-induced gastropathy or gastritis	Pernicious anemia
Radiation gastropathy	Gastritis with autoimmune disease

Note: Although some disorders can present with either erosive or nonerosive picture, each is classified by its most common presentation

Nonerosive Gastritis or Gastropathy

Helicobacter pylori Gastritis

Helicobacter (Campylobacter) pylori are spirochetal-like organisms that were isolated in 1982 from gastric biopsies of adults. *H. pylori* is a gram-negative, flagellated microorganism, that can colonize the gastric epithelium, causing chronic gastritis. Infection with *H. pylori* is strongly associated with duodenal and gastric ulcers, and has been implicated in the etiology of gastric cancer.

H. pylori can be transmitted from person to person via oral–oral and fecal–oral routes. Overcrowded conditions and poor socioeconomic status are risk factors for acquiring the infection.

H. pylori infection is rare in young infants, and its prevalence rises with age. In developing countries, infection occurs at a much earlier age, usually in the first 2 years of age affecting about 40% of children and more than 80% of adults. In developed countries, colonization in childhood is uncommon, and only 40% of adults are infected.

Pathophysiology

H. pylori is capable of withstanding the gastric pH in part due to its ability to secrete urease which hydrolyzes urea into CO_2 and ammonia. Ammonia neutralizes the acid environment in the stomach. In addition, the bacteria posses several flagellae that enable it to penetrate the gastric mucus layer and attach to the gastric epithelium. Production of toxins and bacterial enzymes contributes to epithelial damage.

H. pylori adheres only to gastric epithelium and it is found on the gastric mucosa of almost 90% of children with duodenal ulcers. The mechanisms by which gastric antral colonization with *H. pylori* leads to duodenal ulceration is unclear. Duodenal gastric metaplasia appears to be a risk factor with *H. pylori* colonizing the metaplastic epithelium. Additionally, *H. pylori* induces increased basal and peak acid output contributing to duodenal ulceration.

Although *H. pylori* infection induces a systemic antibody response, this response is incapable of eradicating the bacteria. Up to 15% of patients infected with *H. pylori* develop peptic ulcer disease, and a further 1% may develop gastric cancer.

Clinical Manifestations

Infection with *H. pylori* usually causes asymptomatic chronic gastritis. When symptomatic, patients typically present with epigastric abdominal pain and vomiting. The pain often occurs after meals, but it can also occur early in the morning. Younger children may present with irritability and decreased appetite. Less-frequent presenting symptoms include chest pain, heartburn, nausea, anorexia, or gastrointestinal bleeding.

Chronic iron deficiency anemia has been documented in children with gastritis or ulceration and may be painless.

H. pylori infection also appears to be associated with an increased risk of carcinoma of the stomach especially in those infected as children.

The relationship of chronic *H. pylori*-associated gastritis to symptoms is still controversial. Reports have also indicated that after eradication of *H. pylori*, symptoms resolved only in those patients who had duodenal ulcer disease associated with *H. pylori* gastritis.

Diagnosis

H. pylori infection can be detected by noninvasive and invasive tests.

Noninvasive tests include stool testing for *H. pylori* antigens, urea breath test, and serology.

Stool *H. pylori* antigen test has a sensitivity of 98%, and specificity of 99%. Urea breath test is performed by ingesting a test meal that contains urea labeled with carbon-13 (13C). *H. pylori* urease activity hydrolyses the urea releasing labeled carbon dioxide, which can be detected in the breath. The test is more than 90% sensitive and specific.

Invasive testing is achieved by performing an endoscopic examination. The presence of *H. pylori* correlates better with the histologic rather than with endoscopic finding. Most children with *H. pylori* infection exhibit a nodular pattern in the gastric antrum secondary to lymphoid hyperplasia that can be seen at endoscopy. *H. pylori* can be detected using a rapid urease test by placing a gastric mucosal biopsy in a media containing urea and a pH color indicator; the bacteria cleaves the urea-liberating ammonia, causing a rise in the pH and changing the color of the media from yellow to pink. Microscopic examination of gastric mucosal biopsies identifies the inflammation and the *H. pylori* organisms in the gastric tissue. Tissue culture to detect antibiotic susceptibility patterns can also be performed for patients with refractory disease.

Treatment

H. pylori eradication can be achieved by using a triple therapy consisting of a proton pump inhibitor combined with two antibiotics for 2 weeks. Amoxicillin and clarithromycin are recommended. In persons allergic to penicillin, substitution of amoxicillin by metronidazole should be done. Once the condition is stabilized, it is important to continue therapy with antacids or H2 blockers for a period of up to 2 months.

Patients treated for *H. pylori* should have a noninvasive test (breath test or stool antigen test) 4–6 weeks after treatment to confirm eradication if they remain symptomatic. Patients with ulcer should have a repeat endoscopy 4–6 weeks after therapy to monitor ulcer healing.

More details regarding *H. pylori* gastritis and peptic ulcer disease are covered in the Chap. 181, "Peptic Ulcer Disease."

Inflammatory Bowel Disease

Gastroduodenal involvement is common in Crohn's disease, and is usually associated with distal intestinal involvement. Patients may be asymptomatic, or they may complain of abdominal pain, nausea, or vomiting. Patients may also present with delayed gastric emptying, hematemesis, and melena.

Diagnosis is achieved by histological examination of the gastric mucosa, which may reveal focal chronic active inflammation and noncaseating granulomas.

Allergic and Eosinophilic Gastritis

Eosinophilic gastroenteropathy (EG) is a chronic relapsing disease of unknown etiology, thought to be related to food or environmental allergy, characterized by dense eosinophilic infiltration of parts of the gastrointestinal tract.

EG can present at any age from infancy to adulthood, and can occur in all races, with a slightly higher incidence in males. A personal or family history of allergy or atopy is present in many cases.

The manifestations of the disease vary according to the region and the layer(s) of the gastrointestinal tract involved. In eosinophilic gastritis, the eosinophilic infiltration is limited to the stomach, and can involve the gastric mucosa, the muscularis, or the serosa. Patients with mucosal involvement may present with abdominal pain, vomiting, weight loss, or edema as a result of protein-losing enteropathy. Patients with muscularis disease present with signs of gastrointestinal tract obstruction, while serosal involvement produce eosinophilic ascites, and patients may present with symptoms of peritonitis. Peripheral eosinophilia and an elevated total and food-specific IgE levels may be seen.

Diagnosis

The diagnosis of eosinophilic gastroenteropathy is confirmed by identifying a dense eosinophilic inflammation

in the gastric tissues in the absence of parasitic infection or other causes of intestinal eosinophilia.

Treatment

Although food hypersensitivity plays a major role in eosinophilic gastroenteropathy, no food allergy test (skin, patch, allergen-specific IgE) has been shown to effectively identify culprit foods leading to clinical or tissue eosinophilia improvement. Thus at present there is no evidence base to support routine food allergy testing of eosinophilic gastropathy patients. An empiric elimination diet with the patient avoiding possible culprit allergens (including soy, wheat, corn, egg, milk, peanut, and seafood) may regress the eosinophilic infiltration and alleviate the symptoms. In patients who do not respond to elimination diets, elemental diet may be effective. If symptoms persist despite dietary manipulation, corticosteroids can be used for a short duration to suppress the inflammation. Unfortunately, many patients relapse and may need to be retreated.

Cromolyn sodium, a mast cell stabilizer, may also be used alone or in combination with steroids. Montelukast, a leukotriene receptor antagonist may also be effective. Surgical intervention is rarely required for patients with obstructive symptoms.

Hypertrophic Gastritis (Ménétrier's Disease)

Ménétrier's disease is a disease of unknown etiology, thought to be associated with acute CMV infection. It is characterized by thickening of the gastric mucosal folds associated with protein loss across the abnormal mucosa. Ménétrier's disease can present at any age. The mean age of onset in children is 4.7 years. Patients may present with abdominal pain, anorexia, vomiting, edema, and hypoproteinemia. The diagnosis is confirmed by endoscopy and histological examination of gastric mucosal biopsies. The course in children is self-limited.

Pernicious Anemia

Patients with pernicious anemia have antibodies directed against the gastric parietal cells causing diffuse atrophic gastritis of the gastric body with consequent loss of acid and intrinsic factor secretion. Achlorhydria, and megaloblastic anemia due to vitamin B-12 deficiency result.

At endoscopy, the gastric body appears thin and blood vessels are sometimes visible through the mucosa. Histological examination shows severe atrophic gastritis with absence of parietal cells. Adenocarcinoma may occur.

Other causes of nonerosive gastritis or gastropathy are listed in *Table 179.1*.

Erosive and/or Hemorrhagic Gastritis or Gastropathy

Stress Gastritis

Stress-induced gastric erosions usually occur within 24 h of the onset of a major illness such as shock, sepsis, burns, head injury, and major surgery. The stressor causes a reduction of the gastric mucosal blood flow resulting in ischemia with subsequent gastric erosions and ulcerations. Stress erosions are typically asymptomatic, multiple, and superficial; however, when they are symptomatic, they usually cause overt upper GI hemorrhage, and may lead to perforation. Stress ulcers associated with burns are also known as Curling's ulcers, while those associated with increased intracranial pressure are known as Cushing's ulcers.

Aspirin and Other Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs are common causes of gastric mucosal injury. They may cause superficial petechiae, erosions, gastritis, or gastric ulcers. NSAIDs cause damage to the gastric mucosa directly as well as systematically through inhibiting cyclooxygenase 1 (COX-1) which reduces gastric mucosal prostaglandin synthesis, thereby inhibiting epithelial proliferation and mucosal bicarbonate and mucus secretion. The risk of injury is dose dependent.

NSAIDs should be discontinued or at least the dose should be decreased. A proton pump inhibitor or a prostaglandin E analog such as misoprostol may be used as prophylactic therapy. Patients with active ulcer who need to continue NSAIDs should be treated with a proton pump inhibitor. Alternatively, selective COX-2 inhibitors may be used.

Other drugs that can cause erosive and hemorrhagic gastropathies include valproic acid, dexamethasone, iron, and potassium chloride.

Chronic Erosive Gastritis

Also known as chronic varioliform gastritis, chronic erosive gastritis is an uncommon disorder of unknown etiology characterized by thickened gastric mucosal folds

associated with dense lymphocytic infiltration. Patients may present with upper GI symptoms associated with anemia or protein-losing enteropathy.

Bezoars

Bezoars are collections of indigestible material that accumulate, coalesce, and get retained within the gastrointestinal tract, most frequently the stomach. In rare instances, the impaction advances by long strands of twisted hair into the intestine, a condition recognized as "the Rapunzel syndrome." Bezoars are usually seen in emotionally disturbed and depressed patients as well as in mentally handicapped children. They can also develop in patients with gastric dysmotility, and in patients with surgically altered gastric anatomy

Bezoars can be classified according to their composition. The major types are phytobezoars, composed of vegetable matter; trichobezoars, composed of hair; pharmacobezoars, consisting of medications; and lactobezoars, formed from milk curds.

Phytobezoars are the most frequently observed type of bezoars, accounting for 40% of reported cases. They are composed of aggregations of indigestible food fibers such as cellulose, hemicellulose, lignins, and tannin, most commonly from pulpy fruits, seeds, roots, or leaves. Predisposing factors to phytobezoar formation include poor mastication, excessive intake of fiber, histamine H2 receptor antagonists, and gastroparesis. Phytobezoars are usually found in the stomach, but may also occur in the small intestine and colon.

Trichobezoars (hairball) are mostly seen in young children who practice the habit of eating their own hair or fibers from blankets and rugs. The condition is slowly progressive until it presents with abdominal discomfort, pain, vomiting, and constipation together with evidence of emotional disturbances or mental handicap.

Examination reveals a hard tumor palpated in the left hypochondrium.

The diagnosis is considered by the history of the child's habit and is later supported by barium meal, which shows a filling defect in the stomach. The borders and configuration of the bezoar are highlighted after the passage of barium from the stomach. Ultrasonography, computed tomography, and gastroscopy with biopsy are helpful in supporting the diagnosis of trichobezoars.

Treatment is by surgical removal of the mass. Psychiatric follow-up is essential to diminish the frequency of recurrence. Occasionally, an attempt is made to endoscopically remove the hairball. Gastric perforation is a recognized complication of trichobezoar.

Lactobezoars are concretions of casein, fat, and calcium, and occur most commonly in premature low-birth-weight infants. They have also been reported in full-term, and exclusively breast-fed infants. Factors implicated in lactobezoar formation include formulas with a high casein content, high-caloric density formulas, early and rapid feeding advancement in small infants, thickening agents, and immature gastric motility.

Cement bezoars: several cases of cement bezoars have been reported in children. Cement solidifies after various lengths of time depending on their type. Solidified concretions require surgical removal.

Clinical Presentation

Lactobezoars in the newborns present with feeding intolerance, and infants may develop abdominal distension and vomiting. Physical examination often discloses a palpable mid-abdominal mass.

Trichobezoars form over long periods, and may cause subtle signs of abdominal discomfort, early satiety, or nausea. These bezoars can grow to substantial size and cause pressure necrosis and ulceration of the gastric mucosa, causing gastrointestinal bleeding, melena or guaiac-positive stools, and iron deficiency anemia. They may also cause gastric perforation.

Patients with *Rapunzel syndrome* may present with partial or complete intestinal obstruction, and depending on the size and extent of the "tail" may cause obstructive jaundice, pancreatitis, and protein-losing enteropathy.

Phytobezoars are formed much more rapidly than trichobezoars. Symptoms include nausea, vomiting, and signs of gastric outlet obstruction. Gastric perforation is rare.

The physical examination is unremarkable in most patients with gastric bezoars. Occasionally, abdominal distension or a palpable left upper quadrant abdominal mass may be detected. Crepitus caused by putrefaction and bacterial growth may sometimes be elicited.

Severe halitosis may be present due to the putrefying material in the stomach. Patients with trichotillomania may have patchy areas of alopecia.

Diagnosis

Plain radiographs may demonstrate an air shadow or a mottled-appearing mass in the stomach. Barium studies are much more likely to demonstrate a bezoar;

trichobezoars absorb barium and have a mottled appearance, whereas phytobezoars are typically impermeable to barium and appear as filling defects.

Ultrasound or CT scan may also be used and show the bezoar as a mass or a filling defect. However, radiographic studies identify only one fourth of bezoars; moreover, the use of barium may change the acid environment surrounding enteric-coated pharmacobezoar aggregations, leading to absorption of the medication.

Endoscopy is the diagnostic modality of choice allowing direct visualization of the bezoar, biopsy, and therapeutic intervention.

Management

Management of bezoars depends on their composition, size, and/or associated complications.

Lactobezoars almost always resolve in response to withholding feedings for a couple of days while maintaining the infant on intravenous fluids.

Small bezoars may be managed conservatively with a clear-liquid diet and a prokinetic agent such as metoclopramide. Nasogastric lavage may effectively dissolve small phytobezoars.

Chemical dissolution may be used to dissolve phytobezoars, and can be achieved using any of the following agents:

1. Cellulase: can be used to degrade the cellulose and hemicellulose found in phytobezoars. No adverse effects have been reported with the use of cellulase.
2. Papain: papain used in meat tenderizers can be given to dissolve bezoars; however, adverse effects including gastric ulcer and esophageal perforation have been reported.
3. Acetylcysteine: because many phytobezoars contain mucus, acetylcysteine solution can be used to chemically fragment phytobezoars.
4. Coca-Cola: oral, nasogastric, and endoscopic injection of Coca-Cola can be used to dissolve phytobezoars. The mechanism of Coca-Cola's action may be related to its low pH, high sodium bicarbonate content, and the presence of CO_2 bubbles.

    Endoscopy: most bezoars can be fragmented into small pieces endoscopically, and either removed or allowed to pass through the GI tract.

Trichobezoars are not amenable to chemical dissolution, and are more difficult to remove endoscopically, and may require surgical removal. Surgical removal of bezoars can also be done in patients who fail medical therapy or who have complications such as obstruction or significant bleeding. A small gastrostomy can be done through which gastric bezoars can be removed.

Prevention

Recurrence of bezoars is common unless the underlying predisposing conditions are treated. Patients should also be encouraged to chew food carefully, increase the amount of water intake, avoid the offending foods (i.e., persimmon, raw citrus fruit, and high-fiber food), and to seek psychiatric evaluation if needed (for trichobezoars).

180 Infantile Hypertrophic Pyloric Stenosis

Dena Nazer · Hisham M. Nazer

Epidemiology

Infantile hypertrophic pyloric stenosis (IHPS) is a functional gastric outlet obstruction secondary to hyperplasia and hypertrophy of the muscular layers of the pylorus. IHPS is recognized as one of the most common surgical conditions in young infants. IHPS is more common in whites than Hispanics, blacks, or Asians. The incidence is 2.4 per 1,000 live births in whites, 1.8 in Hispanics, 0.7 in blacks, and 0.6 in Asians. The male/female ratio is about 4:1.

Pathogenesis

The exact nature of the pathogenic process in IHPS remains uncertain. The etiology is probably multifactorial, with both genetic and environmental factors contributing. No special pattern of inheritance has been identified in IHPS, but a familial incidence is recognized.

IHPS has been reported both in nonidentical male triplets as well as in identical male triplets in a family with no previous history of pyloric stenosis. Such observation supports the view that IHPS is the result of a single main dominant gene with multifactorial background working together. IHPS has been associated with other conditions such as trisomy 18, Turner syndrome, phenylketonuria, and maternal myasthenia gravis.

Associated anomalies have been described in up to 33% of cases of IHPS. The condition has mostly been referred to as a congenital disorder, though IHPS is almost unknown in stillbirths. There is an increasing recognition that IHPS is an acquired and not a congenital disorder. The pyloric muscle measurements at birth are reported within the normal range and subsequently hypertrophies resulting in gastric outlet obstruction.

Clinical Manifestations

IHPS classically presents with projectile nonbilious vomiting in the second or third week after birth. Most are symptomatic within the first 2 months of age. Vomiting, which may be intermittent, occurs usually during or shortly after feeding. The vomiting is typically projectile, with gastric contents expelled sometimes for a distance of several feet. The vomiting may occasionally be blood-tinged. The baby initially remains hungry and sucking vigorously after the episode of vomiting. However, if symptoms persist, the baby will be at risk of developing dehydration and hypochloremic alkalosis with failure to thrive. Infants may also develop hypokalemia.

Physical Examination

On examination, visible waves of peristalsis moving from the left hypochondrium downward and to the right are noted. The skin will lose its normal elasticity and subcutaneous tissue. A palpable tumor is usually felt in the right hypochondrium in between the liver and the rectus abdominis muscle. The examination of the pyloric mass is performed while the baby is being fed, lying on his or her back or in the decubitus position. The latter position has been recognized for many years as a useful method for detecting the olive of IHPS. However, the position that seems to be mostly adopted quite satisfactorily is that while the baby is resting on his or her back fed by the mother or the nurse. This will allow observing the baby, the peristaltic waves, and gentle palpation of the tumor with the tip of middle finger of the left hand. The tumor has no fixed consistency and is usually felt to contract and relax under the examining finger. Palpation of the tumor, which requires patience and experience, is positive in over 80% of cases.

The tumor (mass) is usually firm, smooth, nontender, and the size of an olive. It is best felt after vomiting at the end of or during feeding.

Other associated features include constipation, hyponatremia, hypochloremia, and alkalosis, usually precipitated by repeated vomiting. Few patients develop transient jaundice, which resolves after surgery.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_180,

Diagnosis

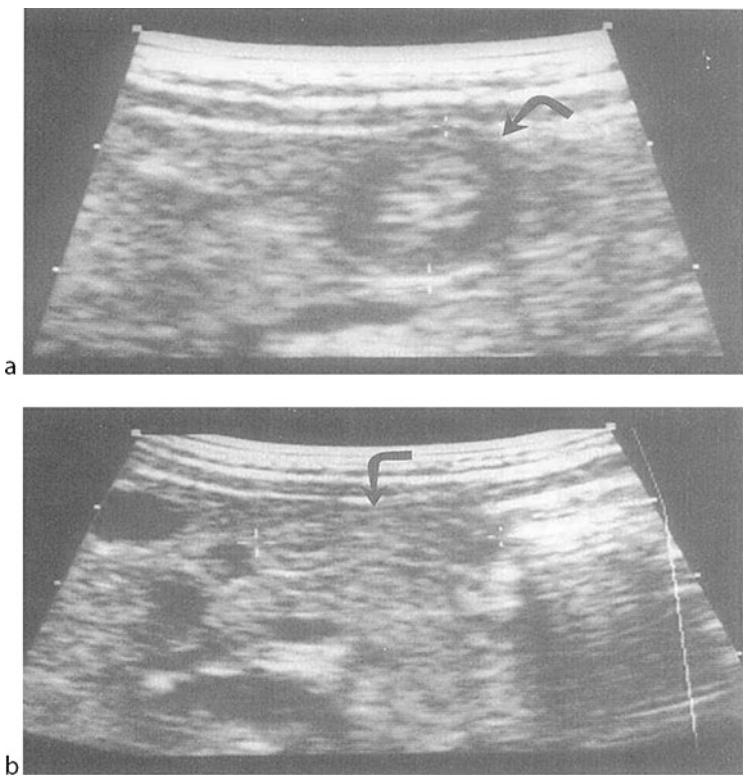
The diagnosis is easily made if the presenting clinical features are typical with projectile vomiting, visible peristalsis, and a palpable pyloric tumor. The loss of hydrogen ions in the vomitus results in metabolic alkalosis with alkaline urine. Secondary hyperaldosteronism leads to retention of sodium and water with excess urinary secretion of potassium. There is usually no need for radiologic investigations once the pyloric tumor is felt on examination. Erect abdominal radiography may show a dilated stomach filled with fluid. Ultrasound examination is considered the diagnostic standard radiologic test to show the elongated hypertrophied pyloric muscle, which is seen as an unechoic mass with strong central echoes (◉ *Fig. 180.1*). The degree of the pyloric hypertrophy tends to be greater the longer the history of the vomiting. It is possible through an ultrasound examination to identify the size of the pyloric mass. The antral region is elongated and thickened to twice its normal size.

Barium studies may have to be performed in a particular case due to lack of supportive findings at examination or through ultrasound examination. The series usually show delayed emptying of the stomach with the demonstration of elongated and narrowed pyloric canal, the *string sign* (◉ *Fig. 180.2*). The barium studies may sometimes show an umbrella-shaped duodenal cap stretched over the pylorus.

Management

Infants with suspected IHPS should be admitted. It is important to have a baseline evaluation of the acid–base status and plasma electrolytes concentration on admission and to correct any present imbalance or fluid deficiency.

The standard surgical procedure for IHPS is pyloromyotomy with an excellent outcome. The Ramstedt pyloromyotomy remains the standard procedure of choice with minimal complications. The usual approach is via



◘ Figure 180.1
(a) Ultrasound scan: hypertrophic pyloric muscle with the characteristic "target sign" of the hypertrophied pyloric muscle (*curved arrow*). (b) Ultrasound, transverse scan, shows elongation of the hypertrophied pyloric muscle (*curved arrow*)

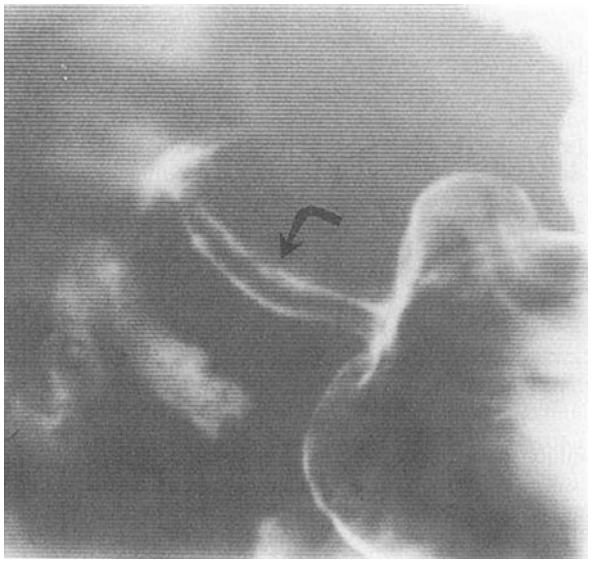


Figure 180.2
Barium meal showing the typically elongated and narrowed pylorus (*curved arrow*) in a 2-month-old infant with IHPS

a right upper quadrant transverse incision that splits the rectus muscle and fascia. Other procedures have been used including: laparoscopic pyloromyotomy, endoscopic pyloromyotomy, and endoscopic balloon dilatation after failed pyloromyotomy. A supraumbilical curvilinear approach has also been used.

Early feeding after surgery is generally recommended. Most patients would have returned to their normal feeding regimen by the second day. Breast-fed infants are usually fed in the first postoperative day. The amounts and duration of feeds are increased gradually. Vomiting will cease after surgery in the majority of cases. Postoperative complications are few. Vomiting may persist for some days after surgery due to pyloric edema, gastroparesis, or pylorospasm. However, if vomiting continues toward the second week, this could well indicate incomplete pyloromyotomy or infection. If symptoms persist for more than 3 weeks after surgery, a second pyloromyotomy is required. Recently, endoscopic balloon dilatation of IHPS after failed pyloromyotomy has been resorted to more often than before.

Nonoperative medical management remains a potential possibility in the management of IHPS. Some patients have responded to oral atropine treatment, especially if it was preceded by intravenous atropine administration until vomiting episodes subside. Further studies are warranted to evaluate the outcome and costs of intravenous atropine medical treatment compared to the standard surgical approach with pyloromyotomy in the management of IHPS.

Prognosis

Resulting mortality and morbidity from IHPS or related complications is extremely low. Very rarely mortality may result from delayed diagnosis and resulting dehydration and shock.

181 Peptic Ulcer Disease

Mohamed A. El Guindi · Hisham M. Nazer

Peptic ulcer disease (PUD) remains an important clinical problem in medical practice especially among adult population, largely because of the increasingly widespread use of nonsteroidal anti-inflammatory drugs (NSAIDs) and low-dose aspirin. With advances in fiberoptic endoscopy, there is an increasing awareness that peptic ulcers do occur among infants, children, and adolescents.

Therefore, PUD is diagnosed nowadays with increasing frequency in children. PUD represents a group of disorders associated with ulceration of the gastric and/or duodenal mucosa. The easy application or endoscopy in the pediatric age group and more so in young infants made it possible to confirm such diagnosis of PUD. Males tend to develop duodenal ulcers earlier and commoner than females; however, gastric ulcers occur at the same frequency in males and females. There is also a positive family history of PUD in up to 50% of cases of duodenal ulcer in children.

The prognosis has also improved among affected children due to the availability of effective medications. Duodenal or gastric ulcers represent ulceration of the mucosa that may also extend to affect the submucosa and the muscularis mucosa. PUD in children is classically divided into primary with no known underlying cause and secondary due to varied causes such as stress, diet, infection, burns, ingestion of drugs (aspirin, nonsteroidal anti-inflammatory drugs, corticosteroids), and smoking.

The lesion of peptic ulcer disease (PUD) is mainly caused by a disruption in the mucosa of the stomach or duodenum. An ulcer is characterized by its penetration through the muscularis mucosa or the muscular coating of the gastric or duodenal wall, which is not the case in the superficial gastric erosion. Many differences are noted between children and adults with peptic ulcer disease, especially in clinical presentation, in the prevalence rates of different types of ulcer disease and complications.

As peptic ulcer disease in children is the result of an imbalance between mucosal defensive and aggressive factors, a short account will be given on the stomach anatomy, the epithelial cells, and the innervations before discussing the peptic ulcer disease.

Anatomy of the Stomach

The stomach is a muscular sac that is having a greater and lesser curvature. It connects between the esophagus (by the lower esophageal sphincter) and the duodenum (by the pylorus) (◉ *Fig. 181.1*). The wall of the stomach contains thick vascular folds known as rugae, and at a microscopic level, the surface epithelium can be seen to be invaginated with a series of gastric pits. Each pit opens to a handful of blind-ended gastric glands.

The stomach can also be divided into three major regions by both structure and function.

Structurally: There are the cardia, body, and pylorus.

Most proximally after the esophageal sphincter, the cardia represents approximately 5% of the gastric surface area. It represents a transitional zone where the stratified squamous epithelium of the esophagus gives way to the columnar epithelium that lines the remainder of the stomach and intestinal tract and this is called the *Z-line*.

Next is the fundus or body of the stomach which contains approximately 75% of the gastric glands, and in this region the so-called oxyntic glands consist of specialized cell types (mentioned later) from which arise the characteristic secretions of the stomach.

Finally, the antrum of the stomach just before the pylorus, and is responsible for the secretion of gastrin, the primary regulator of postprandial gastric secretion.

Gastric Cell Types

Functionally: The oxyntic or parietal glands found in the gastric body contain a variety of specific cell types, the parietal, the chief, the endocrine, and the mucus cells. The most important are probably the parietal cells, which are specialized to secrete acid and intrinsic factor.

The parietal cells are remarkable for their secretory capacity and energetic requirements. The capacity for acid secretion in a given individual is directly dependent on the mass of parietal cells. Parietal cell mass is related to body weight, and declines somewhat with age.

More basally in the gland, there are chief cells, which store pepsinogen in apical granules that can release their

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_181,

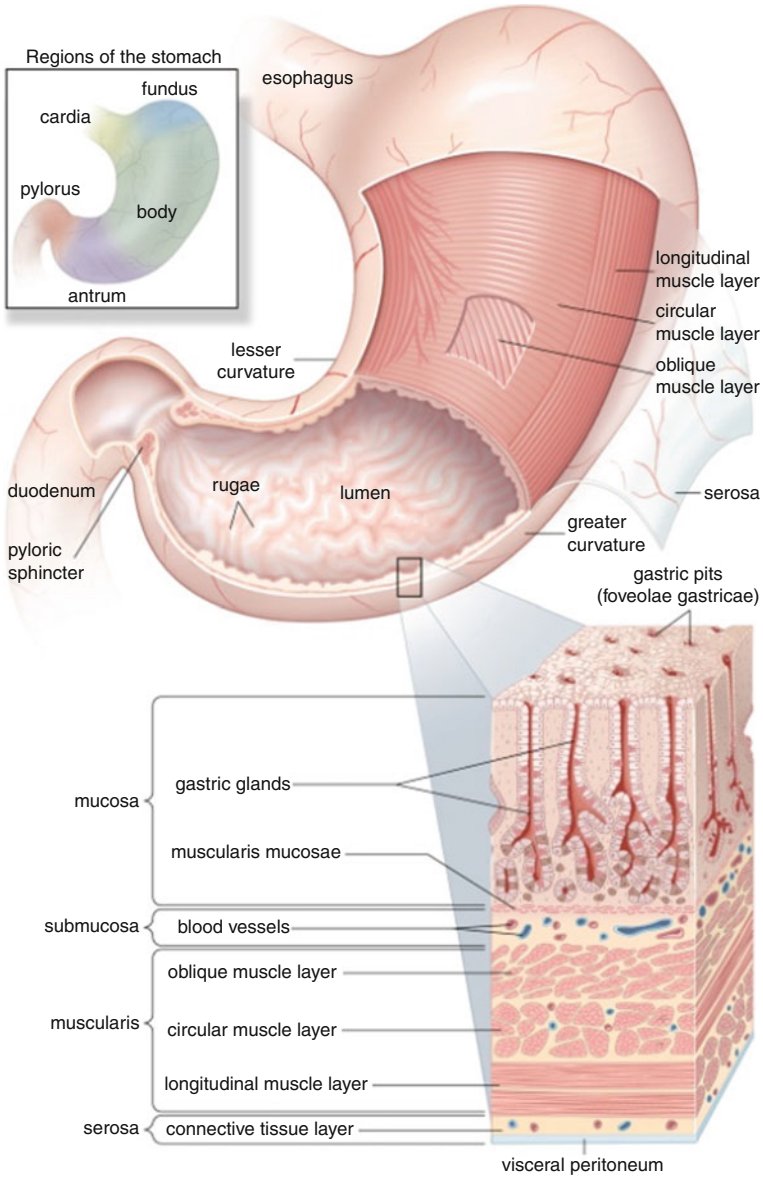

Figure 181.1
A diagram of the stomach structure and stomach wall http://www.britannica.com/EBchecked/topic-art/275485/68634/Structures-of-the-human-stomach-The-stomach-has-three-layer

contents via a process of exocytosis. The glands also contain endocrine cells that are responsible for releasing products that regulate gastric function, particularly the enterochromaffin-like, *or ECL*, cells, that synthesize histamine via the action of the enzyme histidine decarboxylase on the amino acid, histidine.

Toward the top of the gland where it joins with the gastric pit, and moving out onto the gastric surface, the gland contains surface mucous cells that secrete mucus, as their name implies. In the isthmus and neck region of the gland lie the mucus neck cells, which are the precursors for all of the other differentiated cell types in the gland. The anchored stem cells give rise to daughter cells, which migrate downward to become parietal, chief, or endocrine cells, or upward to become surface mucous cells. The surface mucous cells turn over every 1–3 days in adult humans.

In the antral mucosa, the glands do not contain parietal or chief cells, but mainly contains both mucus-secreting cells and enteroendocrine cells that regulate gastric function. Particularly, the glands contain G cells, which synthesize and release gastrin across their basolateral poles, and which have an open morphology implying functionally significant communication with the gastric lumen. Endocrine cells are present, exemplified by D cells, which secrete somatostatin.

Innervation

Nerves carried through the parasympathetic vagus nerve, with both efferent and afferent pathways, richly innervate the stomach. Vagal afferents convey information from the dorsal vagal complex, which is integrated with that coming from higher centers, such as the hypothalamus, to set the overall level of secretory function at any given moment. Visceral inputs also contribute to gastric regulation. Notably, the output of taste receptors travels to a brain region called the nucleus tractus solitarius, where this information is again translated into signals that regulate secretion and other gastric functions.

A more modest amount of sympathetic innervation is also seen, and activation of sympathetic nerves tends to oppose the actions of the parasympathetic limb. Finally, the enteric nerve plexuses that are seen throughout the gastrointestinal tract encircle the walls of the stomach. These allow for some degree of autonomous function, in addition to transmitting effects of central input.

Peptic Ulcer Disease

Primary peptic ulcers are still relatively uncommon in children and account for roughly 1 in 2,500 pediatric hospital admissions. Peptic ulcers can be either primary or secondary. Primary ulcers are more common in adolescents than in children and tend to recur after initial healing. Although affected children are thought to have high acid secretion, this has not been proven. Many of the primary ulcers seen in teenagers are now thought to be associated with gram-negative, spiral-shaped organisms recognized nowadays as *Helicobacter pylori*.

Genetic influences play a role because there is usually a family history of duodenal ulcers among first-degree relatives. The risk of ulcer is increased among siblings of affected parents, among monozygotic and dizygotic twins, and in individuals with the O blood group and HLA-B5 phenotype. The excess in acid output does not necessarily correlate with the severity of the disease. Moreover, PUD affects children with emotional problems more than their counterpart. The likely primary ulcers in young children are gastric, and in older children (>10 years) are likely to be duodenal.

Secondary peptic ulcers, usually silent, account for the overwhelming majority of ulcers that occur in young children in association with either systemic illnesses or drugs. Secondary peptic ulcers are seen in head trauma, severe burns, and with use of corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs).

Demographic Studies

In the United States, the prevalence of *H. pylori* infection is higher in blacks and Hispanics than in whites not of Hispanic origin.

The male-to-female ratio for all childhood peptic ulcer disease is 1.5:1. The incidence of primary peptic ulcer disease is twofold to threefold higher in boys than in girls; however, no sex difference in the incidence of primary peptic ulcer disease has been noted in infants or young children.

Primary peptic ulcer disease is uncommon in infants and in children younger than 10 years. The prevalence of primary peptic ulcer disease increases during adolescence. Secondary peptic ulcer disease can affect patients of all ages, but its prevalence is increased in patients younger than 6 years.

Frequency

The prevalence of *H. pylori* infection in developing countries is as high as 50–100%. The prevalence of peptic ulcer disease is increasing in developing countries. In a retrospective review of 112 Taiwanese children undergoing upper GI endoscopy for upper GI bleeding, gastric ulcer was confirmed in 10% and duodenal ulcer was confirmed in 15%.

Pathophysiology

Peptic ulcer disease in children is the result of an imbalance between mucosal defensive and aggressive factors. The aggressive factors consist of peptic activity that originates from enzymes within the gastric mucosa known as pepsinogen I and II. Pepsinogen I is the major pepsinogen produced by the chief and mucus neck cells of the gastric

fundus and body. The pepsinogen I level is therefore high in duodenal ulcer and gastrinoma.

Pepsinogen II is produced in the antrum, pylorus, and Brunner glands of the duodenum. It is elevated in antral gastritis. All agents that stimulate acid secretion result also in stimulation of pepsin secretion. A physiochemical defense barrier provides cytoprotection of the gastric mucosa. This barrier consists of water-insoluble gastric mucus, gastrically produced bicarbonate, an unstirred water layer, phospholipids, rapid shedding of cells resulting from epidermal growth factor, normal mucosal blood flow, prostaglandin-stimulated bicarbonate, mucus production, and inhibited acid secretion.

The aggressive factors which causes mucosal inflammation and ulceration include endogenous factors, such as gastric acidity (approximates adult values by age 3–4 years), acid-dependent pepsin and mucosal ischemia, and exogenous factors, such as drugs (e.g., NSAIDs, aspirin, corticosteroids), alcohol, cigarette smoking, corrosive chemicals (e.g., lye), and emotional stress.

Causes of patients stress include severe injuries, burns, sepsis, cardiac or respiratory failure, or any other critical systemic illnesses. Other factors that can cause ulcerations include ischemia, increased gastric acid and pepsin production, higher levels of steroids, and decreased prostaglandins and mucus production. Important mediators of mucosal inflammation and resultant ulceration include oxygen free radicals, lymphokines, platelet-activating factors, tumor necrosis factor, leukotrienes, and monokines.

Peptic ulcer disease can be divided into two major categories as mentioned earlier, primary and secondary.

Primary Peptic Ulcer

The primary category includes those few chronic disorders mainly due to *H. Pylori*. Secondary ulceration, which may be gastric or duodenal, occurs in association with acute severe stress.

The gram-negative spirochete, *H. pylori*, was first linked to gastritis in 1983. Since then, further study of *H. pylori* has revealed that it is a major part of the triad, which includes acid and pepsin, and impaired duodenal bicarbonate secretion causing the primary peptic ulcer disease. The unique microbiologic characteristics of this organism, such as the urease catalase, vacuolating cytotoxin, and lipopolysaccharide production, which alkalinize its microenvironment and survive for years in the severe acidic environment of the stomach, leading to inflammation and ulceration.

H. pylori infection in areas of gastric metaplasia induces duodenitis and enhances the susceptibility to acid injury, thereby predisposing to duodenal ulcers. One study that followed 181 patients with endoscopy-negative, nonulcer dyspepsia found that duodenal colonization by *H. pylori* was a highly significant predictor of subsequent development of duodenal ulcers.

The Zollinger–Ellison syndrome (ZES) is a rare disorder that can cause gastric or duodenal ulcers (◉ *Fig. 181.2*) from excessive acid secretion. Consider ZES if a patient has severe peptic ulceration, kidney stones, watery diarrhea, or malabsorption. ZES can also be associated with multiple endocrine neoplasias type I, which occurs earlier than isolated ZES. In addition to the typical pancreatic gastrinomas, ZES has been reported in children with solitary extrapancreatic gastrinomas in the stomach, liver, and kidney. Compared with adult disease, malignant gastrinomas in children are slow growing. Patients with ZES usually have fasting serum gastrin levels of more than 200 pg/mL and basal gastric acid hypersecretion at more than 15 mEq/h. Protein pump inhibitor therapy should be discontinued at least 2 weeks before the gastrin level is measured.

Secondary Peptic Ulcer

PUD may develop secondary to a variety of disorders. Secondary ulcers are often silent and may be diagnosed

Figure 181.2
Endoscopic view of a peptic ulcer in a young infant with Zollinger–Ellison syndrome (Dr. Hisham Nazer)

at endoscopy for other symptoms or due to acute presentation with complications such as bleeding and shock. Patients with cystic fibrosis are prone to develop duodenal ulcers because their pancreatic secretion is deficient in bicarbonate. Other recognized causes that may result in the development of ulcers include drugs (corticosteroids, nonsteroidal anti-inflammatory drugs, tolazoline), cigarette smoking, and stress. Increased incidence of PUD is also recognized as a result of many clinical conditions such as cirrhosis of the liver. Hypergastrinemia, polycythemia vera, Crohn's disease, diabetes mellitus, and chronic pancreatitis.

Children with secondary gastric or duodenal PUD do not commonly suffer from recurrent disease. In severely ill children with secondary duodenal ulcer, there is a high complication rate, particularly from bowel perforation.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with the development of secondary ulcers. Gastric erosions and peptic ulcers have been reported in association with aspirin, indomethacin, naproxen, and many other such medications. Aspirin inhibits the production of protective prostaglandins and increases the production of inflammatory mediators. NSAIDs have both local and systemic effects on the gastric mucosa. Treatment includes the administration of antacids alone or in combination with H2-receptor antagonists. The causative agent should also, when possible be stopped and replaced by a less irritating agent.

Stress-related ulcers are seen usually in life-threatening illnesses, intracranial lesions, severe dehydration, burns, vasculitis, or renal failure. Stress-related ulcers account for 80% of secondary peptic ulceration seen in infants and children. They result from ischemia, disruption of the mucosal barrier, and increased gastric acid. Prevention is an important step in the management of such ulcers. However, H2 antagonists are used as therapeutic measures as well as prophylaxis in those patients prone to develop stress-related ulcers. Sucralfate has also been used with good results.

Clinical Presentations

PUD in childhood has a variable and often nonspecific clinical presentation that varies with age. The well-recognized manifestations of recurrent epigastric abdominal pain, vomiting, hematemesis, and melena are not usually present in young infants or neonates with PUD. There is usually a family history of such disorders.

In the pediatric age group, abdominal pain related to meals is the most common presenting symptom of peptic ulcer disease. Nevertheless, peptic disorders (oesophagitis, gastritis, gastropathy and duodenitis), account for fewer than 5% of children presenting with abdominal pain, even in a subspeciality practice.

Other presenting symptoms include anorexia, nausea, vomiting, fullness, and anemia. Gastrointestinal bleeding may occur with the epigastric pain or with other symptoms, but painless bleeding may be the only manifestation of ulcer disease.

Up to 25% of children with duodenal ulcers have this "silent" presentation, approximately 25% presenting with bleeding and antecedent pain, and the rest with abdominal pain or recurrent vomiting.

On physical examination, epigastric tenderness is an unreliable sign of gastritis or ulcer disease.

It is only with a high index of suspicion that PUD in young infants and neonates may be diagnosed early to avoid late presentation with its serious sequel.

Complications

Since the introduction of H2 receptor antagonist and proton pump inhibitor, and with the recognition and treatment of *H. pylori*, the incidence of bleeding, perforation, and gastric outflow obstruction has dramatically decreased.

Severe GI bleeding is one of the most common complications of ulcer disease in neonates occurring in both primary and secondary peptic ulcer disease. GI blood loss may be acute and catastrophic, particularly in neonates or in children with a critical medical illness or traumatic injuries, or it may have a slow and chronic course, without posing a serious threat to life.

Perforation of an ulcer is the second main complication in early infancy and is often preceded by or associated with GI hemorrhage.

Children with primary gastritis or duodenal ulcer disease have low mortality rates. The highest mortality rates are found in young infants with secondary stress ulcers, who may present acutely with life-threatening GI hemorrhage or intestinal perforation. Mortality rates from perforated peptic ulcers in adolescent are 3.8%.

Management

Diagnosis

The diagnosis of PUD is highly suspected by the associated clinical features or epigastric pain, sometimes related to

meals, but occasionally as a result of acute presentation with a recognized complication as bleeding and shock. Family history as well as drug history or other relevant information add further to support the diagnosis of PUD. However, PUD should be differentiated from other conditions associated with abdominal pain such as esophagitis, cholecystitis, pancreatitis, pyelonephritis, and giardiasis.

Any child with recurrent vomiting and chronic abdominal pain (more than a month) should be investigated to rule out the presence of PUD. Examination may reveal epigastric abdominal pain.

Stool is occasionally positive for blood (guaiac-positive). Endoscopy has made the diagnosis of PUD possible with the least effort and with a high rate of accuracy. Endoscopy is superior to radiologic examination which is unable to reveal small superficial ulcers. Contrast studies may fail to show ulcers in up to one third of cases. Endoscopy was reported to be diagnostic of ulcers in around 90% of cases while reports have indicated that radiology may miss up to 50% of cases.

Single-contrast barium meals may reveal the presence of peptic ulcer, but its contribution to confirmed diagnosis is far less than that provided by endoscopy (◉ *Fig. 181.3*). However, the role of radiology should not be underestimated in the detection of any other associated gastrointestinal anomalies that might have predisposed to some of the clinical manifestations such as hiatal hernia, malrotation, and duodenal bands. In elder children, the diagnostic yield of radiology in PUD may be improved up to 90% by the application of air-contrast study.

Upper gastrointestinal endoscopy is the current diagnostic tool and will reveal the presence of ulcers as circumscribed mucosal defects that extend beyond the muscularis mucosa with a diameter of 5 mm or more (◉ *Fig. 181.4*). Smaller and more superficial lesions (erosions) that disrupt the epithelium may also be detected on endoscopy.

Endoscopic biopsies remain the most accurate means of diagnosis. *H. pylori* has been identified in cultures from antral and/or duodenal tissue in up to 80% of children with duodenal ulcer and antritis. Several kits for rapid diagnosis of *H. pylori* are available based on the use of urea-impregnated agar. Means of diagnosis of *H. pylori* infection include culture, rapid urease test, C-urea breath testing, and serologic assay. The C-urea breath test has been shown to be highly sensitive and specific in diagnosing *H. pylori* infection in children.

Screening for the serum IgG antibody to *H. pylori* is a practical method for diagnosing *H. pylori* infection in children. Serial measurement of the *H. pylori* IgG antibody is also useful in monitoring treatment of *H. pylori*.

Breath testing is now considered to be the best non-invasive assay for evaluating successful eradication of *H. pylori*. The accuracy of the C-urea breath test in diagnosing *H. pylori* has been recently demonstrated by Delvin et al. If endoscopy is performed on a child with abdominal pain and PUD, biopsies of normal-appearing

Figure 181.3
Barium meal and follow-up in 9-year-old boy reveal an active ulcer in duodenal cap (*arrow*)

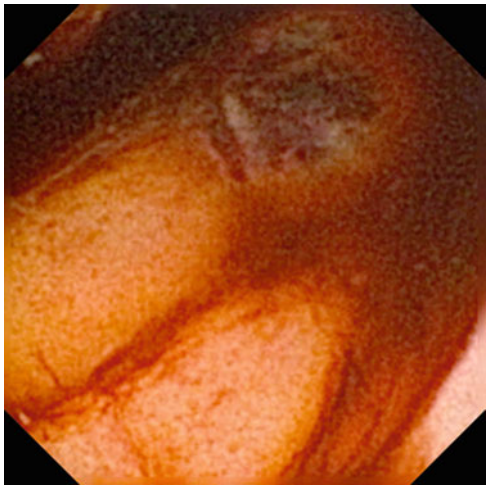

Figure 181.4
Peptic ulcer as seen by endoscopy in a 9-year-old girl (Mohamed El Guindi 2009)

areas of gastric antrum should be stained for *H. pylori* and a biopsy urease test should be done. The increasing recognition of the association of PUD, gastritis, and *H. pylori* colonization of the gastric mucosa has resulted in the availability of more tests to diagnose *H. pylori* PUD related in children. The use of an enzyme-linked immunosorbent assay (ELISA) to test for serum *H. pylori* antibodies has provided clinicians with a simple, reliable, and noninvasive tool to diagnose *H. pylori* infection. An ELISA test may also be used in seroepidemiologic surveys. A recent report on the evaluation of the ELISA test in the diagnosis of *H. pylori* infection was published by de Oliveira et al. in 1999.

The absence of endoscopic abnormalities in some 50% of children with *H. pylori* infection, and the patchy nature of the infection and of gastric mucosa-associated lymphoid tumor (MALT) lymphomas, emphasizes the need to take biopsies from the gastric antrum, body, and cardia as an integral part of diagnostic endoscopy.

Capsule endoscopy is the breakthrough for children refusing to undergo endoscopy and can reveal with accuracy the peptic ulcers (◉ *Fig. 181.5*)

Medical Therapy

All current recommendations support eradication therapy in all children with symptomatic peptic ulcers and proven *H. pylori* infection. The benefits of eradication therapy in children without ulcers or asymptomatic who have gastritis alone are uncertain. Eradication therapy has also been suggested for children with MALT lymphoma, atrophic gastritis, and *H. pylori* with a family history of gastric adenocarcinoma. Eradication therapy could be considered as an option in children with *H. pylori* infection who also have refractory iron-deficiency anemia or autoimmune thrombocytopenic purpura because complete or partial responses are seen in approximately one half of cases.

◘ Figure 181.5
Gastritis and early ulceration as seen by capsule endoscopy in a 12-year-old boy (Mohamed El Guindi 2009)

Drugs used to treat *H. pylori* peptic ulcers are mainly antibiotics, H2 blockers, and proton pump inhibitors.
Antibiotics include metronidazole, clarithromycin, and amoxicillin.
H2 blockers include cimetidine, ranitidine, famotidine, and nizatidine.
Proton pump inhibitors include omeprazole, lansoprazole, rabeprazole, esomeprazole, and pantoprozole.

Several combinations of the above therapeutic agents are recommended. The best success rates are achieved with triple therapy, combining proton pump inhibitors such as omeprazole with two antibiotics (clarithromycin and amoxicillin or metronidazole) for 1–2 weeks: The scheme proton pump inhibitor/amoxicillin/clarithromycin (PPI/AC) is still the first-line treatment for *H. pylori* infections despite evidence suggesting its failure in up to 20–30% of patients.

13C Breath Test is reliable in confirming successful eradication of *H. pylori* infection and should be performed if available at least 4 weeks after completion of therapy. In case of acquired resistance to clarithromycin (up to 45% of *H. pylori* isolates in children) and, to a lesser extent, resistance to metronidazole, an alternative triple-therapy regimen should be used, substituting one or both of the antibiotics. Metronidazole dose of 20 mg/kg/day (maximum 200 mg three times a day) and clarithromycin at a dose of 15 mg/kg/day, maximum 250 mg twice a day are used in children.

Efficacy was determined by negative urease test and absence of *H. pylori* on gastric biopsy samples 12 weeks after the end of treatment.

Acid-suppressing medications, such as H2 blockers, proton pump inhibitors, and mucosal protectants (e.g., sucralfate) are also used in cases of primary and secondary peptic ulcers. Offending substances (e.g., aspirin, NSAIDs, corticosteroids, nicotine, alcohol) should be stopped.

Surgical Therapy

Operation is indicated when blood loss approaches half the blood volume in 8 h or 1 blood volume in 24 h.

With fluid resuscitation and blood transfusions, monitoring for signs of continuous bleeding or hypovolemia is essential. If the rate of bleeding allows the stomach to be lavaged for endoscopy, endoscopic cautery or injection of sclerosants or vasoconstrictors may control the bleeding and prevent further bleeding episodes. If failed, simple oversewing of the ulcer followed by medical therapy is sufficient treatment; resection is seldom required.

Cases of Zollinger–Ellison syndrome can be cured when the gastrinoma is removed. Even with incomplete removal, the use of proton pump inhibitors controls the disease.

182 Intestine: Normal Development, Structure and Function

Shyla Kishore · Sonny K. F. Chong

Introduction

The small and large intestine occupies most of the abdominal cavity and is responsible for digestion, secretion, and absorption of nutrients, including fluid and electrolyte transport, excretion, physical and immunological defense mechanism. The mucosal surface of the small intestine is anatomically and physiologically designed to provide extensive surface area for nutrient absorption. This remarkable adaptation also provides massive interface for possible antigenic interaction with the environment. This interface is modulated via the immuno-endocrine system and the enteric nervous system.

This chapter focuses on embryology, anatomy, and physiology of small and large intestine.

Embryology

The primitive gut is recognizable by the fourth week of gestation and is composed of foregut, midgut, and hindgut. The foregut gives rise to the upper gastrointestinal tract including esophagus, stomach, and duodenum up to the insertion of the common bile duct. The midgut gives rise to the rest of the small bowel and large bowel up to the mid-transverse colon. The hindgut forms the remainder of the colon and upper anal canal. The rapid growth of the midgut causes it to protrude out of the abdominal cavity through the umbilical ring during fetal development. The midgut subsequently returns to the peritoneal cavity and rotates counterclockwise until the cecum lies in the right lower quadrant. The process is normally complete by the eighth week of gestation. The contraction of the muscles in the bowel wall is regulated by the enteric nervous system under the influence of the paracrine system. The enteric nervous system is derived from the neural crest cells that migrate in a cranial to caudal fashion. Migration of the neural crest tissue is complete by the 24th week of gestation. Interruption of the migration results in Hirschsprung disease. Normal fasting upper gastrointestinal motility is characterized by a triphasic pattern known as the migrating motor complex. Migrating motor complex occurs less often in neonates and they have more nonmigrating phasic activity. This leads to ineffective propulsion particularly in premature infants. Motility in the fed state consists of a series of ring contractions that spreads caudally.

Small Intestine

The small intestine is a convoluted tubular organ, extending from the pylorus to the ileocecal valve. The average length of the small intestine is between 250 and 300 cm in the term newborn, increasing to as much as 600–800 cm in the adult. The caliber of the small intestine gradually diminishes from its origin to its terminal end.

The duodenum is derived from the distal foregut during embryologic development. It is partly retroperitoneal. The duodenum is arbitrarily divided into four portions. The fourth portion makes a ventral turn to unite with the jejunum at DJ flexure. The biliary and pancreatic ducts drain into the second portion of duodenum at the ampulla of Vater. In 5–10% of individuals, an accessory pancreatic duct also enters 1–2 cm proximal to the ampulla of Vater as the duct of Santorini.

The duodenum receives its arterial supply from the right gastric, supra-duodenal, right gastro epiploic, superior and inferior pancreaticoduodenal arteries. The jejunal and ileal branches of superior mesenteric arteries form an arterial arcade that comes through the mesentery to supply the ileum and jejunum. The main venous drainage is superior mesenteric and portal veins. Lymphatic drainage is to the thoracic duct via the para-aortic lymph nodes. The terminal ileum lymphatic drainage is to the ileocolic lymph nodes.

The jejunum and ileum are derived from the endodermal midgut. There is no distinct demarcation between them although the proximal jejunum is thicker and more vascular than the ileum. The luminal diameter is greatest

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_182,

in the jejunum reducing in caliber distally in the ileum. Lastly, the plicae circularis (Kerck rings on endoscopy) which are more prominent in the distal duodenum and jejunum also decrease in number progressively in the ileum. The small intestine is a lymphoid organ. The Payer's patches are lymphoid aggregates located along the ante-mesenteric border in the most abundant region of mid to terminal ileum.

The junction of the small intestine with the large intestine is referred to as the ileocecal valve because the end of the terminal ileum is wedged into the wall of the cecum and functions like a flutter valve. The ileocecal valve is open when a peristaltic valve is strong enough to overcome the resistance of the valve that arrives at the terminal ileum. Overdistension or peristaltic contraction of cecum causes reflex contraction of ileocecal valve thus acting as protective mechanism to prevent bacterial influx into ileum. Therefore during colonoscopy, intubation of the terminal ileum may be difficult if the cecum is over distended with air.

The jejunum and ileum with the exception of the terminal ileum are loosely suspended from the posterior abdominal wall by the mesentery, thereby enabling each coil of small intestine to accommodate easily to changes in form and position with propulsive peristaltic movements. The mesentery is attached to the posterior abdominal wall extending from the left side of the body of the lumbar vertebrae to the right sacro iliac joint.

Intestinal Structure and Cellular Morphology

The small intestine is made up of four layers from outside inwardly. These consist of serosa, muscularis propria, submucosa, and mucosa. The mucosa is subdivided into muscularis mucosa and lamina propria and epithelial cell layer.

There are two major ganglionated enteric nervous system plexi embedded within the wall of the intestines. The submucosal (Meissner's) plexus and the myenteric (Auerbach's) plexus. The myenteric plexus is located in the plane between longitudinal and circular layers of the muscularis. The submucosal and myenteric plexus are extensively interconnected by nerve bundles. Interstitial cells of Cajal, present within the myenteric plexus at the interface between circular muscle and submucosa are now recognized as pacemakers of intestinal contractile activity which regulate intestinal tone and motility. Brunner's glands are located almost exclusively in the submucosa of the duodenum. They secrete a layer of mucus that lubricates the mucosal lining of the proximal intestinal tract.

The luminal surface of small intestine is covered by millions of tiny hair-like, highly vascularized structures called villi which are covered by mature absorptive enterocytes. The crypt of Lieberkühn surround the base of the villi and are lined by less mature epithelial cells. The luminal surface is studded with densely packed finger-like cylindrical projections termed microvilli. The apical surfaces of the intestinal epithelial cells carry multiple brush border transporters that couple ionic influxes or exchange one ion for another. Contiguous enterocytes are tightly opposed at their apico-lateral poles by the formation of junctional complexes. Tight junction is leakier and has a low resistance in the proximal intestine where absorption is more efficient, and tighter with a higher resistance in the ileum and large intestine. Goblet cells are mucin-producing cells scattered among other cells of the intestinal villi. The mucin provides a protective lubricant barrier against shearing stress and shields the intestinal mucosa from peptic digestion and chemical damage.

The gastrointestinal tract is a lymphoid organ and the lymphoid tissues are collectively called gut-associated lymphoid tissue or GALT. Payer's patches are lymphoid tissues present mainly in ileum. The epithelial cells overlying the Peyer's patches are columnar epithelial cells, Paneth cells, and structurally distinct membranous cells (M cells). M cells are responsible for transepithelial transport, delivering foreign antigens and microorganisms to the mucosal lymphoid tissue for recognition and handling, an attribute currently being exploited in vaccine production.

The growth and integrity of the intestinal mucosa are maintained under the influence of digested food and several luminal factors such as autocrine, endocrine, and paracrine secretion from surrounding cells. Thus, enteral nutrition is essential for the well-being of intestinal mucosa. It is now evident that glucagon-like peptides secreted from entero-endocrine cells play a major cytoprotective and reparative role in the survival and proliferation of the intestinal mucosa. The glucagon-like peptides, GLP1, and GLP-2 are released from entero-endocrine cells in response to nutrient ingestion. GLP-1 enhances glucose-stimulated insulin secretion, gastric emptying and feeding. It also has proliferative and anti-apoptotic effects on pancreatic B cells. GLP-2 stimulates proliferation and inhibits apoptosis in intestinal crypts. GLP-2 also regulates intestinal glucose transport and glucose transporter (GLVT) 2 expression as well as food intake and gastric acid secretion, gastric motility, and intestinal barrier function. GLP-2 also enhances nutrient absorption and gut adaptation in rodents or human with short gut syndrome.

Physiology of Absorption and Secretion

Absorption and secretion are the main functions of the intestine. Both the small intestine and large intestine absorb and secrete fluid and electrolytes whereas only the small intestine absorbs nutrients. Only during the neonatal period does significant absorption of nutrients takes place in the large intestine. After that, intestinal absorption occurs exclusively in the small intestine. Fluid secretion may be considered an adaptive mechanism used by the intestinal tract to protect itself from bacteria and bacterial toxins.

The small intestine absorbs net amounts of water, Na^+, Cl^-, K^+ and secretes HCO_3 whereas the colon absorbs net amounts of water, Na^+, and Cl^- and secretes both K^+ and HCO_3^-. Solvent drag is the process by which dissolved solute is swept along by bulk movement of the solvent. Solvent drag accounts for significant fraction of Na^+ and urea absorbed in human jejunum. Solvent drag occurs through a paracellular route and depends on the permeability properties of tight junctions. Na/Glucose and Na/Amino acid cotransport in the small intestine is the major mechanism for post-prandial sodium absorption. Electroneutral Na-H Exchange in the duodenum and jejunum is responsible for sodium absorption that is stimulated by luminal alkalinity. Parallel Na-H and Cl-HCO_3 exchange in the ileum and proximal part of the colon is the primary mechanism of Na^+ absorption during the interdigestive period. Epithelial Na^+ channels are the primary mechanisms of electrogenic Na^+ absorption in the distal part of the colon.

The intestines absorb and secrete solutes by both active and passive mechanisms. K^+ absorption in the small intestine occurs probably through solvent drag. Passive K^+ secretion is the primary mechanism of net colonic secretion. Active K^+ secretion is also present throughout the large intestine and is induced both by aldosterone and by cAMP. Voltage-dependent Cl^- absorption represents coupling of Cl^- absorption to electrogenic Na^+ absorption in both the small intestine and the large intestine.

The overall electroneutral NaCl absorptive process is regulated by both cAMP and cGMP as well as by intracellular Ca2+. Increase in each of these messengers decreases NaCl absorption as in acute diarrhea where *E. coli* enterotoxin activates adenylcylase, increases cAMP which decreases NaCl absorption, and stimulates active Cl^- secretion. This toxin does not affect nutrient coupled Na+ absorption. By using this process, oral rehydration solution which contains glucose, Na^+, Cl^-, HCO_3 is extremely effective in enhancing fluid and electrolyte absorption in secretory diarrhea. The congenital absence of an apical Cl-HCO3 exchanger is an autosomal recessive disorder congenital chloridorrhea which is an autosomal recessive mutation on chromosome 7.

Digestive Process in the Intestine

Luminal Digestion

The majority of starch digestion occurs in the duodenum through the effect of pancreatic amylase. α amylase is an endoenzyme that cleaves the alpha 1,4 internal links leaving oligosaccharides maltose and maltriose. Since α amylase does not cleave α 1,6 or adjacent alpha 1,4 bonds, digestion of amylopectin also leaves branched oligosaccharides termed α limit dextrins. Amylase activity produces only small amounts of free glucose molecules. Therefore, only severe pancreatic insufficiency that leaves less than 10% normal amylase levels affect starch breakdown.

Brush Border Digestion

Only monosaccharides can be absorbed across the enterocyte membrane. Therefore, further digestion of the luminal products of starch and ingested disaccharides takes place at the brush border by different hydrolases like maltase, isomaltase, and sucrase. Lactase breaks down lactose into glucose and galactose. The human lactose gene is located on the long arm of chromosome 2. Lactose digestion in the premature neonate maybe incomplete in the small intestine but partially salvaged through colonic fermentation. Lactase level declines from peak at birth to less than 10% of the preweaning infantile level in childhood as dietary consumption falls. With the exception of lactase where enzyme activity is the rate-limiting step for digestion, brush border hydrolases are inducible by the presence of substrate.

Transport After Digestion

Monosaccharides cross the enterocyte apical membrane via carrier-mediated transport since their size is too large to allow for significant passive diffusion. For glucose and galactose, cotransport with sodium down a sodium gradient takes place. Fructose is transported through facilitated diffusion. All monosaccharides exit the enterocyte by facilitated diffusion across the basolateral membrane into portal circulation. Approximately 10% of ingested starch is not digested in the small intestine and is called digestion resistant starch.

Protein Digestion

The main protein digestion site is the proximal small intestine upon exposure to the pancreatic fluid. Pancreatic proteases are secreted as proenzymes. Although the mediators of pancreatic stimulation are incompletely understood, the cholinergic intestinal system appears to have greater influence than cholecystokinin for pancreozymes while secretin mainly promotes bicarbonate flow. Absorption of aminoacids is maximal in the proximal intestine and occurs by active diffusion aided by Na^+ cotransport.

Fat Digestion

Bile acids and biliary phospholipids further stabilize the lipids presented to pancreatic lipase in the duodenum. Ileal bile acid absorption involves Na^+ cotransport down a gradient secured by the basolateral membrane Na^+, K^+ ATPase. Bacterial enzymatic action in the terminal ileum leads to deconjugation of bile acids that escape ileal absorption.

The next step is transport of the hydrophobic digestion products, carried in water-stable micelles from small intestine lumen into brush border membrane. Monoglycerides, fatty acids, cholesterol, and lyophospholipids can pass through the enterocyte membrane by passive diffusion. Once in the enterocyte, triglycerides are resynthesized from 2-mono acyl glycerol and fatty acid as a result of two processes, namely, monoglyceride acylation and phosphatidic pathway. Chylomicrons are made only in the intestinal cells while VLDLs are also synthesized in the liver. Chylomicrons and VLDL exit the enterocytes into the lacteal system. Medium chain triglycerides move directly into the portal system.

Vitamin B_{12} is absorbed in the terminal ileum and therefore children with distal bowel resection may need lifelong supplementation. Vitamin C is absorbed from proximal small intestine. Absorption of Vitamin D occurs mainly in the upper and mid small intestine. Vitamin A, E, and K also absorbed in small intestine. Iron and calcium is absorbed actively from the duodenum. Zinc, copper

Anatomy of Large Intestine

The large intestine consists of the following segments: (1) cecum and vermiform appendix; (2) colon which is composed of four sections – ascending, transverse, descending, and sigmoid colon; (3) rectum; and (4) anal canal. The colon is approximately 60 cm long in the newborn, increasing to approximately 150 cm in the adult.

The colon is easily distinguished from the small intestine by several features, namely, it is larger in caliber and mostly fixed in position. Its outer longitudinal muscular layer is made of three distinct longitudinal bands or taenia coli extending from cecum to the rectum. It has a characterized sacculated and puckered appearance due to outpouchings (termed haustra) of its walls between the longitudinal bands. Fatty projections of the mesentery and the serosa are found scattered over the free surface of the entire length of the colon with the exception of the cecum, vermiform appendix, and rectum. The luminal surface is interrupted by intermittent irregular folds called plicae semilunares.

Originating from the midgut, the proximal colon, cecum, ascending colon, and proximal two thirds of the transverse colon all derive the blood supply from the superior mesenteric artery. The inferior mesenteric artery supplies the remaining one third of the transverse colon, descending colon, sigmoid colon, and rectum. In addition, the rectum and anal canal also receive blood supply from internal iliac and median sacral arteries. The superior and inferior mesenteric veins drain the same regions of the large intestine supplied by the corresponding arteries.

With the exception of the lower half of the anal canal the large intestine derives its nervous supply from parasympathetic and sympathetic systems. The nerve distribution pattern closely mimics the arterial supply. The proximal colon receives its sympathetic neuronal innervation from celiac and superior mesenteric ganglia, whereas the parasympathetic supply is from the vagus nerve. The distal colon receives its sympathetic nerve supply via branches from lumbar segments of the sympathetic trunk and the parasympathetic nerves originate from the pelvic splanchnic nerves. The lymphatic drainage courses through the mesentery close to the arterial and venous supplies. The lymph from the colon drains into the preaortic nodes. The lymph from the rectum and anal canal drains to the inferior mesenteric and iliac nodes via the perirectal nodes.

The cecum commences as a pouch cul-de-sac in the right iliac fossa and continues superiorly with the ascending colon. The ileocecal valve opens into the posteriomedial wall of the cecum. The appendiceal orifice lies 2.5 cm inferior to the ileocecal valve. Vermiform appendix describes the worm-like elongated shape of the appendix. The appendix may vary in position either present below the distal cecal pouch or behind the cecum posterior to the ileum in a retroperitoneal location. The

appendix once regarded as a vestigial organ, is now recognized as an important component of mucosal immune system, particularly B lymphocyte-mediated immune response and extrathymically derived T lymphocytes.

The ascending colon originates at the level of ileocecal valve and ascends to the posterior surface of the liver where it angulates to form the hepatic flexure. It measures 20 cm in adults. The ascending colon merges from its retroperitoneal position anteriorly and medially to become the transverse colon which is approximately 40–50 cm. It is fully enveloped by mesentery (transverse mesocolon) and curves acutely on itself to form the splenic flexure. A thickened reflection of the peritoneum called phrenico-colic ligament suspends the splenic flexure higher than the hepatic flexure. The descending colon emerges from the splenic flexure continuing downward and posteriorly to join the sigmoid colon at the pelvic brim. The rectum extends from the sigmoid colon at the level of the third sacral vertebra following the sacral curvature to the anal canal distally. The anal canal begins where the distal end of the rectal ampulla narrows and passes inferiorly and outward to the anal opening. The anal canal is 2 cm long in the infant increasing to 4.5 cm in the adult. The anorectal junction is situated within the pelvic diaphragm which is made up of levator ani and coccygeus muscle. The segment of the levator ani sling that encircles the anorectal junction is termed the puborectalis muscle. The contraction of this muscle pulls the rectum forward to retain stool and relaxation straightens the anal canal allowing defecation. Commencing at the anorectal junction the circular muscle layer of the large intestine thickens to become the internal anal sphincter which is made up of smooth muscle fibers and surrounds the upper three-quarters of the anal canal. The external anal sphincter is made up of striated muscle. The luminal surface of the anal canal is thrown into longitudinal folds termed anal columns. These columns converge distally to form small crescenteric folds of tissue termed anal valves at the pectinate line. Beyond the pectinate line, the epithelial cell layer of the anal canal transitions from cuboid to stratified squamous epithelium.

Cellular Morphology

The walls of the large intestine are made up of four layers: serosa or adventitia, muscularis mucosa, submucosa, and mucosa. The mucosa has three layers namely epithelial cell layer, lamina propria, and muscularis mucosa. The muscularis mucosa consists of outer longitudinal and inner circular muscle layers. The outer longitudinal layer is thickened to form three prominent muscle bands called taenia coli. In between the muscular folds is the Auerbach's plexus.

Function of Large Intestine

The primary function of the large intestine is water and electrolyte absorption via the mechanisms described previously. The major short-chain fatty acid (SCFA) butyrate is produced in the colonic lumen by bacterial fermentation of dietary fiber. The SCFAs absorbed by the colon contribute only about 7% of the overall body energy requirements with slightly higher amount being contributed during infancy. However, the colonic epithelium depends on luminal SCFAs for their energy supply as evidenced by the development of diversion colitis after the surgical diversion of fecal stream with the resolution of colitis with colonic instillation of n-butyric acid. Thus, butyrate serves as primary energy source for the colonocytes and also ameliorates mucosal inflammation and promotes epithelial barrier function. Disturbed energy homeostasis seen in inflamed mucosa of inflammatory bowel disease patients has been attributed to impaired absorption of butyrate.

183 Approach to a Child with Failure to Thrive

Ruba A. Abdelhadi

Introduction

Failure to thrive is a general descriptive term, which encompasses a multitude of diagnoses sharing the ultimate consequence of inadequate growth in early childhood. There is no consensus on the anthropometric measurements in defining failure to thrive. Most textbooks define failure to thrive as height or weight less than the third to fifth percentiles for age. Others define height or weight measurements that have decelerated by two major percentile lines on the standard growth charts of the National Center for Health Statistics (NCHS). When evaluating a child's growth, it should be emphasized that growth charts are far more important than assessing growth parameters at one point in time. Growth trends provide valuable insight on the growth pattern in terms of dietary milestones in relation to changes in the dietary history and the development of an organic disease.

Etiology

It may well be very convenient to simply divide failure to thrive into two categories: organic versus nonorganic failure to thrive; however, this over-simplification does not underline the unified etiology behind failure to thrive, that is, malnutrition, be it involving increased caloric requirements as in the case of a chronic inflammatory process or organ failure or malignancy, versus suboptimal intake of calories related to inadequate bonding, neglect or emotional deprivation and poverty. Malnutrition carries inevitable consequences of immunocompromise, poor growth, and negative effects on cognitive and learning skills. It is very sad that failure to thrive often times is a consequence of national level poor economy and scarce resources in the society.

History

The child's perinatal history is the first step in discerning the etiology behind failure to thrive, which is, often times multifactorial, involving suboptimal intake of calories in the setting of psychosocial dysfunction with or without organic disease.

History of intrauterine exposure to cigarettes, alcohol or other teratogens, recreational drugs, or maternal peripartum infections may give the answer to the etiology of failure to thrive. The early identification of fetal alcohol spectrum disorder and its concomitant post-neonatal medical and psychosocial factors may improve the prognosis by early neurodevelopmental, psychosocial, and nutritional interventions.

The inadequacy of birth weight in relation to gestational age may shed some light on prenatal causes that may involve congenital infections, chromosomal abnormalities, a genetic disease, or an ongoing high risk-taking behavior by the mother.

Prematurely born infants should have their growth parameters plotted, corrected for gestational age, up to their 24th month of life, nevertheless bearing in mind that very low birth premiees may well remain smaller than their chronological peers until 36 months of life.

The birth weight, birth length, and birth head circumference will identify intrauterine growth retardation (IUGR) which may have prognostic implications on the infant's growth pattern. Asymmetrical IUGR – with the birth weight disproportionately more affected than birth length and head circumference – carries a better prognosis than symmetrical IUGR in terms of postnatal growth with the provision of intensive nutritional rehabilitation and environmental intervention. Symmetric IUGR carries poor prognosis for growth and development, often times related to a genetic disorder, an intrauterine infection, and/or teratogen or illicit drug exposure in utero.

The growth charts of appropriate for gestational age (AGA) babies who have demonstrated deceleration of growth beyond early infancy should be analyzed in the context of a detailed dietary history. The milestones in the child's history, including developmental milestones, onset of new symptoms, and introduction of potentially allergenic or toxic foods, can be linked into a temporal relationship. Infants with metabolic disorders may

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_183,

demonstrate symptoms related to the introduction of potentially toxic diets like fructosemia, phenylketonuria, or much earlier galactosemia; infants with fatty acid oxidation defects may develop clue symptoms as their sleep pattern changes to longer duration fasting. The onset of symptoms after the introduction of gluten in the cereal may give a clue to the diagnosis of Celiac disease.

A detailed review of systems may reveal clues to chronic childhood illnesses, which universally cause growth failure. Increased caloric requirements in the setting of a hyper-catabolic state, suboptimal intake of calories are all complexed into an unfavorable psychosocial milieu, all factors in favor for inadequate nutrition. A detailed diet diary and 3-day calorie count is of paramount importance.

Specific inquiries in the dietary history should include the amount of juice consumed by the child, soda and carbonated beverages, as well as diluting formulas in the face of financial struggles.

Adequate weight gain during hospitalization may not necessarily be a clue to nonorganic failure to thrive. All children will show weight gain with appropriate high calorie nutritional rehabilitation; in fact, children with depression or affective behavioral and feeding disorders may deteriorate when hospitalized without attention to their disordered psyche.

Occult organic disorders should be explored including renal tubular acidosis, dysfunctional oral motor development, and immunodeficiency; by contrast, overdiagnosing eosinophilic gastroenteropathy and food allergies may contribute to failure to thrive by means of restricting their dietary choices and thus caloric intake unnecessarily.

The child's clinical examination should explore clues for eating disorders, with specific inquiries about self-esteem, body image distortion, and ideal weight obsessions. Binge eating, experimentation with laxatives and diuretics, or inducing vomiting behaviors should also be explored.

Parents' heights should be noted in addition to their puberty onset and any history of constitutional delay.

The family history needs to explore chronic illnesses such as cystic fibrosis, autoimmune diseases such as Crohn's disease and insulin-dependent diabetes, metabolic disorders in the setting of consanguinity or sudden infant deaths.

The social history should explore the caregiver's competency, substance use or other high risk-taking behaviors, and psychosocial dysfunction.

Immigrant children or those living in homeless shelters should be evaluated for treatable conditions of malnutrition like giardiasis.

The clinical examination should also explore secondary complications of malnutrition such as impaired cognitive and learning skills, relative immunodeficiency, pica, lead toxicity, and psychosocial retardation, all of which feed into a vicious cycle of more malnutrition and growth failure.

Physical Examination

Thorough clinical evaluation aims at identifying chronic disease, be it a chronic inflammatory process, a malabsorption or a neoplastic process, recognizing genetic syndromes or dysmorphic features as well as identifying the deleterious secondary effects of malnutrition that are feeding into the vicious circle of undernutrition, apathy, and poor cognition.

Signs of systemic illnesses with detailed physical examination to all organ systems, including digital clubbing, cardiac, pulmonary, and abdominal examination, extra-intestinal manifestations, or any features of a systemic, autoimmune inflammatory process, organomegaly, or lymphadenopathy should be sought.

Signs of abuse, neglect, or deprivation should be sought, such as bruises, burns, scars, retinal hemorrhages, genital trauma, hygiene, level of activity, affect, psyche, and adequacy of bonding with the caregiver.

Signs of vitamin and trace element deficiencies should be carefully looked for, such as cheilosis, glossitis, perioral, perianal disease, dental enamel defects, rachitic rosary, brittleness, and pluckability of the hair.

Signs of developmental and cognitive delays should be explored, such as hypotonia, occipital alopecia, and delayed fontanelle closure.

Careful examination of dysmorphic features, eyes, palpebral fissures, philtrum, or any other facial dysmorphism should be done.

Features of immunodeficiency such as skin rashes, skin infections, or draining ears should be explored.

In a patient with body image distortion, disturbed perception of body image, and poor self-esteem, specific attention should be made to clinical signs of self-induced vomiting, like dental enamel erosions, abrasions to the knuckles of the metacarpophalangeal joints, or enlargement of the salivary glands as a result of continued self-induced vomiting.

Laboratory Evaluation

The laboratory evaluation should aim at exploring clues provided in the history and physical examination.

Simple, noninvasive tests, with low risk and high yield, can rule in or rule out organic conditions leading to failure to thrive that is coupled with inadequate nutrition.

Complete blood count, basic metabolic panel including serum electrolytes, bicarbonate, blood urea nitrogen, serum creatinine, lead level, urine analysis, PPD testing, sweat chloride, and pancreatic fecal elastase are easy tests to obtain.

Iron studies, fat-soluble vitamin levels, trace element concentrations, and prealbumin levels can give information to the degree of undernutrition.

Calcium, phosphorus, and alkaline phosphatase may lead to the diagnosis of rickets.

Tissue transglutaminase and quantitative IgA may lead to an endoscopic diagnosis of celiac disease with small intestinal histopathology.

An endocrine workup may be necessary when clinically indicated, such as in clinical feature of thyroid dysfunction. Radiologic bone age can help differentiate constitutional growth delay from endocrine causes of short stature.

HIV testing, in the suggestive clinical setting should also be considered.

Skin patch testing, radio-allergo-sorbent testing along with peripheral eosinophil counts and serum IgE levels may be indicated in the case of severe atopic dermatitis, urticaria, or rash.

In patients with self-induced vomiting, it is not uncommon to find characteristic features of hypokalemic, hypochloremic metabolic alkalosis.

Medical Management

After an initial assessment and hospitalization that has included a detailed dietary history, caloric counts, monitoring of the child's behavior during feeding sessions, a social work evaluation to the home environment, and assessing the caregiver's competence in providing a positive nurturing environment, the child with failure to thrive will need close monitoring with frequent clinic visits and weight checks at regular intervals.

Identifying and properly managing chronic illnesses should be initiated along with high calorie nutritional rehabilitation program. Immunizations should be updated and must include influenza, as malnutrition makes these children relatively immune deficient.

Patients with poor oral motor skills, uncoordinated swallowing or other mechanical feeding difficulties, and behavioral feeding problems should be properly referred for occupational and speech therapy as indicated. In the meantime, as the malnourished child is not taking the high calorie nutritional supplementation orally, the parents are encouraged to accept an alternative method, tube enteral feeding; this, in particular, applies to those chronic silent aspirators with abnormal swallow studies and at high risk for aspiration pneumonias.

Furthermore, the nutritional value of the items listed in a 3-day diet diary should be assessed, as well as proper counseling and education the primary caregiver, and in particular those with strict dietary beliefs or unusual dietary practices or misconceptions.

Nutritional Evaluation

Careful assessment of the child's nutritional status is of paramount importance in planning nutritional rehabilitation, following the effectiveness of re-nourishment, as well as predicting the outcome in terms of developmental potential.

Anthropometric measurements should be taken at baseline as well as at regular intervals along with serial weights and other growth parameters.

Growth parameters should be standardized to minimize subjective variables, using the same scale, in the same setting, preferably by the same health-care provider, and weighed in underwear only.

The National Center for Health Statistics (NCHS) growth charts serve as a standardized tool for realizing the severity as well as the chronicity of malnutrition. There is international consensus that these growth charts should be utilized for children irrespective of their racial or ethnic background.

Looking carefully at a child's weight for age, the clinician can understand the chronicity of malnutrition, the gradual onset, its temporal link to a sub-acute illness/insult, versus a dietary change, versus a major illness. Weight for age has invaluable importance in predicting a mortality outcome.

Looking at a child's standing height (or length) for age, the clinician can predict a genetic, an endocrine, a constitutional delay, or, a long-standing state of undernutrition.

Looking at a child's weight for height, the clinician can predict that the child is failing to thrive due to a fairly recent insult that has required increased caloric requirements, and these have not been met, usually for a variety of mechanisms and confounding factors.

A child with all depressed weight for age, height for age, as well as weight for height has a chronic illness that has long affected the growth parameters, and this state of

chronicity has been complexed with an additional fairly recent state of undernourishment/malnutrition.

Nutritional rehabilitation aims at providing higher calories than children of the same chronological age, to allow for catch-up growth. The aim is to demonstrate a rate of weight gain that is at least twice the median weight gain average for the specific age to allow for catch-up growth and replenish the deficits. The projected weight and caloric goals should be continuously revised as the child's nutritional rehabilitation is monitored.

The caloric goals, the recommended daily allowances of nutrients and other elements, all exceed those age-specific values in a failing to thrive undernourished child, and all are calculated in reference to the ideal weight for chronological age and height.

The trace elements, vitamins, micronutrients should all be taken into account when replenishing the stores and re-nourishment.

Care should be taken to reach caloric goals gradually and over a period of weeks in order to prevent "refeeding syndrome" and its potentially lethal metabolic consequences and electrolyte derangements that may cause circulatory decompensation, cardiac arrhythmias and death; the risk of refeeding syndrome is highest in the first 72 h, during which time, the patient's serum electrolytes should be closely monitored. It is thus the term "re-nourishment" in nutritional rehabilitation as opposed to refeeding is advised.

Special emphasis on high caloric density supplements should be advised in addition to special recipes of high calorie food choices and preparation that are provided by the experienced registered dietician in the team.

Furthermore, nocturnal nasogastric tube feeds can provide 60–100% of the recommended calories for catch-up growth, while allowing the child to eat during the day at their own pace, thus relieving the pressures off of the caregiver's shoulders to meet the caloric goals prescribed.

Continued monitoring to the adequacy of growth should be followed through at least 4–9 months to replenish the stores and allow for catch-up growth; the growth measurements can be followed less often than weekly after multiple weight checks have confirmed at least twice the amount of weight gain recommended for that age (average weight gain in grams per day in the interval).

Psychosocial Aspect

Chronic undernutrition, and depending on the severity and chronicity, has deleterious effects on the sound development of the malnourished child; this includes cognitive development, psychosocial interaction, and learning skills, thus negatively affecting the child's learning potential.

It is well known that nutritional deficiencies impair learning abilities; furthermore, a dysfunctional home milieu, an incapable caregiver, and poor educational opportunities all play a role in a negative cognitive and developmental potential.

Often times developmental testing provides suboptimal and far from accurate results in assessing the child's cognitive and developmental potential as social withdrawal and apathetic response to stimulation and prolonged deprivation. It is therefore crucial after re-nourishment therapy has been initiated and established to have these tests repeated for better prediction of the child's intellectual potential.

Children with malnutrition/undernutrition should receive special attention to their current developmental status, and developmental delays should be addressed and explored and stimulated.

Psychosocial and emotional development, social interactions, response, affect are potentially impaired in the malnourished child and should be properly addressed as well.

An official consult to the social worker in assessing the social situation may unmask psychosocial dysfunction, abuse, violence, and mental illnesses that may render the home situation and/or caregiver a home environment not in the child's best interest to be in.

Intervention

A multidisciplinary approach in evaluating and treating the child with failure to thrive insures the best outcome, as the child's nutritional status, psychosocial development, cognitive and learning skills, and social environment all are properly addressed and appropriately managed.

The team approach involves the pediatrician, the certified dietician, the social worker, the psychologist, the developmental specialist, and other specialists depending on any chronic illnesses.

Regular home visits should be part of the follow-up in addition to clinic visits and weight checks and case conferences. Assessing the home conditions, family resources, financial struggles, and appropriate referrals are made.

Parent training, counseling and education, patient referral for appropriate developmental evaluation, and treatment for early intervention are mandatory for the best outcomes; that includes mental health intervention, and proper management and modification of behavioral feeding issues.

Summary

Failure to thrive is a complex, chronic, and often challenging condition that involves multiple facets leading to this clinical picture. Every aspect needs to be properly addressed, evaluated, and corrected to achieve best outcomes. Chronic organic conditions, nutritional deprivation, social milieu, psycho-emotional deprivation, and secondary cognitive and developmental deficits should all be managed. A multidisciplinary approach insures the most favorable outcomes.

184 Approach to a Child with Malabsorption

Mohammad El Baba

Malabsorption refers to conditions arising from abnormalities in digestion and absorption of nutrients during their passage through the gastrointestinal tract. It can result from defects in any of the three phases of digestion and absorption:

1. Defects in intraluminal hydrolysis of nutrient
2. Defects in mucosal absorption
3. Vascular and lymphatic defects affecting transport of nutrients

Some disorders are more generalized and affect the absorption of many nutrients, vitamins, and minerals; others are more selective and involve specific nutrients.

Etiology and Pathophysiology

Malabsorption can be caused by many diseases affecting the small intestine (*Table 184.1*) and pancreas (*Table 184.2*). It also can be caused by diseases of the liver and biliary system such as cholestatic liver diseases, cirrhosis, portal hypertension, and inborn errors of bile acid biosynthesis.

Lymphatic and vascular disorders causing malabsorption are shown in (*Table 184.3*).

Carbohydrates

Starch is hydrolyzed into oligosaccharides by the action of both the pancreatic and salivary amylase. Brush border oligosaccharidases and disacharidases are responsible for further digestion of starch derivatives and digestion of dietary disaccharides (lactose and sucrose). The derived monosaccharides, glucose, galactose, and fructose, are absorbed by carrier-mediated transport systems located in the brush border membrane of small intestine. The active transport of glucose and galactose absorption is achieved by the sodium-dependent glucose cotransporter (SGLT1). Fructose is transported by facilitated diffusion from the intestinal lumen into the enterocytes.

Deficiency of one or more of the brush border disacharidases or oligosaccharidases may cause diarrhea, bloating, and flatulence after ingestion of sugar. The symptoms are due to colonic bacterial fermentation of unabsorbed carbohydrates into CO_2, hydrogen, methane, and short-chain fatty acids.

Glucose-galactose malabsorption, caused by mutations in the SGLT1 gene, is characterized by severe diarrhea in the neonatal period and after the newborn's ingestion of breast milk or regular infant formula. Since fructose is not well absorbed as glucose, ingestion of large amount of dietary fructose can cause diarrhea, increased flatulence, and abdominal cramping.

Diffuse mucosal diseases are commonly associated with carbohydrate malabsorption. Celiac disease, Crohn's disease, and short bowel syndrome are common causes of acquired carbohydrate malabsorption in children. Post enteritis syndrome is usually associated with transient carbohydrate malabsorption and lactose intolerance especially in infants and young children.

Fats

Ingested fats are emulsified in the small intestine by the action of bile salts, phospholipids, and monoglycerides. Pancreatic lipase hydrolyzes the emulsified fat into fatty acids and monoglycerides which combine with bile salts to form micelles. Micellar formation further solubilizes the fatty acids and other lipolysis products and provides a mechanism for their transport to the enterocytes.

Absorbed fatty acids are reesterified to triglycerides in the enterocytes and combine with protein, cholesterol, and phospholipid to form chylomicrons. The chylomicrons then leave the enterocytes to enter the lymphatics. Medium-chain triglycerides are water-soluble and absorbed directly into the portal blood.

A decrease in luminal bile concentration can impair lipid intestinal absorption. This can result from obstruction of bile flow as in congenital biliary atresia, or interruption of the enterohepatic circulation of bile acids.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_184,

Table 184.1
Intestinal diseases causing malabsorption

1. Congenital mucosal defects
(a) Microvillus inclusion disease
(b) Tufting enteropathy (intestinal epithelia dysplasia)
(c) Carbohydrate transport defects:
(i) Glucose-galactose malabsorption
(ii) Sucrase-isomaltase deficiency
(iii) Congenital lactase deficiency
(d) Amino acids transport defects:
(i) Neutral amino acids defect (Hartnup disease)
(ii) Dibasic amino acids defects (Lysinuric protein intolerance)
(iii) Tryptophan absorption defect (Blue diaper syndrome)
(iv) Methionine absorption defect (Oasthouse syndrome)
(e) Lipid transport defects
(i) Abetalipoproteinemia
(ii) Familial hypobetalipoproteinemia (homozygous)
(iii) Chylomicron retention disease
(iv) Wolman's disease
(f) Other defects
(i) Congenital chloride diarrhea
(ii) Congenital sodium absorption diarrhea
(iii) Acrodermatitis enteropathica
(iv) Enterokinase deficiency
(v) Congenital bile acid malabsorption
(vi) Congenital disorders of glycosylation
2. Intestinal infections
(a) Parasitic infections
(b) Infections in acquired immune deficiency syndrome (AIDS): Cryptosporidiosis, microsporidiosis, *Mycobacterium-avium* complex infection, cytomegalovirus infection
(c) Bacterial overgrowth
(d) Postinfectious enteropathy
(e) Intestinal tuberculosis
(f) Whipple's disease
3. Immune disorders
(a) Primary Immune disorders
(i) Common variable immunodeficiency
(ii) Selective IgA deficiency
(iii) Agammaglobulinemia, X-linked or autosomal recessive
(iv) Hyper IgM syndrome
(v) Severe combined immunodeficiency
(vi) Immune dysregulation, polyendocrinopathy, enteropathy (IPEX) syndrome
(vii) Chronic granulomatous disease (CGD)
(viii) Wiscott–Aldrich syndrome
(ix) Hermansky–Pudlak syndrome
(b) Acquired immune deficiency
(i) HIV infection
(ii) Immunosuppressive therapy
4. Mucosal inflammatory disorders
(a) Crohn's disease
(b) Eosinophlic gastroenteritis
5. Food-induced enteropathy:
(a) Eosinophilic gastroenteritis.
(b) Celiac disease
6. Others
(a) Acquired primary lactase deficiency (adult-type hypolactasia)
(b) Autoimmune enteropathy
(c) Small intestinal resection
(d) Congenital short bowel
(e) Radiation enteritis
(f) Graft-versus-host disease
(g) Chronic malnutrition

Table 184.2
Pancreatic diseases causing malabsorption

1. Pancreatic insufficiency
(a) Cystic fibrosis
(b) Shwachman–Diamond syndrome
(c) Pearson's syndrome
(d) Johanson–Blizzard syndrome
(e) Chronic pancreatitis
2. Congenital pancreatic enzyme deficiency (lipase, colipase, or trypsinogen deficiency)

Decreased hydrolysis of dietary fat results from impaired pancreatic lipase and colipase secretion as a result of exocrine pancreatic dysfunction. Cystic fibrosis and chronic pancreatitis are common causes of pancreatic insufficiency in children. Congenital deficiency of lipase or colipase is extremely rare. Impairment of lymphatic transport of chylomicrons is another cause of malabsorption of dietary fat. Decreased lymphatic transport is seen

Table 184.3
Lymphatic and vascular disorders causing malabsorption

1. Primary intestinal lymphangiectasia
2. Secondary intestinal lymphangiectasia
(a) Cardiovascular disorders
(i) Fontan procedure
(ii) Congestive heart failure
(iii) Restrictive pericarditis
(b) Thoracic duct trauma or obstruction
(c) Portal hypertension
(d) Mesenteric lymph node disorders
(i) Lymphoma
(ii) Radiation
(iii) Mesenteric tuberculosis

in patients with primary lymphangectasisa or secondary lymphatic obstruction.

Unabsorbed fats trap fat-soluble vitamins and interfere with their absorption leading to deficiencies. Small intestinal bacterial overgrowth results in deconjugation of bile acids and leads to malabsorption of fat and fat-soluble vitamins.

Proteins

Gastric pepsin hydrolyzes protein into polypeptides of variable sizes. Polypeptides are further digested in the small intestine by the pancreatic proteolytic enzymes. Enterokinase, a brush border enzyme, is required to activate trypsinogen into trypsin. Trypsin converts chymotrypsinogens into chymotrypsins and other proenzymes into active enzymes. Active proteolytic enzymes hydrolyze proteins into oligopeptides, which are absorbed directly or hydrolyzed into amino acids. The digestion of peptides into amino acids can occur in the intestinal lumen, the brush border, or the cytoplasm of the mucosal cells.

Generalized mucosal diseases such as celiac disease, or reduction of intestinal absorptive surface as in short bowel syndrome, can result in malabsorption of oligopeptides and amino acids. Selective disorders of malabsorption of amino acids are rare and result of defects of amino acid transporters as in Hartnup disease and lysinuric protein intolerance.

Protein-losing enteropathy is a distinct clinical condition which results from excessive loss of serum protein into the gastrointestinal tract and should be differentiated from protein maldigestion or malabsorption.

Clinical Evaluation

Features of malabsorprtion are very variable and depend on etiology and extent of gastrointestinal defect, age of presentation, and other comorbidities. The evaluation of a child for malabsorption should include: confirming the presence of malabsorption, identifying the cause, treating underlying condition, and correcting nutritional deficiencies.

Malabsorption is usually suspected based on clinical history, physical findings, and routine laboratory findings. Symptoms and signs are either secondary to the presence of malabsorbed material in the gastrointestinal tract or related to specific nutrient deficiency. They can be divided into gastrointestinal and extragastrointestinal manifestations:

Gastrointestinal Symptoms and Signs

- *Diarrhea*: Diarrhea is one of the commonest symptoms of malabsorption. Characters and number of stools may be a useful differentiating symptom.
  - Explosive watery stools in the first week of life and after the institution of regular formula are very suggestive of congenital glucose-galactose malabsorption or congenital lactase deficiency. Skin irritation and erythema in the perianal area are characteristic of acidic stools seen in carbohydrate malabsorption.
  - Bulky, greasy, and foul-smelling stools indicate fat malabsorption as in pancreatic insufficiency.
  - Nocturnal diarrhea or diarrhea that does not respond to fasting indicate secretory diarrhea as in toxigenic *Escherichia coli* enterocolitis and in congenital mucosal defects.
  - Bloody stool is a sign of inflammatory process as in inflammatory bowel disease or eosinophilic enterocolitis.
  - Floating of stool can be due to a high stool-fat content, but it also can be caused by high gas content as in carbohydrate malabsorption. Loose stools with undigested food particles are common findings in chronic nonspecific diarrhea of toddlers and not a sign of malabsorption.
- *Abdominal distension and flatulence*: from bacterial fermentation of malabsorbed carbohydrates in colon and in small intestinal bacterial overgrowth.
- *Abdominal pain*: from intestinal distension or inflammation.
- *Edema* of the legs, puffiness and ascites: in protein loss or malabsorption.

Extragastrointestinal Symptoms and Signs

- Failure to thrive and growth retardation: secondary to nutrient malabsorption
- Anorexia and food refusal as in mucosal inflammation
- Weakness, fatigue, and irritability: secondary to poor nutrition or anemia
- Delayed puberty and amenorrhea: in protein-caloric malnutrition
- Bleeding tendencies: in vitamin K deficiency
- Pallor and anemia (iron, folate, or vitamin B12 deficiency)
- Neurologic symptoms and ataxia: vitamin E, vitamin B12, or folate deficiency
- Frontal bossing, widening of wrists, bowed legs, bone pain: vitamin D deficiency
- Acrodermaitis: zinc deficiency
- Cheilitis and glossitis: vitamin B complex deficiency

Useful Clues in the History

- Detailed diet history: diluted formula, high intake of fructose or sorbitol, inadequate caloric intake
- Relation of symptoms to newly introduced food
- History of food allergies
- History of previous gastrointestinal surgeries. History of cardiac surgery
- History of parental consanguinity
- Family history of malabsorption syndromes (celiac disease, congenital mucosal structural defects or transport defects)
- Extraintestinal symptoms suggestive of inflammatory bowel disease or immune deficiency

Diagnostic Approach

Screening Tests for Malabsorption

- Complete blood cell count:
  - Hemoglobin
  - Red blood cell indices: to identify nutritional deficiencies of iron, folate, or vitamin B12, or with anemia of chronic disease
  - Lymphocyte count: low in lymphangectasia
  - Low CD4 count in HIV infection
  - Eosinophils: could see peripheral eosinophilia in allergic conditions
  - Acanthocytes in abetalipoproteinemia
  - Platelets: increased in inflammatory diseases
- C-reactive protein and erythrocyte sedimentation rate: as markers of inflammation
- Low total serum protein and albumin: secondary to protein loss, malabsorption, or inadequate intake
- Prealbumin (Transthyretin): a marker of acute malnutrition (shorter half-life than albumen) and to assess efficacy of nutritional therapy
- Serum iron, ferritin, and iron binding capacity in iron deficiency anemia
- Fat-soluble vitamins (vitamins A, E, and 25-hydroxyvitamin D): in malbsorption syndromes
- Prothrombin times (vitamin K)
- Vitamin B12 level
- Zinc level
- Liver biochemical tests
- Immunoglobulins: immunodeficiency syndromes, IgA deficiency
- Stool tests:
  - Stool pH: low in carbohydrate malabsorption.
  - Reducing substances: suggest carbohydrate malabsorption (glucose, lactose, and fructose).
  - Stool electrolytes (in watery stools) to differentiate secretory from osmotic diarrhea.
  - Fecal occult blood and leukocytes: indicate inflammatory process.
  - Fecal fat (qualitative or quantitative): gives diagnostic clues for fat malabsorption. A 72-h quantitative fecal fat analysis is considered the gold standard for fecal fat analysis. However, this study has several limitations and difficult to perform especially in young children. Acid steatocrit is an alternative and simpler test to perform but has limited applicability in patient with mild steatorrhea.
  - Stool ova and parasites: several studies may be needed to detect Giardia lamblia.

Specific Studies

Sequence of tests to establish the cause of malabsorption is guided by the child's history and results of previous screening tests. Stepwise approach starting with noninvasive tests should be performed initially.

- Serologic studies for Celiac disease: endomysial and tissue transglutaminase antibodies.
- Carbohydrate malabsorption:

  - Lactose malbsorption: lactose breath hydrogen testing. An increase in breath hydrogen concentration of greater than 20 ppm over baseline after ingestion of lactose is considered positive. Early increase within the first 30 min has to be disregarded because it may reflect fermentation of lactose by oral bacterial flora.
  - Fuctose malabsorption: fructose breath hydrogen testing.
- Pancreatic insufficiency: fecal elastase or chymotrypsin. Both are reduced in exocrine pancreatic insufficiency but have variable sensitivity and specificity.
- Protein malabsorption: enteral protein loss could be demonstrated by measuring stool alpha-1 antitrypsin and alpha-1 antitrypsin clearance.
- Small intestinal bacterial overgrowth: by glucose or lactulose breath hydrogen testing.

Imaging Studies

- Upper gastrointestinal series with small intestine follow-through: not routinely used as the radiologic findings in malabsorption are not specific. It can be helpful to identify intestinal abnormalities that can predispose to bacterial overgrowth. It is also a useful technique in evaluating the small bowel for strictures and fistulas in Crohn's disease.
- Abdominal Computed Tomography(CT): This study can be useful in selected cases to detect focal small intestinal lesions such as strictures and abscess formation in Crohn's disease. However, much attention has been pain recently to the potential risks of irradiation to children from CT and fluoroscopy.
- Magnetic resonance imaging (MRI): This study is increasingly being offered to children with suspected small and bowel large diseases because of decreased risk of irradiation.
- Abdominal ultrasound: Abdominal ultrasonography can be useful in detecting bowel wall thickening as in active Crohn's disease. It can also detect complications such as abscesses and fistulas. However, the findings are usually nonspecific and interpretation of the images are operator dependent. It is a valuable and noninvasive toll to evaluate children with chronic pancreatitis and biliary disorders.
- Endoscopic ultrasonography (EUS): The role of EUS is well established in adult gastrointestinal and pancreatobiliary diseases, but the reported experience of its usefulness in children is limited.

Endoscopic Examination

- Endoscopic appearance can provide clues to some underlying disorders. Reduced number of duodenal folds and scalloping are very suggestive of villous atrophy in celiac disease, although may be seen in other disorders such as eosinophilic gastroenteritis and chronic giardiasis. Mucosal aphtous ulceration and strictures suggest Crohn's disease.
- Histology: Findings on mucosal biopsies can be very useful and diagnostic of many malabsorption syndromes.
  - Celiac disease: Villous atrophy and increased intraepithelial lymphocyte are very suggestive of celiac disease. However, definite diagnosis of celiac disease cannot be established by mucosal biopsy alone.
  - Eosinophilic gastroenteritis: Main feature is eosinophilic infiltration of mucosa.
  - Crohn's disease: Patchy inflammation and granulomas.
  - Abetalipoproteinemia: Lipid accumulation and vacuolization of enterocytes.
  - Lymphangectasia: Dilated lymph vessels.
  - Microvillous inclusion disease: Lack of microvilli and presence of secretory granules and inclusion bodies.
  - Infectious:
    - Giardiasis: Parasites may be seen on histologic examination.
    - *Mycobacterium-avium* complex infection: Acid-fast bacilli.
- Duodenal aspiration: Fluid collected from distal part of duodenum can be examined to look for *Giardia lamblia*. It can also be cultured to detect small intestinal bacterial overgrowth.
- Pancreatic stimulation tests: By either secretin, or cholecystokinin stimulation tests. The tests require duodenal intubation to collect serial pancreatic juice samples after stimulation.

Approach to Management

Management should include treatment of the underlying condition if possible, and correction of all nutritional deficiencies.

185 Functional Gastrointestinal Disorders

Hany Banoub · Hisham M. Nazer · Sonny K. F. Chong

Introduction

While gastrointestinal symptoms of abdominal pain, nausea and vomiting, bloating, diarrhea, and constipation due to organic causes can be identified by various investigations, functional gastrointestinal disorders (FGID), on the other hand, are multi-symptomatic conditions that have no underlying mucosal or structural abnormalities. They are diagnosed based on a collection of symptom complexes. Functional Gastrointestinal disorders (FGIDs) are quite common in children. The exact cause remains unknown; however, it has usually been referred to as multifactorial. Noninfectious causes affecting the gastrointestinal tract early in life, such as cow's milk allergy (CMA), can predispose to the development of FGID later in childhood.

There are three common concepts for FGID: (1) no known structural cause, (2) no symptoms due to stress disorders, or (3) due to a motility disorder.

Although FGID have a great impact on patient morbidity and time off work, some physicians deny or belittle their existence, while other physicians exhibit negative attitude toward such patients.

Over the past 2 decades, researchers have started to unravel the underlying mechanisms behind these conditions. For example, impaired gastrointestinal motility and intestinal secretion, along with enhanced visceral sensitivity, have been shown to be key abnormalities associated with the characteristic symptoms of abdominal pain and altered bowel habits as experienced by patients with irritable bowel syndrome.

Gastrointestinal motility disorders that are due to altered physiological factors lead to altered physiological function. In recent years, these factors stem from the brain-gut axis interaction and dysfunction. Gastrointestinal motility can be measured and abnormal patterns can be identified using tests for different part of the gastrointestinal tract which provide information to help with diagnosis and treatment.

Psychosocial factors, through the brain-gut axis, affect the physiologic function of the gut, which in turn alters motility and sensation, modulating inflammation, which may be caused by or associated with altered bacterial flora. These have impact or lead to FGID. Early in life, genetic factors may affect one's psychological development in developing coping skills as well as susceptibility to gut dysfunction-abnormal motility, altered mucosal immunity, or visceral hypersensitivity. In addition, environmental factors such as child and sexual abuse, loss due to death/bereavement/cancer phobia may affect the psychological development and the interaction of the brain-gut axis.

Over the last decade, gut receptor-active agents have been recognized. These include 5-HT agonists and antagonists, and other newer agents, have been used to treat FGID. Other, more centrally acting agents have been used for treating stress-mediated effects of CNS modulation of the gut.

Within the gut, motility assessment advances, test for visceral hypersensitivity, mucosal immunology, alteration of the gut bacterial flora, and other tests have been used to allow us to quantify the association between motility disorders and FGID.

Rome and FGID

Over the last 17 years, FGID have been studied by nonprofit organizations that formed the Rome Foundation who aimed at providing support for activities to create scientific data to assist in the diagnosis and treatment of FGID.

The Rome II criteria developed structured, symptom-based classification for many FGID. Those criteria are not explained by other pathologically based disorders. This has been revised in the Rome III criteria (28 adult and 17 pediatric FGID). The pediatric gastrointestinal symptoms Rome III version criteria for the diagnosis of FGIDs include those of irritable bowel syndrome, functional dyspepsia, and functional abdominal pain.

Cow's milk allergy constitutes a risk factor for the development of FGIDs in children. Rome III criteria were able to diagnose FGIDs more comprehensively than Rome II.

The Pediatric system is classified first by age range (*category G for neonate/toddler, category H for child/adolescent*) and then by symptom pattern or area of symptom location.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_185,

The symptoms of FGID in children less than 5 years depend on maturational factors in anatomy, gastrointestinal physiology, and intellectual and affective functioning.

G. Functional disorders: neonates and toddlers	
G1	Infant regurgitation
G2	Infant rumination syndrome
G3	Cyclic vomiting syndrome
G4	Infant colic
G5	Functional diarrhea
G6	Infant dyschezia
G7	Functional constipation
H. Functional disorders: children and adolescents	
H1. Vomiting and aerophagia	
H1a	Adolescent rumination syndrome
H1b	Cyclic vomiting syndrome
H1c	Aerophagia
H2. Abdominal pain-related functional gastrointestinal disorders	
H2a	Functional dyspepsia
H2b	Irritable bowel syndrome
H2c	Abdominal migraine
H2d	Childhood functional abdominal pain
H2d1	Childhood functional abdominal pain syndrome
H3. Constipation and incontinence	
H3a	Functional constipation
H3b	Non-retentive fecal disorders (incontinence)

Understanding *the adult FGID* is very important in management of *Pediatric FGID. In the adults, the FGID are classified into six major domains; category A to F* (from esophagus to ano-rectum).

Each category site contains several disorders with specific clinical features. For example, the FGID for category C includes IBS (C1), functional bloating (C2), functional constipation (C3), and functional diarrhea (C4), which anatomically is attributed to the small bowel, colon, and rectum. Symptoms may overlap across these disorders, and each of these disorders has a different diagnostic and treatment approach.

Red Flags

The Rome III innovations include alarm symptoms to help alert physicians to possible structural disorders that might require further investigation. There are separate questionnaires for adolescents and parents of children and toddlers. There is also a psychosocial module to help identifying psychosocial difficulties that might require mental health referral.

The following are considered to be the alarm symptoms which might require further testing to rule out structural disease: blood in stools, black stools, vomited blood, fever, loss of weight, anemia. Also, positive family history of gastrointestinal disease such as ulcerative colitis, Crohn's disease, celiac disease, persistent right upper or right lower quadrant pain, dysphagia, persistent vomiting, pain that wakes the child from sleep, arthritis, and delayed puberty are generally absent in FGID.

The physician should ensure that there is evidence of an inflammatory, anatomic, metabolic, or neoplastic process that explains the patient's symptoms. This might indicate the need for other investigations to rule out such conditions. The clinical diagnosis will depend on the judicious exclusion of other diseases. There are also some tests used to diagnose motility disorders and other FGID which might be used as well.

Psychological Alarm Questionnaire

Included in the Rome III guidance are screening questions which will help to identify psychological problems commonly faced by patients with FGID. The physician should acknowledge, discuss with the patient, and agree on the appropriate action, which might include referral to a mental health specialist and or initiate pharmacotherapy.

Those questions explore how the patient feels regarding anxiety, depression, suicidal ideas, and impaired coping. The patient may chose to answer either not at all, or occasionally, or most of the time. If the answer was most of the time for any of the former condition, this is considered as a red flag, which the physician has to address or refer to the child psychiatrist even prior to treatment of the FGID (or simultaneously with treatment).

The psychological alarm questionnaire has a question for abuse (emotional, physical, or sexual) with a red flag situation to consider early referral to a mental health professional provided the patient agrees.

The Enteric Nervous System (ENS)

Abdominal pain and disordered gastrointestinal function (the interaction between the brain, the spinal cord, and the gut) can be understood by studying ENS neurobiology with respect to visceral sensation and its modulation by inflammation and stresses.

The brain-gut axis allows bidirectional input and links emotional and cognitive centers of the brain with peripheral functioning of the GI tract and vice versa. Extrinsic information (vision, smell, etc.) or enteroceptive information (emotion, thought) has the capability to affect GI sensation, motility, secretion, and inflammation. Visceral afferent communications to the brain can affect central pain perception, mood, and behavior.

Increased motor and sensory reactivity to environmental stimuli leads to greater gut physiological reactivity to stress or to its neurochemical mediators.

Genetic factors may predispose some individuals to develop FGID, whereas in others, environmental factors contribute to the expression of these conditions. Psychological factors are not required for the diagnosis of FGID, but they modulate the patient's behavior and experience, and ultimately, the clinical outcome.

Three general observations were noted:

- Psychological stress exacerbates GI symptoms.
- Psychological factors modify illness behavior.
- FGIDs can have psychological consequence (like any other chronic illness).

GI Motility and FGID

The esophagus is capable of peristalsis during the first trimester. However, complex pattern of esophageal motility are clearly detected during the second trimester.

At birth, the motility of the esophagus functionally consists of three regions: the upper esophageal sphincter, body of the esophagus, and the lower esophageal sphincter.

The upper esophageal sphincter. It is physiologically defined as a zone of high intraluminal pressure lying between the pharynx and the cervical esophagus. Its main functions are to provide physical barrier of the proximal gastrointestinal tract against pharyngeal and laryngeal reflux during esophageal peristalsis, and to avoid the entry of air into the digestive tract during inspiration. It relaxes transiently during swallowing to allow the entry of the food bolus into the esophagus and during vomiting to allow the expelling of the gastric contents.

Esophageal body. Three segments can be identified: cervical, thoracic, and abdominal.

The wall of the esophageal body is composed of the mucosa, submucosa, and muscularis propria (which is composed of an outer longitudinal muscle layer and an inner circular muscle layer). In adults, the proximal 4–5 cm of esophageal muscularis propria is composed of skeletal muscle fibers. The mid-third of the esophagus consists of both skeletal and smooth muscles. The distal 10–14 cm consists entirely of smooth muscle fibers.

At rest, the musculature of the esophageal body does not exhibit rhythmic or tonic contraction. Primary peristalsis is defined as a reflex esophageal peristaltic contraction wave initiated by swallowing. It results from a sequential contraction of the esophageal muscle layers moving down the entire length of the esophagus, appearing shortly after the pharyngeal contraction traverses the upper esophageal sphincter.

The efficacy of esophageal emptying is strongly related to the peristaltic amplitude.

Lower esophageal sphincter (LES). The LOS is the high-pressure zone localized at the esophagogastric junction, which regulate the flow of contents between the esophagus and the stomach. The intrinsic smooth muscle fibers of the distal esophagus and the extrinsic skeletal muscle of the crural diaphragm function as a well coordinated and efficient functional unit of the sphincteric mechanism at the esophagogastric junction. The lower esophageal junction is tonically contracted at rest to produce a roughly concentric occlusion. The resting tone of the LOS is determined by excitatory cholinergic neurons and the myogenic properties of the smooth muscle fibers (independent of neural influences and may be produced with ionic movement).

LES pressure is increased by hormones such as gastrin, motilin, and substance P and neural agents such as the cholinergic agonist serotonin, whereas secretin, glucagon, VIP, and the cholinergic antagonist nitric oxide tend to decrease LES. Proteins tend to increase the LES pressure while fat, ethanol, and peppermint tend to decrease the LES pressure. In children, LES pressure ranges between 10 and 40 mmHg. LES pressures of 5 mmHg above intragastric pressure are sufficient to maintain esophagogastric competence.

Gastric Motility

The stomach is functionally divided into two regions: the proximal stomach including the fundus and the proximal one third of the body, and the distal stomach composed of the distal body and antrum.

The proximal stomach is characterized by properties that enable accommodation of larger volumes of food without a great increase in luminal pressure. Eventually, as food accumulates, the pressure in the fundus increases, resulting in a sustained contraction which propels the gastric contents toward the antrum. The distal portion is

electrically active and able to generate contractions that facilitate the mixing of food and passage of chime to the duodenum.

The stomach pacemaker, located in the corpus along the greater curvature near to the proximal one third of the corpus, generates regular electrical slow waves of depolarization at approximately three cycles per minute (cpm) that spread away, circumferentially and distally toward the pylorus. This frequency varies to between 8 and 11 cpm in the small bowel (explaining the difference in the rate of contractions among regions).

The Interstitial Cells of Cajal (*ICC*) are a group of mesenchymal cells distributed throughout the longitudinal and circular muscle layers of the gastrointestinal tract in close contact with smooth muscle cells. They are considered the gut pacemakers and the mediators of neurotransmission. They initiate and actively propagate electric rhythmic activity between nerves and smooth muscles resulting in gut contraction. They are present in the myenteric plexus of the stomach, small intestine, and colon and are responsible for generating electrical slow waves.

Electrogastrography refers to the methods of recording electrogastrograms (EGGs). EGG rhythms reflect the gastric pacesetter potentials or slow wave of the stomach. Pacesetter potentials are crucial electrical depolarization and repolarization waves because they control the timing and propagation velocity of gastric peristaltic contractions.

Thus, the 3-cpm EGG signals are noninvasive recordings of the electrical activity in health. Gastric dysrhythmias are abnormalities of gastric myoelectrical activity. These can be recorded in the EGG signal. Abnormally fast rhythms are called *tachygastrias*, and abnormally slow rhythms are called *bradygastrias*.

Gastric dysrhythmias are frequently present in patients with functional dyspepsia, unexplained nausea, diabetic, idiopathic, and postsurgical gastroparesis. Furthermore, correction of the gastric dysrhythmias with drug therapies or electrical stimulation is associated with improvement in nausea and vomiting.

Bradygastric activity of the stomach predict disgust sensitivity and perceived disgust intensity. The results suggest that feeling of disgust may be specifically related to increased bradygastria, which may represent a prodromal sign of vomiting.

Intestinal Motility

The motility of the small and large intestine is a function of the intestinal smooth muscle, which is controlled by the enteric nervous system (*ENS*) and the interstitial cells of Cajal (*ICC*). Gastrointestinal motility is modulated by the extrinsic input from the autonomic and central nervous system, from gastrointestinal hormones, and the immune system.

Throughout the intestine, *three layers* of muscle contract in a coordinated fashion:

- *The muscularis mucosa*, a thin layer that lies beneath the villi
- *The circular muscle*, which lies outside of the muscularis mucosa and serves as a pacemaker for gut muscle contraction
- *The longitudinal muscle*, the outermost layer of the three muscles

These muscles have oscillatory membrane potentials and their contraction rate is reflective of the electrical slow waves. The slow wave has a different frequency at each level of the gut (9–11/min in the duodenum, 8–10/min in the jejunum, and so forth).

Evaluation of Motility Disorders

The number of diagnostic tests available to evaluate gastric motor functions is steadily increasing. A combination of several testing modalities is often required in the evaluation of the child with suspected gastric dysfunction.

Radiology. The study usually begins with radiologic contrast studies to provide essential information on anatomical abnormalities (malrotation or a superior mesenteric artery that compresses the small bowel) which may result in small intestine dysmotility. However, barium studies are unsuitable to diagnose a specific motility disorder and are unreliable to assess transit time.

Scintigraphy. It is considered the reference standard for measuring gastric emptying. It is minimally invasive, requires relatively low levels of exposure to radiation. In this test, a liquid or solid food is labeled with a nucleotide, the labeled meal is tracked as it passes through the stomach using a gamma camera.

Antroduodenal manometry. It provides direct information on the amplitude, duration, frequency, and direction of propagation of gastrointestinal contractions. It is an essential aid in determining the presence of a motility disorder in patients with suspected enteric neuromuscular disorders.

Other tests. Gastric emptying can also be measured by ultrasonography, magnetic resonance imaging, single-photon emission computed tomography (*SPECT*), external EGG, water load test, breath test using C-octanoate.

Functional Dysmotility of the Foregut

Primary motility disorders of the foregut are rare. They may result in accelerated or delayed transit. Delayed transit may involve the stomach only (gastroparesis) or be part of a generalized gastrointestinal disorder (intestinal pseudo-obstruction).

They mainly present with a combination of symptoms including *nausea, vomiting, abdominal distention, abdominal pain, and weight loss.*

Gastroparesis

Gastroparesis is a chronic disorder caused by stomach pump failure and characterized by delay in gastric emptying of a meal in the absence of a mechanical gastric obstruction, profound nausea, vomiting, and epigastric pain.

Gastroparesis is a disorder characterized by an abnormality in the gastric myoelectrical activity, which may result in delayed gastric emptying and gastric dysmotility. Vomiting is characterized by being postprandial after meal ingestion and containing undigested food from previous meals. Gastroparesis may result from degenerative processes that affect gastric enteric neurons, smooth muscle, and Interstitial Cells of Cajal (ICC).

Gastroparesis can be found in preterm infants with immaturity of the gastrointestinal tract and in dietary proteins allergy. In allergic infants, cow milk provokes gastrointestinal dysmotility that results in delayed gastric emptying, exacerbating gastroesophageal reflux, and inducing vomiting. Using hydrolyzed formula leads to clinical improvement and acceleration of gastric emptying.

Due to the numerous potential etiologies and the highly variable clinical manifestations, the management of gastroparesis is particularly challenging.

The true prevelance of gastroparesis is unknown.

Children with CNS disorders frequently develop abnormal gastric motility and gastroesophageal reflux due to abnormal modulation of the enteric nervous system. Physical and emotional stress has been shown to be associated with delayed gastric emptying.

Patients with symptoms suggestive of gastroparesis can be studied with various techniques to confirm delayed emptying of the stomach.

Diagnosis is usually made using an isotope-labeled test meal (Isotopic gastric scintigraphy).

Diagnosis of gastroparesis is based on the presence of symptoms such as nausea, vomiting, and postprandial abdominal fullness and on an objectively determined delay in gastric emptying. Gastric emptying can be assessed by scintigraphy and stable isotope breath tests.

Treatment options remain limited despite the disabling nature of the disorder. Treatment is incremental and includes education, dietary support, and prokinetic and antiemetic agents. There are no adequately powered controlled trials to support a particular drug regimen.

Therapies for gastroparesis include dietary modifications, behavioral changes, prokinetic drugs and, in the most severe cases, gastric electrical stimulation (gastric pacing) and surgery. Other interventions to ensure adequate nutrient intake include nasoduodenal feeding, percutaneous gastrostomy, or jejunostomy.

Dietary modifications appear more suitable than pharmacological treatment in resolving symptoms since side effects of suggested drugs have been described and recent studies indicated that appropriate dietary modification offer better results than suggested medication in resolving crises. In intractable gastroparesis, gastric neurostimulation appears to offer some benefit.

Electrogastrographic and gastric emptying tests. Patients with gastric dysrhythmias and upper GI symptoms may or may not have delayed gastric emptying. Similarly, patients with atrial fibrillation with palpitations and chest discomfort may or may not have impaired cardiac output. Patients with bradygastrias have normal or near-normal gastric emptying rates, whereas patients with tachygastrias have poorer gastric emptying. Patients with dyspepsia symptoms can be further categorized on pathophysiological basis by combining the EGG and gastric emptying studies (see diagram) *Fig. 185.1*.

Infantile Colic

Infantile colic has been defined as a condition characterized by paroxysmal episodes of unexplained full force crying for at least 3 days a week and continuing for 1 week or more in a thriving well-nourished infant.

The disorder occurs more likely in the evening, without identifiable causes and resolves spontaneously by the fourth month of life.

Infantile colic is a widespread clinical condition in the first 3 months of life which is easily recognized, but incompletely understood and difficult to solve. The available evidence suggests that infantile colic might have several independent causes. Medical hypotheses include food hypersensitivity or allergy, immaturity of the gut function, and dysmotility. The behavioral hypotheses include inadequate maternal–infant interaction, anxiety in the mother, and difficult infant temperament. Other

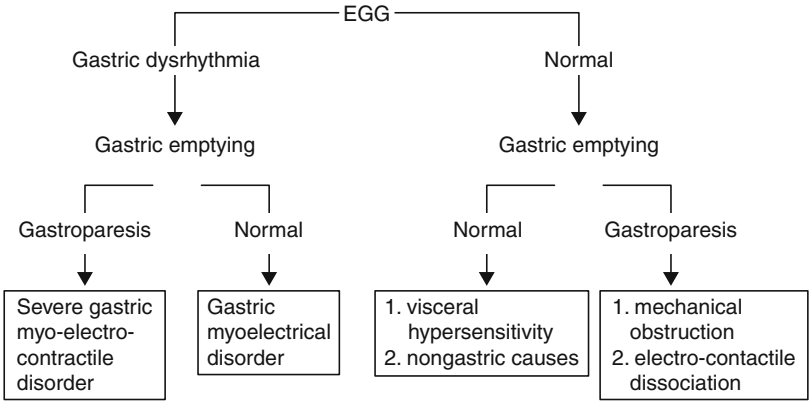

Figure 185.1
Results of Electrogastrogram (EGG) and gastric emptying in patients with dysmotility-like dyspepsia or unexplained nausea and vomiting

recent hypothesis, such as hormone alteration, maternal smoking and alteration in the gut microflora need further confirmation. A safe approach should be adopted which is proportional to the intensity of the infantile colic.

In a small subset of infants with colicky behavior, a specific medical disorder such as GERD or milk protein allergy may be identified.

The most important factors in appropriate intervention are physicians receptivity and sensitivity toward the stressed mother, together with an interested and practical approach to providing adequate support while delineating the individual stress acting on both mother and baby. The several factors involved in the pathogenesis make the management of infants with colic difficult.

Rumination Syndrome

This is a functional gastrointestinal disorder characterized by effortless repetitive regurgitation of undigested food from the stomach into the oropharynx. The food is then partially or completely rechewed, re-swallowed, or rejected.

Postprandial impedance manometry monitoring improves diagnosis of rumination because it allows distinction between rumination and postprandial belching and regurgitation. During rumination, esophageal liquid retrograde flow is first driven by an early small rise in intragastric pressure preceding the peak pressure observed during straining.

Infant rumination syndrome has an onset between 3 and 8 months, not associated with signs of nausea or distress. It constitutes a form of self stimulation, and has been linked to social deprivation. Bonding problems with the mother are frequently described. Adolescent rumination syndrome occurs without retching or nausea. It is immediately preceded by a sensation of belching.

When compared to idiopathic gastroparesis, regurgitation usually occurs during or within minutes from meal ingestion, and in contrast to gastroesophageal reflux disease, it is generally not associated with heartburn, discomfort, or esophagitis.

Rumination syndrome is reported among adolescents and adults of normal intelligence, even though it was initially considered only in infants and mentally retarded individuals. Reassurance and behavioral therapy is the mainstay of treatment with favorable results.

Functional Dyspepsia

Functional dyspepsia (FD) represents a group of gastrointestinal disorders, with patients who experience chronic nausea, postprandial bloating, and epigastric pain centered in the upper abdomen that is not relieved by bowel opening; it is not associated with constipation or diarrhea. Dyspepsia is a highly prevalent condition characterized by symptoms originating in the gastroduodenal region without underlying organic disorder.

While delayed gastric emptying is found in 40% of the patients with functional dyspepsia, other studies have shown accelerated emptying in a subgroup of patients. The possible role of Helicobacter pylori in functional dyspepsia remains controversial.

The 2006 Rome III criteria defined FD and its subgroups, postprandial distress syndrome (PDS), and epigastric pain syndrome (EPS). FD is a very common condition with a high prevalence throughout the world, adversely affecting the quality of life of patients.

Functional dyspepsia in childhood is commonly triggered by food allergen in sensitized individuals. Early onset neuroimmune interactions induced by cow's milk in the gastric mucosa of atopic children are associated with rapid disturbance of gastric myoelectrical activity and dyspeptic symptoms.

Mast cell density is associated with delayed gastric emptying and preprandial dysrhythmia, suggesting that there may be an interaction between antral inflammation and gastric electormechanical dysfunction in the pathophysiology of pediatric functional dyspepsia.

Functional gastrointestinal disorders as functional (or non-ulcer) dyspepsia are characterized by broad spectrum of symptoms referred to the upper abdomen without a detectable cause utilizing routine diagnostic measures. In recent years, placebo-controlled studies have demonstrated superiority of a commercial multicomponent herbal preparation, STW 5, with the trade name of "Iberogast," for the treatment of patients with functional dyspepsia and IBS. This phytopharmacon is a combination of nine plant extracts, each with a number of different active constituents.

Treatment is complex and challenging, as there is insufficient evidence to recommend the use of commonly employed drugs in the management of dyspepsia. Avoidance of nonsteroidal anti-inflammatory agents, spicy and fatty food, and caffeinated and carbonated beverages is generally recommended.

Antisecretory agents (H2 blockers or proton pump inhibitors) are often offered for pain predominant symptoms and prokinetics (metoclopramide, erythromycin, and domperidone) for symptoms associated with bloating and early satiety.

Treatment modalities include helicobacter pylori eradication therapy, tricyclic antidepressants, and psychological therapies.

Intestinal Functional Dysmotility

Irritable Bowel Syndrome (IBS)

In children old enough to provide accurate pain history, IBS is defined as chronic or recurrent abdominal pain, altered bowel habits, and bloating. It is recognized by having at least 12 weeks, which need not be consecutive, of:

1. Abdominal pain that has two or more of the following:
   (a) Improve with defecation
   (b) Onset associated with a change in the frequency of stool
   (c) Onset associated with the change in form (appearance) of stool
2. There is no evidence of an inflammatory, anatomic, metabolic, or neoplastic process to explain the symptoms.

Other features to support the diagnosis of IBS are:

1. Abnormal stool frequency (4 or more stools/day or fewer than 2 stools/week)
2. Abnormal stool form (lumpy/hard or loose/watery stools)
3. Straining, urgency, or a feeling of incomplete evacuation
4. Passage of mucus in the stools
5. Bloating or feeling of abdominal distention

IBS is a multifactorial lower functional gastrointestinal disorder involving disturbances of the brain-gut axis. Numerous studies have found an increased prevalence of abnormal psychiatric disorders, including anxiety, depression, personality disorders.

IBS is not a life-threatening condition, but it can have a serious impact on a patient's daily activities, quality of life and school performance.

Physical examination is generally unremarkable; however, the child may appear tense and anxious with occasional abdominal tenderness.

The diagnosis of IBS requires the identification of the symptoms characteristic of IBS and the exclusion of other clinical conditions of similar clinical presentation. There are no specific laboratory markers for the diagnosis of IBS.

Plain abdominal radiography is recommended during an episode of pain to exclude intermittent obstruction. In some patients, upper gastrointestinal study with small bowel follow through proves useful if a suspicion of Crohn disease or celiac disease does exist. Gastrointestinal manometry can identify patients with suspected intestinal pseudo-obstruction or gastroparesis.

IBS is a chronic illness and has no cure; however, medications targeting associated chronic constipation or diarrhea may result in some relief. Pretreatment with anticholinergic medication in IBS was shown to reduce meal-stimulated pain and diarrhea. Some patients with IBS may benefit from pharmacotherapy and behavioral

treatment. A high-fiber diet is useful in patients with IBS and constipation.

Abdominal Migraine

Abdominal migraine, cyclic vomiting syndrome (CVS), and migraine headache comprise a continuum of a single disorder often progressing from one clinical entity to another.

The diagnostic criteria for abdominal migraine must include all the following:

1. Paroxysmal episodes of intense, acute periumbilical pain that lasts for 1 h or more, with intervening symptom-free intervals lasting weeks to months
2. The pain interferes with normal activity
3. No evidence of an inflammatory, anatomic, metabolic, or neoplastic disease
4. Two or more of these features:
   (a) Headache
   (b) Photophobia
   (c) Pallor
   (d) Anorexia
   (e) Nausea
   (f) Vomiting

Functional Abdominal Pain Syndrome (FAPS)

Rome III (*adult criteria*) states that FAPS represents a pain syndrome attributed to the abdomen that is poorly related to gut function. FAPS is associated with some loss of daily activities, and should have been present for at least 6 months. The pain is constant, nearly constant, or at least frequently recurring. The principal criterion differentiating FAPS from other functional gastrointestinal disorders, such as IBS and functional dyspepsia, is the lack of symptom relationship to food intake or defecation.

The diagnostic criteria for Childhood (4–18 years old): Functional Abdominal Pain is the occurrence at least once per week for at least 2 months of episodic or continuous abdominal pain with insufficient criteria for other FGIDs, and no evidence of an inflammatory, anatomic, metabolic, or neoplastic disease that explains the symptoms.

Childhood Functional Abdominal Pain Syndrome must include childhood functional abdominal pain at least in 25% of the time and one or more of the following:

1. Some loss of daily function
2. Additional somatic symptoms such as headache, limb pain, or difficulty in sleeping

These criteria must be fulfilled at least once per week for at least 2 months.

Constipation and Incontinence

Gastrointestinal motility disorders and chronic constipation are common pediatric problems frequently encountered in the daily practice of pediatricians and pediatric surgeons.

The term "*functional constipation*" describes all children in whom constipation does not have an organic etiology. Because functional constipation and fecal retention often overlap, the two disorders were merged into one category.

Immaturity of the enteric nervous system, but also ganglioneuromatosis, can be the underlying cause of chronic constipation.

The number of affected patients with functional constipation 4 years or younger is much higher than patients older than 4 years.

Emergency department physicians and community pediatricians have an important role in the diagnosis and management of functional constipation despite its relatively low incidence.

Chronic constipation may be caused by myopathy.

For diagnosing functional constipation in infants and toddlers (less than 4 years), there must be at least two of the following criteria (observed for at least 1 month):

1. Two or fewer defecation per week
2. At least one episode per week of incontinence after the acquisition of toileting skills
3. History of excessive stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large diameter stools that may obstruct the toilet

Accompanying symptoms may include irritability, decreased appetite, and/or early satiety. The accompanying symptoms disappear immediately following passage of a large stool.

Functional constipation in child/adolescent is similar to the above in addition to the presence of withholding behavior (retentive posturing or excessive volitional stool retention). The criteria must be fulfilled at least once per week for at least 2 months.

Non-retentative fecal incontinence represents the repeated, inappropriate passage of stool into a place other than the toilet in a child older than 4 years with no evidence of fecal retention. In these children, incontinence

is diurnal, and no fecal mass is found on rectal examination. An abdominal radiograph may show occult fecal retention because of incomplete passage of stool.

Macrogol 4,000 is one of the new generation's osmotic laxatives. It is constituted by a heavy molecular weight polymer without additional salts. In most patients, Macrogol 4,000 shows its efficacy in 48 h from the beginning of therapy.

Functional Diarrhea

The diagnosis of functional disease in patients with chronic watery diarrhea should be performed with caution since in most cases there is an organic cause that justifies diarrhea.

Functional abdominal bloating is a functional bowel disorder dominated by a feeling of abdominal fullness without sufficient criteria for another functional gastrointestinal disorder. Gas-related complaints (i.e., passage of flatus), which are present in a subgroup of these patients, might be associated with carbohydrate malabsorption.

The presence of malabsorption is assessed by means of hydrogen breath test.

Sugar malabsorption and intolerance seem to be frequent in patients with functional abdominal bloating and gas-related complaints. A sugar-free diet might be a long-term effective therapy in a high percentage of patients.

Recently, the use of probiotics in the treatment of diarrhea has been encouraged. The medication can help prevent further antibiotic associated diarrhea.

(N.B. More details on this subject are covered in the chapters on gut motility disorders, intractable diarrhea, and major symptoms and signs of gastrointestinal disorders.)

186 Gut Motility Problem

Abdel-Hai Hammo · Hisham M. Nazer

Introduction

The human small bowel and colon display widely divergent patterns of absorption, motility, and transit. Propulsive, peristaltic motility can move contents over long distances of the small intestine very rapidly, with efficiency approaching that of the esophagus. The small intestine functions to facilitate emptying from the stomach, the mixing of chyme with digestive enzymes and bile, and ultimately delivery of residue to the colon. The ileum possesses a specialized type of contraction (giant migrating contraction) that sweeps unabsorbed residue to the colon and is analogous to the high-amplitude colonic contractions. Intermittent emptying ensures that enough time is available for salvage of the remaining nutrients in the small intestine. The small intestine and colon also set up feedback inhibitory reflexes (e.g., ileal brake) that retard proximal motor functions such as gastric emptying.

Gastrointestinal motility involves a complex processes in which parts of the stomach relax to accept food from the esophagus, whereas other parts deliver chyme to the small bowel at a rate optimal for digestion and absorption. Before delivery to the small intestine, the stomach stores, mixes, grinds, and sorts food substances into liquid and solid components that are processed and cleared by different mechanisms.

The colon receives liquid stool from the small intestine and slowly transports it to the rectum. During this journey, which usually takes 24 h, water is absorbed from the liquid stool, and a semisolid product is presented to the rectum. Rectal motility differs from colonic motility in that it remains stationary and allows the stool to remain there until a socially acceptable time, when a massive contraction (mass peristalsis) pushes the stool out and completely empties the rectum. Smooth muscle and enteric nerves together with interstitial cells of Cajal (ICC) form complex control systems.

Networks of interstitial cells of Cajal embedded in the musculature of the gastrointestinal tract are involved in the generation of electrical pacemaker activity for gastrointestinal motility. This pacemaker activity manifests itself as rhythmic slow waves in membrane potential, and controls the frequency and propagation characteristics of gut contractile activity. Identification of the pacemaker of gut motility will aid in the elucidation of the pathophysiology of intestinal motor disorders, and provide a target cell for pharmacological treatment.

The principal components of the enteric nervous system are two networks or plexuses of neurons, both of which are embedded in the wall of the digestive tract and extend from esophagus to anus:

- The *myenteric plexus* is located between the longitudinal and circular layers of muscle in the tunica muscularis and, appropriately, exerts control primarily over digestive tract motility.
- The *submucous plexus*, as its name implies, is buried in the submucosa. Its principal role is in sensing the environment within the lumen, regulating gastrointestinal blood flow and controlling epithelial cell function. In regions where these functions are minimal, such as the esophagus, the submucous plexus is sparse and may actually be missing in sections.

In addition to the two major enteric nerve plexuses, there are minor plexuses beneath the serosa, within the circular smooth muscle and in the mucosa.

Within the enteric plexuses are three types of neurons, most of which are multipolar:

- *Sensory neurons* receive information from sensory receptors in the mucosa and muscle. At least five different sensory receptors have been identified in the mucosa, which respond to mechanical, thermal, osmotic, and chemical stimuli.

  Chemoreceptors sensitive to acid, glucose, and amino acids have been demonstrated which, in essence, allow "tasting" of luminal contents. Sensory receptors in muscle respond to stretch and tension. Collectively, enteric sensory neurons compile a comprehensive battery of information on gut contents and the state of the gastrointestinal wall.
- *Motor neurons* within the enteric plexuses control gastrointestinal motility and secretion, and possibly absorption. In performing these functions, motor neurons act directly on a large number of effector cells, including smooth muscle, secretory cells (chief,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_186,

parietal, mucous, enterocytes, pancreatic exocrine cells), and gastrointestinal endocrine cells.
- *Interneurons* are largely responsible for integrating information from sensory neurons and providing it to ("programming") enteric motor neurons.

Enteric neurons secrete an intimidating array of neurotransmitters. One major neurotransmitter produced by enteric neurons is acetylcholine. In general, neurons that secrete acetylcholine are excitatory, stimulating smooth muscle contraction, increases in intestinal secretions, release of enteric hormones and dilation of blood vessels. Norepinephrine is also used extensively for neurotransmission in the gastrointestinal tract, but it derives from extrinsic sympathetic neurons; the effect of norepinephrine is almost always inhibitory and opposite to that of acetylcholine.

Two fundamental patterns of motility are conducted by the digestive tube: propulsion, where food must be propelled along the length of the digestive tube for absorption through peristaltic waves and mixing of the ingested materials that simply propelled through the digestive tube. Congenital and acquired derangements in the structure or function of the enteric nervous system are well recognized as causes of digestive tract disease. Examples include small intestinal motility disorders, gastric outlet obstructions, and megacolon.

Normal and Disordered Motility

Gastrointestinal contractions can be broadly divided into three basic types: phasic, tonic, and ultrapropulsive contractions.

Phasic contractions are relatively brief and may be propagated or nonpropagated. Nonpropagated phasic contractions serve to mix the intestinal contents, allowing maximum exposure of the mucosa to luminal contents.

Tonic contractions are prolonged contractions lasting minutes to hours. The gastric fundus and colon exhibit tonic contractions to promote gradual transfer of luminal contents from areas of higher to lower intraluminal pressure.

Ultrapropulsive contractions consist of giant migrating contractions in the antegrade and retrograde direction to move the luminal contents rapidly over relatively large distances.

Intestinal motility disorders apply to abnormal intestinal contractions, such as spasms and intestinal paralysis. This phrase is used to describe a variety of disorders in which the gut has lost its ability to coordinate muscular activity because of endogenous or exogenous causes. GI motility and functional bowel disorders, such achalasia, gastroesophageal reflux disease, gastroparesis, functional dyspepsia, irritable bowel syndrome, colonic inertia, pelvic floor dyssynergia, constipation, and fecal incontinence, comprise high percentage of GI problems for which patients seek health-care advice and management. GI motility disorders affect patients by not only causing symptoms and posing a heavy burden of illness but cause decreased quality of life with decreased work productivity.

Examples of gastrointestinal motility disorders in kids and teens include: Chronic intestinal pseudo-obstruction, Gastroesophageal reflux (GER), Gastroesophageal reflux disease (GERD), Hirschsprung's disease, Constipation, Diarrhea, and Intestinal neuronal dysplasia (IND).

Gastrointestinal motility is defined by the movements of the digestive system, and the transit of the contents within it. When nerves or muscles in any portion of the digestive tract do not function in a strong coordinated fashion, a person develops symptoms related to motility problems. These symptoms may include:

- Heartburn
- Dysphagia
- Abdominal distention and pain
- Nausea
- Vomiting
- Constipation
- Diarrhea

Examples of functional GI and/or motility disorders include:

- Chronic abdominal pain
- Constipation
- Cyclic vomiting syndrome
- Diarrhea
- Dyspepsia
- Encopresis (fecal soiling)
- Functional fecal retention
- Gastroesophageal reflux (GER)
- Gastroesophageal reflux disease (GERD)
- Gastroparesis
- Hirschsprung's disease
- Incontinence
- Intestinal pseudo-obstruction
- Irritable bowel syndrome (IBS)

Dysmotility of the Small Intestine and Colon

The prevalence of small intestinal dysmotility varies according to the underlying disease, and it seems to be less frequent than esophageal, gastric, or colonic dysmotility.

1. *Primary dysmotilities are rare compared with secondary dysmotilities.* They may be familial or sporadic.
   - Familial visceral myopathies
   - Congenital neuropathic motility disorders
     - *Disorders of colonization* by migrating neural crest derived neurons, as in Hirschsprung disease
     - *Disorders of differentiation* of enteric nerves, as in intestinal ganglioneuromatosis
     - *Disorders of survival or maintenance of enteric nerves*, as in hypoganglionosis and possibly congenital achalasia
   - *Childhood visceral myopathies*
2. *Secondary Causes of Small Intestinal Dysmotility*
   - Diabetes mellitus
   - Thyroid and parathyroid disease: Hyperthyroidism, Hpothyroidism, and *Hypoparathyroidis*
   - Celiac disease
   - Anorexia nervosa and bulimia
   - Drug-induced changes in small intestinal motility

Clinical Manifestations

Severe dysmotility of the esophagus, colon, and even the stomach occur much more frequently than dysmotility of the small intestine. Isolated severe small intestinal dysmotility is very unusual. Small intestinal dysmotility is generally associated with dysmotility in other parts of the digestive tract. With a few exceptions, most patients with small intestinal dysmotility have similar clinical manifestations regardless of the underlying causes. The spectrum of clinical manifestations varies widely. At one end, the patient may be asymptomatic, and at the other, the patient may have recurrent symptoms and signs of small intestinal obstruction, termed *chronic small intestinal pseudo-obstruction.*
The patient may have recurrent symptoms of:

1. Postprandial cramping.
2. Periumbilical and epigastric abdominal pain.
3. Abdominal bloating.
4. Easy satiety.
5. Anorexia, weight loss.
6. Nausea and vomiting.
7. Diarrhea can occur in patients with bacterial overgrowth and malabsorption.
8. In severe cases, chronic intestinal pseudo-obstruction syndrome can occur.

The findings on physical examination vary according to the severity of the symptoms. Patients may be cachectic and malnourished because they are unable to take in adequate nutrients, or they may have malabsorption as a consequence of bacterial overgrowth in the small intestine. The abdomen may be distended and mildly tender. The bowel sounds are inactive and infrequent in patients with smooth muscle dysfunction, but they are hyperactive and high-pitched in those with myenteric plexus dysfunction. Borborygmi may be detected in some cases.

In less symptomatic patients, the abdominal examination findings may be normal. In those with chronic intestinal pseudo-obstruction, during an obstructive episode, the abdominal examination findings may be indistinguishable from those of true mechanical obstruction.

Extraintestinal manifestations may be detected in some patients, depending on the underlying disease. Megacystis and megaureter are common in type I familial and childhood visceral mypopathies and may be associated with urinary retention and infection.

Mydriasis, ptosis, and external ophthalmoplegia may be seen in certain forms of familial visceral myopathy, and ataxia, dysautonomia, and neurological symptoms in some forms of visceral neuropathy.

Diagnostic Studies

1. Blood Studies
   (a) Blood Tests: CBC for macrocytosis, anemia, and malnutrition
   (b) Thyroid function tests: T4, TSH
   (c) Blood glucose for diabetes
   (d) Chemistry for malabsorption
   (e) Liver and muscle enzymes and isoenzymes for muscular dystrophy
2. Radiologic Studies
   (a) KUB: gaseous distension. Dilated loops and other anomalies
   (b) Enteroclysis
   (c) Barium enema and intravenous pyelography
3. Whole-gut transit with radiopaque markers
4. Radioactive isotope transit by scintigraphy
5. Small Intestinal Manometry
6. Colonic Manometry

Treatment

Drug Therapy

Drugs that stimulate intestinal motility in normal subjects (e.g., bethanechol, neostigmine, metoclopramide,

erythromycin, tegaserod, prucalopride) have no beneficial effects in patients with small intestinal dysmotility. No information is available on the use of domperidone for small bowel dysmotility. Octreotide, and somatostatin analog, stimulated intestinal motility, possibly reduced bacterial overgrowth, and relieved abdominal symptoms.

Symptomatic and Supportive Treatment

Abdominal pain, bloating, nausea, and vomiting in patients with small intestinal dysmotility are often related to eating. Most of these symptoms can be minimized by manipulating the size, nature, and frequency of meals. When patients still feel full several hours after the first meal, it is important that they do not force themselves to eat subsequent meals to avoid aggravating their symptoms and that they restrict their oral intake to fluids for the rest of the day. In patients with chronic intestinal pseudo-obstruction, recurrent symptoms and signs of intestinal pseudo-obstruction may occur despite those measures.

Medical and Nutritional Approaches

In these situations, nasogastric suction and intravenous fluids are needed when obstructive symptoms develop. When obstructive symptoms and pain persist or occur several times a week despite dietary manipulation, long-term parenteral nutrition is the only treatment that will relieve symptoms and improve nutrition.

Constipation is common in patients who also have colonic involvement. It is important to make certain that the patient has a good bowel movement at least once every few days because constipation tends to increase the symptoms of intestinal dysmotility. Enemas, milk of magnesia, and other laxatives are to be used to relieve the discomfort and constipation.

Those with severe small intestinal dysmotility should avoid bulk-forming laxatives because they increase the load on an inefficient intestine and exacerbate symptoms.

Surgical Treatment

Patients with dysmotility limited to short segments of the small intestine, such as those with megaduodenum, have a better prognosis than those with dysmotility throughout the length of the bowel because the dysfunctional segment can be resected or bypassed.

Venting decompression by percutaneous jejunostomy or minilaparotomy or laparoscopy relieves symptoms and reduces the rate of hospitalization for recurrent exacerbations of pseudo-obstruction.

Any unnecessary surgery should be avoided in these cases because it can create adhesions and additional difficulties.

Complications

- Complications of intestinal motility disorders vary greatly depending on the type of disorder considered.
- Intestinal pseudo-obstruction is often associated with a high morbidity and mortality, depending on associated anomalies.
- Constipation may have a severe complication, impaction.
- Fecal incontinence may cause psychological problems in affected children and have major impact on daily activity and school performance.

Intestinal Pseudo-obstruction

Chronic intestinal pseudo-obstruction is a severe disorder characterized by disabling and potentially life-threatening condition over time.

This condition is characterized by sporadic intestinal obstruction secondary to ileus. There are signs and symptoms of intestinal obstruction but without anatomic or histologic abnormality. It may mimic Hirschsprung disease. The definitive cause of intestinal pseudo-obstruction remains unknown.

The effect of this condition is evident in utero, with fetal abdominal distention and maternal polyhydramnios. After birth, there is failure to pass meconium with repeated vomiting. The condition may be associated with urinary stasis and retention. The condition has to be differentiated from other causes of intestinal obstruction.

Intestinal pseudo-obstruction is defined as a chronic condition, often unrecognized, that represents disorders of the enteric nervous system or the smooth muscle. The disease continues to progress with no definite response to medical therapy. Clinical features are nonspecific and include vomiting in an infant with abdominal pain and distention.

The diagnosis is based on the evidence of recognized typical clinical features, radiological evidence of distended bowel loops with air-fluid levels, and the exclusion of any organic cause for intestinal obstruction. However, because

of lack of high index of suspicion, the diagnosis is often delayed for years resulting in worsening the overall clinical outcome making the prognosis fairly poor.

Barium contrast studies reveal dilated hypomotile intestine with no evidence of mechanical obstruction. Full-thickness intestinal biopsies are helpful in identifying the abnormalities as neuronal or muscular.

Surgical measures are needed in case of urinary tract involvement. Medical therapies have been used, but results were suboptimal.

The majority of patients require parenteral nutrition and if this fails, small bowel transplantation with its guarded prognosis remains the only therapeutic option.

Megacystis-Microcolon-Intestinal Hypoperistalsis Syndrome

Megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS) is a rare congenital, fatal autosomal recessive disorder of unknown etiology that was first described in 1976 by Berdon et al. in a live newborn girl.

MMIHS was originally thought to affect only females, but later on, it was reported to also affect males with a reported female-to-male ratio of 3:1. The condition is characterized by abdominal distention secondary to a distended nonobstructed bladder, microcolon, and normal ganglion cell distribution in the intestine.

The exact etiology of this syndrome remains unknown. The pathophysiology and site of the neuromuscular function disturbances in the gut and bladder are as yet unclear.

The condition may be suspected prenatally with the presence of prominent renal pelvis and bilateral hydronephrosis. It is important that MMIHS be differentiated in utero from posterior urethral obstruction due to urethral atresia or posterior urethral valve. In utero decompression by percutaneous catheter drainage under sonographic guidance may be considered.

MMIHS is a rare cause of functional gastrointestinal and genitourinary obstruction in the newborns of unknown pathogenesis whose genes map to 15q24. MMIHS is well recognized for being the most severe form of functional intestinal obstruction in the newborn.

No specific mechanical obstruction is demonstrated in either the genitourinary or gastrointestinal system.

Clinical Features

MMIHS is a recognized cause of intestinal obstruction in the newborn. The clinical manifestations are similar in broad terms to those of functional intestinal obstruction due to other causes with abdominal distention, vomiting, and delayed or absent bowel movements. The abdominal distention results primarily from distention of the urinary bladder.

MMIHS is a rare cause of functional gastrointestinal and genitourinary obstruction in the newborns. Prenatal diagnosis is warranted for optimal prenatal counseling and postnatal treatment.

MMIHS is associated with both polyhydramnios and oligohydramnios. The clinical manifestation may vary accordingly with predominance of renal failure in cases associated with oligohydramnios.

The patient may also present with lax abdominal musculature, incomplete intestinal rotation, and bilious vomiting. The signs and symptoms of MMIHS vary with each individual patient, presenting a spectrum of severity.

Diagnosis

Diagnosis of MMIHS is possible during antenatal routine visits. Bladder dilatation on fetal ultrasound is a reliable sign for prenatal diagnosis prior to 25 weeks' gestation.

The diagnosis is suggested by radiographic evaluation and detection of an enlarged bladder and bilateral hydronephrosis, hydroureter, and microcolon. Barium enema examination will demonstrate the thin-walled, unused, and displaced microcolon (*Fig. 186.1*).

The cecum is located in the left upper quadrant, suggestive of malrotation. In view of the poor intestinal motility, the contrast material will remain in the bowel for an extended period of lime. Voiding cystourethrogram demonstrates massively distended urinary bladder (*Fig. 186.2*). It may also reveal an associated vesicouretric reflux.

The clinical, radiologic, and surgical findings are relatively constant and characteristic enough to allow prompt diagnosis. MRI is safe, accurate, and can be used for early prenatal diagnosis.

The most frequent findings are massively distended urinary bladder and microcolon with normal neuronal innervation. Electron microscopy of bowel and bladder shows vascular degenerative changes in the smooth muscle cells with abundant amounts of connective tissue between muscle cells.

The diagnosis of MMIHS is highly considered by antenatal detection of enlarged bladder in the second trimester and polyhydramnios in the third trimester.

Barium enema reveals microcolon in a newborn with megacystis-microcolon-intestinal hypoperistalsis syndrome

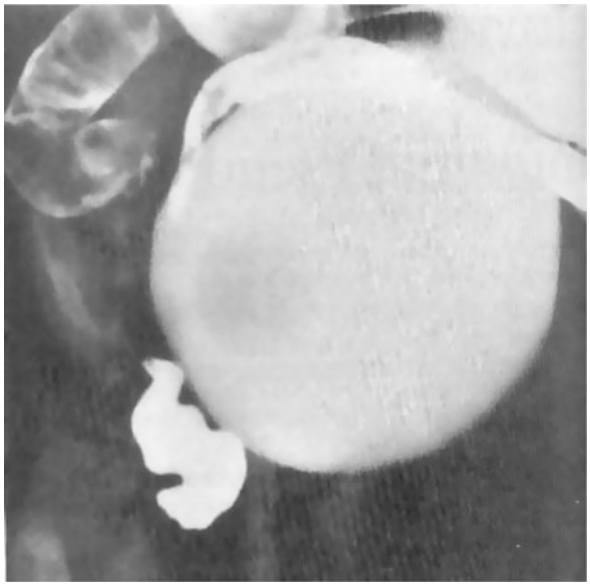

Figure 186.2
Voiding cystourethrogram in a baby with MMIHS at 4 weeks of age demonstrates massively distended bladder

Rectal biopsy is usually obtained to rule out Hirschsprung disease. Ganglion cells have also been present in all reported cases, frequently with areas of hypoganglionosis.

Figure 186.3
Histologic findings in a biopsy from ileum of a baby with MMIHS showing prominent ganglia cell groups in the submucosa (*small arrow*) and in the myenteric plexus (*large arrow*). Hematoxylin and eosin, ×100

Management

Although the urinary tract distention appears to resolve once open drainage has been established, the gastrointestinal tract does not function properly despite the use of various surgical and pharmacologic maneuvers.

Improvement of the nutritional status of affected infants with total parenteral nutrition and effective management of sepsis will ensure a better survival of patients with MMIHS.

A number of prokinetic drugs and gastrointestinal hormones have been tried without a real success (*Fig. 186.3*).

MMIHS is generally incompatible with long-term survival, and death usually occurs in infancy. Intrauterine death has also been reported. Out of the 59 cases reported with MMIHS by the year 1992, 51 (86.4%) died. There is no cure for the disease; however, with increasing recognition of more survivals of patients with MMIHS, it is anticipated that affected patients will gain the benefits of various forms of intestinal diversions and bladder decompression to allow the dilated upper urinary tracts to recover. Young and associate reported one girl with MMIHS still living at age 14 years.

Despite surgical intervention, management generally has been unsuccessful and nutrition must be maintained in most cases by total parenteral nutrition. Recently favorable reports highlighted the favorable outcome in MMIHS combined living–related segmental liver and bowel transplantation.

187 Acute Gastroenteritis in Infants and Children

Asaad M. A. Abdullah Assiri

Definition

Acute gastroenteritis is generally defined as a decrease in the consistency of stools (loose or liquid) and/or an increase in the frequency of evacuations (typically $\geq$3 in 24 h), with or without fever or vomiting. Diarrhea typically lasts less than 7 days and not longer than 14 days. However, a change in stool consistency vs. pervious stool consistency is more indicative of diarrhea than stool number, particularly in the first months of life.

Epidemiology and Incidence

In developing countries, acute gastroenteritis is a common cause of death in children under 5 years of age and that is caused by a wide variety of pathogens. In developed countries death from acute gastroenteritis is less common. Most of acute gastroenteritis is caused by viruses like rotaviruses, calciviruses, astroviruses, and adenoviruses; viral gastroenteritis affects children with two epidemiological patterns. In endemic area it affects children at all ages. Rotavirus is the leading cause of severe diarrheal disease in infants and young children worldwide. About 600,000 children die every year from rotavirus, with more than 80% of all rotavirus-related deaths occurring in resource-poor countries in south Asia and sub-Saharan Africa. Rotavirus-related deaths represent approximately 5% of all deaths in children younger than 5 years of age worldwide. Acute gastroenteritis secondary to rotavirus is severe in infants less than 6 months of age. It has been estimated that 500 million episodes of diarrhea per year occur among infants in Asia, Africa, and Latin America with more than five million deaths.

Risk Factors

Diarrhea-causing pathogens are usually transmitted through the fecal–oral route. Risk factors for this type of transmission include improper disposal of feces and lack of proper hand washing following defecation and feces contact before handling food. Other risk factors include improper food hygiene, inadequate food refrigeration, food exposure to flies, and consumption of contaminated water. Multiple host factors that determine the level of illness once exposure to infectious agents has occurred include age, personal hygiene, gastric acidity and other barriers, intestinal motility, enteric microflora, immunity, and intestinal receptors.

Pathology

Some infectious agents cause mucosal inflammation, which may be mild or severe. Bacteria such as enteroadherent or enteropathogenic *Escherichia coli* and viruses such as rotaviruses and Norwalk agent can cause minimal to moderate inflammation. Bacteria that destroy enterocytes such as *Shigella*, enteroinvasive *E. coli*, the parasite *Entamoeba histolytica*, and bacteria that penetrate the mucosa such as *Salmonella*, *Campylobacter jejuni*, and *Yersinia enterocolitica* result in moderate to severe inflammation with or without ulceration. Ingestion of preformed toxin produced by bacteria such as *Bacillus cereus*, *Staphylococcus aureus*, and *Clostridium perfringens* can result in acute jejunitis.

Causes of Acute Gastroenteritis

Acute gastroenteritis is either caused by viruses like rotaviruses, novoviruses (Norwalk like viruses), enteric adenoviruses, caliciviruses, enteroviruses, or bacteria like *E. coli*, non-typhoid *Salmonella* spp., *C. jejuni*, *Shigella* spp., *Y. enterocolitica*, and *Vibrio cholerae*; other pathogens that cause acute gastroenteritis in children are protozoa like *Giardia lamblia*, cryptosporidium, and *E. histolytica*.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_187,

Causes of Acute Gastroenteritis in Children
Viruses (about 70%) • Rotaviruses • Noroviruses (Norwalk-like viruses) • Enteric adenoviruses • Caliciviruses • Astroviruses • Enteroviruses
Bacteria (10–20%) • *C. jejuni* • Non-typhoid *Salmonella* spp. • Enteropathogenenic *E. coli* • *Shigella* spp. • *Y. enterocolitica* • Shiga toxin producing *E. coli* • *Salmonella typhi* and *Salmonella paratyphi* • *V. cholerae*
Protozoa (<10%) • *Cryptosporidium* • *G. lamblia* • *E. histolytica*

Pathophysiology

Pathogens produce diarrhea by three basic mechanisms:

(1) Enterotoxins that induce active intestinal secretion (*V. cholerae*, *S. aureus*, *B. cereus*, *Clostridium botulinum*, and rotavirus)
(2) Cytotoxic mediators (most bacteria, parasites)
(3) Invasins promoting endocytosis, with subsequent tissue invasion and mucosal injury [*Shigella*, *Salmonella*, enteroinvasive *E. coli* (EIEC)]

In addition to direct effects by microorganisms and their products, enteropathogens induce intestinal damage indirectly via the mucosal inflammatory response, which involves secretion of various powerful mediators of secretion and apoptosis.

On the basis of these three mechanisms, acute infections present as watery, noninflammatory diarrheal syndromes or inflammatory diarrheal syndromes. The majority of watery, noninflammatory diarrhea cases are self-limited diseases characterized by low-grade fever, nausea, vomiting, large-volume diarrhea, and the absence of blood and leukocytes in the stools. This presentation is typically reported in patients infected with enterotoxigenic *E. coli*, *V. cholerae*, clostridial and staphylococcal food poisoning, rotavirus, Norwalk virus agent, *G. lamblia*, and *Cryptosporidium*. On the other hand, the inflammatory diarrheal syndrome is characterized by frequent, small-volume stools that may contain blood and leukocytes, tenesmus, fever, and severe abdominal pain. The most common microorganisms causing this syndrome include *Salmonella*, *Shigella*, *Campylobacter*, enterohemorrhagic *E. coli*, *Clostridium difficile*, *E. histolytica*, and *Yersinia*.

Mechanisms of Acute Gastroenteritis

The majority of bacterial pathogens secretes enterotoxins that selectively activate enterocyte intracellular signal transduction and also affect cytoskeletal rearrangements with subsequent changes in water and electrolyte fluxes across enterocytes upregulations of these mechanism results in inhibition of NaCl paired transport and increased efflux of chloride resulting in secretion and loss of water into the intestinal lumen.

Enterotoxigenic *E. coli* (ETEC) colonizes and attaches its fimbriae to the small bowel enterocyte and leads to hypersecretion of fluids and electrolytes into the small intestine. Both ETEC and *V. cholerae* toxin activate adenyl cyclase and lead to an increase in intracellular cyclic guanosine monophosphate (CGMP).

Non-typhoid salmonella mainly invades the distal ileum and produces toxigenic diarrhea as well as inflammation of the intestine. *Shigella* toxin has both secretory and cytotoxic effects. It invades the colonic mucosa and causes superficial ulceration and increases motility of the large bowel.

Another important pathogen that causes diarrhea is *G. lamblia*, which attaches itself to the small bowel mucosa. *E. histolytica* causes diarrhea through invasion of colonic mucosa.

Viral Gastroenteritis

Viral Pathogens

The viral pathogens that cause acute gastroenteritis represent four distinct viral families. Rotaviruses are members of the family Reoviridae and have a segmented, double-stranded RNA genome enclosed in a triple-layered capsid. Noroviruses and sapoviruses constitute two genera of the family Caliciviridae, with a positive-sense RNA genome inside a capsid composed of a single structural protein. Astroviruses, of the family Astroviridae, are also non-enveloped viruses with a positive-sense RNA genome, but their capsid is composed of several structural protein subunits. Enteric adenoviruses represent a unique

subgroup of the family Adenoviridae and have a double-stranded DNA genome. Each of these viruses also can be distinguished by electron microscopy by their characteristic morphologic features.

Rotavirus

Rotaviruses are 70-nm icosahedral viruses that belong to the family Reoviridae. Seven rotavirus serogroups (serogroups A to G) are described. Most human pathogens belong to groups A, B, and C. Group A rotaviruses are the most important cause of acute diarrhea.

The virus infects the mature villus epithelial cells of the small intestine. Dehydration and electrolyte disturbances are the major sequelae of rotavirus infection and occur most often in the young children. Rotavirus infection is usually localized to the small intestine; however, recent studies reported antigenemia or viremia in children with rotavirus diarrhea. Rarely, rotavirus may involve the extraintestinal sites, including the respiratory tract, liver, kidney, lymph nodes, and central nervous system.

Group A rotaviruses are the most important cause of severe dehydrating diarrhea in infants and children. On a global scale, it is estimated that there are 125 million cases of rotavirus diarrhea, including eight million cases of severe diarrhea and 600,000 deaths.

Children between the ages of 3 months and 3 years are most susceptible to infection. Because immunity to reinfection is not complete, rotavirus disease can also occur in otherwise healthy adolescent, as well as in children who are immunosuppressed.

Infection is transmitted primarily through the fecal–oral route in a highly efficient manner that owes to the large amount of viruses shed in feces. Food and waterborne transmission is not common, but has also been reported. The incubation period ranges from 1 to 3 days and is followed by the abrupt onset of fever, malaise, vomiting, and watery diarrhea. Duration of illness varies from 3 to 8 days. Severely immunocompromised children may have a protracted course. Dehydration, with associated mild elevation of blood urea nitrogen (BUN) and metabolic acidosis, occur most often in young children. Dehydration and electrolyte disturbances are the major sequelae of rotavirus infection and occur most often in the young children.

If specific diagnosis of rotavirus infection is needed, enzyme immunoassays, with >90% sensitivity and specificity, are commercially available. Other diagnostic methods, including immune electron microscopy, nucleic acid hybridization with or without reverse transcriptase and polymerase chain reaction (RT-PCR), RNA electrophoresis, and cell culture isolation, are not as widely available.

Noroviruses

Norovirus is the new name for a genus of the family Caliciviridae that includes a genetically diverse, but related, group of non-enveloped, single-stranded RNA viruses that are a major cause of acute gastroenteritis in humans.

Typically, after an incubation period of 12–48 h, children will experience the acute onset of nausea, vomiting, less diarrhea, and low-grade fever. The symptoms last for 12–60 h, after which there is complete resolution of the illness.

The most widely used assay at present for diagnosing norovirus infection is RT-PCR, which can detect 10^2 to 10^4 viral particles/mL of stool.

Sapovirus

Sapporo virus, a calicivirus with classic morphology, is the prototype of the newly named genus *Sapovirus*.

Sero-prevalence studies indicate that nearly all children have acquired Sapovirus antibodies by the age of 12 years, and these antibodies seem to confer long-term resistance to reinfection. Infection is most likely transmitted through the fecal–oral route. Oysters and cold foods have also been implicated as vectors of transmission. Following an incubation period of 24–72 h, children develop vomiting and diarrhea acutely, with associated fever and respiratory symptoms.

The symptoms, which resemble those of a mild rotavirus infection, last for 24–48 h. The infection can be diagnosed by direct electron microscopy, given the large quantities of viruses shed in feces and their distinctive appearance.

Astroviruses

Human astroviruses primarily cause acute gastroenteritis in children, who are immunocompromised (HIV-infected children and bone marrow transplant recipients). Astrovirus antibodies are acquired early in childhood, with antibody prevalence rates in the range of 70% by school age. A typical case of astrovirus gastroenteritis in an immunocompetent child consists of a mild, watery

diarrhea, vomiting, fever, and abdominal pain, which begin after an incubation period of 1–4 days. The symptoms last 2–3 days. In some immunocompromised children, protracted and severe illness may occur.

Because astroviruses are shed in large quantities during infection and because at least 10% of the viruses display a distinctive surface star, diagnosis can be made by direct electron microscopy.

Enteric Adenovirus

Enteric adenovirus infections have a worldwide distribution, primarily infecting children under the age of 2 years.

After an incubation period of about 7 days, children develop watery diarrhea and less commonly vomiting. Respiratory symptoms and low-grade fever may also develop during the course of illness. Infection can range from mild to severe, but the majority of cases are mild. Viral shedding in stool lasts for up to 2 weeks, substantially longer than for rotavirus. The clinical course may be complicated by prolonged lactose intolerance and malabsorption. The preferred method to detect the presence of enteric adenovirus in stool is the enzyme immunoassay.

Bacterial Gastroenteritis

Bacterial Infections

Salmonellosis

The most common form of salmonellosis is acute gastroenteritis, because the organisms are frequently ingested in foods that have been contaminated by animal feces or by human carriers. The syndrome has often been referred to as salmonella food poisoning. The incubation period varies from 18 to 36 h, although it may be as short as 8 h or as long as 3 days. The first symptoms are nausea and vomiting; abdominal pain is frequent and may be very mild or severe. Fever may be absent, or of low or high degree. Chills occasionally occur. There may be only mild diarrhea; in severe cases the diarrhea is often profuse and bloody. In very young children the disease may cause severe watery diarrhea. Symptoms are present for 3–4 days on the average, although they may last only a day or persist for weeks. Rarely children may develop chronic diarrhea which is marked by remissions and exacerbations of marked diarrhea, fever, and abdominal pain. The white cell count is usually normal, but it might be elevated. Blood cultures are rarely positive; the stool may contain blood and leukocytes if the diarrhea is severe. Septic complications are uncommon except in young children. The carrier state appears in some instances without relation to the severity of the acute episode, and in 10–20% of the cases salmonellae may be excreted for weeks or months after acute gastroenteritis. Acute gastroenteritis with a fatal outcome is most frequent in small infant with impaired immunological defenses.

Shigellosis

The infection is restricted to the large bowel. In some patients the lesions may involve the terminal ileum, but with less inflammation than in the colon.

The incubation period of shigellosis is usually 2–4 days, but it may be as long as a week. Commonly acute gastroenteritis secondary to shigellosis is mild; the classic manifestations of bloody diarrhea, high fever, abdominal pain, and leukocytosis are lacking in the majority of infants and children. In some, the disease is moderately severe, with an abrupt onset, high fever, abdominal pain, vomiting, and frequent, loose, watery stools; in a small group of children, the symptoms are severe and complicated with marked dehydration and shock from loss of fluids and electrolytes. The absorption of large amounts of shigella toxins is thought to play a role in the severe cases.

Yersinia

Y. enterocolitica infection (as its name indicates) is characterized by an enterocolitis, similar to that caused by *Salmonella*, *Shigella*, *Campylobacter*, and invasive *E. coli*. The diarrhea may be mild and self-limiting or it may be severe, with high fever (39°C or greater), vomiting, abdominal pain, and, infrequently, blood in the stools. The organisms may invade the mesenteric lymph nodes, mimicking an acute appendicitis in older children.

C. jejuni

Overall, the clinical picture of *C. jejuni* gastroenteritis in infant and children is characterized by diarrhea which is usually present at the onset of fever and abdominal pain; the diarrhea is watery, profuse, and foul smelling. After 1–3 days of diarrhea, many children have blood-streaked stools. The abdominal pain is periumbilical and colicky and may precede other symptoms. The pain may simulate that experienced with acute appendicitis, mesenteric

adenitis, intussusceptions, or visceral perforation. Vomiting is present in less than 30% of cases, and dehydration is unusual. Fever is variable, usually present, and of low grade; it may be present initially. Bacteremia is rare. The diarrhea usually lasts only 3–5 days.

E. coli

E. coli are gram-negative, lactose-fermenting motile bacilli of the family Enterobacteriaceae. Currently, 171 somatic (O) and 56 flagellar (H) antigens are recognized. Six distinct categories of *E. coli* are currently considered enteric pathogens: enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enterohemorrhagic *E. coli* (EHEC), diffusely adherent *E. coli* (DAEC), and enteroaggregative *E. coli* (EAggEC).

The diagnosis of diarrheagenic *E. coli* relies on isolation from stool and subsequent differentiation from commensal *E. coli* either by using genetic probes or by phenotypic assays. With the exception of *E. coli* O157:H7, assays for detection are not routinely available in clinical laboratories.

Enteropathogenic E. coli: (EPEC)

This was the first group of *E. coli* species shown to be pathogens for humans and has been responsible for devastating outbreaks of nosocomial neonatal diarrhea and infantile diarrhea in virtually every corner of the globe. Species of EPEC are distinguished from other *E. coli* species by their ability to induce a characteristic attaching and effacing lesion in the small intestinal enterocytes and by their inability to produce Shiga toxins.

Clinical Manifestations

The infective dose for EPEC is high ($\approx 10^9$ colony-forming units). EPEC causes a self-limited watery diarrhea with a short incubation period (6–48 h). There may be associated fever, abdominal cramps, and vomiting, and EPEC is a leading cause of persistent diarrhea (lasting 14 days or longer) in children.

Enterotoxigenic E. coli: (ETEC)

Species of ETEC are an important cause of diarrheal disease in humans and animals worldwide. Their pathogenicity is related to the elaboration of one or more enterotoxins that are either heat stable (ST) or heat labile (LT) without invading or damaging intestinal epithelial cells.

Clinical Manifestations

Like EPEC, ETEC requires a relatively high inoculum and a short incubation period (14–30 h). The cardinal symptom is watery diarrhea, sometimes with associated fever, abdominal pain, and vomiting. In its most severe form, ETEC can cause cholera-like diarrhea, even in adolescents. The illness is typically self-limited, lasting for less than 5 days, with few cases persisting beyond 3 weeks. Infection with ETEC has also been associated with short- and long-term adverse nutritional consequences in infants and children.

Enteroinvasive E. coli: (EIEC)

Presenting with bloody mucosy diarrhea associated with fever and abdominal pain, it also causes hemorrhagic colitis.

This group consists of invasive *E. coli* species that are generally, biochemically, and clinically nearly identical to *Shigella*.

Clinical Manifestations

Like *Shigella*, EIEC can produce dysentery, but watery diarrhea is more common.

Enterohemorrhagic E. coli: (EHEC)

These *E. coli* species produce either one or both phage-encoded potent cytotoxins termed Shiga-like toxin (SLT) I (which is neutralized by antisera to Shiga toxin produced by *Shigella dysenteriae* type I) or SLT II (which is not neutralized) and can cause diarrhea or Hemolytic Uremic Syndrome (HUS). *E. coli* O157:H7 is the prototypic (but not the exclusive) EHEC serotype because it is the predominant SLT-producing *E. coli*.

Clinical Manifestations

Illness with EHEC follows 3–9 days after ingestion of as few as 100 organisms. Colicky abdominal pain and

nonbloody diarrhea are the first symptoms, sometimes associated with vomiting. By the second or third day of illness, diarrhea becomes bloody in approximately 90% of cases, and abdominal pain worsens. Bloody diarrhea lasts between 1 and 22 days (median 4 days). Unlike other infectious causes of blood diarrhea, fever is usually absent or remains low grade. Younger children appear to excrete the organisms longer (median 3 weeks) than older children.

Intestinal complications include rectal prolapsed, appendicitis, intussusceptions, and pseudomembranous colitis. Extraintestinal complications are rare.

The most frightening complication of EHEC infection is HUS. It is usually diagnosed 2–14 days after the onset of diarrhea. Risk factors include young and old age, bloody diarrhea, fever, an elevated leukocyte count, and treatment with anti-motility agents. Two-thirds of children who develop HUS are no longer excreting the organism at presentation.

Diffusely Adhering E. coli: (DAEC)

DAEC was considered a nonpathogenic *E. coli* because early studies failed to find an association between this microorganism and diarrheal disease. However, studies performed during the past 15 years have demonstrated such an association, particularly in children older than 2 years of age.

Clinical Manifestation, Diagnosis

The gastrointestinal symptoms that characterize DAEC infection are practically indistinguishable from those caused by ETEC, with self-limiting watery diarrhea rarely associated with vomiting and abdominal pain. The diagnosis is mainly based on DNA probe technique and on the pattern of adherence of the microorganism on Hep-2 cells.

Enteroaggregative *E. coli*: (EAggEC)

EAggEC are diarrheagenic *E. coli* defined by a characteristic aggregating pattern of adherence to Hep-2 cells and the intestinal mucosa. They have been particularly associated with cases of persistent diarrhea. It has been hypothesized that the aggregating pattern of adherence may be a result of nonspecific, possibly hydrophobic, interaction; therefore, not all organisms meeting the definition of EAggEC may be pathogenic in humans.

Clinical Manifestations

Typically, illness is manifested by a watery, mucoid, secretory diarrheal illness with low-grade fever and little or no vomiting. However, in epidemiologic studies, grossly bloody stools have been reported in up to one-third of patients with EAggEC diarrhea.

Diagnosis and Treatment

Colonization of EAggEC is detected by the isolation of *E. coli* from the stools of patients and the demonstration of the aggregative in the hep-2 assay. Implication of EAggEC as the cause of the patient's disease must be done cautiously, given the high rate of asymptomatic colonization in many populations. If no other organism is implicated in the patient's illness and EAggEC is isolated repeatedly, then EAggEC should be considered a potential cause of the patient's illness. A DNA fragment probe has proven highly specific in the detection of EAggAC strains. A PCR assay using primers derived from the aggregative probe sequence shows similar sensitivity and specificity.

Cholera

The incubation period is between 18 and 120 h. Acute watery diarrhea with no abdominal pain and no fever, the stool looks like rice water, infants and children will develop moderate to severe dehydration with electrolyte imbalance within few hours. The condition might be associated with hypovolemic shock, hypoglycemia, and convulsion. Children, if untreated, may die within few hours of the onset of the disease.

The disease may be associated with acute tubular necrosis, hypokalemia and arrhythmia or hypoglycemic is one of the most common serious complication of cholera.

Aeromonas

Aeromonads are gram-negative facultative anaerobic, motile bacilli. Although their association with gastroenteritis is still somewhat controversial, experimental, clinical, and epidemiologic data continue to support evidence that at least certain strains are involved in diarrheal disease. The highest attack rate appears to be in young children, particularly those under 3 years of age. Aeromonas infections occur more frequently during the warm months.

Acute secretory diarrhea is the most commonly reported, with as many as 20 bowel movements a day. Abdominal pain, fever, nausea, and vomiting are common associated symptoms. Although the infection is usually self-limited (<7 days in duration), dehydration or persistent diarrhea may occur in one-third of the cases. The most common *Aeromonas* species isolated in these cases is *Aeromonas caviae*. Some children with this infection experience abdominal complications secondary to their diarrheal episodes, including failure to thrive, gram-negative sepsis, and HUS.

Plesiomonas

Plesiomonas, originally assigned to the family Vibrionaceae but more recently reassigned to enterobacteriaceae, are gram-negative, facultative anaerobic, motile primarily freshwater organisms, with isolation rates increasing during the warm months. Fish and shellfish, especially if associated with mud or sediment, frequently harbor plesiomonads. However, the microorganism can also be isolated from the feces of asymptomatic animals, including cats and dogs.

Typical symptoms of *Plesiomonas shigelloides* infection include secretory or a colitis/proctitis type of diarrhea (one-third of patients experience frank bloody diarrhea), abdominal pain, nausea, vomiting, and fever. Fatal outcomes of severe gastrointestinal infections without apparent dissemination by *Plesiomonas* have also been described.

Parasitic Gastroenteritis

Giardiasis

Giardia is transmitted via ingesting infective cysts in food and more commonly water, which includes water from swimming pools and direct person to person contact. After ingestion, the parasite inhabits the upper small intestine. Incubation period varies from 5 to 20 days. The parasite adheres to the enterocyte by its ventral sucker. *G. lamblia* multiplies in the small bowel and adhere to the mucosa. It is associated with acute diarrhea, bulky and offensive stool, abdominal distention, and abdominal pain. Chronic giardiasis may be associated with weight loss and malabsorption.

The diagnosis is usually made by demonstrating the trophozoites in fresh stool or small bowel aspirate or demonstration of the cyst in stool or by detecting the antigen in the stool by ELISA. Three stool samples need to be tested before *Giardia* is excluded.

The infection can remain asymptomatic or may present as an acute infection, recurrent or chronic disease. The various manifestations include watery diarrhea, anorexia, nausea, bloating, malaise, abdominal discomfort or pain and in heavy infections, failure to thrive as the organism coats the intestine leading to malabsorption.

Cryptosporidium

Cryptosporidium is a coccidian parasite that infects man, cattle, sheep, dogs, and chickens; it causes severe illness in infants and children with immunodeficiency. Immunocompetent children usually develop a short diarrheal illness that is self-limited. Children with defective cellular immunity or AIDS develop severe protracted diarrhea. The diagnosis of cryptosporidiosis is made by finding the pink-staining oocysts in fecal smear. Cryptosporidium is clinically the most important spore-forming intestinal protozoa. Infection occurs with ingestion of the oocysts.

The incubation period is estimated as 5–7 days and also it might range up to 14 days. The protozoa attaches to the enterocyte resulting in fluid loss and malabsorption. In otherwise healthy individuals, the disease may be asymptomatic or may result in a self-limiting watery diarrhea that could be severe and may be accompanied by abdominal pain, nausea, and vomiting. Some children may have a viral flu like syndrome while others could manifest lactose intolerance. The infection lasts about 7–14 days. Though the clinical disease may last only 2 weeks, lethargy and weakness can persist for a month. In addition, the child may continue to discharge oocysts for several more weeks. The diagnosis is made by finding small oocysts in the stool.

Isospora

Isospora belli is similar to *Cryptosporidium* in most aspects including the type of clinical diseases; it causes eosinophilia which has been reported more commonly.

Entamoeba histolytica

The majority of infection with *E. histolytica* causes no symptoms. *E. histolytica* cause mild diarrhea to severe bloody diarrhea, secondary to amoebic colitis with fever and abdominal pain. Amoebic liver abscess is the most

common extra intestinal form of invasive amebiasis. The diagnosis is made by finding the trophozites in fresh stool specimen.

C. difficile and Antibiotic-Associated Colitis

C. difficile causes pseudomembranous colitis, which usually follows ingestion of ampicillin, amoxicillin, clindamycin, and lincomycin. The colitis is mediated by *C. difficile* toxin. Commonly it presents with watery diarrhea, fever, and abdominal cramps. The diagnosis is made by colonoscopy, which shows punctuated, raised, yellowish white plagues with normal skip areas. The diagnosis also depends on demonstration of *C. difficile* toxin in stool and isolation of *C. difficile* from stool.

Fungal Infections

A healthy child with intact host defense mechanisms is generally not considered susceptible to fungal infections of the digestive tract. As immunosuppressive therapies become more aggressive and myelotoxic regimens more effective, opportunities increase for fungi to invade and establish themselves in humans. Patients disabled from chronic malnutrition and those exposed to intense antimicrobial infection are also susceptible to these organisms. HIV infection and AIDS have produced a group of chronically immunosuppressed children susceptible to a wide range of organisms, including fungi. The digestive tract is not a preferred site of infection in cases of disseminated fungal infection, but certain species are capable of infecting the esophagus, the stomach, or the intestine.

Candidiasis

Candida species are oval cells (4–6 μm in size) that produce by budding. There are at least 80 species, of which 8, including *Candida albicans*, are of GI significance. In disseminated candidiasis, there is widespread involvement of several organs. The major risk factor leading to this serious problem is neutropenia. The liver may be involved in addition to the heart, brain, kidney, lung, spleen, and eye.

Candida infection has been associated with acute watery diarrhea in newborn infants, although its causative role has not been definitely established. *C. albicans* can invade the small bowel and large intestine in terminally ill children.

Aspergillosis

Most cases of invasive *Aspergillus* infection are seen in severely immunocompromised children. In about 20% of such cases of invasive infection, the small and large intestines are involved, in addition to the esophagus and stomach.

Food Poisoning

Food poisoning is acute onset of vomiting and or diarrhea after eating a meal. It affects more than one member of a family. Food poisoning may be caused by pre-existing enterotoxins like *S. aureus* or *B. cereus* in which the incubation period is less than 6 h. Vomiting is the predominant picture of the illness. In contrast, food poisoning secondary to *C. perfringens* is characterized by an incubation period of 8–12 h; the diarrhea is severe but brief (less than 3 days) and it is accompanied with abdominal pain. Another cause of food poisoning is salmonella, in which the incubation period is 12–48 h and it presents with diarrhea, vomiting, and abdominal pain. Vomiting and diarrhea that are associated with neurological manifestations indicate botulism as a cause of food poisoning.

Food poisoning is an acute illness that develops from less than 1 h to 15 or more hours after the ingestion of food contaminated with bacterial, viral, or parasitic pathogens or toxins (biological or chemical).

C. perfringens

This form of food poisoning is caused by a heat-labile, 35 kDa enterotoxin produced by *C. perfringens* type A. The enterotoxin is structural protein of the spore coat and is produced during sporulation. The *C. perfringens* enterotoxin has greatest activity in the ileum and can inhibit glucose transport, damage intestinal epithelial cells, and induce protein loss.

The typical episode of food poisoning by *C. perfringens* is characterized by watery diarrhea and severe crampy abdominal pain that develop 8–24 h after the suspect meal. Vomiting is usually not a prominent symptom. The illness usually resolves within 24–36 h after onset, with no sequelae.

S. aureus

S. aureus food poisoning is associated with coagulase-positive strains that elaborate heat-resistant enterotoxins

A, B, C1, C2, C3, D, and/or E. Most outbreaks are caused by strains that produce enterotoxin A alone or together with enterotoxin D.

Staphylococci grow well in foods that have a high salt (e.g., canned meats) or sugar/protein (e.g., custards and creams) content and can be passed to prepared food by food handlers who carry toxin producing *S. aureus.*

After a short incubation period (1–6 h), affected children develop nausea, vomiting, and diarrhea. Profuse vomiting may result in dehydration and metabolic alkalosis. Despite a stormy acute course, the illness resolves completely in 24–48 h.

B. cereus

B. cereus, an aerobic, spore-forming, gram-positive rod is found in soil and water globally, in most raw foods, and in human carriers (10–40%). The spores are heat-resistant. *B. cereus* is associated with two distinct toxin-mediated types of food poisoning: the emetic syndrome, which has a short incubation period (range 1–6 h), and the diarrheal syndrome, which has a longer incubation period (range 8–16 h). The type of toxin elaborated depends on the type of food contaminated with *B. cereus*, rather than the strain of the organism.

Differential Diagnosis of Infantile Gastroenteritis

The differential diagnosis of acute vomiting and diarrhea includes medical condition like infections which include upper respiratory tract infections and urinary tract infections, cow's milk protein intolerance which can be diagnosed by short-term dietary elimination, and hemolytic uremic syndrome.

Other major differential diagnoses are surgical conditions like pyloric stenosis, which affect children from 2 to 8 weeks and characterized by projectile vomiting, pyloric tumor, which can be felt after the test feeding, and intussusceptions, which are characterized by colicky abdominal pain, sausage-shaped mass in abdomen, red currant jelly stool, and atypical or minimal physical signs in most patients.

Clinical Characteristics

Viral infections cause low grade fever and watery diarrhea without blood. Rotavirus infection occurs throughout the year. The peak age for infection is between 6 months and 2 years, the mode of spread is by the fecal–oral or respiratory route.

Children with bacterial gastroenteritis are more likely to have high fever and may have blood and white blood cells in the stool. Infection with Shiga toxin producing *E. coli* or *S. dysenteriae* may cause hemorrhagic colitis (with severe bloody diarrhea), which might be complicated by hemolytic uremic syndrome. This syndrome is characterized by acute onset of microangiopathic hemolytic anemia, thrombocytopenia, acute renal impairment, and multisystem involvement.

V. cholerae toxin causes chloride and water secretion from the small bowel but does not damage the intestinal mucosa; it results in "rice water" stools that have a high sodium content but do not contain blood or white blood cells.

Ingestion of food containing toxins produced by bacterial contaminants (for example, *S. aureus* in ice cream or *B. cereus* in reheated rice) causes acute onset of vomiting or diarrhea shortly after ingestion of the contaminated food.

Diagnosis can be made clinically. Information should be sought about recent contact with children with gastroenteritis, nature and frequency of stool and vomitus, fluid intake and urine output, and travel and use of antibiotics and other drugs that may cause diarrhea. Chronic constipation is common in children, and overflow fecal incontinence may present as spurious diarrhea. Diarrhea and vomiting are nonspecific symptoms in young children, and the diagnosis of gastroenteritis should be questioned in children with high fever, prolonged symptoms, and suspected surgical cause (such as severe abdominal pain, bilious vomiting, and abdominal mass). Children with diabetic ketoacidosis and inborn errors of metabolism may present with vomiting.

Laboratory Evaluation

A gross examination of the stool specimen should be routine on all patients with diarrhea. Stool that is watery and without mucus or blood is usually caused by an enterotoxin or a virus. Stools with blood or mucus suggest a cytotoxin-mediated or enteroinvasive mucosal inflammatory process. When present, blood is usually mixed evenly into the stool except in the case of *E. histolytica*, in which blood is often on the surface of the stool. Stools that are particularly foul smelling are consistent with Salmonella and other bacteria as well as

Giardia, *Cryptosporidium*, and *Strongyloides*. Stools with little odor suggest an enterotoxin such as cholera toxin or *E. coli*; stool should also be examined for ova, parasites, PH, and reducing substance.

Microscopic examination of stool specimens for evidence of fecal leukocytes indicate that the patient has colitis. If the fecal leukocyte is positive, it is likely that the patient has *Shigella*, *Salmonella*, *Campylobacter*, invasive *E. coli*, and *C. difficile*. Fecal leukocytes are generally not present in stools from patients with diarrhea secondary to viruses. The fecal leukocyte examination is performed by mixing fresh mucus from stool with methylene blue and observing the fresh or dried preparation microscopically. When stool culture is indicated, the specimen should be inoculated onto culture plate media adequate to isolate *E. coli*, *Shigella*, *Salmonella*, and *Campylobacter*. Rotavirus as well as other viruses as astrovirus, calicivirus has been identified by the examination of stool specimens for 70-nm particles by electron microscopy. Commercially available enzyme immunoassay and latex agglutination kits are available to detect rotavirus antigen in stool specimens. Other test that should be done is BUN Creatinine electrolytes urine analyses and urine culture; if fever persists, blood culture should also be done.

Assessment of Dehydration

It is important to assess hydration in gastroenteritis as it determines the immediate management of this condition. Assessment of dehydration is shown in ● *Table 187.1*.

Fluid Therapy in Dehydration

Children with no dehydration or mild dehydration can usually be managed at home, although children with high risk for complications or who cannot be adequately cared for at home should be considered for admission. Children with mild–moderate dehydration who do not tolerate oral fluids should be admitted for observation. Oral rehydration solutions are preferable to other clear fluids for preventing and treating dehydration. Fluids high in sugar (such as cola, apple juice, and sports drinks, which contain $\leq$20 mmol/L sodium and have a high osmolality of 350–750 mOsm/L) may exacerbate diarrhea and should be avoided. Breastfeeding should be continued during acute gastroenteritis and supplemented with an oral rehydration solution if needed.

Although most children with dehydration drink readily, some refuse rehydration solutions because they dislike

Table 187.1
Assessment and management of dehydration

Dehydration(% weight loss)	Clinical signs	Pinch test*	Management
No dehydration	None	Normal (skin fold retracts immediately)	Most can be managed at home; encourage normal diet and fluids (continue breast milk); consider admission if high risk of dehydration (very young, diagnosis in doubt, large losses)
Some dehydration: includes previous categories of mild (5%) and moderate (6–9%) dehydration	Two or more of restlessness or irritability, sunken eyes, thirst (eagerness to drink)	Slow (skin fold visible <2 s)	Some can be managed at home with oral rehydration therapy; some need to be observed and, if therapy is not tolerated or large ongoing losses occur, may need nasogastric or intravenous fluids over 4–6 h; normal diet when tolerated
Severe dehydration (>10%) with or without shock	Two or more of abnormally sleepy or lethargic, sunken eyes, drinking poorly or not at all	Very slow (skin fold visible >2 s)	Check acid base status, urea, electrolytes before intravenous fluids; if shock is present, first resuscitate with intravenous bolus; rehydrate intravenously (enteral fluids have been used) over 4–6 h with regular clinical and biochemical review.

Calculation of ORS maintenance fluid requirements
100 mL per kg per 24 h for the first 10 kg of body weight
Added to: 50 mL/kg/day for the next 10 kg of body weight
Added to: 20 mL/kg/day for remaining kg of body weight

the taste, feel nauseated, or have profuse vomiting. Older children may be afraid of vomiting and parents may perceive that fluids are the cause of vomiting. Alternatively, fluids may be given intravenously. Enteral (oral or nasogastric) and intravenous fluids are equally safe and effective for mild–moderate dehydration, and rehydration can usually be achieved in 4–6 h. The obvious major risk in acute diarrhea is the loss of water and electrolytes with consequent dehydration and possibly even loss of Na homeostasis. Rehydration or maintenance of hydration is therefore the cornerstone of treatment. Until the mid-1960s, this was accomplished almost exclusively via the intravenous route. Subsequently, the expanded understanding of the pathophysiologic events in intestinal transport processes allowed a dramatic change of approach. In fact, it became apparent that enterotoxigenic bacteria such as *V. cholerae* or ETEC leave intact small intestinal mucosal morphology and absorptive functions.

Numerous studies, analyzed in a recent meta-analysis published in the Cochrane Library, had shown convincingly that ORT could safely be used to rehydrate children both in developed and developing countries, with fewer than 5% of children failing ORT and requiring intravenous fluids regardless of the etiology of acute diarrhea. ORSs have proved both safe and effective worldwide in hospital settings and also in the home to prevent dehydration. For about 3 decades, the WHO has recommended a standard formulation of glucose-based ORS with 90 mmol/L of sodium and 111 mmol/L of glucose, with a total osmolarity of 311 mmol/L. However, many in vitro and in vivo studies during the late 1980s and 1990s had consistently shown that lower concentrations of sodium and glucose enhance solute-induced water absorption and might therefore be superior to the solution with a higher osmolarity.

Reduced-osmolarity solutions have concentrations of glucose and Na inferior to those in the traditional WHO solution: glucose ranges between 75 and 100 and Na between 60 and 75 mmol/L; so osmolarity is maintained at 225–260 mOsm/L, and the ratio between glucose and Na close to 1:1. Hypo-osmolar ORSs appear to have the additional advantage of allowing a reduced stool output while being just as effective in obtaining and maintaining rehydration and can be safely given throughout the duration of diarrhea, as shown in both developed and in developing countries. Indeed, in 2002, a large meta-analysis of all published controlled trials comparing low-osmolarity solutions with standard WHO formulas appearing in the Cochrane Library concluded that in children hospitalized for diarrhea, reduced-osmolarity ORS compared to WHO standard ORS is associated with fewer unscheduled intravenous fluid infusions, lower stool volume, and less vomiting, without additional risks of hyponatremia. More recently, evidence has been provided that hypo-osmolar ORS can be used safely and effectively even in newborns and infants.

Accepting all the evidence accumulated until then, in 2002 the WHO announced the adoption of a new ORS formulation consistent with these recommendations, with 75 meq/L sodium, 75 mmol/L glucose, and a total osmolarity of 245 mOsm/L. This hypotonic WHO-ORS is also recommended for use in adults and children with cholera, a condition characterized as we have seen by a marked high stool Na, but further studies are underway to confirm the safety of this indication. A large meta-analysis published in the Cochrane Library confirmed the safety, efficacy, and clinical superiority of low-osmolality ORS.

In constant search of a "super-ORS" that would not only be efficacious for rehydration but also could result in a substantial improvement in reducing the stool volume, in recent years the possibility has been advanced that adding to ORS starches resistant to small intestinal hydrolysis by amylase, could be beneficial by allowing an added stimulus to colonic water absorption due to release of fatty acids by the fermenting microflora. This concept was originally tested in adolescents and adults with cholera, where the solution was found able to reduce fecal fluid loss and to shorten the duration of diarrhea. Subsequently, ORSs with amylase-resistant starches have been tried in children, with conflicting results of interest; initial evidence from the laboratory animal seems to suggest that such solutions may prove even more beneficial if associated with a low-osmolarity ORS.

In summary, ORT with a glucose-based ORS must be viewed as by far the safest, most physiologic, and most effective way to provide rehydration and maintain hydration in children with acute diarrhea worldwide, as recommended by the WHO.

Children with shock require intravenous resuscitation before rehydration.

Children who have mild–moderate dehydration secondary to acute gastroenteritis should have their deficit estimated (3–8%) and replaced with ORS (30–80 m/kg) given "little and often" over 3–4 h, whenever this is practically possible.

Regularly assess the success of rehydration (for example, two hourly). If no improvement in clinical signs of dehydration or worsening signs, consider nasogastric tube or intravenous infusion. The child who was not dehydrated and the child who is no longer dehydrated following rehydration should be allowed free fluids, and be encouraged to drink more than usual.

To prevent primary dehydration or recurrence of dehydration, allow unrestricted fluids (for example, milk or water). Ensure that at least maintenance fluids are taken for assessment, and management of dehydration is shown in Table 187.1.

The most common adverse effect of intravenous cannulation is infiltration at the cannula site, but infection, pain, bleeding, and physical and emotional trauma may also occur. Intravenous therapy is more expensive than oral rehydration therapy and requires hospital admission. Iatrogenic complications – especially electrolyte disturbance due to inappropriate composition, rate of administration, or volume of intravenous fluids – may lead to complications, including hyponatremia with brain injury or death. If rapid intravenous rehydration is used, careful supervision is needed to avoid fluid overload and electrolyte imbalance.

The child who was not dehydrated and the child who is no longer dehydrated following rehydration should be allowed free fluids, and be encouraged to drink more than usual.

Feeding During Acute Gastroenteritis

Carbohydrate (particularly lactose) intolerance is a common complication of viral gastroenteritis as a result of damage to and loss of mature enterocytes containing lactase. Lactose intolerance is usually mild and self-limited and does not require treatment. If lactose intolerance persists, a lactose-free formula is recommended for 4–6 weeks. The damaged gut is more permeable to foreign antigens and intolerance to food proteins (β lactoglobulin in cow's milk and other proteins) is occasionally seen after gastroenteritis; it can be managed by a period of dietary exclusion. Feeding during acute gastroenteritis is shown in Table 187.2.

Table 187.2
Feeding during acute gastroenteritis

Breast fed	Continue breast feeding throughout rehydration and maintenance phases
Formula fed	Restart feed at full strength as soon as rehydration is complete (ideally 4 h)
Weaned children	Child's normal fluids and solids following rehydration. Avoid fatty foods or foods high in simple sugars.

Refeeding Following Rehydration

Good evidence exists to show that children who are breast fed should continue breast feeding throughout the rehydration and maintenance phases of their therapy. In so doing they reduce the risk of dehydration, pass smaller volumes of stool, and recover quicker.

Medication Used for Acute Gastroenteritis

There is evidence from several randomized controlled trials that antidiarrheal and anti-motility agents are not clinically beneficial in the management of acute childhood gastroenteritis, and their side effect is unacceptable. Oral zinc given at the onset of symptoms decreases the duration and severity of acute diarrhea and is recommended by the WHO. Vitamin A does not influence the course of acute gastroenteritis. A guide to a drug treatment of acute gastroenteritis is shown in Table 187.3.

Criteria for Admission of Children with Acute Gastroenteritis

Children presenting with acute gastroenteritis who are severely dehydrated should be admitted to hospital.

Those children with mild–moderate dehydration should be observed in a hospital pediatric emergency room for a period of at least 6 h to ensure successful rehydration (3–4 h) and maintenance of hydration (2–3 h).

Those children at high risk of dehydration on the basis of young age (infants <6 months with high frequency of watery stools more than eight per 24 h) or those who vomit more than four times per 24 h should be observed in a hospital pediatric emergency room for at least 4–6 h to ensure adequate maintenance of hydration.

Table 187.3
Guide to a drug treatment in acute gastroenteritis

Antidiarrheal	Infants and children should not be treated with antidiarrheal agents
Antibiotics	Patients with invasive *S. typhi*, *Shigella*, amebiasis, *Isospora*, and giardiasis should be treated with antibiotics. Consider in infants <6 months with either salmonella infections or those who are systematically unwell, and the immunocompromised.

Those children whose parents or carers are thought to be unable to successfully manage the child's condition at home should be admitted to hospital.

Clinicians often overestimate the extent of dehydration. Documented recent weight loss is a good indicator of the degree of dehydration, but this information is rarely available.

Prevention of Acute Gastroenteritis

Breast feeding, cup and spoon feeding, hygienic preparation of feeds, including hand washing is a major factor in reducing contamination, measles vaccine, cholera vaccine, enterotoxigenic *E. coli* vaccine, and rotavirus vaccine.

Rotavirus vaccines have been developed using a "Jennerian" approach. Strains of bovine and simian rotaviruses that are naturally attenuated for humans have been assessed and found to confer immunity that is serotype-specific in a varying proportion of recipients.

The spectrum of protection has been widened by developing reassortants in which the bovine or simian gene coding for VP7 (the major outer capsid protein) has been replaced by the corresponding gene from human VP7 types 1, 2, 3, or 4. Once the protective antigens (s) are identified it may be possible to develop subunit vaccines that eliminate side effects sometimes observed with live vaccine candidates.

Passive prophylaxis has been tried in special situations. Human gamma globulin, given by mouth to newborn premature infants, has been shown to delay onset of excretion and to decrease the severity of rotavirus disease. Addition of bovine milk rotavirus antibody to formula given to infants protected them against symptomatic infection.

Cholera Vaccine

The parenteral killed vaccines in current use have limited efficacy (approximately 50%) and duration (6–12 months or less). Also, they require multiple doses and are poorly immunogenic in young children. Much of the current research is focused on the development of an oral vaccine with both bacterial cell wall and toxin epitopes, based on evidence that there is a strong correlation between protection against experimental cholera and intestinal anti-cholera toxin secretory IgA levels rather than serum antibodies and that antibacterial and antitoxic effects appear to be important for protective efficacy.

Prevention of Food Poisoning

Prevention of foodborne infections begins with good hand washing and safe practices for food preparation. Public education about the risks associated with eating certain foods and transmission of viruses is essential.

Improved methods to decontaminate food or for rapid detection of gastroenteric viruses in food should also be helpful.

188 Intractable Diarrhea of Infancy

Ian R. Sanderson · John A. Walker-Smith

Intractable diarrhea, first described by Avery et al. in 1968, is recognized as prolonged severe diarrhea, associated with malnutrition, not easily dealt with, despite extreme hospital therapy.

The syndrome has the following features:

- Diarrhea of more than 2 weeks duration.
- Age, less than 3 months.
- Three or more stool cultures negative for bacterial pathogens.
- Managed with intravenous fluids.
- Despite hospital management, diarrhea was persistent and intractable.
- There was a high mortality at the time.

Three clinical variants of the syndrome may be recognized:

1. Chronic diarrhea persisting despite intravenous fluid and nil by mouth. This is very likely to be secretory diarrhea.
2. Chronic diarrhea that disappears on intravenous fluids and nil by mouths, only to recur whenever oral feeding is resumed. This is likely to be osmotic diarrhea, and associated with small intestinal enteropathy. Although, in some patients, it is clear that both secretory and osmotic diarrhea are present.
3. Chronic diarrhea that has been managed by a variety of elimination diets but still persists; again this is likely to be associated with small intestinal enteropathy.

Intractable diarrhea of infancy is therefore a heterogeneous syndrome with a number of causes. This heterogeneity is clear from Avery's original report. Eight children, six of whom died, had idiopathic conditions which Avery et al. termed "nonspecific enterocolitis" as both small and large intestinal abnormalities were found; four of these cases were diagnosed on admission as gastroenteritis. However, although the authors listed small intestinal biopsy as a diagnostic test, it was just recommended as a means to confirm or exclude celiac disease. It was only autopsy material which was available for study of small intestinal mucosal morphology.

Shwachman et al. were the first to perform small intestinal mucosal biopsies on 5 such patients, which they later extended to 11 cases. They performed light microscopy and assayed disaccharidase levels and found a moderately severe to mild lesion in nine cases. Their studies were only possible because the children had been kept alive by parenteral nutrition.

It is this development of parental nutrition as a practical option for infants in the early 1970s that transformed the scene and enabled infants, who otherwise would have died, to survive. As a result, it became possible to perform investigations to determine the cause of their intractable diarrhea.

Diagnosis

A full diagnostic workup of these children requires morphological and functional assessment of both the small and large intestinal mucosa, including small intestinal biopsy and colonoscopy with multiple colonic biopsies.

It is now clear that not only is proximal small intestinal biopsy important, but that the development of safe and effective total colonoscopy in infancy has been another major advance which has lead to increased understanding of the intractable diarrhea syndrome.

Functional assessment is more difficult. Testing of stools for excess stool-reducing substances is a practical and simple test for diagnosis of sugar intolerance. Serial estimation of intestinal permeability is a practical opinion. However, this gives very little additional diagnostic information.

The extensive diagnostic approach for children with intractable diarrhea has led to the recognition of specific disease entities and at times, specific therapy resulting in effective treatment and so, elimination of the intractable diarrhea as a symptom complex in many cases. Over the past few years, molecular techniques have enabled scientists to define the exact gene defects causing some of these conditions.

It must be remembered that failure to make a specific diagnosis in children may be due to diagnostic inadequacy, which in turn may be due to lack of the existence of a clinical entity or lack of availability of particular diagnostic techniques. For example, undiagnosed celiac disease can go on to intractable diarrhea. This has clearly

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_188,

been shown in India where only in recent years has it been appreciated that celiac disease in Northern India is an important cause of intractable diarrhea.

Within the broader syndrome of intractable diarrhea is the syndrome known as malnutrition in chronic diet-associated infantile diarrhea (McDAID). The features of this syndrome include: diarrhea of more than 2 weeks duration, malabsorption, and intestinal malfunction, which is further aggravated when food and/or specific dietary products are fed. Fasting usually brings about improvement in the diarrhea, but may lead to considerable nutrition deterioration. These diet-associated problems have dramatically decreased in the developed world. This relates to a decline in gastroenteritis and the recognition of temporary cow's milk protein intolerance occurring as a sequel. Thus, in the past, undiagnosed lactose intolerance and cow's milk sensitive enteropathy were important causes of intractable diarrhea.

In summary, many of the infants who present with intractable diarrhea in fact eventually prove to have a diagnosable condition, i.e., have a specific diagnosis sometimes with specific therapy, sometimes without. Despite advances of the past few years, there remains an important group in whom no primary cause can be determined.

Categories of Intractable Diarrhea

It is now possible, after extensive diagnosis, to divide intractable diarrhea syndrome into four categories:

1. Failure to make a diagnosis of any kind
2. Specific diagnosis but no therapy
3. Specific diagnosis but therapy of variable efficacy
4. No specific or only partial diagnosis

There are now fewer and fewer patients who fit into category 1 and this will not be discussed here.

Specific Diagnosis but No Therapy

Two examples of this are microvillous atrophy and congenital enterocyte heparan sulfate deficiency.

Microvillous Atrophy

Davidson et al. (1978) in Canada described five infants with severe diarrhea and failure to thrive from birth, leading to death in four cases. All infants had small intestinal villous atrophy, without crypt hypertrophy, i.e., hypoplastic villous atrophy. There was a familial history in four cases and the term familial enteropathy was used to describe this syndrome. Electron microscopy of three of the children showed striking ultrastructural changes in one. Involutions of the apical membrane of some surface epithelial cells were seen containing microvilli, and secretory granules accumulated in upper crypt cells. Light microscopy of small intestinal biopsy for infants with congenital microvillous atrophy demonstrated villous atrophy without crypt hypertophy. Schmitz et al. (1982) called this syndrome *congenital microvillous atrophy*. But more recently this entity has been termed *microvillus inclusion disease*. Late-onset cases have also been described where the child was well for the first weeks of life, and then developed the condition. The specific diagnostic features and clinicopathological spectrum of microvillous atrophy have been reviewed by Phillips and Schmitz. The familial nature of the condition has enabled molecular genetics to be performed. The gene was identified on Chromosome 18, and informative families demonstrated that it was due to a defect in a cytoskeletal element MYO5B. Interestingly, this myosin binds to another protein RAB 8. Deleting RAB 8, from enterocyte lines, had shown a lesion similar to that seen in children with microvillous atrophy. It is not yet clear if the late-onset disease is due to a distinct genetic defect from the congenital type.

Tufting Enteropathy

Congenital tufting enteropathy (CTE) is a rare autosomal recessive diarrheal disorder presenting in the neonatal period. It is characterized by intestinal epithelial cell dysplasia leading to severe malabsorption and significant morbidity and mortality. SNP Homozygosity mapping identified in an information family a unique 6.5-Mbp haplotype of homozygous SNPs on chromosome 2p21 where approximately 40 genes are located. Direct sequencing identified the gene epithelial cell adhesion molecule (EpCAM).

Congenital Enterocyte Heparan Sulfate Deficiency

A new cause of intractable diarrhea syndrome of infancy, associated with histologically normal small intestinal mucosa by conventional assessment, has been described by Murch et al. This syndrome begins in the first days of life and is characterized by chronic diarrhea associated

with profound hypoproteinemia. The diarrhea is secretory in character and there is severe protein-losing enteropathy. The small intestinal mucosa is normal on light microscopy, although there is some minor thickening of the subepithelial basement membrane with increased fibrillar collagen on electron microscopy. However, there is almost complete absence of *epithelial glycosaminoglycans*. There is in particular a gross reduction of sulfated glycosaminoglycans (heparan sulfate) in the basolateral membrane, lining the lateral intercellular spaces. As glycosaminoglycans play a major role in retaining circulating proteins within the vasculature, it has been proposed that this loss is responsible for the severe enteric protein loss and secretory diarrhea in these infants. These infants have been thus described as suffering from "minimal-change" enteropathy, analogous to lesions in the glomerulus of the kidney in patients with nephrotic syndrome. So far there is no effective therapy.

Specific Diagnosis but Therapy of Variable Efficacy

The best example of this is *autoimmune enteropathy*. This syndrome describes children with intractable diarrhea and small intestinal enteropathy who possess an antibody against their intestinal epithelium and thus appear to have an *autoimmune enteropathy*. These children represent a very difficult management problem with a high mortality. They have a characteristic clinical syndrome which may be associated with other autoimmune phenomena, e.g., diabetes mellitus associated with islet cell antibody. This syndrome has now been seen in a number of countries. However, its relative frequency is not yet clear. In a highly selected group of 25 infants with intractable diarrhea, 14 in fact had evidence of this syndrome. Cyclosporin can be effective in the management of such children.

In 2001 with the discovery of disease-causing mutations of the FOXP3 gene, located on the X chromosome, a major breakthrough in the understanding of the pathophysiology of autoimmune enteropathies was made. A great variety of different forms of AIE exist with some of them FOXP3-dependent, others FOXP3-independent. A genetic approach, combined to immunological evaluations (as discussed below), can distinguish several forms of autoimmune enteropathy, as recently proposed:

1. A systemic X-linked form associated to different endocrinopathies, hematological symptoms and severe eczematic skin disease, now well characterized as immune dysregulation, polyendocrinopathy, autoimmune enteropathy X-linked (IPEX) syndrome
2. An IPEX-like form a priori FOXP3-independent occurring in both boys and girls
3. A predominantly or isolated gastrointestinal form with typical anti-enterocyte antibodies also occurring in both boys and girls

Another example is congenital secretory diarrhea due to defective jejunl brush border Na/H exchange.

Small Intestinal Enteropathy of Unknown Origin

Small intestinal enteropathy of unknown origin can be a very severe disorder. It is possible that it is a variant of autoimmune enteropathy. These children with intractable diarrhea with an enteropathy of unknown origin may have an immunological pathogenesis, as there are increased numbers of inflammatory cells in the lamina propria. They need to be distinguished from children with autoimmune enteropathy. In an ESPGAN study group of 13 non-autoimmune and 18 autoimmune children with small intestinal enteropathy, these two groups were compared in relation to age and onset of diarrhea. They were all 12 months or under. There was a higher mortality in the autoimmune group. Such children may be totally dependent on home parenteral nutrition and they provide a very great challenge at present for both diagnosis and management.

Intractable Enterocolitis

Intractable ulcerating enterocolitis of infancy is a disorder of unknown origin. This disorder is now often reported in communities with a high degree of consanguinity. It typically presents in infancy. It may sometimes resemble Crohn's disease. The children often require subtotal colectomy for severe colitis. The long-term progress may be quite good. This has been improved by the use of bone marrow transplant. The underlying disorder may include defects in the IL-10 and its signaling pathways, but this is an area of investigation.

Conclusion

As more causes of intractable diarrhea are recognized with better diagnostic techniques, the residuum of cases where the diagnosis is incomplete and therapy unsatisfactory

continues to decline. These cases, however, remain as one of the most difficult problems faced by pediatric gastroenterologists for whom they provide a continuing challenge.

However, the diagnostic advances over the past 40 years, whereby it has become safe and effective to biopsy both the small and large intestine of infants, have led to the notable advances in our ability both to make diagnosis and also to understand pathogenesis. These advances too have in part only been possible because highly effective parenteral nutrition is now able to keep these babies alive. In previous years they would have died.

189 Congenital Chloride Diarrhea

Hisham M. Nazer

Congenital chloride diarrhea (CCD) is a rare autosomal recessive disorder of chloride transport caused by mutations in the down-regulated in adenoma gene, characterized by lifelong watery diarrhea with high fecal chloride concentration. CCD was first described in simultaneous publications by Gamble et al. and by Darrow in 1945, who coined the term "congenital alkalosis with diarrhea."

Though more than one third of reported cases come from Finland, CCD has also been reported from several countries in Europe, America, and the Arabian Peninsula. As in Finland, a major founder effect was observed in Arab patients in whom 94% of the CCD-associated chromosomes carried a nonsense mutation, G187X, which occurred in either a conserved ancestral haplotype or its derivative. The frequency of CCD in Finland is approximately 1 in 43,000 newborns. Three regions were reported to have high incidence: Finland, Poland, and Arab counties in the Gulf Region with supportive evidence from Kuwait and Saudi Arabia.

Pathogenesis

Intrauterine diarrhea predisposes to polyhydramnios, prematurity, and lack of meconium passage. Hyperbilirubinemia is partially caused by the hypovolemia and acidosis in premature infants with CCD.

The basic defect in CCD is impaired active chloride transport in the distal ileum and colon. Perfusion studies have established the absence of active chloride-bicarbonate exchange in the ileum and colon as the primary defect in CCD. The defective Cl^- absorption leads to osmotic diarrhea and hypovolemia. Normally, the chloride is actively coupled in the ileum to bicarbonate. The resultant excess of intraluminal chloride obligates further loss of the positive ions Na^+ K^+, and H^+, while retaining bicarbonate in the serum. Metabolic alkalosis is therefore a recognized biochemical association of CCD. Sodium ion absorption is also impaired when the luminal content is acidic. Moreover, the excess of electrolytes in the gut will retain more water, resulting in severe watery diarrhea and hypovolemia if it is not adequately replaced.

Other recognized laboratory findings in CCD include increased renin and aldosterone levels. The kidney is also involved, which makes CCD a disorder of shared interest between the gastroenterologist and the nephrologist. Recognized renal lesions in congenital chloride diarrhea include juxtaglomerular hyperplasia, hyalinized glomeruli, calcium deposits, and vascular changes resembling those seen in hypertensive disease.

Clinical Features

Congenital chloride diarrhea may be considered during antenatal routine checkup with the finding of polyhydramnios and fluid-filled distended loops of the bowel of the fetus. This combination may result in the baby being delivered prematurely. There is usually no passage of meconium. The infant presents with unremitting watery diarrhea with chloride content of greater than 90 mmol/L. The baby tends to pass a severe watery diarrhea that simulates urine, resulting in rapid weight loss. Some newborns develop jaundice, possibly due to hypovolemia and prematurity. Celiac disease was reported in a girl with CCD.

The disease is therefore characterized by long-standing watery diarrhea, acid stool, metabolic alkalosis, and a high stool chloride concentration, usually exceeding that of the serum chloride. Affected infants present also with abdominal distention and failure to thrive. Children who continue to show growth retardation are usually diagnosed late. If the condition is not properly managed, the baby might suffer the sequelae of severe hypovolemia, electrolyte disturbances with metabolic alkalosis, and presents with evidence of renal impairment and psychomotor retardation. Renal involvement may result in nephrocalcinosis with echogenic kidneys on ultrasonography. Hyperaldosteronism results in hypokalemic alkalosis, which predisposes to nephrocalcinosis. CCD which was considered as a purely pediatric disease has recently been reported to affect adults.

Diagnosis

The diagnosis may be highly suspected from the antenatal period. A history of polyhydramnios and a lack of meconium at birth, together with abdominal distention and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_189,

watery diarrhea are strongly suggestive of CCD. The condition may mimic low intestinal obstruction on ultrasound examination after 30 weeks of gestation.

Congenital sodium secretory diarrhea: Another congenital condition is also recognized to result in intrauterine intestinal secretion due to defect of sodium transport. This condition is also associated with polyhydramnios, which becomes evident toward the end of the second trimester. Ultrasound scan of the mother's abdomen shows an enlarged fetal abdomen containing distended loops of fluid-filled bowel.

Amniotic fluid α-fetoprotein and bilirubin are reported to be abnormally high from around the 29th week of gestation in affected pregnancies with CCD.

The diagnosis is further supported by the laboratory findings of hypokalemia, hyponatremia, hypochloremia, and metabolic alkalosis. Serum sodium may be normal in some patients due to secondary hyperaldosteronism. Hyperuricemia occurs in some patients. Angiotensin II is known to reduce the clearance of urate. The diagnosis is often delayed in the newborn infant, as the diarrheal fluid is frequently mistaken for urine. Abdominal ultrasonography reveals dilated bowel loops with an abnormal echogenic pattern of kidneys (◉ *Figs. 189.1* and ◉ *189.2*).

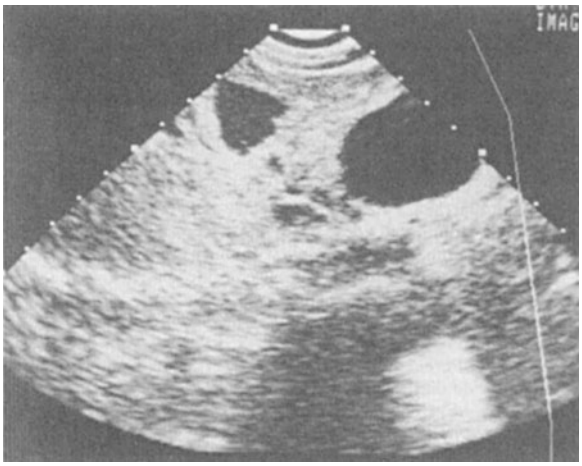
Diagnosis is usually confirmed by the presence of high levels of electrolytes in the stool, with stool chloride concentration of over 90 mmol/L in excess of the sum of sodium and potassium concentration. Lower fecal chloride content has been reported in CCD among affected infants with severe dehydration and electrolyte depiction as well as among newborns. In severe cases that suffered the consequences of delayed diagnosis with severe extracellular fluid depletion, the infant may present with the passage of formed stools or even constipation, which might lead to a serious diagnostic dilemma.

Differential Diagnosis

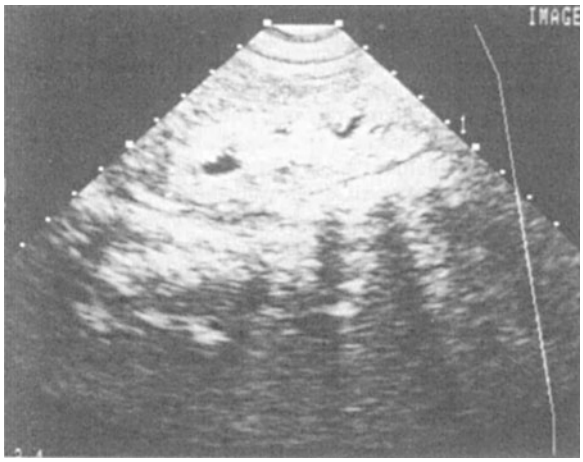
Congenital chloride diarrhea should be differentiated from other conditions associated with antenatal dilated bowel such as cystic fibrosis and intestinal obstruction. CCD should be differentiated from Bartter syndrome, in which there is also hypochloremia with hypokalemic alkalosis, hyperreninemia, and secondary hyperaldosteronism. Diarrhea is not a feature of Bartter syndrome. Moreover, untreated patients with CCD have low or undetectable chloride in their urine, while Bartter syndrome is characterized by high urinary chloride excretion due to impaired chloride reabsorption by the renal tubules.

CCD should also be differentiated from other conditions associated with metabolic alkalosis in infancy such as pyloric stenosis, potassium-losing nephropathies, dietary chloride deficiency, and cystic fibrosis.

Early diagnosis and proper management are essential prerequisites to improve the prognosis of CCD especially among affected infants in the developing world where a high rate of consanguineous marriages prevail. In a multinational



◉ Figure 189.1
Ultrasound of the abdomen showing dilated loops of the intestine in a patient with CCD



◉ Figure 189.2
Ultrasound of the kidneys in a patient with CCD showing increased echogenicity with nephrocalcinosis

study, parental consanguinity was known in all Saudi Arabian and Kuwaiti CCD families included in the study.

Treatment

Early diagnosis and initiation of treatment with replacement of electrolytes and correction of the associated hypovolemia are the essential steps in management of CCD to rescue the patients of its potential renal and central nervous system complications. It is important to stress to the parents that their child's diarrhea is expected to persist in spite of their adherence to therapy, but that the treatment is likely to prevent complication and ensure a better weight gain. Initially, the baby may require intravenous replacement of fluid and electrolyte loss followed later by oral supplement of chloride with sodium and potassium salts.

The treatment should be monitored regularly, especially in the early stage after diagnosis, by serum and urine electrolytes. With the electrolyte supplement the urine, which initially lacks electrolytes, will reveal the presence of some electrolyte excretion after a satisfactory compensation of the electrolyte loss in the stools. The dose is titrated to ensure a urinary chloride concentration in excess of 30 mmol/L. Chloriduria is a convenient indicator of the normality of the extracellular fluid volume and adequacy of the oral replacement of the chloride. With early diagnosis and appropriate therapy, children with CCD achieve adequate growth and development. Though this therapy does not abolish the diarrhea, most children will become toilet trained at a normal age and will lead a normal life with no impairment of social activity.

Prostaglandin synthetase inhibitors like indomethacin and ketoprofen have been tried in the therapy of patients with CCD. Although they tend to improve the electrolyte abnormalities and normalize plasma renin and aldosterone, the efficacy of prostaglandin synthetase inhibitors in the treatment of CCD remains debatable, and their use has not replaced the standard therapy with sodium and potassium chloride solutions.

The Gene for CCD

Recent research with the use of linkage analysis has provided strong evidence that the gene responsible for CCD maps close to but is distinct from the gene for cystic fibrosis transmembrane regulator (CFTR). Further reports have been published to support the gene location in CCD on chromosome 7. There are at least eight Cl^-/$HCO3^-$ exchange protein genes and highly homologous genes from different species encoding exchange proteins in human, mouse, rat, and chicken. More recently, it was demonstrated that mutations of the intestinal anion transport molecule down-regulated in adenoma (DRA) gene cause CCD.

The condition is recognized nowadays to result from mutations in the intestinal $Cl(^-)HCO(3)(^-)$exchange (SLC26A3) which results in sodium chloride and fluid depletion leading to hypochloremic and hypokalemic metabolic alkalosis. Mutations in SLC26A3 (solute carrier 26 family member 3), which functions as a coupled Cl^-/HCO_3 exchanger, cause CCD. Currently there are over 30 mutations in SLC26A3 linked to CCD.

The most frequent Saudi Arabian and Kuwaiti mutation was a G→T transversion at nucleotide position 559. The predicted amino acids change was a substitution of glycine by the termination codon at 187(G187X). This mutation was found in all Saudi Arabian patients and all but one of the Kuwaiti CCD–associated chromosomes included in a major multinational study.

190 Chronic Diarrhea

Jumana Shammout · Hisham M. Nazer

Diarrhea is a recognized manifestation of a variety of gastrointestinal diseases. While the majority of diarrheal episodes last less than 2 weeks and are self-limited, a smaller proportion of diarrheal illnesses persists for more than 2 weeks, substantially impacting the quality of life and the overall health of the individual; not only because of the inconvenience of persistent diarrhea, but also because of the risk of malnutrition and even death.

Definition

Diarrhea is defined as frequent passage of loose stools. Diarrhea occurs when the stool volume exceeds the normal value of approximately 10 g/kg/day in infants and toddlers, and 200 g/day in older children and adults. This is typically manifested as loose or watery stools occurring at least three times a day. However, since the absolute limits of normal bowel movements is difficult to define, with normal bowel movements ranging from three times/week to three times/day, any deviation from the child's usual pattern should raise concern (particularly if passage of blood or mucus, or dehydration occurs), regardless of the actual number of bowel movements or their water content.

Diarrheal episodes are classically divided into acute and chronic based on their duration. The WHO defines acute diarrhea as less than 14 days in duration and persistent diarrhea episodes as 14 days or longer in duration. Such a distinction can help in forming a differential diagnosis, and thus impact management, as well as prognosis. Acute diarrhea lasts no longer than 14 days, is often infectious in etiology (bacterial, viral, or parasitic infections), and is usually self-limited. Chronic diarrhea refers to the persistence of loose stools (with or without an increase in stool frequency) for at least 14 days.

Chronic diarrhea may occur in many conditions, including a variety of infectious and immunologic states, as well as several congenital syndromes. Reports have indicated that between 5% and 18% of all diarrheal episodes are categorized as persistent diarrhea; however the exact cutoff point between acute and chronic diarrhea and persistent diarrhea is arbitrary.

Etiology

Many gastrointestinal and systemic diseases present with diarrhea. In children, the differential diagnosis may be age specific; however, a number of diseases may occur at any age (*Table 190.1*).

Furthermore, the etiology of chronic diarrhea differs between developing and developed countries. In developing countries, most cases of persistent diarrhea are caused by recurrent bouts of enteric infections leading to chronic enteropathy and diminished digestive and absorptive capacity. Poor caloric and protein intake, dietary deficiency of micronutrients such as zinc and vitamin A, and/or immunodeficiency, further contribute to the development of chronic enteropathy and persistent diarrhea.

In developed countries, the causes of chronic diarrhea in children range from dietary factors (e.g., excessive consumption of juice), to diseases causing maldigestion or malabsorption (e.g., celiac disease and other food allergies), to enteric infections (particularly in immunocompromised patients).

Prevalence and Morbidity

Persistent diarrhea occurs in up to 3–5% of the infant population worldwide. The prevalence is substantially higher in developing countries compared to developed countries. Although less than 10% of diarrheal episodes become persistent, persistent diarrhea accounts for more than half of diarrheal deaths, and 30–50% of deaths overall among children younger than 5 years of age in the developing world.

Pathophysiology

The intestine is the major site of gastrointestinal fluid absorption and secretion. It is lined by a single layer of polarized epithelial cells that are joined together by tight junctions. These cells maintain concentration gradients through specialized channels and ion pumps located in their apical and basolateral membranes, and thus regulate

Primary bile acid malabsorption		

ion and water fluxes. The epithelial cells located on the villi are responsible for absorption, while the cells located in the crypts are responsible for secretion.

Sodium transport occurs across the brush border membrane through several mechanisms including passive diffusion, special sodium channels, and chloride-linked protein carriers. A sodium gradient is maintained by a Na^+,K^+, -ATPase pump located at the basolateral membrane.

In contrast to sodium, chloride may be actively secreted into the intestinal lumen and acts as a powerful stimulant for fluid secretion. Chloride secretion may occur in response to changes in the intracellular gradient or messenger pathways. Water absorption for the most part occurs freely in the intestine in response to the osmotic gradient created by Na^+ transport from the lumen across the apical membrane of the enterocytes. Na^+ transport across the enterocytes occur through three major pathways:

1. Selective Na^+ channels
2. Sodium chloride-coupled pathway
3. Cotransport of Na^+ with glucose, galactose, or amino acids

Several other factors play a role in altering the volume of the stools including fluids and electrolytes, dietary factors, gut flora, and various gastrointestinal hormones.

Intestinal secretion is activated by an increase in intracellular level of cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), and Ca^{++}. These mediators increase the secretion of Cl^-, and consequently sodium and water.

In normal conditions, the secretory process is balanced by fluid absorption. Diarrhea occurs when there is an imbalance between those two processes, leading to incomplete absorption of water. This occurs through two basic pathologic mechanisms: secretory or osmotic.

As stool leaves the colon, the fecal osmolality is equal to that of the serum (290 mOsm/kg). Under normal circumstances, the major osmoles in the stool are Na^+, K^+, Cl^-, and $HCO_3{}^+$. The stool osmolality may be estimated by multiplying the stool $(Na+K)\times 2$. The osmotic gap is the difference between the measured osmolality of the stool electrolytes and the total osmolality of the stool (which is approximately 290 mOsm/kg).

$$\text{Stool osmolal gap} = 290 - (2 \times (\text{Na} + \text{K}))$$

Normal stool osmotic gap is <50. An increased osmotic gap indicates the presence of unmeasured substances in the stool (osmotic diarrhea).

Osmotic diarrhea occurs when poorly absorbed osmotically active solutes are present in the gut lumen. These solutes provide an osmotic gradient that draws water into the intestinal lumen. The most common cause of osmotic diarrhea is carbohydrate malabsorption; the classic example is lactose intolerance. In this state, ingested lactose cannot be digested in the small intestine due to deficiency of lactase enzyme and reach the colon intact causing an osmotic load that attracts water and electrolytes into the bowel. The colonic bacteria ferment the unabsorbed sugar into free fatty acids which is absorbed by the colon.

The essential characteristic of osmotic diarrhea is that the stool output is proportional to the intake of the unabsorbable substrate, and the diarrhea disappears with fasting or cessation of ingestion of the offending substance. The stool osmolality is increased, and the osmolal gap is >125. In osmotic diarrhea secondary to carbohydrate malabsorption the stool pH is low (due to the presence of short-chain organic acids produced by bacterial fermentation of the unabsorbed sugar), and the stool may be positive for reducing substances (reducing sugars are glucose, lactose, galactose, maltose, and fructose). Sucrose is not a reducing sugar (Table 190.2).

Secretory diarrhea occurs secondary to upregulation of the mechanisms involved in the active secretion of intestinal fluids, resulting in large fluxes of water and electrolytes into the small intestine. Intestinal fluid secretion results predominantly from the active secretion of Cl^- through the cystic fibrosis transmembrane regulator (CFTR) channel. Activation of the CFTR may occur secondary to increase in intracellular cAMP, cGMP, Ca^{2+}, resulting in Cl^- secretion into the intestinal lumen. Na^+ and water are secreted with Cl^-, maintaining electrogenicity and osmotic balance.

The most common cause for secretory diarrhea is infection. Enterotoxins from a host of infectious agents bind to specific receptors on the enterocytes, a fragment of the toxin then enters the cell and activates either adenylate cyclase (resulting in an increase in intracellular cAMP; e.g., cholera toxin, heat-labile *Escherichia coli* toxin, Salmonella, Campylobacter, Sheila toxins); or guanylate cyclase (resulting in an increase in intracellular cGMP; e.g., heat-stable *E. coli* toxin, *Yersinia* enterotoxin); or Ca^{2+} (e.g., *Clostridium difficile*, *Cryptosporidium*), and stimulate Cl^- secretion. Cl^- secretion can also be activated by several endogenous secretagogues, infiltrating inflammatory cells, and stimulation of the subepithelial neurons that terminate in the basolateral membrane. Secretory diarrhea is characterized by high-volume, extremely watery stools. Stool analysis reveals high sodium and chloride content (>70 meq/L), and a stool osmolal gap less than 50 mOsm/kg. Fecal pH is normal, and the stool is negative for reducing substances. Secretory diarrhea continues with fasting. Congenital defects of chloride transport such as *congenital chloridorrhea* also produce secretory diarrhea.

Diarrhea can be further classified according to the stool characteristics into watery, fatty, or inflammatory. Watery diarrhea implies a defect primarily in water absorption, and as discussed earlier, can either be secretory or osmotic. Fatty diarrhea implies a defect in fat absorption. Inflammatory diarrhea characterized by the present of mucus and pus in the stools, imply an infectious or inflammatory etiology.

Causes of Chronic Diarrhea

Infections

Chronic diarrhea may be associated with intestinal or extraintestinal infections. In developing countries, chronic diarrhea usually results from recurrent enteric infections, often with multiple pathogens, leading to destruction of the intestinal mucosa, with no sufficient time between infections to allow healing. This leads to chronic enteropathy which causes malabsorption, and can result in malnutrition if caloric intake is not sufficient. Malnutrition further contributes to the prolongation of diarrheal episodes by impairing both the immune system and tissue healing.

The most common causes of infectious persistent diarrhea are bacterial microorganisms (enteroadherent *E. coli*, enteropathogenic *E. coli*, *Shigella*, *Cryptosporidium*, and *Cyclospora*). Intestinal parasites can also cause persistent diarrhea, while viruses typically cause acute diarrhea, though prolonged symptoms may occur due to postinfectious enteritis. Rotavirus, cytomegalovirus, Torovirus, and astrovirus have been associated with chronic diarrhea.

Table 190.2
Osmotic versus secretory diarrhea

	Osmotic diarrhea	Secretory diarrhea
Volume of stool	Large	Very large
Response to fasting	Diarrhea stops	Diarrhea continues
Reducing substances	+	–
Fecal pH	<5	>6
Stool osmolality	Normal to increased	Normal
Stool ion gap	>125	<50

Rotavirus: Rotavirus usually causes severe acute watery diarrhea in young children, but may also cause chronic diarrhea in both immunodeficient and immunocompetent hosts.

Yersinia enterocolitica: *Y. enterolitica* is associated with diarrhea, mesenteric adenitis, and terminal ileitis mimicking IBD. Symptoms usually resolve in 5–14 days, but may persist for several months.

C. difficile: *C. difficile* is the most common infectious etiology of antibiotic-associated diarrhea (AAD) accounting for 20% of cases. AAD manifests with variable degrees of severity, ranging from acute mild watery diarrhea to persistent bloody diarrhea and fulminant hemorrhagic colitis. The usual presentation of AAD in children is an acute onset of profuse watery diarrhea, often associated with blood, which begins during the first 5–10 days of antibiotic therapy, but may develop up to 10 weeks after the completion of the antibiotic therapy. The diarrhea is usually associated with abdominal pain, nausea, and vomiting. Low-grade fever and leukocytosis may occur. In uncomplicated cases, the symptoms resolve shortly after stopping the antibiotics. Metronidazole may be used in the presence of fever, colic, leukocytosis, or pseudomembranous colitis. Vancomycin can be used for severe recurrent cases.

Giardia lambilia is the most common cause of intestinal protozoal infection worldwide. The majority of the infections are asymptomatic. Infection occurs by the ingestion of the water-borne cysts; as little as 10–100 cysts can cause infection. Once the cysts reach the upper small intestine, they divide into four trophozites, which colonize the lumen of the duodenum and jejunum. In the small intestine, the trophozites adhere to the enterocytes, causing local effacement of the microvilli which can cause malabsorption. The most common clinical manifestation is diarrhea. Weight loss, crampy abdominal pain, steatorrhea, malabsorption, and failure to thrive may occur.

The diagnosis can be made by identifying the cysts, or antigen in stools, or by identifying the protozoa in a duodenal aspirate or biopsy. Microscopic examination of a single stool specimen is approximately 70% sensitive. Sensitivity increases to 85% when three stool specimens collected on separate days are examined.

Treatment is with metronidazole. Some apparent clinical treatment failures are due to lactose intolerance, which can persist for weeks after successful treatment.

Entamoeba histolytica: *E. histolytica* is transmitted primarily through fecal–oral route via ingestion of the cysts of the protozoan. The cysts can be found in fecally contaminated food and water supplies, and on contaminated hands of food handlers. The cysts remain viable in the environment for weeks to months, and ingestion of a single cyst is sufficient to cause disease. Excystation occurs in the terminal ileum or colon, forming trophozoites. The trophozoites can invade and penetrate the colonic mucosa, leading to tissue destruction and bloody diarrhea (dysentery). Chronic nondysenteric syndrome of diarrhea, weight loss, and abdominal pain, which can last for years, can occur. The trophozoites can also spread hematogenously via the portal circulation to the liver, lungs, heart, and brain.

The best method to diagnose *E. histolytica* is by fecal antigen detection assay, as stool microscopy cannot differentiate between *E. histolytica* and *Entamoeba dispar* or *Entamoeba moshkovskii* which are more common than *E. histolytica* but are nonpathogenic. A minimum of three specimens (85–95% sensitivity), collected on separate days, should be evaluated since shedding of organisms vary from day to day. Antibody measurements (detect *E. histolytica* but not *E. dispar*) can also be used but they remain positive for years.

Treatment is by metronidazole orally (children: 35–50 mg/kg/day in three divided doses for 7–10 days, adults: 500–750 mg/kg/day three times daily for 7–10 days). Following treatment for invasive amebiasis, treatment with a luminal agent (paromomycin, diiodohydroxyquin, diloxanide furoate) may be required to eliminate intraluminal cysts. Follow-up stool examinations are required.

Asymptomatic carriers should also be treated with metronidazole because of the risk of developing an invasive disease, and to prevent shedding of the cysts.

Cryptosporidium: It is a protozoan which causes a self-limited watery diarrhea in normal children, but can cause prolonged diarrhea in immunocompromised patients. Infection occurs by ingesting the cysts from infected feces. The trophozoite divides in the jejunal mucosa and attaches to the intestinal brush border, destroying the microvilli reducing the intestinal absorptive capacity, and producing watery diarrhea and malabsorption. Diagnosis is by stool examination, or by intestinal mucosal biopsy. Patients can be treated with nitazoxanide, or paromomycin, or azithromycin.

Small bowel bacterial overgrowth (*SBBO)*: SBBO is defined as proliferation of bacteria in the upper gastrointestinal tract (stomach, duodenum, and jejunum). In healthy children, the upper small intestinal tract is relatively sterile due to a number of factors including gastric acidity, immunologic factors, and secretory and motility mechanisms. When a disease or therapy interferes with these protective mechanisms, bacteria can proliferate and damage the small intestinal mucosa causing carbohydrate and protein malabsorption. Fat malabsorption can also occur due to bacterial deconjugation of bile acids.

Anaerobic bacteria compete for vitamin B12 uptake, which can result in macrocytic anemia (on the other hand, folate which can be synthesized by luminal bacteria is rarely deficient).

Conditions that predispose to bacterial overgrowth include hypochlorhydria (e.g., acid-secretion blocker medications), motility disorders (e.g., chronic intestinal pseudo-obstruction, scleroderma), and anatomic problems (gastrocolic or enterocolic fistulas).

Although empiric treatment with broad spectrum antibiotics can be tried when the suspicion of SBBO is high, the gold-standard test for diagnosing SBBO is culture of the jejunal aspirate. Glucose breath hydrogen test can also be used to diagnose SBBO. Empiric treatment can be achieved with Rifaximin (800–1,200 mg/day). Other antibiotics that can be used include amoxicillin-clavulanate plus metronidazole, metronidazole combined with a cephalosporin or trimethoprim-sulfamethoxazole, or oral gentamicin. Antibiotic treatment is given for 7–10 days, though some patients require prolonged treatment. Recurrence is common, and retreatment may be needed.

HIV disease: Persistent diarrhea resulting from immunodeficiency, enteric infections, malnutrition, and medications frequently occur in patients with HIV. The infectious pathogens associated with diarrheal diseases in HIV infection may vary with the degree of immunocompromise in the host. Patients with CD4 cell counts <100 cells/microL are at risk for opportunistic infections which are typically chronic, such as Cryptosporidium, Mycobacterium avium complex (MAC), CMV, Isospora, or Microsporidium.

Villous Atrophy

Many pathologic conditions may cause damage to the intestinal mucosa leading to maldigestion/malabsorption and diarrhea. The most common cause is postinfectious enteritis.

Postinfectious enteritis: Postinfectious enteritis is a relatively common complication of acute viral and bacterial infections. Patient presents with a prolonged course of loose diarrhea after an infectious illness had resolved. The etiology is multifactorial and includes acquired lactase deficiency and protein-losing enteropathy that occur secondary to intestinal mucosal injury.

Mild cases can be diagnosed by history alone, while severe, very prolonged diarrhea or weight loss may warrant further investigations. Lactase deficiency can be diagnosed by a hydrogen breath test. Other tests for malabsorption may also be abnormal depending on the extent of the mucosal injury. A small bowel biopsy may be indicated in severe cases for definitive diagnosis.

Mild cases usually respond to a lactose-free diet. Patients with severe cases may require elemental formulas.

Protein-induced proctitis/proctocolitis: It is found almost exclusively in infants. It can occur in both breastfed infants, and infants receiving standard cow's milk or soy-based formulas. Infants usually present by 6 months of age (mean age of presentation is 2 months) with blood-streaked, mucusy, loose stools. Some infants may have increased frequency of bowel movements, but frank diarrhea is not typical. Diagnosis is usually made based on the clinical presentation and the resolution of symptoms upon withdrawal of the offending allergen from the diet.

Dietary protein-induced enteropathy: It occurs in infants with hypersensitivity to cow's milk protein. Food antigens implicated in cow's milk allergy are casein, whey proteins, β-lactoglobulin, and α-lactalbumin. It can also occur secondary to hypersensitivity to other foods, including soy, eggs, rice, poultry, fish or shellfish, as well as following an episode of gastroenteritis. Ingestion of the offending protein causes destruction of the small intestinal villi, causing malabsorption. Infants develop diarrhea, vomiting, failure to thrive, and hypoproteinemia. Intestinal protein and blood loss may occur and stool tests positive for an acidic pH with reducing substances, fecal leukocytes, and blood.

Diagnosis is based on the clinical features, response to allergen elimination, and endoscopy with biopsy.

It is managed by eliminating the causal food from maternal diet in breastfed infants, and substituting cow's milk or soy-based formulas with an extensively hydrolyzed cow's milk formula. Some infants may be sensitive to the residual peptides in extensively hydrolyzed cow's milk formulas and require an amino-based formula. The condition generally resolves after 1–2 years.

Gastrointestinal symptoms may occur along with respiratory and skin manifestations as well. Detection of antigen-specific IgE, either by blood tests (radioallergosorbent test [RAST]) or skin tests, supports the clinical diagnosis. Total IgE determinations and eosinophil counts do not reliably correlate with immediate hypersensitivity responses to foods. Skin testing is done with the puncture or prick method, a drop of food extract placed on the skin.

Food hypersensitivity responses are unusual with a negative skin test, but positive tests carry only a 20–30% chance of predicting a positive food challenge. The RAST and the enzyme-linked immunosorbent assay, (ELISA) are useful for in vitro determination of IgE to antigens. The RAST is the most commonly used in vitro test and is useful particularly when skin tests may be hazardous. Elimination of the offending food is the treatment of choice.

Food protein-induced enterocolitis syndrome (*FPIES*): It most often develops in response to dietary cow's milk protein or soy. Typically, it presents in infants less than 9 months old, with a higher incidence between 1 week and 3 months of age. Patients present with chronic vomiting, diarrhea, malabsorption, or melena. Failure to thrive, anemia, and hypoproteinemia may develop. FPIES may also present acutely if cow's milk protein was previously eliminated from the diet and subsequently re-ingested. In these cases, patients may present with severe vomiting and diarrhea within 2–4 h of ingesting the offending allergen, progressing to profound dehydration, lethargy, and sometimes shock.

Standard skin prick testing and food-specific IgE assays are not helpful in the diagnosis of cow's milk protein allergy, and the diagnosis is based on the clinical features, response to allergen elimination, and endoscopy with biopsies. Symptoms resolve upon elimination of the offending food.

Eosinophilic gastroenteritis is a disorder of unknown etiology, thought to be related to environmental or dietary allergens. It is characterized by eosinophilic infiltration of one or more areas of the gastrointestinal tract, usually the stomach and the small intestine. The disease can affect patients at any age, and usually presents with abdominal pain, nausea, vomiting, and diarrhea.

The clinical features are related to the anatomical location of the eosinophilic infiltration within the gastrointestinal tract and the layer(s) of the bowel wall involved mucosa, muscle, and subserosa. Patients with diffuse small bowel disease may develop malabsorption, protein-losing enteropathy, and failure to thrive. Patients with eosinophilic infiltration of the muscle layer of the gastrointestinal tract may present with symptoms of obstruction (e.g., nausea, vomiting, abdominal distention), while patients with subserosal involvement may present with ascites. Peripheral eosinophilia may be present. Skin prick/patch tests can help identify the culprit allergen.

Management is by dietary exclusion of offending food and/or steroids and immunosuppression.

Celiac disease (*gluten-sensitive enteropathy*): Celiac disease is an immune-mediated inflammation of the small intestine caused by sensitivity to gluten (found in wheat, rye, and barley) in genetically susceptible individuals. The disorder occurs in 0.5–1% of the general population in most countries. It may be asymptomatic, or may present with a variety of gastrointestinal and non-gastrointestinal manifestations, presenting either in childhood or adult life.

Celiac disease often presents during late infancy or early childhood with chronic diarrhea, with or without malnutrition. Stools are typically bulky, foul smelling, and may be floating steatorrhea; alternatively, it may be watery, and in some patients manifested as frequent passage of normal soft stools. The stools may also be bulky but infrequent, and some patients even present with constipation. Patients may also have abdominal distension, anorexia, weight loss, muscle wasting, and hypotonia. Non-gastrointestinal manifestations include irritability, mouth ulcers, dermatitis herpetiformis, dental enamel hypoplasia, osteopenia/osteoporosis, short stature, fatigue, delayed puberty, iron-deficiency anemia resistant to oral iron supplements, hepatitis, arthritis, and infertility.

Celiac disease is associated with IgA deficiency, Type I diabetes, autoimmune thyroiditis, Down syndrome, Turner's syndrome, and William's syndrome. Screening for celiac disease is best done using serum tTG IgA. Recently, saliva tTG IgA has showed promising results as a screening test for celiac disease. The disease should be confirmed by intestinal biopsy.

Treatment is by a lifelong adherence to a gluten-free diet.

Microvillous inclusion disease (*microvillous atrophy*): is an inherited abnormality of the intestinal mucosal structure characterized by hypoplastic atrophy of the intestinal villi that can be identified on light microscopic examination of small intestinal biopsies. Further confirmation is made through electron microscopic examination. Affected individuals present with severe secretory diarrhea within days of birth. Patients may pass over 250–300 mL/kg/day of stool containing electrolyte concentrations similar to those seen in small intestinal fluid. Intestinal transplantation is the only definitive treatment.

Intestinal epithelial dysplasia (*Tufting enteropathy*): Its presentation is very much similar to microvillous atrophy.

Enterocyte heparan sulfate deficiency: similar presentation to microvillous atrophy.

Inborn Errors of Electrolyte Transport

Congenital sodium diarrhea: Congenital sodium diarrhea is an inherited defect in the Na^+/H^+ exchanger in the jejunal brush-border membrane, causing high stool Na^+ concentration, often more than 100 mmol/L. Patients present in utero with maternal polyhydrominous. Prenatal ultrasound shows a distended fetal abdomen with fluid-filled loops of bowel. Abdominal distension at birth may be marked, and can be misdiagnosed as intestinal obstruction. Profuse watery, secretory diarrhea is present from birth. Patients develop metabolic acidosis, and have increased serum aldosterone and renin activity. Normal colonic salvage of sodium can subsequently mask net intestinal secretion, and the diarrhea resolves during the

first year of life. The prognosis is generally good provided fluid and electrolyte losses are replaced in the first few months of life.

Congenital chloride diarrhea: It is the only type of diarrhea that causes metabolic alkalosis rather than acidosis. Affected babies are clinically indistinguishable from patients with congenital sodium diarrhea. Abdominal distension at birth may be marked, and can be misdiagnosed as intestinal obstruction. Stool may be so profuse and watery that it is mistaken for urine. Stool chloride concentration is greater than the sum of sodium and potassium (>90 mmol/L). The prognosis is good if it was early diagnosed and properly managed.

Acrodermatitis enteropathica: A recessively inherited defect in the intestinal absorption of zinc. Zinc deficiency becomes apparent in the first few months of life, manifesting by characteristic symmetrical, scaling erythematous skin lesions around the mouth, perianal area, and elbows. Patients also develop diarrhea, alopecia, and failure to thrive.

Plasma zinc is low as is alkaline phosphatase activity. If untreated, the disease is usually fatal. Lifelong treatment with oral zinc (30–45 mg elemental zinc per day) is curative.

Carbohydrate Intolerance

Carbohydrate intolerance results from the inability to digest certain carbohydrates due to deficiency of one or more of the intestinal disaccharidase enzymes. Disaccharidases, located in the brush border of the small-intestines' enterocytes, split disaccharides into monosaccharides to be absorbed (lactose is split into glucose and galactose, maltose into glucose and glucose, sucrose into glucose and fructose). Undigested disaccharides cause an osmotic load that attracts water and electrolytes into the bowel, causing watery diarrhea. Colonic bacteria ferment the carbohydrates in the colon-producing gases (H_2, CO_2, and methane), resulting in excessive flatus, bloating, distention, and abdominal pain.

Disaccharidase deficiencies can be congenital, late-onset (primary), or secondary. Congenital deficiencies are rare.

Late-onset lactase deficiency (*primary adult hypolactasia*): The most common form of carbohydrate intolerance is late-onset lactase deficiency. Lactase levels are high in neonates, permitting digestion of milk; however, in most ethnic groups, the levels decrease later on in life, rendering older children and adults unable to digest significant amounts of lactose. The decline in lactase activity level is genetically regulated, with the majority of the world's population developing low intestinal lactase levels during mid-childhood (approximately at age 5 years). Lactose that is not absorbed by the small intestine is passed rapidly into the colon, where it is converted by the bacterial flora to short-chain fatty acids and hydrogen gas. The short-chain fatty acids are absorbed by the colonic mucosa, thereby salvaging the malabsorbed lactose for energy utilization. The production of hydrogen by colonic bacteria serves as the basis for the lactose breath hydrogen test used to diagnose lactose maldigestion.

Secondary lactase deficiency: It occurs in conditions that damage the small-bowel mucosa (e.g., celiac disease, acute intestinal infections) due to loss of the brush border lactase enzyme. The deficiency of the lactase enzyme in this case is transient, and the enzyme activity normalizes following the recovery from the underlying disease. In infants, temporary secondary disaccharidase deficiency may complicate enteric infections resulting in prolongation of diarrhea, which may be severe enough to purge other nutrients before they can be absorbed. On biopsy, the intestinal mucosa appears abnormal with varying degrees of villous atrophy, and lactase enzyme activity is reduced concomitantly with other disaccharidases.

The diagnosis of carbohydrate intolerance is suggested if the stool is acidic (pH < 6), and positive for reducing sugars. Diagnosis can also be done by stool sugar chromatography. Lactose intolerance can be confirmed by H_2 breath test.

Management of disaccharidase deficiency consists of dietary restriction of the carbohydrates that cannot be absorbed. However, because the degree of lactose malabsorption varies greatly in patients with lactose intolerance, many patients can ingest up to 12 oz (18 g of lactose) of milk daily without symptoms. Yogurt is usually tolerated because it contains an appreciable amount of lactase produced by intrinsic Lactobacilli. Commercially prepared predigested milk (i.e., pretreated by the addition of lactase) can be used. Lactase drops and pills are also available.

Sucrase-isomaltase deficiency: can be congenital (CSID), or acquired.

CSID is an autosomal recessive inherited disorder characterized by the absence of intestinal sucrase, with varying degrees of isomaltase activity. The exact incidence of this condition is unknown. A high incidence has been observed in the Eskimo population of Greenland, where it has been reported in 10% of the population. Heterozygote carriers occur in 1 in 50 persons, and have a lower than normal sucrase activity. Symptoms will not appear until sucrose is introduced into the child's diet, and the severity of the symptoms depends on the residual enzyme activity, the amount of sucrose ingested, the rate of gastric emptying, the colonic bacteria, and the absorptive capacity of the colon. Infants usually present with severe watery diarrhea

associated with poor weight gain. Older children and adults may have less severe symptoms of an osmotic-fermentative diarrhea following ingestion of disaccharides and oligosaccharides. They may present with a picture identical to a diarrhea-predominant irritable bowel syndrome, with flatulence, especially at the end of the day, and episodic diarrhea associated with large sucrose intake.

The condition may also present with incontinence and intermittent watery diarrhea, or incontinence and intermittent abdominal distention in the older child. Stools are usually acidic and positive for reducing substances. The diagnosis can be confirmed by a sucrose breath test. An enzyme assay of the small intestinal mucosa will demonstrate the characteristic sucrase-isomaltase deficiency in morphologically normal mucosa. Affected children usually respond to a sucrose free diet within 24 h. Sacrosidase (Sucraid) supplement can be taken with each meal and snack.

Colonic adaptation to fermentation may result in spontaneous improvement.

Inflammatory Bowel Diseases Including Crohn's Disease, Ulcerative Colitis, and Indeterminate Colitis

Diarrhea associated with abdominal cramps, weight loss, and the presence of blood in the stools raises suspicion for *inflammatory bowel disease*. Although the incidence of *inflammatory bowel disease* is lower in young children, well-documented cases of *Crohn* and *ulcerative colitis* have been seen in children between 2 and 4 years of age.

Crohn's disease (*CD*): CD is an idiopathic chronic inflammatory disease that can affect any part of the gastrointestinal tract, from mouth to anus, with the terminal ileum being most frequently affected. CD of the gastrointestinal tract is characterized by "skipping" lesions, with inflamed areas interspersed with normally appearing mucosa. The rectum is usually, but not always, spared in CD. *Crohn disease* is characterized by transmural inflammation, anywhere in the gastrointestinal tract, with fissures, cobble-stone appearance, and skip areas. The inflammation can affect all layers of the bowel wall, and may lead to perforation, abscess, and fistula formation. Patients frequently present with chronic diarrhea that is usually not grossly bloody, and abdominal pain that is frequently located in the right lower quadrant. Growth retardation is common. Intestinal biopsy may detect noncaseating granulomas.

Pharmacologic treatment, during an acute exacerbation, includes the use of methylprednisolone at 1–2 mg/kg/day, tapered slowly over 4–6 weeks, depending on response. Sulfasalazine and meselamine are used to induce remission.

Ulcerative colitis (UC): UC virtually always involves the rectum, and the inflammation may extend proximally in a continuous manner to variable lengths of the colon though a backwash ileitis may occur in the presence of severe cecal disease. Patients with UC typically present with bloody diarrhea, associated with abdominal pain that is relieved by bowel movement.

Autoimmune enteropathy: Presents with severe, persistent, secretory diarrhea caused by circulating anti-enterocyte and/or anticolonocyte antibodies. The severity of the enteropathy is highly variable. Some patients respond to dietary manipulation, but most require immunosuppression, to which not all respond. In these, the outcome is often fatal.

Pancreatic Diseases

Pancreatic diseases include conditions associated with a total pancreatic insufficiency, such as cystic fibrosis and Shwachman–Diamond syndrome, or with selective enzyme deficiency, such as congenital lipase deficiency.

Cystic fibrosis (*CF*): *CF* is the most common cause of exocrine pancreatic disease in white Caucasian children, occurring in 1 per 2,500 live births. The disease is caused by mutation of the cystic fibrosis transmembrane conductance regulator (CFTR) gene located on the long arm of chromosome 7. There are over 640 well-recognized mutations, the commonest being ΔF508 mutation. These mutations lead to impaired chloride transport in epithelial tissues, and inspissation of secretions and obstruction in the respiratory tract, pancreatic ducts, biliary tree, and intestines, as well as impaired chloride reabsorption from sweat duct which result in the characteristic high sweat chloride. Clinical signs of pancreatic insufficiency develop when less than 10% of normal pancreatic enzyme activity is present in the duodenum.

Most patients with *CF* (80–90%) have pancreatic insufficiency. In pancreatic insufficient patients, *CF* usually presents before 6 months of age with malnutrition and failure to thrive. Hypoalbuminemia and edema may also occur. Patients may also present with chronic diarrhea; with bulky, loose, foul, oily or watery bowel movements, and are at risk of fat-soluble vitamins deficiency (vitamins A, D, E, K).

Diagnosis is by a sweat chloride test (chloride level equal or more than 60 is diagnostic). Intermediate results of sweat testing (30–59 mmol/L in infants younger than

6 months, and 40–59 mmol/L for older children), should be clarified by DNA analysis using a CFTR multimutation method, and the sweat test should be repeated.

Shwachman–Diamond Syndrome (*SDS*): SDS is a rare autosomal recessive disorder characterized by exocrine pancreatic insufficiency, ineffective hematopoiesis, and skeletal abnormalities. After cystic fibrosis, SDS is the second most common cause of pancreatic insufficiency in childhood. Patients with SDS have exocrine pancreatic insufficiency as a result of failure of the pancreatic acinar cells to develop in utero and their replacement with fatty tissue. Pancreatic endocrine functions generally remain intact. Patients typically present in early infancy with malabsorption, steatorrhea, failure to thrive, and deficiencies of fat-soluble vitamins A, D, E, and K. They may have fatty stools but this tends to improve with age. Recurrent bacterial infections are common because of a neutropenia/neutrophil migration defect.

Evaluation may include a CBC (which may reveal neutropenia, anemia, or thrombocytopenia), but since neutropenia may be intermittent, CBC counts may need to be repeated biweekly over a 3-week period to document neutropenia. Fetal hemoglobin is elevated in approximately 80% of the patients. Neutrophil function studies may reveal neutrophil migration defect. Low serum pancreatic trypsinogen and low isoamylase levels are helpful markers for pancreatic insufficiency depending on the age of the patient. Fecal fat loss varies from 3% to 60%, and tends to decrease with age, so absence of steatorrhea in a 72-h fecal fat measurement test does not exclude the diagnosis of SDS. Pancreatic insufficiency can be diagnosed by the absence or decrease of pancreatic enzymes after stimulation with intravenous secretin and cholecystokinin.

For unknown reasons, pancreatic lipase secretion increases with age, often resulting in normal fat absorption. Approximately 50% of patients with SDS become pancreatically sufficient later in childhood.

Bile Acid Deficiency

Bile acids play an important role in micelle formation and fat absorption. Deficiency can occur in cirrhosis and chronic cholestatic liver diseases (e.g., biliary atresia, primary biliary cirrhosis), diseases affecting the terminal ileum (where bile acid absorption takes place), and following extensive resection of the terminal ileum. Bile acid can also be deconjugated by bacteria in patients with small bowel bacterial overgrowth.

Deconjugation of bile acids renders free bile acids amenable for absorption, thus lowering the luminal bile acid available for micelle formation and fat absorption, leading to steatorrhea. Additionally, free fatty acids may cause damage to the mucosa and further contribute to malabsorption.

Motility Disorders

Functional diarrhea (also known as chronic nonspecific diarrhea of childhood, or *toddler's diarrhea)*: Toddler diarrhea is the most common cause of chronic diarrhea in otherwise well children referred to pediatricians in the developed world. It is a benign disorder characterized by daily passage of three or more large, unformed stools foul-smelling, mushy stools containing undigested food, with onset between 6 and 36 months of age. It is characterized by normal growth unless the child has been placed on a hypocalorie diet to relieve symptoms. It may result from dietary factors such as excessive fiber and low fat intake, ingestion of large amounts of osmotically active carbohydrates such as fruit juice, carbonated beverages, sorbitol.

Children with functional diarrhea usually pass stools only during waking hours. Early morning stools typically are large and semi-formed, then stools become progressively looser as the day progresses. There are periods of relatively normal stools or even constipation between the bouts of diarrhea. Virtually all children develop normal bowel patterns by 4 years of age. Apart from restricting fruit juices and carbonated beverages and increasing dietary fat to 30–50% of total calories, no other intervention is necessary. Response to the dietary intervention supports the diagnosis.

Fecal impaction and overflow incontinence: Chronic constipation often presents with the complaint of diarrhea. This results from seepage of loose stools around a hardened fecal matter in the rectum. The rectum becomes chronically dilated, and the child may lose the sensation of rectal fullness and the need to defecate. Soiling of the child's underwear occurs, which the parent may perceive as the loose stool and loss of control of diarrhea.

Irritable bowel syndrome (*IBS*): The typical presentation of IBS is that of multiple bouts of diarrhea alternating with constipation, associated with lower abdominal pain and flatulence. There is no weight loss, and the stool is negative for blood. Physical examination is normal. Some patients respond to fiber intake, others to elimination of suspected offending food. Antispasmodics, loperamide, and anticholinergics can be given.

Other Causes

Drugs: Many drugs can cause diarrhea. Identification of drugs as the cause of diarrhea depends on recognition of

the coincidence of the initiation of drug ingestion with the onset of diarrhea.

Lymphangectasia: Intestinal lymphangectasia is characterized by the formation of dilated lymphatic channels in the small intestine. These dilated lacteals result in poor lymphatic drainage which results in increased intestinal lymphatic pressure and leakage of protein, lymphocyte, and chylomicron-rich lymph into the intestinal lumen. Lymphangectasia may be congenital, or it can occur secondary to disorders that interfere with intestinal lymphatic drainage (e.g., constrictive pericarditis, patients with cavopulmonary anastomosis (Fontan), retroperitoneal tumors that compress the lymphatic drainage). Patients may present at any age, with diarrhea, vomiting, growth retardation, peripheral edema, or lymphopenia.

A number of congenital diseases are associated with lymphangectasia, including autoimmune polyglandular disease type 1, Noonan's syndrome, and aplasia cutis congenita.

Diagnosis can be established by measuring the fecal concentration of alpha1-antitrypsin. Alpha1-antitrypsin is a protease inhibitor that is present in the serum and not present in diet. Therefore, its presence in the stool indicates a protein-losing enteropathy. Mucosal biopsies show dilated lymphatic channels.

Since intestinal lymph flow varies with meal composition, dietary manipulation can provide symptomatic improvement. A low fat diet can reduce protein loss. Medium-chain triglycerides (MCT) are transported in portal blood and do not increase lymph flow, and can be used in the diet.

Prognosis is good, and spontaneous remission may occur.

Neuroendocrine tumors: Neuroendocrine tumors affecting the gastrointestinal tract are rare in children, and usually cause secretory diarrhea.

Gastrinoma (*Zollinger–Ellison syndrome*): Gastrinomas arise from enteroendocrine cells, located mainly in the pancreas and the small intestine, and result in unregulated gastrin secretion which in turn causes hypersecretion of gastric acid, and consequent peptic ulcers and chronic diarrhea. Diarrhea occurs because of the high volume of the gastric acid secreted, which exceeds the neutralizing capacity of the pancreatic bicarbonate, resulting in inactivation of the pancreatic enzymes, and interfering with the emulsification of fat by bile acids. The acid also damages the intestinal mucosa, causing malabsorption.

Less than 5% of patients with ZES present during adolescence. The disorder may be suspected in patients with multiple or refractory ulcers, or ulcers located distal to the duodenum and/or a secretory diarrhea and fat malabsorption. Fasting serum gastrin levels are usually elevated five- to tenfold.

VIPomas: Unregulated hypersecretion of vasoactive intestinal polypeptide (VIP) causes watery diarrhea, hypokalemia, and achlorhydria. VIPomas are very rare in children, but may occur as ganglioneuromas and ganglioneuroblastomas.

Diagnosis

History and Physical Examination

A detailed history and physical examination can often provide clues to the diagnosis, and point toward appropriate investigations. Neonatal onset of watery diarrhea suggests a congenital disorder (e.g., congenital chloride diarrhea, congenital sodium diarrhea, Tufting enteropathy). Steatorrhea and recurrent respiratory infections suggest cystic fibrosis. A history of excessive ingestion of carbonated drinks or fruit juices with normal growth parameters suggest chronic nonspecific diarrhea. Stools that become looser as the day progresses are typical of functional diarrhea. Small-volume fecal incontinence occurs with constipation and fecal impaction. An irritable child with failure to thrive, abdominal distention, and foul-smelling diarrhea may have celiac disease.

Diarrhea of abrupt onset suggests an infectious etiology. Diarrhea that develops during or within 6–8 weeks of antibiotic therapy suggests antibiotic-associated diarrhea. Stools that contain blood or pus suggest inflammation, which can be caused by dietary protein intolerance (common in infants), inflammatory bowel disease, or rarely chronic enteric infections. Passage of diarrheal stools at night raises the suspicion of an organic etiology.

A family history can suggest inherited disorders as celiac disease, cystic fibrosis, and inflammatory bowel disease. It is important to remember that as important a positive family history is, a negative family history does not rule out the possibility of an inherited disorder.

On physical examination, dry, brittle hair may suggest fat malabsorption. Pale mucous membranes are seen in anemia, and may suggest blood loss or iron or vitamin B12 malabsorption. Dental hypoplasia may be seen in patients with celiac disease or Shwachman–Diamond syndrome. Clubbing of the fingers suggests a chronic disease like cystic fibrosis or IBD. Muscle wasting may be noted on the proximal limbs, and suggest malnutrition or chronic malabsorption. Edema may be noted on extremities, and suggest protein-losing enteropathy. Bony defects suggest Shwachman–Diamond syndrome.

Abdominal examination may reveal abdominal distension that can be seen in celiac disease and carbohydrate malabsorption. A tender abdomen may suggest enterocolitis. Signs of severe perianal erythema point toward carbohydrate malabsorption. Rectal examination may reveal skin tags, fissures, or fistulas that occur in inflammatory bowel disease. Soiling may be noted on the underwear, and fecal impaction may be noted on rectal examination, suggesting overflow incontinence.

Laboratory evaluation: Because the etiology of chronic diarrhea differs between developed and developing countries, and in situations where limited resources exist in developing countries, the diagnostic approach varies according to the situation.

In the developing countries, the predominant cause of chronic diarrhea is persistent infectious gastroenteritis, and because the diagnostic resources are often limited, an algorithmic approach to diagnosis and management is practical and usually effective.

Infectious diarrhea can be classified based on the appearance of the stools into watery or bloody. Most cases of persistent watery diarrhea in children in developing countries improve with improving the nutritious status and reducing the likelihood of reinfection, and require no further workup or medications. If watery diarrhea persists, stool microscopy can be performed to detect trophozoites or cysts.

Bloody diarrhea in most cases is caused by Shigella spp (45–67%), or Campylobacter (35–37%). If available, bloody diarrhea should be tested by stool microscopic examination, and treatment based on local resistance patterns should be started empirically. If no improvement is seen within 2 days, treatment should be changed to another agent known to be effective against local strains.

E. histolytica is the most important nonbacterial pathogen in bloody diarrhea, but is responsible for less than 3% of the episodes. Empiric treatment of intestinal parasites is not recommended, except for persistent bloody diarrhea in a patient who has failed trials of two different antimicrobials known to be effective against local strains of *Shigella*. In this case, the patient can be treated empirically for amebiasis.

Comorbid conditions that may be the underlying cause of the malnutrition, such as cystic fibrosis, congenital heart disease, HIV disease, and tuberculosis, should also be looked for and addressed. All children should also be evaluated (and treated) for associated nonintestinal infections, including pneumonia, urinary tract infections, sepsis, and otitis media.

In developed countries, given the high prevalence of celiac disease and the availability of noninvasive, sensitive, and specific testing, most if not all children with chronic diarrhea should be screened for celiac disease. Serum testing for anti-tissue transglutaminase antibodies (tTG) is recommended. Testing serum immunoglobulin A (IgA) levels at the same time is suggested to avoid the possibility of a false-negative result in patients deficient in IgA (IgA deficiency is 10–15 times more common in patients with celiac disease than in healthy subjects).

Categorizing the stool type into watery, inflammatory, or fatty can help narrow the diagnostic possibilities.

In patients with watery diarrhea, assessing the effects of fasting on stool output can help distinguish between secretory and osmotic diarrhea, as fasting is associated with decreased stool volume in osmotic but not secretory diarrhea. Further distinguishing between osmotic and secretory types of watery diarrhea can be done by measuring fecal electrolytes, pH, reducing substances, and calculating the osmotic gap (*Table 190.2*). In children with secretory diarrhea, an infectious etiology should be suspected and evaluated.

Pure secretory diarrhea occurs in some congenital diarrheas, and should be evaluated according to likely etiologies. Patients suspected of hyperthyroidism should have TSH measured. Antienterocyte anticolonocyte antibodies should be done in patients suspected of autoimmune enteropathy.

The presence of reducing substances in the stool or low fecal pH (<6) suggest carbohydrate malabsorption. Patients suspected of lactose intolerance can undergo a hydrogen breath test (H_2 breath test).

In patients suspected of factitious diarrhea, stools should be checked for phenolphthalein, magnesium, sulfate, and phosphate to determine whether the diarrhea is secondary to laxative abuse.

Empiric treatment with broad spectrum antibiotics can also be done.

In patients with gross or occult blood, fecal leukocytes, or fecal calprotectin (a protein found in leukocytes), an inflammatory etiology of the diarrhea should be suspected and evaluated. A stool examination should be performed to exclude infection. If this is negative, the patient must be evaluated for inflammatory bowel disease; a complete blood count (may depict anemia, or thrombocytosis), and an increased erythrocyte sedimentation rate and/or C-reactive protein level, although not specific for IBD, suggest an inflammatory process. Further evaluation include small bowel contrast radiographs or CT scan (which can reveal mucosal thickening, strictures, fistulas) and upper endoscopy and colonoscopy with biopsies.

In patients with fatty diarrhea, fat malabsorption should be investigated. Celiac disease should be tested, and if excluded the patient should be tested for pancreatic

exocrine insufficiency. Cystic fibrosis can be tested by a sweat test and genetic screening. A secretin test can be done to evaluate pancreatic insufficiency.

Munchausen's syndrome by proxy: Measurement of stool electrolytes, osmolality, and magnesium content should be performed in any case of unexplained chronic diarrhea to evaluate for Munchausen's syndrome by proxy. Low stool electrolytes and osmolality suggests the addition of water to the stool. If magnesium concentration in the stool exceeds that in the plasma, it indicates cathartic administration. Stools should also be tested for phenolphthalein cathartics, emetine, and bisacodyl and its metabolites. A negative study may have to be repeated since children may ingest the laxatives intermittently.

Laboratory Evaluation of the Nutritional Status in Children with Chronic Diarrhea

CBC and red blood cell indices: Identify children with anemia. A microcytic, hypochromic anemia suggests iron deficiency which can occur in malabsorptive conditions such as celiac, or chronic blood loss, such as cow's milk allergy or ulcerative colitis. Serum ferritin level should be checked (may be falsely elevated in inflammatory conditions since ferritin is an acute-phase reactant). A macrocytic anemia suggests folate, or vitamin B12 deficiency (e.g., Crohn's disease of the distal ileum). The levels of these vitamins can be measured in the blood.

Prealbumin and albumin levels are good indicators of short- and long-term dietary intake, respectively. Prealbumin has a short half-life (approximately 2 days); thus it falls rapidly with poor dietary intake, and rises to normal values within 10 days of initiation of adequate nutritional treatment. Therefore, prealbumin can be used as a marker of acute malnutrition, and as a predictor of adequate nutritional therapy.

Albumin has a longer half-life (14–20 days), reflecting dietary intake during the preceding 3 weeks, and serves as a marker of chronic malnutrition (e.g., Crohn's), and as an indicator of the adequacy of long-term dietary intake.

Vitamins: The assessment of specific vitamin deficiencies may be necessary in children with chronic diseases associated with malabsorption or inflammation. Serum concentrations of vitamin A, E, and 25-hydroxy vitamin D can be measured directly. Vitamin K can be assessed by measuring prothrombin time.

Deficiency of water-soluble vitamins is less common, and levels should only be measured when clinically indicated.

Minerals: Zinc and magnesium deficiency may occur in patients with chronic diarrhea. Bone density studies may be indicated in children at risk for osteopenia (e.g., IBD, celiac disease).

Zinc therapy has proven its efficacy in reducing the severity and duration and mortality from diarrheal disease.

Treatment

The most important step in managing a child with chronic diarrhea is to assess and stabilize the hydration and nutritional status. Children with severe malnutrition should be treated in an inpatient setting. Hypokalemia and hypophosphatemia caused by intracellular ion shifts may occur during the early refeeding period, and can cause serious arrhythmias; therefore, serum potassium and phosphorous concentrations should be carefully monitored early in the course of nutritional rehabilitation of severely malnourished children. In most cases, breast feeding should be continued.

Children with moderate malnutrition, and those with dehydration, systemic infections, or infants less than 4 months of age, should be treated in an inpatient setting if possible. Malnutrition complicates the course of most cases of persistent diarrhea in developing countries, and is the primary target for treatment. Dietary therapy should aim at providing 150 Cal/kg/day. Deficiencies of vitamin A, zinc, folic acid, copper, and selenium are common in malnourished children, and should be supplemented. The WHO recommends zinc supplementation for children with diarrhea in developing countries at a dose of 10 mg/day for infants up to 6 months of age, and 20 mg/day for older infants and children, for 14 days. The WHO also recommends providing at least two times the recommended daily allowance (RDA) for folate, vitamin A, iron, copper, and magnesium, for 2 weeks.

Further treatment depends on the specific etiology of the chronic diarrhea.

Prognosis

Prognosis in chronic diarrhea depends on the etiology and the degree of dehydration/malabsorption and associated comorbidities.

Prevention

Control of sanitary conditions decreases the risk of infectious diarrhea. Breastfeeding, especially exclusive breastfeeding, protects against exposure, furthermore, breast milk contains lactoferrin, lysozyme, and oligosaccharides against enteropathogens, as well as antibodies which have a protective effect. In developing countries, breastfeeding to 2 years of age is recommended by the World Health Organization (WHO) and other agencies.

Treating cyst carriers can prevent shedding and spreading of *E. histolytica*.

191 Gastrointestinal Food Allergy in Infancy and Early Childhood

Ian R. Sanderson · John A. Walker-Smith

The term "food idiosyncrasy" has been used in the sense of a non-immunological abnormal response to food. There is, however, increasing evidence that dietary protein intolerance may be mediated by an allergic reaction or reactions affecting the gastrointestinal tract. It is those syndromes of dietary protein intolerance occurring in infancy and childhood that have an immunological pathogenesis which are the subject of this chapter.

Intolerance to various food may be due to a variety of causes; for example, a congenital enzyme defect such as sucrase-isomaltase deficiency, an acquired digestive enzyme defect such as lactase deficiency secondary to small intestinal mucosal damage, or may be immunological in origin.

Definitions

Gastrointestinal food allergies may be defined as clinical syndromes that are characterized by the onset of gastrointestinal symptoms following food ingestion where the underlying mechanism is an immunologically mediated reaction within the gastrointestinal tract.

A food-sensitive enteropathy is a disorder characterized by an abnormal small intestinal mucosa while having the offending food in the diet; the abnormality is reversed by an elimination diet only to recur once more on challenge with the relevant food. It may be permanent as it occurs in celiac disease. It may however be temporary, and such disorders are generally confined to infancy and early childhood.

Food-induced colitis is a disorder where ingestion of food produces a colitis which is reversed by an elimination diet and which relapses on challenge.

Clinical Spectrum

There is no consistent association between a particular food and any specific syndrome. Clinical intolerance to a variety of food proteins has been described. The most common variety of food protein intolerance described are those to cows' milk, cereals, soy protein, eggs, and fish and intolerance to tomatoes, oranges, bananas, meat, nuts, and chocolates.

Gastrointestinal reactions to food in children with food allergy may be divided into those that manifest quickly, i.e., within minutes to an hour of food ingestion, and those in which the onset is slow, taking hours or days after food ingestion. Both types of reaction may occur individually or together in different children. Yet there are clear immunological differences between these groups. For example, it has been shown by Fallstrom et al. (1986) that children with slow onset reactions to cows' milk feedings have significantly elevated titers of IgG antibodies against both native and digested beta-lactoglobulin, when compared with both controls and those children who develop symptoms quickly after milk ingestion. These children also tend to have higher levels of IgA antibody to both native and processed milk.

Elevated titers of IgE antibodies to cows' milk protein are typical of quick reactors. However, IgE is also elevated in some children with slow onset reactions with enteropathy. Such elevated titers can on occasion be found in milk-tolerant, atopic children. These gastrointestinal food syndromes of early childhood appear to be temporary in duration, although it does seem possible – as in the case of cows' milk protein intolerance – that gastrointestinal syndromes may be replaced with the passage of time by syndromes involving other systems.

Quick Onset Syndromes

The children with quick onset syndrome often have an individual and family history of atopy, peripheral eosinophilia, elevated total serum IgE levels, and positive RAST and skin prick tests to specific foods.

Little information is available concerning small intestinal mucosa in these quick onset syndromes as children with these disorders are not usually biopsied. Theoretically, from animal studies the small intestinal mucosa may be normal.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_191,

When there is intolerance to a number of foods, diets involving the elimination of a number of foods may be impractical or ineffective on their own. However, the addition of disodium cromoglycate may be effective. Curiously, if oral disodium cromoglycate alleviates symptoms these may not relapse when the drug is discontinued.

These patients need to be distinguished from cases of eosinophilic gastroenteritis.

Eosinophilic gastroenteritis is a disorder characterized by gastrointestinal thickening with edema and dense infiltration of eosinophils. It usually affects the gastric antrum and proximal small intestine. It is usually a disorder of young adults but may occur in children. Clinically it is characterized by protein-losing enteropathy and peripheral eosinophilia. IgE levels may be elevated and some patients have been reported to respond to a cows' milk-free diet. Although most patients are not responsive to diet manipulation, some do respond to disodium cromoglycate.

Slow Onset Syndromes

Slow onset syndromes usually present as a gastrointestinal problem to pediatric or pediatric gastroenterology clinics. Affected children may often have failure to thrive. In these cases there is often no clear history of food ingestion being related to the onset of symptoms. Diagnosis may be difficult. Accurate diagnosis requires further investigations of gastrointestinal and immunological functions.

Once the initial investigations have been performed, dietary elimination and challenge continue to have an important diagnostic role. This approach is of best value when such elimination and challenge is related to gastrointestinal structure and function, i.e., serial observations. At present, there are no simple laboratory tests available for routine diagnostic screening of children with these slow onset gastrointestinal symptoms. In individual patients cows' milk antibody estimation is not diagnostically useful. In children, such problems often overlap with gastrointestinal infection thus making diagnosis difficult. Full microbiological study of the stools is needed, i.e., stool virology, as well as stool bacterial culture, because infection of the gastrointestinal tract can be easily overlooked in children presenting these symptoms.

Transient Food-Sensitive Enteropathies

Changes in the structure of the small intestinal mucosa in response to the ingestion of particular foods provide clear objective evidence of food-sensitive disorders affecting the small intestinal mucosa. This approach of using serial small intestinal mucosal biopsies related to dietary elimination and challenge was first used for the diagnosis of celiac disease in the Interlaken or European Society of Pediatric Gastroenterology and Nutrition (ESPGAN) Diagnostic Criteria. In recent years the use of a small biopsy capsule has been replaced by endoscopy and biopsy. Celiac disease is a state of permanent food sensitivity, but there also exists a group of temporary food-sensitive enteropathies, presenting in infancy. Indeed a number of foods apart from gluten have now been shown to produce food-sensitive enteropathies in infancy. These include cows' milk protein, soy protein, eggs, chicken, ground rice, and fish.

Pathology

Most information available concerns cows' milk–sensitive enteropathy and is based upon small intestinal mucosal biopsy. What evidence there is for other food-sensitive enteropathies suggests that the pathology is essentially similar. The characteristic feature is small intestinal mucosal damage of variable extent and severity. The lesion is often patchy. Within one biopsy there may be a wide range of morphological appearances from normal to severe abnormality. Indeed a single normal small intestinal mucosal biopsy does not exclude this diagnosis.

The changes are nonspecific and can only be established to be induced by cows' milk by means of serial small intestinal biopsies taken first at the time of initial diagnosis on a cows' milk containing diet; second after clinical remission on a cows' milk-free diet; and third after a clinical relapse after a return to a cows' milk containing diet, i.e., a cows' milk challenge. Despite their nonspecific nature, when these biopsy changes are found in children with the typical clinical features, i.e., chronic diarrhea and failure to thrive and other causes such as giardiasis have been excluded, their presence is an indication for a therapeutic trial with a cows' milk-free diet. When there is a rapid clinical response to such a diet, from a practical view-point the diagnosis can only be said to have been established when this is followed by a clinical and histological relapse following cows' milk challenge.

The histological changes found in cows' milk–sensitive enteropathy are indistinguishable from those found in post-enteritis enteropathy. As the two disorders overlap it may not be possible to distinguish them without an early cows' milk challenge. This in practice may not be practical as it may not be seen to be a helpful aid to

management, and early cows' milk challenge carries the risk of a severe relapse.

The classical lesion found in the small intestinal mucosa is villous atrophy of variable severity. It is usually less severe than that found in celiac disease. A flat mucosa is quite uncommon. The mucosa is typically thin. While there may be some lengthening of the crypts the most characteristic feature is shortening of the villi, the epithelial abnormality is less severe than in celiac disease. However, functional damage to the enterocyte is usually present.

There may be an elevation of the intraepithelial lymphocyte count. This is not usually as high as in celiac disease. Gamma/delta T cells density is increased in the intraepithelial lymphocyte population of patients with celiac disease.

There is increased DR^+ $CD4^+$ cells in the lamina propria in children with CMSE and increased intraepithelial $CD8^+$ cells. This suggests that a cell-mediated reaction is the basis of the abnormality. In addition, T cell in the duodenal mucosa produced less TGF-beta in children with food allergy suggesting a loss of the ability to downregulate immune responses. This is important because Peyer's Patch T cells in humans have been shown to be sensitized to dietary antigen, and display TH1 phenotypes.

However, the involvement of IgE in the immunological response of the lamina propria to cows' milk challenge in children with cows' milk–sensitive enteropathy has also been described. Furthermore, infiltration of both eosinophils and mast cells occur in cows' milk–sensitive enteropathy. After a relatively short period on a cows' milk-free diet all these changes either heal completely or significantly improve on a cows' milk-free diet.

Pathogenesis

In order to explore the pathogenic role of allergic reactions in gastrointestinal allergy, Type I, Type III, and Type IV reactions have been induced in experimental animals.

Type I or immediate reaginic allergic reaction results in the development within 5 or 10 min of microscopic edema, mucus secretion, and increased blood flow. Histologically, the mucosa may be entirely normal or just show some edema of the lamina propria and small subepithelial blebs.

In a study of intraluminal antigen challenge of actively or passively immunized pigs to produce a type III or immune complex allergic reaction, a massive influx of polymorphs to the mucosa was shown but without morphological damage.

A variety of type IV, local cell-mediated reactions in the mucosa have been produced in animals. The earliest changes in these cell-mediated reactions are infiltration of lymphocytes into the lamina propria and the epithelium. The crypts lengthen (i.e., become hypertrophied) and crypt cell production rate is increased. Villi are shortened. These changes are mediated by lymphokines secreted by activated T cells. So it could be hypothesized in gastrointestinal food allergy, where there is a cell-mediated reaction, that lymphocytes in the small intestinal mucosa lamina propria, which have been sensitized to dietary antigen, interact with food antigens that enter the mucosa from the gut lumen. This leads to activation of T lymphocytes leading to crypt hypertrophy and reduction in villous height. Whether an IgE-mediated reaction plays any part such as triggering the reaction remains unclear.

The evidence that the small intestinal enteropathy, reported in children with gastrointestinal food allergy, is directly related to the ingestion of a particular food is based upon serial small intestinal biopsy studies related to dietary elimination and challenge. The enteropathy is not usually severe as that seen in celiac disease, although a flat mucosa may occasionally be seen.

The underlying causes of temporary food intolerance, in some children following an acute episode of gastroenteritis, probably relate to a transient sensitization of the child to dietary antigens, which may be a result of a breach of the mucosal barrier. The precise mechanisms that cause the enteropathy are unclear. For the reactions to occur the offending food antigen must enter the mucosa in appropriate amounts to cause sensitization. Post-enteritis food-sensitive enteropathies may result from excess local food antigen entry in susceptible individuals following gut damage induced by viral or bacterial pathogens.

There are probably two syndromes, a primary disorder of immunological origin and a secondary disorder, a sequel of mucosal damage. Abnormal handling of dietary antigens across the intestinal mucosa probably occurs in infants with gastrointestinal food allergy. This may be related to a temporary immunodeficiency state such as transient IgA deficiency or to nonspecific small intestinal mucosal damage from any cause permitting excess antigen entry. The pathogenetic role of circulating antibodies to cows' milk remains to be established.

Involvement of systemic immunity, and the local immune system, could explain the transient nature of the illness. The illness could disappear after a period on a milk-free diet when the small intestinal mucosa local immune system was mature enough to prevent much antigen getting through. The role of cell-mediated immunity would come into play in the case of those children who mounted a cell-mediated reaction in the small intestinal mucosa.

Genetic Factors

Although an atopic family history is often very common, no definite genetic factor has been identified. Boys and girls appear to be equally affected. A genetic variation in the control of antigen absorption by the gut has been shown in animals. If this is so in humans, certain individuals may be more predisposed to develop dietary protein intolerance than others.

Food-Sensitive Colitis

Rectal loss of fresh blood that responded to cows' milk withdrawal is well recognized. The advent of safe colonoscopy and multiple mucosal biopsy even in early infancy has clearly established food-sensitive or allergic colitis as an important cause of chronic bloody diarrhea in infancy. Colonoscopically, there is patchy erythema of the mucosa and petechiae and there may be aphthoid ulceration. Histopathologically, edema and infiltration with eosinophils have been reported although others describe a histopathological appearance not dissimilar to ulcerative colitis with an inflammatory infiltrate; however, both changes disappear on a cows' milk-free diet only to reoccur on early challenge. Even breast-fed infants whose mothers drink much cows' milk may develop cows' milk colitis. β-Lactoglobulin has been demonstrated in the breast milk of lactating mothers although the amounts are very small. This disorder needs to be distinguished from ulcerative colitis and Crohn's colitis. The diagnosis rests upon endoscopy and the histopathology demonstrated by mucosal biopsy and the subsequent clinical course, including resolution of symptoms with cows' milk elimination. In food-sensitive colitis, there may be a dense infiltration of eosinophils in the mucosa and the lesion resolves on food elimination pari passu with clinical remission.

It is now clearly established that a variety of foods, but particularly cows' milk, may be associated with food allergy in early childhood causing structural and functional damage to the intestinal mucosa both large and small. Temporary elimination of the offending food is recommended.

192 Probiotics in Gastrointestinal Disorders

Aziz Koleilat

Introduction

Probiotic is currently defined as a live microbial food supplement with a proven beneficial effect on human health. Probiotics are live microorganisms that occur naturally in the human digestive system. They consist of yeast or bacteria, especially lactic acid bacteria, and are available as capsules, powder, fermented milks, or yoghurts. Most probiotics are bacteria, which are small, single-celled organisms, normal inhabitants of microflora that may confer several benefits, including prevention against intestinal inflammation. Bacteria are categorized by scientists with genus, species, and strain names. Probiotics exhibit strain-specific differences in their resistance to acid and bile, ability to colonize the gastrointestinal tract, clinical efficacy, and benefits to the health of the host.

Health benefits attributed to probiotics have been described for decades. They include the treatment and the prevention of gastrointestinal diseases, vaginal and urinary infections, as well as allergies.

Mechanisms of Action of Probiotic Bacteria

Human beings, like all animals, play host to many types and high numbers of microbes on our skin, mouths, in women's vaginal tracts, and all the way throughout gastrointestinal tract. In fact, it has been estimated that there are more microbes associated with the human body (about 10^{14}, or 100,000,000,000,000 bacterial cells) than there are human cells in it (about 10^{13}). In addition to this very large number of bacteria, there is also a very large diversity of bacteria. It has been estimated that more than 400 different species, or types, of bacteria make their homes on humans.

Taking this into consideration, it is not surprising that microbes have been found to play an important role in human health. Most of these bacteria are not harmful, and in fact contribute positively to normal human growth and development. But some of these bacteria can have negative influences. It is therefore important that the balance of microbes be maintained to favor the beneficial bacteria over the potentially harmful ones as is necessary for digestive and immune health.

To understand how probiotics work, it is important to understand a little about the microbiology and physiology of the human gastrointestinal tract. Probiotic bacteria are normal inhabitants of microflora and may confer several benefits, including prevention against intestinal inflammation. However, the exact mode of action of probiotics is still largely unknown. The first line of defense against the entry of pathogen is represented by the gut membrane barrier and probiotics may prevent pathogen-induced membrane damage by inhibiting pathogen adhesion and maintaining the correct organization of the tight junction and cytoskeleton proteins.

The origin of microbiota and its development depends on genetics, mode of delivery, early feeding strategies, and the hygienic conditions around the child. In diseases with a defective mucosal barrier, probiotics have been documented to decrease intestinal permeability. Mucus production increases in response to certain probiotics, and cytokine-induced apoptosis of enterocytes may be prevented. Complex interactions between the probiotic microorganism and the host may turn out to be more important than the more simple interactions that have been demonstrated with other bacteria.

It is probable that probiotics do not exert their effects by one single mechanism. However, which of the putative modes of action that is relevant when treating a specific disease is still unsettled.

Due to the incomplete understanding of how probiotics work, in vitro methods are not useful tools for evaluation of probiotics and randomized clinical trials have to be performed to test the probiotic abilities of each specific strain for each specific condition. However, this is a very tedious task to handle in a systematic way. Although the number of bacterial species with theoretical probiotic potentials is limited, the number of specific bacterial strains within each species is countless. For the time being, data obtained from in vitro studies and animal models has to be relied on, and carefully designed randomized clinical trials have to be

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_192,

carried on. The native microbiota of an infant gastrointestinal tract is modulated through contact and interaction with the microbiota of the parents and the infant's immediate environment. Modifying this exposure can take place by probiotic bacteria when breastfeeding is not possible. Thus, incorporating specific probiotics may form a beneficial possibility for future infants feeding purposes.

Many probiotics have documented strain-specific health-promoting effects, and most of the effects have been demonstrated in infants and children.

Molecular and cellular mechanisms of probiotics in therapy are mainly manifested as:

- Restoration of microbiologic balance in the intestine
- Competition with pathogenic bacteria for specific binding sites on intestinal epithelial cells
- Protective functions through modulation of immune activity and epithelial function in both the large and small intestine
- Demonstration of enhanced phosphorylation of actinin and occludin in the tight junction region of epithelial cells
- Maintenance of barrier function by preventing cytokine-induced apoptosis in intestinal epithelial cell models through the inhibition of tumor necrosis factor
- Epithelial cell response to whole bacteria and bacterial components in a differential manner, releasing interleukin-8 in response to pathogenic bacteria such as *E. coli* but not to probiotic strains

The Effects of Probiotics in Various Disorders

Inflammatory Bowel Disease (IBD)

The first evidence for the use of probiotics in IBD in humans comes from pouchitis patients. Pouchitis is a complication after ileal–anal pouch anastomosis in ulcerative colitis (UC) patients. Therapeutic strategies are designed to intervene in these abnormal host microbial communications. A novel approach in the last decade has been to use other bacteria or selective foods to induce beneficial bacteria to normalize inflammation. No superiority of any probiotic was clearly evident, but a multiagent mixture, VSL3# maybe better suited in ulcerative colitis while the probiotic *Lactobacillus rhamnosus GG* appears less useful in other IBD, especially Crohn's disease (CD). The number of studies published with Crohn's disease patient is limited and results are conflicting.

Acute Infectious Diarrhea

Many studies have been performed on the effect of probiotics in acute diarrhea. Gastrointestinal infections are characterized by acute diarrhea. Administration of probiotics in combination or not with an antibiotherapy has shown to decrease the duration and the frequency of diarrhea.

Probiotics may be an effective adjunct to the management, *Lactobacillus GG Saccharomyces boulardii* in appropriate doses is mostly used.

Clostridium difficile Diarrhea

The efficacy of probiotics in *Clostridium difficile* diarrhea has been reviewed. *S. boulardii* and *L. plantarum* 299v were able to prevent disease recurrence in individuals who have more than one *Clostridium difficile* sequential infection, but did not have a beneficial effect on the first *Clostridium difficile* infection.

Antibiotic-Associated Diarrhea

Antibiotic-associated diarrhea is caused by a disturbance of the intestinal microbiota, direct tissue damage, or modulation of the immune system. Probiotics administered as yoghurt prevented antibiotic-induced changes in *Bacteroides fragilis* microflora cultured from human feces. In addition, *L. plantarum* 299v diminished antibiotic-induced overgrowth of *Candida albicans.*

Radiation-Induced Diarrhea

VSL#3 is a high-potency probiotic preparation that contains eight different probiotics. Significant reduction of radiation-induced diarrhea was seen in a clinical trial in patients undergoing pelvic radiation. Furthermore, patients treated with placebo had more severe radiation injury and higher mean daily number of bowel motions.

Irritable Bowel Syndrome (IBS)

Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder, characterized by symptoms such as abdominal pain, bloating, diarrhea, or constipation. Growing evidence suggests a potential role of intestinal microbiota in IBS pathophysiology and symptom generation in IBS patients. Initial evidence indicated the presence of increased amounts of bacteria in the upper small

intestine of IBS patients, a condition known as small intestinal bacterial overgrowth. Studies in IBS patients have attempted to target changes in intestinal microflora with different therapeutic approaches, such as the use of probiotics. Overall, results obtained in probiotics clinical trials suggest some beneficial effects over placebo in the relief of IBS symptoms. However, the number of dropouts in these studies was high and the role of concurrent medication and diet were not always taken into consideration.

Acute Pancreatitis

Infection of pancreatic necrosis is the major cause of death in acute pancreatitis. Microbial antibiotic resistance has become a worldwide problem due to excessive use. Several trials with enteral probiotics have shown a significant reduction of infectious complications in acute pancreatitis. It has been suggested that multi-species probiotics are more effective, because effects are strain specific.

Chronic Liver Diseases

Chronic liver diseases such as alcoholic hepatitis and cirrhosis are at risk of developing ascites and spontaneous bacterial peritonitis. Malondialdehyde and 4-hydroxynonenal (markers of lipid peroxidation) improved significantly in alcoholic liver cirrhosis patients while TNF-α, IL-6, and IL-10 improved significantly in chronic hepatitis C patients.

Helicobacter pylori Infection

Several clinical trials have suggested a role of probiotics in the treatment and prevention of *Helicobacter pylori* infection through both a probiotic-induced inhibition of *H. pylori* growth and adhesion to epithelial cells and an effect on the host immune system. Once again, probiotic species specificity is necessary for the therapeutic effect.

Postoperative Complications After Intestinal Surgery

Liver transplant recipients receiving fiber-containing enteral formula plus living *L. plantarum* 299v developed fewer bacterial infections than those receiving standard enteral formula. A larger prospective randomized trial showed that the incidence of bacterial infections after liver, gastric, or pancreatic resections was lower in the probiotic group.

Necrotizing Enterocolitis (NEC)

Probiotics could inhibit or reduce inflammatory signaling in the intestinal cells by inhibition of NF-Kb cascade or pathway, by inducing interleukin 10.

Probiotics might reduce the risk of necrotizing enterocolitis (NEC); however, the short-term and long-term safety of probiotics needs to be assessed and studied further in large trials.

Other Conditions

The potential role of probiotics in the prevention and treatment of lowering cholesterol levels, constipation, and cancer should be evaluated.

The Reasonable Move Toward the Use of Probiotics

Probiotics such as *Lactobacillus* species have been theorized to improve the balance of gastrointestinal tract flora and immune function within the gut. Through biopsies of the gastrointestinal tract, researchers have shown that probiotic bacteria can colonize and grow within the gut following oral administration. Moreover, in children with diarrhea due to rotavirus, *Lactobacillus* administration has been demonstrated to improve IgA humoral immunity compared with controls.

In addition, several clinical trials have provided evidence of probiotic effectiveness for the treatment and prevention of acute diarrhea and antibiotics-induced diarrhea as well as for the prevention of cow's milk-induced food allergy in infants and young children. Probiotics are also effective for the prevention of traveler's diarrhea.

Live probiotic bacteria and dietary prebiotics oligosaccharides are being used in infancy increasingly and they seem to be safe and increase resistance to respiratory infection during the first 2 years of life. They are beneficial to the gastrointestinal health of infants, and infants fed formulas containing probiotics or synbiotics proved to be safe and tolerable.

Conclusion

Probiotic bacteria are used to treat or prevent a broad range of human diseases. The intestinal microbiota is a very complex ecosystem, which has several important functions for the host. The efficacy of probiotics is

currently well documented with regard to the improvement of gastrointestinal functions.

Probiotics are normal living bacteria that give benefit if given in adequate and specified amount on the intestinal mucosal membranes. It plays an important role in the defense against potential pathogens, inflammation, and infection.

It stimulates the infant's immune system to respond with specific immunological tolerance, avoiding the development of allergic, inflammatory, and autoimmune diseases.

193 Protein-Losing Enteropathy

Hisham M. Nazer

Protein-losing enteropathies (PLEs) comprise a group of disorders associated with the loss of abnormal amount of protein into the gastrointestinal tract due to impaired integrity of the mucosa either due to systemic disorders or primary gastrointestinal disorders.

Protein-losing gastroenteropathy (PLGE) includes a large group of diseases characterized by enteric loss of plasma protein in abnormal amounts.

In most instances, PLGE is caused by enhanced mucosal permeability to proteins consequent to cell damage, mucosal erosions or ulcerations, and lymphatic obstruction.

The condition may be short-lived, as in the case of postgastroenteritis, or chronic, as in intestinal lymphangiectasia (IL) and celiac disease. The clinical presentation is highly variable depending on the underlying cause. The diagnosis should be suspected by the presence of hypoalbuminemia presenting usually with edema but without albuminuria. Other causes of hypoproteinemia should be considered. This may be due to either protein loss from intestinal lymphatics or due to loss of protein through an abnormally inflamed mucosal surface.

PLE is commonly diagnosed with radiotracer scintigraphy. MRI is recognized as a useful tool in diagnosis of primary PLE.

Management of PLE should also include dealing with the underlying cause (e.g., celiac disease or inflammatory bowel disease). Some of the recognized clinical conditions associated with PLE are listed in *Table 193.1*. These disorders are usually associated with either blockage of lymphatics or with abnormal mucosal permeability to protein.

Treatment is usually based on providing patient with high protein, low fat with medium chain triglycerides diet, fat-soluble vitamins, as well trying to treat the underlying cause. It is important to emphasize that PLE may complicate some cardiac disorders that result in protein loss through the gastrointestinal tract.

Prognosis: depends upon the severity and treatment options of the underlying disease.

Intestinal Lymphangiectasia

Intestinal lymphangiectasia (IL) is a rare disorder of the lymphatic system, inherited in an autosomal recessive manner characterized by the presence of PLE and dilatation of the small intestinal lymphatics. IL is the main cause of PLE in children. The disorder was originally described by Waldmann et al. (1961). IL may be primary or secondary to some other disorders as in constrictive pericarditis. IL is a potentially fatal disorder if not recognized early and treated properly.

Intestinal lymphangiectasia is characterized by obstruction of lymph drainage from the small intestine and dilated lacteal vessels that distort the villous architecture. It has been described prenatally and in preterm as well as full-term infants' siblings. IL is characterized by lymphopenia, peripheral edema and hypoalbuminemia, thickening of the small bowel wall, PLE, ascites, and pleural effusion.

Once suspected, the diagnosis is usually confirmed by increased fecal concentration of alpha-1-antitrypsin. The underlying cause may be further identified through stool cultures, cardiac screening, serology, or further radiological imaging.

Waldmann Disease is a rare digestive disorder characterized by abnormal dilatation of lymph vessels supplying the Lamina Propria of the small intestine. The main symptoms are abdominal discomfort and swelling of the limbs. The disorder may be congenital, present at birth, or acquired later on in life with abdominal discomfort and swelling of the limbs.

Pathogenesis

Primary IL (PIL) is a rare disorder characterized by dilated intestinal lacteals resulting in lymph leakage into the small bowel lumen and responsible for protein losing enteropathy leading to lymphopenia, hypoalbuminemia, and hypogammaglobulinemia. PIL is caused by a generalized disturbance of the lymphatic system that is probably congenital. The abnormal lymph vessels are located primarily at the level of the small intestine. IL may be generalized or localized depending on the site of blockage of mesenteric lymphatic drainage.

Lymphatic vessel obstruction and elevated intestinal lymphatic pressure results in lymphatic leakage into the intestinal lumen, thus resulting in malabsorption and

PLE. The exact mechanism of protein loss in the gut is not fully understood. Edema develops due to increased protein loss in the intestine. Lymphopenia is a recognized sequel due to the sequestration of lymphocytes in the intestine.

The main symptoms are predominantly bilateral lower limb edema; edema may be moderate to severe with anasarca and include pleural effusion, pericarditis, or chylous ascites, fatigue, abdominal pain, weight loss, inability to gain weight, moderate diarrhea, and fat-soluble vitamin deficiencies due to malabsorption may be present.

IL is a well-recognized complication of the Fontan procedure occurring in up to 24% of patients. Standard medical and cardiac surgical interventions are generally ineffective and the condition is potentially fatal.

Clinical Features

Intestinal lymphangiectasia is characterized by generalized disorders of the lymphatic channels with dilatation of the lymphatic vessels of the intestinal mucosa. There is also obstruction to the lymphatic drainage, which results in dilated intestinal lacteals.

Intestinal lymphangiectasia in the pediatric age group has a wide spectrum of clinical and laboratory manifestations determined by the anatomic location and extent of lymphatic anomaly. Some patients are mildly affected, while others may remain asymptomatic. There is no sex predominance in this disorder.

Symptoms include diarrhea, nausea, vomiting, fatty stools and abdominal pain, edema, low protein levels and low albumin levels. Peripheral edema is the most common complaint. The edema may be asymmetric.

The clinical presentations and radiologic findings of IL may mimic other gastrointestinal disorders, thus contributing to its delayed diagnosis. Nazer et al. (1991) reported three patients with IL who were previously considered to have celiac disease.

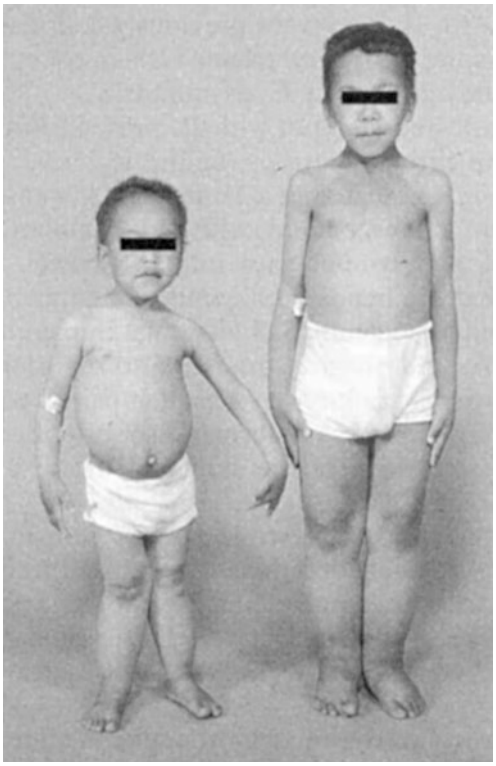

Figure 193.1
Two siblings with protein-losing enteropathy due to primary intestinal lymphangiectasia. Note the marked generalized edema in both siblings

Most affected children with IL present during their infancy with chronic diarrhea, failure to thrive, generalized edema (*Fig. 193.1*), steatorrhea, tetany, and increased susceptibility to infections. Patients with IL lose albumin, immunoglobulins, and lymphocytes into the bowel.

Laboratory findings include hypoalbuminemia, lymphopenia, hypocalcemia, and hypogammaglobulinemia. Impaired neutrophil chemotaxis and phagocytosis were also reported in IL. Affected patients are known to have impaired cell-mediated immunity. Affected patients may also suffer from recurrent bacterial infections of the skin, respiratory and urinary tracts.

Intestinal lymphangiectasia may present in association with other clinical conditions. Recognized associations include those with lymphedema, Zellweger syndrome, congenital hepatic fibrosis, and intussusception where IL acted as a lead point for intussusception.

Diagnosis

Intestinal lymphangiectasia is characterized by dilated lymphatic channels in the mucosa, submucosa, and serosa as well as the mesentery or the intestine. Most cases are diagnosed during childhood. Diagnosis of IL requires a high index of suspicion in a child with chronic diarrhea, failure to thrive, hypoalbuminemia, edema, and no albuminuria. Serum calcium is frequently reduced and stool fat content is usually elevated. Lymphopenia is usually present. Serum levels of IgG, IgA, and IgM are usually reduced.

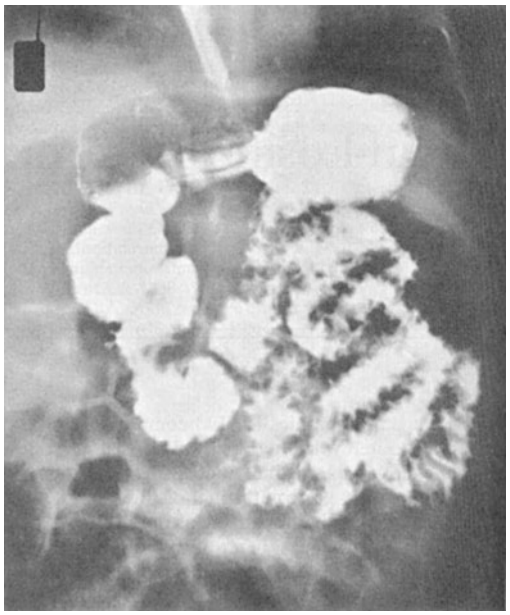
Small bowel follow through is often the initial examination performed. Typical findings include small bowel dilatation, diffusely thickened, coarse, mucosal folds, as well as haziness of the barium due to increased secretions (◉ *Fig. 193.2*).

CT and MRI can play an important role in suggesting the diagnosis and discriminating many secondary forms of IL. MRI can also provide information on the characteristics of fluid content in the small bowel because of the high concentration of protein and/or lipid. The absence of ionizing radiation makes MRI more suitable than CT in the follow up of patients with IL.

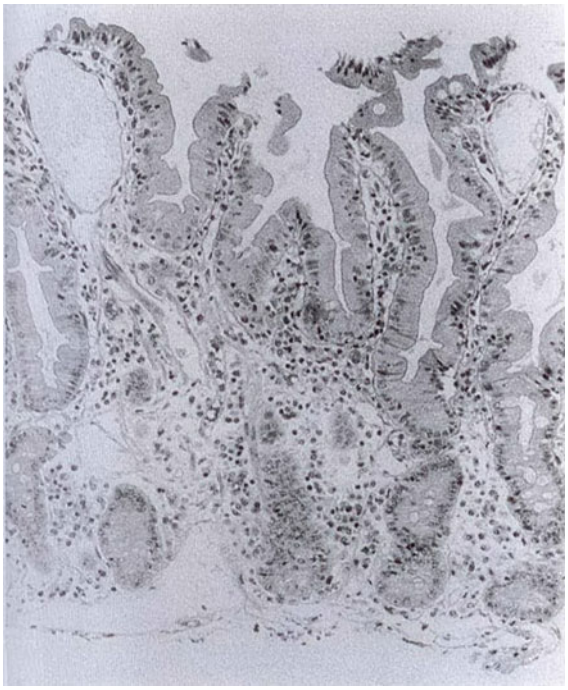
The diagnosis of PIL is that of exclusion, taking into account the wide variety of pathologic conditions that may be associated with intestinal lymphangiectasia, including Crohn disease, Whipple disease, Celiac disease, sarcoidosis, amyloidosis, tuberculosis, lymphoma, Budd–Chiari syndrome, systemic lupus erythematosus, chronic congestive heart failure, and constrictive pericarditis. The diagnosis may be supported by the demonstration of abnormal radioisotope protein loss through the gut.

Small bowel biopsy is still necessary to make the definitive diagnosis. Pathological findings vary from a normal appearance to severe changes. Findings at pathology include a dilatation of the lymphatics in the mucosa and submucosa of the small bowel with resultant bowel wall thickening due to edema and congestion (◉ *Fig. 193.3*). The disease may be patchy, which may result in the biopsy showing normal histologic findings and may have to be repeated if histologic diagnosis is to be established.

In view of the potential failure or blind small bowel biopsies in confirming the diagnosis of IL in some cases, endoscopically directed duodenal biopsies are preferred diagnostic measures. The intestinal changes are more likely to be demonstrated if the child was offered fatty



◘ Figure 193.2
Barium meal and follow-through in a child with intestinal lymphangiectasia. Note the thick irregular mucosal folds in the jejunum



◘ Figure 193.3

meals prior to endoscopy. The biopsies should be taken from the endoscopically abnormal mucosa at the sites of the dilated lacteals. The endoscopic appearance in IL is characterized by plaque-like white lesions overlying the mucosal folds. Biopsies should be obtained from those sites. Villous atrophy and cellular infiltration are absent.

The presence of alpha-1-antitrypsin in the stool is an important diagnostic clue because it is not normally absorbed or secreted into the bowel.

Lymphangiogram may be required to establish the diagnosis. The dye that is injected into the lymphatics of the leg is shown within the small intestinal lumen.

Some authors reserve the investigations of labeled protein excretion, being nonspecific, and the intestinal biopsy, which may miss the lesion, to those patients who do not show the well-recognized clinical findings of IL.

Treatment

Early diagnosis and treatment of IL is of great importance for diet therapy to be effective.

There is no definite cure for lymphangiectasia. Treatment is focused on control of complications, through dietary habits and possible drug therapy for various symptoms. In case of secondary lymphangiectasia, treatment also focuses on the underlying cause.

The treatment is essentially based on limiting the amount of long-chain fat in the diet. This will result in the reduction of the pressure within the dilated lacteals as long-chain fat is absorbed through the intestinal lymphatics. A low-fat diet is recommended for patients with IL. The diet is supplemented by medium-chain triglycerides, which are absorbed through the portal system and not through the lymphatics. In affected young babies, medium-chain triglycerides-based milk is administered. This dietary regimen usually results in clinical remission and cessation of symptoms. In most patients with primary IL, the underlying lymphatic defect and thus the need for dietary treatment appears to be permanent. Water-soluble vitamins and calcium supplements are needed.

Corticosteroid administration should be avoided. Some children who do not adhere to their diet or suffer from severe disease may at times require albumin transfusions. The parents should be advised that this dietary management may well be a lifelong measure that they should adhere to.

Octreotide, in combination with a low-fat diet, has been suggested as a medical treatment option in refractory cases of primary IL. Studies have shown that octrotides, 15–20 μg per body weight two times daily subcutaneously, may help to maintain serum albumin levels, improve clinical findings, and decrease the requirement of albumen infusion in refractory cases of primary IL.

Surgical resection of localized affected loops is rarely resorted to due to the difficulties in localizing the only affected segment and the uncertainty of its outcome. Surgical bowel resection is useful in the rare cases in which IL is segmental or localized.

194 Celiac Disease

Hisham M. Nazer · Mohamed Rawashdeh

Celiac disease (CD) is an immune-mediated enteropathy affecting the proximal small intestinal mucosa resulting in a permanent intolerance to dietary gluten in susceptible children. CD is characterized by an abnormal small intestinal mucosa leading to malabsorption and associated hematologic and clinical abnormalities.CD is one of the most frequent genetically based diseases of mankind.

Historical Background

The word *celiac* was first used in the second century BC by Cato. Aretaeus, the Cappadocian in the first century AD used the phrase the *celiac diathesis* to describe a condition characterized by the passage of undigested food accompanied by severe emaciation. In 1888 Gee, at St. Bartholomew's Hospital, London, published a paper on *the celiac affection*, describing it as "chronic indigestion," which is commonest in patients between 1 and 5 years of age. This was subsequently followed by the recognition that celiac disease is a lifetime disorder and may affect adults.

Dr. W. K. Dicke in Leiden, Holland, in 1950 was the first to observe that celiac children had improved on a gluten-free diet, as was the case under the appalling conditions of World War II famine, but had relapsed after bread and biscuits were flown to them from Sweden. In 1957, Sakula and Shiner in London demonstrated an abnormal jejunal mucosa in celiac children obtained through laparotomy. In 1969, the European Society of Pediatric Gastroenterology and Nutrition (ESPGAN) established the diagnostic criteria for celiac disease. Such criteria have been subsequently revised and so were the criteria set by the North American Society for PGHCN. The main objectives of such criteria were to ensure a definitive diagnosis from the start supported by well-recognized changes on small intestinal biopsies in the hope that such approach could well minimize the numbers of endoscopies and biopsies the child was supposed to have according to the initial criteria. The objective of such criteria was to make sure the diagnosis is definite especially as it is well known at present that CD is a diagnosis for life.

Incidence and Genetic Factors

Celiac disease is considered as one of the most important, genetically based, disease of the small intestine in childhood. The clinical classification of CD can be divided into *classic CD* (with the typical presentation and supportive histological changes on small intestinal biopsy) and other forms as follows:

Silent CD: patients who are asymptomatic but with a flat mucosa that reverts to normal after introduction of a gluten-free diet.

Potential CD: patients with positive serology and HLA DQ2 /DQ8 but normal or mildly abnormal small bowel histology.

Latent CD: patients with a normal jejunal biopsy when on a normal diet and that at some other time the biopsy has been flat and recovered on a gluten-free diet.

Atypical CD: patients with unusual gastrointestinal or extra-intestinal manifestations but with definite small bowel histology.

Celiac disease has a worldwide distribution, with a high prevalence in northwestern Europe. CD remains underdiagnosed with not more than 20% of patients identified. The incidence varies in different countries and at different times in the same country. For example, the incidence reported in Ireland between 1960 and 1974 was 1 in 300, but this has decreased to 1 in 1,376 in 1981. In Sweden, the incidence was 1 in 6,500 in 1968; this has increased to 1 in 285 in 1992. Accurate figures are not available for the USA or Canada, but a recent study based on the presence of serum endomysial antibodies suggests an incidence of 1 in 7,750 in the New York area.

The occurrence of celiac disease in Arab children has been the subject of only a few reports. In a survey of 34 celiac children between 1991 and 1994 in northern Jordan, the incidence was found to be 1 in 2,800 live births. This incidence is comparable to that of Europe and higher than that of the USA. The disease is certainly very uncommon in blacks living in North America, South Africa, or Britain.

Family studies have established that susceptibility to celiac disease is genetically determined. CD has a strong hereditary component; the reported prevalence of CD in

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_194,

first-degree relatives is approximately 10%. Fourteen percent of all jejunal biopsies of first-degree relatives of celiacs have been found to be flat, while monozygotic twins display a 70–100% concordance for the disease. This genetic influence has been mapped at least in part to the short arm of chromosome 6, and in particular to the region encoding the class II human leukocyte antigen. Initially, the disease was found to be associated with HLA class I alleles HLA-A1 and B8. More recently, closer associations have been described with HLA class II alleles DR3 and DQ2. These associations are insufficient, however, to be useful in the screening for celiac disease, in which multiple genes are probably involved. Genes encoding HLA DQ2 or DQ8 are found in the vast majority of patients with CD and testing for their presence can be useful for the diagnosis of CD.

Pathogenesis and Pathophysiology

Celiac disease is induced by the introduction of gluten to the diet of susceptible patients. Gluten is the protein found in wheat, barley, oats, and rye. Gluten from wheat and rye is toxic to all celiacs, while the toxicity of gluten from barley and oats is less established. Gluten is a large complex molecule that has four heterogenous classes of protein: gliadins, glutenins, albumins, and globulins. Gliadin has been recognized to be the toxic molecule. It has also been classified into four parts of protein called α, β, γ, and ω. α-Gliadin is the most toxic part to patients with celiac disease.

The mechanism by which mucosal damage occurs is not known. It was proposed that a protease or peptidase deficiency in the mucosa of the small intestine results in accumulation of gluten or its partially digested products that are toxic to the small intestinal mucosa. There is, however, increasing evidence favoring all immunologic abnormality as the cause for celiac disease. This is evident from an increase in local and systemic production of immunoglobulin (Ig) A and IgG antigliadin antibodies accompanied by autoantibodies (antireticulin and antiendomysial) against structural proteins of the small intestinal mucosa, leading to autodestruction. These antibodies are used in screening for celiac disease. Many diseases have been recognized to occur concomitantly with celiac disease. Many of these have an autoimmune basis, such as type I diabetes mellitus, IgA nephropathy, hyperparathyroidism, chronic active hepatitis, and juvenile rheumatoid arthritis. A higher incidence of celiac disease has been shown to occur in children with IgA deficiency.

Changes in the immune status occur in celiac disease, involving both cellular and humoral antibodies. Increased intraepithelial lymphocyte counts is a recognized finding in the intestinal mucosa of children with celiac disease. Recent studies have indicated that a defect in gluten-specific suppressor T cells precipitates celiac disease in genetically predisposed individuals. *In vitro* studies have indicated that crypt hyperplasia and villous atrophy may be the result of activation of lamina propria T cells.

Intestinal biopsy is essential for the diagnosis of celiac disease. Since 1960 biopsies were obtained using a Crosby capsule from the mucosa at the angle of Treitz. At present, intestinal biopsies are more often obtained through a fiberoptic endoscope from the first, second, and third part of the duodenum. The proximal small intestinal mucosa is abnormal, whereas the distal mucosa is usually normal, indicating that a noxious agent in the diet becomes completely hydrolyzed before it reaches the ileum.

Examination of small intestinal biopsies under the dissecting microscope allows rapid diagnosis of a flat or convoluted mucosa described in celiac disease compared to the fingers and leaves appearance in normal subjects (*Figs. 194.1a* and *194.2a*).

On conventional histologic examination, the characteristic though nonspecific changes include (a) partial to total villous atrophy, (b) absence of identifiable brush border, (c) crypts hyperplasia, (d) increased mitotic index in the crypts, (e) increased intraepithelial lymphocytes, and (f) increased plasma cells in the lamina propria (*Fig. 194.2b*). However, flat small intestinal mucosa with atrophied villi is not pathognomonic of celiac disease and may be seen in other conditions. Causes of flattening of small intestinal mucosa in childhood are listed below.

- Celiac disease
- Transient gluten intolerance
- Cow's milk protein intolerance
- Soy protein intolerance
- Gastroenteritis and postenteritis syndrome
- Giardiasis
- Protein energy malnutrition
- Intractable diarrhea of infancy
- Immunodeficiency
- Bacterial overgrowth

Clinical Features

Celiac disease was recognized as a disease with quite uniform clinical presentation with chronic diarrhea, abdominal distention, and weight loss or poor weight gain. Nowadays, CD is considered a disease with a wide clinical

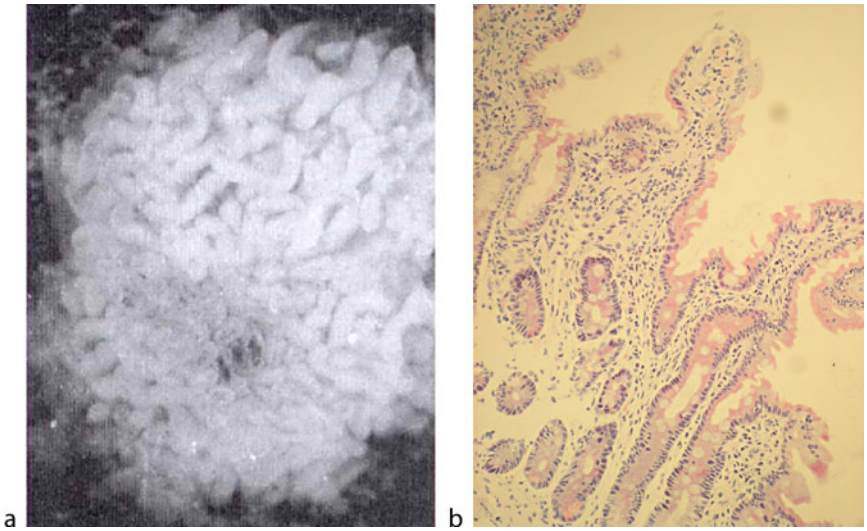

Figure 194.1
(a) Dissecting microscope appearance: normal small intestinal mucosa with leaf-like and tongue-like villi. (b) Histology: small intestinal mucosal biopsy with normal-looking villi

spectrum of intestinal as well as extra-intestinal presentation. Symptoms tend to occur weeks or months after the introduction of gluten-containing diet.

The age of onset of celiac disease is variable. Most cases are diagnosed in the second year of life. There is usually latent interval of variable duration between the introduction of gluten into the diet and the development of symptoms. This may take weeks, months, or even years. In the last few years, a new terminology was introduced within the more comprehensive definition of celiac disease because the numbers detected by screening are five or six times greater than those who received a clinical diagnosis The classic syndrome of chronic diarrhea, anorexia, failure to thrive, muscle wasting, and abdominal distention are most often encountered in young children (*Fig. 194.3*). In a retrospective study of 19 Saudi-Arab celiac children, the mean age of

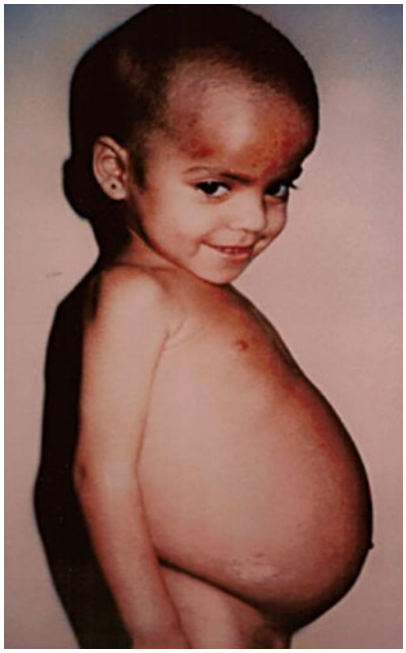

Figure 194.3
A child with active celiac disease: Note the marked abdominal distention

onset was 24 months. CD is no longer a disease of childhood and it could affect adults (Adult CD).

In a study of 34 Jordanian children with celiac disease, the mean age at presentation was 55 months. This rather late presentation may be related to the high prevalence of prolonged breast-feeding in Jordan, where 61% of mothers would still breast-feed at 15 months. Episodes of diarrhea may alternate with constipation, which occurs mainly in children who have anorexia and are generally hypotonic. The colon may be dilated, giving a clinical pattern that may be confused with Hirschsprung disease. Isolated short stature was the second most common presenting symptom.

Gastrointestinal complaints are often revealed only on direct questioning. In these children, there is often little to find on physical examination apart from shortness of stature. Celiac disease is estimated to cause 8–20% of cases of short stature in children.

At diagnosis, anemia, failure to thrive, short stature, and abdominal distention are commonly seen. Height and weight are usually below the 10th percentile, but can also be below 3% for age. However, with increasing new clinical patterns of CD experienced recently, some patients with confirmed CD may have normal weight for age and occasionally may be overweight. Such new trends pose more challenge to consider the diagnosis of CD in a wider spectrum of clinical feature much more than the classically recognized picture known for years. Other recognized rare associations of CD include some neurological disorders such as epilepsy with intracranial calcification seen on computed tomographic scan.

Bleeding disorders related to vitamin K deficiency have also been described. Skin manifestations such as dermatitis herpetiformis have been associated with celiac disease and subsided once a gluten-free diet is introduced. Recent report from Egypt has indicated the high prevelance of CD among Egyptian children with autoimmune hepatitis for which reason a recommendation was made to screen patients with autoimmune hepatitis for CD irrespective of presence or absence of gastrointestinal manifestations. CD is therefore looked at nowadays as a disorder associated with multisystem involvement.

Investigations

Iron deficiency anemia is more common, though less pathognomonic than megaloblastic anemia caused by folate deficiency. Low serum albumin and globulins may result from poor intake, malabsorption, and protein-losing enteropathy. Significant steatorrhea (>10% of fat intake) is found in the majority or cases.

Different screening tests were designed to avoid the conventional repeated jejunal biopsies. The sensitivity of IgG antigliadin antibodies reaches 100%; on the other hand; they are detected in 22% of patients with other gastrointestinal disorders. The IgA antigliadin antibodies are less sensitive (90%), but more specific (97%). Antiendomysium antibodies are most useful antibodies to look for in the screening for celiac disease, with a sensitivity and specificity approaching 100% in untreated celiac disease. Duodenal juice should be obtained and examined immediately for the presence of *Giardia* and sent also for culture if bacterial overgrowth is suspected.

IgA testing is recommended in children with suspected CD; if IgA deficiency is found, a duodenal biopsy or CD serology should be performed.

Diagnosis

The diagnosis of celiac disease is based on the presence of an abnormal small intestinal mucosa using the technique of small intestinal biopsy. Long-term treatment with a gluten-free diet should never be instituted without this evidence, especially in the developing world, where wheat

bread is the staple food. Celiac disease may exist latent in patients having normal mucosa when eating a gluten-containing normal diet.

When celiac disease is suspected, initial testing for serum immunoglobulin A (IgA), tissue transglutaminase (tTG) antibodies is useful because it offers adequate sensitivity and specificity for the diagnosis. A positive IgA tTG should prompt small bowel biopsy to confirm the diagnosis. Failure to diagnose CD can lead to significant long-term sequel.

Inspite of the well-recognized progress in serologic and genetic testing for CD, the definite diagnosis of CD upon which the decision to start gluten-free diet can only be made at the present by small intestinal biopsy and classical histology.

To establish the diagnosis, three jejunal biopsies and a gluten challenge were needed. These diagnostic criteria have been recently revised. Repeated biopsies and gluten challenge are indicated only when there is a doubt about the original diagnosis from the jejunal biopsy and if the child was less than 2 years of age at the time of diagnosis, where cow's milk protein intolerance and transient gluten intolerance may resemble celiac disease. Confirmation of the diagnosis is not needed if the initial diagnosis is based first on the appearance of flat mucosa while the patient is eating adequate amount of gluten.

The detection of circulating antibodies (lgA antigliadin, antireticulin, and antiendomysium) at diagnosis and their disappearance on a gluten-free diet supports the diagnosis. It is highly recommended that at least four biopsy samples should be obtained from the duodenum including the bulb because mucosal changes in celiac disease may be patchy.

The diagnosis is occasionally made difficult when a patient is suspected to have CD, has a negative anti-endomysial antibodies with a borderline histology.

Gluten challenge is usually performed 2–4 years after exclusion and preferably just before school entry. The gluten challenge is performed by adding to the diet 5–10 g/day of powdered gluten, or by allowing the child to gradually resume a normal diet. If significant symptoms occur, then a further biopsy is performed after a week following the return of symptoms. If the mucosa is abnormal, then the diagnosis has been established. If symptoms do not develop, a biopsy is done after 2 years of exposure to gluten. Such a practice is not universally agreed on as the recent trend is to make sure the diagnosis is confirmed at initial presentation without having to subject the child to a period of relapse in the course of trying to confirm the diagnosis. It is only in the situations stated above that the treating physician may be obliged to repeat the biopsies.

The diagnosis of CD is considered definitive when there is complete symptom resolution after treatment with a strict GFD in a previously symptomatic individual with characteristic histological changes on small intestinal biopsy. Genetic testing (HLA-DQ2 & HLA-DQ8) proved to be useful in the diagnosis of CD especially when the small intestinal biopsies and/or serology were inconclusive.

Treatment

A gluten-free diet produces dramatic and rapid clinical response in affected children with celiac disease. All foods containing wheat or rye should be excluded from the diet. Oats and barley are better avoided. Corn, rice, and potato flour are safe. Patients and parents should receive full instructions from the hospital dietitian or doctor and labels of commercially prepared food should be carefully checked. It may be advisable to exclude lactose for 1–2 weeks due to secondary lactase deficiency and to supplement the child with calcium, folate, and vitamins for 2 months Treatment with a gluten-free diet is expected to result in full clinical and mucosal recovery, and subsequent gluten challenge provokes a clinical and mucosal relapse.

There is at present some controversy on whether oat should be considered as part of a gluten free diet. There is no universal agreement on this issue at present as there are some patients who seem to tolerate oat and others who do not. As there are reports of intestinal damage following oat consumption, it may better to keep the child off oat at least for the initial stage of treatment until fully stabilized and then gradual challenge, with close observation and proper assessment, may be attempted.

A lifelong gluten-free diet is mandatory to prevent relapses of the disease, to attain growth potentials, and to prevent the development of malignant diseases like lymphomas as a complication of celiac disease. Treatment requires regular assessment by a medical specialist and an expert dietician, along with education and access to a support group in order to maximize the clinical outcome.

Celiac crisis with severe diarrhea and weight loss is often accompanied by acidosis, hypokalemia, and prolonged prothrombin time. Treatment includes intravenous replacement therapy, a gluten-free diet, and corticosteroids. Within 1 week of gluten restriction, behavioral disorders and appetite improve dramatically. This is followed by stools returning to normal and abdominal distention subsiding. Normal villous architecture is restored within a few months to 1 year. IgA antigliadin antibodies levels fall to

normal within 2–3 months. A small percentage of patients with CD may not improve on GFD as expected. Such patients often have severely damaged intestine that cannot heal even after they eliminate gluten from their diet. Therefore, those patients need to receive intravenous nutrition supplement and lactose-free milk formula.

Future Directions

Screening of high-risk groups and patients with the common symptoms of short stature, irritable bowel syndrome, iron-deficiency anemia, and unexplained arthritis.

One-time screening may be insufficient to detect all those who will develop CD.HLA-related genetic risk has been evaluated and revealed that future siblings of children with celiac disease are at increased risk to develop celiac disease.

The gold standard for diagnosis remains histological confirmation of small intestinal biopsies although serology remains useful for screening purposes. There is an increasing recognition that antigliadin antibody testing is no longer considered as part of the diagnostic strategy.

More efforts should be made to improve the accuracy of CD diagnosis and thus limit the number of patients with unresolved diagnostic dilemma. Researches into the use of genetic and serological markers for the diagnosis of CD should be encouraged to help ease the diagnostic difficulties that do arise in certain cases and to help the family in accepting this lifelong diagnosis with an easy long-term management.

Much research remains to be done to further refine our understanding of CD and to devise more effective strategies for treatment, compliance, and prevention of long-term complications.

195 Inflammatory Bowel Disease

Fayez K. Ghishan

Definition

Inflammatory bowel disease (IBD) refers to chronic inflammatory disorders of the gastrointestinal tract. The main diseases involved in these pathologic processes are Crohn's disease (CD) and ulcerative colitis (UC). The two diseases are different but appear to share some common clinical and pathogenetic features. The inflammation in CD extends throughout the thickness of the bowel wall from the mucosa to the serosa, whereas in ulcerative colitis the inflammation is confined to the mucosa and submucosa. Although the majority of CD cases involve the ileocolic segment of the gastrointestinal tract, it can affect any region of the gut. In contrast, ulcerative colitis is confined to the colon and always involves the rectum. The clinical, endoscopic, radiologic, and histologic features may distinguish between the two diseases in 85% of patients, another 15% will suffer from indeterminate colitis (IC). The diseases also appear to share some common immunopathogenetic factors. Epidemiological studies suggest that 70–80% of families with members affected by CD, have greater risk of developing CD than UC. The remaining 20% of multiply affected families are mixed (i.e., one member will have CD, whereas others will have UC).

Etiology/Pathogenesis

Recent advances in IBD research suggest a major role for genetic/environmental factors involving the innate and adaptive immunity resulting in dysregulated immune response to commensal bacteria in the intestinal tract.

Genetic Factors

The hypothesis of genetic susceptibility is supported by the higher frequency of IBD in first-degree relatives compared to the general population. Similarly, identical twins have a greater tendency to develop IBD than do fraternal twins. Moreover, Jewish populations seem to be at more risk. An association between different HLA types and susceptibility to IBD has also been proposed. Genome-wide association studies in families with CD compared to controls have shown that more than 40 genes are involved in patients with CD. Alterations in genes of the innate immune system, such as NOD2 (which encodes nucleotide-binding oligomerization domain protein 2; also known as CARD15), ATGI6L1 (which encodes autophagy related 16-like protein 1), and IRGM (which encodes immunity-related GTPase family M) are specific for patients with CD, whereas genes in the IL-23 pathway including IL23R (which encodes a critical subunit for IL-23 receptor), IL12B (which encodes the P40 subunit of IL-R and IL-23), and STAT3 (which encodes signal transducter and activator of transcription 3), have been shown in both CD and UC.

Immunological Factors

Accumulating evidence suggests that dysregulation of the normally controlled immunoresponse to commensal bacteria in a genetically susceptible host derives the development of IBD. Evidence for this concept comes from animal models of IBD, in which spontaneous chronic ileitis/colitis seems to be dependent in the presence of commensal luminal flora. In addition, enteric flora of IBD patients have been found to be more commonly associated with strains of *Escherichia coli* that adhere to the epithelium. Furthermore, empirically antibiotic therapy in patients with CD has beneficial effects.

Epithelial Barrier Function

The epithelial lining of the intestinal tract provide a barrier against luminal bacteria and environmental agents including food antigens. Earlier studies have shown abnormal intestinal permeability in first-degree relatives of CD patients. Expression analysis of biopsies from patients with IBD reveal downregulation of junctional complexes involved in the integrity of the epithelial lining such as E-cadherin and β-catenin. In addition to the columnar

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_195,

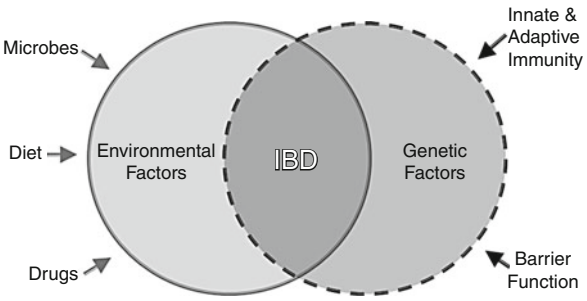

Figure 195.1
Pathogenesis of IBD

epithelial cells, paneth cells in the base of the crypts secrete α-defensins against microbes and their downregulation may contribute to the pathogenesis of IBD. Goblet cells which secrete trefoil peptides and mucus are also involved in the defense of the epithelial barrier, and indeed $Muc2^{-}/^{-}$ mice deficient in goblet cells develop spontaneous colitis. *Figure 195.1* depicts the pathogenesis of IBD.

Clinical Epidemiology of IBD

Incidence (frequency of new case over a certain time) and prevalence (total number of cases of a disease in the population at a given time) of IBD are beginning to stabilize in the Western world. However, they continue to rise in low incidence areas such as the Middle East and much of the developing world. In addition, racial and ethic differences seem to be narrowing. In the USA, 1.4 million people are affected by IBD and 2.2 million in Europe. In North America, the incidence rates for IBD range from 2.2 to 14.3 cases per 100,000 person-years for UC and from 3.1 to 14.6 cases per 100,000 person-years for CD. The peak incidence of IBD is between the ages of 15–25 years. Males and females are equally affected. *Table 195.1* depicts age distribution of IBD patients based on a composite of several studies.

Ulcerative Colitis

Ulcerative colitis (UC) is an idiopathic chronic inflammatory process confined to the colon with occasional cases of backwash ileitis. In almost all cases, the rectum is involved with varying degrees of proximal extension. Disease localized to only the rectosigmoid occurs in 15% of patients, disease extending to the left colon occurs in 22% of patients, while pancolitis occurs in 62% of pediatric patients. Involvement is usually continuous without the skip lesions characteristic of CD.

The clinical spectrum of the disease is wide and depends on the severity, extent, and the duration of the disease.

Table 195.1
Inflammatory bowel disease age of onset[a]

Clinical Manifestations

Intestinal Manifestations

Diarrhea with or without abdominal pain is the main complaint in most children. The stools may contain mucus and gross or occult blood. Nocturnal diarrhea should alert the physician to an organic disease. Abdominal pain in UC is less severe and frequent than in CD. The pain is usually colicky, is worse with food intake, and may precede bowel movements. Tenesmus can be severe and cumbersome. The sense of urgency and lower abdominal cramps are not relieved with defecation.

In acute exacerbations, anorexia can be severe. Lack of appetite can be related to a depressed mood or fear of abdominal pain brought about by food intake. Nausea and vomiting are uncommon. Their presence may indicate the development of toxic megacolon, intestinal perforation, or misdiagnosis of CD. Sixty percent of pediatric patients generally present with moderate to severe disease.

The most extreme presentation of the disease is the development of toxic megacolon. Toxic megacolon is a severe and life-threatening complication of the disease, occurring in 2–4% of children with UC. Patients develop severe bloody diarrhea, constant abdominal pain with distention, fever, pallor, and tachycardia. Abdominal x-rays show a distended colon with a diameter that exceeds 6 cm. Intestinal perforation and sepsis are the major complications.

Unlike CD, intestinal strictures and perianal lesions are uncommon in UC.

Extraintestinal Manifestations

Systemic manifestations are common in children and may wax and wane with disease activity.

Growth Failure and Delayed Puberty

Growth retardation is less severe and less frequent in UC (19%) than in CD (56%). It is related mainly to reduced food intake and increased loss of nutrients.

Musculoskeletal Lesions

Arthralgias are common in UC children, found in 24% of patients. On the other hand, arthritis is less common. Ten percent of children with ulcerative colitis have a migratory, asymmetric arthritis affecting the large joints of the lower extremities. Joint deformity is rare, and flare-ups usually indicate active colonic involvement. Ankylosing spondylitis, on the other hand, occurs in 6% of patients but the spinal disease progresses independent of colonic activity.

Ocular Lesions

There is a wide range of ocular manifestations in UC but these are not usually seen in children. Among the lesions described are uveitis, episcleritis, cataracts, and keratopathy.

Dermatologic Lesions

Erythema nodosum is seen in less than 5% of patients. Pyoderma gangrenosum rarely occurs in children. Oral aphthous ulcers occur in 2% of patients. The presence of any of these lesions is indicative of increased colonic activity, and the lesions resolve with treatment of colonic disease.

Liver Lesions

Fatty infiltration of the liver is the most common hepatic lesion and probably reflects chronic malnutrition. It is usually reversible. Pericholangitis, sclerosing cholangitis, and chronic hepatitis have been described in children, although less commonly than in adults. These diseases may predate the onset of ulcerative colitis and bear no relationship to colonic disease activity.

Hematological Findings

Iron deficiency anemia is common in children and is usually related to blood loss and nutritional deficiency. Patients on sulfasalazine may have macrocytic anemia due to folate malabsorption.

Renal Findings

Approximately 5% of patients with UC have renal calculi composed of calcium oxalate or uric acid. These are thought to be caused by chronic dehydration, decreased water absorption, and infections.

Fever

A history of fever is reported in up to 40% of patients at initial presentation.

Diagnostic Evaluation

Laboratory Tests

Stool examination usually reveals the presence of blood and leukocytes. With bloody diarrhea and fever, it is essential to obtain appropriate studies to rule out infectious agents such as *Salmonella*, *Shigella*, *Yersinia enterocolitica*, *Campylobacter jejuni*, *E. coli*, *Clostridia difficile*, and amoeba.

The erythrocyte sedimentation rate and c-reactive protein (CRP) are elevated during active disease. Hypoalbuminemia is more commonly seen in advanced UC and correlates with the severity of colonic mucosal lesions. Stool lactoferrin and calprotectin are elevated during active disease. Microcytic anemia and leucocytosis are common.

Serological Markers

The dysregulated immune response in IBD patients leads to the development of circulating antibodies in the serum of those patients. The antibodies are directed against multiple targets including autoantigens and bacterial antigens. The autoantigens include perinuclear anti-neutrophil cytosplasmic antibodies (PANCA) and antipancreas antibodies. The antibodies against microbial antigen include anti-sacchromyces cerevisial antibodies (ASCA),

Table 195.2
Serological markers in IBD

	Crohn's (%)	UC (%)	Healthy (%)
PANCA	10	50–60	0.5–1
ASCA	50–60	10	0.5–1
AntiOmpC	50–60	10	0.5–1
Antil2	50–60	10	0.5–1
AntiCBirl	50–60	10	0.5–1

anti-OmpC (outer membrane porin C antibodies), anti-CBirl (antibodies against pseudomonas fluorescens). *Table 195.2* shows the incidence of these antibodies in UC, CD, and healthy controls. In general, PANCA is positive in UC, whereas antimicrobial antibodies are positive in CD.

Endoscopic Studies

Endoscopic studies are the most reliable means for evaluating IBD. The findings on endoscopy are extremely variable. In the early stages, the mucosa is erythematous and edematous with loss of the normal vascular pattern. As the disease progresses, granularity and friability are noted with subsequent development of frank ulcerations surrounded by hyperemic, edematous, and friable mucosa. Pseudopolyps are sometimes noted. However, it is important to note that in the early stages, the mucosa may appear grossly normal. Therefore, obtaining mucosal biopsies is essential if clinical suspicion is strong.

Histologic Evaluation

The most commonly recognized histologic findings in UC are mucosal ulcerations, lymphocyte and plasma cell infiltrates in the lamina propria, crypt abscesses, and the absence of goblet cells. Although these findings are very suggestive of UC, they are not pathognomonic since similar findings can be seen in other pathologic conditions such as infectious colitis. Photomicrographs of mild, moderate, and severe ulcerative colitis are shown in *Figs. 195.2a–c*, respectively.

Radiological Evaluation

Radiological studies compliment endoscopy by evaluating the severity and extent of the disease. Plain films of the abdomen are valuable to evaluate the degree of bowel dilatation and to look for perforation in fulminant disease. Air contrast enemas are no longer utilized, rather CT scans with oral and IV contrast are preferred. Barium studies should be avoided in acutely ill children since they may precipitate a fulminant colitis with incipient toxic megacolon. In the early stages of the disease, findings are nonspecific and can be normal. As the disease progresses, there is usually loss of haustration, superficial ulceration, and thickening of the bowel wall. In more advanced disease, there is complete loss of haustration, narrowing, and shortening of the colon giving the *classically* narrowed and shortened "lead-pipe" appearance.

Differential Diagnosis

Several conditions can mimic UC. The clinical presentation and diagnostic evaluation should help establish an accurate diagnosis in most cases. Infectious colitis, caused by such agents as shigellosis, salmonellosis, yersiniosis, and clostridia difficile should be considered. Stool cultures are therefore necessary. Parasitic infestations, such as amebic colitis and schistosomiasis must also be considered. The diagnosis is established by the finding of parasites in the stool or on histological examination. CD has clinical and histological features that overlap with ulcerative colitis. Indeed, in about 15–20% of the patients, distinction between UC and CD cannot be made. In infancy, cow's milk allergy may present with bloody stools. Distinctive features are a history of allergy in the child or family, eosinophilia, high serum IgE levels, and a high number of eosinophils in the lamina propria. Connective tissue diseases, such as scleroderma and systemic lupus, may mimic some of the clinical features of UC. Such disorders are characterized by systemic manifestations with suggestive laboratory findings that may aid in the differential diagnosis.

Complications

Risk of Cancer

The risk for developing colonic adenocarcinoma in ulcerative colitis is a major concern, especially in patients in whom the disease starts in early childhood. It is estimated that the yearly risk of cancer is about 0.5–1% after 10 years of the disease. Surveillance at regular intervals is strongly recommended. The youngest patient reported to have colon cancer was 16 years old. In patients who have had

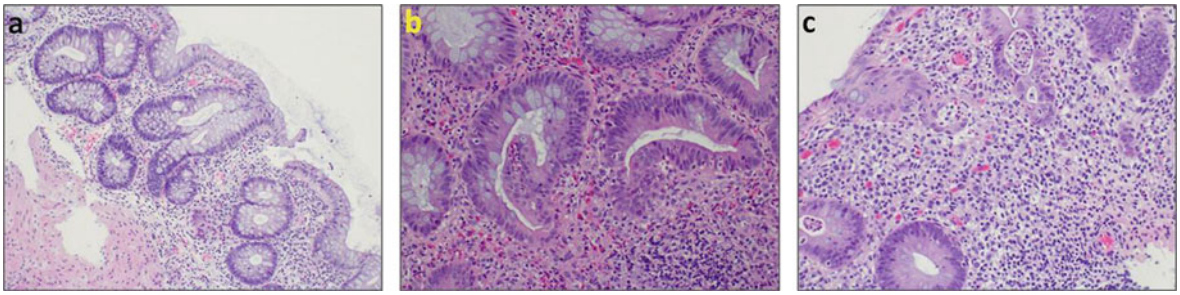

Figure 195.2

(a) Ulcerative colitis, mildly active. Rectal mucosa with crypt distortion, increased chronic inflammation and mild acute inflammation (magnification 100×). (b) Ulcerative colitis, moderately active. Colon mucosa with architectural distortion, increased chronic inflammation, cryptitis, and an early crypt abscess (magnification 200×). (c) Ulcerative colitis, marked activity. Colon mucosa with architectural distortion, increased chronic inflammation, cryptitis, and scattered crypt abscesses (Courtesy of Judith Pugh, M.D., Pediatric Pathologist, University of Arizona)

the disease for more than 10 years, an annual colonoscopy is generally recommended to evaluate for histological dysplasia.

Treatment

The approach to each patient is individualized and is based on the severity and the extent of the disease. First-line therapy for patients with mild to moderate disease is 5-amino salicylic acid (Mesalamine), which includes oral and rectal Mesalamine formulations and oral pro-drugs such as sulfasalazine (5-aminosalycilic acid linked to sulfapyridine), olasalazine (5-aminosalycilic acid dimmer), and balasalazide (5-aminosalycilic acid linked to 4-aminobenzoyl-beta alanine). Dosages vary depending on age, but in older patients, a dose between 2.4 and 4.8 g/day is needed to induce remission. For patients with left-sided colitis, topical 5-aminosalycilic acid alone or in combination with oral 5-aminosalycilic acid is needed to induce remission. For patients with Proctitis, suppositories of 5-aminosalycilic acid (Canasa®) may suffice, whereas enemas (Ruwasa®) will be needed for distal colitis. Mesalamine compounds should be used for maintenance therapy. Patients with moderate to severe disease, who fail Mesalamine, should be treated with steroids, plus azathioprine (2.5 mg/kg) or 6-mercaptupurine (1–1.5 mg/kg). Steroids are used to induce remission, whereas azathioprine or 6MP are used for maintenance. Patients who are unresponsive to conventional therapy may need infliximab at a dose of 5 mg/kg at 0, 2 and 6 weeks followed by maintenance therapy every 8 weeks. Other therapeutic modalities for patients who are refractory include cyclosporine and tacrolimus. Colectomy should be considered when all medical therapies are not effective. *Table 195.3* shows all masalamine compounds and their site of action.

Sulfasalazine

Sulfasalazine is effective in cases with mild to moderate disease activity and as a prophylactic agent to prevent relapses. Sulfasalazine is a compound drug that, when taken orally, is split by the colonic flora to sulfapyridine and 5-aminosalicylic acid (5-ASA). The latter is poorly absorbed and is the active anti-inflammatory agent that acts by inhibiting local prostaglandin and leukotriene synthesis. Side effects are common and are thought to be caused by the rapidly absorbable sulfapyridine moiety. These include anorexia, nausea, vomiting, and a serum sickness-like reaction. Anemia may also occur from either hemolysis or folic acid deficiency due to interference with folate absorption. Rarely, some patients may develop fever, vomiting, and bloody diarrhea.

Due to the high risk of adverse reactions, it is important to start with a low dose of 0.25–0.5 g daily and to increase the dose over 1–2 weeks to 2–3 g daily. Blood counts and red blood cell indices should be checked regularly. Folic acid supplementation is recommended to prevent macrocytic anemia.

Long-term therapy after controlling the acute episode is recommended in an effort to prevent relapses.

Aminosalicylates

Various new drugs have been developed that allow the delivery of 5-ASA without much of the systemic side

Table 195.3
5-Aminosalicylic acid preparations

Generic name	Trade name	Mechanism	Delivery site
Sulfasalazine	Azulfidine®	5-ASA-sulfapyridine coupling	Colon
Olasalazine	Dipentum®	5-ASA-5-ASA coupling	Colon
Mesalamine	Azacol®	pH-dependent capsule	Distal ileum
Mesalamine	Pentasa®	Time-release capsule	Jejunum, ileum, colon
Mesalamine	Lialda®	pH release with hydrophilic and hydrolipophilic coats	Colon

effects associated with sulfapyridine. 5-ASA, when not coupled to sulfapyridine, is easily absorbed by the stomach. In order to allow for delivery of 5-ASA to the colon, various mechanisms have been developed. These include drugs in which 5-ASA is linked to a new carrier moiety that is cleaved by colonic bacteria. Other drugs have been formulated in which 5-ASA is encapsulated by a time-release or pH-dependent coating (*Table 195.3*). (Lialda®) is another compound which utilizes a pH release mechanism with hydrophilic and lipophilic coats. These developments have also enabled the delivery of the drug to more proximal portions of the intestinal tract.

Topical delivery is in the form of 5-ASA enemas or suppositories have also been developed. These have been efficacious in treating active distal colonic and rectal disease, as well as preventing their relapse.

Corticosteroids

The efficacy of corticosteroids in UC is well established. These can be given orally, intravenously or rectally, depending on the severity and the extent of the disease. Patients with mild disease may respond to 5-ASA alone. However, patients with moderate and severe disease will require steroids.

Parenteral administration is reserved for severe and fulminant disease. It is given in the form of either hydrocortisone, 10 mg/kg/daily; or methylprednisolone, 2 mg/kg/daily. With the improvement in bloody diarrhea and appetite, therapy should be switched to oral prednisone, 1–2 mg/kg/daily in two divided doses. Treatment should be continued for 6–8 weeks followed by gradual weaning over a period of several weeks. In patients who relapse after cessation of therapy or in those with chronic smoldering disease, a low maintenance dose of 5–15 mg every other day may be required. In contrast to 5-ASA preparations, corticosteroids alone do not appear to maintain remission.

Local administration of corticosteroids in the form of retention enemas or foam is especially useful in patients with left sided and proctosigmoidal colitis.

Immunosuppressive Therapy

Azathioprine and 6-mercaptopurine have been used as corticosteroid-sparing agents in patients with chronic active UC, who fail to respond to conventional therapy. Oral cyclosporin A has shown some short-term efficacy in patients with fulminant ulcerative colitis in that it allows short-term improvement. This permits avoiding a precipitous colectomy. Cyclosporin A does not appear to result in long-term remission.

Total Parenteral Nutrition (TPN)

The efficacy of hyperalimentation and total bowel rest is well established in CD, but is not as promising in UC. Patients with moderate and severe colitis with anorexia, hypoalbuminemia, and malnutrition, generally will require nutritional rehabilitation in the form of parenteral and/or enteral alimentation.

Surgical Therapy

Unlike CD, surgery is curative in ulcerative colitis. Emergency surgery is life saving in severe fulminant colitis with or without toxic megacolon that fails to respond to adequate medical therapy, and in patients with evidence of perforation or peritonitis. Elective surgery is indicated in chronic smoldering and incapacitating colitis that fails to respond to adequate medical therapy, in patients with long-standing colitis with dysplastic changes, and in patients with delayed puberty and severe growth retardation before epiphyseal closure occurs.

Several surgical options exist, including a proctocolectomy with an ileostomy, a colectomy with an ileorectal anastomosis, and a colectomy with a mucosal proctectomy and an ileoanal anastomosis. The latter procedure is now the most popular as it preserves continence with a diminished risk of relapse.

Crohn's Disease

Crohn's disease (CD) is a chronic inflammatory disease which may affect any part of the gastrointestinal tract from mouth to anus. The disease involves the full thickness of the bowel and is characterized by the presence of granulomas. The involvement is generally discontinuous and most commonly involves the terminal ileum.

Intestinal Manifestations

Signs and symptoms of CD are variable and depend on duration and extent of the disease, and the portion of the GI tract involved.

In children, the disease is limited to the terminal ileum in 26% of patients while extensive small bowel disease is seen in 10% of patients. The disease is limited to the colon in 3% of patients and involves the ileum and proximal colon in 61% of cases.

Abdominal pain can be mild or severe, mimicking an acute abdomen. Most commonly, the pain is cramping, constant, and tends to localize to the right lower quadrant. In some patients with ileal involvement, a tender mass can be felt in the right lower quadrant. This mass represents thickened and matted loops of bowel. The pain is triggered by meals and patients tend to avoid eating in fear of pain. Epigastric pain is seen in patients with gastroduodenal involvement, whereas dysphagia and odynophagia are seen in patients with esophageal involvement.

Diarrhea is less common in CD than in UC, especially in patients with no colonic involvement. Patients with colonic or rectosigmoid disease can have severe and massive bloody diarrhea. Patients with ileal disease and strictures can present with constipation. Steatorrhea is seen in 25% of patients. This may be due to extensive small bowel disease or to bacterial overgrowth due to partial obstruction or ileocolonic fistulae.

Anorexia, nausea, and vomiting can represent a substantial problem in children with CD, leading to a reduced caloric intake and increased nutritional losses. This contributes significantly to the malnutrition and growth retardation frequently encountered in children with CD.

Perianal disease is one of the hallmarks of CD. Perirectal skin tags, fistulas, and fissures are commonly seen. Fistulas are more commonly external and communicate with the perianal area. Internal fistulas are less common and can be ileoileal, ileocolic or communicate with the bladder, vagina, or bone.

Extraintestinal Manifestations

Growth retardation and malnutrition are extremely common in CD with the majority of children below the fifth percentile for weight and at least 30% of patients below the fifth percentile for height. Reduced caloric intake is the single most important element in growth failure. Enteric protein loss and malabsorption are important contributing factors.

Mucocutaneous Lesions

Aphthous stomatitis is common in patients with CD, particularly during active bowel disease. Erythema nodosum, pyoderma gangerenosum, and epidermolysis bullosa are less commonly seen.

Genitourinary Lesions

Hyperoxaluria and renal stones are common in CD with ileal disease due to bile acid loss, resulting in fat malabsorption that binds calcium leaving oxalate to be absorbed in the colon. Enterovesical fistulas or ureteral obstruction by an inflammatory mass are other renal manifestations.

Musculoskeletal Lesions

Arthralgias and arthritis are observed in 15% of children with CD. Arthritis is usually mild, migrating and nondeforming, and involves any joint, particularly the large joints of the legs. It is more commonly seen with colonic involvement. Ankylosing spondylitis (AS) is rarely seen. The activity of peripheral joint disease follows intestinal disease activity, while progression of AS is independent of bowel disease. Clubbing of the fingers is seen in up to 25% of the patients, particularly when the small bowel is affected. Osteopenia has been reported in 31–59% of adult IBD patients with overall risk for fracture in about 40%. The pathogenesis of decreased bone mineralization is related to TNF-α (tumor necrosis factor-α), which downregulates genes involved in bone formation.

Ocular Lesions

Up to 10% of patients have ocular lesions including iritis, episceleritis, and uveitis. Cataracts may be seen with prolonged corticosteroid therapy.

Heptobiliary Manifestations

Abnormalities of the biliary system and liver include pericholangitis, sclerosing cholangitis, fatty liver, chronic hepatitis, hepatic granulomas or abscesses, cholelithiasis, and granulomatous or acalculus cholecystitis.

Fever

Fever occurs in up to 50% of patients. It may be low grade or spiking.

Laboratory Findings

Laboratory findings are nonspecific. The sedimentation rate and c-reactive proteins are usually elevated. A microcytic, hypochromic anemia is common and results from blood loss, reduced intake, and chronic illness. Macrocytic anemia is less common and results from vitamin B12 and/or folate deficiency due to severe ileal disease and/or sulfasalazaline therapy.

Hypoalbuminemia is seen in 50–60% of patients due to malnutrition and protein losses in the stool. Examination of the stool may reveal leukocytes and blood in patients with colonic involvement, as well as increased stool fat in patients with steatorrhea. Stool lactoferrin and calprotectin are elevated with active disease. Urinalysis may reveal evidence of pyuria in patients with an enterovesical fistula.

Radiologic Evaluation

A plain abdominal radiograph may reveal evidence of partial obstruction of the small bowel due to narrowed intestinal segments. An upper gastrointestinal series with small bowel follow through is essential when evaluating for CD because the small bowel is involved in 80% of cases. *Figure 195.3* shows an upper GI series of Crohn's disease of the terminal ileum. Irregular nodular lesions (cobblestoning), thickened bowel loops, stenotic areas (string sign) are seen. Deep ulcers and fistulas may be identified by this technique. Ultrasonography may reveal bowel wall edema, as well as extramural extension of inflammation in the form of a phlegmon or an abscess. Computerized tomography and magnetic resonance imaging utilizing enterography is helpful in defining gastrointestinal involvement as well as delineating extramural extension by fistulization. Capsule endoscopy is gaining wide acceptance to visualize small bowel lesions.

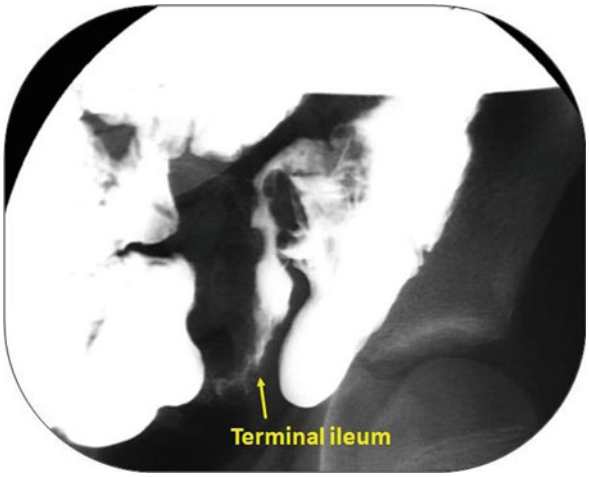

Figure 195.3
Crohn's of the terminal ileum is often first identified on upper GI with small bowel radiograph, which shows ileal stenosis and separation of bowel loops

Endoscopic Evaluation

A colonoscopy is essential in evaluating patients with suspected CD. The presence of a normal rectum and sigmoid colon virtually excludes a diagnosis of ulcerative colitis in a patient with persistent bloody diarrhea. Moreover, the finding of focal or segmental involvement of the colon with intervening areas of histologically normal mucosa is highly suggestive of CD. The involved segments may be edematous and erythematous, may have small aphthous lesions, or may appear to have deep, serpiginous, linear ulcerations with normal appearing mucosa surrounding the ulcer. This normal mucosa is responsible for the "cobblestone" appearance of the lumen in CD. The ability to perform a biopsy of the terminal ileum during colonoscopy greatly increases the sensitivity of this evaluation.

Serological Markers

Antibodies against microbial agents and *Saccharomyces cerevisiae* are seen in 60% of patients with CD (see *Table 195.2*).

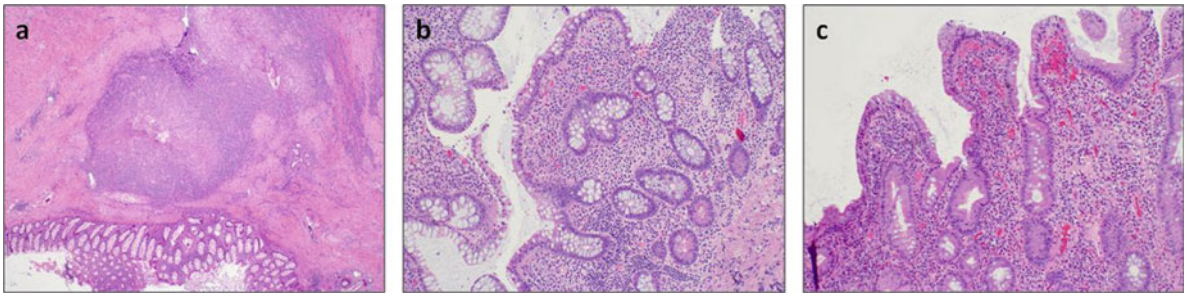

Figure 195.4
(a) Crohn's disease. Terminal ileum with transmural inflammation and prominent lymphoid aggregates within the submucosa and muscularis propria (200× magnification). (b) Crohn's. Terminal ileum with loss of villous architecture, crypt distortion and mild acute and increased chronic inflammation (magnification 100×). (c) Crohn's disease. Terminal ileum with loss of villous architecture, crypt distortion, and marked acute and chronic inflammation (magnification 100×) (Courtesy of Judith Pugh, M.D., Pediatric Pathologist, University of Arizona)

Histology

The earliest lesion of CD is the aphthous ulcer. As the disease progresses, aphthous ulcers become large and coalesce to form longitudinal and transverse linear ulcers. Fissures develop from the base of the ulcers and extend all the way to the serosa. *Figures 195.4a–c* show photomicrographs of mild, moderate, and severe CD of the ileum.

Transmural inflammation is a histologic hallmark of CD. Lymphoid aggregates in the submucosa, and occasionally the muscularis, are common. Noncaseating granulomas are found in most surgical specimens but may be missed on biopsy specimens obtained endoscopically because granulomas are typically submucosal rather than mucosal. Therefore, the presence of granulomas is helpful in distinguishing CD from ulcerative colitis, but the absence of granulomas is not helpful.

Treatment

CD is a chronic debilitating disease. There is no curative medical or surgical treatment available yet. Therapy, in general, is directed toward controlling acute relapses, maintaining remission, improving growth via adequate nutrition, and preventing complications.

Nutritional Support

Several studies have conclusively shown that bowel rest and enteral or parenteral nutrition in children with CD have a substantial positive impact on the disease. In addition to reversing malnutrition and improving growth, it is reported to induce remission in acute episodes and to promote fistula closure.

In active disease, it is often helpful to adhere to a low residue, low lactose diet. This will minimize the postprandial abdominal cramps and promote healing. The diet should be high in protein, calories, folic acid, trace minerals, and vitamins. With extensive ileal disease or after extensive ileal resection, intramuscular vitamin B12 should be provided.

In patients with significant steatorrhea leading to loss of trace minerals and fat-soluble vitamins, a modest restriction of fat intake is recommended. Supplemention with medium chain triglycerides (MCT) may be necessary. It is essential to avoid unnecessary and prolonged fat restriction since this may contribute further to malnutrition.

In more severe disease, where a single modification of the diet is not adequate, an enteral elemental diet or parenteral nutrition is mandatory. Continuous enteral alimentation without drugs has been shown to be effective in inducing remission, and in healing some fistulas. Patients with less acute disease may tolerate supplementation with low residue elemental formulas.

In severely ill patients who are unable to tolerate oral intake and in patients who are candidates for surgical intervention, total parenteral nutrition (TPN) has proven to be effective in the management of this disease.

Sulfasalazine and 5-Aminosalicylic Compounds

Sulfasalazine drug appears to be most effective in patients with colonic involvement; however, it is also reported to

be of benefit in patients with ileal disease only. Newer 5-aminosalicylic preparations allow delivery of 5-ASA to the small intestine (Table 195.3). Some studies have reported measured success in treating ileal and colonic disease. These medications have shown some efficacy in preventing relapses in patients with inactive CD and in those patients who had undergone bowel resection.

Corticosteroids

The majority of children with CD will require prednisone. Prednisone is effective in inducing remission and controlling extraintestinal manifestation. The dose is 1–2 mg/kg/daily for 6–8 weeks followed by gradual weaning. Some patients who relapse after discontinuation of steroids may require a maintenance dose administered daily or every other day. Budesonide (Enterocort) combines potent anti-inflammatory activity with rapid first-pass hepatic catabolism to minimize systemic side effects, which has shown promising results in CD patients with terminal ileum involvement.

Immunosuppressive Therapy

Azathioprine or 6-mercaptopurine (6MP) are usually used to maintain remission in patients with CD and those who require steroids to maintain a remission. Before starting those medications, measurements of the enzyme thioprine methyltransferase (TPMT) is important, as severe deficiency of this enzyme can lead to high levels of 6-thioguanine (6TG), which can cause severe bone marrow toxicity. 6TG is the active metabolite responsible for the immunosuppressive activity of Azathioprine and 6MP. Response is usually seen in 10–12 weeks of the initiation of these drugs. Studies have not shown cyclosporine to be significantly effective in CD.

Surgical Therapy

The role of surgery in CD is less defined than in UC and is used mainly to manage complications. It is indicated in patients with intractable and invalidating disease with or without growth failure; in patients with acute or subacute intestinal obstruction who fail to respond to medical therapy; in patients with intractable intra-abdominal abscesses and/or internal fistulae; in patients with severe hemorrhage or perforation; and in prepubertal patients with growth failure.

Antibiotics and Probiotics

Several antibiotics have shown therapeutic efficacy in patients with CD. Metronidazole, ciprofloxacin, and rifaximin are generally utilized, especially in patients with perianal diseases. The use of probiotics has been shown to be effective in pouchitis; however, their role in IBD patients remains to be determined.

Biologics

The introduction of monoclonal antibiotics against TNF-α has revolutionized the treatment of IBD patients. Table 195.4 depicts the available biologic therapies for the treatment of CD. Only infliximab is approved for the treatment of UC.

Infliximab (*Remicade®*), a chimeric monoclonal antibody is given as an IV infusion at a dose of 5–10 mg/kg at 0, 2, and 6 weeks as induction therapy; and then every 8 weeks as maintenance therapy.

Adalimumab (*Humira®*), a fully human antibody is given subcutaneously (S.C.) at a dose of 160 mg as induction therapy followed by 80 mg 2 weeks later and then 40 mg every other week for maintenance.

Certolizumab pegol (*CIMZIA®*) is a pegylated Fab fragment (the component that binds TNF-α) is also given as SC injection. The dose for adult patients is 400 mg at 0, 2, and 4 weeks as induction and then every 4 weeks as maintenance.

The use of biologic therapy has been shown to be highly effective in inducing remission in adult and pediatric patients. Up to 50–80 % of patients show a decrease in Crohn's disease activity index and endoscopic healing. Most recent studies suggest that the combination of monoclonal antibodies and immunosuppressive drugs (Azithioprine or 6MP) is more effective than monotherapy alone. However, the risk of complications is higher.

Table 195.4

• Anti-TNF agents
– Infliximab (remicade®) – chimeric mab
– Adalimumab (Humira®) – humanized mab
– Certolizumab pegol (Cimza®) – pegylated Fab fragment of humanized mab
• Anti-integrin agents
– Natalizumab (Tysabri®)
• Granulocyte-macrophage colony stimulating factor
– Sargramostim (Leukine®)

For patients unresponsive to anti-TNF-α's, Natalizumab (α-4-integrin inhibitor) is approved for patients with CD. Side effects of biologic therapy include development of serious infections such as tuberculosis and fungal infections, hypersensitivity reaction secondary to the development of autoantibodies, headaches, rash, demyelinating disorders, pancytopenia, hepatomas, and T-cell lymphoma.

Of all these complications, the most serious is the development of hepatosplenic T-cell lymphoma (HSTCL). This is certainly rare, however it is often fatal. Signs and symptoms associated with this type of lymphoma include fever, fatigue, anemia, leucopenia, hepatosplenomegaly, and abnormal liver function tests. HSTCL is seen more commonly in young male patients who were treated with biologic therapy and Azathioprine or 6MP.

Prognosis

Crohn's disease is a chronic and disabling disease. Newer therapeutic biological agents have improved the quality of life of patients; however, many patients will have ongoing smoldering disease with acute exacerbations. Biological agents can induce remission for extended periods of time.

196 Short Bowel Syndrome

Ruba A. Abdelhadi · Hisham M. Nazer

Short bowel syndrome (SBS) is a condition characterized by malabsorption, diarrhea, steatorrhea, fluid and electrolyte disturbances, and malnutrition. It is a clinical state of small intestinal failure that occurs following extensive bowel resection, with deleterious metabolic and nutritional consequences.

A full-term newborn has an average of 250 cm of small bowel and 50 cm of colon with maximal increase in length in the first year of life. The small-bowel length doubles during the last trimester of gestation; this implicates a worse prognosis on the short-bowel remnant of a preterm infant. An adult has 600 cm of small bowel and 150 cm of colon; consequently, infants and young children's outcome on the long run is more favorable than adults, since they have the advantage of potential intestinal growth after intestinal resection.

Among the factors predicting the development of short bowel syndrome (SBS) are the premorbid length of small bowel, its functionality and adequacy of perfusion, the cause of the surgical resection, the site of resection, patient age at time of surgery, the remaining length of small bowel and colon, and the presence or absence of the ileocecal valve. The loss of the ileocecal valve creates favorable conditions for bacterial overgrowth and decreases the transit time of the small intestine.

Intestinal adaptation is a long process that involves multiple compensatory changes that involve all layers of the bowel wall, leading to dilatation, lengthening, and thickening of the small bowel. The degree of adaptational changes including epithelial hyperplasia and increase in mucosal mass and surface area is influenced by the amount of resected bowel. It is of vital importance to provide nutritional support through various therapeutic measures, including parenteral nutrition. With major strides in the development and progress of enteral and parenteral nutrition, the long-term outcome of children with SBS has much improved. Patients are now able to grow during the intestinal adaptation phase of the remaining small bowel.

Causes of SBS

- Intestinal resection in severe Crohn's disease that has failed medical treatment and resulted in stricturing or fistulizing disease
- Necrotizing enterocolitis that has failed conservative management and required intestinal resection
- Midgut volvulus resulting in intestinal ischemia
- Long segment Hirschsprung disease
- Abdominal wall defects, omphalocele, gastroschisis
- Intestinal atresias, congenital short intestine
- Intestinal angiomas requiring extensive small-bowel resection
- Complicated intussusception that has failed conservative reduction
- Arterial and venous thrombosis resulting in ischemia
- Post-trauma resection
- Severe motility disorders
- Functional intestinal failure associated with cloacal exstrophy
- Functional short bowel syndrome secondary to radiation enteritis

Expected Consequences of Intestinal Resection

As a consequence to intestinal resection, recognized associated presentations include severe diarrhea and failure to thrive. Factors influencing patient outcome include the age and indication for surgery, the extent of resection, the portion resected, and the functional integrity of the remaining small bowel. The site and length of the small bowel resected influence the degree of functional impairment. The age of the infant or child and the clinical condition that led to the resection influence the potential for the remaining intestine to adapt.

In short resection, there is more than 100–150 cm remaining small intestine according to the measured length of the small intestine along the anti-mesenteric border; in

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_196,

large resection, there is 40–100 cm remaining, and in massive resection there is less than 40 cm remaining.

The reduction of the absorptive surface area and bacterial overgrowth lead to malabsorption, vitamin and mineral deficiencies, significant water and electrolyte losses with the disrupted enterohepatic cycle resulting in hyperoxaluria. There is gastric acid hypersecretion and pancreatic insufficiency. The need for long-term parenteral nutrition leads to cholestatic liver disease, biliary lithiasis, and bone disease.

Jejunal Resection

The degree of nutrient and electrolyte malabsorption is a reflection to the extent of jejunal resection resulting in severe diarrhea, vitamin and trace element deficiencies.

Ileal Resection

While the ileum has the potential to adapt after jejunal resection and compensate with macronutrient absorption, the reverse is not true: jejunal adaptation cannot compensate for ileal resection, as the terminal ileum has the exclusive capacity to reabsorb bile salts and vitamin B12. Patients with ileal resection are especially at risk for micronutrient deficiencies; bacterial overgrowth further exacerbates vitamin B_{12} malabsorption. These patients require biochemical screening for micronutrient deficiencies.

Terminal ileal resection with subsequent bile salts malabsorption results in lipid malabsorption, steatorrhea, and fat-soluble vitamin deficiency. Lipid malabsorption with hyperoxaluria predisposes for nephrolithiasis. Bile salt malabsorption and the disruption of the enteroheptic circulation predisposes for gall stones. Colonic mucosal damage from bile salts excess and unabsorbed and hydroxylated fatty acids results in secretory diarrhea.

Ileocecal Valve Resection

With the resection of the ileocecal valve, there is marked decrease in transit time; bacterial overgrowth further potentiates nutrient malabsorption and contributes to colonic mucosal injury by dehydroxylating the bile salts. Bacterial overgrowth also has a negative impact on the normal motility of the remaining gut. Ileocecal valve resection predisposes the infants to bacterial translocation and subsequent sepsis.

Clinical Manifestations

The clinical features of SBS are very much influenced by the primary clinical condition together with associated subsequent complications. Diarrhea, weight loss, abdominal distension, and malnutrition are the most important clinical features of SBS. Ileal resection disrupts the enterohepatic circulation of bile salts and causes depletion of the bile salts pool leading to fat malabsorption.

The clinical course of SBS has been divided into three stages:

Stage 1: This constitutes the initial phase after small-bowel resection, characterized by massive diarrhea with excess loss of fluid and electrolytes. Feeding in this stage is limited to total parenteral nutrition (TPN) for a variable duration of several weeks to a few months; enteral feeding is minimal but advisable as soon as the postoperative condition allows. The mainstay of medical management in this stage involves replenishing the intestinal losses and assessing the potential for reducing them.

Stage 2: This is mainly the phase of progressive adaptation that enables the infant to tolerate some enteral feeds initially through continuous drip infusion but later on by bolus and oral feeding. This stage may suffer a few relapses requiring the return to Stage 1. In general, this stage may last for up to a year but occasionally longer. In an attempt to reach the maximum adaptation potential, cautious advances in enteral feeding are coupled with gradual cycling of TPN.

Stage 3: This is defined as the stage of maximum adaptation with the possibility to tolerate full enteral nutrition without having to require cyclic or home TPN.

Intestinal Adaptation

Intestinal adaptation is a gradual and slow physiologic process that allows the remaining small bowel to assume functional and histological compensatory changes that may accommodate the massive loss of absorptive surface and allow eventual weaning from parenteral nutrition.

Multiple humoral endogenous factors are involved in promoting successful intestinal adaptation. These include insulin-like growth factor (IGF), growth hormone (GH), enterogulcagon, and neurotensin. *Insulin-like Growth Factor* 1 (IGF-1) is produced by the ileum and plays a role in tissue proliferation. The result is multiple functional and histological changes that include mucosal

hyperplasia, lengthening of the villi, deepening of the crypts, increased rate of enterocyte proliferation, and increased number of enterocytes per small-bowel length. Glucagon-like peptide 2 (GLP-2) has shown promising results in promoting intestinal adaptation following ileal resection. Recent studies have demonstrated that subcutaneous injections of GLP-2 had a positive effect on the lengthening of jejunal villi and deepening of the crypts and increasing fluid absorption. GLP-2 may be the medical option for patients with ileal resection and loss of the GLP-2 producing ileum. Exogenous treatment with GH and glutamine supplementation has a positive effect on growth parameters and promotes intestinal adaptation.

It cannot be over-emphasized that small trophic enteral feedings play a vital role in promoting and facilitating intestinal adaptation, healing, and resumption of the absorptive potential of the remaining small bowel by stimulating the secretion of cholecystokinin, neurotensin and gastrin, in addition to enteroglucagon, which plays a role in augmenting the remaining intestine's absorptive potential via stimulating cell turnover and improving motility. Glutamine must be included in parenteral nutrition as it plays a vital role in enterocyte metabolism.

Enteral glutamine supplementation is well tolerated but does not seem to influence the duration of parenteral nutrition or show demonstrable effect on intestinal absorptive or barrier function. Dietary fibers included in enteral or parenteral nutrition undergo fermentation and produce short-chain fatty acids which provide nutrition to the enterocytes and promote adaptation.

Medical Management of Short-Bowel Syndrome

Management of extreme SBS has changed dramatically over the past decade with satisfactory improvement in survival and quality of life in patients with short bowel syndrome. Infants with as little as 20–30 cm of the small bowel are expected to survive well with the support of specialized enteral and parenteral nutrition. Parenteral nutrition is essential in the initial management to stabilize fluid, electrolyte, and nutritional balance. This therapy is planned as a long-term one administered through a permanent central line. It is only rarely that infants with SBS can survive without parenteral nutrition.

In the early stages of adaptation, patients with a short jejunal remnant may not be able to digest and absorb polymeric feeds or those with long-chain triglycerides (LCT). Therefore, continuous infusion of dilute elemental diet is initiated. During the early phase of management of SBS, regular and close supervision of the fluid and electrolyte balance are essential with proper monitoring of nutrient supplement and early awareness of the potential hepatobiliary complications of TPN. The biochemical abnormalities of cholestasis are reversible provided that TPN is discontinued at an early stage. As the techniques of TPN therapy improve and knowledge expands, such therapy is more effective with fewer complications.

Enteral nutrition is introduced once the baby settles on the initial phase of management with TPN. The present trend toward earlier introduction of enteral feedings has very much reduced the risk of TPN-related cholestasis. It is advisable to commence enteral nutrition as continuous enteral infusion through a nasogastric tube or gastrostomy feeds. The baby may require months or years prior to being able to tolerate an adequate amount of enteral feeds to ensure satisfactory progress. This period is very much influenced by the length of the remaining bowel and by the central line-related complications as well as by the baby's tolerance to the gradual increase in his enteral intake. Various formulas are used with variable rates of success for enteral nutrition such as protein hydrolysates, essential amino acids, Neocate and Alimentum. To ensure optimal intestinal adaptation, the enteral supplement should contain fat. Medium-chain triglycerides (MCTs) are more readily absorbed, especially in the absence of bile acids. Nevertheless, long chain triglycerides seem to have a better trophic effect than MCTs in further potentiating better intestinal adaptation; LCTs also are a source of linoleic and linolenic acid. It is advisable in such situations to add cholestyramine, a bile acid-binding resin, to reduce the osmotic diarrhea.

Expressed breast milk that is delivered enterally and gradually by small trophic feeding volumes has unique and invaluable benefits to the infant with short bowel syndrome; a multitude of bioactive constituents influence the infant's intestinal microflora with positive effects on the gut function and development. Mucins and oligosaccharides help eliminate viruses and bacteria from the body; lactoferrin makes iron unavailable to pathogenic bacteria, and interferon and fibronectin have antiviral activities. Furthermore, the high secretory Immunoglobulin A (sIgA) content is specifically tailored to the neonate's needs with the maternal antigenic specificity that is directed against the same antigens in the neonate. Other bioactive substances and growth modulators seem to enhance the maturation of the neonate's gut by stimulating small intestinal cell proliferation; these include interleukins, insulin-like growth factor (IGF), epidermal growth factor (EGF), transforming growth factors (TGFs)–alpha and beta.

During the phase of continuous enteral feeding, gradual increase in concentration is dictated per digestive tolerance; it is essential to monitor the stool output and reducing substances in that regard. Semi-elemental diets contain medium chain and long chain triglycerides; the low osmolality of oligosaccharides makes them better tolerated in view of the relative disaccharidase deficiency. Protein hydrolysates in the form of lactalbumin are better absorbed than casein.

Broad-spectrum antibiotics are needed in case of bacterial overgrowth, especially in those who have had the ileocecal valve resected. It is advisable to combine therapy with antibiotics such as clindamycin or metronidazole. Occasionally, surgery is required to reduce the problems of bacterial overgrowth and its associated complications.

Every effort should be exercised to minimize TPN-related liver injury by prevention of hyperglycemia, TPN cycling, use of ursodeoxycholic acid, provision of essential fatty acids, and decreasing the likelihood of developing hyperinsulinism and its negative consequences of hepatic steatosis. Equally important is the prevention and treatment of bacterial overgrowth. In a recent study published in August 2009, Puder et al. concluded that parenteral fish oil-based lipid emulsion improves the outcome of parenteral nutrition-associated liver injury.

Cholestyramine may improve diarrhea by binding bile acids but may contribute to fat-soluble vitamin malabsorption and deficiency. Octreotide slows intestinal transit time but has a negative effect on the splanchnic circulation and potential intestinal adaptation. Loperamide may be useful in reducing fluid losses and decreasing intestinal transit time, but carries the risk of promoting bacterial overgrowth in the setting of intestinal dysmotility.

Measurement of serum citrulline levels—an intestine-synthesized amino acid, is a useful test that predicts enteral tolerance and TPN independence. Serum citrulline level correlates linearly with the percentage of enteral calories tolerated as well as remaining bowel length. A serum citrulline level above 19 μmol/L has 94% sensitivity and 67% specificity for TPN independence.

Surgical Management of Short Bowel Syndrome

The noticeable progress in the nonsurgical management of patients with SBS has resulted in fewer patients requiring surgical procedures to increase the intestinal transit time and maximize the absorptive potential of the remaining intestine. Multiple surgical procedures have evolved to address SBS functional and anatomic abnormalities, although the overall impact of such procedures has yet to be fully evaluated. Bianchi intestinal lengthening surgery may be encouraging. This surgery is indicated in severe SBS without expectation of further intestinal growth. It is important to introduce enteral feeds as soon as possible to promote gut adaptation. Longitudinal intestinal lengthening and tailoring (LILT) procedure facilitates TPN independence.

Intestinal lengthening and tapering to dilated bowel segments have to be applied cautiously, as the viability of the intestinal segments as well as the function and long-term patency may be at risk. Colonic segment interposition surgeries have shown poor outcome. It must also be emphasized that such procedures (e.g., colonic interposition, reversed small-bowel segment to create retrograde peristalsis) are not without complications such as bacterial overgrowth; so far clinical results have been conflicting.

The serial transverse enteroplasty (STEP) lengthening procedure was developed by the pediatric surgeons at Children's Hospital Boston, to maximize enteral nutrition tolerance and TPN independence. In this procedure, special devices are used to simultaneously cut and staple the bowel in a direction parallel to the direction of the blood supply, which travels from the mesentery and traverses the bowel perpendicular to its long axis.

Home parenteral nutrition has proved to be beneficial for all parties involved in the care of a child with SBS. It may take weeks or months at home before the child should be able to depend in its nutrition supplement mainly on enteral feeds, subsequent to which the parenteral nutrition will be discontinued.

Intestinal Transplant

Today's management of patients with SBS highlights more the importance of intestinal adaptation and delaying surgical intervention for at least a year to verify that the child is not making noticeable progress on a parenteral or enteral regimen.

In some patients with increased rate of central line-related sepsis or TPN-related cholestasis, surgical intervention may be considered. However, it has become clear that there are major difficulties associated with small-bowel transplantation because of the presence of substantial lymphoid tissue. During the first years of attempts to transplant patients with SBS, all recipients died due to technical failure, rejection, suspected graft-versus-host disease, or systemic sepsis. Such results have prompted more work to improve the already existing regimens of enteral and parenteral nutrition in SBS.

The first long-term successful small-bowel transplantation was performed in 1988 using a two-step technique and

a living-related donor. Subsequently, more reports of successful intestinal transplantation in children have been published. Simultaneous bowel–liver transplantation was found to reduce the risk of intestinal rejection. In 1990, Grant et al. reported the first successful small bowel–liver transplantation.

It must be emphasized that in spite of the encouraging results of small-bowel transplantation over the past several years, such procedures as well as that with simultaneous liver transplantation should only be offered to a minor proportion of affected patients with SBS with severe complications on nonsurgical measures.

Complications

The noticeable improved survival of infants with SBS with the application of TPN has left the affected babies with two major causes of mortalities: TPN-related cholestasis and central line-related sepsis.

TPN-related cholestatic liver disease is one of the major complications of parenteral nutrition. TPN cholestasis remains a major cause of morbidity and mortality, with an incidence that has been reported to vary from 7.4% to 33%. The disease is progressive with a characteristic sequential pattern of histological liver damage. The biochemical indices of liver function do not necessarily correlate with liver histology as severe liver injury can occur in the presence of normal liver enzymes; as such, TPN-related cholestasis should be confirmed histologically. The recognized histological pattern in TPN-related cholestasis includes biliary stasis, portal tract inflammation, bile duct proliferation, and portal fibrosis.

TPN-related cholestasis may be predisposed by – or at least contributed by – lack of enteral feeding. Recent reviews recommended early introduction of partial enteral feeding to preserve liver function. Bacterial overgrowth contributes to liver damage and further potentiates hepatotoxicity by facilitating bile acids' reabsorption by deconjugation.

In addition to contributing to TPN-related cholestasis, *bacterial overgrowth* also causes mucosal injury and worsens the malabsorption state related to short bowel and the compromised absorptive surface area and dysfunction. It also predisposes to sepsis by bacterial translocation. Major contributing factors to bacterial overgrowth include bowel dilatation, dysmotility, and stasis, as well as loss of the ileocecal valve. The clinical suspicion of bacterial overgrowth is supported by abnormal breath hydrogen testing in age-appropriate patients or duodenal aspirates and stool studies. Treatment with clindamycin and metronidazole combination is indicated in such clinical setting.

Furthermore, lactobacilli and other bacteria cause *lactic acidosis* by fermenting the non-absorbed carbohydrates. Patients may develop neurological manifestations and episodes of encephalopathy along with high anion gap metabolic acidosis. This is also contributed to by liver dysfunction and thiamine deficiency. Treatment with neomycin, metronidazole, and vancomycin is indicated. Probiotics may be of benefit to repopulate the small intestinal flora. However, Probiotics themselves can contribute to lactic acidosis as evidenced by a case report published by Ku et al. in 2006. On the long term, metabolic acidosis is a potential complication in children with SBS and can lead to growth failure and contribute to failure to thrive.

Loss of the terminal ileum predisposes to *vitamin B12 and fat-soluble vitamins deficiencies.* These patients should receive vitamin B12 and ADEK vitamins supplementation, and get vitamins B12, A, E, 25-hydroxyD checked regularly in addition to PT. Children who have undergone ileal resection are at an increased risk of developing *calcium oxalate nephrolithiasis* as a consequence to hyperoxaluria. These children should have renal sonograms once or twice a year; they should be on a low-oxalate, low LCT diet, and receive calcium supplementation.

Outcome

The survival and prognosis of infants with SBS has improved since the application of long-term TPN. The majority of infants and children now survive after extensive small-bowel resection. Cholestasis and age-adjusted small-bowel length are the major predictors of mortality in pediatric SBS. Prognosis is more favorable when the ileocecal valve is preserved, and directly related to the length, functionality, and adaptability of the remainder of the small bowel and subsequently the shorter duration of PN requirement. Close monitoring of growth velocity and weight gain is of paramount importance. A nutritionist's input is invaluable as a member of a multidisciplinary team approach, which allows fostering the coordination of surgical, medical, and nutritional management to improve survival. Intestinal transplantation option is reserved to those patients with complete PN dependence and extreme short bowel.

Summary

Early and careful introduction of enteral feeding has the strongest impact on intestinal adaptation, prognosis, and eventual outcome. Cholestatic liver disease remains the

leading cause of morbidity in SBS patients with failure of intestinal adaptation and TPN dependence. Intestinal and liver transplantation is reserved to those patients with extreme short bowel, failure of intestinal adaptation, parenteral nutrition dependence, TPN cholestasis, and end-stage liver disease.

Background

Intestinal transplantation has made dynamic progress in the last 20 years, benefiting from important developments in preservation technology, surgical technique, improved perioperative care, and innovative immunosuppressive strategies. It is now recognized as an established modality of care for patients suffering from failure of their intestinal function and requiring Total Parenteral Nutrition (TPN). The dramatically improved outcomes for intestinal transplantation over the last decade have allowed more patients to benefit from this therapy. More importantly, however, an important component of the legacy of intestinal transplantation has been the development of intestinal failure management which has opened a focus of multidisciplinary care to this field. This chapter is intended to review the various components of this field and address the challenges which remain to further progress, which include improvements in intestinal adaptation and prevention of TPN-associated liver disease, enhancing access to organs and transplantation, and decreasing waiting list mortality. Understanding long-term function of the intestinal graft and nutritional outcomes will further help define the optimal timing and role of intestinal and multivisceral transplantation in patients with intestinal failure.

Management of the Intestinal Failure Syndrome

Intestinal failure is defined as the anatomic or functional loss of the ability of the intestine to provide for normal absorption of nutrients and fluid. Patients suffering diseases which result in intestinal failure are managed by administration of total parenteral nutrition (TPN) through catheter placed in a central venous position, usually through access of the Internal Jugular, Subclavian, or Iliac veins. Such acute care management is variable in duration and depends on the adaptive capacity of the remaining intestine. The development of multidisciplinary team management and formation of intestinal rehabilitation programs has resulted in improved long-term outcomes in TPN-dependent patients. There remain, however, a subset of patients who develop irreversible intestinal failure and a syndrome of satellite complications when left on TPN, and where intestinal transplantation may be lifesaving.

A comprehensive assessment includes understanding the etiology/cause of intestinal failure, disease history and surgical procedures, epidemiology of infections, number and location of previous venous catheters, patency of central veins, nutritional history which includes TPN care and enteral feeding. Further assessment often includes radiographic studies of upper and lower gastrointestinal tract using contrast enhanced small bowel follow-through's, contrast enema's, Doppler ultrasound studies of the liver, vena cava, and central veins. A liver biopsy may be indicated if there is evidence of liver dysfunction or portal hypertension.

Management of intestinal failure is focused on enhancement of gut adaptation and preventing/improving the satellite complications of liver dysfunction and infections. To this end, various surgical (non-transplant) procedures that have developed which provide for improved adaptation, the most recent and successful of which has been the serial transverse enteroplasty (STEP). In cases of extreme short gut (loss of the entire small bowel and much of the colon) or severe dysfunction, intestinal failure may be considered irreversible; some patients may be managed with long-term TPN, achieving or maintaining growth and development in children and adults. However, the development of complications of TPN management may limit this form of care.

The development of TPN-associated liver disease has by far been the most critical challenge in this patient population. The 1-year mortality with such complication in patients who are not able to wean off TPN or receive an intestine transplant exceeds 70%. The development of cholestasis may be relatively early in small infants, as compared to adults, so consequently the efforts in prevention, management, and evolution may vary. A general approach to this problem has been the treatment of sepsis, minimizing bacterial overgrowth in the bowel, optimizing enteral nutritional supplementation, interval cycling TPN (to more off time from this therapy), and preventing over feeding.

The role of cholecystectomy in the management of this complication is controversial, as has been the manipulations of the various TPN components; however, excessive glucose and improper ratios of glucose to amino acid have

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_197,

been associated with hepatic steatosis and consequent steato-hepatitis. The manipulation of the lipid component of TPN has led some to advocate for the removal of soy-based lipid solutions and their substitution with Omegaven (a fish-oil based, intravenous lipid solution rich in omega-3 fatty acids); the apparent clinical and laboratory improvement in liver function has had an important impact in the progression to worsening liver failure in this patient population.

Catheter-associated sepsis has been the next most common and severe TPN-associated complication, resulting in life-threatening instabilities and need for intensive care unit management, renal failure, and death; it often results in thrombosis and loss of venous access, and may necessitate removal of the venous catheter, thought infants with limited venous access may require preservation of an infected line.

Patients with intestinal failure behave with relative susceptibility to infections, both through the gastrointestinal translocation of bacteria (in a setting of gut dysfunction, bacterial overgrowth, liver dysfunction, and portal hypertension) with sepsis and with community acquired infections.

Indications for Transplant

Intestinal transplantation was approved by the Center for Medicare and Medicaid Services in October of 2000 as a standard of care for patients with irreversible intestinal failure who could no longer be maintained with TPN; this includes isolated intestinal, combined liver-intestine, and multivisceral transplant operations. The limitations of TPN therapy include the aforementioned complications, those who cannot tolerate quality of life limitations associated with TPN therapy, or who must undergo native bowel resection for potentially life-limiting indications or tumors. Causes of intestinal failure are categorized into those entities most commonly found in children or adults and which result in loss of bowel length or function; these include diseases such as necrotizing enterocolitis, volvulus, and mesenteric thrombosis, motility dysfunction such as Crohn's disease, or acquired disorders such as radiation enteritis (*Table 197.1*).

With the development of specialized intestine rehabilitation centers (which include transplant care) overall improved outcomes in these patients have been observed, many of whom have not required transplantation. In a recent consensus panel on intestinal failure management, the following recommendations regarding criteria for consultation for intestine transplant evaluation were endorsed: (1) extreme short gut from massive bowel resection; (2) severely diseased bowel and unacceptable morbidity; (3) uncertain prognostic course; (4) microvillous inclusion disease or intestinal epithelial dysplasia; (5) unresolved clinical jaundice (>6 g/dl); (6) thrombosis of >50% of central veins; (7) the request of the patient or family.

Table 197.1
Indications for intestine transplantation

Children	Adults
Volvulus	Superior mesenteric artery thrombosis
Gastroschesis	Crohn's disease/IBD
Necrotizing enterocolitis	Desmoid tumor
Pseudo-obstruction	Volvulus
Microvillus inclusion disease	Trauma
Intestinal polyposis	Familial polyposis
Hirschsprung's disease	Gastrinoma
Trauma	Budd–Chiari disease
	Intestinal adhesions
	Pseudo-obstruction
	Radiation enteritis

The type of intestinal graft required in a patient with intestinal failure is based on the comprehensive evaluation of the function and anatomy of the remaining bowel and other abdominal organs (liver and pancreas). Intestinal grafts may be of the following general types: isolated intestine, combined liver and intestine (which includes the duodenum and pancreas), and multivisceral graft which includes the liver, stomach, duodenum, pancreas, and small bowel (the modified multivisceral graft excludes the liver); some transplant centers may include allograft colon with these variants. The determination of what would constitute a "multivisceral transplant," however, hinges on the need to "replace" the entire native gastrointestinal tract (resection of same). Important factors in determining whether to replace the liver in patients with intestinal failure is the severity of liver dysfunction and the structural consequences of end stage disease, cirrhosis, and portal hypertension. Some patients with liver fibroses, mild portal hypertension, and normal liver function should be cautiously considered for isolated intestinal transplant.

Evaluation for Transplant

Most patients with intestinal failure are suffering from dramatic complications of their disease and require an inpatient evaluation and management. After initial

assessment of disease, status of nutritional care, and management of complications, the goal of the multidisciplinary team is to determine a need for transplantation and what graft type would be most suitable, weigh in alternatives to transplant, consider potential contraindications, and provide education regarding the transplant experience.

Transplantation Operations

The procurement of intestinal grafts follows the same principles of core cooling and perfusion with preservation solutions as described with other organs; the evolution of these techniques has been one of the most important contributions to the field. The implantation of these grafts follows the principles of arterializations (generally through donor vascular conduits anastomosed to the aorta) and venous outflow to vena cava (or the liver in select isolated intestine recipients). Intestinal continuity follows standard general surgical procedures, establishing proximal (always) and distal (if feasible) continuity, with placement of an allograft decompressing ileostomy. Gastric and intestinal feeding tubes are very important procedural adjuncts which, though not essential to the implantation operation, are essential to optimum postoperative care.

Isolated Intestine

With the isolated intestinal graft (jejunum and ileum), the donor superior mesenteric vessels may be anastomosed directly to the recipient's superior mesenteric artery and vein (portal drainage; this may also be achieved through a donor vascular conduit to native portal vein); however, usually these are anastomosed to interposition vascular conduits attached to the recipient infrarenal aorta and inferior vena cava (systemic drainage).

The intestinal continuity is established proximally to native duodenum or jejunum, and distally to residual ileum or colon (if feasible); a temporary end ileostomy (or loop ileostomy) allows access to the allograft intestine for endoscopic surveillance and biopsies.

Liver and Intestine

In this operation, the recipient liver is removed with preservation of the native retro-hepatic vena cava, preserving the recipient foregut (stomach, pancreas, and duodenum): the venous outflow to these organs is maintained with a permanent end-to-side portocaval shunt. Arterial inflow is achieved using a donor arterial interposition conduit to the recipient infrarenal aorta. The venous outflow is achieved through the donor hepatic veins anastomosed to the confluence of the recipient hepatic veins and vena cava. Intestinal continuity is reestablished in a similar fashion as in an isolated intestinal transplant, with the placement of feeding tubes and ileostomy.

Multivisceral

The crux of the multivisceral operation is removal with replacement of the entire gastrointestinal tract of the recipient (stomach, duodenum, pancreas, liver, and remaining small bowel) and liver, preserving the inferior vena. Vascular inflow is through a donor vascular conduit which now includes celiac inflow to the allograft stomach, and the vascular outflow is identical to liver-intestine transplant. Intestinal continuity is established proximally with the native gastric stump to donor stomach anastomosis, and the distally as in previously described intestinal transplants. A pyloroplasty is routinely performed after reperfusion, as is the allograft ileostomy and placement of feeding tubes.

In a "modified" version of the multivisceral operation, the native recipient liver is preserved along with its vasculature and extrahepatic biliary system, with removal of the native gastrointestinal tract. This procedure requires reconstitution of the biliary tract either with a recipient duct-to-donor Roux-en-Y choledochojejunostomy or a recipient duct-to-donor duct anastomosis; also, the intestinal allograft venous drainage of superior mesenteric vein is anastomosed to the recipient's portal vein.

Immunosuppression

Tacrolimus (Prograf, Astellas, Tokyo, Japan), in conjunction with other medications, has been the cornerstone of immunosuppressive therapy for over 20 years. The field of immunosuppressive management has hinged on prevention of rejection, so common with intestinal transplantation, and initially was fraught with toxicity and infectious complication of this management which included viral, fungal, and bacterial infections, as well as renal failure as the most common complications. Consequently, other drug therapies and immunosuppressive strategies have included IL-2 antibody inhibitors, and the addition of drugs such as cyclophosphamide, azathioprine, mycophenolate mofetil, and rapamycin. Treatment of the donor prior to organ retrieval

with antilymphocyte antibody preparations has also been used with the intent of preventing graft-versus-host disease from the transfer of donor passenger cells with the graft.

Recently, two classes of immunomodulatory drugs have been introduced and associated with improved outcomes and are based on depleting antilymphocyte antibody therapies and include: rabbit anti-thymocyte globulin (rATH, Thymoglobulin, Genzyme Corp., Cambridge, MA) and alemtuzumab (Campath-1 H, Genzyme Corp., Cambridge, MA). Immunosuppression for intestinal and multivisceral transplantation now involves perioperative antibody induction in 60% of cases.

Immunologic Monitoring

Routine allograft ileoscopy and biopsy remains the gold standard of graft monitorization and is performed with varying frequency and when clinically indicated. Noninvasive serologic, proteomic, or genomic markers, as well as the assessment of preformed antibody and de novo anti-donor-specific antibody may identify patients who are at risk of rejection or who may benefit from decreased levels of immunosuppression. The detection of circulating donor cells in the recipient peripheral blood may be serially evaluated by either flow cytometry or PCR; however, the clinical significance of this finding is uncertain. There are reports of the use of fecal calprotectin or serum citrulline as noninvasive biochemical markers of allograft rejection.

Infection Control

The routine use of broad-spectrum antibiotics and antiviral prophylaxis post transplant is important and, though it follow similar guidelines as with other types of organ transplants, there are specific indicators which merit discussion. A thorough history of previous infections prior to transplant (particularly fungal) should guide with the administration of appropriate specific antibiotics, and also a focus on possible specific immune deficiencies. Oral nonabsorbable antibiotics to achieve selective bowel decontamination is performed routinely, though the significance of this management is controversial.

Viral infections can cause significant morbidity with common pathogens including CMV, EBV, herpes simplex virus (HSV), adenovirus, and influenza viruses. Advances in viral monitorization, prophylaxis, and preemptive therapy have significantly decreased morbidity associated with EBV, CMV. EBV/CMV prophylaxis includes a 2-week course of intravenous ganciclovir with concomitant administration of cytomegalovirus-specific hyperimmune globulin (Cytogam).

Nutritional Support

Standard TPN is administered routinely in the postoperative period; however, tapering is aggressively performed as enteral feeding is advanced. Selection of feeding formula usually follows an initial use of isotonic solutions and are changed based on age group and clinical assessment of intestinal allograft function. Because many intestinal failure patients have an oral aversion, tube feeding is usually required.

Assessment of the Intestinal Allograft

Endoscopic evaluations are performed are performed regularly and when clinically indicated based on changes in stomal output or aspect of the allograft stoma itself such as edema, cyanosis, or congestion. These changes, however, are not specific to rejection and may reflect infection or dysfunction of the graft (absorption or motility).

Management of Allograft Rejection

Acute cellular rejection has been previously reported in 70–90% of intestinal allograft recipients; however, recent improvements in immunosuppressive strategy have resulted in reduction of rejection rates to 30–40%.

Endoscopic evaluation may demonstrate normal mucosa despite histologic mild to moderate grades of acute cellular rejection; moderate to severe rejection of the intestinal allograft is reflected in mucosal inflammation with erythema and friability, and may progress to sloughing of the mucosa with the formation of ulcers. Histologically, mononuclear cell infiltrates and intestinal crypt apoptosis with regeneration are the hallmark signs of intestinal allograft rejection that establish the diagnosis.

Treatment of acute cellular rejection is based on intravenous steroids and optimization of Tacrolimus levels. Antilymphocyte antibodies for steroid-resistant rejection includes anti-thymocyte globulin (rATG, rabbit-derived, Thymoglobulin). Addition of a third agent such as mycophenolate mofetil (MMF, CellCept, Roche) or sirolimus (Rapamune) may be indicated if rejection is refractory or recurrent.

Chronic rejection has been observed in 10–15% of intestinal allografts, and occurs more commonly in

isolated intestinal transplantation. The most common clinical presentation of chronic rejection is graft dysfunction with dysmotility and also structural changes of strictures and dilations, with intestinal allograft obstruction and gastrointestinal bleeding. The histologic changes are nonspecific and characterized by villous blunting, focal ulcerations, epithelial metaplasia, and scant cellular infiltrates on endoscopic mucosal biopsies; full-thickness samples will demonstrate obliterative thickening of intestinal arterioles.

Posttransplant Lymphoproliferative Disorder

Posttransplant infection with EBV may result in a spectrum of diseases from mononucleosis syndromes and plasma cell hyperplasia to neoplastic PTLD (lymphoma). Significant risk factors include the type of induction/immunosuppressive regimen used and EBV serology status prior to transplant. The historically high incidence of rejection with intestinal transplantation warranted higher levels of immunosuppression in this recipient population; however, the complications of infection, toxicity, and PTLD made this strategy untenable for long-term success. The monitoring of EBV viral load in the peripheral blood allowed for early detection and management of EBV; however, it was with the present strategy of antilymphocyte antibody induction and minimization of Tacrolimus levels that there has been a true decrease in the incidence of acute rejection/need to treat rejection, with improvement in the incidence of EBV disease.

Treatment of PTLD involves minimization of immunosuppression, and possible discontinuation. Unresponsiveness to this strategy may warrant treatment with a monoclonal antibody (rituximab) if the lesions are shown to be CD20 positive. PTLD refractory to this may require low-dose cytotoxic chemotherapy.

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) results from immunocompetent donor T cells causing attacking recipient tissues after transplantation, the incidence after intestinal transplantation ranging from 5% to 10%. Major targets of GVHD are epithelial cells of skin, intestine, and liver. Clinical presentation may include fever, rash on the upper torso, neck, or palms of hands and feet, and which may evolve to form blisters or more diffuse erythema. Other signs and symptoms include oral lesions, diarrhea, native intestinal ulceration, native liver dysfunction, and peripeheral lymphadenopathy, and bone marrow suppression with pancytopenia.

The diagnosis of GVHD is based on the clinical presentation and histological confirmation. Corticosteroids are the first-line therapy to control epithelial damage caused by GVHD, and are effective in most cases. Concomitant with this, reduction of calcineurin-based immunosuppression may be necessary and desirable.

Outcomes

Patient and Graft Survival

Over the last decade, significant improvement in early and late patient and graft survival has been achieved, with 1-year patient and graft survival reaching 89.3% and 78.9% for intestine-only recipients and 71.5% and 69.0% for liver-intestine recipients, survivals comparable to those following pancreas, lung, and liver transplantation. Contributing factors to this include the increasing experience with this patient population, and advances in immunosuppressive management.

Summary

Improvements in outcomes after intestinal transplantation have been achieved through advances in multidisciplinary care of intestinal failure, surgical technique, innovative immunosuppressive strategies, and an improved understanding of intestinal transplantation immunology. These accomplishments, however, are overshadowed by the still high waiting list mortality, particularly for infants and adults who have concomitant liver failure. Long-term data on nutritional and functional outcomes and quality of life are necessary to further assess the role of intestinal transplantation in patients with intestinal failure.

198 The Pancreas

H. Hesham A-Kader · Fayez K. Ghishan

The pancreas is an elongated retroperitoneal gland in the upper abdomen that has both an exocrine and an endocrine component. The pancreas is divided into three parts: the head, the body, and the tail. The head lies in the C-shaped region of the duodenum, while the body and tail extend from the C-loop of the duodenum across the midline of the body toward the spleen. Pancreatic secretion empties through the pancreatic duct which merges with the common bile ducts into the duodenum via the ampulla of Vater.

In this chapter, the embryology, histology, ultrastructure, and development of the functions of the pancreas have been reviewed. In addition, the physiology of the pancreas, congenital diseases of the exocrine pancreas, and the evaluation of pancreatic function will be discussed. A detailed review of acute and chronic pancreatitis will also be provided.

Embryology

By the fifth week of gestation, the pancreas arises as two outpouchings from the junction of the foregut and midgut. The large dorsal bud enlarges rapidly and contributes to most of the pancreas. The small ventral bud contributes to the uncinate process and the inferior part of the head of the pancreas. The ventral bud, connected to the bile duct, rotates with the duodenum and fuses with the dorsal bud. By the seventh week of gestation, as the two buds join, the ventral duct fuses with the dorsal duct to form the main pancreatic duct (duct of Wirsung). This duct communicates with the common bile duct before entering the duodenum via the ampulla of Vater. The proximal portion of the dorsal duct forms the accessory duct of Santorini, which opens separately above the main papilla. Developmental deviation from these steps may result in clinically significant anomalies as will be discussed later. The pancreatic acini and the islets of Langerhans start developing during the third month of gestation.

Histology and Ultrastructure

The pancreas is composed of the exocrine system involved in digestion, and the endocrine system involved in secretion of hormones such as insulin and glucagon. Histologically, the exocrine system consists of lobules composed of numerous acini lined with epithelial cells which contain zymogen granules. Each acinar gland is drained by a small ductule connected to larger ducts which in turn connect to the major pancreatic duct. The zymogen granules are secretory vesicles that release trypsinogen, chymotrypsinogen, procarboxypeptidase, amylase, and lipase for the purpose of food digestion.

The endocrine system consists of the islets of Langerhans, which are interspersed among the acinar glands. Three major cell types are recognized in these islets: Alpha cells produce glucagon, β-cells produce insulin, and γ-cells produce somatostatin.

Physiology of the Pancreas

The acinar cells secrete the enzymes responsible for the degradation of food, while the epithelial cells lining the pancreatic ducts secrete fluid and bicarbonate that render the duodenal lumen pH alkaline. This provides the optimal milieu for enzymatic activity.

Pancreatic exocrine secretions are under neural and hormonal control. The neural phase is mediated by vagal stimulation and results in the mobilization of enzymes from the acinar cells to the ducts. The hormonal phase is triggered by the passage of the acidic gastric contents into the duodenal lumen and results in the release of secretin from the duodenal mucosa. Secretin stimulates the secretion of bicarbonate and fluids. The hydrolytic products of proteins and fat stimulate the release of cholecystokinin (pancreozymin), bombesin, and neurotensin. These, in turn, stimulate the release of the pancreatic enzymes trypsinogen, chymotrypsinogen, procarboxypeptidase, amylase, colipase, and lipase.

The proteolytic enzymes (trypsinogen, chymotrypsinogen, and procarboxypeptidase) are released in their inactive form in order to protect the pancreas from autodigestion. Enterokinase, an intestinal brush border endopeptidase, activates trypsinogen to trypsin. Trypsin, in turn, activates chymotrypsinogen to chymotrypsin and procarboxypeptidase to carboxypeptidase. These

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_198,

pancreatic enzymes are thus activated in the intestine where the digestive process takes place. Endopeptidases (trypsin, chymotrypsin, and elastase) cleave internal bonds within protein chains. Exopeptidases (carboxypeptidase A and B) cleave the bond adjacent to either the amino or carboxyl terminus. Pancreatic lipase is the principal enzyme needed for the hydrolysis of dietary triglycerides. Colipase is a pancreatic enzyme required to prevent the inactivation of lipase by bile salts. Amylase functions to hydrolyze starches into glucose oligomers and α-limit dextrins.

Development of Pancreatic Function

Studies in human fetuses have shown that zymogen granules are first detectable at a fetal length of 14 cm. The number and electron density of these zymogen granules increase as the fetus grows in length. Enzyme measurement of trypsin, chymotrypsin, lipase, and phospholipase are detected at about the same length, increasing slowly until the fetus reaches 40 cm in length. This is followed by a dramatic increase in enzyme activity. Amylase is absent in all fetuses.

In human infants between the ages of 1 day and 1 month, considerable amounts of proteases are found in duodenal fluids. The activity of carboxypeptidase B represents 10–25%, chymotrypsin 50–60%, and trypsin about 90–100%, respectively, of the activity levels found in children at the age of 2 years and older. Basal concentrations of lipase are barely detectable, and those of amylase are totally absent. Moreover, newborns are not responsive to pancreaozymin stimulation at 1 month of age, with only a minimal increase in the output of chymotrypsin. Similarly, the response to secretin stimulation is minimal. A pronounced response is not seen until 2 years of age for both pancreozymin and secretin.

These findings clearly indicate that the infant's digestive capacity of fat and starch are less mature than those for proteins. Although lingual and breast milk lipase may compensate for the low levels of pancreatic lipase, low pancreatic-lipase levels may explain some of the transient malabsorption reported in infancy.

Anomalies of the Pancreas

Pancreas Divisum

Typically, anomalies of the pancreas represent failure of rotation or fusion, or both. Pancreas divisum results from the failure of the ventral and dorsal pancreas to fuse, resulting in separate drainage systems for each bud. As a result, the majority of the exocrine pancreatic flow arising from the dorsal bud is drained by the smaller accessory duct of Santorini and the smaller accessory papilla. This is felt to represent an area of relative stenosis, potentially explaining the association of this anomaly with chronic pancreatitis in some clinical series. Other series, however, have failed to demonstrate a similar association.

In the clinical setting of recurrent pancreatitis, endoscopic and surgical approaches have been used for treatment of this anomaly, including sphincterotomy, stent placement, and pancreaticoduodenectomy. Pancreas divisum detected incidentally in the absence of pancreatitis should be treated expectantly.

Annular Pancreas

Annular pancreas results from a histologically normal pancreas partly or completely encircling the second part of the duodenum distal to the ampulla of Vater. The formation of the annulus is believed to result from the failure of the tip of the ventral pancreas to rotate completely to the right and posteriorly with the duodenum.

Annular pancreas is frequently associated with Down's syndrome, intestinal malrotation, tracheoesophageal fistulas, and congenital heart disease, especially tetralogy of Fallot.

In patients with a complete annular pancreas resulting in duodenal obstruction, presentation is usually in early infancy with bilious vomiting, abdominal distention, and a double bubble sign on plain abdominal films representing duodenal obstruction. If the annulus is incomplete, the patient may be asymptomatic or present later in life with intermittent abdominal pain or discomfort, epigastric fullness, nausea, and vomiting. Rarely, the annulus may compress the common bile duct or the pancreatic duct causing jaundice and/or pancreatitis.

In complete obstruction and in symptomatic patients, surgical intervention with a duodenostomy or duodenojejunostomy is the therapeutic procedures of choice.

Ectopic Pancreas

This is a relatively common developmental anomaly with an estimated incidence of 15%. The ectopic pancreas is found most commonly in the prepyloric region of the stomach, duodenum, and jejunum.

The composition of the ectopic pancreas is variable. It may show normal pancreatic tissue with acini, islets, and ducts, or it may be rudimentary, consisting only of a few ducts and acini. At endoscopy, the ectopic pancreas appears as a firm yellow nodule 0.5–4 cm in diameter with an umblicated center.

Most patients are asymptomatic. However, it has been postulated that ectopic secretions may produce inflammation, spasm in the gut, and pain. Hemorrhagic ulceration and pyloric obstruction have been reported. The nodules may also act as a lead point for intussuscetion. In symptomatic patients, treatment is with simple surgical excision.

Evaluation of Pancreatic Function and Pancreatic Disease

Despite the large array of available tests for evaluating pancreatic function, the definitive diagnosis of pancreatic disorders is often difficult. This is particularly so because the pancreas has significant functional reserves. For example, it is estimated that loss of 99% of lipase and colipase activity is required before steatorrhea is observed. More sensitive tests are required to detect impairment, resulting in less than 98% loss of enzyme secretory capacity. It is therefore important to appreciate the capabilities and limitations of available tests.

Tests for Pancreatic Insufficiency

Stool examination for fat: A simple screening test for the presence of pancreatic insufficiency is examination of a stool smear, preferably stained with Sudan III, under a light microscope. This allows detection of undigested and neutral fat. This test is not reliable in mild steatorrhea. However, it serves as a crude test to identify patients who may need more accurate quantification of fat stool losses.

72-four stool fat: The 72-h stool fat quantification represents a very reliable diagnostic test for steatorrhea. The pediatric patient is instructed to take at least 3 g/kg/day of dietary fat. Intake is documented and stools are collected over a 72-h period. Stool fat is then extracted. Excretion of more than 10% of ingested fat is abnormal in children older than 6 months, while excretion of more than 15% would be abnormal in infants less than 6 months of age.

Oral tolerance tests: This test consists of giving individuals a standard amount of fat (50 g), then measuring their serum triglycerides and chylomicron levels at different time points (0, 2, 3, 5 h). Values are then compared to controls. To determine if an abnormality is a result of pancreatic disease, the test is repeated after the enteral administration of pancreatic enzymes.

Steatocrit: This novel concept of measuring stool fat has recently been proposed and requires further substantiation. In this test, a homogenized sample of stool is centrifuged at 15,000 rpm for 15 min in a hematocrit tube. Lipids separate to the top and are quantitated in a fashion similar to a hematocrit.

Measurement of trypsin and chymotrypsin activity in stool: Measurements of trypsin and chymotrypsin activity in stool are widely used to evaluate pancreatic exocrine function. A recently introduced photometric assay for chymotrypsin has improved the reliability of this method, with measurements correlating well with data for chymotrypsin from stimulated duodenal output. However, the sensitivity of this test is affected by bacterial proteases that may lead to the breakdown of trypsin and to a lesser extent, chymotrypsin.

Bentiromide: Bentiromide is a nonabsorbable synthetic peptide, which is cleaved in the upper small intestine by chymotrypsin to yield the rapidly absorbable compound, para-aminobenzoic acid (PABA). Assuming intestinal mucosal integrity, serum PABA levels would then reflect pancreatic exocrine function. Urine PABA levels can also be measured but rely on normal hepatic, renal, and intestinal function. Different modifications on this test have been introduced to improve its sensitivity.

Fluorescein dilaurate test: The principal behind this test is similar to that of Bentiromide. Fluorescein dilaurate is orally administered and is then subject to hydrolysis by pancreatic cholesterol ester hydrolase to yield water soluble Fluorescein. Fluorescein is rapidly absorbed by the intestine, conjugated in the liver and excreted by the kidney as Fluorescein diglucoronide. Either urine collected over a 10-h period or a serum sample collected at 4–5 h is assayed for Fluorescein diglucoronide. These levels would then indirectly reflect pancreatic exocrine function. Different modifications of this test have been introduced to improve its sensitivity and to eliminate any possible effects of the intestine, liver, and kidney on this assay.

Isotope-labeled breath test: The use of stable isotopes to label ingested triglycerides is gaining momentum. In this test, triglycerides are radiolabeled with ^{13}C, and labeled CO_2 excreted in breath is then measured. The appearance of ^{13}C in the breath is reflective of intraluminal digestion of lipids. This test may eventually be used as a screening test for steatorrhea to replace the 72-h fecal fat test. Specificity for pancreatic disease may be improved by

repeating the assay after enteral administration of pancreatic enzymes.

Measurement of serum pancreatic enzymes: Serum pancreatic enzyme determinations can be specific tests for pancreatic insufficiency in the absence of acute pancreatitis, ductal obstruction, or renal insufficiency. Serum determinations for amylase and lipase are unreliable during early infancy because these enzymes do not reach mature levels until 3–6 months of age. Trypsinogen is the serum pancreatic enzyme of choice for pancreatic exocrine function testing.

Pancreatic stimulation tests: The tests discussed thus far are only able to detect severe cases of exocrine pancreatic insufficiency, where the pancreas has little functional reserve. Assessment of pancreatic reserve in patients without overt malabsorption is achieved through direct stimulation tests. These techniques are valuable in determining pancreatic function in those patients with greater than 2% functional residual capacity. Here the pancreas is stimulated pharmacologically or nutritionally, and pancreatic secretions are collected and analyzed for output of ions, water, and enzymes. This technique involves intubating the duodenum with a double lumen tube. After the collection of baseline duodenal fluids, secretin and panceozymin are infused intravenously, followed by the collection of duodenal fluids at specific intervals. The fluid volume, fluid pH, and HCO_3 and electrolyte concentrations are determined. The fluid is also assayed for activity of trypsin, lipase, and colipase.

Nutrient stimulation tests: This test follows the same principal as pharmacologic tests but utilizes physiologic stimulation of the pancreas via the intraluminal infusion of nutrients. These tests have several disadvantages, including contamination by gastric secretions, and interference of nutrient substances with accurate enzymatic determinations.

Biochemical Tests for Pancreatitis

Serum amylase: Measuring serum amylase level is one of the most commonly used biochemical tests in the diagnosis of pancreatitis. Serum amylase levels increase within 3 h of pancreatic inflammation and may persist for 2–4 days. There is no correlation between the degree of serum elevation of amylase, or other pancreatic enzymes, and the severity of pancreatitis. However, hyperamylasemia may be in association with impaired renal function, in patients with perforated gastric or duodenal ulcers, postabdominal surgery, alcohol poisoning, pancreatic duct obstruction, and salivary-glands inflammation. On the other hand, normal amylase level may be seen in 20% of patients with acute pancreatitis.

The measurement of serum pancreatic isoamylase in the diagnosis of pancreatitis is a more useful test as it may help delineate the source of amylase.

Traditionally, measurement of urinary amylase clearance has been advocated because renal tubular reabsorption of amylase is decreased in pancreatitis. However, it does not provide any advantage over measurement of total serum amylase, except in the setting of macroamylasemia, which is a benign condition seen in 1% of healthy individuals. In the latter condition, serum amylase is conjugated with IgM and, therefore, cannot be excreted through the kidney. Urine amylase clearance would be normal in macroamylasemia.

Serum lipase: Increased serum lipase level is more specific for acute pancreatitis than serum amylase, and the specificity increases when the serum level increases by threefold. Similar to amylase, lipase can come from different sources such as lingual, gastric and breast milk. However, studies in animals have shown that serum lipase is mainly pancreatic in origin. The reabsorbtion of cleared lipase by kidney tubules may keep serum levels elevated as long as 14 days. There is no other source for serum lipase, except the pancreas.

Serum cationic trypsinogen: Serum cationic trypsinogen has been used as a sensitive diagnostic screening test, especially in newborns. Infants with cystic fibrosis usually have manifold elevation in serum trypsinogen level. These values usually decline during the first 7 years in patients with pancreatic insufficiency.

Other tests: Several other tests have been evaluated for the diagnosis of acute pancreatitis. However, none has been proven superior to amylase and lipase. In adults, several tests have shown to be useful in predicting severity, including C-reactive protein, phospholipase A, interlukin 6, SPINK-1, Trypsinogen activator Peptide (TAP), and TNF α receptor. Trypsinogen 2 has been shown to be useful in diagnosing pancreatitis secondary to ERCP.

Radiological Evaluation of the Pancreas

Plain radiography: Plain abdominal films in chronic pancreatitis may show calcification of the pancreas. In acute pancreatitis, radiographs may show generalized ileus or a localized "sentinel loop," which is a loop of dilated jejunum in the midepigastrium or left upper quadrant adjacent to the pancreas. Radiographs may show the "colon cut-off sign" which represents distention of the transverse colon with collapse of the descending colon.

Barium studies: Barium studies of the gastrointestinal tract may show esophageal varices due to splenic vein thrombosis and portal hypertension. An extrinsic mass effect on the stomach and duodenum from an inflamed and swollen pancreas or from a pseudocyst can be seen in some patients. Duodenal loop changes consisting of mucosal edema, distention, and air-fluid levels are frequently seen. Other signs include inverted "3" sign (Frostberg sign) which can be seen in the middle of the duodenum with the middle apex of the "3" representing the origin of the pancreatic duct and curves resulting from the swollen pancreatic head. Another sign is the Poppel sign, defining widening of the duodenal loop with prominent duodenal mucosal folds and the sphincter of Oddi.

Ultrasonography: Abdominal ultrasonograms provide good visualization of the pancreas as well as associated organs such as the hepatobiliary system. In acute pancreatitis, ultrasonography may reveal increase in the size and/or reduced echogenicity of the pancreas compared with that of the liver. Other findings may poorly define borders, dilated pancreatic ducts, and pseudocyst. Ultrasonography has several advantages such as simplicity, lack of radiation, and wide availability. Drainage of pseudocysts can be also done with ultrasonography guidance. Disadvantages of ultrasonography include poor imaging due to overlying gas obscuring the pancreas and the fact that it is operator-dependent. In chronic pancreatitis, in addition to the findings seen in acute conditions, ductal dilatation and accentuated echoes due to calcification are frequently observed. Ultrasonography is also a very useful tool in detecting and following up on pseudocysts.

Computerized tomography: Computerized axial tomography (CT scans) can detect calcification and calculi not evident by other radiologic modalities. Findings on CT scans include diffuse enlargement in patients with acute pancreatitis, hemorrhagic necrosis, and traumatic damage. It can also distinguish between pseudocysts and phlegmons. Therefore, when an ultrasound is inconclusive, CT scans could contribute to the diagnostic evaluation of pancreatic disorders and their complications. The drawback of the use of CT in children with pancreatitis is the need for sedation. A normal CT does not rule pancreatitis as 20% of patients with acute pancreatitis have normal CT.

Magnetic resonance cholangiopancreatography (MRCP): Advances in magnetic resonance technology has allowed the development of MRCP which is an excellent modality for obtaining images of the pancreaticobiliary tree. This imaging technique poses several advantages, including lack of radiation and lower complication rate compared to ERCP. The main disadvantage is poor ability to diagnose peripheral biliary tree in children. Most centers, including ours, have been relying on this imaging modality to diagnose structural abnormalities of the pancreaticobiliary tree in children. The use of MRCP has replaced ERCP as a diagnostic modality limiting the use of ERCP in cases in which MRCP has been inconclusive or when therapeutic intervention is needed, such as stone removal, or when papilotomy or stent placement are needed.

Endoscopic retrograde cholangiopancreaticography (ERCP): This technique involves endoscopic intubation of the pancreatic and biliary ducts. Despite the lack of experience in performing ERCP in children, it may provide very valuable information in patients with chronic pancreatitis. It allows identification of partial or complete obstruction of the intrapancreatic portion of the common bile duct. It also detects areas of narrowing, dilation, and tortuosity, or the presence of intraductal stones. Pancreas divisum can also be identified. Other diagnostic evaluations include measurement of sphincteric and ductal pressures. Therapeutic interventions such as dilatation and sphincterroplasty can also be performed in addition to stone removal and pseudocyst drainage. ERCP can also provide guidance prior to surgical intervention. However, the procedure is technically difficult in small children. Complications of ERCP are not different from those in adults and include pancreatitis, pain-requiring analgesia, perforation, ileus, and fever.

Congenital Diseases of the Exocrine Pancreas

Shwachman–Diamond Syndrome

Shwachman–Diamond Syndrome (SDS) is an autosomal recessive disorder characterized by pancreatic exocrine dysfunction, bone marrow failure, skeletal abnormalities, and leukemia predisposition. Mutations in Shwachman–Bodian–Diamond Syndrome (SBDS) gene located on chromosome 7 account for 90% of patients. The gene product is a protein likely involved in accelerated apoptosis.

The hallmark of this disease is the association of exocrine pancreatic insufficiency, bone marrow hypoplasia, and bony changes. Several other features have been also reported (*Table 198.1*).

Exocrine Pancreatic Insufficiency

Most patients present with steatorrhea in the first year of life. However, residual pancreatic function may allow

Table 198.1
Feature of Shwachman–Diamond Syndrome

Exocrine pancreatic insufficiency	Recurrent infections
Short stature	Renal tubular defects
Bone marrow hypoplasia	Fatty liver
Skeletal abnormalities	Dental effects
Hirschsprung disease	Ichthyosis
Impaired neutrophil functions	Diabetes mellitus
Endocardial fibrosis	

some patients to go unnoticed for several years. Exocrine function is abnormal with lipase being more severely depressed than other enzymes.

The pancreas appears grossly lipomatous. Histologically, the acinar glands are scarce or absent and are replaced entirely by fatty tissue. The islets of Langerhans appear intact.

Bone Marrow Hypoplasia

Bone marrow abnormalities may occur in one or all three blood lines. Neutropenia can be recognized in up to 95% of the patients, thrombocytopenia in 70%, and anemia in 50%. Neutropenia is usually cyclic with some patients mounting leucocytosis in response to infection. In vitro studies show impaired neutrophil mobility and chemotaxis. Bone marrow aspirates reveal hypocellularity and maturational arrest. Otitis media, sinusitis, osteomyelitis, and skin infections may be seen. However, overwhelming sepsis is usually the leading cause of death in this disorder.

Skeletal Abnormalities

Metaphyseal dysostosis in the femur, tibia, and ribs is recognized in about 10–15% of patients. The hip is the most frequently affected site thus adversely affecting the child's gait. The pathogenesis of these bony lesions is poorly understood. Spontaneous and complete resolution of these lesions after puberty has been reported in some patients. Early features include thoracic dystrophy manifesting as short ribs with flared anterior end "cup deformities" which may result in narrowing of the thoracic cage, causing respiratory distress. Clinodactly of the fifth finger is a frequent finding seen in up to 50% of affected individuals. However, the most frequent radiologic abnormality is delayed bone age.

Growth Retardation

Growth retardation is characteristic of this disease. While pancreatic enzyme replacement may improve weight gain, linear growth is usually not ameliorated. The severity of skeletal abnormalities also does not correlate with the retardation of height. Intrauterine growth retardation may occur, but in most patients, growth retardation manifests in the first year of life.

Diagnosis

SDS should be considered in any patient with malabsorbtion, hematologic or skeletal abnormalities, and negative sweat chloride test. Evaluation of pancreatic function by the pancreozymin-secretin stimulation test is the most sensitive test in evaluating pancreatic function. Patients with SDS characteristically show normal or slightly low bicarbonate levels with depressed or absent pancreatic enzymes. Blood counts reveal variable neutropenia, thrombocytopenia, and anemia. Bone marrow aspiration may show hypocellularity. Abdominal ultrasonography may reveal normal pancreatic size with fatty tissue infiltration. Bony films show the characteristic of metaphyseal dysostosis.

Treatment

Pancreatic enzyme replacement is usually effective in controlling steatorrhea and improving weight gain. However, it rarely influences linear growth. Pancreatic enzyme supplementation may be eventually discontinued because most patients achieve normal fat absorption with age. Fat-soluble vitamins supplementation is usually recommended. Patients with neutropenia require no treatment when asymptomatic. However, these patients should be treated

as immunosuppressed individuals when presenting with fever, and appropriate antibiotic therapy and cultures are indicated. Cyclosporin A has been found to be efficacious in treating aplastic anemia associated with this disorder.

Johanson–Blizzard Syndrome

Johanson–blizzard syndrome is an extremely rare ectodermal dysplastic disorder characterized by microcephaly, aplasia or hypoplasia of alae nasi, midline scalp defects, abnormal hair pattern, absence of permanent teeth, growth retardation, mental retardation, hypothyroidism, exocrine pancreatic insufficiency, Café au lait spots, genitourinary anomalies, congenital heart defects, thyroid dysfunction, imperforate or anteriorly displaced anus, and congenital deafness. This condition results from an autosomal recessive disorder. The molecular basis of this disorder has been recently defined as mutations in the ubiquitin protein ligase E3 component n-recogenin1 gene (UBRI) located on chromosome 15q.

Isolated Enzyme Deficiencies

Enterokinase deficiency: Enterokinase, an enzyme secreted by duodenal mucosa, is responsible for activating trypsinogen to trypsin. Accordingly, enterokinase deficiency results in trypsin, chymotrypsin, and procarboxypeptidase deficiency. Patients present early in life with diarrhea, anemia, hypoproteinemia, and failure to thrive.

Treatment with exogenous enterokinase is highly effective in controlling symptoms and improving growth.

Trypsinogen deficiency: Trypsinogen is activated by intestinal enterokinase into trypsin, which in turn activates chymotrypsinogen and procarboxypeptidase into their active form. Therefore, trypsinogen deficiency results in protein malabsorption. The clinical manifestations of this disease are indistinguishable from enterokinase deficiency. Treatment requires pancreatic enzyme replacement and providing formulas composed of protein hydrolysate.

Lipase and colipase deficiency: Lipase and its cofactor, colipase deficiencies are rare but well-recognized causes of steatorrhea and failure to thrive. Treatment with pancreatic enzymes and a low fat diet are effective means of controlling symptoms.

Acute Pancreatitis in Childhood

Acute pancreatitis refers to acute pancreatic inflammation with return of pancreatic morphology and function to normal between attacks. Hemorrhagic or necrotizing pancreatitis refer to severe disease with extensive pancreatic necrosis associated with life-threatening systemic manifestations.

Previously considered to be uncommon in the pediatric age group, acute pancreatitis has been recognized more frequently in recent years. The disease carries with it a high rate of morbidity and mortality. The disorder should be considered in children with abdominal pain and elevated pancreatic enzymes. Lack of awareness and a delay in diagnosis may contribute to these high rates. It is therefore essential to keep a high index of suspicion to allow the early diagnosis and management of acute pancreatitis.

Etiology

While alcoholism and biliary tract disease are the most common causes of pancreatitis in adults, drugs, abdominal trauma, and multisystem disease are recognized to be the major offenders in children. *Table 198.2* depicts the major causes of pancreatitis in childhood.

Trauma could be blunt, penetrating, or postsurgical. Some children may present immediately after the trauma with abdominal pain and vomiting, but in most cases, the presentation is delayed days to weeks, which makes the causal relationship between the trauma and pancreatitis uncertain. Child abuse is increasingly recognized as a cause of pancreatitis in toddlers and infants.

Many drugs are known to induce pancreatitis in all age groups. Corticosteroid-induced pancreatitis is known to be associated with a high mortality rate, probably related to the underlying disease process for which the steroids were given. Valporic acid has been strongly linked to acute pancreatitis, although the process is reversible upon withdrawal of the drug. With aggressive therapies that increase survival of children with malignancies, an increasing number of cases of pancreatitis induced by chemotherapeutic agents have been recognized.

Although mumps virus is the most frequent viral infection thought to be responsible for pancreatitis, several other viruses have been recently recognized as causative agents. These include coxsackie B_5 virus, EB virus, adenovirus, reovirus, and Hepatitis A and Hepatitis B viruses. Most viral-induced pancreatitis are of the interstitial variety that usually run a milder course than hemorrhagic pancreatitis.

Several metabolic disorders have been associated with acute pancreatitis, including hyperlipoproteinemia type I, IV, and V, hyperparathyroidism, diabetes mellitus, and cystic fibrosis. Recently, refeeding pancreatitis in

Table 198.2
Causes of acute pancreatitis in children

1. *Trauma* – blunt or penetrating
2. *Drugs and toxins* (a) *Anti-inflammatory agents*: Corticosteroids, salicyclates, and indomethacin (b) *Chemotherapeutic agents*: L-Asparaginase, 6-mercaptopurine, and azathioprine (Imuran) (c) *Diuretics*: Furosemide, chlorothiazides, and ethycrynic acids (d) *Anticonvulsants*: Valporic acid and dilantin (e) *Antibiotics*: Tetracycline and sulphonamide (f) *Anticoagulants* (g) *Alcohol* (h) *Venom of Scorpions* (i) *Organophosphates*

4. *Parasites* – Ascaris and hydatid cysts
5. *Anatomic anomalies* – Choledochal cyst, annular pancreas, anomalous insertion of common bile duct, pancreas divisum, and stenosis of ampulla of vater
6. *Metabolic and nutritional disorders* – Hypercalcemia, hyperlipoproteinemia Type 1, IV & V, Diabetes mellitus, cystic fibrosis, high concentrations of intralipids, and refeeding of malnourished children
7. *Vascular diseases* – Systemic lupus erythematosis, hemolytic uremic syndrome, and Henoch–Schönlein purpura
8. *Biliary diseases* – Gall stones, choledochal cyst, and biliary tree anamolies
9. *Hereditary*
10. *Shock*
11. *Idiopathic* (25%)

malnourished children and pancreatitis associated with high concentrations of lipid emulsions have been recognized with increasing frequency. Patients with 3-hydroxy-3 methyl glutaryl-coenzyme A lyase (HMG-CoA lyase) deficiency who present with recurrent pancreatitis are successfully managed with a low leucine diet. Patients with HMG-CoA lyase deficiency usually present with a clinical picture indistinguishable from Reye's syndrome, which has also been shown to be associated with pancreatitis.

Anatomic malformations are frequently encountered in patients with recurrent, relapsing pancreatitis. One common example is stenosis of the ampulla of Vater, which is amenable to sphincteroplasty in most cases. Other conditions include an annular pancreas, choledochal cysts, and anomalous insertions of the common bile duct.

Biliary disorders as a cause of pancreatitis are encountered much less frequently in children than in adults. However, a high index of suspicion is essential in high-risk groups, such as patients with hemolytic anemia who are susceptible to cholelithiasis and subsequent pancreatitis.

Pathophysiology

As mentioned earlier, pancreatitis has a variable etiology. However, the fundamental event that leads to the pathology in pancreatitis is the activation of pancreatic zymogen and initiation of enzymatic autodigestion of the pancreas. The mechanism by which these zymogens are activated within the pancreas is as yet not completely clear.

Studies in experimental animals have shown that the retrograde injection of activated proteolytic enzymes (trypsin, chymotrypsin, and elastase) in small amounts results in interstitial edema and, in larger doses, leads to extensive vascular damage, edema, and hemorrhage. Kallikrein, also activated by trypsin, liberates bradykinin and kallidin, both of which induce vasodilation and increase vascular permeability, ultimately leading to hypotension.

Phospholipase A contributes to the pathogenesis of pancreatitis in several ways. Studies in rats have shown that the injection of phospholipase A into the pancreatic duct results in severe pancreatic parenchymal necrosis indistinguishable from that seen in human pancreatitis. The lecithin of pulmonary surfactant can be a target for phospholipase A and may contribute to the adult-type acute respiratory distress syndrome encountered in severe cases of acute pancreatitis. Phospholipase A can also release histamine from mast cells and potentiate the refractory hypotension seen in acute pancreatitis.

Lipase, which is present in the pancreas in the active form, results in parapancreatic and peritoneal fat necrosis when released from the pancreas. Circulating lipase may lead to fat necrosis in skin, bone, and joints. Medullary fat necrosis may result in pulmonary or cerebral fat embolization with a catastrophic outcome.

Refractory hypotension and respiratory failure are the leading causes of death in severe pancreatitis.

Many factors may contribute to the hypotension, sometimes seen in acute pancreatitis. Recognized entities include the acute loss of plasma and blood into the peritoneum caused by disruption of the blood vessel integrity and by increased permeability and vasodilatation, resulting from kallikrein and histamine release.

Respiratory compromise ranges from mild hypoxia to full blown respiratory distress syndrome. Many factors are implicated in its pathogenesis, including pleural effusions, fat embolization, pseudocyst formation, and surfactant destruction by phospholipase A.

Hypocalcemia seen in acute pancreatitis is thought to result from the binding of calcium with fatty acids in the areas of fat necrosis.

Clinical Manifestations

Abdominal pain, nausea, and vomiting are the most common presenting symptoms of acute pancreatitis. Abdominal pain is usually constant and severe but may be mild and intermittent. Pain is usually localized to the epigastric region and may spread to the back, although some children may localize the pain to the periumbilical region or the right upper quadrant. The pain is aggravated by oral intake and not relieved by vomiting. The child may lie on his or her side and assume the knee-chest position. Other symptoms may include anorexia, nausea, and vomiting which may be bilious.

The physical exam may reveal a low-grade fever, tachycardia, and hypotension. The patient may be dyspneic with decreased breath sounds due to the presence of a pleural effusion. The abdomen is usually tender with some guarding, especially in the epigastric region. Bowel sounds may be normal, hypoactive, or completely absent in patients with advanced paralytic ileus. Subcutaneous fat necrosis may result in bluish discoloration of the skin in the flanks (Turner's sign) and the periumbilical area (Cullen's sign). Other manifestations include hematemesis, melena, abdominal mass, and coma.

Diagnosis and Laboratory Data

The diagnosis of acute pancreatitis rests on compilation of clinical features, laboratory findings, and imaging techniques. Careful medical history is mandatory with special emphasis on family history and history of trauma in order to define the cause of pancreatitis.

Pancreatic enzyme levels: The most common laboratory changes are elevated serum lipase, amylase, and trypsin levels, as well as an elevated renal amylase/creatinine clearance ratio (above 4 is abnormal). Keeping in mind the several clinical entities that may result in similar chemical derangements and correlating these data with the clinical findings and radiological studies is the correct approach to reaching an early diagnosis of this catastrophic disease. Although measuring serum lipase level is the most commonly used test in the diagnosis of pancreatitis, 35% of cases of acute pancreatitis may be missed if serum amylase is the only test done.

Hypocalcemia: Hypocalcemia is usually seen in severe cases of acute pancreatitis and correlates with a poor prognosis.

Hyperglycemia: Hyperglycemia is frequently encountered in acute pancreatitis. This complication is believed to result from an insult to β cells in the islets of Langerhans. However, plasma cortisolglucagon and growth hormone may also play a role. Glucose intolerance is usually transient; however, lifelong diabetes mellitus has resulted from viral infections of the pancreas, especially mumps and coxsackie virus.

Hyperlipidemia: Hyperlipidemia not only induces pancreatitis but may also result from the metabolic derangements induced by acute pancreatitis.

Hypoalbuminemia: Hypolbuminemia may be seen in patients with acute pancreatitis as albumin is an acute phase reactant and may be also seen secondary to expansion of the intravascular compartment with fluids.

Hematologic disturbances: Mild leukocytosis with left shift and hemoconcentration may be seen in some patients. Rapid decline in hematocrit indicates hemorrhagic pancreatitis.

Plain abdominal films should be done in patients with acute abdomen in order to exclude other abdominal disorders. As mentioned earlier, plain films may provide helpful information and characteristic signs that can help establishing the diagnosis (see Evaluation of Pancreatic Function and Pancreatic Disease).

Chest film should be obtained to rule out diaphragmatic or pulmonary involvement such as pleural effusion or adult respiratory distress syndrome (ARDS).

Abdominal ultrasounds, or CT scans, may reveal an enlarged and edematous pancreas with reduced echogenicity. It may also show a pseudocyst in the vicinity of the pancreas.

Complications of Acute Pancreatitis

Pseudocysts is a common complication following acute pancreatitis and may develop in 16–50% of the patients. The lining of the pseudocyst is composed of fibrous or granulation tissue without an epithelial component. It is fluid filled with pancreatic juice, blood, and tissue debris. It may develop in the course of the acute attack or many weeks later. In contrast to pseudocysts associated with chronic pancreatitis in patients with acute pancreatitis, psudocysts do not communicate with pancreas. The presentation is usually that of a prolonged course of acute pancreatitis with persistent nausea and

vomiting, and prolonged elevation of serum amylase and lipase. Ultrasounds or CT scans are diagnostic. Small pseudocysts will most likely resolve spontaneously. However, large cyst, those that last more than 6 weeks, and those with abscess formation require immediate drainage. Ruptured cysts may cause severe and life-threatening chemical peritonitis.

Other complications such as respiratory, renal and hepatic failure, and refractory hypotension correlate with severe disease and a grave outcome.

There is no available data regarding mortality rate following acute pancreatitis in children. In adults, mortality rate is usually 9% per attach. On the other hand, the mortality rate following hemorrhagic and necrotic pancreatitis ranges between 15% and 50%.

Treatment

Treatment of acute pancreatitis is primarily supportive. The treatment should be directed toward the cause whenever identified. Other than avoiding the precipitating factors, maintaining intravascular volume, the mainstays of therapy are minimizing the stimulation of pancreatic exocrine secretions and pain management.

Almost all patients will have some degree of dehydration due to decreased intake, vomiting, leakage of intravascular fluids to the peritoneum, or hemorrhage. Based on the degree of dehydration, patient will require replacement of deficits, ongoing losses, and maintenance fluids. Caution should be applied in order to avoid fluid overload, which may result in pulmonary edema and congestive heart failure commonly seen 3–7 days from the onset of pancreatitis. Potassium should not be added to intravenous fluids before establishing acceptable urine output as renal failure may be seen in 2% to 17% of patients with acute pancreatitis. Monitoring electrolytes, including calcium and magnesium, is mandatory. If shock and hemorrhage are present, fresh frozen plasma or blood may be required. Treatment with intravenous pressor agents may be needed if these measures have failed in improving blood pressure. H2 blocker or proton pump inhibitors may help reduce duodenal acidity and prevent gastritis and ulcer formation.

Complete bowel rest and employing gastric suction will reduce the dietary and hormonal stimulation of the pancreas. Oral feedings should not be resumed until pain and ileus have resolved and amylase normalized. When oral feedings are resumed, carbohydrates should be introduced first, avoiding fats and proteins in order to decrease pancreatic stimulation. If the patient requires prolonged therapy, total parenteral nutrition is in order. In the past, anticholinergic drugs were frequently used to suppress the neural stimulation of pancreatic secretions. However, controlled studies have failed to prove their efficiency.

Adequate pain relief is essential. This can be accomplished with meperidine. Opiates should be avoided because they may cause spasm of the sphincter of Oddi. Persistence of pain beyond 2 weeks may indicate the development of pseudocyst, and ultrasound is usually recommended every few days to detect to monitor for this complication.

Prophylactic antibiotics are not recommended since studies have failed to substantiate their efficacy in preventing secondary infection.

Many patients with pancreatitis may have some degree of hypoxia which requires oxygen administration. With respiratory failure, ventilatory support may also be required. Thoracentesis may help in relieving the respiratory compromise resulting from pleural effusions.

Surgical intervention is usually reserved for treatment of complications of the disease or for the correction of underlying anomalies.

Chronic Pancreatitis

Chronic pancreatitis is a chronic inflammatory process with progressive and permanent damage to the structure and function of the pancreas. The disease is uncommon in childhood; however, it is encountered frequently enough to require a high index of suspicion.

Etiology of Chronic Pancreatitis

There are numerous causes of chronic pancreatitis. Hereditary or familial pancreatitis is an autosomal-dominant disease with incomplete penetrance, recognized mainly among whites in Europe and North America, and among Chinese children. The onset of this disease is usually in the second decade of life. Several mutations have been described such as mutations in the cationic trypsinogen (PRSS1) gene. In addition, mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) and the serine protease inhibitor Kazal type 1 (SPINK1) genes are also associated with pancreatitis.

Juvenile tropical pancreatitis inflicts young people in the tropics, where low protein staples are commonly consumed. The largest series has been reported from the southern Indian state of Kerala. It is also recognized in Zaire, Nigeria, Uganda, South Africa, and Malaysia.

The disease has been strongly linked to protein calorie malnutrition, although conclusive data is lacking.

Chronic pancreatitis may also result from obstructive processes usually arising from congenital anomalies. These include stenosis of the papilla of Vater, choledochal cysts, an annular pancreas, and pancreas divisum.

Chronic pancreatitis also arises from systemic and metabolic disorders, including hypercalcemia, hyperparathyroidism, hyperlipidemias, alpha-1-antitrypsin deficiency, cystic fibrosis, and inflammatory bowel disease.

Biliary disorders such as cholecystitis, cholelithiasis, and sclerosing cholangitis may also lead to chronic pancreatitis.

Chronic pancreatitis also results from extensive necrosis and fibrosis following an episode of acute pancreatitis.

Idiopathic chronic pancreatitis requires the exclusion of recognizable causes.

Clinical Presentation

The most common initial presentation of chronic pancreatitis is a clinical picture suggestive of repeated episodes of acute pancreatitis. Approximately one-half of patients present initially with episodes of acute pancreatitis. The other half will present with insidious pain, and a small percentage of patients will have no pain at all. Therefore, the majority of children with chronic pancreatitis have either intermittent or chronic abdominal pain lasting for weeks. The pain is localized to the epigastrium, the upper abdominal quadrants, the back, or occasionally the periumbilical area. As the disease progresses, the pain may diminish. Patients with chronic pancreatitis usually present between 10 and 12 years of age. By the age of 20 years, 75% of the patients are symptomatic. Males and females are equally affected. The diagnosis of chronic pancreatitis should be considered in patients presenting with obstructive jaundice, malabsorption, and diabetes.

Some patients may present with obstructive jaundice, with or without abdominal pain, secondary to narrowing of the distal common bile duct due to extensive fibrosis.

Exocrine insufficiency with steatorrhea and failure to thrive can be the presenting symptom in up to 20% of patients. Pancreatic exocrine failure could result from destruction of more than 98% of pancreatic acini or from obstruction of pancreatic ducts.

Glucose intolerance with hyperglycemia and glucosuria are common in the early stages of the disease. As the disease progresses, lifelong diabetes mellitus may develop, particularly in calcifying pancreatitis and tropical pancreatitis.

There have been numerous reports of pancreatic malignancies in some etiologic subgroups of patients with chronic pancreatitis. Nonpancreatic malignancies are also reported in patients with familial pancreatitis.

Splenic vein thrombosis has been reported in chronic pancreatitis secondary to perivenous inflammation. Gastric varices secondary to splenic vein thrombosis is a common finding in patients.

Diagnosis

(See ❯ Evaluation of Pancreatic Function and Disease)

The same diagnostic tests used in acute pancreatitis also apply to chronic pancreatitis. However, it is important to recognize that serum amylase and lipase may be normal or decreased in advanced cases due to pancreatic insufficiency. Pancreatic function evaluation with pancreozymin-secretin stimulation is a very valuable tool in assessing the degree of compromise in pancreatic exocrine function. Malabsorbtion may cause fat-soluble vitamin deficiency. Serum vitamin D and vitamin E carotene level and essential fatty acids may be decreased with prolongation of prothrombin time. Endoscopic retrograde cholangiopancreatography (ERCP) is the most sensitive diagnostic test in chronic pancreatitis. However, normal studies do not exclude the existence of pancreatitis.

Therapy for Chronic Pancreatitis

In the management of acute episodes of chronic pancreatitis, the same measures taken in acute pancreatitis are applied.

Management of malabsorption is also important. Fat intake should be limited while providing adequate protein and calories for growth. Use of medium chain fatty acids for improved absorption may be required. Continuous nasogastric alimentation with elemental formulas may be necessary in some patients. Pancreatic enzyme supplementation will also result in improvement of steatorrhea. Since lipase is inactivated in acidic pHs, gastric acid blockade with H_2-blockers or proton pump inhibitors can lead to increased bioavailability of pancreatic enzyme supplements. Patients may need insulin therapy with the development of diabetes mellitus.

Management of pseudocysts requires surgical internal or external drainage. Surgical therapy or ERCP-directed therapy is indicated for patients with intractable pain and for patients with obstruction of the common duct. ERCP can drain pseudocysts and allow removal of intraductal stones, placement of drains and stents, in addition to performing sphincterotomy. For definitive drainage of

the pancreas, a pancreaticojejunostomy may be required. In some patients, a partial or subtotal pancreatectomy may be required. With complete common bile duct obstruction, a choledochojejunostomy may be indicated. Pancreatic transplantation has recently become available, but experience in children is limited.

199 Gastrointestinal Bleeding

Mark A. Gilger · Hisham M. Nazer

Introduction

Gastrointestinal bleeding in infants and children is a potentially life-threatening problem that can be quite alarming for the child and his family. The cause, however, is usually benign; however, the differential diagnosis is so extensive and does vary with age. The approach to diagnosis and management of gastrointestinal bleeding by the physician should be calm and expeditious to help allay the fears of the patients and the family and to reduce any likely associated morbidity. This chapter is intended to review the spectrum of GI bleeding in infants and children and to discuss means of investigations and therapy (*Fig. 199.1*).

Initial evaluation should aim at confirming that the child has definitely an upper or lower gastrointestinal bleeding. Detailed history is a very important first step in the evaluation of a child with gastrointestinal bleeding. There is a tendency to overestimate the amount of blood loss; therefore, a detailed history is a very important first step in patients' evaluation. Identification of heme products is based on the interaction of peroxidase activity found in the hemoglobin and various reagents. Food-coloring agents added to cereals, drinks, and medications could result in discoloration of the stools. Vegetables, iron-fortified cereals, ketchup, and gelatin deserts are also some other examples to be considered in the initial evaluation to confirm that the child has really had upper or lower gastrointestinal bleeding. Guaiac-based tests are most reliable, but still have a false-positive rate of 1–2%. Hemoglobin in red meat will also result in a false-positive test. None of the available tests for occult blood are 100% specific.

A normal physical examination is not uncommon in patients with GI bleeding. It is important to document the vital signs of the child on admission as part of the initial evaluation. A comprehensive checkup on abdominal distention, masses, hepatosplenomegaly, rectal prolapse, and anal fissure should be also made.

The child should be admitted to prevent any potential subsequent complications and to manage early any potential further bleeding. The site and cause of bleeding should be determined as soon as possible.

Hemorrhagic disease of the newborn is due to vitamin K deficiency and responds fairly well to vitamin K injection. In up to 50% of cases, the actual cause of bleeding is not defined in the neonate whose general condition remains good and fairly stable. Gastrointestinal bleeding beyond the neonatal period is usually due to esophagitis, gastritis, or peptic ulcers. Other important cause to be considered is Mallory–Weiss Syndrome especially in young infant with hematemesis or melena and a history of paroxysmal cough or vomiting resulting in longitudinal mucosal laceration at the gastroesophageal junction.

Helicobater pylori should also be considered as an important cause of GI bleeding. The recurrence of the infection and GI bleeding can be prevented with eradication of *H. pylori.*

Endoscopy is the investigation of choice. Diagnostic endoscopy may have to be performed in the first hours following admission. Other investigations of importance in infants and children with gastrointestinal bleeding include Meckel's scan, red blood cells scan, angiography, and contrast barium studies.

Pathophysiology

When a child bleeds, a number of homeostatic mechanisms interact. These include an increase in the sympathetic activity, with catecholamine and release of adrenocorticotropic hormone, antidiuretic hormone, aldosterone, glucocorticoids, and prostaglandins. The rapidity of blood loss may be a more important factor than the volume that is lost. As much as 15% of our blood volume can be lost slowly without any hemodynamic response. The venous bed normally contains a substantial volume of blood that can easily compensate for minor losses to prevent any changes in cardiac output and oxygen consumption. Blood flow to the brain and heart is maintained. A very narrow pulse pressure may be a valuable warning of impending vascular collapse as compensatory vasoconstriction is exhausted. Patients may experience shock with as little as 10% volume loss if bleeding is extremely rapid.

When the blood loss exceeds 15% of the blood volume, compensatory mechanisms are no longer adequate. Cardiac output is maintained by sympathetic stimulation

Approach to GI bleeding in children

resulting in increased heart rate. Peripheral vasoconstriction and increased secretion of aldosterone and antidiuretic hormone also assist in maintaining blood volume. Oxygen consumption as well as blood lactate levels increase in response to tissue hypoxia, hyperventilation, and respiratory alkalosis before significant metabolic acidosis presents.

In case of severe blood loss greater than 30% of the circulatory blood volume, hypotension is invariably present together with decreased cardiac output, tissue damage, cardiac infarction, and metabolic acidosis. Acute renal failure may develop, determined by the degree of vasoconstriction and duration of hypotensive episodes. Hepatic ischemia can lead to tremendous elevation in transaminases and bilirubin. Sepsis may develop as a result of impaired organ function or depressed immune status. Both acidosis and sympathetic activity may increase the degree of myocardial damage during shock.

Table 199.1
Causes of upper gastrointestinal bleeding in children

In neonates
Swallowed blood: during birth, epistaxis
Hemorrhagic disease of the newborn
Stress ulcer, esophagitis
Foreign body irritation, trauma
Duplication cyst
In older children
Esophagitis, peptic ulcer disease, gastric erosions
Esophageal varices, portal hypertension
Mallory–Weiss syndrome
Pyloric stenosis
Blood dyscrasia: thrombocytopenic purpura, von Willebrand disease, leukemia
Tumor, vascular anomalies
Epistaxis, foreign body
Duplication cyst, acute poisoning

Upper Gastrointestinal Bleeding

Upper gastrointestinal bleeding is a relatively common problem and is occasionally a life-threatening emergency in infants and young children. Causes of upper gastrointestinal bleeding in children are summarized in *Table 199.1*. Hematemesis imply bleeding proximal to the ligament of Treitz. The vomiting may be bright red or coffee ground in appearance if it has been altered by the gastric acid. Blood from the upper gastrointestinal tract may appear per rectum as black or tarry in color, *melena*.

The odor of melena is quite distinct. In Melena, the lesion is usually proximal to the ascending colon.

The following points are important to consider in the overall management of a child with upper gastrointestinal bleeding:

1. Most children stop bleeding prior to or early in their hospital course.
2. Localization of the bleeding site can be established in more than 90% of cases.
3. Flexible fiber-optic endoscopy is the investigation of choice for upper gastrointestinal bleeding.
4. Erect and supine (or lateral decubitus) plain films are useful investigations to exclude bowel obstruction and free intra-abdominal gas. Barium examination of the upper gastrointestinal tract has little to offer in the initial evaluation of the actively bleeding child.
5. Nearly 20% of patients with varices who bleed do so from sources other than varices.
6. Avoid overtransfusion, especially in case of esophageal varices.
7. In suspected hepatic encephalopathy, sedation, if any, should be minimal.

History

Parents tend to overestimate the amount of blood lost by hematemesis and even more so the amount of bleeding per rectum. Confirm that the child has in fact had a bleeding. Detailed history taking is a very important first step in the evaluation of a child with gastrointestinal bleeding. One must inquire about possible cough or epistaxis and the duration of the vomiting before the blood appeared. Projectile vomiting in young infants points to pyloric stenosis with secondary gastroesophageal reflux and esophagitis. Vomiting of coffee ground-like material does not necessarily signify a specific quantity of blood, nor does vomiting of bright red blood mean that major bleeding is taking place. It is important to note that as much as 20% of upper gastrointestinal tract bleeding occurs without hematemesis.

Passage of bright red blood on the toilet paper or in the toilet bowl or on the surface of the stool suggests anorectal pathology, as in the case of anal fissure, proctitis, or polyposis.

Other points of importance in the history include inquiry about associated findings or complaints such as fever, postprandial pain, colic pain, anorectal pain, history of drug ingestion, or similar disorders in the family. Special enquiry should be made concerning the child's ingestion of nonsteroidal anti-inflammatory drugs prior to admission.

Physical Examination

A normal physical examination is not uncommon in patients with gastrointestinal bleeding. It is important to document the vital signs of the child on admission and initial evaluation. The skin should be examined for ecchymosis, purpura, petechia, rashes, jaundice, and pigmentation. The skin is further evaluated for signs of collagen vascular disorders or infections.

Examination should also include assessment of lymph nodes. The mucous membrane is also inspected for signs of hemorrhage from the nose, nasopharynx, and mouth. Examination should also include checking for abdominal distention, masses, hepatosplenomegaly, anal fissure, and rectal prolapse.

General Management

The child should be admitted to prevent any potential subsequent complications and to manage any further bleeding. There is also a potential risk of hypotension, impairment of hepatic perfusion, with deterioration of liver functions resulting in the appearance: of further evidence of hepatic involvement with jaundice, ascites, and encephalopathy.

The doctor should determine the cause and locate the site of the bleeding as soon as possible. History and physical examination should provide detailed answers to the following questions: Is it really blood? How much blood is lost and its effect on the child? Is the child still bleeding?

On admission, the child should have a baseline laboratory assessment with full blood count and differential, liver function tests, and renal function rests. At least a unit of whole blood should always be kept available in the blood bank. In case of bleeding varices in an older child, 3–4 units of blood should be kept on standby. The intravenous infusion line should be secured, whether peripheral or central. Serial evaluations of vital signs, urinary output, and hematocrit are critical. Nasogastric tube insertion may provide important diagnostic information. It is a useful adjunct for monitoring bleeding. The size of the nasogastric tube depends on the size of the patient. The smaller bore lubes may be adequate for assessing bleeding but not for removing large clots. The larger bore nasogastric tubes may cause trauma to the gastric mucosa. Gastric lavage with the nasogastric tube helps the endoscopist to obtain a clear view of the bleeding site. The presence or potential presence of esophageal varices should in no way preclude the use of a tube.

The presence of bright red blood is a marker of active bleeding. Avoid overtransfusion especially in patients with esophageal varices.

Water is found to be as efficacious as saline to lavage the stomach. Tap water would appear to be a suitable solution for gastric lavage because of its low cost and its temperature. All patients in whom the level of gastrointestinal bleeding is not obvious should have a nasogastric tube passed and their stomach aspirated, especially if there was no previous history of gastrointestinal bleeding.

In severe cases and in those patients requiring intensive care nursing, endotracheal intubation is required to protect the airway and prevent aspiration. It is important to notify, in advance, the intensive care unit staff of any potential admission or referral. Emergency drugs like vasopressin and ranitidine should be made available as well as a Sengstaken-Blakemore tube if the unit staff are familiar with its application and complications.

Intravenous vasopressin has been used to control gastrointestinal bleeding. Vasopressin in a dose not exceeding 0.01 U/kg/min intravenously is recommended. Higher doses were reported to be associated with complications without improving the control of hemorrhage. Tuggle et al. recommend starting vasopressin at 0.002–0.005 U/kg/min, which would allow increasing the dose of vasopressin before the risk of complications increases.

Urine output should be measured carefully. Foley catheterization of the bladder may be required. In massive bleeding, replacement fluid should contain whole blood. The patient's vital signs give some indication of blood volume to be replaced. The hemoglobin and hematocrit are not accurate reflections of blood volume during an acute hemorrhage. The usual goal of transfusion is to restore an adequate circulatory volume to allow tissue perfusion. A hemoglobin level of 10 g/dL or a hematocrit of 30% is adequate. Monitoring of blood gases is important, especially in those patients who have had severe bleeding with poor tissue perfusion. All patients with massive bleeding should receive oxygen.

Diagnostic endoscopy and injection sclerotherapy may have to be performed in the first hours following admission, especially in patients known to have esophageal varices or if the bleeding recurs. It is essential to confirm the presence of varices, to ascertain the cause of bleeding, and to determine the sites of ulceration and erosions. Coagulation disorders and hemodynamic instability must be corrected before performing any endoscopic procedure. Variceal banding with a well-set elastic band to an esophageal varix through the endoscope may have to be performed soon after admission. The varix is sucked into the device and a band of fired to ligate the varix. Multiband set does allow the application of several bands without the need for reloading.

Upper gastrointestinal endoscopy should not be performed in an uncooperative patient. The most common reason for inadequate examination is inadequate sedation. Shock, perforated hollow viscus, and cervical spine injury are contraindications to upper gastrointestinal endoscopy. In a small percentage of patients in whom endoscopy and barium studies have failed to determine the source of bleeding or when bleeding is massive, arteriography should be performed. This examination of the superior and inferior mesenteric arteries and the celiac axis may reveal some common causes of bleeding as well as unusual causes such as hepatic artery aneurysm, gastropancreatic duplication, and arteriovenous malformations.

Upper Gastrointestinal Bleeding in the Neonate

Most neonates who bleed do so within 48 h of birth. The bleeding usually stops within the next 24 h and rarely recurs. Most bleeding in the first month of life does not require surgery. Major bleeding in the neonatal period may be the result of hemorrhagic gastritis or stress ulcers caused by perinatal insult of hypoxia, sepsis, or lesions of the central nervous system.

The common causes of upper gastrointestinal bleeding in the neonates include the following

Hemorrhagic Disease of the Newborn

This is due to vitamin K deficiency, resulting in generalized bleeding that may be massive. It is usually treated with 1 mg of vitamin K intramuscularly followed by 1 mg of vitamin K each day for 5 days.

Swallowed Maternal Blood

One of the most common causes of hematemesis or melena in the neonate is swallowed maternal blood during delivery or during breast-feeding if the mother has cracked nipples. The Apt test may have to be used at bedside to differentiate fetal from maternal blood based on the fact that fetal hemoglobin is more resistant to alkali denaturation than adult hemoglobin.

Cow's Milk Protein Allergy

This should also be considered and confirmed by the presence of high serum milk antibodies and endoscopic and histologic changes of the intestinal mucosa. Other causes of bleeding in the neonates, though rare, include duplication cysts of the intestine, midgut volvulus, peptic ulcer disease, and esophageal varices.

In up to 50% of cases, the actual cause of bleeding is not defined in the neonate, whose general condition remains good and fairly stable.

Upper Gastrointestinal Bleeding in Infancy and Childhood

Gastrointestinal bleeding beyond the neonatal period is usually due to esophagitis, gastritis, or peptic ulcers. Other causes to be considered include Mallory–Weiss syndrome and swallowed foreign body. Zollinger Ellison syndrome is a well-recognized condition affecting young infants associated with peptic ulcer–like disease.

Zollinger Ellison syndrome is typically caused by a gastrin-secreting tumor, usually located in the pancreas, occasionally in the duodenum, lymph nodes. Rare locations in children include the liver, kidney, and heart. Peptic ulcer disease is a recognized presentation of ZES with the presence of single or multiple ulcers in the first part of the duodenum. The diagnosis is considered even further if peptic ulcers were found in the second or third part of the duodenum or in the jejunum The associated peptic ulcers in this condition are usually big and about 2 cm in diameter or more and are seen in multiple sites.

The diagnosis of ZES is considered when plasma gastrin is >1,000 pg/ml, basal acid output is >15 meq/h, or when associated with a pH 2. Secretin stimulation test is considered as the most important diagnostic test for ZES. Eighteen to twenty-five percent of patients do not have ulcers at diagnosis.

The treatment is directed toward controlling gastric acid hypersecretion, and localization of the tumor and its metastasis. Associated peptic ulcers are known for being resistant to conventionl therapy.

Mallory–Weiss Syndrome

Mallory–Weiss syndrome is a condition associated with upper gastrointestinal bleeding due to longitudinal mucosal laceration at the esophagogastric junction (*Fig. 199.2*). The bleeding in Mallory–Weiss syndrome is due to a tear precipitated by forceful vomiting, repeated retching, cough, trauma, or even straining at stool resulting in a rise in intragastric pressure and presenting usually as hematemesis or less commonly as melena.

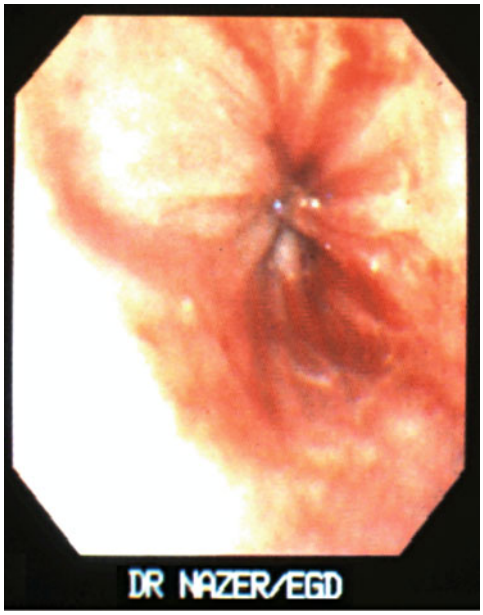

Figure 199.2
Mallory–Weiss syndrome: endoscopic appearance of Mallory–Weiss tears in young infant with upper gastrointestinal bleeding

The patient may have two to three forceful emeses without blood followed by massive hematemesis. Mallory–Weiss tears have been reported in children as young as 16 weeks of age; bleeding usually stops spontaneously and surgery is rarely indicated. The tear may sometimes result in severe upper gastrointestinal bleeding that warrants immediate attention and intensive care management.

Diagnosis is confirmed endoscopically. Ninety percent of the tears are in the stomach at or near the gastroesophageal junction. In only 10%, the rears involve the esophagus. Treatment is conservative, as the bleeding usually stops on its own. The patient should receive no feeds or fluid by mouth. He or she should be given H2-blockers or antacids or both for a period of at least 48–72 h before the nasogastric tube is withdrawn. Feeding can be commenced 24 h after withdrawing the nasogastric tube and with no evidence of recurrent bleeding.

Esophageal Varices

Variceal bleeding is usually painless but profuse. Endoscopy enables detection of the bleeding site in about 90%

of cases. Variceal bleeding may be the initial presentation of portal hypertension as in congenital hepatic fibrosis. Esophageal varices is discussed in a separate chapter together with portal hypertension.

Other causes to consider in the evaluation of an elder child with upper gastrointestinal bleeding include hemolytic uremic syndrome and Henoch–Schönlein purpura.

Diagnostic Techniques

After stabilizing the patient's vital signs, nasogastric aspiration is the second recognized step in the management to identify the severity and continuity of the bleeding.

Endoscopy

Upper gastrointestinal endoscopy is the diagnostic technique of choice in evaluating the upper gastrointestinal bleeder. It is extremely accurate in establishing the diagnosis in over 90% of patients compared to not more than 60% using upper gastrointestinal barium study. Barium contrast studies will not identify some conditions such as esophagitis, gastritis, and Mallory–Weiss tear. Therefore, barium studies should not be used as the first diagnostic modality for upper gastrointestinal bleeding if flexible fiber-optic endoscopy is available. However, it must be accepted that although emergency endoscopy is the most effective diagnostic procedure, it has no relevant influence on mortality if endoscopic hemostatic procedure is not employed simultaneously. Furthermore, the diagnostic yield of endoscopy performed 12–24 h after admission is no less than that performed immediately on admission. Current studies have not confirmed that early diagnosis improves mortality and morbidity associated with upper gastrointestinal bleeding.

Meckel Diverticulum Scan

Technetium-99m pertechnetate is concentrated in the gastric mucosa as well as in the ectopic gastric mucosa of a Meckel diverticulum, which is usually responsible for associated gastrointestinal bleeding.

Red Blood Cells Scan

This test offers a definite advantage for intermittent bleeds. The scans are done at intervals of 5–15 min for 1–3 h. The tagged red blood cells scan may not be positive until 4–6 h after injection or even after 12–24 h. The exact site of bleeding cannot be ascertained as accurately as with angiography.

Arteriography

Arteriography may be used in critically ill patients. The patient must be bleeding approximately 0.5–2 ml/min before the study is expected to be positive. The study should include injection of superior and inferior mesenteric arteries and celiac axis. Angiography should be considered when medical measures employed in the control of the bleeding gastrointestinal lesion have been unsuccessful. Embolic therapy may be performed through the angiographic catheter in an attempt to stop the bleeding and avoid surgery.

Contrast Barium Studies

Contrast upper gastrointestinal barium studies are not routinely resorted to in the workup of gastrointestinal bleeding as was the case a few decades ago. Such contrast studies rank last in the diagnostic workup list in upper gastrointestinal bleeding.

Endoscopic Approach to Upper Gastrointestinal Bleeding in Children

Upper gastrointestinal (UGI) bleeding is unusual in children. Data from the Pediatric Endoscopy Database System–Clinical Outcomes Research Initiative (PEDS-CORI) indicates that hematemesis accounts for only about 5% (327 of 6,337) of indications for upper endoscopy in children. In general, UGI bleeding is rarely life threatening and usually stops. UGI bleeding is considerably more common in critically ill children with an incidence ranging from 6% to 25%. However, even in this critically ill population, life-threatening UGI bleeding was rare, found in only 0.4% of children. Although the causes of UGI bleeding have remained unchanged, the treatment, such as the use endoscopic therapy, has evolved.

Initial Assessment and Intervention

As a rule, UGI bleeding always warrants further investigation. Prior to considering endoscopy, any child with gastrointestinal bleeding must have a brief history followed by a quick assessment of the physical status, especially the

vital signs and level of consciousness. If the bleeding is severe, therapy should begin before the location of the bleeding can be ascertained. For example, significant gastrointestinal bleeding will be manifested by tachycardia, followed by hypotension, an ominous signal of impending cardiovascular collapse. Immediate therapy is aimed at correction of volume loss and anemia, which should include aggressive fluid and blood resuscitation.

If the patient remains unstable after transfusion of 85 ml/kg or greater of blood, emergency exploratory surgery is indicated. Surgical consultation is mandatory in any case of severe UGI bleeding. Varices, ulcers penetrating into an artery, or tears into arterial vasculature must be considered.

Laboratory evaluation should include a complete blood count with platelets and reticulocyte count, prothrombin time and partial thromboplastin time, and a blood type and cross match. Assessment of liver function (alanine aminotransferase, aspartate aminotransferase, and albumin) may prove useful in that elevated transaminases and a low albumin or an elevated protime can be an indication of chronic liver disease. Assessment of kidney function (blood urea nitrogen (BUN) and creatinine) is also recommended as an elevated BUN (azotemia) may indicate UGI bleeding which may result from intestinal absorption of the blood and hypovolemia.

Endoscopy

Esophagogastroduodenoscopy (EGD) is the preferred approach to assess the UGI tract for bleeding. EGD is indicated for acute UGI bleeding requiring transfusion or unexplained recurrent bleeding and it determines the source of the bleeding in 90% of cases. EGD is particularly useful in the diagnosis of mucosal lesions such as gastritis, esophagitis, peptic ulcers, and Mallory–Weiss tears. Most UGI bleeding in children stops spontaneously; thus, emergency endoscopy is indicated only when the findings will influence clinical decision, such as the need for medical or surgical therapy. EGD is contraindicated if the patient is clinically unstable.

Endoscopic Therapy

Many endoscopic therapies are now available for the treatment of UGI bleeding. These include electrocoagulation (bipolar electocoagulation [BICAP], heater probe, and monopolar probe), laser photocoagulation, argon plasma coagulation, injection of epinephrine and sclerosants, band ligation, and mechanical clipping. There is little published experience with these techniques in children; hence, which approach is best in children remains unknown. Perhaps the most widely used approach is injection therapy followed by BICAP. This approach is appealing because it is simple, inexpensive, and uses a sclerotherapy needle, all of which are familiar to the pediatric endoscopist. Although no data exist, the combination of 1:10,000 epinephrine injection followed by bipolar electrocoagulation is likely the most commonly performed endoscopic treatment of UGI bleeding in children.

Thermal coagulation of a bleeding ulcer using a heater probe has been reported to be safe in neonates. The argon plasma coagulator is useful as it fits through small pediatric endoscopes and has a controlled depth of penetration. Unfortunately, it remains expensive. Laser therapy is commonly applied in adults, but there is a significant learning curve and high potential for full-thickness wall injury and is even more expensive that argon plasma coagulation.

Endoscopic treatment of esophageal varices includes either injection sclerotherapy or variceal banding. Sclerotherapy has been used for the treatment of variceal hemorrhage in children since 1959. Control of bleeding is achieved in over 90% of cases and varices are eradicated in over 80% of cases. Complications after sclerotherapy are common, such as strictures, recurrence of the varices, and recurrent bleeding. Variceal banding was introduced in 1989 as an adaptation of the treatment for hemorrhoids. Meta-analysis studies in adult patients demonstrate no difference between sclerotherapy and banding in the control of bleeding or mortality. There are no comparative studies between sclerotherapy and banding in children, but some studies suggest that banding may be the preferred method in children. Banding appears to be better tolerated in children compared with sclerotherapy, causing less retrosternal pain and no fever. Unfortunately, banding devices remain too large for use in infants and small children. Although variceal banding is effective in controlling bleeding, rebleeding occurs in up to 80% of patients.

Endoscopic treatment of gastric varices remains controversial. Endoscopic visualization during UGI bleeding is imperative but often difficult. Studies indicate that the prokinetic erythromycin given prior to EGD is effective in clearing the gastric lumen, providing better visualization of the mucosa during endoscopy.

Lower Gastrointestinal Bleeding

Rectal bleeding is an alarming symptom in children but is usually not life threatening. Bleeding per rectum can be bright red (hemotochezia) or tarry black and sticky with

a characteristic smell (melena). Hemotochezia usually results from lesions in the colon or terminal ileum, while melena is typical of sources above the ligament of Treitz.

Melena is defined as the passage of black tarry stools due to the presence of digested blood. The stool is shiny, sticky, and virtually always extremely foul smelling.

Hematochezia is the passage of bright red or maroon blood from the rectum. This may be pure blood, bloody diarrhea, or blood mixed with the stool. The site of the bleeding is usually in the left colon and primarily in the anorectal region.

Recognized causes of lower GI bleeding in young infant include anal fissures, cow's milk protein intolerance, necrotizing enterocolitis, gastritis and peptic ulcer disease, Meckel's diverticulum, gastrointestinal polyps, intestinal duplication, and intussusception. Meckel's diverticula and intestinal duplications may cause gastrointestinal bleeding in almost any age group and require a high index of suspicion for diagnosis. Bleeding usually is painless but may be massive. The advent of technetium (Tc) 99m pertechnetate radionuclide scanning has greatly facilitated the diagnosis. A positive scan requires the presence of ectopic gastric mucosa, which may be identified in both Meckel's diverticula and intestinal duplications The significance of ectopic gastric mucosa is that it contains acid-secreting parietal cells, which may cause ulceration and bleeding. After initial fluid resuscitation, bleeding from Meckel's diverticula and intestinal duplications require surgical intervention.

Causes of lower gastrointestinal tract bleeding are summarized in *Table 199.2*.

Table 199.2
Causes of lower gastrointestinal tract bleeding in childhood

In neonates
Anal fissure
Duplication of bowel
Arteriovenous malformation
Necrotizing enterocolitis
Peptic ulcer
Milk allergy
Intussusception
Tumor
Ischemic colitis
Midgut volvulus
In the older child
Anal fissure
Peptic ulcer
Enterocolitis: infective, allergic
Pseudomembranous colitis
Meckel diverticulum
Henoch–Schönlein purpura
Autoimmune disorders
Arteriovenous malformation
Foreign body intussusception
Antibiotics
Inflammatory bowel disease
Ischemic colitis
Polyps
Infection
Hemolytic uremic syndrome
Duplication cyst
Trauma

Rectal Bleeding in the Neonate

The most common cause for rectal bleeding in the neonate may also be swallowed maternal blood. Necrotizing enterocolitis in the preterm or the stressed term infant and enterocolitis secondary to Hirschsprung disease may frequently cause occult to moderate bleeding per rectum.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is the most common serious gastrointestinal disorder encountered in neonatal intensive care units. NEC is a major cause of morbidity and mortality in the newborn, particularly the preterm infant. The incidence is inversely proportional to birth weight and degree of maturity.

NEC should be suspected in any infant, especially if premature and stressed, who develop abdominal distention, decreased gastric emptying, apnea or bradycardia, and heme-positive stools. There is also abdominal wall discoloration with visible bowel loops. NEC may result in moderate rectal bleeding that is maroon to bright red in color and tissue may be present. NEC varies widely in severity and rate of progression. Although NEC can be suspected on clinical grounds, confirmation usually requires the demonstration of characteristic and radiologic findings that include pneumatosis intestinalis (intramural air) in up to 90% of cases and portal air (*Fig. 199.3*). Perforation is the most common and urgent early complication. Late complications include

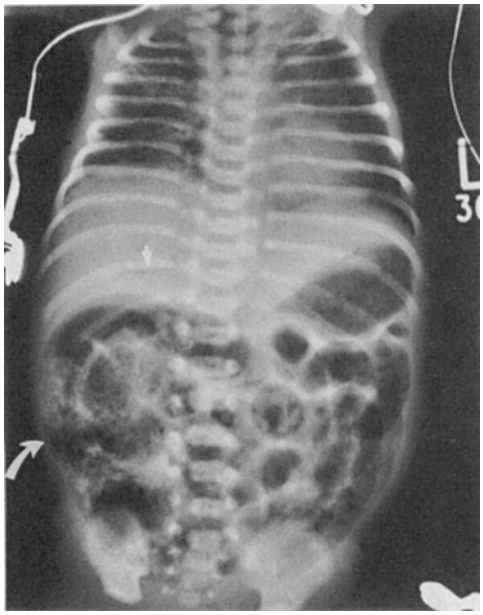

Figure 199.3
Necrotizing enterocolitis: abdominal radiograph of a preterm infant with abdominal distention showing dilated bowel loops with intramural gas; pneumatosis intestinalis (*curved arrow*) and portal vein gas (*straight arrow*)

intestinal stricture and short-bowel syndrome. Other radiologic findings include small bowel dilatation, ileus, and ascites. Diagnosis is also confirmed at surgery and histologic examination of the intestine if the radiologic features are not conclusive.

Treatment consists of nasogastric decompression, withholding enteral feeding, intravenous antibiotics, and close radiologic and clinical monitoring to diagnose perforation. Surgery is performed on those with perforation or in whom supportive therapy proves ineffective. Some complicated cases with gangrene warrant resection of good length of the bowel, resulting in short-bowel syndrome with its associated serious complications. For more information about NEC in the newborn, see section "Neonatology."

Anal Fissure

This is a relatively common neonatal condition associated with lower gastrointestinal bleeding. Most anal fissures occur in the sagittal plane secondary to constipation. Anal fissure may also be seen in late childhood associated with other disorders such as Crohn disease. Perianal fissures are the most common cause of mild bright red rectal bleeding in children. Blood tends to streak the stool and may be mixed with flecks or mucus. The fissures may be apparent by gently spreading the buttocks. Rectal fissures can be felt by digital palpation with a well-lubricated glove. Most anal fissures heal spontaneously. Healing may be facilitated by anal dilatation by the mother's own lubricated finger twice daily for 7–10 days. In the presence of constipation, a mild stool softener such as natured bran may be useful, If symptoms persist in spite of all conservative measures, surgical management such as stretching of the anus with excision of the fissure may be required.

Rectal prolapse is also a recognized cause of bleeding per rectum. This condition is usually associated with constipation. Other causes to be ruled out include cystic fibrosis and parasitic infestations.

Rectal Bleeding in the Elder Child

There is some overlap in the conditions associated with hematemesis and melena. It is quite possible for one condition to be presented as upper or lower gastrointestinal bleeding or both. Detailed history and thorough physical examination assist in making the likely diagnosis. Some of the relatively common causes of rectal bleeding beyond the neonatal age group include the following.

Meckel's Diverticulum

This diverticulum is a remnant of the omphalomesenteric duct, which connects the yolk sac to the intestine. It occurs in about 2% of the population. It is found on the antimesenteric border of the ileum, usually within a foot of the ileocecal valve. Meckel diverticulum is the most common cause of severe lower gastrointestinal bleeding at all age groups. The bleeding is usually painless and typically maroon colored alternating with bright red–colored bleeding per rectum. Other associated complications include inflammation, intussusception, ulceration, and obstruction. About 4% of patients with Meckel diverticulum will develop complications, most of them in the first 2 years of life.

The diagnosis is made on clinical grounds and supported by positive technetium-99m scan. A negative scan does not rule out the diagnosis. False-negative or false-positive results occur in about 15% of cases.

The sudden onset of melena with bilious vomiting in an apparently healthy child should suggest malrotation or midgut volvulus. Barium enema should be performed

immediately if such diagnoses are suspected to confirm the malrotation and to ensure emergency laparotomy if the diagnosis is confirmed.

Duplication

Duplication has been attributed to a failure of recanalization after the solid stage of intestinal development. Gastric duplication is usually cystic or tubular structure that usually occurs within the wall of the stomach. Intestinal duplications share a common wall and blood supply with native bowel. Diagnosis is confirmed by Tc-99M radionuclide scan. Approximately two thirds of all intestinal duplications are discovered within the first 2 years of life.

Duplications may be classified into three categories:

- Localized duplications, duplications associated with spinal cord defects, and vertebral malformation duplications of the colon.
- Communicating duplications may cause gastric ulceration and be associated with hematemesis or melena that may result in significant morbidity and mortality if left untreated. The most common clinical manifestations are associated with partial or complete gastric outlet obstruction. The treatment is surgical resection and management of associated defects.

Gastrointestinal Polyps

Single and multiple colonic polyps are recognized causes of rectal bleeding. Painless intermittent fresh rectal bleeding is likely to be due to polyps in the large bowel.

Although polyps may undergo autoamputation, profuse bleeding or malignancy remains a potential complication. Fiber-optic colonoscopy is the best way to diagnose polyps and permits immediate painless removal under mild sedation by snare polypectomy.

Colonic polyps also include those associated with familial syndromes such as in Peutz-Jeghers syndrome in which the polyps are hamartomas with rare incidence of malignant transformation.

Gastrointestinal polyps are divided into the following main types.

Juvenile Polyps

The juvenile polyps are benign lesions of the colon associated with few problems and tend to undergo autoamputation. They are the commonest form of intestinal polyposis in childhood (>90%). Juvenile polyps are most commonly seen in early childhood and are rarely encountered after the age of 16 years. Juvenile polyps are hamartomas, usually solitary and located in the rectum or sigmoid colon. They appear as smooth red or brown, round or ovoid, cyst-like projections into the intestinal lumen. Painless rectal bleeding is invariably the presenting symptom. Intussusception is not a common complication, but low-lying polyps tend to prolapse. Juvenile polyps can be easily visualized in most cases through the sigmoidoscope. A barium enema and air-contrast study may detect solitary polyps in the anorectal region (*Fig. 199.4a*) or higher up in the colon. Diagnosis is confirmed on histology.

Treatment is primarily conservative and supportive. If symptoms persist after I year, snare polypectomy is performed (*Fig. 199.4b*). Once removed, a simple juvenile polyp does not recur. Juvenile (retention) polyps are generally hamartomas with link malignant potential. Colorectal carcinoma is a rare complication with either single or multiple juvenile polyps. Patients with multiple juvenile polyps and a positive family history should undergo surveillance for colorectal carcinoma.

Juvenile Polyposis

This is a rare condition of familial polyposis predominantly in the colon. The polyps may be segmental or diffuse and extend through the colon with age. There is now little doubt that juvenile polyposis is a premalignant condition.

Generalized Juvenile Gastrointestinal Polyposis

This is a serious and fatal disease of infancy. The polyps extend from the stomach through the small intestine, colon, and rectum. Recognized clinical manifestations include rectal prolapse, gastrointestinal hemorrhage, and intussusception.

The diagnosis is suspected by a positive family history. Sigmoidoscopy shows numerous rectal and sigmoid polyps. Rectal polyps are removed to prevent prolapse. The treatment is basically conservative. The disease carries a high mortality rate.

Familial Polyposis Coli

This disease, inherited as an autosomal dominant trait, carries with it the formidable risk of carcinoma. Colectomy is the treatment of choice as soon as diagnosis is made. The polyps occur mostly in the sigmoid colon but

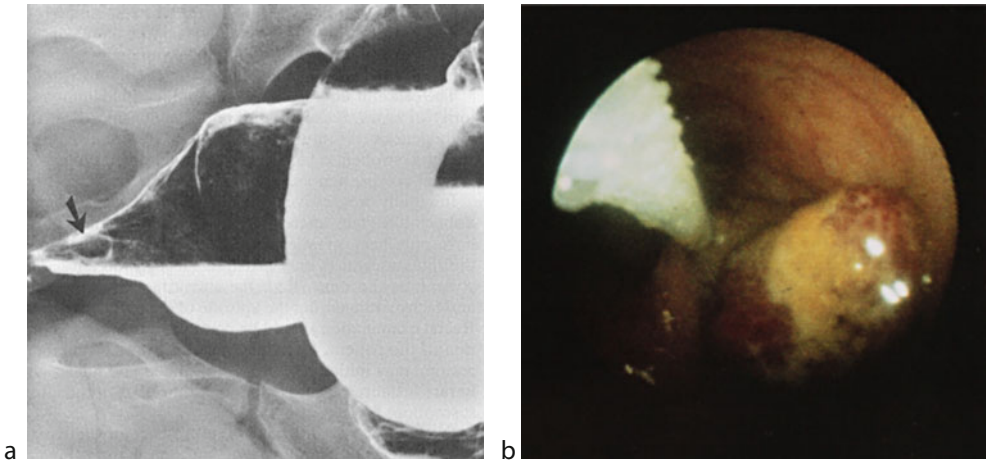

Figure 199.4
Juvenile rectal polyp. (a) Barium enema with air contrast (anteroposterior decubitus) showing solitary polyp in the anal canal of a 4-year-old girl with intermittent rectal bleeding. (b) Snare polypectomy of a solitary juvenile polyp

may extend through the entire colon and rectum. The number of the polyps is variable, from only a few to thousands. Although the disease is usually recognized in late childhood and adolescence, it has been reported in young infants. Clinical features include bloody diarrhea, abdominal pain, and weight loss.

Diagnosis is made through sigmoidoscopy, which reveals the numerous polyps in the rectum and sigmoid colon. Air-contrast enemas are particularly helpful in demonstrating multiple polyps. The accepted treatment for familial polyposis coli is proctocolectomy and ileostomy. All siblings of affected patients should be screened by sigmoidoscopy and radiology.

Gardner Syndrome

This is a familial disorder of diffuse adenomatous polyps as seen in familial polyposis coli together with soft tissue tumors and osteomas of the skull, mandible, and long bones.

Peutz-Jeghers Syndrome

This syndrome consists of multiple polyposis of the gastrointestinal tract associated with melanotic spots of the buccal mucosa, lips, and skin. Inheritance is through a dominant gene of high penetrance. The polyps, which are hamartomas, usually extend from the stomach to the rectum. The polyps are not present at birth but develop later with age. The polyps are subject to intussusception, torsion with infarction, and hemorrhage. Melena occurs in about one third of patients. Rectal prolapse is not unusual. The typical mucosal pigmentation is the prerequisite for the diagnosis. Asymptomatic polyps need not be treated. Surgical resection is required in case of intussusception or obstruction.

Intussusception

Intussusception is defined as the invagination of a segment of the intestine within the lumen or the adjoining segment. Intussusceptions are most often ileocolic and ileoileocolic. Other areas of the gut including the appendix may also be involved. Intussusception is a well-recognized surgical emergency in infants and children. It is a common cause of both intestinal obstruction and strangulation as well as a cause of bleeding per rectum. Therefore, once intussusception is diagnosed, appropriate management should immediately follow. The incidence of intussusception ranges between 1 and 4 per 1,000 live births. Intussusception is more common in males than in females. The condition is seen mostly in young infants (6–10 months of age) who present with severe abdominal pain associated with flexion of knees and hips.

The child looks normal in between the episodes of pain. Abdominal examination may also be normal at this stage. A palpable "sausage-shaped" mass in the right upper and middle abdomen is recognized on clinical examination. The passage of "currant jelly" stools or its detection on rectal examination is not essential for the

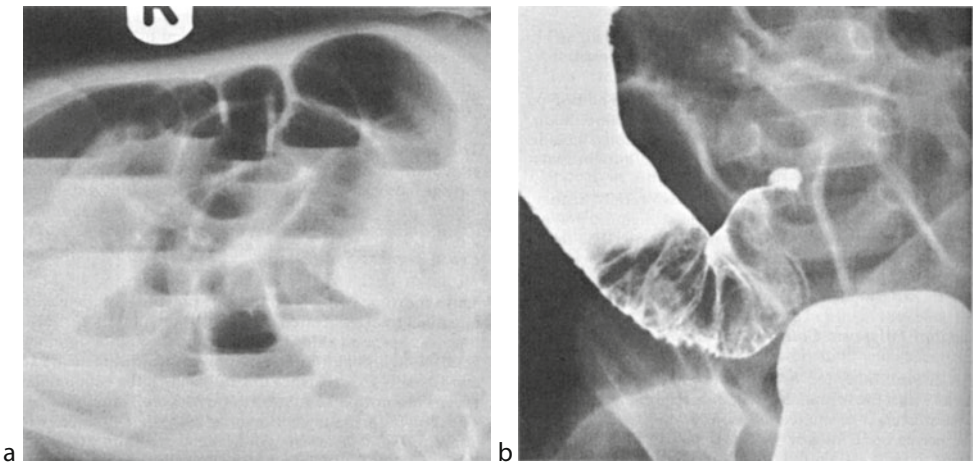

Figure 199.5
Ileo-colic intussusception in a 9-month-old female infant. (a) Abdominal radiograph (anteroposterior decubitus): features of intestinal obstruction with multiple fluid levels in the small bowel. (b) Barium enema: filling defect in cecum and ascending colon with "coil-spring" appearance

diagnosis when other clinical features and radiologic findings are very much supportive of the diagnosis.

However, intussusception is almost always accompanied by rectal bleeding, especially in young infants. The condition is uncommon in babies under 4 months of age.

The clinical picture is generally different among babies with intussusception aged less than 4 months than those aged 4 months or more. Affected babies with intussusception in the younger age group (<4 months) have less painful episodes, more vomiting, and rectal bleeding. Their response to hydrostatic reduction is also less than that of the elder age group. Vomiting, which is a common symptom of intussusception, may become bile-stained.

The cause of intussusception is not identified in the majority of cases. Some conditions to be considered in the pathogenesis of intussusception are Henoch–Schönlein purpura, swollen Peyer patches, Meckel diverticulum, intestinal polyps, tumors, and hemangioma.

In rapidly progressive cases, the infant may present with a shock-like state where the classic clinical features could have only been manifested at home. On rare occasions, the intussusception may prolapse through the anus. The patient may become pale at the initial stage, with sweating and tachycardia during the episode of the abdominal pain. Rectal examination should be performed at initial evaluation of the patient. Examination, which reveals an empty rectum, may initiate the passage of blood and mucus and in rare instances enable palpation of the apex of the intussusception.

Diagnosis is not difficult in the presence of the typical clinical presentation and radiologic confirmation (*Fig. 199.5*). A barium enema may show the "coiled-spring sign" at the site of the intussusception; however, ileoileal intussusception is not usually demonstrated by barium enema. The usual site of intussusception is in the region of ileocecal valves.

The application of air-contrast enema has contributed favorably to the diagnosis and management of intussusception. Ultrasound examination is resorted to more often nowadays early following admission of a child with suspected intussusceptions, and in positive findings, it could well save affected child the needs for subsequent radiation. The well-recognized ultrasound findings in intussuception may be so typical and supportive to the diagnosis to warrant considering the child for surgery with no further delay.

Once the diagnosis of intussusception is made, there is hardly any time for observation. Reduction may first be attempted by hydrostatic or pneumatic pressure under fluoroscopy, provided the surgeon and the operating theater staff were already informed of the plan and the possibility of surgery should the nonsurgical reduction fail. The prognosis in intussusception is very much related to the time interval between clinical manifestations and successful reduction, whether through hydrostatic pressure or surgical measures.

200 Gastrointestinal Tumors

Issam M. Halabi

Gastrointestinal tumors are less common in children compared to adults. Furthermore, the presentation can mimic common gastrointestinal disorders. Therefore, a high index of suspicion is needed to detect these tumors in children.

Luminal Gastrointestinal Tumors

These tumors constitute about 5% of all childhood tumors. Presentation is variable and relatively nonspecific. The symptoms and signs include abdominal pain, abdominal distension, vomiting, palpable mass, anemia, GI bleeding, or weight loss. They can also be found in the course of surgery for intussusceptions, bowel obstruction, or perforation as well as the incidental finding during a surgical or radiological procedure for other reasons. Definitive diagnosis usually requires a biopsy for histopathological examination and possibly immunotyping and cytogenetics, depending on the tumor.

Luminal tumors are divided according to their cells of origin: lymphoid, epithelial, or mesenchymal. Lymphoid tumors are the most common. Any of these types can be benign or malignant. In the following sections, the types, diagnosis, treatment, and prognosis of the more common tumors will be discussed.

Lymphoid Tumors

The gastrointestinal tract is rich in lymphoid tissue, particularly the ileum. This represents an adaptation for response to antigens.

Lymphonodular Hyperplasia

Lymphonodular hyperplasia (LNH) is a benign condition that is common in early childhood and adolescence parallel to the lymphoid tissue growth. It is more common in males. It can present with diarrhea, rectal bleeding, abdominal pain, or intussusceptions. Endoscopically nodular and frequently umbilicated mucosal lesions are seen in small and large intestines. Reactive hyperplasia and prominent germinal cells are seen on histology. No specific therapy is required and prognosis is excellent.

Lymphoma

The gastrointestinal tract is second to nodal tissue for the incidence of lymphomas. It represents 15% of all small bowel malignancies. The vast majority are non-Hodgkin. The most common site (40–50%) is terminal ileum, cecum, and appendix. This is contrary to adult data showing stomach as the most common site. Lymphomas secondary to celiac disease are exception to this rule with the jujenum being the most common location.

Lymphomas present most commonly with abdominal mass or intussusceptions. Diagnosis usually requires surgical resection. Endoscopic biopsy is inadequate since lesions may involve deeper layers than mucosa or submucosa. If suspected, tumor distribution should be determined using abdominal CT, bone scan, lumbar puncture, and bone marrow aspirate. Certainly, consultation with an oncologist is needed.

The histological appearance is characterized by "starry-sky" appearance. This image is created by sheets of mitotically active cells with scanty cytoplasm and round to oval nuclei with small nucleoli.

Treatment is mainly chemotherapy with radiotherapy as an augmentation. Surgical resection is only helpful in focal disease. Prognosis depends on several factors, with staging being the most important. Resectability also is a favorable factor.

Epithelial Neoplasm

Tumors of epithelial origin are either carcinoma or carcinoid with the latter being uncommon in childhood.

Carcinoma of the Colon

Despite infrequency of colorectal cancer in children compared to adults, it remains the most common primary

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_200,

solid malignancy of the GI tract in this age group. It is reported in less than 0.1 cases per million children less than 20 years of age.

Colorectal cancer can be sporadic or familial with 70–80% of cases belonging to the former. It is widely believed that that environmental factor play significant role in the etiology. This belief is based on the higher incidence seen in the Western world with high-fat/low-fiber diet as a variable.

Besides the sporadic type, a familial type with autosomal dominant pattern was also described in the absence of polyposis or ulcerative colitis. There are two patterns recognized. Lynch 1 syndrome with no associated extracolonic carcinoma while in Lynch syndrome 2 such an association with carcinoma of genital tract, breast, and pancreas is seen.

The clinical presentation is vague abdominal pain in 95% of cases, altered bowel habits in 17–32%, and rectal bleeding in 14–23%. Abdominal mass is appreciated in 59%, abdominal distension in 48%, and anemia in 25%. Diagnosis needs high index of suspicion. Any suspected mass on CT or MRI should be followed by lapratomy and surgical resection. Pathology is needed for diagnosis. Surgical resection is the mainstay of treatment. Staging is necessary by bone scan and chest CT.

The genetic basis for colorectal carcinoma is the mutational inactivation of the APC gene in the colonic epithelial cells.

Carcinoids

These tumors originate from differentiated endocrine cells; therefore, they may secrete GI peptides and hormones including serotonin, 5-hydroxytryptophan, histamine, prostaglandins, catecholeamines, and bradykinins. Metastasis to the liver can happen. Most common site is the appendix. Although most of these tumors are asymptomatic in adults, children can present with appendicitis.

Symptoms related to secreted substances include diarrhea, bronchoconstriction, edema, and flushing. Diagnosis can be established on surgical resection. Some patients have high urine level of 5-HIAA a serotonin metabolite. Histological appearance is remarkable for islands of tumor cells with granular cytoplasm and round nuclei with chromatin seen within.

Treatment is by resection. However, if metastasis has taken place, symptomatic relief should be sought by somatostatin analogues. Chemotherapy is needed sometimes. Prognosis depends on the presence of metastasis. In this regard, appendiceal tumors have much lower chance of metastasis (4%) compared to intestinal (55–70%).

Neoplasm of the Liver

Represent 1–4% of pediatric solid tumors. Metastatic tumors are more common. The vast majority 80% of primary tumors are seen in children before the second birthday with hepatoblastoma and infantile hemangioendothelioma the two most common.

Hepatoblastoma

Hepatoblastoma (HB) is the most common pediatric liver malignancy. It represents 43% of all pediatric primary hepatic tumors. Male to female ratio is 2:1. It occurs in association with a number of familial cancer syndromes. Beckwith–Wiedemann syndrome and familial adenomatous polyposis are clear examples. Non-tender abdominal mass is the most common presentation. Anorexia, weight loss, nausea, vomiting, and abdominal pain are less common.

Diagnosis is established by histology. Because these tumors originate from undifferentiated cells pathologically, they are characterized by fetal and embryonal hepatocytes. However, alpha fetoprotein (AFP) is elevated in 90% of patients. It has diagnostic, prognostic, and monitoring indication. It correlates with the size of the tumor and metastasis. It drops with treatment and resurges with recurrence. Hypercalcemia and hyperlipidemia are also seen. Imaging is helpful in suggesting the diagnosis. Ultrasound is a good initial test but inadequate particularly for the extent of the tumor and the detection of small-size tumors. CT or MRI with contrast can show right lobe mass with calcification found in 50%. Surgical resection is the treatment for early stage tumors. It should be preceded by chemotherapy for advanced stages.

Infantile Hemangioendothelioma

Hemangioendothelioma is a benign vascular tumor. It is most commonly seen in the first 6 months of life. One third of these cases are seen in the first month of life. A distinction should be made between these tumors and their counterparts in adults with malignant potential.

Anemia is the most common presentation (50%) and congestive heart failure can develop in 10–15% of cases. Abdominal distension is common. Less common signs include jaundice, thrombocytopenia, failure to thrive, fever, and intrahepatic hemorrhage.

Diagnosis is suspected with ultrasound. Ultrasound shows lesions of different echogenecity depending on the

vascularity. CT and MRI are diagnostic in defining the extent of lesions. Histology is not necessary for diagnosis. It shows ecstatic vascular spaces lined by endothelial cells and contains erythrocytes.

Treatment strategies are directed toward tumor regression. Resection is indicated if heart failure is associated. Embolization can also be considered. Diuretics, alpha interferon, and steroids have been used in hemodynamically stable patients. Prognosis is excellent.

Hamartomas

Hamartomas are rare benign fluid-filled tumors as visualized on US, CT, and MRI. They are seen usually in the first 2 years of life. Resection is the treatment of choice.

201 Capsule Endoscopy in Childhood

Issam M. Halabi

Introduction

Video capsule endoscopy (VCE) helps close the gap in the evaluation of the small bowel, which has been regarded as the "black box" of endoscopy. The invention of the PillCam SB capsule endoscope, a small, ingestible camera, established a minimally invasive method for imaging the gastrointestinal (GI) tract in its natural physiological state. A second version, the PillCam ESO capsule endoscope, was subsequently developed for imaging of the esophagus.

The disposable PillCam capsule endoscope glides through the digestive system and takes high-quality color pictures of the inner GI tract. The pictures are immediately transmitted by radio via antennas attached to the patient's abdomen to an external, belt-worn data recorder. The data recorder picks up the images, allows for immediate real-time viewing of the captured images, and stores them for later review.

The pictures may be viewed in a real-time by connecting the data to RAPID Access, a special system for display of real-time pictures captured by the PillCam capsule (*Fig. 201.1*). Otherwise, the patient is free to move around, wearing the data recorder.

When the test is done, the antennas and data recorder are removed from the patient and the pictures are downloaded from the data recorder to a computer workstation featuring the RAPID application. This process automatically prepares a RAPID video movie from the captured pictures for diagnostic review and evaluation. The capsule continues to pass through the digestive system until it is excreted naturally.

Once the RAPID video is ready in the RAPID Workstation, it can be viewed either on the RAPID Workstation or transferred to and viewed on any computer installed with the RAPID Reader application, which is a read-only application for RAPID videos.

The main components of the given diagnostic system are:

1. PillCam capsule endoscope
2. Data Recorder
3. RAPID Workstation with RAPID Application
4. RAPID Reader Application

Capsule endoscopy does not need any sedation to perform. There is no loss of work since the patient can conduct usual daily activities during the recording process. There is no insufflation or forcing instruments through the GI tract that diminishes the likelihood of perforation. The capsule passes through by virtue of peristaltic propulsion.

PillCam incorporates a small video camera complete with light emitting diode (LED)-based illumination, optics, wireless radio transmitter, all encapsulated in a biocompatible and inert plastic casing (*Fig. 201.2*). The capsule is 26 mm long and 11 mm in diameter. Pictures are taken and transmitted at a rate of two per second. This means that an 8-h recording by which time the capsule reaches the cecum, a total of 56,700 images are produced. It is activated when taken out of its holder. The holder keeps the capsule from activation by a magnet incorporated.

Procedure

The capsule endoscopy procedure involves ingesting the capsule endoscope, collecting the captured pictures in belt-worn Data Recorder, returning the Data Recorder to the physician, and downloading the accumulated data to the RAPID Workstation and viewing the RAPID Video. The patients are asked to fast for eight hours prior to the ingestion. Ordering GI prep is controversial among gastroenterologists.

Indications

According to 2005 ICCE Consensus, the indications for this study include:

1. Obscure GI bleeding
2. Crohn's disease
3. Polyposis syndrome
4. Small intestinal tumor

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_201,

Figure 201.1
Illustration of the relative size of ingested capsule

Obscure GI Bleeding

Defined as GI bleeding with negative EGD and Colonoscopy. The source is most likely small intestines. It can present with iron deficiency anemia, melena, or guaiac positive stools. In published meta-analysis, VCE has been shown to have superior diagnostic yield compared with small bowel follow through (SBFT) and push enteroscopy.

Crohn's Disease

VCE is superior to SB barium evaluations and colonoscopy with ileoscopy in the diagnosis of Crohn's disease. This is particularly obvious when upper studies show "indeterminate colitis." Detection of small bowel (SB) lesions settles the diagnosis. In addition VCE helps in determining the extent of the disease in those patients with established diagnosis.

Polyposis Syndrome

VCE can detect SB involvement in familial adenomatous polyposis (FAP) and Peutz–Jeghers syndrome. It is superior to more conventional methods including SBFT.

Small Intestinal Tumors

VCE is considered first-tier imaging modality for the small intestine based upon the literature and data presented to the US Food and Drug Administration. Earlier detection of such lesions improves the outcome and enables earlier intervention.

Complications

To date a total 750,000 procedures have been performed. Capsule retention in the SB is the most common serious complication. It happens in about 1% of ingestions. It is more likely to happen in patients with Crohn's disease. Retention of the capsule would warrant surgical extraction. However this does not have to be done urgently since the risk of perforation is minimal. Using an Agile patency capsule will minimize the potential of retention (see following section).

Other less likely complications include tracheal aspiration of the capsule.

Contraindication

Implanted cardiac devices (pacemakers and defibrillators) are absolute contraindications. Intestinal strictures are relative contraindications because of retention risk. VCE can still be performed provided that the stricture is not significant enough to prevent the passage of the capsule. To aid in that determination Agile patency capsule is performed prior to VCE (see following section). Another contraindication is swallowing disorders for aspiration risk. This can be overcome by introducing the capsule through EGD.

Patency Capsule

Capsule retention is the most common serious complication of VCE, as discussed previously. This usually occurs in the setting of undiagnosed SB stricture. Crohn's disease, abdominal radiation or surgery history, NSAID use, or obstructive symptoms may warrant confirmation of SB luminal patency prior to VCE. Barium studies of the SB are helpful for significant strictures, but are of limited utility in the detection of mild to moderate luminal narrowing, which may cause capsule retention.

The patency capsule consists of a radiofrequency tag within a lactose composition that dissolves after

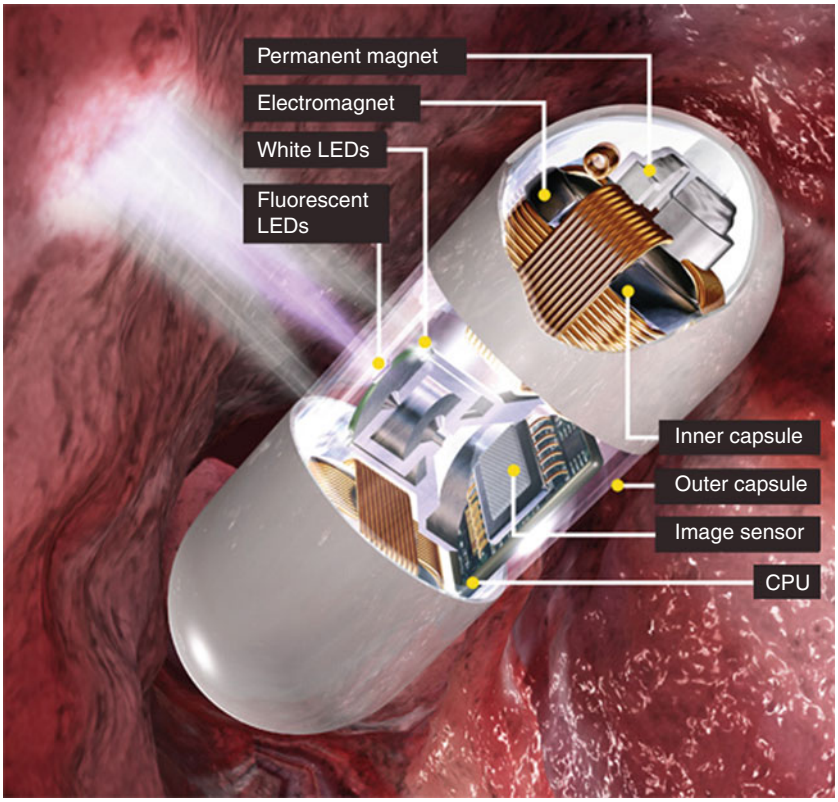

Figure 201.2
Longitudinal section of the capsule illustrating different components

approximately 30 h if retained in the luminal tract. The persistence of the patency capsule and tag is detected by a handheld scanner in the office or endoscopy setting. This capsule does not produce images. In contrast to VCE, the risk of acute intestinal obstruction with the patency capsule is finite.

Procedure Details

The exam begins between 7 and 8 a.m. with capsule ingestion, following 12 h of fasting. It ends the same day at 4 p.m. with the patient being disengaged from the data recorder. Initially, the 8-lead sensor array is fixed to the patient's abdomen. The capsule is activated by removal of the magnet, followed by confirmation of signal transmission to the data recorder. During the day-long procedure, patients may return, work, or engage in other activities. They may drink water 2 h after ingestion. They may then take their medications and eat a light lunch 4 h after ingestion. Patients should exercise care with the sensor array when changing clothes or in the bathroom. A study is considered complete when on VCE recording review the capsule reaches the cecum before the end of recording. In this case no radiologic confirmation of passage is needed. Otherwise a plain film should be checked in 2 weeks.

Bowel prep may improve the quality of visualization of the SB with VCE, but the recommendations are in evolution. Optimal prep type, dosage, and timing remain to be defined.

Conclusion

In summary, capsule endoscopy is a safe, well-tolerated exam, which provides for unique visualization of the small intestine. Small bowel indications are expanding beyond the current focus on OGIB and CD. The growing literature and extensive international experience underscore the diminishing numbers of contraindications, particularly in carefully selected patients. The development of the patency capsule significantly decreases the complications.

202 The Liver and Biliary System

Bernadette Vitola · Jorge A. Bezerra

Embryogenesis and Anatomy

The liver is a cellular organ that executes vital cellular functions and communicates with the remainder of the digestive system by a series of ductular and vascular structures essential for normal metabolic and excretory pathways. Its developmental landmarks begin in early embryogenesis, when the liver begins as a thickening of endothelial cells that proliferate and invade the neighboring mesoderm of the septum transversum. This is followed by a series of steps involving cellular proliferation, migration, and differentiation to give rise to the hepatic parenchyma and additional morphogenic changes to form the bile ducts. These processes occur in an orderly fashion during embryogenesis and establish structural and functional features that are well recognized in the mature liver (*Table 202.1*).

The Liver

The first identifiable structure indicating the developing liver appears in the ventral part of the foregut at about 4 weeks of gestation, just cranial to its opening into the yolk sac. At this stage, the cellular plate projects ventrally and lies closely to the endothelial lining of the heart in the transverse septum. Soon thereafter, this plate forms the hepatic diverticulum, and subsequently a (cystic) diverticulum develops caudally (*Fig. 202.1a*). The cells from the hepatic diverticulum advance into the splanchnic mesoderm of the transverse septum, between the heart and the midgut, and form cellular masses that intermingle with the epithelium-lined spaces, which arise from closed vesicles (vitelline veins). These invading cells, also known as hepatoblasts, unite and form hepatic cords, anastomosing around these vesicles to form the configuration of parenchyma and sinusoids. This "*primordial parenchyma*" is at first three to five cells thick, but later is reduced to a single-cell layer due to growth of the blood vessels. The proximity of two or more adjacent hepatocytes forms *biliary canaliculi*, which lose continuity with the perisinusoidal space (of Disse) by the formation of junctional complexes. Lastly, these canaliculi are connected with the developing interlobular bile ducts in the portal areas by short intercalated ductules (or *canals of Hering*). Together, the proliferation of endoderm-derived epithelial cells and the expansion of hematopoietic mesenchymal cells establish a configuration of a solid organ that begins to bulge out of the transverse septum, and later becomes an intra-abdominal organ lying within the mesentery.

The Biliary System

The biliary ductular system develops from the hepatic and cystic diverticula (*Fig. 202.1a*). The intrahepatic bile ducts derive from hepatoblasts, bipotential endodermal cells capable of differentiation into hepatocytes or bile duct cells. Hepatoblasts adjacent to mesenchyme around the largest hilar portal vein branches shift their phenotype toward bile duct-type cells. These cells form a layer that surrounds the portal vein branches and become the ductal plate. Soon, the ductal plate acquires a second cell layer and a progressive remodeling occurs, first with tubular dilatation of the slit-like lumen within the double-layered plate, and subsequently with disappearance of most of the nontubular portions of the ductal plate. The remaining structure is the *bile duct*, which is further separated from hepatoblasts by expansion of the mesenchyme and formation of the portal space. These morphogenic steps also occur toward the periphery, around smaller portal vein branches. Toward the hilum, the ducts enlarge by merging with neighboring ducts, finally uniting with extrahepatic ducts.

The extrahepatic ducts derive from the cystic diverticulum, which becomes solid due to the migration of endodermal cells into the original lumen. By the end of the first trimester, the lumen is reestablished and the bile duct is formed by recanalization of the stalk that connects the hepatic and cystic ducts to the duodenum. This establishes a continuous ductular unit that extends from the biliary canaliculi to the most terminal end of the extrahepatic bile duct as it enters the duodenum (*Fig. 202.1b*).

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_202,

Table 202.1
Developmental landmarks during embryogenesis of the human liver

Embryonic age	Developmental landmark
3–4 weeks	Formation of hepatic diverticulum
	Hepatic diverticulum projects as an epithelial plug into the septum transversum
5 weeks	Hepatic parenchyma can be seen
	Primordial hepatocytes are identified as large polygonal cells
6 weeks	Formation of bile duct-type cells (begins closer to hilum)
	Formation of ductal plate
	Primitive gallbladder and common bile ducts are solid cords of epithelial cells directly underneath the developing liver
	Bile canaliculus is present
7–9 weeks	Hepatocytes acquire apical-basal polarity
	Lumen in the common bile duct
	Lumen in the hepatic duct
	Lumen in the gallbladder and cystic duct
10 weeks	Hepatoblasts close to portal space (but not involved in ductal plate formation) lose cytokeratin 19 and retain 8 and 18
12 weeks	Glycogen granules are seen in hepatocytes
16 weeks	Bile secretion begins
20 weeks	Cytokeratin 7 appears in cells of developing ducts

Vascular Structures and Ligaments

The developing liver incorporates the omphalomesenteric and umbilical veins. The inferior segments of the omphalomesenteric (vitelline) veins feed the sinusoidal plexus and later become *the portal vein*, while the superior segments form the hepatic veins, which receive the sinusoidal blood and drain it into the sinus venosus (suprahepatic inferior vena cava). The placental blood flows through the umbilical veins, which send branches to the liver; part of the left umbilical vein becomes *the ductus venosum*, which shunts placenta-derived arterial blood from the umbilical vein to the inferior vena cava. After birth, the obliterated pre-hepatic segments of the umbilical veins atrophy become *the round ligament of the liver*, while the ductus venosus becomes the ligamentum venosum. The residual transverse septum forms *the falciform ligament*, hepatic capsule, and mesothelium. Later, the mesothelium becomes the visceral peritoneum, which will cover the entire liver, except for the bare area of the liver, where it maintains original contact with the transverse septum. Finally, by 6 weeks of human gestation, the liver appears bilobed and branches of the hepatic and portal veins are evident.

Cellular Composition

Microscopically, the developing liver is populated by endodermal cells (*hepatocytes and bile duct cells*) and mesenchymal cells (sinusoid endothelial, stellate and Kupffer cells, and lymphocytes). The existence of a pluripotent (stem) cell in the adult liver, which is able to give rise to hepatocytes or bile duct cells, has been suggested to reside in the periportal space, at the junction between hepatocytes and the small ductules of the biliary tree. Together, cords of hepatocytes maintain close proximity with neighboring sinusoidal endothelial, stellate, and Kupffer cells; they assume a typical architectural frame, which links the central vein to the portal space and form the liver acinus. Hepatocytes are grouped into concentric zones surrounding the terminal afferent vessels in the portal space: cells proximal to these vessels comprise *zone 1, followed by zone 2, and then zone 3*, which contains hepatocytes more proximal to the central vein. In this organization, *zone 1 cells* are exposed to high nutrient and oxygen content, whereas those of *zone 3* receive blood of considerably less oxygen content and are possibly more susceptible to vascular and toxic forms of liver injury. The directional blood flow from zones 1–3 is important for the development of functional differences among hepatocytes according to their placement along the liver acinus.

Anatomy and Geography

The liver is held in place below the diaphragm in the right upper quadrant of the abdomen by the falciform, coronary, triangular, and hepatoduodenal ligaments. The location of the *falciform ligament* divides the liver into the right and left lobes, with the right lobe typically being larger than the left lobe. The liver can be further divided into eight segments based on the distribution of blood vessels and bile ducts.

The biliary system drainage begins with canaliculi, formed by canalicular domains of adjacent hepatocytes, which evolve into intrahepatic bile ducts that drain bile by maintaining continuity with extrahepatic bile ducts.

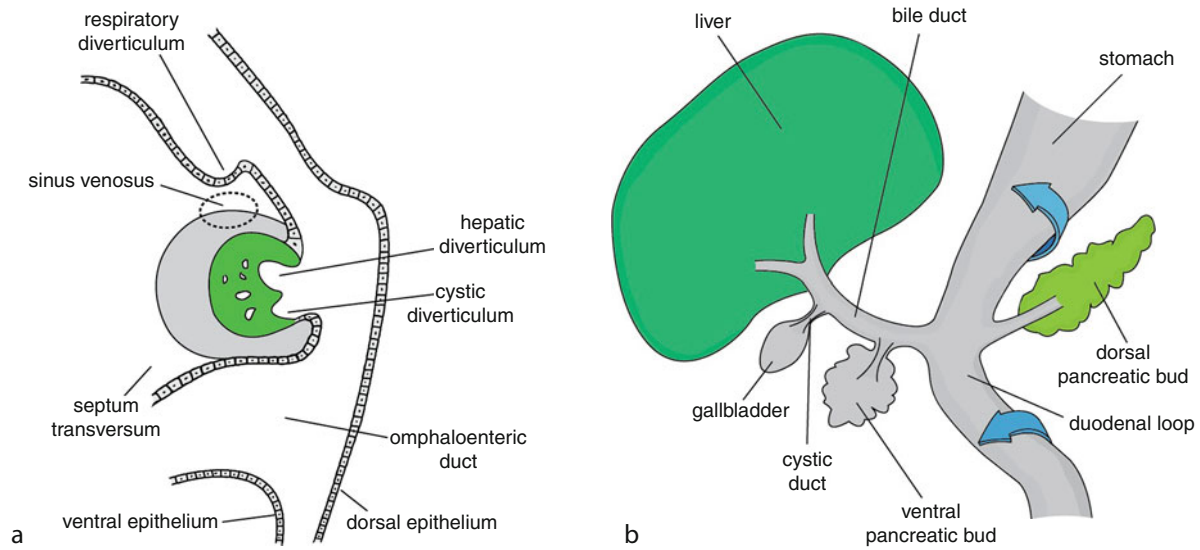

Figure 202.1

(a) Development of the liver and biliary system from the embryonic endoderm. The figure depicts a medium section of the developing embryo at 4.5 weeks of gestation, a time when the hepatic and dystic diverticula can be seen in relation to the respiratory diverticulum and septum transversum. (b) Development of the extrahepatic biliary system. At 6 weeks of gestation, the extrahepatic ductal system has continuity with intrahepatic ducts, the pancreatic exocrine ductal system, and with the developing duodenum

The gallbladder stores bile excreted from the liver until it is needed for a meal.

The primary blood supply to the liver is *the portal vein*, which is formed by the union of the splenic and mesenteric veins. *The common hepatic artery* also supplies blood to the liver, especially the bile ducts. Both the portal vein and hepatic artery divide into right and left branches to supply the lobes of the liver.

Functions

Metabolic Function

Carbohydrate Metabolism

One of the most important functions of the liver is to maintain appropriate serum glucose values, which it does by converting ingested fructose and galactose to fuel-ready glucose or trioses, storing glucose excess as glycogen, and by a combination of glycogenolysis (timely breakdown of glycogen) and gluconeogenesis (formation of glucose by amino acids and fatty acids). The formation of glycogen from glucose and the enzyme-dependent breakdown of glycogen to release glucose are regulated by enzymes that are functional prior to birth. This enables the fetal liver to efficiently store enough glycogen to prepare for the energy needs of birth. By the third postnatal week, glycogen stores reach sufficient levels in most full-term newborns. Therefore, neonates are dependent on external source of nutrients (via frequent feeding) to maintain adequate serum glucose after the initial glycogen stores are depleted immediately after birth.

Protein Metabolism

Amino acids are a major source of energy utilization in the fetus providing up to 40% of fetal energy needs. The liver uses deamination and transamination of amino acids to remove the nitrogen portion of the protein, with the remaining protein to be converted to lipid or carbohydrate for further metabolism. Excessive nitrogen is prevented by metabolism of ammonia to urea, which is the major source of clearance of urea. The liver is also able to synthesize nonessential amino acids from uptake of free amino acids.

Lipid Metabolism

The liver plays a central role in how the body handles lipids, including bile acid-driven digestion and absorption,

packaging into lipoproteins, esterification, and storage. When the supply of glucose is limited, the liver utilizes ketones produced from fatty acid oxidation to provide an energy source for gluconeogenesis. This represents a major source of calories in early infancy given the high-fat, low carbohydrate diet in this age group. The liver also esterifies glycerol to form triglyceride as a mechanism to store fat when glucose is in abundance.

Metabolic Defects and Clinical Syndromes

Defects in any of the enzymatic steps involved in carbohydrate, protein, and lipid metabolism can result in severe liver and/or extrahepatic disease. For carbohydrates, the excessive storage of normal substrates (example: glycogen) or the production of metabolic precursors that are toxic to hepatocytes (example: galactose-1-P) can manifest as hepatomegaly with hypoglycemia or liver failure (◉ *Table 202.2*), respectively. Liver failure in young infants can also result from the inability to complete final steps in the degradation of tyrosine in infants with *hereditary tyrosinemia*. In older infants, the disease may present with rickets and hepatocellular carcinoma as clinical manifestations of the underlying chronic exposure to abnormal metabolytes. Interestingly, liver function and anatomy are normal in children who are unable to metabolize ammonia due to main enzymatic defects in the urea cycle, but the abnormal accumulation of ammonia is toxic to the central nervous system with high mortality or devastating neurologic sequelae (◉ *Table 202.2*).

Disorders of fatty acid oxidation present with muscle weakness and lethargy, often precipitated by prolonged fasting or stress; cardiomyopathy and coma can be severe manifestations. Laboratory studies show hypoketotic hypoglycemia and variable degrees of liver dysfunction. Fatty acids, substantial sources of reserve energy, are utilized during periods of prolonged fasting since hepatic glycogen stores are depleted within a few hours of no caloric intake. Similar symptoms may also be present in children with mitochondrial dysfunction, which leads to primary energy failure (unavailability of ATP) and secondary disruption of fatty acid oxidation (◉ *Table 202.2*).

Table 202.2
Examples of liver-based metabolic defects that result in significant hepatic and/or extrahepatic clinical syndromes

Substrate or organelle	Disease	Key clinical features
Glucose	Glycogen storage disease	Hepatomegaly, hypoglycemia
Galactose	Galactosemia	Hypoglycemia, neonatal liver failure, sepsis
Fructose	Fructosemia	Vomiting, lethargy, hypoglycemia, liver failure
Tyrosine	Hereditary tyrosinemia	Acute form: Coagulopathy, liver failure
		Chronic form: Coagulopathy, liver tumor, rickets
Ammonia	Urea cycle disorders	Vomiting, seizures, coma
Fatty acid	Fatty acid oxidation defects	Lethargy, muscle weakness, cardiomyopathy, hepatomegaly, hypoketotic hypoglycemia
Carnitine	Carnitine deficiency	Lethargy, vomiting, cardiomyopathy, muscle weakness, hypoglycemia
Bile acids	Bile acid defects	Jaundice, malnutrition, coagulopathy, rickets
Mitochondria	Mitochondriopathies	Metabolic acidosis, nausea, vomiting, hypotonia, seizure, cardiomyopathy, liver failure

Synthetic Function

The liver is central to the synthesis of a wide range of soluble factors and hormones, besides the production of albumin, clotting factors, carrier proteins, complement, and lipoproteins. Albumin is commonly low when children have decreased liver synthetic function, but it is not a reliable marker of recent changes in synthetic function because it has a long serum half-life and its production is usually preserved until the liver injury is widespread and advanced. A more timely evaluation of hepatic function is best obtained by prothrombin time, whose assay takes into account the presence of clotting factors that are synthesized in the liver and have a short half-life. Thus, measuring the prothrombin time or the

levels of vitamin K-dependent factors II, V, VII, X, especially after the parenteral administration of vitamin K, gives a very reliable indication of the extent of liver cell loss and the potential for recovery.

Excretion

The liver excretes a variety of substances into bile, *including bilirubin, bile acids*, and xenobiotics. Bilirubin is a lipid-soluble byproduct of hemoglobin breakdown. It circulates in blood bound to albumin and is actively taken up by hepatocytes, where it is conjugated to glucuronic acid and transported to the canaliculi as conjugated bilirubin for final excretion into bile. A similar parallel process involves the *synthesis of bile acids from cholesterol*, followed by conjugation with glycine or taurine for excretion, transport by canalicular proteins, and final excretion as part of bile into the duodenum. The synthesis and delivery of bile acids into the gut are the most important means for the body to excrete cholesterol. Further, an adequate intraluminal concentration of bile acids is critical for the efficient absorption of fat and fat-soluble vitamins. Thus, impairment in formation and excretion of bile acids results in decreased cholesterol output and impaired absorption of lipids and lipid-soluble vitamins. Bilirubin, the colored pigment in bile, is responsible for the typical color of stools. When it is absent, stools become white, gray or pale yellow (acholic stools), which is often seen in young infants with impaired bile formation and/or secretion because of hepatocellular injury (e.g., viral hepatitis) or obstruction of extrahepatic bile ducts (e.g., biliary atresia).

Biochemical Evaluation of Liver Disease

Markers of Liver Injury or Impaired Bile Excretion

Acute hepatocellular injury typically results in elevation of the aminotransferases: aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Although these enzymes are also expressed in extrahepatic organs (e.g., erythrocytes and muscle), their primary source is the hepatocyte. Regardless of the type of liver injury, such as viral infection, metabolic defects, autoimmune disease, or drug toxicity, a rise of AST and ALT is a good marker of hepatocyte injury. Generally, ALT rises more or at the same level of AST; however, acute ischemia and alcohol toxicity are more associated with higher levels of AST. If the acute liver injury is widespread, serum AST and ALT may rise >100-fold above baseline; with persistent injury, a sudden drop in the level of the enzymes may indicate liver failure. In contrast, the degree of elevation of aminotransferases in chronic hepatocellular injury is more modest, often ranging from two- to tenfold above normal. This is typically seen in chronic viral hepatitis, syndromes of intrahepatic cholestasis, autoimmune hepatitis, biliary atresia, and some metabolic diseases.

A rise in bilirubin is a common hallmark of biliary injury or abnormal bilirubin transport at the level of hepatocyte canaliculi. Jaundice is the typical manifestation of hyperbilirubinemia; pruritus may also be present. Elevation of unconjugated bilirubin can be caused by hemolytic diseases or genetic abnormalities that decrease the function of UDP-glucuronosyltransferase, the enzyme that conjugates newly formed bilirubin before transport into bile. In both settings, there is no intrinsic hepatocellular injury. In contrast, a rise in conjugated bilirubin is a hallmark of liver disease. Although most liver diseases display variable elevations of conjugated bilirubin sometime during progression of the disease, a rise in conjugated bilirubin disproportionate to more modest elevations in AST and ALT point to cholestatic liver disease, such as biliary atresia, syndromes of intrahepatic cholestasis, and obstruction of extrahepatic bile ducts. Elevated bilirubin can also be detected in the urine, which sometimes is the first indication of liver disease when a urinalysis is obtained during a health screen or as part of an evaluation of an acute illness.

Two other enzymes may also increase in cholestasis: alkaline phosphatase and γ-glutamyl transpeptidase (GGT). High levels of serum alkaline phosphatase and GGT are seen with biliary obstruction (e.g., cholelithiasis and biliary atresia) or injury of biliary canaliculi and bile ducts (e.g., intrahepatic cholestatic syndromes and sclerosing cholangitis). Alkaline phosphatase is also found in a variety of tissues including bone, enterocytes, and kidney. Therefore, in growing children, alkaline phosphatase may be elevated from bone growth. Unlike alkaline phosphatase, GGT does not increase with bone growth and is somewhat more specific to biliary duct disease; however, it often increases transiently upon exposure to common drugs and toxins. In newborns, GGT is typically elevated with peak concentrations in the first 2 weeks of life. In patients with intrahepatic cholestasis, GGT concentrations may enable the differentiation between these specific syndromes. Among these syndromes, deficiency of the canalicular transporters familial intrahepatic cholestasis-1 (FIC1) or bile salt export pump (BSEP) have normal or low serum GGT despite high levels of conjugated bilirubin,

Table 202.3
Relationship between serum markers of cholestasis and clinical syndromes with functional or anatomical impairment of bile flow

	UB	CB	GGT	AP	Bile acids	Cholesterol
Physiologic jaundice	High	Normal	Normal	Normal	Normal	Normal
Breast milk jaundice	High	Normal	Normal	Normal	Normal	Normal
Biliary atresia	Variable	High	High	High	High	Normal
Alagille syndrome	Normal	High	High	Normal	High	High
PFIC types 1 or 2	Normal	High	Normal	Normal	High	Normal
PFIC type 3	Normal	High	High	Normal	High	Normal
Obstructive cholelithiasis	Normal	High	High	High	Variable	Normal
Choledocal cyst	Normal	High	High	High	High	Normal

UB unconjugated bilirubin, *CB* conjugated bilirubin, *GGT* γ-glutamyl transpeptidase, *AP* alkaline phosphatase, *PFIC* progressive familial intrahepatic cholestasis

whereas defects in MDR3, a phospholipid flippase, results in high levels of GGT (Table 202.3). Another marker of cholestasis is the increased concentration of serum bile acids. A rise in serum bile acids (before feeds in young infants or after an overnight fast in older children) indicates abnormal canalicular function or impaired excretion by bile ducts. Increases in serum bile acids and/or the presence of xanthomas may be the only clinical manifestation of cholestasis (Table 202.3), thus comprising the clinical signs of "anicteric cholestasis."

Laboratory evaluation of synthetic function includes prothrombin time (PT)/international normalized ratio (INR), albumin, and vitamin K-dependent factor levels (factors II, V, VII, X). Typically, impairment of liver synthetic function results in coagulopathy with an elevated PT and INR and variable decreases in albumin and factor levels. The clinical consequences of decreased synthetic function can be mild, as in easy bruising, epistaxis, and small hematomas, or more severe with gastrointestinal and intracranial bleeding.

Other Laboratory Tests

A variety of other laboratory tests are used to diagnose specific hepatic disorders. For example, in the evaluation of disorders of protein metabolism, serum and urine amino acid profiles are important diagnostic tools for urea cycle defects and amino acidopathies. Familial hyperlipidemias can be characterized by serum lipid profile, in which the determination of high, low, and very low-density lipoproteins, cholesterol and triglycerides enables subtyping and treatment with lipid-lowering agents. Finally, the evaluation of children with *syndromes of energy failure* involves a combination of routine and specialized metabolic tests. These syndromes usually present with altered mentation (changes in behavior, somnolence, coma), sepsis-like illnesses, seizures or sudden cardiac arrest during febrile illnesses or prolonged fasting. Very useful routine tests include serum bicarbonate, glucose, and ammonia, coupled with the concentration of lactate and pyruvate, plasma acyl-carnitine profile and urine organic acids. These tests are critical for the evaluation of infants and children suspected of having disorders of mitochondrial function, fatty acid oxidation, and carnitine metabolism.

The type and titer of circulating antibodies and the detection of viral DNA or RNA by reverse transcription-polymerase chain reaction can be used individually and in combination with other tests to diagnose viral hepatitides and other viral infections of the liver. The presence and high titers of autoantibodies (e.g., anti-nuclear, anti-smooth muscle, anti-liver/kidney/microsome), total immunoglobulin levels, and abnormal gamma-tracing in electrophoresis of serum proteins are helpful in establishing autoimmune liver disease. Lastly, a serum level of alpha-fetoprotein, a protein that is normally expressed during embryogenesis, is used to screen for liver cancer in patients with chronic liver disease.

Imaging Techniques to Evaluate the Liver

Ultrasound

Ultrasound can evaluate the texture and shape of the liver, the gallbladder, and extrahepatic bile ducts. It provides very useful information about intrahepatic, gallbladder or

ductal gallstones, the presence of choledochal cysts, and dilatation of bile ducts. The benign nature of sound waves enables the performance of the test during gestation, and can diagnose cystic malformations in the liver and porta hepatis. The use of ultrasound has become widespread in pediatric hepatology, and is often the first test to evaluate the anatomy of the liver and biliary system in children with abnormal liver function tests. Specific signals can point to the presence of fatty liver or hepatic inflammation.

The addition of doppler-based imaging provides insight into the arterial and venous blood flow to the liver, and reliably assesses the status of the portal blood flow, including patency and the existence of portal hypertension by the presence of excessive collateral vessels and/or abnormal direction of venous blood flow away from the liver. The detection of arterial flow in cystic lesions is indicative of vascular malformations. Ultrasound and doppler are routinely used in interventional radiology to direct biopsies to specific anatomic location (as in the evaluation of liver mass or cysts). Ultrasound is also useful in confirming the presence of ascites, detecting small amounts of ascitic fluid that moves freely in the abdominal cavity, or fluid that is loculated within a specific location as seen when the ascitic fluid is infected in children with recurrent bouts of spontaneous bacterial peritonitis in the setting of chronic liver disease.

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

CT and MRI provide more detailed evaluation of intrahepatic lesions when compared with ultrasound. Administration of intravenous contrast is particularly useful to define vascular patency and anatomy, as well as the relationship between blood supply and intrahepatic lesions. CT provides great anatomical detail of lesions within individual anatomical domains, which is very useful in assessing the feasibility of surgical approaches to remove masses or cystic lesions (*Fig. 202.2*). CT images can be obtained very quickly, thereby making this technique useful in infants and young children who require immobilization or sedation for more prolonged imaging that is required for MRI. The primary concern with CT is the patient's exposure to ionizing radiation. To minimize this exposure, ultrasound should be used preferentially as a follow-up study of lesions detected by CT scan.

MRI provides great anatomical details of the liver, biliary system, and blood vessels. One superior feature of MRI is the ability to change the contrast of the image,

Figure 202.2
Computerized tomography of a 7-year-old boy with hepatomegaly showing multiple cysts in the right liver lobe. Right hepatectomy was performed and the histopathology was consistent with hamartoma

which can generate very useful information regarding fat accumulation in the liver. An improvement in the technique offers a noninvasive alternative to diagnostic endoscopic retrograde cholangiopancreatography (ERCP) when evaluating diseases of the biliary tract, known as magnetic resonance cholangiopancreatography (MRCP). The technique is performed with the use of heavily T2-weighted sequences to visualize fluid-containing bile ducts as anatomically distinct high-signal-intensity structures. Despite the noninvasive advantages over endoscopic cholangiography, MRCP is limited in the evaluation of bile duct diseases in infants and young children, although advances in the field are likely to facilitate the performance and accuracy of this imaging technique in this patient population in the future.

Cholangiography

ERCP allows direct visualization of the biliary tract by the injection of contrast through the ampulla of Vater during endoscopy. Images obtained with ERCP provide very detailed information about the intra- and extrahepatic bile ducts. ERCP also permits intervention for stone removal, ductal strictures, or obstructions. When performed by experienced endocopists, ERCP is very useful in the evaluation of hepatobiliary diseases in all age groups. A technique that also requires sedation/anesthesia is percutaneous

transhepatic cholangiography (PTC); it is often under the domain of interventional radiologists. PTC is used when ERCP expertise is not readily available, and it is commonly used in the evaluation of biliary lesions following liver transplantation. When evaluating infants for extrahepatic biliary diseases, of which the most common is biliary atresia, *intraoperative cholangiogram* remains the most direct modality to evaluate patency and anatomy of bile ducts.

Hepatobiliary Scintigraphy

Scintigraphy uses technetium-labeled iminodiacetic acid to assess hepatocellular uptake (function) and patency of the biliary tract by documenting the production and flow of bile from the liver to the small intestine. Following administration of the labeled agent, sequential images of the liver, biliary tract, and intestine are obtained. Computer acquisition and analysis enable the visualization of uptake by the liver and whether bile ducts are patent, as demonstrated by enhancement of the small intestine. To improve uptake and excretion, children may be given doses of phenobarbital. While this technique has high sensitivity in detecting biliary atresia by demonstration of optimal liver uptake but no excretion, it may lead to false-positive results since poor excretion may also be seen in other liver disease. Further, the time required for preparation of the patient and the need for delayed images may limit the usefulness of hepatobiliary scintigraphy in the diagnosis of biliary atresia, in which the timely diagnosis and treatment with hepatoportoenterostomy are key to improve long-term outcome. Hepatobiliary scintigraphy is very useful in demonstrating biliary leaks, as in spontaneous perforation of the gallbladder in infants or in complications of biliary surgery.

Microscopic Evaluation of the Liver

There are two purposes for performing a *liver biopsy:* diagnosis of liver disease and monitoring of chronic liver disease. For diagnosis, obtaining liver tissue is useful for a number of reasons. The histologic appearance alone of certain diseases is highly suggestive of the diagnosis. For example, livers of infants with biliary atresia have expanded portal tracts, portal edema, bile duct proliferation, and bile plugs (*Fig. 202.3a*). In congenital hepatic fibrosis, the portal tract is expanded by dense collagen deposition and the bile ducts display features typical of ductal plate malformation, in which bile duct profiles surround the edges of portal tracts (as well as within the portal space). Examination of the lobular domains can show panlobular injury to hepatocytes, or the typical centrilobular injury induced by acetaminophen toxicity. Giant cell transformation of hepatocytes is a frequent feature of injury to the neonatal liver, especially in inborn errors of bile acid metabolism. An assessment of the presence, type, and location of inflammatory cells is very important in the evaluation of elevated liver enzymes secondary to viral infection or autoimmune liver disease (*Fig. 202.3c*).

Fragments of liver biopsies can be used for quantitative analysis of a variety of substances (iron, copper, glycogen, lipid) and for assays of specific enzyme activity, such as the activity of glucose-6-phosphatase to determine the type of glycogen storage disease. In patients with chronic liver disease, biopsy can provide information regarding the status of the liver, as demonstrated by excessive collagen deposition visualized by trichrome staining in liver biopsies of children with cirrhosis (*Fig. 202.3b*). Liver biopsies can also be very useful in assessing the efficacy of therapy, such as in children on corticosteroid

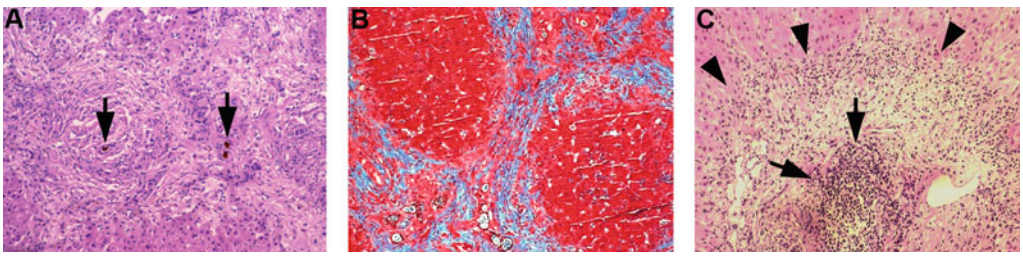

Figure 202.3

(a) shows hematoxylin/eosin staining of a liver section depicting an expanded portal tract with proliferation of bile ducts, some of which contain bile plugs (*arrows*). In (b), trichrome stain shows increased collagen deposition of expanded portal tracts, encasing hepatocytes and forming micronodules. (c) shows hematoxylin/eosin staining of a liver section from a child with autoimmune hepatitis, in which there is dense inflammation within the portal tract (*arrows*) and along the limiting plate (*arrow heads*).

treatment for autoimmune hepatitis or in older children and adolescents on iron-chelating agents for hemolytic disorders.

Percutaneous liver biopsy is usually a safe and relatively straightforward procedure when performed by a skilled hepatologist. In specific instances where the anatomy is modified, as in segmental liver transplantation, or when there are concerns for abnormal blood flow, liver biopsy is best performed under ultrasound guidance. The primary risk is bleeding since the liver is a highly vascular organ. Thus, it is important to assess the bleeding risk prior to performing a liver biopsy. Patients who are thrombocytopenic or coagulopathic need these issues to be addressed with the administration of blood products prior to and/or during the procedure; otherwise, percutaneous biopsies are contraindicated and a surgical approach must be considered.

Although most liver biopsies are obtained for evaluation by light microscopy, there are additional types of evaluation that can be invaluable. Immunostaining can be applied to detect abnormal accumulation of alpha-1-antitrypsin, to identify markers of neoplastic cells within the hepatic lobule, or to detect the abnormal expression or absence of specific molecules. When there is concern for a viral infection (e.g., cytomegalovirus and Epstein-Barr virus), in situ hybridization may be utilized to confirm the presence of viral particles. In situ hybridization utilizes a labeled DNA or RNA probe to bind to viral mRNA in the liver tissue.

Liver biopsies can also be used for electron microscopy to establish the diagnosis of diseases that involve malformation or injury of specific cellular organelles or the cytoplasmic accumulation of substrates. For example, livers of children with mitochondrial disorders may demonstrate large numbers of disorganized mitochondria with shortened, fragmented, or absent cristae. The cytoplasm may show accumulation of glycogen or other substrates in storage diseases, or may uncover virus particles. The ultrastructural visualization of the canalicular lumen may reveal the presence of granular bile, which is typical in children with an inherited syndrome of progressive familial intrahepatic cholestasis type 1 (*Table 202.3*).

Clinical Manifestation of Liver Disease

Jaundice

Jaundice is the physical manifestation of hyperbilirubinemia, either conjugated or unconjugated. Total serum bilirubin needs to be 2–3 mg/dL before jaundice can be noted on sclera or skin. Unconjugated bilirubin is common in healthy neonates owing to a developmental delay in conjugation of bilirubin with glucuronic acid within hepatocytes, and in breastfed infants. Unconjugated bilirubin also increases with hemolysis, genetic defects that impair hepatic conjugation (as in *Gilbert and Crigler-Najjar syndromes*), or increased enterohepatic circulation. Although jaundice is common in newborns, the presence of jaundice beyond the second week of life requires fractionation of serum bilirubin even if the infant is breastfed, so that further investigation can be pursued if there is a concomitant rise in conjugated bilirubin. Such an increase in conjugated bilirubin should immediately raise concerns for liver disease, especially if the conjugated fraction represents >20% of total bilirubin. Jaundice owing to conjugated hyperbilirubinemia can be caused by a specific defect in the transport of conjugated bilirubin into bile (e.g., *Dubin–Johnson syndrome*). More commonly, however, it can be a manifestation of a systemic disease that indirectly affects the hepatobiliary system, as is seen in septicemia, or represents the first sign of primary disease of the liver or the biliary tract, as in biliary atresia.

Hepatomegaly

Liver size can be assessed by palpation below the costal margin and by percussion of the liver span. For children with diffuse storage of substances (e.g., glycogen) in hepatocytes, hepatomegaly is easily detected by the palpation of the liver edge well below the right costal margin. An abnormally long end of the right lobe may be present in normal children *(Riedel's lobe)*, but the presence of a firm liver edge below the xyphoid process can be seen in children with advanced fibrosis and hypertrophy of the left lobe. Ultrasound is useful in assessing the size and consistency of the liver. Generally, hepatomegaly can result from storage of glycogen, lipid, mucopolysaccharides and other substances, from infiltration of inflammatory or neoplastic cells, or from venous obstruction.

Ascites

Ascites, an accumulation of fluid in the peritoneal cavity, is a common manifestation of advanced liver disease. Ascites results from portal hypertension accompanied by hypoalbuminemia (secondary to impaired liver synthetic function) and inappropriate sodium and water excretion (secondary to an imbalance of the rennin-angiotensin system). Accumulated fluid can become secondarily infected from translocation of gastrointestinal pathogens in a condition known as spontaneous bacterial peritonitis.

Ascites is usually managed by sodium restriction and diuretics, primarily spironolactone and furosemide. With progression of liver disease, ascites becomes difficult to manage with standard medical therapy; the child may develop hyponatremia and may not tolerate feedings or meals owing to compression of the gastrointestinal tract. It may become necessary to perform paracentesis to remove ascitic fluid if the child develops respiratory distress and has no response to diuretic therapy.

Portal Hypertension

The excessive deposition of collagen and other matrix fibers in the portal space and along the sinusoids impairs portal blood flow and raises intravascular portal pressure. As the pressure rises, collateral channels develop, the umbilical vein becomes recanalized, and portal venous flow may be reversed. Venous collaterals can form almost anywhere in the abdomen, but those in the esophagus and stomach have greater clinical significance because they form varices and can be the source of gastrointestinal bleeding. Within the abdominal wall, collaterals can be seen arising from the paraumbilical veins, which are referred to as *caput medusae* due to their tortuous appearance. In addition, increased portal pressure leads to splenomegaly and *hypersplenism* resulting in pancytopenias.

Bleeding/Bruising

Easy bruising and epistaxis can be presenting features of impaired protein synthesis, which decreases the levels of clotting factors. In children with advanced liver disease, the combination of coagulopathy and thrombocytopenia increases the risk of severe gastrointestinal bleeding. Any child with brisk variceal hemorrhage, hematemesis, or hematochezia should be promptly evaluated, receive blood products as needed, and admitted to a specialized service. If red blood cells are administered, they should correct hemoglobin levels to 8–9 g/dL to avoid over-filling of vascular beds, which may increase intravascular pressure and precipitate new episodes of variceal hemorrhage. Specific treatment of variceal hemorrhage may be performed with banding or sclerotherapy by an experienced endoscopist.

Encephalopathy

Hepatic encephalopathy is a manifestation of advanced liver disease.

It is divided into four stages based on clinical manifestations:

The first stage is associated with day–night sleep disturbance and impaired mentation. Without treatment, the child evolves into *the second stage* with lethargy, confusion, and asterixis, and *the third stage is* characterized by an arousable stupor; *the fourth stage* manifests as coma. It is not uncommon for a patient to move between stages rapidly.

The pathogenesis of hepatic encephalopathy is not clear. However, it is associated with impaired clearance of metabolic products, which may be toxic to the central nervous system. Serum ammonia is often used as a marker of encephalopathy, but the serum concentration does not correlate well with the stages of encephalopathy. Although protein intake is often restricted to reduce ammonia production, children still need to maintain adequate caloric intake to prevent further deterioration of malnutrition and decreased muscle mass. *Lactulose*, a non-digestible disaccharide, is frequently given to induce ammonia loss in the stools and decrease serum ammonia. Children with encephalopathy must be evaluated for liver transplantation.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome occurs in children with portal hypertension, most commonly associated with chronic liver disease. It is characterized by an intrapulmonic shunt and manifests as hypoxemia. Although the pathogenesis of hepatopulmonary syndrome is not well understood, it probably relates to the uncontrolled exposure to vasoactive substances that are not properly processed by the liver. Symptoms include exercise intolerance, digital clubbing, and dyspnea. Screening for hepatopulmonary syndrome can be performed by quantification of oxygen saturation by pulse oxymetry; arterial gasometry and bubble echocardiography demonstrate shunting more precisely. Hepatopulmonary syndrome can be reversed in children after transplantation.

Malnutrition

Malnutrition is highly prevalent in children with chronic liver disease and is a known risk factor for adverse outcomes after transplant. The factors leading to malnutrition include decreased intake, poor digestion, and impaired absorption. Fat malabsorption is present even in early phases of disease due to a decrease in the

intraluminal concentration of bile acids. Even when caloric intake is optimized, children with chronic liver disease exhibit resistance to growth hormone with low levels of insulin growth factor-1.

It is not unusual to supplement the child's diet with continuous enteral feedings, often as overnight infusions, in an attempt to meet a child's daily energy requirements for growth. The use of formulas that contain medium-chain triglycerides improves absorption as they do not require bile acids for digestion and absorption. Parenteral nutrition may be considered for those children who do not tolerate enteral feedings, but it brings new risks of infections related to the presence of indwelling catheters.

In addition to general nutrition support, children with chronic liver disease are at high risk of fat-soluble vitamin deficiency. Supplementation with vitamins A, D, E, and K is almost universally indicated given the high frequency of fat-soluble vitamin deficiency. Vitamin A, D, E, and K deficiency occurs in approximately 30%, 70%, 5%, and 70% of children with liver disease, respectively. It is important to follow the levels of these vitamins because fat-soluble vitamin deficiency is still common despite supplementation. If deficiency develops, children may present with coagulopathy (vitamin K deficiency), peripheral neuropathy and cerebellar ataxia (vitamin E deficiency), eye dryness, corneal damage and night blindness (vitamin A deficiency), and osteomalacia and rickets (vitamin D deficiency). Therefore, supplementation of all vitamins should be common practice to prevent morbidity associated with chronic liver disease in children.

203 Practical Approach to a Child with Hepatobiliary Disorder

H. Hesham A-Kader

The practical approach to a child suspected to have hepatobiliary disorder should entail detailed history, careful physical examination, and judicious selection of biochemical tests and imaging techniques.

When evaluating a patient with possible hepatobiliary disorder the goal is to determine whether or not the patient has hepatobiliary disorder and if he does how severe is it. The priority should be focused on the disorders for which an early recognition and intervention can prevent long term sequelae and prevent vertical and horizontal transmission. These goals should be achieved in the most cost-efficient and noninvasive manner without subjecting the child to unnecessary tests or invasive procedures unless indicated.

For example, during the neonatal period the initial evaluation of a newborn with cholestasis should initially focus on the exclusion of manageable metabolic diseases such as tyrosinemia and galactosemia, treatable infections such as *E. coli*, and surgically correctable disorders such as biliary atresia and choledochal cyst. The prompt diagnosis and immediate intervention for these disorders is of paramount importance to prevent damage to liver and other organs.

Therefore, the selective choice of currently available diagnostic tools commonly used in daily practice requires understanding of their justification, implications, as well as limitations.

History

Age is an important factor in reaching the diagnosis of a child suspected to have a hepatobiliary disorder. Inborn errors of metabolism and disorders of biliary tract development are commonly seen early in life. It is uncommon to diagnose Wilson's disease before the age of 4 years. Autoimmune hepatitis is more commonly seen in teenagers and Reye syndrome is usually diagnosed in the 4–8 year range. The sex of the patient should be recorded. Autoimmune hepatitis and cholecystitis are more commonly diagnosed in girls while Indian childhood cirrhosis is more often seen in boys.

Information regarding the ethnic background of the child should be obtained. Hepatitis B is common in people from Southeast Asia and Eastern Europe. Portal vein thrombosis is common among Egyptian children while veno-occlusive is common in Jamaica. Cystic fibrosis is the most common genetic disease in Caucasians affecting 1 of 2,000 individuals.

History of drug intake is also very important. Several drugs and excessive vitamin intake, such as vitamin A, can be hepatotoxic. (A detailed description of drugs and hepatotoxicity will be covered in the section on Drug Induced Liver Injury.) Similarly toxins exposure can result in hepatotoxicity. An example is aflatoxin from toxigenic strains of *Aspergillus flavus* which occurs commonly in parts of Asia and Africa. Aflatoxin may play a role in the pathogenesis of Reye syndrome. Similarly bush tea has been linked to the development of veno-occlusive disease.

Physical Examination

Careful physical examination is an integral part of the diagnostic process of hepatobiliary disorder in the pediatric age group. Physical examination is never complete without assessment of vital signs (temperature, pulse, blood pressure, and respiratory rate). Patients with liver cirrhosis may develop hyperdynamic circulation due to arteriovenous shunts manifesting with rapid high-volume pulse, increased pulse pressure, and ejection systolic murmur.

Weight, height, and head circumference need to be assessed at the time of presentation and during every visit and plotted on the growth charts. Patients with hepatobiliary disorder commonly present with failure to thrive. Growth retardation is more profound if the hepatic dysfunction results from an inborn error of metabolism. Intrauterine infection such as rubella, cytomegalovirus, and toxoplasmosis may be associated with microcephaly. On the other hand hydrocephalus may be a feature of syphilis or toxoplasmosis.

Examination of the abdomen begins with careful inspection. Abdominal distension may be seen in patients

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_203,

with hepatosplenomegaly and ascites. Patients with portal hypertension may have dilated veins in the epigastrium and flanks or caput medusae radiating from the umbilicus. Palpation of the abdomen requires patience and expertise as children usually cry during examination tensing their abdomen. Distracting the child by conversation or with a colorful stethoscope may facilitate the examination process. In some cases asking the mother to keep the patient on the mother's lap may comfort the child. The lower liver edge may be palpable in normal infants and children. The lower lobe may be felt up to 3.5 cm below the costal margin in the first 6 months of life, up to 3 cm in the first 4 years and 2 cm in children between 4 and 10 years old. Since lung inflation can push the liver down the liver span as measured between the upper border determined by percussion and the lower border detected by palpation provides a more accurate measure of the liver size. Lawson et al. measured the liver span in 350 infants and children by percussion of the upper and lower borders in the midclavicular line. Mean liver span ranged from 1.9 cm at 1 week of age to 7.7 cm in males and 6.3 cm in females at 20 years of age and was found to be related to age in a curvilinear manner.

Age and sex were found to be the main factors influencing liver size. Although height and weight correlated with liver span they did not add substantially to the correlation using age and sex.

Normal livers usually have a smooth round edge. Cirrhotic liver usually have a sharp irregular border. Patients with acute hepatitis may experience tenderness to palpation or percussion. Palpation of the abdomen may reveal anatomical abnormalities such as central liver in patients with polysplenia, laevo-position of the liver or a Reidel's lobe projecting inferiorly from the right hepatic lobe.

The spleen is usually felt on the left. However, palpation for the spleen should begin from the right iliac as very large spleens can cross the midline and felt on the right side. The spleen is usually not palpable unless it is at least three times the normal size. The spleen size should be recorded in centimeters measured in its long axis. If the spleen is not felt the Short's maneuver can be used. With patient being asked to lie on the right side, the examiner places the left hand on the lower left ribs in the midscapular line pushing the spleen forward while palpating for the spleen with the other hand.

Patients with suspected liver disease should be evaluated for the presence of ascites. Generally there are two methods to detect free fluid in the peritoneal cavity: A fluid wave may be elicited with the patient in the supine position and an observer placing his hand on the midline of the abdominal wall while the examiner is placing one palm on one side of the abdomen and tapping on the opposite flank with the fingers of the other hand. In the presence of free fluid a fluid wave can be felt. Another method is to ask the patient to lie in the supine position and the examiner's finger is placed on one flank parallel to the midline and percusses on a dull area. The patient is asked to lie on the opposite side while keeping the finger on the same place. After allowing the fluid to settle repercussion will give a tympanic note. Small amounts of fluid may be detected by placing the patient in knee-chest position while percussing the periumbilical area. This area should not be dull under normal circumstances.

Clinical Features

Unlike adults, symptoms of liver disease can be subtle in children and the majority of patients with infectious hepatitis are asymptomatic. Among the common signs and symptoms of hepatic dysfunction in children are:

Symptoms

Abdominal pain in the right upper quadrant	Fever
Malaise	Nausea
Vomiting	Pruritus
Bleeding	Irritability
Mental changes	

Signs

Jaundice	Dark urine
Pale stools	Anemia
Abdominal distension	Hepatomegaly
Splenomegaly	Ascites
Clubbing	Failure to thrive
Xanthomas	Ecchymosis
Palmer erythema	Edema
Altered skin pigmentations	

Biochemical Tests

Unfortunately the currently available liver function tests do not actually quantitate liver function but merely indicate the presence or absence of hepatic dysfunction.

In addition they do not assess severity, predict prognosis, or monitor disease activity as they often stay normal despite progression of the disease. The presence of one abnormal test should be considered in the context of the whole clinical presentation.

Transaminases

Aminotransferases (transaminases) are intracellular enzymes frequently measured as indicators of hepatocellular necrosis. Aspartate aminotransferase (AST, formerly serum glutamic oxaloacetic transaminase) and Aspartate aminotransferase (ALT, formerly serum glutamic pyruvic transaminase) catalyze the transfer of α-amino groups of aspartate and alanine, respectively, to the α–keto group of ketoglutaric acid.

ALT is primarily localized in the liver while AST is found in many tissues including liver, kidney, muscle, heart, and brain. Another difference between AST and ALT is the fact that ALT is a cytosolic enzyme while AST is present in the cytosol as well as the mitochondria.

Mild to moderate rise in transaminases is usually seen in patients with chronic viral hepatitis and cholestatic disease. On the other hand marked elevation is observed in acute viral hepatitis, following ischemia, and in patients with drug and toxin-induced hepatitis. The decline of the transaminases is seen with improvement but can be observed in patients with massive hepatic necrosis. Rise of serum bilirubin and worsening coagulopathy can help differentiating between the two conditions.

AST/ALT ratio can provide diagnostic information. Patients with alcoholic liver disease usually have a ratio of two or more because alcohol is a mitochondrial toxin. It should be noted that a decline of the ratio is seen with the development of cirrhosis. On the other hand ALT is usually higher than AST in patients with nonalcoholic fatty liver disease.

Serum transaminases levels should be cautiously interpreted in patients undergoing hemodialysis which can decrease the normal upper limits of these enzymes considerably.

Alkaline Phosphatase

Alkaline phosphatase (ALP) is a group of isoenzymes which catalyze the hydrolysis of phosphate esters at an alkaline pH. The enzymes are widely distributed in different tissues including liver, bone, kidney, intestine, and placenta. Therefore, elevation of ALP can be seen in multiple disorders in the absence of liver involvement. Mild elevation of ALP is seen in infiltrative hepatic diseases while marked elevation suggests the presence of extrahepatic biliary obstruction such as biliary atresia, choledochal cyst, and sclerosing cholangitis. Unfortunately the degree of elevation cannot differentiate between extra and intrahepatic obstruction. Actively growing children and adolescents may have increased serum level of ALP up to threefold and high ALP may be seen also as a familial trait.

Depressed serum ALP levels may be associated with congenital hypophosphatasia, hypothyroidism, pernicious anemia, and zinc deficiency. Patients with fulminant Wilson's disease complicated with hemolysis may have undetectable serum ALP levels possibly due to replacement of the cofactor zinc by copper leading to inactivation of ALP.

Gamma-Glutamyl Transpeptidase

Gamma-glutamyl transpeptidase (γ-GT) has been localized to the entire hepatobiliary tree with the greatest concentration in the epithelial cells lining the biliary ductules. Similar to ALP, γ-GT is widely distributed in different tissues including heart, kidney, brain, spleen, pancreas, and seminal vesicles. Elevated serum levels have been associated with an array of disorders such as pancreatitis, myocardial infarction, and renal failure. However, γ-GT is not found in bone and can help exclude bone disease as the source of elevated ALP.

Elevated γ-GT levels may be seen due to enzyme induction by alcohol and phenytoin. Normal levels can be seen in some forms of familial intrahepatic cholestasis. γ-GT normal levels are sex and age-related with levels higher in men. Neonates may have values five to eight times greater than adults with gradual decline during infancy.

5′-Nucleotidase

5′-Nucleotidase catalyzes the hydrolysis of nucleotides by releasing inorganic phosphate from the 5′-position of the pentose ring. 5′-Nucleotidase is present in the liver, intestine, brain, heart, and blood vessels. Despite the wide distribution of 5′-Nucleotidase elevated serum levels are usually from hepatic origin due to the unique detergent effect of bile salts on plasma membrane. Therefore measuring 5′-Nucleotidase can help distinguishing between hepatic and non-hepatic causes of raised serum ALP levels. Unfortunately measuring 5′-Nucleotidase is technically difficult.

Albumin

Albumin is made by the liver and is commonly used to measure hepatic synthetic function. Patients with liver disease may have low serum albumin levels due to decreased synthesis, increased degradation, or increased volume of distribution such as in the case of ascites. However, the long half-life of albumin (20 days) makes it an unreliable measure of recent hepatic function in patients with acute liver disease. Prealbumin may serve as a better index of recent hepatic protein synthesis due to its short half-life (1.9 days). Albumin is an acute phase reactant and serum levels may be also decreased in patients with non-hepatic disorders such as nephrotic syndrome, malnutrition, and protein-losing enteropathy. Hypergammaglobulinemia may lead to feedback inhibition of albumin synthesis by increasing the contribution of serum immunoglobulins to the plasma oncotic pressure.

Prothrombin Time and Coagulation Factors

The liver synthesizes all clotting factors with the exception of factor VIII which is made by the reticuloendothelial system. Prothrombin time evaluates the extrinsic coagulation pathway by measuring the rate of conversion of prothrombin to thrombin in the presence of thromboplastin and Ca^{2+} ions. Although the International Randomized ratio has been widely used it does not offer an advantage over prothrombin time in the evaluation of patients with liver disease.

With the deterioration of hepatic function the ability of the liver to synthesize the clotting factors declines and prolongation of prothrombin time is seen. Prolongation of 2 or more seconds poses risk for bleeding while prolongation of 3 or more seconds is a contraindication for invasive procedures such as liver biopsy.

Certain coagulation factors (II, VII, IX and X) are vitamin K-dependent. Vitamin K deficiency commonly seen in patients with cholestasis and steatorrhea can result in prolongation of prothrombin time. Parenteral injection of vitamin K usually results in at least 30% improvement in 24 h. Prolongation of prothrombin time can be also seen in association with congenital coagulation factors deficiency, consumptive coagulopathy, and the ingestion of drugs antagonizing the prothrombin complex such as bishydroxycoumarin derivatives.

Measuring clotting factors with short half-life can be used as a prognostic index in patients with acute liver failure. Although factor VII has the shortest half-life factor V is usually utilized since it is not vitamin K-dependent.

Des-γ-carboxy prothrombin is elevated in patients with cirrhosis due to defective γ-carboxylation of prothrombin which results in failure to bind calcium ions and functional impairment. Elevation of elevation of des-γ-carboxy prothrombin is also seen in patients with hepatocellular carcinoma and can be used as a complementary test to the measurement of alpha fetoprotein. Elevated serum level of Des-γ-carboxy prothrombin in liver donors has also been suggested as an indication for possible graft dysfunction in potential recipients.

Ammonia

Most centers no longer depend on ammonia level as an index for hepatic function for several reasons. Unless the sample is properly handled the ammonia level can be falsely raised. Samples should be run immediately or placed on ice. Following venipuncture ammonia levels can rise secondary to the action of the adenylic deaminase enzyme in the erythrocytes. Hemolysis can also increase ammonia levels since the majority of blood ammonia resides within the erythrocytes. The technique of obtaining blood samples in newborns by heel stick is commonly associated with hemolysis and falsely elevated ammonia, LDH, and AST.

On the other hand the elevation of ammonia levels do not correlate with the staging of portosystemic encephalopathy [PSE], normal levels do not rule out the diagnosis of PSE and raised values do not indicate the presence of PSE since it can be elevated in patients with urea cycle defects.

In most cases the diagnosis of PSE does not rely on determining ammonia level and is usually made clinically and measuring ammonia does not change management.

Imaging Studies

Plain Radiography and Barium Studies of the Upper Gastrointestinal System

Plain abdominal radiographs can provide helpful diagnostic information regarding the size of liver and spleen and the presence of ascites. More important, it can detect calcified lesions particularly gall stones, hepatic tumors, and granulomas.

Gas in the portal circulation can be seen in patients with itra-abdominal sepsis, ischemia, and perforated ulcers. Biliary gas may be seen following biliary surgery due to abnormal communication between the gut and biliary system.

Chest X-ray may show evidence of congenital heart disease or butterfly vertebrae commonly associated with Alagille syndrome. Wrist and knee X-rays may demonstrate the presence of osteopenia or rickets and can help determine bone age.

Although barium swallow may show large esophageal varices, it is much less sensitive than endoscopy.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

ERCP is a useful procedure with several diagnostic and therapeutic advantages. During the procedure the scope is introduced into the duodenum where the ampulla of Vater is identified and both biliary and pancreatic ducts can be cannulated and contrast material injected. The procedure has a definite value in the assessment of patients with extrahepatic biliary disease as well as patients with chronic and recurrent pancreatitis.

Although ERCP can help differentiate neonatal hepatitis from extrahepatic biliary atresia in patients with neonatal jaundice, the procedure is technically difficult in infancy and the development of smaller scopes is needed.

Therapeutic benefits of ERCP include placement of biliary stent, removal of biliary stones, and sphincterotomy. However these procedures are uncommonly needed in the pediatric age group.

Ultrasound

The development of Doppler Ultrasonography has been a major advance in the investigation of liver disease in children and adults. Ultrasonic examination can provide helpful information regarding the presence of gall stones and the size of spleen, pancreas, kidney, and gall bladder. However, it is imprecise in estimating the size of the liver. The detection of gall bladder makes the diagnosis of extrahepatic biliary atresia less likely. It can identify tumors, cysts, abscesses, and hemangiomas. It also helps in ultrasound-marked and guided liver biopsies especially when targeting a specific lesion. Extrahepatic bile ducts can be easily identified in most cases but intrahepatic ducts can rarely be seen except when dilated.

Portal hypertension is suggested by the presence of ascites, splenomegaly, gastric, and splenic varices. In patients with cirrhosis reversal of flow in the portal vein, increased pulsatility in the hepatic artery and, in advanced cases, reversal of flow during diastole may be seen.

Color-flow Doppler is extremely valuable pre- and post liver transplant for the evaluation of the patency of portal vein, hepatic veins and artery, and splenic vessels.

Computed Tomography (CT)

CT can help identify and perform biopsy on hepatic tumor and other space-occupying lesions. The use of oral contrast defines the bowel lumen while intravascular contrast enhances blood vessels and tissues. The introduction of spiral CT has been a major advancement allowing a faster collection of CT data than conventional scanners and permitting the scan of the entire liver at the peak enhancement of the contrast. CT of the brain can help detect cerebral edema in patients with acute liver failure as well as cerebral atrophy in children with metabolic disorders. CT angiography can provide noninvasive evaluation of the vascular structures.

CT has several advantages over ultrasonography. It is not operator-dependent, not affected by gas or obesity, and provides more global examination of the abdomen and pelvis. However, it is more expensive, requires general anesthesia in infants and small children, and involves radiation exposure.

Magnetic Resonance Imaging (MRI)

Magnetic resonance imaging (MRI) is done by placing the patient in a uniform magnetic field and the images are obtained by applying and sampling of repetitive radiofrequency waves.

The technique of MRI has greatly improved recently and has replaced angiography in the diagnosis and staging of hepatic tumors. With the development of new software, three-dimensional images of the biliary system can be obtained (magnetic resonance cholangiography (MRC)) without the need to inject contrast material.

Currently with faster scans and new software noninvasive angiography (MRA) can provide very helpful information regarding portal venous hemodynamics such as direction and flow speed, anatomy, and patency.

MRI can also provide important information regarding consistency and storage of heavy metals in the liver and brain such as iron in patients with hemochromatosis and copper in patients in Wilson's disease.

The biliary and pancreatic ducts can be visualized in a noninvasive manner using MRCP which is an imaging technique that uses magnetic resonance imaging. MRCP is a much less invasive investigation when compared to

endoscopic retrograde cholangiopancreatography (ERCP) in the diagnosis of biliary and pancreatic pathologies. Therefore MRCP is currently used with increasing rate as an alternative to ERCP. In addition to imaging the biliary system in detail, MRCP has the advantage of imaging the surrounding tissues. In a recent study the diagnostic accuracy of MRCP with a heavily T2-weighted TSE MR sequence compared favorably with ERCP in various hepatobiliary disorders (Hekimoglu et al.).

Quantitative Liver Function Tests

Since most available liver function tests do not quantitate hepatic function and usually fail to provide prognostic information in patients with acute and chronic liver disease there is a pressing need for newly developed liver function tests especially in the era of liver transplantation.

Several quantitative liver function tests have been developed based on the ability of the liver to clear a substance from the blood.

Indocyanine green (ICG) is removed by the hepatocytes following intravenous injection. The administration of low doses can be used to measure hepatic blood flow. On the other hand, administration of higher doses can lead to uptake saturation and therefore can be used to measure hepatic function.

Aminopyrine breath test has been used to provide prognostic information in patients with chronic liver disease. However the test requires the administration of a radioisotope which limits its usefulness in children.

Serial measurement of galactose elimination capacity (GEC) by the 14C-galactose breath test can provide prognostic information regarding mortality in patients with chronic liver disease. However, similar to aminopyrine test, it requires radioisotope administration, and the ability of some tumors to metabolize galactose has limited its usefulness to measure hepatic residual function prior to tumor resection.

Caffeine breath test has been also investigated as a simple noninvasive way to measure hepatic function which does not require the administration of radioisotopes. Hoverer, the test fails to provide useful information in patients with mild liver disease. The common exposure to caffeine and the long half-life have limited the application of this test.

Lidocaine is metabolized by cytochrome p450 into monoethylglycinexylidide (MEGX). The measurement of MEGX is a simple, fast, and safe way to measure hepatic function. Measuring MEGX does not need sophisticated equipment and results can be rapidly obtained within minutes. MEGX levels have been shown to correlate with lack of serious complications in patients with liver cirrhosis. MEGX has also been shown to provide prognostic information regarding primary malfunction in liver transplant.

Liver Biopsy

Liver biopsy is a very valuable tool in the assessment of children with hepatic dysfunction. The morphological features seen in liver biopsy combined with the clinical manifestations can help to establish the diagnosis, assess severity, monitor response to treatment and follow progress of the disease. In addition liver biopsy can provide tissue for enzyme analysis in patients suspected to have inborn errors and to assess stored materials such as iron and copper. Although percutaneous liver biopsy is the most commonly used technique for collecting a liver sample other techniques include transvenous, laparoscopic, and open surgical biopsy.

Percutaneous liver biopsy may be performed via an anterior abdominal, right lateral abdominal, or right lateral intercostal (usually the tenth intercostal space) approach. The site for the procedure is usually chosen by physical examination or with an ultrasound. A percutaneous image-guided liver biopsy is similar to the one described above except that the needle is guided by CT scan or ultrasound images. In young infants (below the age of 6 months) percutaneous liver biopsy can be performed with a local anesthetic (lidocaine 1%); however, in older infant and young children a brief general anesthesia is preferred in order to guarantee compliance.

Following the procedure the patient is usually asked to lie on the right side for 4 h during which the vital signs are frequently monitored. Arguments against liver biopsy include cost, sampling error, variability of pathological interpretation, the lack of effective therapy for many disorders, morbidity, and mortality. The procedure is usually safe in expert hands. Complications of percutaneous liver biopsy include local pain, pleura pain, infection pneumothorax, peritonitis, hemorrhage, hematoma, hemobilia, arteriovenous fistula, and death.

Contraindications include coagulopathy, thrombocytopenia, suspicion of cystic, vascular or infectious lesions in the path of the needle, and extensive ascites. If fresh frozen plasma and platelet transfusion fail to correct the coagulopathy and thrombocytopenia, the most reasonable approach is to do a laparoscopic liver biopsy which is usually done in order to obtain a tissue sample from

a specific area(s) of the liver or when the risk of spreading cancer or infection exists.

Another option is performing transjugular liver biopsy which is done by a catheter passed through the internal jugular vein into the right hepatic lobe and then cannulating the hepatic vein. In addition to obtaining liver tissue this technique can measure intracardiac and hepatic vein pressure.

Open surgery liver biopsies are rarely performed nowadays unless they are part of another surgical procedure. During open surgery the liver tissue sample may be obtained by surgical excision or by using a biopsy needle.

204 Disorders of the Gallbladder and the Biliary System

Mortada El-Shabrawi · Fetouh Hassanin

Introduction

Although gallbladder and biliary tract diseases are relatively uncommon in infants and children, pediatric patients comprise a relatively big number of cholecystectomies, with a rising rate in recent years. Pediatric gallbladder stones (cholelithiasis) and bile duct stones (choledocolithiasis) are most commonly associated with hemolytic diseases or hemoglobinopathies; however, other risk factors are recognized. Extended administration of total parenteral nutrition (TPN) support and prolonged survival after extensive bowel resection increase the risk of gallbladder disease, a cause that will likely continue to increase as survival rates improve in extremely low birth weight infants. In addition, as childhood obesity reaches near-epidemic proportions in many Western countries, gallbladder disease related to dietary factors is increasing.

Gallbladder and biliary tract diseases should be in the differential diagnosis of any pediatric patient who presents with right upper quadrant pain, jaundice, or unremitting dyspepsia with normal endoscopic gastric findings. Asymptomatic gallstones and symptomatic pigment gallstones in children are common indications for surgery. Noncalcified gallstones due to long-term cholestasis or TPN may respond to medical therapy with choleretics such as ursodeoxycholic acid (UDCA). Aside from gallstones, the pediatric population can experience anatomical abnormalities including hydrops of the gallbladder, extrahepatic biliary atresia (EHBA), and choledochal cysts discussed below. Other anomalies as intrahepatic biliary hypoplasia, Caroli disease, perforations, and biliary dyskinesia are beyond the scope of this chapter.

Hypdrops of the Gallbladder

Hydrops, or mucocele, describe an overdistended gallbladder filled with mucoid or clear, watery content. It is rarely seen in childhood and characterized by massive acalculous distention of the gallbladder.

Causes

Hydrops can result from various causes including complicated gallstone disease. Gallbladder dilatation is largely due to atony or failure of muscular contractions. Children with acute hydrops may have salmonellosis or *Enterococcus* sepsis. Other conditions associated with hydrops are mesenteric adenitis, staphylococcal infection, Henoch–Schönlein purpura, sepsis, prolonged fasting, sickle cell crises, thalassemia, ascariasis, Kawasaki disease, viral hepatitis, threadworm infestation, necrotizing enterocolitis, and typhoid fever.

Diagnosis

The most consistent clinical features are fever, nausea, vomiting, and abdominal pain. Diagnosis is often easy by abdominal ultrasonography (US), as in *Fig. 204.1*.

Since the clinical picture may mimic common surgical conditions of childhood such as appendicitis, intussusception, or volvulus, early diagnosis is important.

Treatment

The treatment of hydrops of the gallbladder varies depending on the etiology and the clinical presentation. Most cases are self-limited, and the gallbladder may spontaneously decompress with the treatment of the underlying systemic disease within approximately 2 weeks. Associated cholelithiasis, complications as gallbladder perforation, and deterioration of abdominal signs are indications for surgical exploration.

Extrahepatic Biliary Atresia

EHBA is one of the most challenging conditions in pediatric hepatology practice. It is characterized by complete obliteration or partial discontinuity of the biliary system outside the liver, resulting in obstruction to the bile flow.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_204,

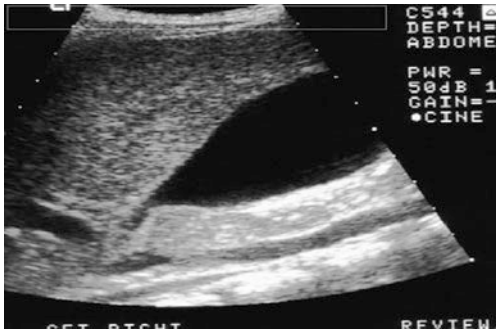

Figure 204.1
Ultra sonogram of the right upper quadrant shows hydrops of the gallbladder. Note the size of the gallbladder compared with that of the inferior vena cava (Courtesy of Dr. S. Methratta, UMDNJ-New Jersey Medical School)

Infants with EHBA can be subdivided into two distinct groups:

1. Patients with isolated biliary atresia (postnatal form), which accounts for 65–90% of cases
2. Patients with associated situs inversus or polysplenia/asplenia syndrome with or without other congenital anomalies (fetal/embryonic form), comprising 10–35% of cases

The pathology of the extrahepatic biliary system varies widely in these patients. Based on the predominant site of atresia, EHBA is classified into three classic types:

- Type I involves obliteration of the common bile duct; the proximal ducts are patent, therefore called *common bile duct type.*
- Type II is characterized by atresia of the hepatic duct, with cystic strictures found in the porta hepatis, called *common hepatic duct type.*
- Type III (>90% of patients) involves atresia of the right and left hepatic ducts to the level of the porta hepatis and called *porta hepatis type.*

These variants should not be confused with intrahepatic biliary hypoplasia, which comprises a group of distinct and surgically non-correctable disorders characterized by diminution in size and/or number (paucity) of the interlobular bile ducts.

Causes

EHBA is rarely seen in stillborn or in premature infants, which supports a rather late gestational insult. By contrast, infants with idiopathic neonatal giant cell hepatitis, which is the major differential diagnosis of EHBA, might be preterm, small for gestational age, or both.

- Infectious agents

  No single agent has been identified as causative for EHBA, although the role of infecting organisms has been the most extensively studied.

  Fischler et al. (1998) reported cytomegalovirus (CMV) infection in almost 25% of affected infants in one study based on immunoglobulin M (IgM) serology. Interestingly, an even higher frequency of CMV infection has been found by Chang et al. (1992), in patients with idiopathic neonatal giant cell hepatitis, lending support to the concept that both disorders might be the extreme ends of the same pathological spectrum, originally described by Landing (1974) as the infantile obstructive cholangiopathy.

  Investigations of reovirus type 3 have yielded conflicting results. Wilson et al. (1994), noted in one study that the virus damages the bile ducts and hepatocytes in weanling mice, whereas another study by Steele et al. (1995), failed to demonstrate evidence of infection in infants with cholestasis.
- Genetic factors

  The existence of the fetal/perinatal form of EHBA, frequently associated with other gastrointestinal and cardiac anomalies, suggests the possibility of a disorder in ontogenesis. Studies have identified specific genetic mutations in mice with visceral heterotaxy and cardiac anomalies, defects similar to those found in conjunction with the fetal/perinatal form of biliary atresia.

Diagnosis

Any cholestatic young infant with persistently acholic or clay-colored stools must raise the suspicion of EHBA which has to be diagnosed as soon as possible. Diagnosis largely depends on abdominal ultrsonographic findings after 2–4 h fast, percutaneous liver biopsy and laparoscopic or intraoperatve cholangiography. The role of technetium^{99m} labeled hepatic imino-diacetic acid (HIDA) radionuclide scans in diagnosis of EHBA and its differentiation from idiopathic neonatal giant cell hepatitis has decreased in the past few years due to the time consumed in preparations for HIDA scan and the technical limitations of the procedure.

Treatment

Apart from vitamin K_1 administration to prevent unexpected bleeding, no primary medical treatment is relevant in the management of EHBA. Surgical intervention is the only mechanism available for a definitive diagnosis by intraoperative cholangiography and therapy by Kasai porto-enterostomy.

- Practice guidelines for the evaluation of a patient for liver transplantation set by the American Association for the Study of Liver Diseases (AASLD) have defined factors that predict improved long-term outcome after Kasai porto-enterostomy including:
  - Young age less than 10 weeks (in other reports, 8 weeks only) at operation
  - Preoperative histology and ductal remnant size
  - Presence of bile in hepatic lobular zone 1
  - Absence of portal hypertension, cirrhosis, and associated anomalies
  - Experience of the surgical team
  - Postoperative clearing of jaundice

Choledocal Cysts

Choledochal cysts are congenital anomalies of the bile ducts consisting of cystic dilatations of the extrahepatic biliary tree, intrahepatic biliary radicles, or both. Alonso-Lej et al. provided the first systematic description of choledochal cysts, based on the clinical and anatomic findings. They classified choledochal cysts into three types and outlined therapeutic strategies for each. The classification system was further refined by Todani and colleagues, and currently includes five major types:

- Type I choledochal cysts – These are the most common, representing 80–90% of the lesions. Type I cysts are dilatations of the entire common hepatic and common bile ducts or of segments of each. They can be saccular or fusiform.
- Type II choledochal cysts – These are relatively isolated protrusions or diverticula that project from the common bile duct wall. They may be either sessile or connected to the common bile duct by a narrow stalk.
- Type III choledochal cysts – Also called choledochoceles, these are found in the intraduodenal portion of the common bile duct.
- Type IV cysts – These are further subclassified into:
  - Type IV-A cysts – These are characterized by multiple dilatations of the intrahepatic and extrahepatic biliary tree. Most frequently, a large, solitary cyst of the extrahepatic duct is accompanied by multiple cysts of the intrahepatic ducts.
  - Type IV-B choledochal cysts – These consist of multiple dilatations that involve only the extrahepatic bile duct.
- Type V choledochal cysts – These are defined by dilatation of the intrahepatic biliary radicles. Often, numerous cysts are present with interposed strictures that predispose the patient to intrahepatic stone formation, obstruction, and cholangitis. The cysts are typically found in both hepatic lobes. Occasionally, unilobar disease is found and most frequently involves the left lobe.

Diagnosis

The clinical history and presentation of a patient with a choledochal cyst varies with the patient's age. Overt, dramatic signs and symptoms are more common in infancy, whereas manifestations are more subtle and protean in adulthood. Infants frequently come to clinical attention with jaundice and the passage of acholic stools. If this presentation occurs in early infancy, EHBA must be excluded. Infants with choledochal cysts can have a palpable mass in the right upper abdominal quadrant; this may be accompanied by hepatomegaly. US is the best initial study. In neonates, it may be the only test needed. US can demonstrate changes in the bile ducts as well as in the liver. Endoscopic retrograde cholangiopancreatography (ERCP) was, until recently, the standard diagnostic study. In expert hands, ERCP can be performed with a high rate of success, even in small infants clearly showing the anatomy of the pancreatico-biliary junction. Magnetic resonance cholangiopancreatography (MRCP) has largely supplanted ERCP as the standard diagnostic test of choice for choledochal cysts because it offers high resolution and detailed images of relevant anatomy, is noninvasive, and does not result in complications such as post-procedure pancreatitis. MRCP detects most choledochal cysts with sensitivities from 90% to 100% and specificities from 73% to 100%, with the exception of small choledochoceles and minor ductal anomalies. MRCP has been shown to be effective not only in neonates and children, but even in fetuses.

Children in whom the condition is diagnosed after infancy present with a different constellation of symptoms and signs, including intermittent bouts of biliary obstructive symptoms or recurrent episodes of acute pancreatitis. Children in whom biliary obstruction is present have jaundice and may also have a palpable mass in the right upper quadrant. The correct diagnosis is occasionally more difficult in children with pancreatitis. Often, the only clinical symptoms are intermittent attacks of colicky abdominal pain. Eventually, an analysis of biochemical laboratory values reveals elevations in serum amylase and lipase levels. This leads to the proper diagnostic imaging workup.

Treatment

Total excision of the cyst in types I, II, and IV followed by reconstruction of the biliary tree with hepatico-jejunostomy in a Roux-en-Y fashion has been widely accepted as the procedure of choice in treating choledochal cysts, and has been found to be superior to hepatico-duodenostomy. This procedure involves excision of the distal common bile duct (CBD). Consequently, it blocks the reflux of pancreatic enzymes into the biliary tract decreasing the incidence of carcinoma of the bile duct. With type III choledochal cysts, the general approach is one of lateral duodenotomy with unroofing of the choledochocele to drain the bile duct and pancreatic duct directly into the duodenum. The two ductal openings should be carefully examined to determine whether ductoplasty is required.

Complications after surgery have been mainly observed with types I, IV, and V choledochal cysts. They are much less common in excisional procedures. The overall morbidity rate is less than 10%. Mortality and repeat surgery rates are low after excision, compared with those associated with internal drainage operations. The complications include cholangitis, biliary stone formation, anastomotic stricture, residual debris in the intrahepatic bile ducts, intrahepatic bile duct dilatation, and malignant transformation.

Cholelithiasis and Choledocolithiasis

Cholelithiasis is uncommon in otherwise healthy children and usually occurs in patients who have predisposing factors such as hemolytic disease, hepatobiliary disease, obesity, prolonged TPN, abdominal surgery, trauma, sepsis, impaired immune system, and spinal injury. Adolescents exposed to hepatitis C virus (HCV) infection and teen age pregnancy have an increased incidence of gallstones. Less-prominent risk factors identified to increase the incidence of gallstones include acute renal failure, prolonged fasting, low-calorie diets, and rapid weight loss. Biliary pseudolithiasis, or reversible cholelithiasis, has been identified with the use of certain medications, primarily ceftriaxone. Gallstones are a frequent complication in children with hemoglobinopathies because of the recurrent episodes of hemolysis leading to increased bilirubin excretion and pigment gallstones formation. The incidence of gallstones in children with sickle cell disease (SCD) has increased over the past few years due to both the regular use of the noninvasive detection technique (US versus cholecystography) and the longer survival of these patients. The frequency of cholelithiasis in children with SCD is almost double that of the general population. The development of pigment gallstones in patients with SCD is age dependent: 15% under 10 years of age, 22% between 10 and 14 years of age, and 36% between 15 and 18 years of age, with a reported prevalence of 50% by the age of 22.

Diagnosis

Gallstones in children with hemoglobinopathies are most commonly an incidental finding, but should be strongly suspected in the workup of nonspecific intermittent abdominal pain with risk factors. Murphy sign is the expiratory arrest with palpation in the right upper abdominal quadrant, and it is almost always pathognomonic. US is the study of choice in patients with uncomplicated cholelithiasis (*Fig. 204.2*). It can be used to identify the location of the stone, gallbladder wall thickening, the presence of gallbladder sludge, and peri-cholecystic fluid.

Gallstones are typically classified as cholesterol, black pigment, and brown pigment stones. Typically, only one type of stone forms at a given time. The distribution of gallstone types in children differs from the adult population with cholesterol stones being the most common type of stone in adults, and black pigment stones being the most common type in children. Cholesterol stones are formed from cholesterol supersaturation of bile and are composed of 70–100% cholesterol with an admixture of protein, bilirubin, and carbonate. These account for most gallstones in adults, but comprise only about 21% of stones in children. Black pigment stones comprise 48% of gallstones in children. They are formed when bile becomes supersaturated with the calcium salt of unconjugated bilirubin (calcium bilirubinate). Black

Figure 204.2
Choledocholithiasis: A Common bile duct stone. The sensitivity of transabdominal US for choledocholithiasis is approximately 75% in the presence of dilated ducts and 50% for nondilated ducts (Image courtesy of DT Schwartz)

pigment stones are commonly formed in hemolytic disorders, and can also develop with TPN. Brown pigment stones are rare, accounting for only 3% of gallstones in children, and form in the presence of biliary stasis and bacterial infection. They are composed of calcium bilirubinate and the calcium salts of fatty acids, and occur more often in the bile ducts than in the gallbladder. Calcium carbonate stones, which are rare in adults, are more common in children and account for 24% of stones in children. The remaining portion of gallstones in children is protein-dominant stones, which comprise about 5%. The incidence of gallstones among boys and girls is almost equal, with a slightly high incidence among boys.

Treatment

Treatment for simple cholelithiasis is symptomatic. Surgical removal of asymptomatic gallstones is currently not the standard practice. Expectant management with periodic clinical and US surveillance is appropriate for asymptomatic cholelithiasis. Elective cholecystectomy is the treatment of choice for symptomatic cholelithiasis. Twenty years after its first introduction, laparoscopic chloecystectomy has been confirmed to be a safe and efficacious treatment for pediatric cholelithiasis. In uncomplicated cholelithiasis with biliary colic, medical management may be a useful alternative to cholecystectomy in selected patients, particularly in patients with high surgical risk. Medical treatment, beyond pain control, however, is not initiated in the emergency department, and patients should be referred to their primary care provider for further medical management. Laparoscopic cholecystectomy has also been demonstrated to be both safe and effective in SCD patients. In addition, because gallbladder sludge is frequently documented in patients with SCD and most patients with SCD who have biliary sludge go on to develop gallstones, elective cholecystectomy has been recommended with evidence of biliary sludge, with or without stones. Surgical complications of laparoscopic cholecystectomy include CBD injury, bile leaks, as well as complications of hemolytic disease in those at risk.

Medical management of gallstones used alone or in combination includes the following: oral bile salt therapy (UDCA and chenodeoxycholic acid), contact dissolution, and extracorporeal shockwave lithotripsy. Medical management is more efficacious in patients with small stones (<1 cm), high cholesterol content, and good gallbladder function.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic disease of unknown etiology that is characterized by inflammation and fibrosis of the intra- and/or extrahepatic bile ducts. Despite its importance, there have been few advances in understanding the pathogenesis of PSC. Furthermore, there are uncertainties regarding optimal means of diagnosis, monitoring, and therapy. Greater use of ERCP led to the identification of many cases, suggesting a higher incidence of PSC in childhood than would appear from the pediatric literature.

Causes

The mechanism(s) responsible for the development of PSC are still largely unknown. Immunologically mediated damage to the biliary tree remains the most likely etiology. The relationship between PSC and inflammatory bowel disease (IBD) offers several clues. The biliary injury may be initiated by an immune-mediated destruction of the hepatobiliary tract that is perhaps caused by transient infection or the absorption of bacterial by-products in genetically predisposed individuals with colonic disease. In children, PSC is commonly associated with markers suggestive of an autoimmune process. Some patients have elevated levels of circulating immune complexes, immunoglobulins, and/or non-organ-specific autoantibodies. Clinical and histologic overlap with autoimmune hepatitis (i.e., overlap syndrome) may be observed. While often associated with non-organ-specific

autoantibodies and closely linked to IBD, PSC is not a typical autoimmune disease and responds poorly, if at all, to standard immune suppressive therapy.

Diagnosis

The clinical presentation in children with PSC varies widely, and frequently lacks the obvious features of cholestasis. Patients may be asymptomatic with hepatomegaly or elevated biochemical liver function test (LFT) results, prompting further workup for PSC. Patients may also present with fatigue, pruritus, fever of unknown origin, intermittent jaundice, or weight loss. Some patients present with manifestations of chronic liver disease and cirrhosis. The onset and progression tend to be insidious. The modes of presentation include the following:

- Asymptomatic patients present with incidental finding of hepatomegaly on examination or abnormal LFT results.
- Symptomatic patients may present with nonspecific complaints, including fatigue, pruritis, abdominal pain, fevers, weight loss, and intermittent jaundice.
- Complications of prolonged cholestasis including pruritis, cholangitis, and malabsorption of fat/fat-soluble vitamins.
- Patients with cirrhosis present with complications of portal hypertension including splenomegaly, ascites, and variceal bleeding.

The overall diagnostic accuracy of MRCP in patients with PSC is 90%, compared to 97% for ERCP or percutaneous transhepatic cholangiography (PTC). The advantages of MRCP include less risk for complications as compared with ERCP as well as visualizing bile ducts proximal to obstructed areas.

Treatment

PSC is a rare, but important, cause of chronic liver disease. The chronic inflammation and obliterative fibrosis of the biliary tree leads to bile stasis, hepatic fibrosis, and ultimately to cirrhosis, end-stage liver disease, and need for orthotopic liver transplantation (OLTx). PSC can lead to cholangiocarcinoma, a highly malignant tumor, in adulthood. Treatment of patients with PSC should be directed at managing each of the following:

- Chronic cholestasis with pruritis and fat malabsorption
- Cirrhosis and portal hypertension
- Ductular complications, such as dominant strictures, cholelithiasis, and ascending bacterial cholangitis
- Other associated diseases such as IBD or other autoimmune diseases

Recent meta-analysis of many studies found that UDCA can improve liver biochemistry, and there is a trend toward improvement in liver histology and cholangiography, but does not improve survival and was associated with higher rates of serious adverse events.

Dominant strictures of the extrahepatic biliary tree, most often at the bifurcation of the hepatic ducts, are major problems for patients with PSC. They can be treated by transhepatic or endoscopic balloon dilatation that has been shown to be useful in children. Short-term stenting of strictures has also demonstrated clinical improvement of symptomatic strictures. Surgical, endoscopic, and interventional radiologic procedures to relieve symptomatic dominant strictures have been demonstrated to prolong survival time of the native liver in patients with PSC. None of these interventions have altered the ultimate rate of progression of PSC to end-stage liver disease. Bacterial cholangitis, which can occur spontaneously, is more common after endoscopic or surgical manipulation of the biliary tree. Episodes of cholangitis require prompt antibiotic therapy.

OLTx has been proven successful in treating children with PSC. Data from numerous liver transplant centers demonstrate excellent long-term patient and graft survival in end-stage PSC with actuarial patient survival rates at 1 and 5 years after OLTx greater than and approximately equal to 90%, respectively.

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis (PFIC) is a genetically determined group of autosomal-recessive disorders. Consanguinity is a major risk factor. The condition is clinically characterized by hepatocellular cholestasis and normal or low serum levels of gamma glutamyl transpeptidase (GGT) activity. It was initially described in the ethnic Amish descendants of Jacob Byler, so the condition was originally named Byler disease. Subsequently, numerous phenotypically similar non-Amish patients were reported, and the term "Byler syndrome" was used to describe these patients' condition. These terms now have been superseded by the term "PFIC."

PFIC is considered as a chronic cholestasis syndrome that begins in infancy and usually progresses to cirrhosis

within the first decade of life. The average age at onset is 3 months, although some patients do not develop apparent cholestasis until later, even as late as adolescence. PFIC can progress rapidly and cause cirrhosis during infancy or may progress relatively slowly with minimal scarring well into adolescence. Few patients have survived into the third decade of life without treatment.

Causes

At present, specific gene defects have been identified for two subtypes of low-GGT types: PFIC-1 (the former Byler disease) and PFIC-2. Despite their genetic distinctiveness, PFIC-1 and PFIC-2 have few clinical differences, and both are caused by the absence of a gene product function for canalicular export and bile formation.

Patients with PFIC but with high serum GGT have a condition termed high-GGT PFIC. These patients manifest severe progressive intrahepatic cholestasis in the first year and progress toward hepatic failure in the first few years of life. Liver biopsy results reveal expanded portal areas with proliferation of interlobular bile ducts plugged with bile sludge. Several clinical differences have been reported between patients with PFIC-2 and patients with PFIC-1, although the distinction remains in question. Clinically, patients with PFIC-2 seem to lack the relapsing course seen in the early stages of PFIC-1 and, instead, have a more rapidly progressive course to fibrosis. Light microscopy and transmission electron microscopy demonstrate that liver tissue from patients with PFIC-1 has coarse granular bile and bland canalicular cholestasis, whereas patients with PFIC-2 have amorphous or finely filamentous bile and neonatal hepatitis.

Patients with PFIC-1 are more likely to have associated watery diarrhea, some of which are severe. This secretory diarrhea may persist or even increase after OLTx, and may reflect an important role for FIC-1 in the intestine, where it is expressed in quantity.

Diagnosis

The disease typically does not respond to any form of medical therapy. Some have reported success in treating patients having low-GGT PFIC with UDCA (20–30 mg/kg/day), which may be tried as an initial treatment. Surgical therapy that diverts bile salts from the enterohepatic recirculation arrests the progression of disease and relieves pruritus in most patients with low-GGT PFIC. The most common procedure, partial cutaneous biliary diversion, diverts gallbladder bile to a cutaneous stoma. Patients typically drain 30–120 mL of bile per day, which is discarded. A variation on this procedure is the limited ileal diversion, in which the distal 20–25% of the ileum is removed from the intestinal mainstream and made into a self-emptying blind loop.

UDCA therapy should be initiated in all patients to prevent liver damage. In some PFIC-1 or PFIC-2 patients, biliary diversion can also relieve pruritus and slow disease progression. However, most PFIC patients are ultimately candidates for OLTx. Monitoring for hepatocellular carcinoma, especially in PFIC-2 patients, should be offered from the first year of life. Hepatocyte transplantation, gene therapy, or specific targeted pharmacotherapy may represent alternative treatments in the future.

OLTx is indicated in patients with decompensated cirrhosis or with a failed diversion with debilitating pruritus. Survival rates after OLTx are excellent. OLTx is the only effective treatment of high-GGT PFIC.

205 Neonatal Cholestasis

Ronen Arnon · Fredrick J. Suchy

Cholestasis, associated clinically with conjugated hyperbilirubinemia, may be defined as a decrease in bile flow due to impaired secretion by hepatocytes or to obstruction of bile flow through the intra- or extrahepatic bile ducts. The consequences of chronic cholestasis are related to the retention of potentially noxious substances that are normally excreted into bile including bilirubin, bile acids, copper, and lipids and to a deficiency of micelle-forming bile acids within the intestinal lumen that are essential for dietary lipid and fat-soluble vitamin absorption. Damage to the liver may be progressive from the underlying disease and from secondary effects of cholestasis. Owing to an immaturity of hepatobiliary function, the number of distinct disorders presenting with cholestatic jaundice may be greater during the neonatal period than at any other time of life. The myriad conditions, manifesting as neonatal cholestasis, are shown in *Table 205.1*. These diseases reflect the unusual susceptibility of the neonatal liver and biliary tract to many bacterial and viral infections and the initial presentation of many inborn errors of metabolism and structural abnormalities.

The overall incidence of neonatal liver disease manifesting clinical or biochemical evidence of cholestasis is approximately 1 in 2,500 live births. Idiopathic neonatal hepatitis, an anachronistic term, has been reported to have an incidence of 1 in 4,800–9,000 live births. However, reliable figures do not exist regarding the current incidence because newer and more accurate diagnostic methods have decreased markedly the number of infants previously labeled as having idiopathic neonatal hepatitis. The incidence of biliary atresia ranges from 1 in 8,000 to 21,000 live births according to reports from several centers around the world.

Figure 205.1 shows an estimate of the relative frequency of the most important disorders producing cholestatic liver disease. Biliary atresia is the most common disease and consistently has accounted for one third of all cases in multiple reports over several decades. Various forms of inherited cholestasis may occur in 10–20% of cases. Approximately 10% are caused by alpha1-antitrypsin deficiency. Other inborn errors of metabolism comprise about 20% of all cases.

Congenital infections, including those caused by so-called TORCH agents, account for about 5% of cases. In contrast to reports as late as 10 years ago, in which idiopathic neonatal hepatitis accounted for almost one third of the cases, improved diagnostic methods has decreased this category to no more than 10–15% of cholestatic infants.

Cholestatic jaundice may present in the first weeks of life as part of a severe acute illness with impairment of other liver functions or as an isolated finding. The possibility of cholestatic liver disease should be considered in any infant who is jaundiced beyond 14 days of age. Acholic stools may also occur in severe liver dysfunction and with biliary obstruction, but stools may be only lightly pigmented or intermittently pigmented with partial or evolving obstruction. The urine is usually dark. Bleeding secondary to vitamin K deficiency may be a presenting feature of cholestasis.

In cholestatic infants, there are usually few clues regarding the etiology of the disorder. Maternal illness during pregnancy, low birth weight, or microcephaly may suggest hepatitis from a congenital infection. Metabolic disturbances, particularly hypoglycemia, may be a feature of liver failure or an endocrinopathy such as panhypopituitarism. Extrahepatic anomalies, including dysmorphic facies, should prompt evaluation of the biliary system.

Evaluation

Urgent evaluation of the cholestatic infant is critical to treatment of life-threatening metabolic or infective liver diseases and for the surgical management of biliary anomalies. The general features of the many cholestatic liver diseases of the neonate are similar, and it remains one of the most difficult pediatric problems to differentiate severe intrahepatic from extrahepatic cholestasis.

The approach to the evaluation of the infant with cholestatic liver disease is outlined in *Fig. 205.2*.

The most important initial test should be the measurement of a serum conjugated bilirubin level to establish that liver disease is present. The conjugated fraction of serum bilirubin should be no higher than 15% of the total serum

bilirubin concentration. Standard liver biochemical tests usually show variable elevations of aminotransferase levels, serum alkaline phosphatase, gamma-glutamyl transferase (GGT), and serum lipids. These tests along with others of

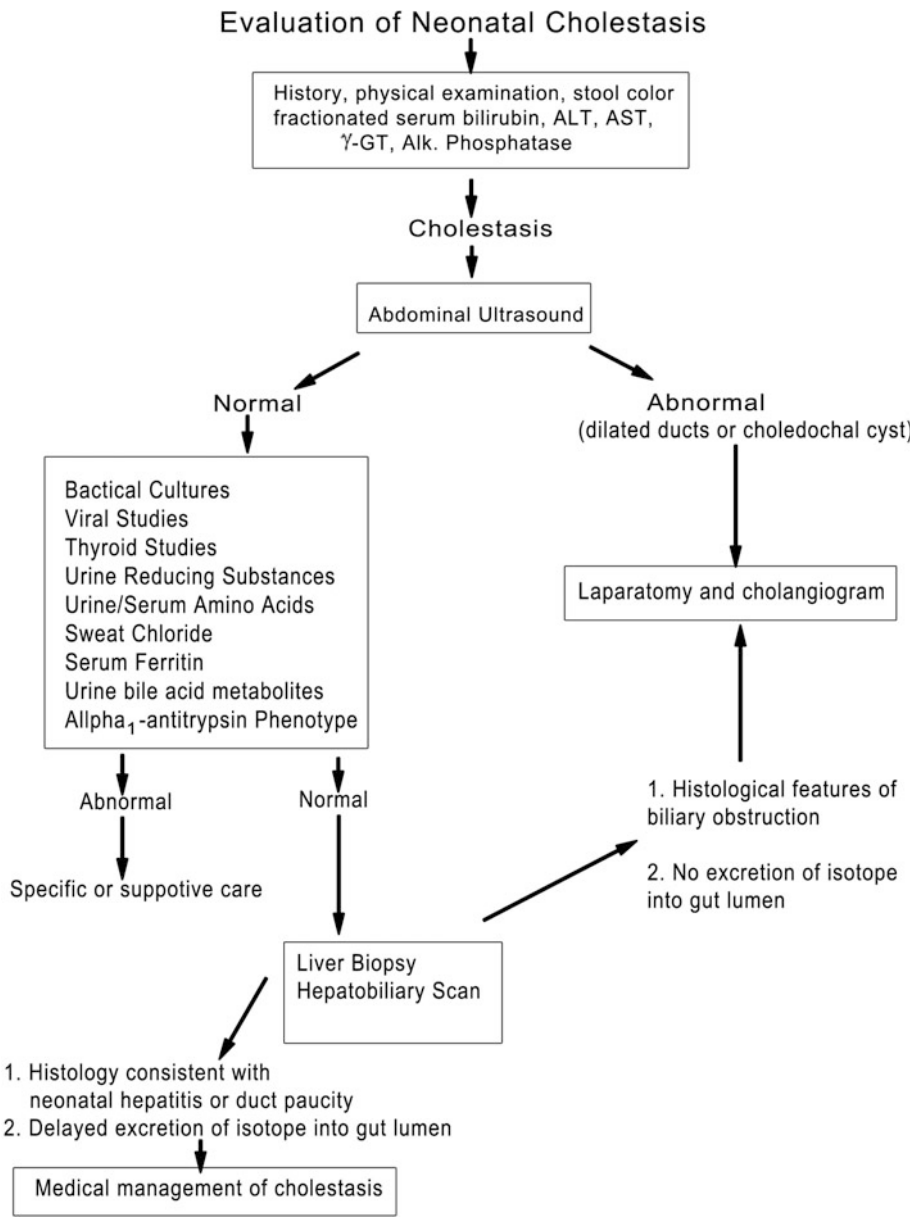

Figure 205.2
Flow diagram for the evaluation of neonatal cholestasis

hepatic function such as blood glucose and ammonia levels and coagulation studies may provide insight into the severity of the liver dysfunction but are not specific.

Numerous routine and specialized biochemical tests and imaging procedures have been used to help distinguish between infants with intra- and extrahepatic cholestasis and, thus, avoid unnecessary surgical exploration. Unfortunately, no single test has proven to be of satisfactory discriminatory value, since at least 10% of infants with intrahepatic cholestasis will have sufficient bile secretory failure so as to have diagnostic tests that overlap with biliary atresia.

Ultrasonography can be used to assess the size and composition of the liver and can usually define the

presence and size of the gallbladder, detect stones and sludge in the bile ducts and gallbladder, and demonstrate cystic or obstructive dilatation of the biliary system. Extrahepatic anomalies may also be identified.

Hepatobiliary scintigraphic imaging with agents such as the technetium-99 m iminodiacetic acid derivatives has been used to differentiate biliary atresia from other causes of neonatal jaundice. A 5-day period of pretreatment with phenobarbital is required to maximize bile secretion and visualization of the biliary tract. In patients with biliary atresia, hepatic uptake of the isotope occurs rapidly because liver function is usually preserved early in the disease but excretion into the intestine is absent even on scanning 24 h later. In contrast, uptake is poor in cases of neonatal hepatitis, but excretion of bile into the intestine should eventually be detected. In practice, the distinction between severe hepatocellular disease and biliary obstruction may not be reliably made using this technique.

Percutaneous transhepatic cholangiopancreatography (PTC) or endoscopic retrograde cholangiopancreatography (ERCP) may be of value in visualizing the biliary tract in selected patients.

Magnetic resonance cholangiopancreatography (MRCP) is being performed more frequently in cholestatic infants. The instrumentation and software have improved significantly to allow the imaging of a normal biliary tree in infants. In several small studies, patent extrahepatic bile ducts and a gallbladder could not be demonstrated in infants who had biliary atresia. Further studies are required before MRCP evaluation of the cholestatic infant can be considered reliable.

The percutaneous liver biopsy remains particularly valuable in the evaluation of the cholestatic patient and can be performed in even the smallest infants employing only sedation and local anesthesia. A diagnosis of biliary atresia can be successfully made on the basis of clinical and histological criteria in 90–95% of patients. In the small number of cases where doubt about the diagnosis persists, the patency of the biliary tree can be directly examined at the time of a mini laparotomy and operative cholangiogram. Liver tissue may also be used for ultrastructural analysis and enzymatic assays, and can be cultured for infectious agents.

Disorders of the Bile Ducts

Biliary Atresia

Biliary atresia is a cholestatic disorder presenting in infancy caused by a complete obstruction of bile flow due to destruction or absence of all or part of the extrahepatic bile ducts. The disorder occurs worldwide, affecting an estimated 12,000–18,000 live birth. It is the single most frequent cause of death from liver disease and of referral for liver transplantation (up to 50% of all cases) in children. In most large series, it accounts for approximately one third of the cases of neonatal cholestatic jaundice.

There are two different forms of biliary atresia: (1) fetal or embryonic form and (2) peri or postnatal form.

In the fetal form (10–20% of all patients), cholestasis is present from birth with no jaundice free interval, bile duct remnant may not be detectable in the hepatic hilum. There are associated anomalies in 10–20% of patients such as the splenic malformation syndrome. Associated findings may include cardiovascular defects, asplenia, abdominal situs inversus, intestinal malrotation or atresia, and positional anomalies of the portal vein and the hepatic artery. The fetal form of biliary atresia may represent defective embryogenesis. The postnatal form, in which there are no associated congenital anomalies, may be the result of an acquired obliteration. There is no difference in the histologic features of the liver between infants with and without congenital anomalies.

The etiology of biliary atresia is unknown. Viral, toxic, and developmental causes have been proposed but not proven. The disease is not inherited. Familial cases have been reported rarely but in most a detailed histologic description of the extrahepatic biliary tree was not provided to convincingly exclude narrowing or "hypoplasia" of the common duct due to severe intrahepatic cholestasis.

Numerous mechanisms have been proposed to account for the progressive obliteration of the extrahepatic biliary tree. There is little support for an ischemic or toxic origin of extrahepatic bile duct injury. No abnormal toxic bile acid metabolite specific for the disorder has been identified. Congenital infections with cytomegalovirus, Epstein–Barr virus, or rubella virus have been occasionally found, but the presence of these common agents may be coincidental. A possible role for *reovirus type 3* has been proposed based on serologic evaluation of patients and controls. Further evidence that reovirus type 3 may cause some cases of biliary atresia has come from immunolocalization of reovirus 3 antigens in a bile duct remnant of a patient with biliary atresia and by the apparent ability of reovirus 3 to produce extrahepatic biliary atresia in an infant rhesus monkey. However, these serologic data have not been confirmed by other workers.

Biliary atresia may be a result of a "multiple hit" phenomenon. A viral or toxic insult to the biliary epithelium leads to newly expressed antigens on the surface of the bile duct epithelia. Recent studies from a mouse model

of biliary atresia and microarray analysis of liver tissue from affected infants with the perinatal form of the disease further suggest that immune dysregulation is central to the pathogenesis of the disorder. It remains unknown whether this immune response is induced by a viral infection or reflects a genetically programmed response to an infectious or environmental exposure. In a microarray analysis of liver tissue from infants with a so-called embryonic form of biliary atresia in which extrahepatic malformations and early onset of cholestatic jaundice occur, a unique pattern of expression of genes involved in chromatin integrity/function and overexpression of five imprinted genes (Igf2, Peg3, Peg10, Meg3, and IPW) was found, implying a failure to downregulate embryonic gene programs that influence the development of the liver and other organs.

Histopathologic findings early in the course of the biliary atresia generally show good preservation of the hepatic architecture with a variable degree of bile ductular proliferation, canalicular and cellular bile stasis (*Fig. 205.3*), portal tract fibrosis, inflammation, and edema. The presence of bile plugs in portal triads is an important feature of large duct obstruction. Bile ductules show variable injury to the biliary epithelium including swelling, vacuolization, and even sloughing of cells into the lumen. Giant cell transformation of hepatocytes may also be present to a degree more commonly seen in neonatal hepatitis. Intrahepatic bile ductules may occasionally assume a ductal plate configuration, suggesting that the disease process has interfered with the developmental process of ductular remodeling. Biliary cirrhosis may be present initially or can rapidly evolve over the first months of life with or without the successful restoration of bile flow. Complete fibrous obliteration of at least a portion of the extrahepatic bile ducts is a constant feature. Other segments of the biliary tree may demonstrate lumina with variable degeneration of bile duct epithetial cells, inflammation, and fibrosis in the periductular tissues. A useful classification of the anatomic variants is based on the predominant site of the atresia:

Type I atresia: Involves obliteration of the common bile duct but the proximal ducts are patent.

Type II atresia: The hepatic duct is obstructed, but cystically dilated bile ducts are found at the porta hepatis. In type IIa the cystic and common ducts are patent, while in type IIb these structures are also obliterated.

These forms of biliary atresia have been referred to as "surgically correctable" but, unfortunately, comprise less than 10% of all patients with the disorder.

Type III atresia: Type III atresia (present in 90% or more of patients) involves obstruction of ducts at or above the porta hepatis. The entire perihilar area is encased in a cone of dense fibrous tissue. The gallbladder is involved to some extent in approximately 80% of patients. The type III variant has been referred to as "noncorrectable" in that there are no patent hepatic or dilated hilar ducts that can be used for a simple biliary-enteric anastomosis.

Most infants with biliary atresia appear healthy at birth and are of normal birth weight. Female infants are affected more commonly than males. Jaundice may be observed by the parents or the physician after the period of physiologic hyperbilirubinemia. The possibility of liver or biliary tract disease must be considered in any neonate jaundiced beyond 14 days of age. Stools of a patient with complete biliary obstruction are acholic; however, early in the course with incomplete or evolving atresia, stools may appear normally pigmented or only intermittently pigmented. Moderate hepatomegaly with a firm liver edge is commonly observed. The spleen is usually not enlarged early in the course but will become enlarged as portal hypertension develops. Bleeding due to vitamin K deficiency may be a presenting feature. Ascites and edema are not initially present.

Laboratory studies initially show a variable elevation of serum bilirubin levels, often between 6 and 12 mg/dL, with at least 50% of the total conjugated. Serum aminotransferase, gamma-glutamyltransferase, and alkaline phosphatase levels are moderately elevated. Various laboratory tests, imaging methods, and biopsy samples have been suggested in attempts to establish the diagnosis of

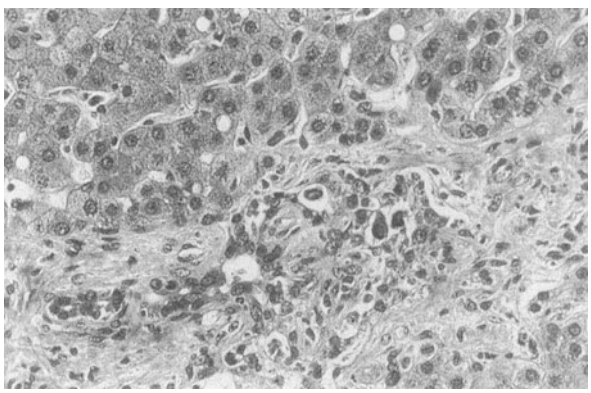

Figure 205.3
Liver biopsy from patient with biliary atresia showing portal fibrosis and bile plugs in bile ducts

biliary atresia and to differentiate it from various forms of intrahepatic cholestasis.

The most reliable information is obtained by liver histopathology followed by intraoperative cholangiography. Exploratory laparotomy and operative cholangiography are necessary to document the site of obstruction and properly direct attempts at surgical treatment of biliary atresia. Patent proximal portions of the bile ducts or cystic structures in the porta hepatis allow a conventional anastomosis with a segment of bowel in approximately 10% of patients. The most common operative approach in cases with obliteration of the proximal extrahepatic biliary tree requires the hepatoportoenterostomy or Kasai procedure. The fibrous extrahepatic biliary tree is resected with the dissection carefully progressing backward and laterally to include a fibrous cone of tissue in the area of the porta hepatis. The fibrous tissue is transected flush with the liver surface to expose an area that may contain residual, microscopic bile ducts. The operation is then completed by the anastomosis of a Roux-en-Y loop of jejunum around the bare edge of the transected tissue to provide a conduit for biliary drainage. Multiple attempts at reexploration and revision of nonfunctional conduits should be avoided.

A number of factors have been identified that contribute to the success of hepatic portoenterostomy. First, the age at which the operation is performed has been found to be most critical. Bile flow has been reestablished in several recent series in 80–90% of infants who were referred for surgery within 60 days after birth. Predictors of a bad outcome have been of Caucasian race, with an operative age greater than 60 days, the presence of cirrhosis on initial biopsy, totally non-patent extrahepatic ducts, and absent ducts at the level of transection in the liver hilus.

The prognosis of untreated biliary atresia is extremely poor, with death from liver failure usually occurring within 2 years. Children with biliary atresia derive long-term benefit from the hepatic portoenterostomy procedure even though in most cases the operation is not curative. Progressive biliary cirrhosis may eventually result in death from hepatic failure or need for liver transplantation despite an apparent successful relief of biliary obstruction. The overall management of extrahepatic biliary atresia in the era of liver transplantation is illustrated in Fig. 205.4.

Liver transplantation is frequently required in children whose operation is not successful in restoring bile flow, who are referred late (probably at 120 days of age or later), and who eventually develop progressive hepatocellular decompensation, recurrent cholangitis, refractory growth failure with hepatic synthetic dysfunction, coagulopathy or intractable portal hypertension with recurrent variceal bleeding, ascites, and hypersplenism. With the use of reduced size allografts and living-related donors, rates of survival at 1 year have exceeded 90% in most centers.

Spontaneous Perforation of the Common Bile Duct

Spontaneous perforation of the common bile duct is a rare disorder of the infant presenting with cholestatic jaundice.

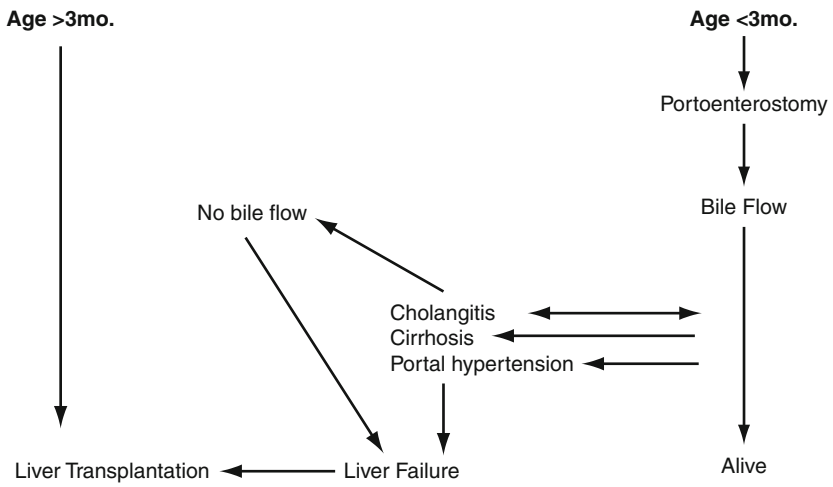

Figure 205.4
Flow diagram for the management of biliary atresia in the era of liver transplantation

The cause is unknown, but in some cases there may be obstruction at the distal end of the common bile duct secondary to stenosis or inspissated bile. Congenital weakness in duct wall or inflammation from infection at the site of the perforation may be causal.

Clinical signs of irritability, jaundice, acholic stools, dark urine, and ascites typically occur during the first months of life. Progressive abdominal distension is a regular feature. Bile staining of fluid within umbilical or inguinal hernias may be observed. The diagnosis is suggested by the relatively mild elevation of aminotransferase levels in association with acholic stools.

Ultrasonography reveals ascites or loculated fluid in the right upper quadrant. Hepatobiliary scintigraphy may demonstrate the free accumulation of isotope within the peritoneal cavity. Abdominal paracentesis reveals clear bile-stained ascitic liquid which is usually sterile.

Operative cholangiography is required to demonstrate the site of the perforation, which usually occurs at the junction of the cystic and common ducts. Surgical treatment may involve simple drainage of the bilious ascites and repair of the site of the perforation, but with an obstruction of the common bile duct, drainage via a cholecystojejunostomy may be required.

Spontaneous posterior perforation of the biliary tract and portal vein thrombosis in infancy has been reported, presumably due to their intimate anatomical relation.

Bile Plug Syndrome

A plug of thick, inspissated bile and mucus may obstruct the common bile duct. The condition occurs particularly in sick premature infants who cannot be fed and require prolonged parenteral nutrition. Otherwise healthy infants have been affected. Bile stasis, prolonged fasting, infection, and an increased bilirubin load may contribute to the pathogenesis. Bile plug syndrome is associated with other etiologic factors such as cystic fibrosis, severe erythroblastosis fetalis, and altered biliary dynamics with total parenteral nutrition. The "inspissated bile syndrome" associated with massive hemolysis may have been a variant but is now infrequent with current measures to prevent and treat blood group incompatibilities.

The differential diagnosis of inspissated bile syndrome in the neonatal period includes biliary atresia.

Abdominal US may reveal dilated intra- and extrahepatic bile ducts secondary to impacted inspissated bile in the distal common bile duct. *Magnetic resonance cholangiography* has been shown to be useful in the evaluation of bile plug syndrome in children.

Percutaneous transhepatic cholangiography (PTC) may be diagnostic and occasionally can be therapeutic after flushing the biliary tree via small catheter. It may be a difficult procedure because of the small size of the intrahepatic ducts and the need to obtain a sufficient flushing pressure.

Exploratory laparotomy and operative cholangiography may be required for diagnosis and treatment. Recently, laparoscopic-aided cholecystostomy as a treatment of inspissated bile syndrome has been described. The use of ursodeoxycholic acid (UDCA) 20 mg/kg/day may help to avoid the need for surgery.

Neonatal Sclerosing Cholangitis

An idiopathic form of primary sclerosing cholangitis may present in the neonate. Immunodeficiency states and histiocytosis *X* should be considered in the differential diagnosis. The presenting features of cholestatic jaundice and acholic stools within the first weeks of life may mimic biliary atresia. Liver histology findings in infancy suggest bile duct obstruction. Percutaneous cholecystography reveals a patent biliary system with rarefaction of segmental branches, stenosis, and focal dilatation of the intrahepatic bile ducts. The extrahepatic bile ducts are often involved. Although jaundice may subside, liver disease is usually progressive with evolution to biliary cirrhosis and portal hypertension.

Neonatal sclerosing cholangitis has been reported in association with Kabuki syndrome (involving facial dysmorphism, mental retardation, growth deficiency, skeletal abnormalities, and congenital heart defects) and neonatal ichthyosis – sclerosing cholangitis (NISCH) syndrome. The latter is a disease of tight junctions which result from Claudin-1 gene mutations.

In contrast to sclerosing cholangitis of the adult and older child, intestinal disease has not been detected in these patients.

Children with neonatal sclerosing cholangitis have been treated with UDCA with variable results. Patients with recurrent cholangitis and progressive liver disease may require liver transplantation.

Choledochal Cysts

Choledochal cysts are congenital anomalies of the biliary tract characterized by cystic dilatation of the extrahepatic and intrahepatic bile ducts. The cysts occur in an

incidence of 1 in 13,000–1 in 15,000 in Western countries and as high as 1 in 1,000 in Japan. They are not familial; females are more commonly affected (3–4:1). A choledochal cyst may be detected at any age and in any portion of the bile duct. Cysts can be present in up to 2% of infants with obstructive jaundice and 18% of the patients with choledochal cyst are diagnosed before 1 year. Cases have been described in utero and are an important, treatable cause of obstructive cholestasis in the neonate. In certain patients, choledochal cyst is associated with other anomalies of the biliary tree and with polycystic and hypoplastic kidneys.

Segmental or diffuse fusiform dilatation of the common bile duct (*type I cysts*) accounts for 80–90% of the cases. *Type II cysts* consist of a true choledochal diverticulum. A dilatation of the intraduodenal portion of the common bile duct, or a so-called choledochocele (*type III*), may be a variant of this condition. *Type IV cysts* may be subdivided into type IVa, multiple intrahepatic and extrahepatic cysts, and type IVb, multiple extrahepatic cysts. The type lVb variant is either uncommon or may overlap with type I. *Type V cysts* (*Caroli disease*) consists of single or multiple dilatations of the intrahepatic ducal system, probably should not be considered a choledochal cyst.

The etiology of choledochal cysts has not been established. Congenital weakness of the bile duct wall, a primary abnormality of epithelial proliferation during embryologic ductal development, and congenital obstruction have been suggested.

The infantile presentation of a choledochal cyst must be distinguished from the other forms of hepatobiliary disease of the neonate, particularly biliary atresia. Patients often present during the first months of life with cholestatic jaundice and acholic stools. Vomiting, irritability, and failure to thrive may occur. At this time hepatomegaly is present, but less than half the patients may have a palpable abdominal mass. Progressive hepatic injury can occur during the first months of life as a result of biliary obstruction. Prolonged obstruction results in biliary cirrhosis. Portal hypertension and ascites may be present. Recurrent pancreatitis is an unusual complication of this malformation. Spontaneous perforation of a choledochal cyst in infancy can cause biliary peritonitis.

The diagnosis of a choledochal cyst is best established by MRCP (magnetic resonance cholangiopancreatography) or by ultrasonography, which may also demonstrate the presence of a choledochal cyst in the fetus. Pediatric surgeons rely on an operative cholangiogram to confirm the diagnosis of a choledochal cyst and define the extent of intra- and extrahepatic disease.

Surgical excision of the cyst and reconstruction of the extrahepatic biliary tree to jejunal Roux-en-Y loop is the preferred method of treatment. Excision of the cyst reduces bile stasis and the risk for cholangitis and malignancy (adenocarcinoma or cholangiocarcinoma) within the cyst wall. Recently, laparoscopic resection of choledocal cyst and Roux-en-Y hepaticojejunostomy was reported in children. Preoperative pancreatitis may cause increased technical difficulty, necessitating a conversion to laparotomy. If segmental intrahepatic cystic disease with area of stenosis (Caroli's disease) is present, cyst excision and hepatic lobectomy is indicated. If the intrahepatic disease is diffuse and involves all hepatic lobes, and successful decompressive drainage is not possible, liver transplantation may be indicated.

Paucity of the Interlobular Bile Ducts

A paucity of interlobular bile ducts can occur as an isolated and unexplained finding in infants with idiopathic cholestasis. Bile duct injury and loss seem to be prototypic response to neonatal liver disease, and may be observed in congenital infections with rubella and cytomegalovirus and in metabolic disorders such as α1-antitrypsin deficiency and inborn errors of bile acid metabolism. Paucity of interlobular bile ducts can be defined as the ratio of the number of interlobular bile ducts to the number of portal tracts of less than 0.4 on a liver biopsy with at least ten portal tracts. The prognosis is highly variable. Severe cholestasis may develop early in infancy and may be associated with progressive liver disease.

Alagille Syndrome (Syndromic Paucity of Interlobular Bile Ducts)

Syndromic paucity of interlobular bile ducts (*Alagille syndrome, or arteriohepatic dysplasia*) is the most common form of familial intrahepatic cholestasis. This disorder is characterized by chronic cholestasis, a decreased number of interlobular bile ducts, and a variety of other congenital malformations.

The disorder is inherited as an autosomal-dominant trait with incomplete penetrance and variable expressivity. Mutations in the jagged 1 (JAG1) gene have been identified in approximately 94% of affected patients. JAG1 encodes a ligand in the Notch signaling pathway that is involved in cell fate determination during development. Mutations in the gene encoding for the NOTCH2 receptor have recently been found in patients with Alagille syndrome who were negative for JAG1 mutations.

Chronic cholestasis of varying severity affects 95% of patients, and may be observed during the neonatal period. Intense pruritus may be present by 6 months of age. The liver and spleen are often enlarged. During the first years of life, xanthomata appear on the extensor surfaces of the fingers and in the creases of the palms and popliteal areas. Dysmorphic facies are usually recognized during infancy and become more characteristic with age. The forehead is typically broad, the eyes are deeply set and widely spaced, and the chin somewhat small and pointed, imparting a triangular appearance to the face. The malar eminence is flattened and the ears are prominent (*Fig. 205.5*).

Extrahepatic anomalies have been described with this syndrome, but there is considerable variability in phenotypic expression. In a 1999 series of 92 patients, cholestasis occurred in 96%, cardiac murmur in 97%, butterfly vertebrae in 51%, posterior embryotoxon in 78%, and characteristic facies in 96% of patients. Short stature is a regular feature but is only partially attributed to the severity of chronic cholestasis. Mild-to-moderate mental retardation affects 15–20% of patients. Congenital heart disease occurs in most patients, and peripheral pulmonic stenosis is observed in approximately 90%. Systemic vascular malformations also may be present. Osseous abnormalities include a decreased bone age, variable shortening of the distal phalanges, and vertebral arch defects (e.g., butterfly vertebrae, hemivertebrae, and a decrease in the interpedicular distance). Eye anomalies include posterior embryotoxon (mesodermal dysgenesis of the iris and cornea), retinal pigmentation, and iris strands. Renal abnormalities and hypogonadism may be present.

An elevation of total serum bilirubin levels (usually 2–8 mg/dL) is found during infancy and intermittently later in life. Approximately 50% of the total serum bilirubin is conjugated. Serum alkaline phosphatase, gamma-glutamyl transpeptidase, 5′ nucleotidase, and bile acid levels may be extremely high. Serum aminotransferase levels are mildly to moderately increased. Serum cholesterol levels may be 200 mg/dL or higher. Serum triglyceride concentrations may range from 500 to 1,000 mg/dL.

On liver biopsy, the cardinal feature of this disorder is a paucity of interlobular bile ducts (*Fig. 205.6*). The number of interlobular bile ducts may not be decreased on initial liver biopsy, but there may be evidence of bile duct injury. The histologic features during the first months of life may overlap with those of neonatal hepatitis with ballooning of hepatocytes, variable cholestasis, portal inflammation, and giant cell transformation. Serial biopsies of an individual patient may initially show bile duct proliferation, followed later in life by a paucity of bile ducts. Paucity of interlobular bile ducts is usually apparent after 3 months. There may also be mild periportal fibrosis, but progression to cirrhosis is uncommon. The extrahepatic bile ducts are patent but usually narrowed or hypoplastic.

The mechanisms involved in the pathogenesis of bile duct paucity and cholestasis are not settled. It is also unknown how the bile duct abnormalities relate to the

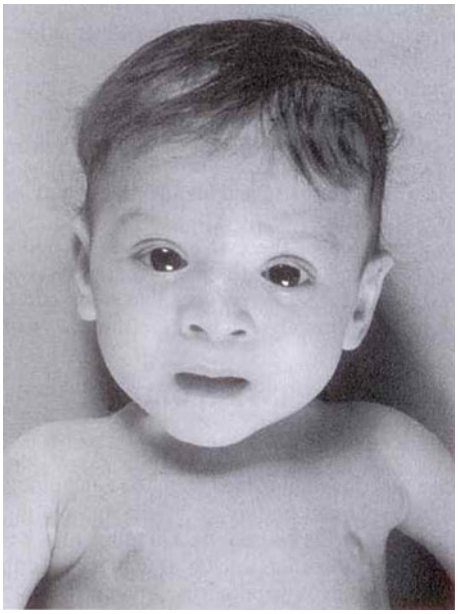

Figure 205.5
Child with Alagille syndrome (Courtesy of Prof. Hisham Nazer, Amman, Jordan)

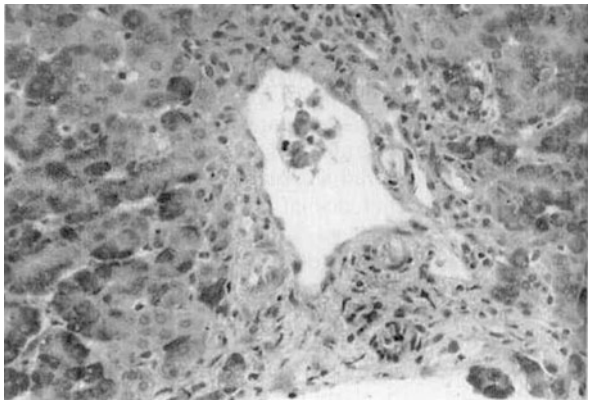

Figure 205.6
Liver biopsy from a child with paucity of interlobular bile ducts (Courtesy of Prof. Hisham Nazer, Amman, Jordan)

congenital anomalies found in other organ systems. The strong jagged 1 expression during human embryogenesis, both in the vascular system and in other mesenchymal and epithelial tissues, suggests that abnormal angiogenesis may be a key factor in the pathogenesis of Alagille syndrome. Although a vascular basis for the anomalies in Alagille syndrome seems possible, the precise mechanisms leading to bile duct paucity remain unknown. Notch signaling has an important role in the differentiation of biliary epithelial cells and is essential for their tubular formation during intrahepatic bile ducts development. There is recent evidence that a lack of branching and elongation of bile ducts during postnatal liver growth contributes to peripheral bile duct paucity and cholestasis.

The clinical course of Alagille syndrome is marked by varying degrees of cholestasis that may be exacerbated by intercurrent viral infections. Neonatal cholestatic jaundice has been associated with poorer survival with native liver. Significant morbidity may result from pruritus, cutaneous xanthomata, and neuromuscular symptoms related to vitamin E deficiency. Treatment involves the provision of good nutrition including prevention or correction of fat-soluble vitamin deficiencies. Symptomatic measures to relieve pruritus are variably successful. Partial external biliary diversion may be effective for treating severe pruritus and hypercholesterolemia in Alagille patients without cirrhosis who did not respond to medical therapy. The factors contributing significantly to the mortality are hepatic disease or complications of liver transplantation (25%), complex congenital heart disease (15%), and intracranial hemorrhage (25%). Hepatocelluar carcinoma may occur. Survival and candidacy for liver transplantation may be limited by the severity of associated cardiovascular anomalies. The 20-year predicted life expectancy is approximately 75% for all patients, approximately 80% for those not requiring liver transplantation, and approximately 60% for those who require liver transplantation. In patients requiring liver transplantation, a higher than expected mortality rate can be attributed to cardiac disease or a previous Kasai procedure.

Cystic Fibrosis

Patients with cystic fibrosis may rarely present in the neonatal period with cholestatic jaundice and acholic stools. It may be associated with meconium ileus. Clinical features may mimic extrahepatic biliary atresia. Cholestasis may develop as a result of inspissated bile in the biliary tree.

Intraheptic Cholestasis

Neonatal Hepatitis

Neonatal hepatitis refers to a hepatocellular process characterized by swelling and multinucleated giant cell transformation of hepatocytes and variable cholestasis, inflammation, necrosis, and fibrosis. This process should be considered a pattern of injury typical of the neonatal liver rather than a specific diagnosis. In many series of infants with cholestatic jaundice, at least one third of the patients fell into the category of so-called idiopathic neonatal hepatitis. The relative incidence of the disorder in early reports varied from 1 in 2,500 to 1 in 8,000 live births. A familial form affects 10–15% of patients suggesting causation by an underlying immunologic defect or inborn error of metabolism. At present, the incidence of idiopathic neonatal hepatitis is likely to be much lower because advances in virology and application of novel biochemical and molecular methods more commonly lead to a precise diagnosis. For example, perinatal infection with parvovirus B19 and human herpesvirus-6 has been associated with neonatal hepatitis. Other important associations include neonatal lupus erythematosus, α1 antitrypsin deficiency, and inborn errors of bile acid metabolism.

The clinical presentation and course are highly variable. However, the infant is often born prematurely or is of low birth weight. Cholestatic liver disease may be noticed during the first week or life or escape recognition until 1–2 months of age. A third of infants may fail to thrive. Cholestatic jaundice and acholic stools may suggest biliary obstruction. Hepatosplenomegaly is usually present. A hemorrhagic diathesis may result from deficiency of coagulation factors and from thrombocytopenia. Congenital malformations are found less commonly than with the cholangiopathies, but microcephaly and chorioretinitis strongly suggest intrauterine infection with rubella or cytomegalovirus. A fulminant course, reflecting massive necrosis of hepatocytes, can occur with herpes simplex and enteroviral infections or with inborn errors of metabolism such as neonatal iron storage disease or tyrosinemia.

Standard liver biochemical tests are variably abnormal. Total and conjugated serum bilirubin levels are elevated. Serum aminotransferases are moderately elevated, but markedly abnormal levels may be found with significant necrosis. Alkaline phosphatase, 5′-nucleotidase, and γ-glutamyltransferase levels are raised but usually to a degree less than in biliary obstruction.

Liver biopsy is valuable in defining alterations of the hepatic parenchyma in neonatal hepatitis that in most

cases can help differentiate the process from biliary atresia. The lobular architecture may be severely disturbed with variable swelling, degeneration, and necrosis of hepatocytes and extramedullary hematopoiesis. Multinucleated giant cells, thought to be formed by fusion of hepatocytes, may be prominent throughout the lobule (*Fig. 205.7*). Hepatocellular and canalicular bile stasis are regular features, but ductular bile plugs and proliferation should be negligible. Periportal and lobular fibrosis may be present. Pseudoacinar arrangement of hepatocytes and steatosis should suggest a metabolic cause for the liver disease.

There is no specific treatment for neonatal hepatitis. Efforts should be directed toward correction and prevention of fat-soluble vitamin deficiencies and provision of a formula containing high medium-chain triglycerides (MCTs).

The prognosis of idiopathic neonatal hepatitis is highly variable. Approximately 60% of patients with the sporadic form recover completely, one third die from rapidly progressive disease, and about 10% develop chronic liver disease.

α1-Antitrypsin Deficiency

α1-Antitrypsin, a 50-kDa glycoprotein synthesized predominantly in the liver, is the major serum protease inhibitor and acts to inhibit a broad range of proteolytic enzymes, particularly neutrophil elastase. The protease inhibitor occurs in over 75 variants, known Pi phenotypes, which are inherited as codominant alleles.

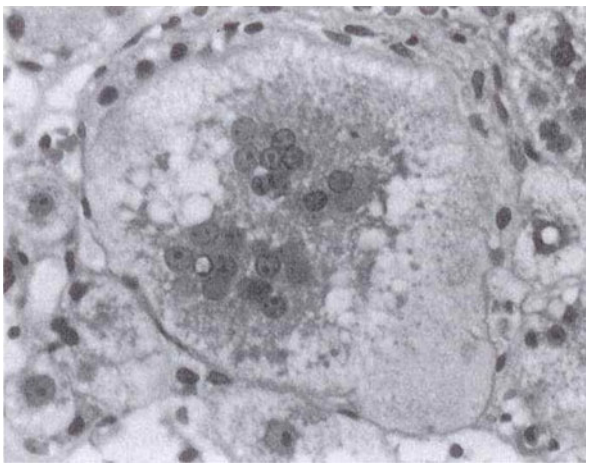

Figure 205.7
Liver biopsy from patient with idiopathic neonatal hepatitis showing multinucleated giant cell

The normal phenotype, determined by protein electrophoresis, is designated MM. Patients with a homozygous deficiency state or ZZ phenotype have low serum α1 antitrypsin levels, usually 10–15% of normal values. The incidence of the PiZZ phenotype is 1 in 2,000–1 in 4,000. The deficiency state can be associated with progressive liver disease in infants children and adults. Heterozygotes with the SZ and MZ phenotypes have a less-severe reduction in serum α1-antitrypsin concentration. The role of α1-antitrypsin heterozygosity as a modifier for other liver diseases remains unsettled.

Approximately 10–15% of patients with the P1ZZ phenotype develop cholestasis in the newborn period. Hepatomegaly and acholic stools are typical in these patients. Patients may rarely present with ascites or bleeding. Although asymptomatic, another 40–50% of infants may have abnormal liver biochemical tests in the first months of life. The diagnosis should be made by determination of the α1-antitrypsin phenotype. Measurement of α1-antitrypsin levels alone is not reliable, since the protein is an acute phase reactant.

Liver biopsy in the neonate often shows giant cell hepatitis. Bile ductular proliferation may be variably observed; paucity of bile ducts may be found later. The presence of periodic acid-Schiff-positive diastase-resistant inclusions within hepatocytes, representing the abnormal α1 antitrypsin, is a characteristic feature but is not usually prominent before 4 months of age. A variable degree of fibrosis may be present. Cirrhosis has been reported in the neonate.

The pathophysiology of liver disease in α1-antitrypsin deficiency is not entirely clear, particularly as to why only 10–15% of neonates manifest liver disease. The PiZZ defect, caused by the substitution of a lysine for a glutamate at position 342, leads to misfolding of the protein and its retention in the endoplasmic reticulum. Studies in transgenic animals expressing the abnormal human protein support the notion that the retained α1-antitrypsin is toxic to the liver. The mutant α1-antitrypsin molecule polymerizes in the ER by a novel loop-sheet insertion mechanism. The intracellular accumulation of the mutant Z protein in the liver leads to the activation of autophagy, mitochondrial injury, and caspase activation, which causes progressive liver damage. The subpopulation of α1-antitrypsin-deficient individuals who develop liver disease may have another trait that reduces the efficiency with which the mutant α1-antitrypsin protein is degraded in the endoplasmic reticulum.

The course of patients with neonatal liver disease related to α1-antitrypsin deficiency is variable. Rare patients presenting with cirrhosis may deteriorate rapidly within the first months of life. However, in most patients, the jaundice clears by 4 months of age. Nearly equal proportions of patients will manifest one of the following outcomes:

Continued liver dysfunction with progression to cirrhosis and end-stage liver disease by age 10 years, persistent liver test abnormalities with slow progression to cirrhosis in adolescence or later, mild liver test abnormalities and minimal fibrosis with survival into adulthood, and apparent complete resolution of hepatic disease. Hepatocellular carcinoma may occur in these patients. There is no specific treatment for α1-antitrypsin deficiency. Liver transplantation is curative for patients progressing to end-stage liver disease; the recipient assumes the Pi type of the donor organ.

Progressive Familial Intrahepatic Cholestasis

The group of inherited disorders of bile formation, known as progressive "familial intrahepatic cholestasis" (PFIC) often present in infancy and are associated with progression at a variable rate to end-stage liver disease. Mutations in several genes encoding transport proteins located on the liver canalicular membrane have been defined.

PFIC1 (also called *Byler disease*) is characterized by unremitting cholestasis with pruritus and jaundice that usually starts before the age of 1 year. Progression to cirrhosis and liver failure occur at a variable rate. Diarrhea, malabsorption with fat-soluble vitamin deficiencies, and failure to thrive are common. Intractable pruritus, often out of proportion to the level of jaundice, is the dominant feature of cholestasis. Serum γ-glutamyl transpeptidase activity and cholesterol concentrations are paradoxically normal. The serum bile acid concentration is markedly elevated. Liver biopsy shows hepatocellular and canalicular cholestasis early in the course of the disease.

Cirrhosis eventually occurs. Electron microscopy shows distended bile canaliculi with effaced microvilli that contain unusually coarse and granular bile (so-called Byler's bile). Patients with PFIC1 have mutations in the gene FIC1 that encodes for ATP8B1, a P-type ATPase localized to the liver canalicular and cholangiocyte apical membranes. ATP8B1 is thought to maintain asymmetry of aminophospholipids in lipid bilayers, and may play a role in regulating important lipid-dependent signaling pathways and the activity of membrane receptors and transport proteins. The loss of canalicular phospholipid membrane asymmetry in PFIC1 also renders the canalicular membrane less resistant to the damaging effects of hydrophobic bile salts. The FIC1 gene is also expressed in other organs including the lungs, small intestine, pancreas, and kidneys. This may account for some of the extrahepatic symptoms in PFIC1. Biliary diversion or ileal bypass are used often to treat pruritus and slow the progression of liver damage by depletion of hydrophobic bile acids. Liver transplantation may be required in some patients. Owing to the extrahepatic expression of FIC1, patients may still suffer from growth failure, malabsorption, and pancreatitis after an otherwise successful liver transplant.

Benign recurrent intrahepatic cholestasis type 1(BRIC1) is also caused by FIC1 mutations. Attacks of jaundice and pruritus occur separated by symptom-free intervals. The age of presentation ranges from 1 to 50 years but usually before the age of 20 years. Episodes begin with 2–4 weeks of malaise, anorexia, and pruritus, followed by an icteric phase that may last from 1 to 18 months. Progression to cirrhosis and long-term complications of chronic liver disease do not occur.

PFIC2

Patients with PFIC2 usually present in the neonatal period with a giant cell hepatitis and severe cholestasis. Pruritus is the dominant feature of the disorder in most patients. Patients with PFIC2 have low serum γGT and normal or near-normal serum cholesterol levels. In contrast to patients with PFIC-1, serum aminotransferase levels are usually elevated to at least five times normal values. A rapid progression to cirrhosis is seen without therapy. Patients with PFIC2 are at risk for developing hepatocellular carcinoma and cholangiocarcinoma. PFIC2 is caused by mutations in ABCB11 which encodes for the bile salt export pump (BSEP), the predominant transporter for bile acids on the liver canalicular membrane. Progressive liver damages result from bile secretory failure with retention bile salts and other biliary constituents in the hepatocyte. Liver morphology in PFIC2 shows a neonatal hepatitis with giant cell transformation of hepatocytes and lobular cholestasis that may persist beyond infancy. Electron microscopy demonstrates effaced microvilli and dilated bile canaliculi that contain finely granular or filamentous bile. Patients demonstrating the phenotype of BRIC have recently been described with mutations in ABCB11. These patients have recurrent episodes of cholestasis and are clinically healthy and biochemically normal between attacks. The age of onset and total number of recurrent episodes are variable.

Several patients have been reported who developed permanent cholestasis as adults after initial periods of recurrent attacks as children. Biliary diversion and ileal exclusion have been done to treat intractable pruritus and progression of liver disease. A risk for liver cancer may still exist. Liver transplantation may be required, but extrahepatic complications seen in PFIC1 patients post-transplant do not occur.

PFIC3

The age of onset of PFIC3 with jaundice, hepatomegaly, and acholic stools can range from 1 month to over 20 years (mean age ~3.5 years). The disorder is caused by mutations in the ABCB4 (MDR3) gene which encodes a transporter required for biliary phosphatidylcholine secretion. The formation of mixed micelles with phosphatidylcholine, cholesterol, and bile salts is needed to protect the canalicular and cholangiocyte membranes from damaging effects of bile acids. Pruritus is less severe than in the other types of PFIC. Growth failure may occur as the disease progresses. Evolution occurs slowly to biliary cirrhosis with or without overt cholestatic jaundice. Portal hypertension may occur early in childhood, or can be a presenting feature in adolescents and young adults. In contrast to the other forms of PFIC, the serum concentration of γ-glutamyltranspeptidase is elevated in PFIC3, often over ten times the normal value. The serum aminotransferases, conjugated bilirubin, and alkaline phosphatase are variably elevated. The serum cholesterol concentration is usually normal. Biliary phospholipids are markedly reduced.

Liver biopsy shows bile ductular proliferation, mixed inflammatory infiltrates, and eventually periductal sclerosis affecting the interlobular bile ducts. Biliary cirrhosis may occur in older children. Treatment with ursodeoxycholic acid (UCDA) appears to be of value in patients with milder MDR3 missense mutations and residual biliary phospholipid secretion. Enrichment of bile with this hydrophilic bile acid reduces cytotoxic injury to hepatocytes and bile ducts and stimulates bile flow. Other patients progress to end-stage liver disease at a variable rate and require liver transplantation.

Inborn Errors of Bile Acid Metabolism

Nine inborn errors of bile acid metabolism have been described that have different clinical phenotypes. Defects in modification of steroid ring of cholesterol are most likely to produce severe cholestasis and liver disease, whereas defects in side chain modification lead to neurological dysfunction, fat-soluble vitamin malabsorption, and milder liver disease (Table 205.2).

Primary defects in enzymes mediating bile acid biosynthesis may present with cholestasis and sometimes liver failure in the neonate.

An enzymatic block in bile acid synthesis leads to a lack of primary bile acids critical for generating bile flow and the concomitant accumulation of unusual toxic bile acids and metabolites in the hepatocyte. However, in contrast to other cholestatic disorders, impaired synthesis of bile salts is not associated with either pruritus or elevated serum bile salt concentrations because the normal end products are not synthesized. Indeed, measurement of serum bile acid concentrations by standard clinical assays shows paradoxically low to absent primary serum bile acids in the face of severe cholestasis. The serum γ-glutamyl transpepsidase concentration is often normal. A high index of suspicion for these disorders needs to be maintained because their features are variable. The possibility of a primary abnormality in bile acid biosynthesis should be entertained in any child with chronic cholestasis or hepatitis of obscure etiology. Screening for these defects requires specialized testing by liquid secondary ionization mass spectrometry of urine. Additional information is derived from gas chromatography–mass spectrometry of urine, serum, and bile. Genetic diagnosis of some disorders is available.

Prompt diagnosis of an inborn error of bile acid metabolism is essential because several of these disorders can be treated with oral bile acid replacement. Treatment with the primary bile acid, cholic acid, has been particularly successful in patients with the more common defects,

Table 205.2
Inborn errors in bile acid metabolism associated with neonatal cholestasis

Enzyme defect	Phenotype
3β-hydroxy C_{27} steroid oxireductase	Severe, progressive cholestasis.
Δ*-3-oxosteroid 5β reductase	Severe, progressive cholestasis, liver failure
Sterol 27-hydroxylase	CTX, neonatal cholestasis
Oxy 7α-hydroxylase	Hyperoxysterolemia, neonatal liver failure
2-methyl-CoA-racemase	Adult sensorimotor neuropathy, neonatal liver disease

3β-hydroxy-C27-steroid oxidoreductase deficiency and Δ4-3-oxosteroid 5β-reductase deficiency. Cholic acid provides the primary bile acid required to generate bile flow and to downregulate the production of toxic bile acid precursors by feedback inhibition at the level of the rate limiting enzyme 7α-hydroxylase. Ursodeoxycholic acid that is commonly used in other forms of cholestasis is ineffective because it does not inhibit bile acid synthesis. Therapy must be continued life long.

Medical Management of Chronic Cholestasis

In the infant with chronic, and sometimes progressive, cholestatic liver disease, efforts should be directed toward promoting growth and development and minimizing discomfort.

As a result of impaired intraluminal long-chain triglyceride lipolysis, solubilization and absorption leading to steatorrhea, failure to thrive is common in children with cholestasis. Medium-chain triglycerides (MCTs) do not require prior bile salt solubilization for their absorption, and thus can provide needed calories when administered in one of several commercial formulas or as an oil supplement. However, it is important to recognize that essential fatty acid deficiency can develop if MCT is the only source of dietary fat.

Fat-soluble vitamin deficiencies can result in significant morbidity, and might largely be prevented in the cholestatic child. Metabolic bone disease, manifesting as rickets and pathologic fractures, can occur from vitamin D deficiency.

Vitamin D supplementation as D2 (5,000 IU/day) may be required. In patients with severe cholestasis, supplementation with 1,25 (OH) 2 (Calcitriol) at a dosage of 0.05–0.2 microgram/kg/day should be administered. This requires monitoring (including 1,25 (OH) 2 levels) because there is no physiologic regulation of this compound. Supplements of elemental calcium (50–100 mg/kg/day) and phosphorous (25–50 mg/kg/day) may also be required.

Vitamin A deficiency may manifest as xerophthalmia, night blindness, and thickened skin. Oral supplements of 5,000–25,000 IU/day should be administered.

Coagulopathy related to vitamin K deficiency may be treated with an oral water-soluble supplement twice weekly (2.5–5 mg) up to a daily dose of as much as 5 mg. Intramuscular injections of vitamin K may be required in children with advanced liver disease.

A degenerative neuromuscular syndrome characterized by areflexia, ophthalmoplegia, cerebellar ataxia, peripheral neuropathy, and posterior column dysfunction occurs in children with chronic deficiency of vitamin E. Onset can be observed within the first 2 years of life. Since serum vitamin E levels may be spuriously elevated in the presence of hyperlipidemia, the serum vitamin E/total serum lipids ratio (deficiency in a child <12 years old indicated by a ratio <0.6) is used in monitoring the vitamin E status. Since the infant may fail to respond to even massive doses of standard vitamin E preparations (up to 150–200 IU/kg/day), therapy with a water-soluble form of vitamin E, D-alpha-tocopheryl polyethylene glycol-1000 succinate (TPGS) (15–25 IU/kg/day) should be initiated. The polyethylene glycol-1000 in this preparation will also promote the absorption of other fat-soluble vitamins if administered at the same time. Significant discomfort may be a consequence of xanthomas and pruritus. Pruritis may be observed by 3 months of age. Regression of the symptoms may follow efforts to increase the conversion of cholesterol to bile acids, reducing the regurgitation of biliary constituents into the systemic circulation, and enhancing the elimination of bile acids, cholesterol, and putative pruritogenic substances. The success of most therapies depends on the presence of patent bile ducts, which allow bile acids and other biliary constituents to reach the gut lumen.

The nonabsorbable anion-exchange resin, cholestyramine, may be used to bind bile acids, cholesterol, and presumably other potentially toxic agents in the intestinal lumen. The agent is often effective in lowering serum lipid levels and in binding of substances involved in the pathogenesis of pruritus. A dose of 0.25–0.5 g/kg/day is given before breakfast or in divided doses before meals for relief of severe pruritus and xanthomas. However, cholestyramine is relatively unpalatable and may cause intestinal obstruction from inspissation of the drug and a hyperchloremic acidosis. The antibiotic rifampicin (10 mg/kg/day, 300 mg maximum), through undefined mechanisms and the choleretic bile acid ursodeoxycholic acid (10–20 mg/kg/day), may be used for the treatment of pruritis. Biliary diversion has been used as a successful alternative to relieve intractable pruritus in some patients with intrahepatic cholestasis.

206 Alpha-1 Antitrypsin Deficiency

H. Hesham A-Kader · Fayez K. Ghishan

Alpha-1 antitrypsin (α_1-AT) deficiency is the most common genetic cause of liver disease. The inheritance of α_1-AT deficiency follows an autosomal recessive pattern. It affects 1–1,600 to 2,000 live births in North Americans and the European population, respectively, but is less common in other ethnic groups.

α_1-AT is a glycoprotein synthesized primarily in the liver and to a lesser extent by other tissues, including macrophages, renal tubular, and small intestinal epithelial cells. It functions as a serine protease inhibitor with its main target being leukocyte elastase. The most common form of the disease, P_iZZ, results in the production of abnormal α_1-AT. Only a small proportion of patients with α_1-AT deficiency will develop clinically significant liver disease but it is the main cause of emphysema in adults. In addition to lung and liver disease, several disorders have been reported in association with α_1-AT deficiency including systemic vasculitis, interstitial fibrosis in patients with rheumatoid arthritis, relapsing panniculitis, multiple sclerosis, peripheral neuropathy, and intracranial aneurysms.

Classification of Human α_1-AT Variants

The gene encoding for α_1-AT has been localized to the q 31–32.2 locus on the long arm of chromosome 14. This locus is termed P_i (protease inhibitor). At least 75 genetic structural variants of α_1-AT have been identified based on their different mobilities on acid starch gels. The variants are assigned a letter using alphabetical order from high to low migration rates. For example, the most common normal α_1-antitrypsin haplotype are members of the M family because these variants migrate to the M isoelectric point. On the other hand, patients with the most common severe deficiency have an α_1-AT variant that slowly migrates to the Z isoelectric point.

Variants of α_1-AT associated with serum concentrations and functional activity in the normal range are classified as normal allelic variants, and include M_1, M_2, M_3, and X. Variants of α_1-AT associated with a reduction in serum concentration or functional activity of α_1-AT are classified as deficiency variants and include S, M_{Duarte}, and Z. Thus, patients with liver disease usually have the P_iZZ phenotype in which the abnormal α_1-AT is synthesized in hepatocytes but not secreted at a normal rate. Clinically important phenotypes include P_iMM, P_iMZ, P_iMS, P_iSZ, and P_iZZ – these correlate with total serum α_1-AT concentrations of 100%, 60%, 45%, less than 40%, and 15% of normal, respectively. Significant hepatic and pulmonary disease is usually associated with serum α_1-AT concentrations less than 40%. Variants of α_1-AT in which α_1-AT is absent from the serum are classified as null allelic variants and include $Null_{Granite\ Falls}$ and $Null_{Hong\ Kong}$. These variants, when inherited with other null variants or with deficiency variants, are associated with the development of emphysema but not liver disease.

Pathogenesis

α_1-AT functions as a serine protease inhibitor (serpin), and its predominant inhibitor is neutrophil elastase. Similar to other proteins in the serpin family of protease inhibitors, α_1-AT undergoes conformational change after encountering elastase which cleaves the reactive center of α_1-AT allowing marked structural change in α_1-AT, which irreversibly destroys its structural integrity promoting its degradation.

The most common α_1-AT mutant molecule, PiZ, results from a single amino acid substitution of lysine for glutamate at position 342 in the coding sequence. The mutation promotes spontaneous polymerization in the hepatocyte through insertion of the reactive center of one protein into the β-sheet of another, known as "loop-sheet" insertion and therefore polymers of α_1-AT protein are retained in the endoplasmic reticulum of the hepatocyte due to failure of the secretory process.

Not all patients with PiZZ patients develop liver disease, which suggests that other factors are involved in the pathogenesis of the disorder. One possible mechanism is that susceptible individuals may have delayed intracellular degradation of the mutant protein, rather than its accumulation in the endoplasmic reticulum. It has been suggested that delay in degradation of the mutant protein may result of abnormalities in calnexin, a protein that interacts with the mutant α_1-AT protein in the endoplasmic reticulum.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_206,

While liver injury results from retained alpha α_1-AT glycoprotein in the endoplasmic reticulum, the mechanisms of lung injury are different. Lung damage occurs as a result of uninhibited proteolytic changes of the connective tissue secondary to low concentration of circulating alpha 1-antitrypsin.

Clinical Manifestations

One of the intriguing facts about this disease is the variable presentation and significant variation in outcome even in members of the same family. These observations are true for both P_iZZ disease and disease caused by other variants.

Hepatic Disease in Infancy and Childhood

A picture regarding the varied natural history of P_iZZ disease in infancy and early childhood was first provided by landmark studies in Swedish infants. One hundred and twenty two children with P_iZZ α_1-AT deficiency and 48 with P_iSZ α_1-AT deficiency were identified and followed prospectively till the age of 8 years. Fourteen patients (12%) of infants with the P_iZZ phenotype presented with neonatal jaundice. Seven percent had clinical evidence of liver disease in infancy but by 6 months of age they had clinically recovered. The remaining P_iZZ infants were initially clinically normal, but 47% had elevated liver enzymes at 3 months of age. Thus, 64% of P_iZZ infants were found to have clinical or laboratory evidence of hepatic disease. The outcome for children with liver disease is variable. Around 25% will persist in having abnormal liver function tests and may develop cirrhosis rapidly and die from hepatic complications. Approximately 25% will have minimal liver abnormalities, but will have slow progression to cirrhosis. Another 25% will have minimal liver dysfunction and fibrosis, and will live to adulthood. Another 25% will recover from the initial insult and return to normal liver function.

Occasionally, chronic liver disease or cirrhosis can be identified in older children without a history of neonatal liver disease. As many as 50% of the children presenting with cirrhosis due to α_1-AT deficiency have no antecedent history of neonatal disease. Hepatomegaly is a common presenting finding while splenomegaly is usually seen in those presenting with decompensated advanced cirrhosis. Some patients may also present with vitamin K deficiency manifesting as coagulopathy especially in patients who did not receive vitamin K injection at birth and breast-fed babies. Coagulopathy may result in umbilical bleeding and bruising in the first few days of life or may present later with intraventricular hemorrhage.

Hepatic disease in α_1-AT deficiency is more commonly seen in children than in adults. In adults, premature pulmonary emphysema is the most common presentation. Pulmonary emphysema in α_1-AT deficiency is essentially an adult disease. There is evidence of hyperactive airway disease in 3–8% of children with α_1-AT disease. However, several cases of chronic hepatic disease and cirrhosis in the presence and absence of emphysema have been reported in adults with α_1-AT deficiency. Hepatocellular and cholangiocellular carcinomas are strongly linked to α_1-AT deficiency in adult patients. Thus, similar to tyrosinemia, α_1-AT deficiency can be viewed as a potentially premalignant metabolic liver disease.

Diagnosis of Liver Disease in α_1-AT Deficiency

The diagnosis of α_1-AT deficiency is suggested by low-level α_1-AT serum level. However, one should bear in mind that α_1-AT is an acute phase reactant and can be falsely elevated in association with inflammatory processes or decreased in patients with protein-losing enteropathy. The diagnosis is usually established by α_1-AT phenotype determination using isoelectric focusing or agarose electrophoresis at acid pH.

It is also now possible to detect specific α_1-AT variants by amplification of genomic DNA using polymerase chain reaction techniques.

The diagnosis is also suspected from the characteristic periodic acid-Schiff (PAS) positive, diastase-resistant globules found on histologic sections, in the endoplasmic reticulum of hepatocytes.

Biochemical abnormalities demonstrate hepatocellular and obstructive patterns with elevation of aminotransferases, alkaline phosphatase, and bilirubin. Hepatobiliary scintigraphy may show decreased excretion of the dye into the intestine. Patients may also show signs of coagulopathy secondary to vitamin K deficiency resulting from malabsorption due to cholestasis or due to impaired hepatic synthetic function in subjects with advanced disease.

Antenatal diagnosis is feasible by chronic villous sampling using synthetic oligonucleotide probes specific for the M and Z genes or by restriction fragment length polymorphism.

Histopathologic Findings

Patients with α_1-AT deficiency characteristically show diastase-resistant, periodic acid-Schiff (PAS)-positive

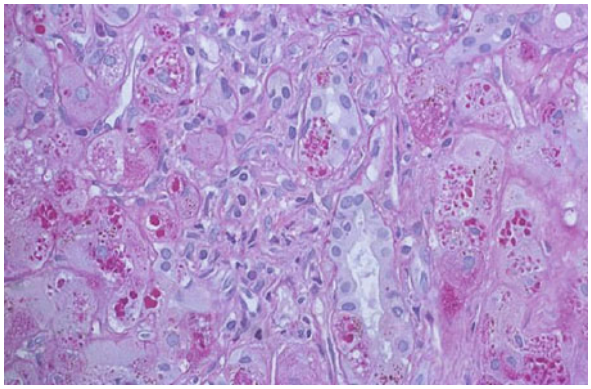

Figure 206.1
Characteristic diastase-resistant, periodic acid-Schiff (PAS)-positive globules in the cytoplasm of the hepatocytes in a patient with alpha-1-antitrypsin deficiency

globules in the cytoplasm of periportal hepatocytes (*Fig. 206.1*). These globules are found in P_iZZ patients but have been recognized in heterozygote variants as well as in patients without Z allele because of M variant associated with accumulation of hepatocellular α_1-AT. These globules have been shown by immunoperoxidase technique, to be misfolded alpha-1-antitrypsin. These inclusion bodies should be differentiated from the similar centrilobular globules seen as a result of sinusoidal congestion and anoxia.

In addition to the characteristic globules, newborns commonly show cholestasis with portal tract expansion by fibrous tissue, marked biliary duct proliferation, and very few inflammatory cells. Intrahepatic biliary hypoplasia has been seen in some patients, while classic giant cell neonatal hepatitis has been recognized in others.

Micronodular or macronodular cirrhosis is seen in older children and adults, although well-established cirrhosis has been documented in some newborns.

Therapy

Patients with α_1-AT deficiency should refrain from smoking and avoid secondary smoke in order to slow the progression of lung emphysema.

Children with cholestatic liver disease should be supplemented with fat-soluble vitamins and treated for pruritus and ascites with diuretics and paracentesis as indicated.

Pharmacologic therapy with stanzol and danazol, drugs effective in other serine proteinase inhibitor deficiencies, has failed to show substantial improvement in α_1-AT serum levels.

Patients with progressive emphysema have been treated with infusions of purified plasma α_1-AT in limited clinical trials, a process known as augmentation therapy. This therapeutic modality has been associated with elevation of serum levels of alpha 1-antitrypsin in the absence of significant decrease of FEV1 (forced expiratory volume in 1 s). This form of therapy is not being considered for patients with liver disease because deficient serum levels of α_1-AT are not thought to be the cause of liver disease (see "Pathogenesis").

Gene augmentation has been conducted in animal models using adenovirus-associated, recombinant gene therapy and demonstrated successful gene transfer to peripheral skeletal muscle with elevation of serum alpha 1-antitrypsin concentration. However, concomitant expressions of the mutant allele would restrict benefit from this form of therapy to patients with emphysema.

In patients with end-stage liver disease, liver transplantation may be the only left consideration. Although α_1-AT deficiency is a rare indication for liver transplantation among adults in pediatric patients, liver transplantation for metabolic liver disease is second only to biliary atresia as the most common indication for transplant. α_1-AT deficiency is the primary metabolic liver disease leading to a transplant in the pediatric age group. The outcome of liver transplantation is excellent in children with α_1-AT deficiency, with 3-year survival rates approaching 85%. Without transplantation poor prognostic variables include jaundice lasting more than 6 weeks, higher aminotransferases at presentation, and severe bile duct proliferation and stage of fibrosis on liver biopsy. Transplant recipients acquire the donor phenotype and have normalization of alpha 1-antitrypsin levels. However, the effect of liver transplantation on the lung disease is not known.

Few patients with metabolic defects of liver function have been treated with hepatocyte transplantation including patients with urea cycle disorders, ornithine transcarbamylase deficiency, Crigler–Najjar syndrome, and α_1-AT deficiency. Hepatocyte transplantation at the time being is still considered an experimental procedure but may prove to be an effective therapeutic modality in the future for the treatment of patients with metabolic liver disease or as a bridge for those waiting for liver transplantation.

Future therapeutic strategies may include the development of chemical chaperones, aiming at blocking the aberrant β-stand linkage with competing peptides and targeting small molecules to an allosteric cavity. None has yet been shown to be effective in humans.

207 Inherited Deficient Conjugation of Bilirubin

Dena Nazer · Hisham M. Nazer

Hyperbilirubinemia results from three major mechanisms: excessive bilirubin production (e.g., hemolysis), impaired hepatic handling of bilirubin (e.g., inherited disorders and hepatitis), or defective biliary outflow (e.g., intrahepatic or extrahepatic biliary obstruction). Unconjugated hyperbilirubinemia may present as an isolated finding in the newborn infant without evidence of overt hemolysis or structural liver disease. This chapter focuses on genetic disorders associated with unconjugated hyperbilirubinemia in childhood. Other conditions associated with hemolysis in the newborn or later childhood are discussed elsewhere. It is not uncommon to have an isolated unconjugated hyperbilirubinemia in symptom-free individuals. There is no generally agreed-upon approach to the evaluation of such affected children. The child is considered to have unconjugated hyperbilirubinemia if the direct-reacting bilirubin comprises less than 15–20% of the total serum bilirubin.

Unconjugated hyperbilirubinemia is characterized by the absence of bile in the urine. The total serum bilirubin in normal infants is usually less than 1.5 mg/dL (25 μmol/L), with the conjugated or direct reacting portion less than 0.5 mg/dL (7 μmol/L). The plasma concentration of unconjugated bilirubin reflects a balance between bilirubin production and hepatic bilirubin clearance. Jaundice appears in children and adults when the serum bilirubin concentration exceeds 2 mg/dL (34 μmol/L).

Neonatal hyperbilirubinemia including physiologic and pathologic neonatal jaundice as well as hemolytic conditions are discussed in other sections. In this section, two genetically inherited disorders presenting with unconjugated hyperbilirubinemia will be discussed: Crigler–Najjar syndrome (CNS) ((a) Type I glucuronyl transferase deficiency, (b) Type II glucuronyl transferase deficiency) and Gilbert syndrome.

Crigler–Najjar Syndrome

Crigler–Najjar (CN) syndrome is a well-recognized congenital familial nonhemolytic jaundice associated with high level of unconjugated bilirubin due to deficiency or almost complete absence of the hepatic microsomal bilirubin uridine 5-diphosphate glucuronosyltransferase (UDPG-T) activity. Bilirubin UDPG-T is a membrane-bound enzyme system concentrated in the lipid bilayer of the endoplasmic reticulum in hepatocytes and cells of the intestine, kidneys, and other tissues.

Crigler–Najjar syndrome (CNS) results from a mutation in one of the five exons of the gene coding for the enzyme bilirubin-UDP-glucuronosyl transferase by exon 1*1 and exons 2–5 of the UDP-glucuronosyl transferase 1 locus, the bilirubin glucuronidating isoform of UDP-glucuronosyltransferase.

This syndrome was first recognized by Crigler and Najjar (1952) in their report of six infants of three related families with severe unconjugated nonhemolytic jaundice. Arias et al. subdivided the disease into two types (1 and 2) based on the responsiveness of serum bilirubin to phenobarbital therapy. However, the clinical differentiation of both types can be difficult, especially in early infancy. It has even been suggested that both types are merely different expressions of one disease.

Crigler–Najjar Syndrome Type1

Definition and etiology: This type constitutes the more serious form of CN syndrome, with severe jaundice in the first few days of life and potential risk of developing kernicterus in early infancy. The mode of inheritance of this type of CN syndrome with almost complete absence of UDPG-T activity in the liver is in an autosomal recessive fashion. Heterozygotes are phenotypically normal with normal serum bilirubin.

Reports have suggested a considerable heterogeneity with regard to the expression of UDPG-T isoenzymes among CN type 1 patients. Bilirubin UDPG-T activity arises from a gene complex of unusual structure located on human chromosome 2. Affected patients with this type of CN syndrome do not respond to phenobarbital therapy

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_207,

and may require repeated exchange transfusions followed by long-term phototherapy to prevent the development of neurologic complications.

Clinical Manifestations

In spite of the severe jaundice with very high levels of serum unconjugated bilirubin, there is no evidence of hemolysis or liver disease. The newborn usually appears normal at birth apart from jaundice, which progresses rapidly to reach a high level that warrants exchange transfusion in spite of phototherapy. The serum bilirubin is recognized in this group of patients to reach a very high level by the end of the first week, reaching as high as 45 mg/dL (765 μmol/L) or even higher.

Kernicterus is a neurologic syndrome resulting from the deposition of unconjugated bilirubin in the basal ganglia and brainstem nuclei. It is an almost universal complication of CN type 1 and is first noted in the early neonatal period. Initial symptoms include lethargy, poor sucking, and loss of Moro reflex. Infants then develop respiratory distress, diminished tendon reflexes, opisthotonos, convulsions, and spasms.

Treatment with exchange transfusions and phototherapy should be intensified at the early stage to ensure a relatively safe level of unconjugated bilirubin to prevent the development of kernicterus. There is usually a family history of consanguinity or similarly affected siblings.

Diagnosis

The diagnosis is usually suspected in view of the family history, severe jaundice with absence of hemolysis, or evidence of liver disease. History of exchange transfusions in the index case and/or other siblings adds further to the consideration of such diagnosis. Liver function tests are usually normal.

Persistence of unconjugated hyperbilirubinemia at a level higher than 20 mg/dL, (340 μmol/L) after the first week of life in the absence of hemolysis or evidence of liver disease should suggest the diagnosis. Bilirubin concentration in the bile is less than 10 mg/dL (normal concentration 50–100 mg/dL) and there is no bilirubin glucuronide. Parents of affected children have normal serum bilirubin concentrations, but have partial defects in conjugation detected when glucuronide formation is measured.

The diagnosis is confirmed by percutaneous liver biopsy, which reveals normal histology apart from occasional bile plugs in the bile canaliculi (*Fig. 207.1*). Intrahepatic cholestasis may be detected in some cases, which could account for the occasional slight elevation in liver enzymes. The measurement of hepatic glucuronyl transferase activity in the liver specimen establishes the diagnosis. DNA diagnosis is also available.

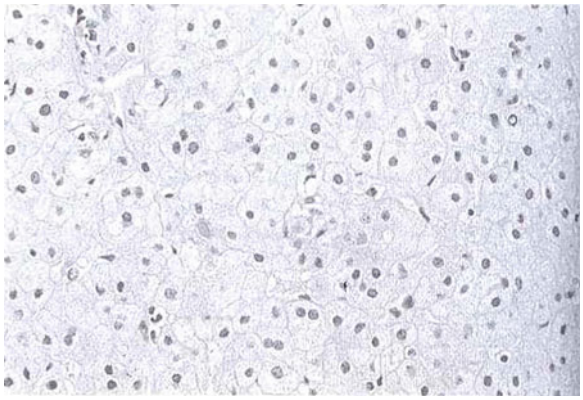

Figure 207.1
Percutaneous liver biopsy (hematoxylin and eosin) from an infant with Crigler–Najjar syndrome type 1; the liver histology is normal without fibrosis but with only few bile plugs

Treatment

Affected patients with CN syndrome type 1 do not respond to phenobarbital therapy. They require repeated exchange transfusions followed by long-term phototherapy to prevent the development of neurologic complications. It is crucial that infants are recognized and treated promptly to prevent neurological sequelae which if untreated are lethal. Exchange transfusions may be required in the neonate with CN syndrome type 1 to ensure a safe level of unconjugated bilirubin (<20 mg/dL) in spite of continuing phototherapy for up to 18 h/day. Later on, the child may settle on fewer hours of phototherapy, especially as the child grows older and cannot accept as many hours of phototherapy. Double phototherapy may be required to achieve this with allowances for fewer hours of phototherapy. It is important to recognize the adverse side effects of long-term phototherapy such as impaired weight gain, developmental delay, and possible psychological disturbances.

Oral cholestyramine may be added to therapy to bind the bilirubin in the gut. Other adjunct therapy

includes calcium phosphate and agar. These agents bind photobilirubin products and interfere with the enterohepatic bilirubin circulation.

Liver transplantation is the only guaranteed form of therapy to save the child the risk of kernicterus. As phototherapy becomes less effective and practical with age, liver transplantation is expected to be performed on young patients with CN syndrome type 1 prior to the development of neurologic manifestations. Despite long-term phototherapy, adolescents and adults with CN syndrome type 1 almost invariably develop some neurologic damage secondary to chronic unconjugated hyperbilirubinemia.

Orthotropic liver transplantation has been performed on patients with CN syndrome type 1 since 1980. It has proved its efficacy in curing such patients and improving their lifestyle with an excellent survival rate. Auxillary partial orthotopic liver transplantation has proved to be technically feasible and it does provide adequate hepatocyte mass to correct the underlying metabolic abnormality in CN syndrome. Since the application of living-related liver transplantation, patients with CN syndrome are saved the long delay of waiting for transplantation. In addition, with increasing demands for liver grafts, affected patients have also benefited from split liver transplantation and also from orthotropic auxiliary liver transplantation by leaving the recipient right lobe in place. This latter approach could be repeated if necessary without the risk of whole-liver replacement. It also ensures less dependence on the graft function should the graft fail.

Hepatocyte transplantation is a promising treatment for several liver diseases and can also be used as a "bridge" to liver transplantation in cases of liver failure.

Over the last decades ex vivo and in vivo gene therapy using viral and nonviral vectors has been used to correct hyperbilirubinemia in Gunn rats, the relevant animal model for CN syndrome. Several of these approaches resulted in long-term correction of serum bilirubin levels in this animal model. Future directions aim to translate this model into human clinical trials.

Crigler–Najjar Syndrome Type 2

This is a milder form of CN syndrome. CNS type 2 is caused by a single base pair mutation leading to a decreased but not totally absent enzyme activity. In these patients, the enzyme remains responsive to phenobarbital induction therapy and their bile contains low amounts of bilirubin mono- and diglucuronides. Serum unconjugated bilirubin does not usually exceed 20 mg/dL (340 μmol/L) and responds satisfactorily to phenobarbital therapy. The inheritance of CN syndrome type 2 is still unclear. Both autosomal dominant transmission with variable penetrance and autosomal recessive transmission have been reported. Hepatic UDPG-T activity is usually deficient but not absent. The majority of patients survive into adulthood.

Clinical Features

The baby is normal at birth with no evidence of liver disease. Jaundice develops later in early infancy but it is usually mild. However, kernicterus has been reported in CN syndrome type 2.

Diagnosis

A positive family history supports further the clinical suspicion of this entity. A provisional diagnosis is made on the presence of unconjugated hyperbilirubinemia, and family history with no evidence of hemolysis or liver disease. Liver function tests are usually normal.

The diagnosis is confirmed by enzymatic assay on liver tissue obtained through a percutaneous liver biopsy. Hepatic UDPG-T activity is diminished but not absent. Liver histology is also normal.

The satisfactory response to phenobarbital therapy supports further the diagnosis.

Treatment

Phenobarbitone 5–10 mg/kg body weight per day results in a satisfactory reduction of the elevated serum unconjugated bilirubin. It is only rarely that patients with confirmed CN syndrome type 2 require exchange transfusions or long-term phototherapy.

Treatment of patients with CN syndrome is not limited to phototherapy and/or phenobarbital therapy. Other recognized therapies include plasmapheresis, hemoperfusion, cholestyramine, and oral agar. Sn-protoporphyrin, a heme oxygenase inhibitor, is considered to prevent the increase in serum bilirubin level. This medication and more recently, tin-mesoporphyrin are recognized modes of therapy adjuvant to phototherapy in the management of patients with CN syndrome type 1 to prevent heme catabolic breakdown to bilirubin.

Genetic Research

The application of the newly developed intragenic polymorphic probes may prove useful in carrier detection and prenatal/presymptomatic diagnosis.

Should enzyme replacement therapy become available, patients with CN syndrome may be cured early in life without liver transplantation.

Gilbert Syndrome

Gilbert syndrome is characterized by a mild form of unconjugated hyperbilirubinemia with serum bilirubin rarely reaching a level higher than 5 mg/dL (85 μmol/L). The familial nature of this disorder was first recognized by Gilbert and Lereboullet in 1901. There is usually no evidence of hemolysis or liver disease. The condition is often but not always familial. Liver function tests are also normal. Liver biopsy will only be necessary if additional abnormalities of liver function tests are found. There may be impaired hepatic uptake of bilirubin.

The mode of inheritance is autosomal dominant with incomplete expression. The condition may result from a reduction in hepatic bilirubin clearance to about one third of the normal value. The percentage of bilirubin disconjugates in bile is reduced.

Clinical Features

Affected patients with Gilbert syndrome may present with vague abdominal symptoms of pain and discomfort in association with mild fluctuating jaundice. It may also be associated with asthenia, dyspepsia, and lethargy. There is no real explanation to account for such varied symptoms in this disorder.

Diagnosis

A history of mild fluctuating jaundice with elevated level of serum unconjugated bilirubin together with the absence of hemolysis or evidence of liver disease should alert the physician to such diagnosis. This is further supported by normal liver function rests. The diagnosis is confined by the documentation of deficient enzymatic assay of UDPG-T activity on percutaneous liver biopsy.

Treatment

Gilbert syndrome is a mild benign condition of fluctuating jaundice. There is no morbidity directly related to this disorder. The condition is recognized to respond fairly well to phenobarbital therapy in a dose of 5–10 mg/kg of body weight per day.

208 Congenital Hepatic Fibrosis

Dena Nazer · Hisham M. Nazer

Congenital hepatic fibrosis (CHF) is a rare hereditary disorder characterized by hepatic fibrosis, intrahepatic portal hypertension, esophageal varices, and well-defined histologic changes on liver biopsy. CHF is also associated with cholangitis and impairment of renal functions, usually due to an autosomal recessive polycystic kidney disease (ARPKD), which is described more frequently in neonates and infants and characterized by cystic and tubular dilatation affecting both cortical and medullary portions of the kidney.

CHF has also been reported in association with autosomal dominant polycystic kidney disease (ADPKD). The disease is reportedly inherited in an autosomal recessive fashion. However, about 50% of cases occur sporadically. CHF is known to occur in association with a range of both inherited and noninherited disorders with multi-organ involvement as a result of ductal plate malformation. CHF has been reported also in association with other conditions as choledochal cyst and nephrolithiasis.

Cystic disease of the liver and kidney has been recognized for centuries. The term "congenital hepatic fibrosis" with its varied clinical presentation was first recognized in 1960 (Dobbs RH) and described further in 1961 by Kerr et al.

Clinical Manifestations

The first clinical manifestations in most patients with CHF are signs and symptoms related to portal hypertension especially splenomegaly, and varices, often with gastrointestinal bleeding. Most affected neonates and young infants with predominant kidney disease die of renal failure within the first year of life. When hepatic lesions dominate the clinical expression of the disease, the affected child may remain asymptomatic with hepatomegaly involving especially the left lobe. The hepatic disease progresses to develop portal hypertension associated with splenomegaly and esophageal varices. Portal hypertension in CHF has been attributed to the hypoplasia or compression of the portal vein radicles in the fibrous bands. Abdominal pain is rare, but when present, it is usually localized to the right upper quadrant. Some patients may remain asymptomatic until late childhood or even adulthood.

Coexisting renal lesions may also remain asymptomatic until early adulthood. The typical lesions of congenital hepatic fibrosis have also been reported in adults with the autosomal dominant form of polycystic kidney disease.

The majority of fibropolycystic hepatic disorders are thought to result from the same embryonic defect, the so-called ductal plate malformation. Associated conditions include choledochal cysts, medullary sponge kidney, ARPKD and ADPKD, and cholangiocarcinoma.

On physical examination, the liver is firm on palpation with a smooth or finely nodular surface. The liver edge is sometimes irregular, suggesting cirrhosis.

Diagnosis

Congenital hepatic fibrosis is a rare autosomal recessive disorder that is diagnosed essentially by finding a firm liver with rather classic histologic changes in a good size liver biopsy. Microscopically, *ductal plate malformation* (DPM) is always found, and the involved bile ducts are in communication with the rest of the biliary system.

The diagnosis of CHF is dependent on histologic findings of liver biopsy preferably obtained through minilaparotomy. Percutaneous liver biopsy is not recommended because the pathologic lesions may not be uniform throughout the liver. Liver biopsy reveals a variable degree of periportal fibrosis and irregularly shaped proliferating bile ducts lined by normal cuboidal epithelium. Unlike cirrhosis, hepatic lobules are usually normal with normal hepatocyte morphology. Liver biopsy is essential in confirming the diagnosis of CHF and differentiating it from similar clinical conditions as idiopathic portal hypertension and early liver cirrhosis.

The liver histology is not uniform and does shows extensive hepatic fibrosis. The widened fibrous bands in the portal tract contain increased number of ectatic and dysplastic branches of the interlobular bile ducts. The irregularly shaped proliferating bile ducts are lined by normal cuboidal epithelium. The hepatic lobules are usually normal (*Fig. 208.1*). Cholestasis is rarely observed except when associated with cholangitis.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_208,

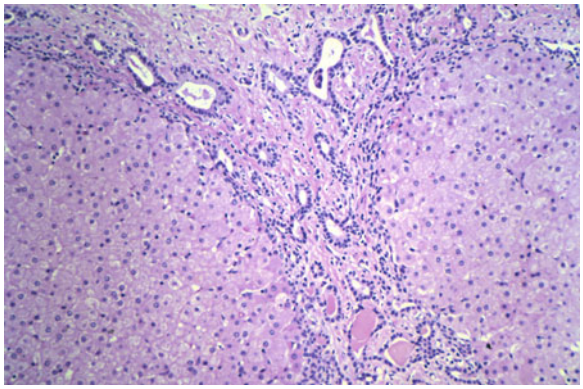

Figure 208.1
Liver biopsy in congenital hepatic fibrosis (hematoxylin and eosin) shows widened portal tract with bands of fibrous tissue that separate areas of normal hepatic parenchyma. Within the fibrous bands are multiple irregularly shaped, narrow, and elongated spaces lined with bile duct epithelial cells

The typical histopathologic changes in CHF are quite distinct from those with cirrhosis. Other findings include portal vein branch hypoplasia, degeneration of the bile duct epithelium, and mild cholestasis.

Liver function tests are usually normal, although serum alkaline phosphatase or y-glutamyl transpeptidase (GGT) may be elevated. Serum bilirubin, albumin, and prothrombin time are usually normal. Hypersplenism is manifested by thrombocytopenia and leukopenia.

In the presence of renal involvement, there is elevation of serum urea and creatinine. The intravenous pyelogram may be abnormal, showing alternation of radiodense and radiolucent streaks radiating from the medulla to the cortex.

Splenoportography may show an abnormality of the intrahepatic portal venous system characterized by duplication of the venous channels. Angiography further illustrates the details of the vascular anatomy, patency, as well as the extent of the variceal formation (*Fig. 208.2*).

Diagnosis is further supported by the recognized changes on ultrasonography or computed tomographic scan of the abdomen. Sonographic evaluation should include Doppler flow studies of the portal vasculature. Portal vein morphology should be evaluated in all patients with CHF since portal vein involvement may well result in more severe and complicated portal hypertension.

Ultrasonography is generally regarded as the first-line modality in the diagnostic process with its high utility, lack of radiation exposure, and its capability of detecting the parenchymal heterogenicity and the associated kidney abnormalities that strengthens its role in the diagnosis. Characteristic imaging findings are generally present and in progress so that they may well prove by time their efficacy to give as accurate a diagnosis as liver biopsy and thus save the affected child the risk of liver biopsy.

(a) Arterial phase shows narrow intrahepatic arteries (b) Venous phase shows tortuous veins within porta hepatis and dilated coronal veins (*arrow*) with esophageal varices

Clinical Course and Management

Congenital hepatic fibrosis is an infrequent cause of recurrent cholangitis. The disease might manifest in early infancy, late childhood, or in adulthood. The condition progresses to portal hypertension with the potential possibility for recurrent hemorrhages due to the development of esophageal varices. The course of the disease is largely

influenced by the recurrent episodes of gastrointestinal bleeding that are often well tolerated by the patient and are not usually followed by hepatic encephalopathy.

Portal hypertension is a common and serious sequela of CHF, the cause of which is suggested to be secondary to presinusoidal block. It has been reported that cavernous transformation of the portal vein, a congenital component of CHF, is an important causative factor of portal hypertension in affected patients.

Four clinical forms of CHF are recognized:

1. Portal hypertensive form: This is the most common type with periportal fibrosis and features of portal hypertension as described earlier.
2. Cholangitic form: This is manifested with cholestasis and recurrent cholangitis. It may be associated with Caroli syndrome.
3. Mixed form: This is characterized by both portal hypertension and cholangitic symptoms.
4. Latent form: This is recognized late in life and may even be diagnosed at autopsy.

CHF was recognized to be associated with varied clinical conditions far more than just renal anomalies such as infantile polycystic disease of the kidneys. Portal hypertension with congenital hepatic fibrosis may be the initial manifestation of ARPKD or ADPKD. Other associations include: gluten-sensitive enteropathy, congenital heart disease, pulmonary hypertension, intestinal lymphangiectasia, tuberous sclerosis, Caroli disease, pulmonary fibrosis, pancreatic fibrosis, and secretory diarrhea. CHF occurs in association with a range of both inherited and noninherited disorders, with multigorgan involvement. The exact correlation between those conditions and CHF warrants further appraisal.

It is important to recognize the presence of cholangitis and prevent its recurrence by appropriate surgical procedure. Transhepatic cholangiography is a safe and direct means of identifying this entity.

Treatment

There is no definitive treatment that could stop or reverse the pathological process in CHF. Antibiotics are prescribed in the presence of cholangitis. The role of antifibrotic therapy has shown some promising results in animal studies but not in human.

Early surgery with portacaval anastomoses may be required if repeated endoscopic sclerotherapy or variceal banding could not arrest the variceal bleeding. The incidence of hepatic encephalopathy post shunt surgery is low. Cholangiocarcinoma and amyloidosis have been reported as late squeal of CHF.

Liver transplantation is also considered in the management of CHF complicated by recurrent cholangitis or failure to respond to various medical and surgical therapeutic modalities with progressive hepatic dysfunction.

Prognosis

The majority of patients do well. The prognosis in CHF is expected to be good if bleeding from varices can be controlled. However renal failure limits the survival in those patients with renal involvement.

Caroli Disease

This disease was originally described by Jacques Caroli. It is characterized by nonobstructive saccular or fusiform dilatation of the intrahepatic bile ducts. The dilatations may involve a part or the whole of the liver. Though renal involvement has been described in Caroli disease as in congenital hepatic fibrosis, there is no associated hepatic fibrosis and portal hypertension.

There are two types of Caroli disease:

1. The rare variety (pure form) originally described by Caroli and characterized by segmental saccular and communicating intrahepatic bile duct ectasia, frequently associated with cholangitis and stone formation but without fibrosis. Recognized and fatal associated complications include cholangiocarcinoma, septicemia, and hepatic abscesses.
2. The more common variety, which is associated with congenital hepatic fibrosis. This entity is now referred to as Caroli syndrome. Bile duct dilatation is less prominent. Associated complications include esophageal varices, portal hypertension, and liver failure.

The disease is occasionally segmental and limited to one lobe, usually the left lobe of the liver. The renal abnormality in Caroli disease occurs in up to 25% of cases and includes both cortical cysts and features of medullary sponge kidneys. Caroli disease is sporadic, whereas Caroli syndrome is generally inherited in an autosomal recessive manner.

Therapy in Caroli disease is similar to that for CHF. However, Caroli disease may only require antibiotic therapy to combat the risk of cholangitis and in severe cases lobectomy of the affected lobe may have to be performed.

209 Metabolic Liver Disease

Fayez K. Ghishan

This chapter will deal with some of the more common inborn errors of metabolism that lead to hepatic dysfunction. This includes three inborn errors of carbohydrate metabolism: Galactosemia, hereditary fructose intolerance, and glycogen storage disease types I, III, and IV and VI. Tyrosinemia, a disorder of amino acid metabolism will also be reviewed.

Galactosemia

Galactose is the end product of hydrolysis of lactose. Galactosemia is a rare inherited defect in galactose metabolism transmitted by autosomal recessive inheritance. Three distinct disorders of galactose metabolism and several variant forms have been identified. These disorders are expressed as a cellular deficiency of one of the three enzymes in the metabolic pathway through which galactose is converted to glucose: galactose-1-phosphate uridyl transferase, galactokinase, and uridine diphosphate (UDP) galactose-4-epimerase. Each enzymatic defect results in a distinctive clinical presentation. Thus, the disease is now classified in terms of transferase deficiency Galactosemia, galactokinase deficiency Galactosemia, and epimerase deficiency Galactosemia.

Physiology of Galactose Metabolism

Galactose is a monosaccharide that is derived from the hydrolysis of lactose, the major sugar in breast milk and dairy products. Lactose is hydrolysed into glucose and galactose by the disaccharidase, lactase, present on the brush border membrane of enterocytes. Galactose is transported across the brush border membrane of enterocytes by means of the Na^+-dependent glucose-galactose transporter. Galactose is metabolized to glucose in a series of reactions as depicted in (*Fig. 209.1*).

Transferase Deficiency Galactosemia (Classic Galactosemia)

Molecular Basis of Disease

Transferase deficiency Galactosemia is an inborn error of metabolism resulting from deficiency of the human galactose-1-phosphate uridyl transferase enzyme. The cDNA that encodes the human transferase enzyme is 1,295 bases in length and encodes a 43,000 molecular weight protein. Most individuals with transferase deficiency have missense mutations, resulting in low or undetectable enzymatic activity. The most common transferase mutation identified in caucasean populations is an arginine for glutamine substitution at position 188 (Q188R), accounting for 60% of transferase deficiency mutations. S135L mutation (substitution of leucine for serine) is common in African-American patients. Several other mutations have been described suggesting that the variability in clinical outcome is a result of different mutations at the molecular level.

Multiple variants of transferase deficiency have become apparent since the advent of genetic screening for the disease. Three common homozygotic types exist:

1. Classic Galactosemia is autosomal recessive, and transferase activity is absent in red cells, hepatocytes, and presumably in other tissues. Asymptomatic heterozygotic carriers, on the other hand, exhibit 50% enzyme activity. The incidence of classic Galactosemia in the United States has been estimated to be 1 in 63,000 births.
2. The most frequently detected abnormality in neonatal screening is the compound heterozygous state consisting of allelic genes for classic Galactosemia and the Duarte variant (N314D substitution of aspartic acid for aspargine); presence of the Duarte variant is quite common affecting up to 15% of the general United States population.
3. The Negro variant has complete absence of transferase activity in erythrocytes, whereas the liver and intestine exhibit 10% of normal activity. Clinical manifestations of the Duarte and Negro variants range from complete lack of symptoms to symptoms similar to classic Galactosemia.

Recently, several heterozygotic forms of Galactosemia have been identified, including the Indiana, Rennes, Los Angeles, Chicago, and West German variants.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_209,

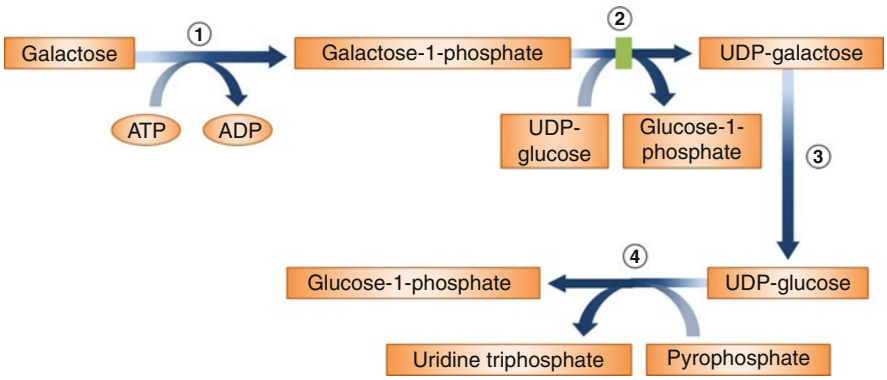

Figure 209.1

Clinical Manifestations

The clinical presentation of classic transferase deficiency Galactosemia varies in severity from an acute fulminant illness characterized by abdominal distention, vomiting, diarrhea, anorexia, and hypoglycemia following the first milk feeding to a subacute illness beginning within the first few days of life. Failure to thrive is the most common presenting symptom and occurs in almost all patients. Vomiting and diarrhea may occur in 95% of patients. Jaundice and hepatomegaly develop almost as frequently after the first week of life. Severe hemolysis may accentuate jaundice due to intrinsic liver disease. Prolonged conjugated hyperbilirubinemia is a common presenting symptom in infants with this form of Galactosemia. Therefore, urine screening tests for reducing sugars should be performed in all infants presenting with jaundice. Ascites may develop within 2–5 weeks after birth as a result of continued galactose ingestion and has been present in most infants who succumb to the disease.

Cataracts may develop early within the postnatal period, or they may be present at birth if the mother ingested generous amounts of dairy products in late pregnancy. These punctuate lesions may be so small that slit-lamp examination is required for visualization.

Signs of increased intracranial pressure and cerebral edema have also been observed as presenting features in transferase deficiency Galactosemia.

Escherichia coli sepsis at about 7–14 days of age occurs with a higher frequency in patients with classic Galactosemia compared to controls. It appears to be directly associated with continued galactose ingestion and subsequent inhibition of leukocyte bactericidal activity. As a result of these important clinical observations, neonates diagnosed with Galactosemia or *E. coli* sepsis should undergo further evaluation to rule out the alternate condition.

Mild symptoms of vomiting and diarrhea may be the only presenting symptom in infants with mild forms of the disease.

Lactose-free formulas have been increasingly accessible, and feeding trials with these products are often used in infants with recurrent vomiting and growth failure early in life. Since these are the most common presenting symptoms of Galactosemia, a child with the disorder may display improvement in symptoms without recognition of the underlying defect. In such cases, Galactosemia may remain undetected through the first several months of life until motor retardation, hepatomegaly, or cataracts develop.

Renal tubular acidosis with proteinuria, amino aciduria, glucosuria, phosphaturia, and bicarbonaturia may occur in some patients as part of other systemic manifestations.

Biochemical Basis of Disease

The metabolic defect in transferase deficiency (*Fig. 209.1*) results in toxic insults in galactosemic patients, primarily due to the accumulation of two metabolites: Galactose-1-phosphate, the metabolite which accumulates prior to the metabolic block, and galacticol, the product of an alternate pathway for galactose metabolism. Various organs are influenced differently by these two compounds.

Liver The cause of hepatic toxicity in transferase Galactosemia has not been fully elucidated. In affected persons, galactose ingestion results in elevated levels of galactose-1-phosphate, galacticol, and galactonate in the liver.

However, other findings suggest that one or more additional metabolites act singly or together to produce liver damage. For example, humans with galactokinase deficiency accumulate large amounts of galacticol but develop no liver damage. Moreover, evidence from rat models suggests that hepatic accumulation of galactose-1-phosphate does not result in liver damage.

Kidney The renal tubular dysfunction seen in transferase deficiency appears to result primarily from accumulation of galactose-1-phosphate in these tissues. Evidence for this arises from the observation that patients with galactokinase deficiency who characteristically excrete large amounts of galacticol do not develop renal impairment.

Lenticular Changes Changes in the lens seem to result primarily from galacticol accumulation in the lens. Poor diffusion of galacticol from lens tissue and subsequent increased osmotic pressure result in water accumulation and eventually to cataract formation.

Brain Neurotoxicity in Galactosemia has been attributed to changes in osmolality of brain tissue, abnormal synthesis of glycolipids, and inhibition of glucose uptake by the central nervous system due to elevated serum galactose levels.

Intestine Gastrointestinal symptoms such as vomiting and diarrhea following galactose ingestion are hypothesized to be secondary to effects on the central nervous system. This is suggested partly by the fact that galactose transport appears to remain normal in deficient patients.

Gonads Most galactosemic females have ovarian failure characterized by hypergonadotropic hypogonadism. This process appears to start postnatally, and appears to be related to galactose-1-phosphate toxicity. Interestingly, males do not appear to have gonadal atrophy.

Red Blood Cells Toxicity Toxicity to red blood cells in transferase deficiency appears to be secondary to galactose-1-phosphate toxicity.

Liver Histopathology in Galactosemia

The initial hepatic changes consist of cholestasis and extensive fatty infiltration. Bile duct proliferation and pseudoglandular proliferation of hepatic plates could occur very early in the course of the disease. With continuing hepatic damage, extensive fibrosis and progressive regenerative nodules replace the normal liver parenchyma and cirrhosis ensues.

Laboratory Findings and Diagnostic Studies

Aberrant laboratory findings in Galactosemia vary but may include elevations in blood and urinary galactose levels, hypercholeremic acidosis, hypoglycemia (occasionally severe and prolonged in nature), abnormal liver function tests, albuminuria, and amino aciduria.

Galactosuria with resulting positive urinary reducing substances occurs only intermittently during periods of substantial food intake and completely resolves within 3 days of intravenous feeding. Thus, diagnosis of Galactosemia may be overlooked if a urine test for reducing sugar is timed inappropriately. Typically, patients have a positive urine reducing substance by the clinitest (Benedict test) and a negative clinistex (glucose oxidase test) indicating a reducing sugar in the urine other than glucose. In contrast, the presence of urinary reducing sugars does not confirm the diagnosis since other conditions that impair blood galactose clearance such as severe liver disease may lead to galactosuria. In the first 2 weeks of life, some normal infants may excrete galactose in their urine. Moreover, fructosuria and lactosuria due to the absorption of intact lactose in patients with intestinal lactase deficiency also result in positive urinary sugars; the specific sugar may be identified by paper or gas-liquid chromatography. More recently, screening for galactosuria has been simplified by the availability of paper impregnated with galactose oxidase. Nevertheless, galactose restriction should be promptly instituted if no other dietary carbohydrate is identified as even limited exposure to a large quantity of galactose may produce brain injury from prolonged hypoglycemia.

Confirmation of the diagnosis should be made through direct measurement of transferase activity. This is based on quantitation of UDP-glucose before and after incubation of galactose-1-phosphate using added red-cell hemolysate as the enzyme source. Homozygous patients exhibit complete absence of enzyme activity. Heterozygous carriers typically display intermediate levels of enzyme activity. Multiple variants of Galactosemia have been identified and are more prevalent than classic (complete) transferase deficiency Galactosemia. Therefore, infants with 50% enzyme activity should undergo further tests to identify a specific variant of the disease. This may be achieved by starch gel electrophoresis of red blood cells to determine differing transferase mobilities.

Cloning of the cDNA encoding for the transferase enzyme as well as the observation that most galactosemic patients have a missense mutation allowed introduction of rapid molecular techniques for analysis of common mutations such as Q188R.

Treatment

Elimination of dietary galactose is the only available approach to treatment of transferase deficiency. Traditionally, patient management has focused on the elimination of milk and dairy products. In infants, this involves use of soy formulas. The use of soy preparations has been questioned in the past because of the presence of galactose in oligosaccharides such as raffinose. However, evidence has accumulated that galactose absorption does not occur from these products. Careful attention to elimination of galactose should be given throughout progression to solid foods because of the frequent unsuspected use of dairy products in food preparation. Absorbable galactose is also found in grains, fruits, and vegetables. Therapeutic nutritional regimens now account for this finding, although the actual impact of eliminating this dietary source of galactose awaits further clinical investigation.

Most patients experience an improved tolerance to galactose around puberty, postulated to be due to the development of an alternate pathway of galactose metabolism. Therefore, in older patients, liberalization of the diet to include limited quantities of foods containing dairy products should be considered to minimize the psychological effect of lifelong stringent restrictions. However, milk restriction should be maintained. Compliance with therapy may be followed by monitoring galactose-1-phosphate content of erythrocytes which should be maintained below 4 mg/g hemoglobin. Pregnant women with galactosemic children are advised to eliminate galactose from their diet in subsequent pregnancies.

Subsequent Course and Prognosis

All acute manifestations of galactose toxicity show marked improvement by the end of 1 week of dietary elimination. Nausea and vomiting abate, hepatic function returns to normal, acute central nervous system changes as shown by CT scan improve, and catch up growth ensues.

Cataracts regress substantially with elimination of dietary galactose. Residual and ongoing central nervous damage sometimes continues even in patients maintained on appropriate restriction of galactose from their diet. This is usually manifested by lower IQ values compared to the normal population.

As previously mentioned, a high incidence of hypergonadotropic ovarian failure is seen in female patients. This is usually irreversible when it occurs. It has been proposed that this phenomenon occurs despite adequate dietary control. However, other findings suggest that ovarian failure develops as a result of ongoing galactose exposure.

Galactokinase Deficiency Galactosemia

Galactokinase deficiency is a rare autosomal recessive disease characterized by cataract formation very early in life. Its incidence is one per 100,000 births. Due to lack of galactokinase, galactose is metabolized via the alternate pathway (*Fig. 209.1*) with production of galacticol. Galacticol accumulates in the lens and results in cataracts. There are no other systemic manifestations presumably due to the lack of galactose-1-phosphate accumulation. However, pseudotumor cerebri has been reported in some patients. Treatment of this defect requires lifelong restriction of galactose intake. Fetal cataract formation may even result from maternal galactokinase deficiency.

Uridine Diphosphate Galactose-4 Epimerase Deficiency Galactosemia

UDP galactose epimerase catalyzes the third reaction in galactose metabolism. Epimerase deficiency is apparently caused by diminished stability of the enzyme, leading to an inadequate reserve in such cells as erythrocytes in which turnover is slow or absent. Incidence of epimerase deficiency has been reported as one per 46,000 in Switzerland. This form was discovered incidentally through screening for Galactosemia. The diagnosis is suspected in persons having low galactose-1-phosphate levels despite normal erythrocyte transferase activity.

Initially, epimerase deficiency was considered a benign condition due to the lack of symptoms in affected persons and limitation of the deficiency to erythrocytes and leukocytes. Recently, however, cases of generalized epimerase deficiency have been reported, and affected patients exhibit symptoms identical to those of the classic form of the disease. With UDP-4-epimerase deficiency, in contrast to transferase deficiency, treatment may mandate inclusion of small quantities of dietary galactose because no galactose is synthesized endogenously to meet body requirements. Frequent monitoring of erythrocyte galactose-1-phosphate levels is required to determine the optimal level of dietary restriction.

Disorders of Fructose Metabolism

The monosaccharide fructose is an important source of carbohydrates in the human diet. Free fructose is found in fruits and honey. Another major source of fructose is the disaccharide sucrose which is hydrolyzed into

fructose and glucose through the action of sucrase at the brush border membrane of enterocytes. Fructose metabolism takes place mainly in the liver (75%) and to a lesser extent in the intestine and kidney (25%). Therefore, it is not surprising that disorders of fructose metabolism manifest mainly as dysfunction of these organs. Three enzymopathies are recognized in fructose metabolism: fructokinase, fructose-1-phosphate aldolase, and fructose 1-6-diphosphatase deficiencies. A fourth potential defect characterized by incomplete fructose absorption has been reported in children with unexplained abdominal pain, but the underlying defect has not been elucidated.

Essential or Benign Fructosuria (Hepatic Fructokinase Deficiency)

Benign fructosuria is a rare disorder inherited as an autosomal recessive gene. It results from a deficiency of fructokinase, the first enzyme in the metabolic pathway of fructose (◉ *Figs. 209.2* and ◉ *209.3*).

In the absence of fructokinase, the body utilizes a minor pathway for fructose metabolism catalyzed by the enzyme hexokinase in muscle and adipose tissue. In addition, there is no accumulation of the toxic metabolite, fructose-1-phosphate, which is believed to be the main offender in hereditary fructose intolerance. Hence, apart from the fructosemia and fructosuria upon consuming large quantities of fructose, patients are healthy and free of symptoms. Diagnosis is usually made incidentally by the finding of a positive reducing substance and verified by the identification of fructose by thin layer or paper chromatography. Confirmation of the diagnosis is made by enzyme assay in a liver biopsy specimen. However, this is not always necessary as the disorder is benign.

Hereditary Fructose Intolerance (HFI)

Hereditary fructose intolerance is a rare disease seen mainly in Europe and North America. It is inherited as an autosomal recessive gene with an estimated incidence of 1 in 20,000.

This disorder is caused by the catalytic deficiency of aldolase B normally found in the liver, kidney, and small intestine. The activity of tissue aldolase B is reduced to less than 15% of normal values. The enzymatic activities of aldolase A, found in muscle, and aldolase C, found in the brain, are normal.

The aldolase B gene has been sequenced and mapped to human chromosome 9 q 13 → q 32. Several missense mutations in this gene sequence resulting in different abnormal products have been identified. These include a mutation resulting in a proline residue substituting for an alanine at position 149 (A149P), a mutation resulting in alanine being replaced by aspartic acid at position 174 (A174D), and a mutation resulting in aspargine being replaced by lysine at position 334 (N 334 L). Testing for these mutations by DNA amplification using polymerase chain reaction technology with a limited panel of allele-specific oligonucleotides identifies more than 95% of patients with HFI.

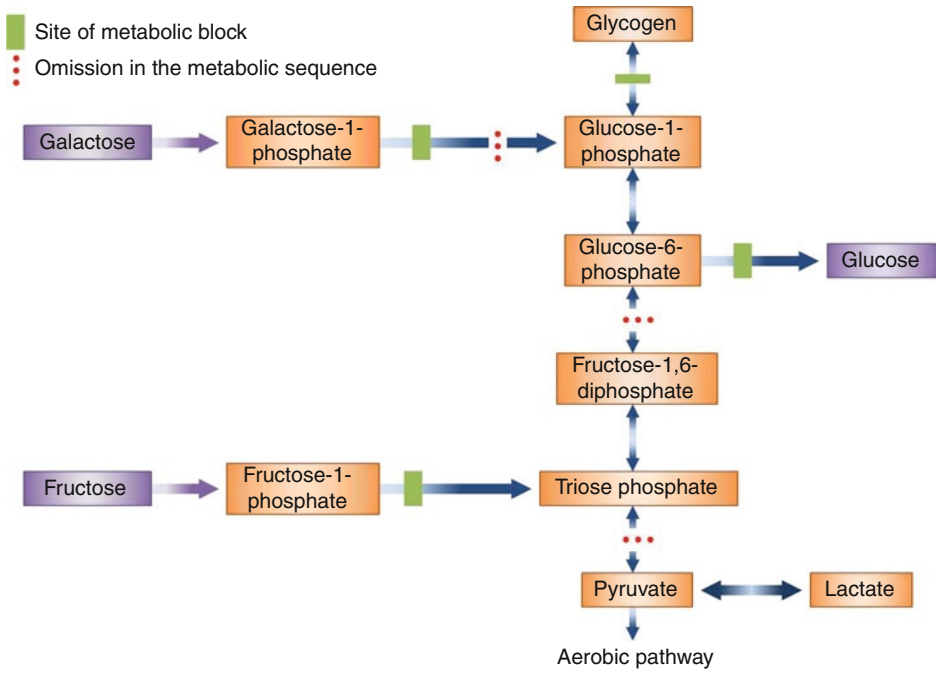

Figure 209.3

Metabolic relationship between disorders in glycogen, galactose, glucose, and fructose metabolism. Solid rectangle indicates site of metabolic block indicates omission in the metabolic sequence. (Modified Fig. 69.1, Ghishan, 2006)

Pathophysiology

Deficiency of fructose-1-phosphate aldolase results in the accumulation of fructose-1-phosphate, a known toxic metabolite, in the liver, intestine, and kidney cortex. Some of the toxic effects of fructose-1-phosphate are the result of ATP depletion as a result of continuous utilization by the fructokinase reaction. The loss of hepatic ATP results in inhibition of protein synthesis, liver failure, and subsequent hyperaminoacidemia. Hemorrhage results from decreased synthesis of coagulation factors as a result of protein synthesis inhibition in the liver.

Renal tubular dysfunction is believed to result from ATP degradation in the kidney.

Fructose-1-phosphate also inhibits glycogenolysis and gluconeogenesis at the level of fructose-1-diphosphate inducing severe hypoglycemic episodes.

Metabolic acidosis results from lactic acidosis and renal tubular acidosis. Hyperuricemia results from purine degradation induced by both ATP depletion and phosphate sequestration (in the form of fructose-1-phosphate).

Clinical Manifestation

Newborns are asymptomatic as long as they are on breast milk or formulas lacking sucrose. Acute symptoms develop as soon as formulas or solid food containing fructose or sucrose are introduced. The reaction to fructose introduction is most prompt and dramatic in newborns and infants and can be fatal. Acute symptoms include nausea, vomiting, and refusal to eat. Hypoglycemic episodes result in sweating, trembling, convulsions, lethargy, and coma. If exposure to fructose continues, the clinical picture may progress rapidly to hemorrhage, acute hepatic failure, coma, and death.

If the patient escapes the acute episode or in infants whose exposure to fructose is delayed long enough for them to develop an aversion to sweets, the disease may go undiagnosed for a long time. Chronic exposure to small quantities of fructose results in severe failure to thrive, gastrointestinal symptoms that include nausea, vomiting, diarrhea, and poor feeding. Hepatic dysfunction is also noted, manifesting as jaundice, hepatomegaly, ascites, and hemorrhage resulting from deficiency of hepatic coagulation factors. Hypoglycemic episodes result in drowziness, tremors, and convulsions.

Laboratory Data and Diagnosis

Fructosemia, fructosuria, hypoglycemia, hypophosphatemia, hypermagnesemia, hyperuricemia, and lactic acidosis are the major biochemical changes.

Liver dysfunction manifests as hyperbilirubinemia, hypoalbuminemia, increased transaminases, prolonged prothrombin time, and partial thromboplastin time, as well as increased plasma levels of the amino acids, methionine, and tyrosine.

Disturbed proximal renal tubular function, manifesting as proteinuria, amino aciduria, phosphaturia, and bicarbonaturia, is a common finding. Suspicion is fostered by the presence of reducing sugars in the urine. Traditionally, definitive diagnosis requires an enzyme assay in liver or intestinal biopsy specimens as this enzyme is not normally found in the circulation. A liver biopsy is preferred as this allows assessment of liver tissue damage. Currently, more than 95% of HFI cases can be diagnosed through amplification of DNA with a limited number of allele-specific oligonucleotide probes circumventing the need for a tissue biopsy.

Histologically, liver tissue shows diffuse fatty infiltration of hepatic cells, scattered necrosis of hepatocytes, biliary duct proliferation, and periportal, as well as intralobular, fibrosis. In more advanced cases, hepatic cirrhosis may ensue.

Treatment and Prognosis

Prompt and permanent elimination of fructose, sucrose, and sorbitol (converted to fructose) results in substantial and rapid improvement of gastrointestinal symptoms.

Hepatic changes regress rapidly, with return of hepatic enzymes, bilirubin, and coagulation factors to normal levels. However, some degree of hepatomegaly and steatosis may persist for a long time.

Despite the recurrent episodes of hypoglycemia, intellectual development seems to proceed normally with maintenance of a fructose-free diet.

Fructose-1,6-Diphosphatase Deficiency

Fructose-1,6-Diphosphatase deficiency is a rare disorder believed to be inherited as an autosomal recessive gene. Fructose-1,6-diphosphatase is a key enzyme in gluconeogenesis from lactate, glycerol, and amino acids. In patients with fructose-1,6-diphosphatase deficiency, fasting results in glycogenolysis and glucose release. However, after depletion of hepatic glycogen stores the liver is no longer capable of providing glucose through gluconeogenesis. Therefore, fasting is a major trigger of severe episodes of hypoglycemia and acidosis, especially in the newborn who has limited hepatic glycogen stores.

Similar episodes also result from fructose ingestion or acute febrile illnesses. Patients usually present with signs and symptoms of hypoglycemia and acidosis. Hepatomegaly is usually moderate. Liver histology characteristically shows fatty infiltration of the liver. The derangements in liver function tests are less drastic than in hereditary fructose intolerance. Diagnosis is confirmed by enzyme assay in a liver biopsy specimen. The gene (FBP-1) has been localized to chromosome qq22.2–q22.3 and several mutations have been described in the gene which leads to a decreased activity of fructose-1,6-diphosphatase enzyme. Treatment consists of management of hypoglycemic and acidosis episodes with intravenous glucose and bicarbonate infusions. Long-term management includes complete avoidance of fructose, sucrose, and sorbitol, avoidance of fasting, and following a diet which is low in fat, high in carbohydrate, and moderate in protein.

Glycogen Storage Diseases with Hepatic Manifestations

Glycogen, a polysaccharide, is the primary carbohydrate storage compound in animals. It is present in all animal cells but is particularly abundant in liver and muscle tissue. It undergoes depolymerization through phosphorylsis and hydrolysis to release free glucose when needed to sustain cellular processes, and to maintain normal blood glucose concentrations during fasting. The formation and degradation of glycogen are highly regulated processes involving at least eight enzymes. Deficiencies of these enzymes have been identified in humans and result in 12 recognized forms of glycogen storage disease (GSD). The following discussion will be limited to types I, III, IV, and VI, because the clinical expression of these forms of GSD primarily involves the liver. In type I, the accumulating glycogen is structurally normal, while in types III, IV, and VI it is structurally abnormal.

Physiology and Biochemistry of Glycogen Metabolism

Glycogen is a polymer of glucose units linked between the C_1 of one D-glucopyranosyl residue and the hydroxyl group at C_4 of the adjacent residue (1,4 linkage). Short chains of glucose residues linked through the hydroxyl groups at C_6 of some of the residues (α-1,6 linkage) represent 7–8% of glucose found in glycogen. The role of glycogen in the liver is to provide glucose to the blood for various organs. At times of stress or when blood glucose levels fall, the liver rapidly releases glucose into the blood stream, and blood carries it to organs such as the brain which cannot synthesize glucose. Glycogen in muscle serves as a reserve of glycolytic fuel to be used locally when oxygen or glucose availability declines. *Figure 209.4* depicts the sequence of reactions involved in glycogen synthesis and degradation.

Type I Glycogen Storage Disease (GSD) (Glucose-6-phosphatase Deficiency, Von Gierke's Disease)

This is the most recognized form of glycogen storage disease. The disease is autosomal recessive and has two major subtypes. GSD type1a is caused by deficiency of glucose-6-phosphatase (G6Pase) in the liver, kidneys, and intestine. GSD type1b is caused by a deficiency in the glucose-6-phosphate transporter (G6PT). Together, G6Pase and G6PT are functionally linked and are responsible for the formation of the majority of glucose from glycogenolysis and gluconeogenesis. GTPase is present in the liver, kidney, and intestinal mucosa, whereas G6PT is expressed ubiquitously. Therefore, a mutation in either enzyme results in a common metabolic phenotype of disturbed glucose homeostasis (*Fig. 209.5*). Recently, a second

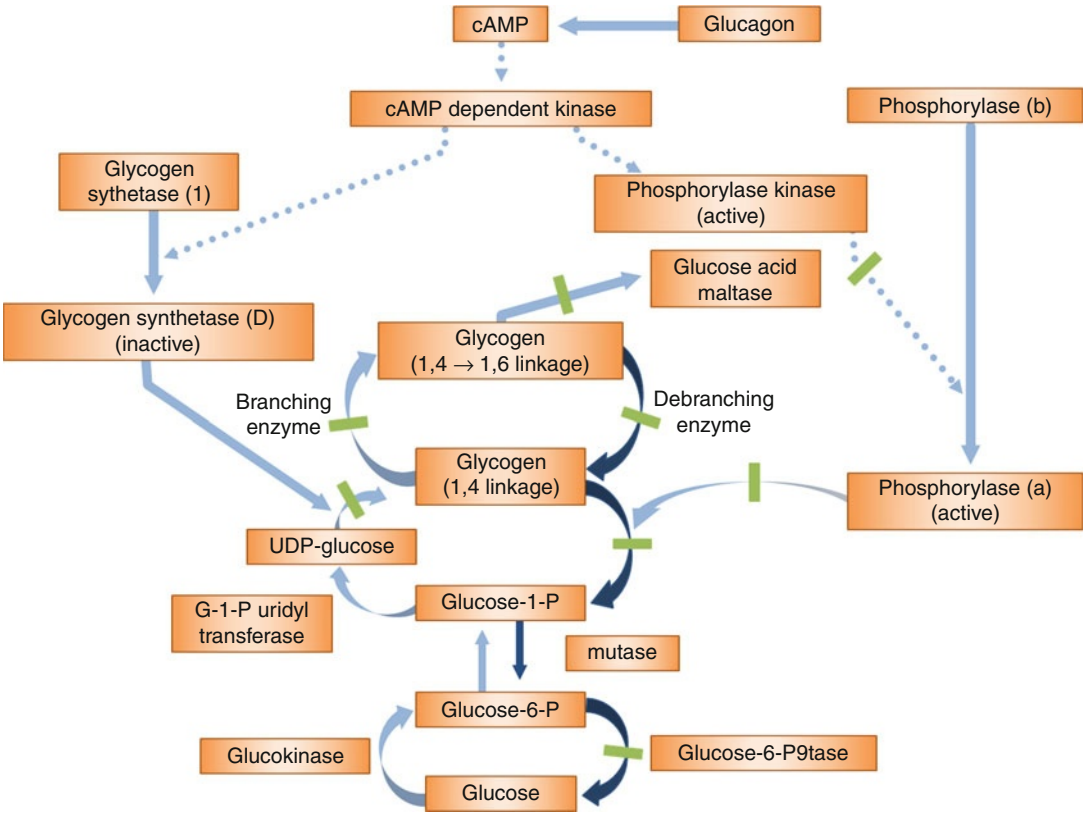

Figure 209.4

Pathway for glycogen synthesis and degradation to glucose. *Broken lines* indicate enzymic activation after glucagon simulation, *heavy arrows* indicate glycogen degradation from glucagon infusion; and *hatched boxes* indicate points in the metabolic sequence where enzymic defects have been identified. (Modified Fig. 69.5, Ghishan FK (2006) Inborn errors of metabolism that lead to permanent liver injury. In: Boyer T, Zakim D (eds) Hepatology: a textbook of liver disease. Elsevier, Canada)

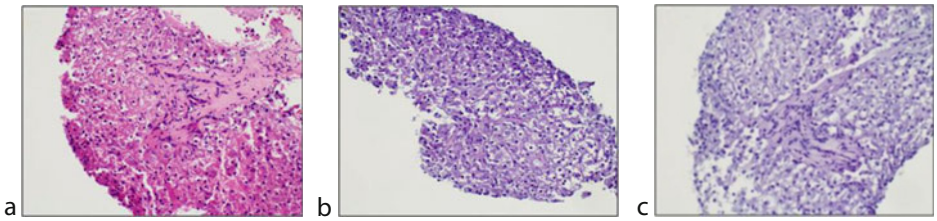

Figure 209.5
Histological photomicrograph of liver biopsy of a patient with glycogen storage disease type 1a. (a) Sections of liver including portal area, hematoxylin, and eosin stain showing increased glycogen deposition in hepatocytes (200 × magnification); (b) Sections of liver with PAS stain showing PAS stain of glycogen (200 × magnification); (c) Section of liver with PAS stain after diastase treatment showing decrease in glycogen (200 × magnification)

G6Pase has been described and designated G6Paseβ, which is ubiquitously expressed and forms functional unit with G6PT as well in nongluconeogenic tissues including neutrophils.

Classification of Type I Glycogen Storage Disease

Two forms of the disease are recognized:

1. Patients with type Ia GSD have complete absence of glucose-6-phosphatase activity.
2. 2-Type Ib has a clinical picture similar to type Ia. However, in these patients the activity of glucose-6-phosphatase in fully disrupted microsomes is completely normal, whereas the activity in intact microsomes and in vivo is abnormal. These patients have a defect in the endoplasmic reticulum–bound glucose-6-phosphate transporter and classically have neutropenia.

Molecular Basis of Glycogen Storage Disease Type Ia

The gene encoding for the enzyme glucose-6-phosphatase has been cloned. So far, 76 mutations in the glucose-6-phosphatase gene have been identified resulting in greatly reduced enzymatic activity of glucose-6-phosphatase. The most common mutations in Caucasian populations are a cystine substitution for arginine at position 83 (R83C) and unspecified amino acid for glutamine (Q347X). In the Arab world, 50% of the alleles analyzed are V166G (glutamine substitution for valine) which appear to be unique in ethnic Arabs. Sixty-nine mutations have been described in the G6PT gene and are responsible for GSD type1b. These include 28 missense mutations, 10 nonsense, 17 insertion/deletion, and 14 splicing mutations. Similar to Typ1a mutations in type1b shows ethnic variability.

Clinical Presentation

The expression of clinical and biochemical symptoms of type I GSD varies considerably among patients. Some persons require frequent hospitalizations because of marked metabolic abnormalities. Others experience only mild symptoms and slightly delayed growth.

Children with the full spectrum of this disorder characteristically have proportionate short stature, massive hepatomegaly leading to a protuberant abdomen, renal enlargement, hypoglycemic episodes, lactic acidosis, hyperuricemia, hyperlipidemia, xanthomas, and a bleeding tendency.

Hypoglycemia Hypoglycemic episodes are one of the most striking and detrimental factors in type I GSD. Glucose-6-phosphatase deficiency results in impairment of glucose release resulting in hypoglycemic episodes that may follow a short period of fasting. Except in severe cases, hypoglycemia may not become apparent in the first several weeks of life when the infant feeds every 2–3 h. However, septicemia may lead to earlier recognition of this symptom, particularly in patients with type Ib GSD. Convulsions associated with hypoglycemia can occur in patients without symptoms. Metabolic acidosis due to hypoglycemia may cause weakness, malaise, headache, an increased respiratory rate, and fruity breath; a few patients experience recurrent fevers with these symptoms. In other patients, profound hypoglycemia can occur without symptoms. It is believed that these asymptomatic patients utilize β-hydroxybutyrate and acetoacetate in lieu of glucose as the primary fuel of the brain.

Growth Failure Growth failure can be profound. The exact mechanism behind this is not completely clear, although chronic acidosis and hypoinsulinemia associated with hypoglycemia are believed to be the major

contributing factors to growth impairment. Correction of hypoglycemia and metabolic acidosis results in improved growth.

Lactic Acidosis Lactic acidosis is one of the major features of glycogen storage disease type I. Blood lactate levels in these patients are generally four to eight times the normal values. Hypoglycemia results in decreased insulin and increased glucagon which promotes glycogenolysis. Glycogen degradation proceeds normally until the last step in which glucose release from glucose-6-phosphate is impaired because of glucose-6-phosphate deficiency. The accumulated glucose-6-phosphate is diverted into the glycolytic pathway resulting in increased lactate production.

Hyperlipidemia Hyperlipidemia is a striking abnormality in patients with type I GSD. Serum levels of triglycerides may reach 4,000–6,000 mg/dl, and cholesterol elevation to levels of 400–600 mg/dl is common. The mechanisms underlying hyperlipidemia relate to the increased products of glycolytic pathways such as NADH, NADPH, glycerol-3-phosphate, and acetyl coenzyme A. These compounds are essential for fatty acid and cholesterol synthesis. They are synthesized abundantly in patients with GSD type I as a result of the block in the glycolytic and gluconeogenic pathways. Moreover, elevation of free fatty acids occurs in the serum secondary to hypoglycemia. Although controlling hypoglycemia with frequent and nocturnal intragastric feeding seems to promote growth and controls acute metabolic disturbances, its influence on hyperlipidemia has been variable. The exact mechanism behind this variable response is not well known.

Hyperuricemia Hyperuricemia appears in early infancy, but gouty complications such as arthritis or nephropathy rarely develop before puberty. It has been suggested that because of glucose-6-phosphatase deficiency, the rate of purine synthesis increases due to increased availability of the purine precursors, glutamine, and ribose-5-phosphate. In addition, the trapping of phosphate in glucose-6-phosphate and lowering of ATP levels promotes degradation of preformed purines to xanthine and uric acid.

Bleeding Tendency The presence of bleeding tendency is well recognized in type I GSD. Abnormalities in platelet aggregation and adhesiveness have been described in these patients. These abnormalities are thought to be the result of impairment of the ability of platelet membranes to release ADP secondary to changes in membrane fluidity. Presence of xanthomas, which usually appear during puberty, also contributes to frequent nosebleeds in patients with type I GSD.

Neutropenia Neutropenia has been documented in most patients with type Ib GSD. The degree of neutropenia varies among such patients, especially during periods of infection. The functional impairment is related to impaired glucose production by neutrophils resulting in endoplasmic stress and increased apoptosis.

Liver Manifestations Hepatic adenomas are frequently found in patients with type I GSD, usually during the second decade of life. However, these have been detected as early as 3 years of age. Malignant transformation has been reported in a large number of adult patients. Controlling the metabolic disturbances through dietary therapy may retard the growth of these adenomas or may result in the regression of existing adenomas. However, adenomas are even reported in patients who are under tight metabolic control. On the other hand, liver abnormalities usually include only slight elevations in serum transaminase which improve quickly with stabilization of blood glucose between 70 and 110 mg/dl. Type I GSD does not lead to hepatic cirrhosis or liver failure.

Renal Disease Although renal enlargement is a frequent finding in type I GSD, significant renal disease has not been recognized in the early stages of the disease. Patients with renal involvement usually present with persistent proteinuria and hematuria. The predominant histologic findings in kidney biopsies are focal segmental glomerulosclerosis and glomerular basement membrane abnormalities that include thickening of the membrane and glycogen deposition. Moreover, those who survive beyond puberty may develop progressive nephropathy and gouty complications due to uncontrolled hyperuricemia.

Diagnosis

The diagnosis of type I GSD is suspected in patients with the above presentation. The need for accurate diagnosis of type I GSD has become critical since the development of an effective approach to treatment. Traditionally, direct assay of hepatic enzyme activity of glucose-6-phosphate in a fresh liver biopsy is utilized.

The diagnosis is also suspected from the microscopic examination of the biopsy which characteristically shows striking steatosis and high glycogen content in hepatic cells. Usually there is no fibrosis or cirrhosis. Adenomatous changes may also be seen very early in the course of the disease. Mutations in the gene encoding for

the glucose-6-phosphatase enzyme is becoming the standard mode of making a diagnosis.

Treatment

The pioneering work of Folkman and associates led to the development of current treatment strategies for patients with type I GSD. Through the use of total parenteral nutrition, these researchers were able to effect dramatic improvement in most biochemical abnormalities associated with the disease. Other researchers have subsequently shown equally positive results with continuous nasogastric infusion of nutrients. This has led to the speculation that when blood glucose levels fall below 70–90 mg/dl, compensatory mechanisms result in the breakdown of glycogen to glucose-6-phosphate. Thus, any treatment that maintains blood glucose levels above the critical level reduces the stimulus for glycogenolysis and the subsequent accumulation of abnormal metabolites. Parenteral and entered nutrition produce the desired effect by providing a continuous source of glucose, but are impractical for long-term use. Thus, a more feasible approach has been devised using frequent daytime feedings of a high-starch diet in combination with a continuous nocturnal enteral infusion. Raw cornstarch, which undergoes slow degradation to glucose by α-amylase, has been shown to be effective in maintaining glucose levels during the daytime. A dose of 2 g/kg of raw cornstarch every 6 h has provided a suitable alternative to nighttime infusions in some patients.

More aggressive approaches have been used in the treatment of patients with type I GSD, including liver transplantation and gene therapy. Renal complications have been recognized and their management includes alkalinization of urine with citrate for prevention of urolithiasis and nephrocalcinosis and angiotensin converting enzyme inhibitors for persistent microalbuminemia.

Recommendations for treatment of type Ib GSD patients are identical to those for type Ia. Similar results may be expected with the exception of lack of improvement of the neutropenia that accompanies this form of the disease. Prophylactic antibiotics may reduce the incidence of infections.

Prognosis

The use of current treatment strategies has significantly altered the clinical course and prognosis of patients with type I GSD. Life expectancy now extends beyond the third decade. Prior to the mid-1970s, patients required frequent hospitalizations due to hypoglycemia, fever, and acidosis. Current treatment has been successfully used in a group of patients who have experienced near normal growth and have remained relatively symptom free for 10 years. Furthermore, the tendency to develop hypoglycemia seems to mitigate as patients reach adulthood. Complete resolution of adenomas has been documented as a result of this therapy. On the other hand, suboptimal treatment will continue to result in the consequences of poor metabolic control and development of hepatic adenomas which can progress to hepatocellular carcinomas. Unfortunately, adenomas have been reported in patients who are under good control. Therefore, careful follow-ups and monitoring are essential.

Type III Glycogen Storage Disease (Amylo-1,6-Glucosidase Deficiency, Debrancher Deficiency, Forbes Disease)

This is an autosomal recessive disease resulting from debrancher enzyme deficiency most commonly found in Jewish communities of North African descent. Under normal conditions debrancher enzyme coupled with phosphorylase and phosphorylase kinase allows the release of glucose from 1,6 glucosyl linkages. However, the absence of the debrancher enzyme interferes with the release of glucose from 1,6 glucosyl linkages. This results in the accumulation of abnormal glycogen molecules that have an excessive number of shorter outer branch points (1,6 linkages), similar to the structure of limit dextrins.

Debranching enzyme contains two catalytic activities on a single 160-kd polypeptide chain; oligo-1,4-1,4-glucantransferase and amylo-1,6-glucosidase. Complete absence of enzyme activity has been designated GSD IIIa. Absence of debrancher enzyme in only the liver or only the kidney has been designated GSD IIIb and GSD IIIc, respectively. Some patients have isolated oligo-1,6-1,4 glucantransferase deficiency with retention of glucosidase activity (GSD IIId).

Clinical Presentation

The clinical manifestations of patients with type III GSD result directly from its effects on hepatic and muscle tissue, although amylo-1,6-glucosidase activity is generalized to most cell types.

In infancy and childhood type III and type I GSD are not readily distinguishable by physical examination alone, primarily because hepatic manifestations predominate in this age group. Growth failure and hepatomegaly may be striking early in life. Hepatic fibrosis may lead to the development of splenomegaly in some children by the time they are 4–6 years of age. However, a decrease in liver size has been noted to occur in some patients around

puberty. Nevertheless, hepatic fibrosis has progressed to cirrhosis and liver failure in a few patients with type III GSD who have concomitant phosphorylase or phosphorylase kinase deficiencies. Moderate elevations in serum transaminase levels (300–600 IU) are consistently seen in almost all patients. Hypoglycemic episodes in type III GSD are milder than in type I and occur mainly with prolonged fasting. This results from the release of glucose from 1,4 glucosyl linkages and through gluconeogenesis, which is not impaired in type III GSD. Unlike type I GSD, serum levels of uric acid and lactic acid are usually normal.

Onset of muscular symptoms usually occurs in adulthood and is primarily manifested as muscle weakness and muscle wasting.

Renal enlargement is not seen in type I GSD. Glycogen accumulation in the heart may produce cardiomegaly and nonspecific electrocardiographic changes.

Histopathologic Features

The appearance of the liver in type III GSD is remarkable for the presence of fibrous septa and paucity of fat, unlike type I GSD in which there is striking steatosis with no fibrosis. Evidence of cirrhosis is present in some patients with concomitant phosphorylase or phosphorylase kinase deficiencies. Glycogen content of hepatic tissue is also abnormally high.

Diagnosis

The diagnosis is suspected based on distinguishing clinical and laboratory features. The presence of elevated creatine kinase supports the diagnosis. While various sugar tolerance tests have been traditionally used to confirm the diagnosis, these have shown inconsistent results. Direct measurement of amylo-1,6-glucosidase activity in liver and muscle samples and concomitant examination for abnormal glycogen structures should be relied on for the definitive diagnosis. Means of prenatal diagnosis are also now available via enzyme analysis in amniotic fluid cells. The gene encoding the debrancher enzyme was cloned and mapped to chromosome lp21. Mutations in exon 3 of the gene were found in the majority of the patients with GSD3b. So far 31 mutations have been identified.

Treatment

Dietary regimens similar to, but less stringent than, those for patients with type I GSD have been used in the management of debranching enzyme deficiency. Improvement of liver transaminases, liver size, and growth has been demonstrated following a high-starch diet containing only the recommended dietary allowance (RDA) for protein. For the most part, treatment of type III GSD remains investigative and should be reserved for patients with progressive muscle disease or hepatic fibrosis.

Type IV Glycogenesis, Amylopectinosis Amylo-1,4-1,6-Transglucosidase (Brancher) Enzyme Deficiency

This is a rare inborn error of glycogen metabolism that results from brancher enzyme deficiency. Only about 20 cases have been documented in the literature. The disease is inherited as an autosomal recessive gene. Absence of brancher enzyme activity results in the accumulation of an abnormal glycogen molecule that has a long outer chain and fewer than normal number of branch points. This abnormal glycogen molecule resembling amylopectin may accumulate in the liver, cardiac muscles, and the nervous system, with subsequent dysfunction of these organs.

Clinical Presentation

The disease usually presents in early infancy with failure to thrive, hepatosplenomegaly, progressive cirrhosis, and hepatic failure. Most children die in the first 2 years of life. Recently, several variants of the disease have been reported with presentations including cardiomyopathy, arthrogryposis, and hydrops fetalis. Fasting-induced hypoglycemia has been reported in two infants. The heart can be enlarged with nonspecific electrocardiographic changes. Some children may show significant hypotonia and muscular atrophy. A less severe form of type IV glycogen storage disease with a mild course presenting at 2 years of age has been described. Serum transaminase levels are characteristically elevated in this form of glycogenesis.

Diagnosis

Definitive diagnosis is by enzyme assay in hepatic tissue and in skin fibroblasts. Identification of the characteristic abnormal glycogen in liver tissue, either ultrastructurally or histochemically, also points to the diagnosis. Prenatal diagnosis is possible by enzyme analysis of cultured amniotic fluid cells. The gene is located on chromosome 3p14. Mutations in the gene have been reported.

Treatment

Controlling fasting-induced hypoglycemia resulted in some improvement in liver dysfunction and reduction of the hepatosplenomegaly in two infants. The only available

definitive treatment for the fatal form of the disease is liver transplantation. However due to the accumulation of the abnormal polysaccharide in muscle and nervous system, the long-term effect of liver transplantation on these organs is uncertain.

Type VI Glycogenesis (Liver Phosphorylase Deficiency)

This is a rare inborn error of glycogen metabolism that results from hepatic phosphorylase deficiency. The disease is inherited as an autosomal recessive gene. Affected children are usually asymptomatic except for massive hepatomegaly. Hypoglycemia after prolonged fasting is rare. Glucagon tolerance tests reveal a flat curve. Diagnosis is by demonstrating low hepatic levels of phosphorylase.

Hereditary Tyrosinemia Type I

Hereditary tyrosinemia type I is a disorder of tyrosine metabolism which is strongly linked to deficiency of the enzyme, furmarylacetoacetate hydrolase (FAH). This enzyme is normally found mainly in the liver and kidneys. It is inherited as an autosomal recessive gene with a very high prevalence (1/700) in the Quebec province of Canada and in Scandinavian countries.

It is characterized by progressive hepatic fibrosis leading to cirrhosis, hepatomas, proximal renal tubular dysfunction, and hypophosphatemic rickets.

Pathophysiology

The cause of hereditary tyrosinemia is a reduction in the activity of fumarylacetoactate hydrolase (FAH), the final enzyme in tyrosine degradation. Absent to low activity of the enzyme p-hydroxyphenylpyruvate dioxygenase in liver tissue is also recognized but this enzyme deficiency has been shown to be secondary to the disease rather than the primary cause of hereditary tyrosinemia. FAH is a 419 amino acid protein found in the liver, kidney, lymphocytes, erythrocytes, and fibroblasts. A human liver FAH cDNA has been sequenced and the human gene has been localized to chromosome 15q23 → q25.

The deficiency of the enzyme FAH results in the accumulation of fumaryl and maleylacetoacetate. These compounds are metabolized to succinylacetone (SA) and succinyl acetoacetate (SAA) which are elevated in the serum and urine of patients with hereditary tyrosinemia type I and absent in other forms of disorders of tyrosine metabolism. Therefore, succinylacetone and succinylacetoacetate are virtually diagnostic of hereditary tyrosinemia type I when combined with assays of hepatic tissue for FAH. Succinylacetone has been used for neonatal screening in areas with a high prevalence of the disease.

Succinylacetone (SA) is a potent inhibitor of delta-aminolevulinate dehydratase (porphobilinogen synthetase) and leads to increased serum levels and urinary excretion of delta-aminolevulinic acid. The latter is believed to be responsible for the neurologic symptoms resembling acute intermittent porphyria. SA is also believed to be toxic to the proximal renal tubules leading to pronounced tubular dysfunction manifesting as renal tubular acidosis and rickets. Other causes of rickets include impaired hepatic and renal hydroxylation of vitamin D. SA inhibits several enzymes of tyrosine metabolism and results in a reduction of glutathione levels. The significance of this observation is not known, but free sulfahydryl groups play a role in protection from free radicals.

Genetics and Screening

Tyrosinemia is inherited as an autosomal recessive trait. Heterozygotes are asymptomatic because they possess 50% of normal enzymatic activity leading to normal levels of tyrosine-related metabolites.

A human liver FAH cDNA has recently been sequenced and the human gene localized to 15q23 → q25. The gene contains 14 exons and spans approximately 35 kilobases of DNA. The disease in Quebec families has been found to be caused by a guanine to adenine change in the splicer-donor sequence of intron 12 of the gene leading to aberrant splicing and an inactive product. In Northern Europeans, multiple missense and complex splicing defects have been detected. Once the major mutations have been identified, use of allele-specific oligonucleotides will become established as a diagnostic and screening test for this disorder.

Clinical Manifestations

Tyrosinemia should be suspected in a child or infant with unexplained hepatocellular necrosis, cirrhosis, or decreased hepatic synthetic function for which a cause is not immediately evident. Rickets, characteristic renal or

neurologic findings, especially if associated with abnormal hepatic function, should raise suspicion of this disease.

Two forms of the disease have been recognized, *acute and chronic:*

In the *acute* form, the enzyme deficiency is more profound. Patients may present in the neonatal period or early infancy with fulminant hepatic failure, renal dysfunction, and disseminated intravascular coagulation. A large proportion of patients have a fatal outcome. In others, the presentation can be less dramatic with failure to thrive, vomiting, and diarrhea. These patients die within a few months from liver failure.

In the *chronic* form, the enzyme deficiency is believed to be less severe than in the acute form. Patients present with failure to thrive, hypophosphatemic vitamin D-resistant rickets, hepatomegaly, and progressive hepatic failure. Some patients may present with severe attacks of abdominal pain resembling those of acute intermittent porphyria. Other patients may have acute episodes of lower extremity pain followed by transient paralysis. Up to 37% of the patients develop hepatomas with some risk of malignant transformation.

Laboratory Findings and Diagnosis

Liver function tests reveal hypoproteinemia, deficient vitamin K-dependent coagulation factors, and moderate elevation of transaminases and bilirubin. Alpha-fetoprotein is characteristically elevated in the presence or absence of hepatomas.

Phosphaturia, glucosuria, and generalized amino aciduria are common findings. Urinary excretion of delta-aminolevulinic acid, succinylacetone, and succinylacetoacetate are pathognomonic of type I hereditary tyrosinemia. Elevated serum levels of succinylactone detected using blood samples dried on a filter paper are very specific and serve as a reliable neonatal screen. Serum levels of tyrosine, methionine, and phenylalanine are usually increased but these are nonspecific findings as they may occur with any form of liver failure. The diagnosis is confirmed by enzyme assay for FAH in hepatic tissues, and more recently, on lymphocytes and fibroblasts.

Prenatal diagnosis can be achieved by FAH assay in cultured amniotic fluid cells or chorionic villus cells, as well as measuring succinylacetone in amniotic fluid.

Histopathology

The liver shows fatty metamorphosis, inflammatory cell infiltrate with lymphocytes and plasma cells, extensive fibrosis, and nodular regeneration. Hepatomas are frequently seen in advanced cases.

The kidneys are usually enlarged with tubular epithelium degeneration, as well as evidence of glomerulosclerosis. The pancreas shows diffuse hyperplasia of the islets of Langerhans although most patients have normal blood glucose levels.

Treatment

Dietary restriction of tyrosine and its precursor phenylalanine has been the standard treatment of type I hereditary tyrosinemia although the long-term outcome of this approach has not been formally documented. This dietary regimen has a substantial beneficial effect on renal function with reduction in renal loss of phosphate, glucose, and amino acids. However, the effect of this diet on hepatic dysfunction is uncertain. Limited amounts of tyrosine and phenylalanine are reintroduced as the patient's clinical status improves to allow adequate growth. Control of infections, fasting, and other stressors that liberate amino acids through catabolism should be dealt with appropriately by treating the underlying condition and by providing sufficient calories for tissue repair during catabolic states. The use of 2 - (nitro-4-trifluoromethylbenzoyl) - 1–3 - cyclohexanedione (NTBC) which inhibits the enzyme 4-hydroxyphenylpyruvate oxidase has resulted in improvement in clinical and biochemical parameters in a large study involving 207 patients. Children treated before 6 months of age have a 10-year survival rate of 85%. This treatment reduced the need for liver transplantation. Side effects of NTBC include thrombocytopenia, leukpenia, and cutaneous disorders. Liver transplantation remains a life-saving treatment modality in patients with late diagnosis and failure to respond to NTBC. In patients with advanced renal disease a liver-kidney transplant may provide a solution to failure of both organs.

210 Wilson Disease

Hisham M. Nazer

Wilson disease (WD) is a disorder of copper transport caused by mutation within the ATP7B gene. WD is an autosomal recessive inborn error of metabolism in which there is an excessive deposition of copper in many tissues, especially the liver, brain, cornea, bones, and kidneys, resulting in a variable spectrum of clinical presentation, the exact of mechanism for which is not well known.

Wilson disease, previously called hepatolenticular degeneration, was first described in 1912 by the American neurologist Samuel Alexander Kinnear Wilson, who was working in England at the time. Wilson recognized the disease as being familial and associated with cirrhosis and progressive lethal neurologic disorder together with degeneration of the lens of the eye. Although the neurologic features were dominant in Wilson's original report, it is the liver that is the site of the biochemical abnormality and also the organ most frequently damaged by the excessive deposition of copper.

The disease is also associated with the presence of corneal rings previously recognized by Kayser and Fleischer in 1902–1903. Walsh introduced the chelating agent penicillamine as the medical therapeutic agent in WD. This treatment resulted in a radical change in the prognosis of the disease, especially when introduced at an early stage. Without treatment, there is usually progressive damage to the liver and the brain, with a fatal outcome.

WD is a rare disorder, with an incidence of 15–30 affected individual per one million population. WD is still considered as probably the most frequent cause of chronic genetic liver disease in the pediatric age group.

Pathogenesis

The basic defect in WD is not known, but the sequel of the disease seems to be caused by the accumulation of copper in various organs, especially the liver. Copper is not incorporated into its carrier protein ceruloplasmin within the liver. There is some evidence that the excretion of copper via the bile is disturbed in WD.

It has been established that the disease results from failure of the biliary copper excretion, with accumulation of the metal in various organs leading to hepatic cirrhosis and brain damage. Copper incorporation into ceruloplasmin is also impaired. There is accumulating evidence to dispute the longstanding recognition that ceruloplasmin has a primary role in the pathogenesis of WD. Moreover, the gene for ceruloplasmin is localized to chromosome 3, while that of WD is localized on chromosome 13.

GP73, a Golgi membrane protein is expressed in hepatocytes in response to acute or chronic liver disease. Increased hepatocyte GP73 expression is more commonly a feature of hepatic than neurologic WD.

Liver damage results from massive accumulation of copper in the tissue. Brain damage subsequently develops when the cerebral copper-binding proteins are saturated.

Clinical Features

Wilson disease has varied clinical manifestations. It may mimic most if not all forms of liver disease, but it is also associated with highly variable neurological symptoms with basal ganglia and cerebellar manifestation. Some patients with hepatic manifestations present with clinical features similar to those of autoimmune hepatitis. Unexplained hepatomegaly, progressive liver disease, behavioral or neurologic abnormalities, and hemolytic anemia are the most common presenting features in WD.

Occasionally, the incidental finding of Kayser–Fleischer (K-F) rings or of renal tubular acidosis leads to the diagnosis of WD.

A number of reports have emphasized the difficulty of differentiating chronic active hepatitis from WD. As the management is different, it is extremely important to make this distinction in all young patients with such histologic features. Liver copper concentration is found to be a useful test in enabling the clinician to differentiate chronic active hepatitis from WD.

Initial symptoms in WD are frequently nonspecific and delay in diagnosis and institution of penicillamine therapy is all too common. This is particularly important, as once signs of hepatic failure develop, the response to medical therapy is often disappointing. Nazer et al.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_210,

introduced a prognostic score based on the severity of the abnormalities of serum aspartate aminotransferase, bilirubin, and prothrombin time on admission. Such a score facilitated separation of fatal and nonfatal cases in a series of 27 patients. Cases with indices in the fatal category may do well after emergency liver transplantation.

WD is unlikely to manifest clinically before the age of 4 years and may remain latent until the fifth decade. It is likely to produce signs and symptoms of hepatic involvement, and then at a later age, the neurologic manifestations appear if the disease continues to progress. The younger the patient, the more likely the presentation of WD is that of predominant hepatic manifestations. The variable presentation of WD raises the possibility that there could be a genetic basis for such varied manifestations and that some form of mutation may influence the severity of the disease with its multisystem involvement.

The varied clinical manifestations may be outlined as follows.

Hepatobiliary Manifestations

Asymptomatic hepatomegaly with or without splenomegaly and jaundice are well-recognized manifestations of WD. The disease is also characterized by chronic aggressive hepatitis with evidence of progressive hepatic insufficiency, and portal hypertension with its associated complications such as ascites and gastroesophageal varices. Hepatic cirrhosis may be well compensated with normal liver function tests for quite some time. Later in the course of the disease, the child may suffer from rapidly progressive jaundice, coagulopathy, fulminant hepatic failure, and encephalopathy. The disease may progress rapidly with fatal outcome within months to a few years without a definite diagnosis made. Fulminant hepatic failure secondary to WD is usually associated with intravascular, Coombs-negative hemolytic anemia, and low-serum alkaline phosphatase and aminotransferase levels. The prevalence of fulminant hepatic failure in WD is unknown.

The evidence of hepatoma complicating cirrhosis appears to be lower than in other types of cirrhosis. Moreover, it has been postulated that the high tissue copper might protect against tumor formation.

Neurologic Manifestations

Neurologic abnormalities usually develop at a later age than that of hepatic manifestations. They may result directly from deposition of copper in the brain, indirectly as an encephalopathy complicating progressive liver disease, or as a combination of both. The neurologic manifestations of WD result primarily from the anatomic disruption of the basal ganglia, cerebellum, and brain stem. The putamen is most severely affected with diffuse symmetric softening, atrophy, and cavitation.

Early diagnosis and subsequent initiation of adequate chelating therapy can reduce neurologic disturbances or prevent their development. Early manifestations include tremors, dysarthria, ataxia, grimacing, and incoordination. Late manifestations include dystonia, spasticity, and rigidity.

Computed tomographic (CT) scan can demonstrate brain involvement in WD and has been used to follow the effects of therapy. Comparative studies have shown superiority of magnetic resonance imaging (MRI) over CT scan, and the efficacy of MRI has been well documented.

Ophthalmic Manifestations

K–F rings consist of electron dense granules containing both copper and sulfur. They are usually bilateral, green, yellow, or brown-green rings located at the periphery of the cornea on the posterior surface close to the limbus (*Fig. 210.1*). These rings are very important findings in WD as they are present in most if not all cases of WD with neurologic presentation. The rings vary from full to incomplete circles with deposits seen in the superior and inferior poles of the cornea. The rings may be seen by naked eyes but, in most cases, they are only visible on slit-lamp examination.

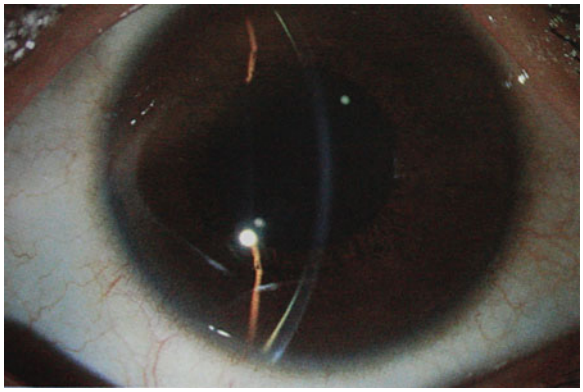

Figure 210.1
Kayser–Fleischer ring in a patient with Wilson disease (slit-lamp examination)

K-F rings have a variable appearance in different patients. The development of the rings usually occurs after the age of 4 years. With chelating therapy, there is reduction in the deposits, although complete disappearance is not guaranteed in spite of adequate therapy and satisfactory compliance on the part of the patient.

It is important to recognize that K-F rings, which are considered to be diagnostic of WD in patients with neurologic presentation, are frequently absent in young patients with hepatic manifestations. They may also be absent in patients with neurologic manifestations of WD and present in conditions other than WD. Some of the conditions associated with K-F-like rings include primary biliary cirrhosis, chronic active hepatitis, cholestasis syndromes, and multiple myeloma.

Sunflower cataracts due to copper deposition in association with K-F rings have also been reported in WD. They do not impair vision. Sunflower cataracts are also seen through slit-lamp examination in about 10% of patients with WD. They are usually located beneath the anterior and posterior lenticular capsules.

Hematologic Manifestations

These include nonspherocytic, Coombs-negative intravascular hemolysis. Acute hemolysis may be the first indication of the disease in about 10% of cases. Fulminant hepatitis in WD is usually associated with severe hemolysis.

Psychiatric Manifestations

These are comprised of behavioral, affective, psychotic, and neurotic disorders. Symptoms may be vague and nonspecific, such as fatigue, anorexia, and mood disturbances. Other recognized manifestations include deterioration in the patient's performance at work or at school.

Renal Manifestations

Renal manifestations include proximal or distal renal tubular acidosis, microscopic hematuria, proteinuria, aminoaciduria, and reduction in glomerular filtration rate. Other features of renal lesions include hypercalciuria, uricosuria, and renal tubular acidosis. Renal damage may result from copper deposition in the renal tubules. The phosphaturia may result in hypophosphatemia and bone disease. The disease may present with features of renal rickets and Fanconi syndrome (generalized aminoaciduria, glucosuria, uricosuria. hypercalciuria, hyperphosphaturia, and reduced specific gravity).

Rheumatologic Manifestation

Osteomalacia, rickets, osteoporosis, localized bone demineralization, and spontaneous fractures

Other Miscellaneous Manifestations

These include congestive heart failure, cardiac arrhythmia, cardiomyopathy, acanthosis nigricans, gynecomastia, glucose intolerance, parathyroid insufficiency, amenorrhea, and hepatocellular careinoma.

Diagnosis

Wilson's disease is rare and has no specific early manifestation; thus, clinicians may not suspect it, and clinical signs tend to be overlooked causing delay in diagnosis.

Wilson disease may have many clinical presentations. Early diagnosis is difficult unless a high index of suspicion is maintained. The availability of an effective treatment makes it prudent to diagnose WD early enough to prevent irreversible damage to vital organs such as the liver and the brain. It is even essential to try and diagnose WD in the asymptomatic stage by screening siblings of affected patients.

In view of the variable clinical manifestations of WD, the diagnosis should be considered virtually in any child with hepatic disorder presenting in early childhood, especially if it is associated with neurologic abnormalities, renal or bone disease, hemolytic anemia, or deteriorating school performance. The presence of bilateral K-F rings supports the diagnosis, though their absence in children with hepatic manifestations or with hemolytic anemia does not rule out the diagnosis. Multiple laboratory studies are usually needed to confirm the diagnosis of WD.

The diagnosis of WD might pose some challenge to the clinician as not only the classic triad of K-F rings, hepatic cirrhosis, and neurologic disorders may be absent, but serum ceruloplasmin may also be normal.

Most patients with WD (>90%) show low levels of serum ceruloplasmin, whether measured by enzymatic activity or immunochemical methods. Normal levels are seen in about 5–10% of cases. Serum copper concentration is also low, but the free (nonceruloplasmin bound) copper concentration is elevated. Rarely, serum copper concentration may be normal in WD or even above normal.

Peripheral blood examination may show features of hemolytic anemia or hypersplenism. Failure to consider diagnosis early results in unnecessary morbidity and mortality.

Liver enzymes are usually only moderately elevated, whereas the bilirubin level is markedly raised.Such findings should alert the clinician to the possibility of WD, especially in an affected child with hepatic failure.

Ceruloplasmin is a blue α2-glycoprotein. The gene for ceruloplasmin is now mapped to chromosome 3. WD is associated with a low serum ceruloplasmin (normal levels, 20–40 mg/dL). A low serum ceruloplasmin is not diagnostic of WD as it may be found in other conditions such as in normal neonates, chronic active hepatitis, intestinal malabsorption, protein calorie malnutrition, protein-losing enteropathy, nephrotic syndrome, and fulminant hepatic failure. Ten to twenty percent of heterozygotes for WD also have low serum ceruloplasmin. Ceruloplasmin concentration is the most useful adjunct to clinical information for differentiating WD and chronic active hepatitis. Serum ceruloplasmin itself does not distinguish between chronic active hepatitis and WD.

Elevated urinary and hepatic copper have also been reported in patients with chronic active hepatitis. High urinary copper excretion of 25 mmol of Cu or more over 24 h is considered diagnostic of WD. However, urinary copper excretion is increased in patients with cholestasis, hepatitis, and cirrhosis. Estimation of 24-h urinary copper excretion is performed first as a baseline and second after challenge with penicillamine. Though the urinary copper excretion is increased, the positive copper balance persists.

When serum ceruloplasmin and urinary copper are equivocal, determination of the liver copper will usually enable the diagnosis to be confirmed.

The discriminatory value of hepatic copper concentration makes this test the most reliable test for differentiating chronic active hepatitis and WD in children and adolescents.

Liver copper concentration remains the most important laboratory information on which the diagnosis of WD may be based, supported by consistent clinical features. In homozygous WD, copper concentrations are usually more than 250 μg/g dry liver tissue.

Recent reports have also indicated that high liver copper concentration is not specific for WD as the copper deposition in the liver parenchyma may be inhomogenous. Increased liver copper concentration is seen in all chronic cholestasis and in chronic active hepatitis.

Clinicians should recognize that there are problems in the estimation of hepatic copper concentration. Furthermore, such investigation may not be possible in advanced hepatic involvement in WD with severe coagulopathy, so the diagnosis may have to be established without such investigation.

Occasionally, the tissue copper concentration is inconclusive in confirming the diagnosis, in which case it might be necessary to perform *radioactive copper studies* to establish the diagnosis. Patients with WD fail to incorporate radioactive copper into the newly synthesized ceruloplasmin. In patients with equivocal copper studies and in whom liver biopsy is contraindicated, the rate of copper incorporation into ceruloplasmin may be helpful in the diagnosis. Patients with WD do not show a normal secondary rise in plasma radioactivity or incorporation of radioactive copper into ceruloplasmin even in patients with normal ceruloplasmin levels.

Establishing the diagnosis of *fulminant Wilson disease* can be difficult, especially in situations where the clinical features and laboratory data are neither specific nor diagnostic. Recent reports highlight the use of diagnostic criteria for the diagnosis of acute liver failure (ALF) in WD; however, the value of slit-lamp examination for the presence of K-F rings and liver biopsy for the determination of hepatic copper concentration still remain important for the diagnosis of ALF due to WD.

Laboratory investigations may confirm the existence of renal involvement by the presence of hematuria, proteinuria, aminoaciduria, phosphaturia, and defective acidification of the urine.

Recent reports indicate that CT scan changes may lack correlation with neurologic status and may even worsen despite clinical improvement. CT scan changes may reveal dilated ventricles together with abnormalities in lenticular, thalamic, caudate, and dentate nuclei even in the absence of neurologic manifestations. MRI has contributed to early detection of cerebral lesions in WD. Aisen et al. were the first to report MRI changes of partial necrosis in the basal ganglia in patients with WD. The changes are usually more evident on MRI than on CT scan, especially those in the brain stem. As with CT scan, there is no definite correlation between MRI changes and clinical features (i.e., MRI may be normal in patients with neurologic manifestations or abnormal in those with the hepatic form of the disease).

Hepatic Pathology

The diagnosis of WD is rather incomplete without the evaluation of liver histology by percutaneous or wedge liver biopsy, and histochemical staining for excess copper and liver copper concentration. Hepatic pathology in WD is characterized by marked fatty infiltration of the

hepatocytes associated often with prominent glycogen nuclei. There are also Kupffer cell hypertrophy, hepatocellular necrosis, and fibrosis. The liver may be enlarged, but in more advanced cases, it is normal in size or even shrunken due to multilobular cirrhosis with nodules showing variable amounts of stainable copper (◉ *Fig. 210.2*). Orcein staining and rubeanic acid staining are usually negative in early WD. Later in the course of the disease, the histochemical staining for excess copper is usually positive. The rhodanine stain seems to provide reproducible and satisfactory results in demonstrating excess tissue copper in liver biopsies from patients with WD (◉ *Fig. 210.3*).

Histologic changes consistent with chronic active hepatitis, subacute hepatitis, or postnecrotic cirrhosis may be seen in WD, which contribute further to the diagnostic dilemma occasionally experienced in new cases of WD. Mallory cytoplasmic hyaline bodies are also seen in liver biopsy from patients with WD. With the progress of the disease, the child may manifest features of hypersplenism and portal hypertension.

Electron microscopic examination contributes further to the diagnosis by the presence of abnormalities in the mitochondria in the form of dilatation of the tips of the cristae with abnormal morphology and condensation of dense bodies.

The cerebral changes are seen mostly in the corpus striatum and to a lesser extent in the cerebellum, cortex, and thalamus. The changes include decrease in the number of neurons and in the myelinated nerve fibers with increased astrocytosis.

Presymptomatic Wilson Disease

Once the diagnosis of WD has been established in a patient, it is mandatory that all siblings be screened since there is a one-in-four chance of them having the disease. It is also advisable to screen any blood relative for the presence of WD.

Diagnosis of asymptomatic patients is important so that treatment can be initiated and neurologic and hepatic damage can be avoided.

Even with extensive biochemical testing, it is not always possible to distinguish heterozygous WD from affected homozygous.

In normal newborn, the biochemical copper profile mimics that seen in WD; therefore, screening affected siblings should not be performed on those below the age of 3 years. Treatment of the asymptomatic homozygous will prevent the evolution of the disease manifestations.

Screening should include serum ceruloplasmin, 24-h urinary copper excretion, slit-lamp examination, and standard tests of liver function. K–F rings should also be looked for. Urinary copper excretion greater than 40 μg/24 h is suggestive of WD in Asymptomatic children, whereas penicillamine challenge does not have a diagnostic role in this group of patients.

If the results are abnormal or equivocal, a liver biopsy for histologic examination and determination of copper content should be performed.

DNA markers may nowadays contribute to the diagnosis of presymptomatic WD. The use of molecular genetics for screening siblings plays a role in the diagnosis

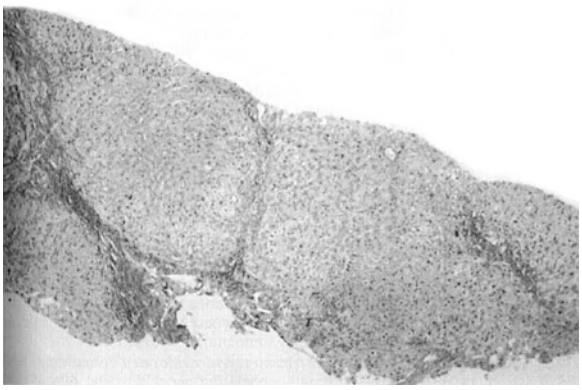

Figure 210.2
Percutaneous liver biopsy from a child with Wilson disease and predominant hepatic manifestation. Note the severity of hepatic involvement with nodular cirrhosis (hernatoxylin and eosin)

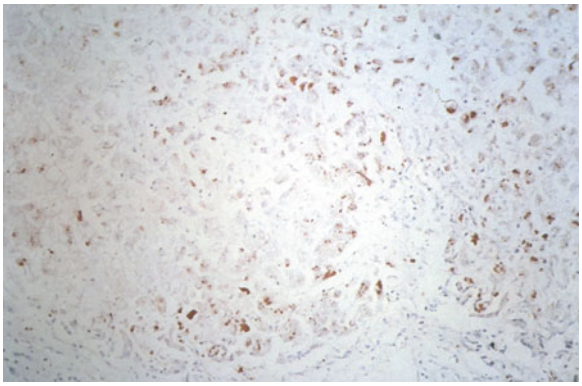

Figure 210.3
Percutaneous liver biopsy from a child with Wilson disease and advanced hepatic involvement. Note the extensive tissue copper deposition (rhodanine stain)

of presymptomatic patients. A probe from the linked retinoblastoma (RB) gene can be very helpful in problem cases. The quantitative determination of liver copper concentration remains the definitive diagnostic criterion.

Treatment

The availability of an effective treatment makes it important to diagnose WD before overt clinical manifestations appear. Early diagnosis and therapy could prevent irreversible tissue damage. Screening of sibs is vitally important. Untreated WD is invariably fatal.

D-*penicillamine*, a metabolite of penicillin, is currently the drug of choice. Penicillamine functions as a chelating agent with its free sulfhydryl group excreted in the urine intact. Penicillamine interferes with collagen cross-linking and acts also as an immunosuppressant.

Treatment with D-penicillamine is started with a dose of 15–20 mg/kg/day divided into four daily doses half an hour before meals and before retiring. If there is no response within 4–6 months, the dose should be increased up to 1.5 g/day. Only rarely is a higher dose than this required. Pyridoxine (5–10 mg/day) should also be given to compensate for the weak antipyridoxine effect of D-penicillamine. Liver functions slowly improve. The dose of penicillamine may be reduced once symptoms are controlled. A useful indicator of successful decoppering is the fall in the plasma nonceruloplasmin copper (the difference between the total serum copper and the ceruloplasmin copper) to virtually zero.

Approximately 30% of patients have some side effects to penicillamine therapy. It is not effective in patients with acute liver failure, which signifies once more the importance of early diagnosis and initiation of therapy before it is too late. It is important to recognize that though penicillamine remains the first line of therapy, neurologic status may worsen at the initiation of therapy.

Recognized side effects of penicillamine include bone marrow suppression, proteinuria, nephrotic syndrome, systemic lupus erythematosus, Goodpasture syndrome, aphthous ulceration, arthralgia, and loss of the sense of taste. In view of the relatively high frequency of side effects, white blood cells and platelet counts should be checked twice weekly for the first 6–8 weeks of treatment then at monthly intervals for the first 4 months.

Neurologic abnormalities may be reversible if therapy is commenced early. However, it has also been emphasized that neurologic disturbances may progress or even appear de novo during D-penicillamine therapy. If left untreated, WD progresses to hepatic failure or severe neurological disability and death. While those adequately treated are expected to have normal life span.

Treatment with penicillamine should continue during pregnancy. However, the teratogenic effects of the drug and its effect on the newborn need to be considered. The dose of penicillamine is best reduced to about 1 g daily during pregnancy.

Triethlyene tetramine hydrochloride (Trientine) is an effective alternative chelating agent introduced by Walshe as an alternative copper-chelating agent for WD patients with D-penicillamine-induced side effects such as neutropenia, thrombocytopenia, and nephrosis. Trientine is a less potent chelating agent than penicillamine. Copper is chelated by forming a stable complex with the four constituent nitrogens. Trientine increases urinary copper excretion and may interfere with intestinal absorption of copper. Trientine has one advantage over penicillamine in that treated patients are not at risk of rapid clinical deterioration on discontinuation of therapy. In contrast to penicillamine, trientine therapy results in an elevated serum free Cu concentration. Initially, 0.5 g of trientine should be given daily for children less than 10 years old and 1 g to older patients, taken in divided doses at least 1 h before or 2 h after meals. Dosage is increased only if the clinical response is inadequate after 6 months of treatment or if the concentration of free serum copper remains persistently above 20 μg/dL.

In a recent report by Dahlman et al., long-term treatment with trientine was evaluated in 19 patients with WD. The authors concluded that in spite of reported serious colitis in two patients and duodenitis in one patient, therapy with trientine remains a drug of first choice in parallel with penicillamine in patients with WD. Lupus nephritis has also been reported in patients receiving trientine therapy. Trientine chelates dietary iron and may result in iron deficiency. Recent study from King's college Hospital, London, has indicated that trientine is as efficacious as penicillamine with possibly lower side effect.

Zinc sulfate or acetate is also implicated in the medical management of WD. The postulated mechanism of zinc is that excess zinc induces metallothionein in enterocytes, which have greater affinity for copper than zinc. The average dose of zinc sulfate is about 150 mg orally three times daily. Once bound, the copper is not absorbed but is lost in the feces as enterocytes are shed in normal turnover. Recognized side effects of zinc therapy include gastritis and microcytic anemia by interference

with iron utilization. More patients, especially new cases, are currently placed on zinc therapy.

Reports have indicated that oral zinc used as the initial treatment for WD can control the illness effectively and prevents its progress, provided it is given early in the course of the disease. Recent reports have also indicated the efficacy and safety of zinc acetate for the prophylactic treatment of presymptomatic WD patients.

The treatment is nontoxic and does not carry the risk of worsening the neurologic manifestations recognized with D-penicillamine therapy. Zinc therapy is also recommended for WD mothers during pregnancy.

In view of the recognized deteriorating neurologic manifestations in some WD patients following the initiation of D-penicillamine therapy, Brewer et al. introduced a new drug, ammonium tetrathiomolybdate, which might save patients of that potential complication. *Tetrathiomolybdate* functions as an immediate blocker of copper absorption as well as forming complexes with copper in the blood, rendering the copper nontoxic. The authors concluded from their study on five WD patients with acute neurologic symptoms that ammonium tetrathiomolybdate is an effective therapy with a favorable outcome. The drug in bulk form stored under anaerobic conditions at room temperature is adequately stable. Other study has indicated that Tetrathiomolybdate is a better choice than trientine for patients with neurological WD. More studies are needed to confirm the superiority of tetrathiomolybdate over other available chelating agents.

It has been reported that histopathological correlations with treatment should better be made through liver biopsy with hepatic copper quantification every 3 years.

Symptomatic treatment may be required for ascites and edema. Spironolactone together with a potent loop diuretic may considerably improve the patient's well-being.

A low-copper diet is required, though the issue of compliance is often in question. The child is advised to stay away from food with a high copper content such as nuts, chocolates, mushrooms, liver, and fish.

Death may occur as a result of fulminant hepatitis or bleeding esophageal varices. Other recognized causes of death include central nervous system disease or as a sequela to other system involvement or to surgical intervention.

Recent Advances

In 1985, the WD gene was localized to chromosome 13, also the site for the retinoblastoma protein gene. In the meantime, the gene for Menkes disease was cloned. The gene for Menkes disease is technically named ATP7A but conventionally called MNK.

The identification of the WD gene on chromosome 13 constitutes a stimulating factor to the ongoing research on WD. In 1993, the gene was identified. The gene, technically called *ATP7B* but conventionally called *WND*, codes for an enzyme that is a P-type ATPase, which has six copper-binding sites and acts as a copper transporter.

Mutations may account for some of the varied clinical manifestations of WD.

The Long-Evans cinnamon (LEC) rat is a highly inbred strain of rat that develops hepatic disease similar to WD due to copper deposition in the liver. The LEC rat is recognized as the animal model in the research on WD, though it does not develop the neurologic abnormalities.

The gene (ATP7B) for WD is localized to chromosome 13 at location 13q14. The WD gene has 57% homology with the copper-binding domain or Menkes disease, whose gene is ATP7A. The encoded protein for transporting copper is P-type ATPase.

Mutation analysis is a future prospect for diagnosis, DNA linkage studies have been shown to aid in identifying affected sibs of index cases or for prenatal diagnosis. However, the increasing number of mutations raises some difficulty if there is not already a well-authenticated case in the family.

Haplotype analysis offers an alternative approach. It may enhance identification of currently unrecognized mutations in WD.

WD is recognized to pose a diagnostic challenge, especially when the important diagnostic criteria do not all support the diagnosis. With the identification of the gene locus of WD, DNA markers can be used to discriminate between presymptomatic patients and nonaffected individuals when biochemical results are equivocal.

Yuzbasiyan-Gurkan et al., in their study on the use of molecular genetics for screening siblings of affected patients for WD, have concluded that a probe from the linked retinoblastoma gene can be very helpful in problem cases.

Walshe and Yealland reviewed 189 patients with neurologic signs and symptoms referred to the WD clinic over 30 years. The review concluded that the referral diagnosis was correct in only 72% of cases.

It is hoped that with the available knowledge of WD genetic methods for diagnosis, an effective genetic treatment will be available in the near future.

Liver Transplantation

Liver transplantation is performed more often than previously on patients with progressive hepatic involvement and those with fulminant hepatitis. It is also performed in young cirrhotic patients with laboratory findings of severe hepatic compensation with lack of response after a few months of medical therapy. Liver transplantation is also indicated in progressive hepatic insufficiency and hemolysis, especially that following discontinuation of penicillamine.

Orthotopic liver transplantation is now accepted as the only effective treatment of WD presenting with fulminant hepatic failure and end-stage chronic liver disease that have not responded to medical therapy. Early referral of such patients for liver transplantation ensures a better outcome. However, based on recent reports, the need for liver transplantation in acute liver failure in WD should be evaluated carefully as the prognosis is not necessarily fatal. Some affected children have survived without having to have liver transplantation. The role of liver transplantation in the management of WD with neurologic manifestations in the absence of hepatic insufficiency remains rather uncertain. Some reports have indicated that neurologic and psychiatric symptoms due to WD have improved after liver transplantation.

Liver transplantation corrects completely the biochemical abnormality and reverses many of the clinical features of WD, although lifelong immunosuppression is required in most cases. After transplant, patients do not require penicillamine.

211 Noninvasive Diagnosis of Liver Fibrosis

Mortada El-Shabrawi · Fetouh Hassanin

Introduction

Hepatic fibrosis is an important consequence of inflammatory disorders affecting the liver, that might ultimately progresses to cirrhosis. Several methods for the detection and monitoring of hepatic fibrosis have been proposed, particularly in chronic hepatitis C virus (HCV) infection, alcoholic liver disease, nonalcoholic fatty liver disease (NAFLD) and during methotrexate therapy, in all of which progressive fibrosis can develop over a number of years in a minority of patients. Establishing the presence of fibrosis or cirrhosis in patients with chronic liver disease is important for assessment of prognosis and for evidence of progressive disease. Liver biopsy currently remains the gold standard to assess fibrosis. However, it has several limitations ranging from manpower issues and cost, to risk of patient injury, mortality and morbidity, as well as inter- and intra-observer variability and sampling variation. Liver biopsy is also a relatively costly and invasive procedure, associated with pain and discomfort, which render it not well accepted by patients, especially when it has to be occasionally repeated. Infrequent but serious complications such as profuse bleeding may occur. Even when an experienced physician performs liver biopsy and an expert pathologist reads and interprets the findings, up to a 20% error rate in disease staging has been reported. Regev and colleagues found a difference of at least one fibrosis stage between the right and left lobes in 33% of 124 patients, whereas Siddique and colleagues observed a difference of at least one fibrosis stage between two specimens of at least 15 mm taken at the same puncture site in 45% of patients. In addition, Colloredo and colleagues reported a tendency to underscore fibrosis as the size of the biopsy sample diminished. All the previous observations and findings prompted an active search over the past few years for a noninvasive method(s) to diagnose liver fibrosis that might supplement or probably replace liver biopsy.

Ideally, a noninvasive marker of liver fibrosis should be liver-specific, easy to perform, reliable, and inexpensive. It should be also accurate not only for the grading of fibrosis, but also for the monitoring of disease progression and the efficacy of therapy. Various direct and indirect serum biochemical markers as well as imaging modalities have been proposed as noninvasive diagnostic markers of liver fibrosis. To date, almost all the data regarding the use of noninvasive markers of fibrosis have originally been generated in patients with chronic HCV infection. Several markers of liver fibrosis have been proposed and actively investigated in immune-competent patients with chronic HCV infection. These data are being extended to other chronic liver diseases.

Serum Biochemical Markers

Direct markers of fibrosis refer to the measurement of specific substances involved in liver fibrosis generation and modeling. They are expensive and not easily available in all laboratories. Indirect markers have gained popularity as they could provide clinical useful information utilizing readily available clinical parameters. Several laboratory noninvasive liver fibrosis tests (NILFT) have been developed to assess liver fibrosis, including a combination of prothrombin time (PT), gamma glutamyl transpeptidase (GGT), apolipoprotein A1 (Apo-A1) and alpha-2 macroglobulin (α-2 M) levels called the PGA and PGAA index, serum hyaluronic acid (HA) levels, PT alone and the aspartate aminotransferase (ASAT) to platelet ratio index (APRI).

Aspartate Aminotransferase to Platelet Ratio Index (APRI) Test

APRI was the most promising of the NILFT that have been recently studied. It is a simple tool based on AST measurement and platelet count. Progression of liver fibrosis may reduce AST clearance, leading to increase in its serum levels; in addition, liver disease may be associated with mitochondrial injury, resulting in further AST release from the hepatocytes. The platelet count decreases, in inverse proportion to progressive liver fibrosis, due to worsening of portal hypertension with consequent increased platelet

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_211,

sequestration and destruction in an enlarging spleen. Interestingly, the diagnostic value of APRI was found to be influenced by sex; APRI was found much more sensitive in female (91%) than in male (60%) patients. A possible explanation relates to the correction, required by the formula by which APRI is calculated, for AST upper normal limit. Mean aminotransferase values are higher in men than in women, in relation to confounding factors such as body mass index (BMI), alcohol consumption, and lipid metabolism profiles. Accelerated liver fibrosis progression due to recurrent HCV is more frequently observed in female than in male liver transplant recipient. This finding is confirmed by some researchers who found that significant liver fibrosis (Ishak staging score >2) was observed more frequently among female recipients. This is another factor suggesting that the diagnostic value of APRI would be better in women, as where the prevalence of the condition to be identified is supposedly high, the positive predictive value of the test is increased. Among NILFT, APRI has the highest diagnostic value in discriminating liver transplanted patients with progression to significant liver fibrosis, although its accuracy is influenced by recipient sex. APRI was recommended by some researchers as the most accurate simple marker for predicting significant hepatic fibrosis in various etiologies of chronic liver diseases, especially in chronic hepatitis B, though APRI and the platelet count were also good indirect markers. Concerns were also raised regarding the impact of serum lipid abnormalities and modifications induced by cholesterol altering medications.

Patients with and without significant fibrosis could be excluded with negative and positive predictive values of 86% and 88%, respectively. This test is very simple, but is subject to issues related to the reproducibility of AST measurement and platelet count.

FibroTest (FT)

The limitations of single parameters to assess liver fibrosis have led to the development of algorithms or indices combining the results of panels of markers that substantially improve diagnostic accuracy. Imbert-Bismut and colleagues were the first to propose an index based on a mathematical formula combining five variables: total bilirubin, GGT, haptoglobin, α-2 M, and Apo-A1. The results of this test, known as the FibroTest (BioPredictive; Paris, France), are scored from 0 to 1. In the initial report, a score <0.1 allowed for the exclusion of significant fibrosis (METAVIR score F2 or greater), with a 100% negative predictive value, whereas a score >0.6 allowed for the diagnosis of significant fibrosis, with a 90% positive predictive value, using liver biopsy as the reference. Overall, liver biopsy could have been avoided in 46% of the patients on the basis of these study findings. FibroTest has been extensively evaluated by the developers and other groups. El-Shabrawi and his colleagues found a significant linear trend and correlation between FT-related fibrosis and fibrosis stage by METAVIR scoring on histopathological examination of biopsies from children with chronic HCV infection. The FT area under the receiver operating characteristic curve (AUROC) was found to be 0.97, which could diagnose patients with mild stage of fibrosis, thus discriminating them from those with no (or minimal) fibrosis. This test is now licensed in several European countries as well as in the United States. When using FT in clinical practice, the interpretation of the findings should take into account each of the five components individually so as to avoid false-positive results related to hemolysis (decrease in haptoglobin), Gilbert syndrome (increase in bilirubin), or false-negative results related to inflammation (increase in haptoglobin or in α-2 M levels).

Forns' Index

Forns and colleagues reported a fibrosis index based on age, platelet count, GGT, and cholesterol levels. The lower cut-off value (4.2) had a 96% negative predictive value for excluding significant fibrosis, whereas the upper cut-off value (6.9) had a 66% positive predictive value for diagnosing significant fibrosis. This test was shown to be useful in excluding patients with minimal fibrosis, but was of limited utility in identifying patients with more advanced fibrosis.

Other Biochemical Markers

Several other indices have been developed including FibroSpect (Prometheus Laboratories Inc.; San Diego, California), the Sud score, Leroy's score, and the European Liver Fibrosis (ELF) Study score.

Although the diagnostic performance of these indices is generally good, with areas under the ROC curves ranging from 0.77 to 0.88, more than half of patients are not appropriately classified relative to findings on liver biopsy. Another limitation of these markers is that none is liver-specific and they may be influenced by changes in their clearance and excretion. Additionally, in clinical practice, the reproducibility in the measurement of some parameters, such as AST levels or platelet count, is questionable.

Imaging Modalities

Two noninvasive imaging techniques to assess hepatic fibrosis have been studied. The first is ultrasound elastography and the second is magnetic resonance elastography (MRE), both rely on assessment of the effect of liver stiffness (fibrosis) on the velocity of transmission of a shear wave through the parenchyma of the liver to determine hepatic stiffness. Both techniques are similar in assessment of fibrosis, although it has been suggested that MRE may have less variability with repetitive imaging than ultrasound. Acquisition time is similar for both techniques.

Ultrasound Elastography

Ultrasound elastography, commercially known as the FibroScan®, uses a modified ultrasound probe to measure the velocity of a shear wave created by a vibratory source. Estimates of stiffness of the liver by ultrasound correlate with fibrosis stage. Ultrasound elastography can be performed in approximately 95% of patients, although older patients and patients who are obese can be more difficult to study. With ultrasound elastography, a transducer probe is mounted on the axis of a vibrator. Vibrations of mild amplitude and low frequency are transmitted inducing an elastic shear wave that propagates through the underlying tissues. Pulse-echo ultrasound acquisitions are then used to follow the propagation of the shear wave and measure its velocity, which is directly related to tissue stiffness (the elastic modulus): the stiffer the tissue, the faster the shear wave propagates. Transient elastography measures liver stiffness in a volume that approximates a cylinder 1 centimeter (cm) wide and 4 cm long, with a measurement depth between 25 millimeter (mm) and 65 mm below the skin surface. This volume is at least 100 times larger than a biopsy sample and is therefore far more representative of the hepatic parenchyma. Transient elastography is painless, rapid (takes less than 5 min), and easy to perform at the bedside or in the outpatient clinic. The results are immediately available and independent from the operator. Transient elastography has been shown to be reliable in the assessment of liver fibrosis in patients with chronic HCV infection. Transient elastography has its own limitations. Measurement of liver stiffness can be difficult in obese patients and impossible in patients who have ascites. Ultrasound elastography does not distinguish patients with no fibrosis from patients with minimal fibrosis. Ascites can interfere with the generation of a shear wave through the liver.

Ultrasound elastography is strongly correlated with advanced fibrosis in patients with chronic hepatitis, and values above 12.5 kilo Pascal (kPa) are indicative of cirrhosis. This technique works best for separating patients with minimal or no fibrosis from those with significant fibrosis. A linear correlation with increasing fibrosis has not been demonstrated, and 15% discordance between elastography scores and histologic fibrosis has been observed. Advanced fibrosis may be underestimated and patients with macronodular cirrhosis may be classified as noncirrhotic. Fibrosis may be overestimated in patients with extrahepatic cholestasis or acute hepatocellular injury due to the effects of these conditions on liver stiffness.

The use of the ultrasound elastography for the noninvasive diagnosis of liver fibrosis has been widely validated in patients with HCV infection, with a significant correlation between liver stiffness and grades of portal and periportal fibrosis, fibrosis area, chronic HBV infection, HIV–HCV coinfection, cholestatic intrahepatic diseases, and the diagnosis of cirrhosis. Foucher and colleagues assessed the accuracy of FibroScan® for the detection of cirrhosis in 711 patients with chronic liver disease. Liver stiffness was significantly correlated with clinical, biological, and morphological parameters of liver disease and came to the conclusion that FibroScan® is a promising noninvasive method for detection of cirrhosis in patients with chronic liver disease. They noted that its use for the follow-up and management of these patients could be of great interest and should be further evaluated.

Corpechot and associates assessed the diagnostic performance of liver stiffness measurement for the determination of fibrosis stage in chronic cholestatic diseases. The authors concluded that FibroScan® is a promising tool to assess antifibrotic therapies in primary biliary cirrhosis (PBC) or primary sclerosing cholangitis (PSC). The Canadian Agency for Drugs and Technologies in Health (CADTH) performed an evaluation on FibroScan® for noninvasive assessment of liver fibrosis. It stated that the diagnostic performance of FibroScan® is good for identifying severe fibrosis or cirrhosis, but it is less accurate for milder presentations. CADTH concluded that additional studies are necessary to evaluate the comparative cost-effectiveness of different methods of assessing liver fibrosis. de Franchis et al., stated that transient elastography (Fibroscan) reproducibility needs to be further validated. Furthermore, Berrutti et al. suggested that the exact role of FibroScan® needs to be defined. de Lédinghen et al., assessed the feasibility of liver stiffness measurement and compared FibroScan®, FibroTest, and APRI with liver biopsy for the diagnosis of cirrhosis in children with chronic liver diseases. They stated that a specific probe dedicated

to children and slender patients has thus been developed and is currently under evaluation. Therefore, a FibroScan® equipped with this specific probe could become a useful tool for the management of chronic liver diseases in children. Shaheen et al., stated that in adults FibroTest and FibroScan® have excellent utility for the identification of HCV-related fibrosis/cirrhosis, but lesser accuracy for earlier stages. They noted that refinements are necessary before these tests can replace liver biopsy. Sagir et al. noted that inspite that FibroScan® frequently yields pathologically high values in patients with acute liver damage and is unsuitable for detecting cirrhosis/fibrosis in these patients. Han and Yoon noted that based on accumulating clinical data, clinical applications of elastography will increase in the near future. Sporea and colleagues stated that despite the fact that FibroScan® is not a perfect test, in a few years, most authorities in the field will consider it to be useful and necessary for the evaluation of chronic hepatopathies. Castera and associates stated that combining transient elastography with serum markers increases diagnostic accuracy and as a result, liver biopsy could be avoided for initial assessment in most patients with chronic hepatitis C. They strongly recommended constucting guidelines for the use of elastography in clinical practice. In a meta-analysis, Friedrich-Rust et al. concluded that transient elastography can be performed with excellent diagnostic accuracy and independent of the underlying liver disease for the diagnosis of cirrhosis. However, for the diagnosis of significant fibrosis, a high variation was found dependent on the underlying liver disease. Abenavoli et al. noted that currently most of the studies that were done for evaluating the effectiveness of transient elastography are used for patients infected with HCV. They suggested that its application must also be studied in the monitoring of patients suffering from other chronic liver diseases with possible fibrosis.

Magnetic Resonance Elastography (MRE)

Magnetic resonance plays an increasingly important role in assessment of patients with chronic liver disease because of the lack of ionizing radiation and the possibility of performing multiparametric imaging. Many researchers are prefering and encouraging the use of MRE as it can enable a safe, prompt, and accurate diagnosis of liver fibrosis and help the physician proceed with the most appropriate treatment plans. MRE may soon be established as the only technique able to stage fibrosis or diagnose mild disease.

212 Cirrhosis and Ascites

Jumana Shammout · Hisham M. Nazer

Cirrhosis

The World Health Organization defined cirrhosis as a diffuse liver process characterized by fibrosis and the conversion of normal liver architecture into structurally abnormal nodules. Cirrhosis is a recognized end-stage irreversible pathologic condition of chronic liver disease. The hepatocytes show considerable pleomorphism, with some cells appearing normal while others grossly abnormal.

Clinically, some affected patients with cirrhosis may remain asymptomatic for years (compensated cirrhosis), while others present with features of hepatocellular failure (decompensated cirrhosis). The normal anatomic relationship of the portal tract and hepatic veins is completely disrupted. Moreover, the normal flow pattern of blood from the portal tracts via the sinusoids to the central veins is impeded. In view of the presence of irreversible distortion of intrahepatic vascular and biliary structures, further liver cell damage and lobular collapse develop. There are many classifications for cirrhosis depending on the etiology, pathogenesis, clinical status, stage of development, and amount of hepatocellular necrosis. Some affected patients continue to have reasonably normal biochemical data (inactive cirrhosis), while others are seen with abnormal biochemical laboratory data (active cirrhosis).

Pathologically, cirrhosis is classified into micronodular cirrhosis with small nodules surrounded by bands of fibrous tissue (*Fig. 212.1*) as in extrahepatic biliary atresia, and macronodular cirrhosis with larger nodules and broader fibrous septa as in Wilson disease, or mixed with features of both micronodular and macronodular cirrhosis (incomplete septal cirrhosis). The histologic hallmarks of cirrhosis are increased liver fibrosis, collapse of normal lobular architecture, and the formation of regenerative nodules. Some children with chronic bile duct obstruction progress to develop fibrosis within the portal tracts extending into the parenchyma (biliary cirrhosis).

Postnecrotic cirrhosis due to chronic or recurrent cell destruction is characterized by piecemeal necrosis, bridging fibrosis, and regenerative nodules. This may be seen as a sequela to neonatal hepatitis or chronic active hepatitis.

Pathogenesis

Various hypotheses have been put forward to explain why livers of affected patients respond to varied forms of insults with the development of hepatocellular injuries, regenerative nodules, and prominent fibrous tissue formation. An important factor in the pathogenesis is the abnormal accumulation of extracellular matrix components, collagens, Iaminin, and fibronectins.

Hepatocyte injury causes cell death (necrosis), followed by scar formation (fibrosis), and in some cases, nodule formation (cellular regeneration). The reduction in the amount of viable hepatic tissue leads to compensatory growth and regenerative nodule formation as the cells replicate within a restrictive connective tissue framework. The hepatic nodules compress the hepatic arterial and venous blood flow further impeding the hepatic blood flow. The cycle of necrosis, fibrosis, and nodule formation results in cirrhosis.

Hepatocellular injury can result from various insults, including infections, hepatotoxic compounds, immune-mediated cytotoxicity, ischemia, and biliary obstruction.

The extracellular matrix is vital to the survival and proper function of hepatocytes. In cirrhosis, the extracellular matrix is altered qualitatively and quantitatively. Biochemical assays for enzymes and metabolites associated with fibrogenesis have been developed. Factors controlling connective tissue synthesis and degradation remain poorly understood. Pericellular fibrosis may also interfere with the nutrition of the hepatocytes. Lymphocytes activated either as an integral part of the liver-damaging process or activated in response to liver injury produce lymphokines, which induce fibroblast migration and proliferation. The factors that control hepatic regeneration are also poorly understood.

Many hormones are known to influence the process of hepatic regeneration including insulin, glucagon, adrenocorticotropic hormone, vasopressin, estrogen, and growth hormone. Hepatocyte growth factors and fibroblast growth factors are also involved in hepatic embryogenesis and regeneration. Interleukin-6 also plays a role in hepatocyte proliferation.

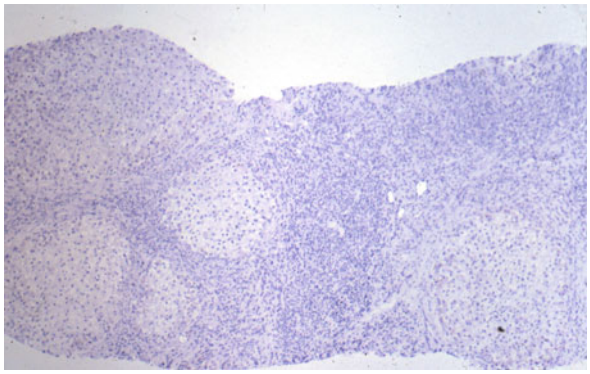

Figure 212.1
Percutaneous liver biopsy. Microscopic findings of nodular cirrhosis with marked fibrosis and distortion of the hepatic architecture

Etiology

Cirrhosis in children may result from metabolic disorders, infectious diseases, inflammatory diseases, biliary abnormalities, toxins, and vascular diseases (*Table 212.1*).

Clinical Features

Cirrhosis in children is often compensated, presenting as asymptomatic hepatosplenomegaly, splenomegaly, or any other stigmata of chronic liver disease. Cirrhosis may be discovered incidentally by abnormal laboratory tests. Alternatively, patients may present with decompensated cirrhosis; with signs related to decreased hepatic synthetic function (e.g., coagulopathy, fat-soluble vitamin deficiency), or decreased detoxification abilities of the liver (e.g., hepatic encephalopathy), or portal hypertension (e.g., variceal bleeding, hypersplenism, ascites).

Moreover, patients with cirrhosis usually present with features of the primary disease, chronic hepatocellular failure, together with those of subsequent complications such as portal hypertension. There is also evidence of malabsorption, failure to thrive, and malnutrition.

Some patients may complain of abdominal pain, which may be due to peptic ulcer disease, gastritis, gallstones, or gastroesophageal reflux. Patients may also present with evidence of florid rickets (*Fig. 212.2*) or

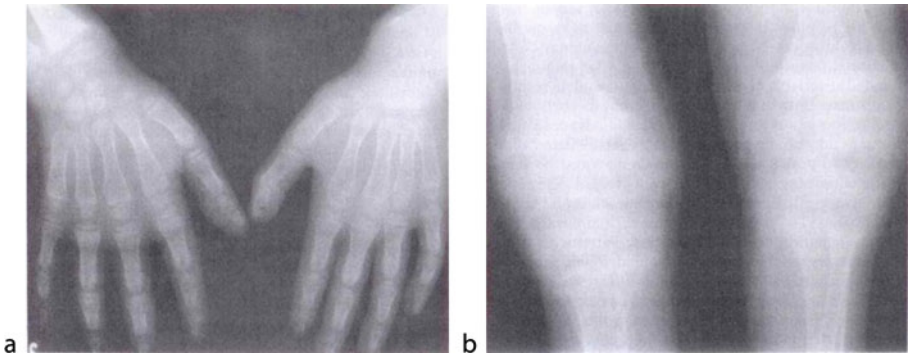

Figure 212.2
Plain radiograph in a child with cirrhosis showing features of florid rickets with poor mineralization of the bones and widening and fraying of the metaphysis of both wrists (a) and knee joints (b)

Figure 212.3
A young infant with cirrhosis and deformed right thigh as a result of pathologic fracture of the right femur secondary to florid rickets

even an associated pathologic fracture (*Fig. 212.3*). This is important to note at the time of examination and initial evaluation and to inform the parents of its presence.

Other recognized features include jaundice, spider hemangiomata, palmar erythema, and clubbing of fingers and toes.

In advanced liver disease, there are features of hyperdynamic circulation with increased cardiac output and decreased vascular resistance.

Hypoxemia, largely due to intrapulmonary shunting, is a relatively common complication of cirrhosis. Later on, peripheral edema, ascites, and hepatoencephalopathy develop. Spontaneous bruising, epistaxis, and septicemia are often indicative of serious outcome and grave prognosis.

Physical Examination: physical examination in patients with cirrhosis may reveal the following:

Jaundice, a yellow discoloration of the skin and mucus membranes secondary to increased serum bilirubin. Jaundice is usually not clinically detectable until the bilirubin is greater than 2–3 mg/dL.

Pruritus is intense generalized itching, possibly related to endogenous opioids, may be the sole presenting symptom of cirrhosis. The degree of pruritus is not directly related to the degree of hyperbilirubinemia.

Xanthomas are deposits of lipids in the dermis and subcutaneous tissue as a result of marked elevation of serum cholesterol due to chronic cholestasis. They are usually located over the extensor surfaces of the extremities.

Spider angiomata (also known as spider telangiectasias) are vascular lesions consisting of a central pulsating arteriole from which many smaller vessels radiate. Spider angiomata are most commonly located on the trunk, face, and upper limbs, and are believed to result from

alterations in sex hormone metabolism associated with an increase in the estradiol/free testosterone ratio.

Spider angiomata are not specific for cirrhosis and may be seen in otherwise healthy individuals as well as during pregnancy and in patients with severe malnutrition. The number and size of spider angiomata correlate with the severity of liver disease. Patients with numerous and large spider angiomata may be at increased risk for variceal hemorrhage.

Palmar erythema, most noticeable on the thenar and hypothenar eminences and on the tips of the fingers, is also believed to be caused by altered sex hormone metabolism and vasodilation with increased blood flow. Palmar erythema however is not specific for cirrhosis and can be seen in association with pregnancy, rheumatoid arthritis, hyperthyroidism, and hematological malignancies.

Nail changes, paired horizontal white bands separated by normal color nail plate (Muehrcke's nails), or whitish discoloration of the proximal two-thirds of the nail plate with the distal one-third being red (Terry's nails) can be seen in patients with cirrhosis. The exact pathogenesis for these nail changes is unknown but believed to be caused by hypoalbuminemia. Clubbing and hypertrophic osteoarthropathy may also be seen in patients with cirrhosis though none of these nail features is specific for liver disease.

Gynecomastia is a benign proliferation of the glandular tissue of the male breast possibly caused by enhanced aromatization of androstenedione to estrone, and increased conversion of estrone to estradiol. Gynecomastia can be seen in a variety of conditions other than cirrhosis.

Caput medusae is the term used to describe the prominent abdominal wall veins that occur secondary to shunting of the blood from the portal venous system into the umbilical vein and ultimately to the abdominal wall veins. A venous hum may be auscultated. Dilated abdominal veins can also be seen in other diseases (e.g., inferior vena cava syndrome, superior vena cava syndrome).

Ascites is the pathologic accumulation of fluid in the peritoneal cavity, and in cirrhosis ascites is a sign of decompensated hepatic cirrhosis. (Further details on ascites will be presented later in this chapter).

Hepatomegaly may be detected on physical examination by assessing the hepatic span. The cirrhotic liver may be enlarged with a firm nodular consistency, or normal sized, or it may be small and shrunken.

Splenomegaly is common and is believed to be caused by congestion of the red pulp as a result of portal hypertension. However, splenic size does not correlate well with portal pressures, suggesting that other factors may be involved.

Fetor hepaticus is a sweet, pungent smell to the breath, caused by increased concentrations of dimethylsulfide that occur in cirrhosis secondary to severe portal-systemic shunting.

Encephalopathy, secondary to accumulation of ammonia, aromatic amino acids, gamma aminobutyric acid, and other substances that are normally removed by the hepatic cells, may occur with the loss of functioning liver parenchyma. Patients may present with altered mental status, neuromuscular dysfunction, or change in the level of consciousness.

Asterixis is bilateral, asynchronous flapping of outstretched, dorsiflexed hands, and can be seen in patients with hepatic encephalopathy. Astrexis is potentially reversible, and may also be seen in patients with uremia and severe heart failure.

Variceal bleeding, portal hypertension results in portosystemic blood shunting, leading to the formation of esophageal, gastric, and rectal varices. Those varices can rupture causing profuse gastrointestinal bleeding.

Hepatorenal syndrome refers to the development of renal failure in a patient who has advanced liver disease. The pathophysiology is poorly defined and may be related to reduced renal blood flow and altered hormonal metabolism. The urinary sodium concentration is low, and the sedimentation is normal. Serum creatinine is increased. The diagnosis is achieved after excluding other causes of renal failure. Kidney function usually improves after liver transplantation.

Hepatopulmonary syndrome patients develop intrapulmonary arteriovenous shunts with resultant hypoxemia and cyanosis. The diagnosis is established by ruling out an underlying cardiac defect.

Diagnosis

Diagnosis may be easy if the liver is enlarged, hard, and irregular. Laboratory investigations indicate varying degrees of hepatic dysfunction. Protein electrophoresis may reveal hypoalbuminemia with normal or increased gammaglobulins. Serum complement component C3 may be decreased, while serum alkaline phosphatase is often elevated. The prothrombin time is frequently prolonged. Serum transaminases may be normal or increased.

Aminotransferase: The intracellular hepatic transaminases, aspartate aminotransferase (AST), and alanine

aminotransferase (ALT) are sensitive indicators of hepatocellular injury. AST elevation is not specific for liver disease. ALT, however, is more specific.

Markedly elevated aminotransferase levels occur with acute hepatocellular injury, such as acute viral hepatitis, hypoxia, or toxic injury. In chronic liver disease, the levels are usually mildly to moderately elevated. Normal aminotransferase levels do not rule out cirrhosis.

Alkaline phosphatase (ALP): ALP is often elevated.

Gamma-glutamyl transpeptidase (GGT): GGT levels often correlate with the level of alkaline phosphatase.

Bilirubin: Bilirubin level may be normal in compensated cirrhosis, but rise as the cirrhosis progresses.

Albumin: Albumin is synthesized exclusively in the liver, and its level falls with the loss of hepatic parenchyma. Thus, serum albumin can be used to assess the liver synthetic ability and grade the severity of cirrhosis. Hypoalbuminemia is not specific to liver disease and may be seen in nephrotic syndrome, protein-losing enteropathy, and malnutrition.

Prothrombin time (PT): Loss of the hepatic parenchyma in cirrhosis causes decline in the liver's synthetic ability and may result in deficiency of the clotting factors that are synthesized by the liver (all coagulation factors except factor VIII). This results in prolongation of PT.

The liver also synthesizes inhibitors of coagulation including protein C and S, plasminogen, and antithrombin III.

Hematologic abnormalities include thrombocytopenia, which results from platelets sequestration in the enlarged spleen. Anemia may result from gastrointestinal blood loss, hypersplenism, bone marrow suppression or inflammation (anemia of chronic disease). Leukopenia and neutropenia may occur secondary to hypersplenism with splenic margination.

Testing for specific diseases guided by the available information from the history, physical examination, laboratory and radiologic tests, should be performed (◉ *Table 212.2*).

Table 212.2
Investigation of chronic liver disease in children

General	Specific
Bilirubin	*Infections*
AST, ALT	HBV: HBsAg, HBeAg, HBe antibody, HBV DNA
ALP, GGT	
Albumin	HCV: HCV Ab, HCV RNA
Prothrombin time (PT)	CMV: CMV serology, urine for CMV antigen
Cholesterol	
Complete blood count	EBV: EBV serology, heterophile
Urea and creatinine	Wilson's disease: serum copper, serum ceruloplasmin, 24-h urine collection for copper, slit-lamp examination, liver copper concentration
Ammonia	
Alpha-fetoprotein	
Chest X-ray	Autoimmune chronic active hepatitis: ESR, ANA, anti-smooth muscle antibody, antimitochondrial antibody, anti-liver-kidney microsomal antibody
Hepatobiliary and renal ultrasound	Glycogen storage disease: lactic acid, fasting blood sugar, uric acid, liver and muscle tissue enzyme level
Electrocardiogram	Galactosemia: urinary non-glucose reducing sugar, red blood cell galactose-1-phosphate uridyl transferase level
Electroencephalogram	Tyrosinemia: serum amino acid levels, urine organic acids
Upper endoscopy	Alpha-1 antitrypsin deficiency: serum alpha 1-antitrypsin level, Pi type
Liver biopsy	Hemochromatosis: serum iron, TIBC, ferritin
	Cystic fibrosis: sweat chloride test, genotype analysis
	Toxic ingestion: toxic screen, serum acetaminophen level

Radiographic Findings

Although radiographic findings can occasionally suggest the presence of cirrhosis, they are not adequately sensitive or specific for use as a primary diagnostic modality. The major utility of radiography is in the evaluation of the presence of complications in cirrhotic patients.

Ultrasonography: An abdominal ultrasound can reveal the presence of ascites, splenomegaly, portal vein thrombosis, or cystic malformations, and should be routinely obtained. An increased diameter of the portal vein and the presence of collateral veins suggest portal hypertension.

Ultrasonography may also be used as a screening test for hepatocellular carcinoma.

A barium meal may show esophageal varices (◉ *Fig. 212.4*) and peptic ulceration. Flexible fiberoptic endoscopy is performed to confirm varices, assess its severity, and identify the site of bleeding.

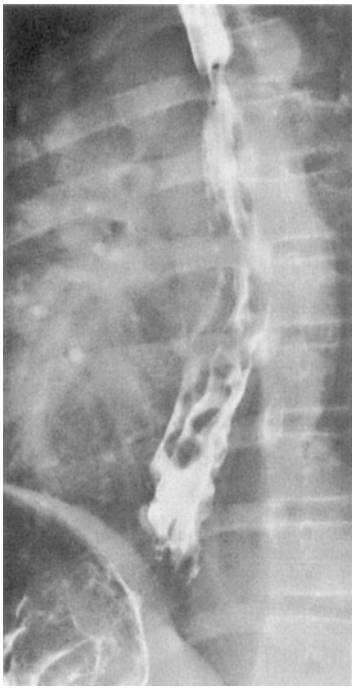

Figure 212.4
Barium study (esophagogram) showing longitudinal mucosal defects in the distal half of the esophagus: Esophageal Varices

CT scanning provides similar information to ultrasonography, and is not routinely used in the diagnosis and evaluation of cirrhosis.

Magnetic resonance imaging provides similar information to ultrasonography, and is not routinely used in the diagnosis and evaluation of cirrhosis.

MRI may reveal iron overload and provide an estimate of the hepatic iron concentration in patients with hemochromatosis.

MR angiography can be used to diagnose portal vein thrombosis and is more sensitive than ultrasonography.

Biliary scintiscan may be obtained in infants suspected of biliary atresia.

Liver Biopsy

The gold standard for diagnosis of cirrhosis is by histological examination of the hepatic tissue. A liver biopsy can be obtained either by a percutaneous, transjugular, laparoscopic, or radiographically guided fine-needle approach. The severity and sometimes the etiology of cirrhosis can be suggested by the histological examination of a liver biopsy (e.g., hemochromatosis, Wilson's disease, and alpha-1 antitrypsin deficiency).

Management

Management of cirrhotic patients is very much oriented toward prevention and treatment of life-threatening complications such as portal hypertension, gastrointestinal hemorrhage, hypersplenism, and hepatic encephalopathy. Increased awareness of the possible etiologic factors and initiation of appropriate therapy in the course of the disease influence the outcome of management of relevant conditions associated with cirrhosis. Careful monitoring of the hepatic status with periodic physical examinations and liver function tests are essential steps in the management.

Special emphasis should also be put on the dietary regimen of the patients to ensure adequate nutrition and optimal growth. The caloric intake may be increased with the supplement of glucose polymers and medium-chain triglycerides.

Caloric supplementation to achieve 120–130% RDI should be instituted, providing 3–4 g/kg/day of protein. This can be achieved by nocturnal enteral nutrition.

Parenteral vitamin K (2.5–5 mg/day) should be given to any patient with prolonged PT. Fresh frozen plasma infusions and cryoglobulin and/or platelet transfusions should be reserved for bleeding episodes and for patients undergoing invasive procedures such as liver biopsy.

Vitamin D (50 ng/kg), vitamin E (50–400 IU/day), and vitamin A (5,000–10,000 IU/day) should be supplemented.

Zinc deficiency commonly occurs in patients with cirrhosis, and zinc supplementation may stimulate appetite. Zinc is also effective in treating muscle cramps and may be used as an adjunctive therapy for hepatic encephalopathy.

Patients with cirrhosis, especially those with biliary cirrhosis, may also suffer from intractable pruritus that fails to respond to various medical therapeutic modalities. Cholestyramine, phenobarbitone, and/or rifampicin have been tried in this regard with variable degrees of response. Cholestyramine in a dose of 4 g given with meals two to three times daily is recommended for children with cirrhosis not only to relieve pruritus but also to improve liver function in patients with postnecrotic cirrhosis.

Spontaneous bacterial peritonitis is best treated as dictated by bacteriology. Early institution of therapy with a third-generation cephalosporin (such as cefotaxime

or ceftriaxone) is recommended. Prophylactic treatment for recurrent cases can be achieved by oral cotrimoxazole, ciprofloxacin, or norfloxicin.

Hepatic encephalopathy can be managed by avoiding triggering factors like fasting, sedatives, and by reducing the intestinal nitrogen load.

Since protein restriction in children may result in growth failure, dietary and/or intravenous protein restriction to 1–2 g/kg should be used only in acute or very symptomatic patients. The protein should be reintroduced as the encephalopathy subsides.

Administration of neomycin with or without lactulose can reduce intestinal bacterial flora, thus reducing the amount of bacterial urease and ammonia formation. Lactulose, an unabsorbable sugar, is metabolized by colonic bacteria producing lactic acid, which results in a drop in pH in the colon and a reduction in ammonia reabsorption.

In cases where an acute encephalopathy is precipitated by gastrointestinal bleeding, a reduction in the intestinal protein load can be achieved by enemas.

Monitoring Patients with Cirrhosis

Routine monitoring with complete blood count, renal and liver chemistries, and prothrombin time should be performed (e.g., q3–4 months in stable patients).

Diagnostic endoscopy to determine if the patient has asymptomatic esophageal varices may be done. Patients with varices may be started on a nonselective beta-blocker (e.g., propranolol, nadolol), titrating the dose to achieve a 25% reduction in heart rate.

Patients should be monitored for the development of hepatocellular carcinoma by abdominal sonography and alpha-fetoprotein testing every 1–2 years.

Ascites

Ascites is an accumulation of fluid, usually serous, in the peritoneal cavity. The causes of ascites are not limited to gastrointestinal conditions, but may occur in diseases affecting other systems such as the renal and the cardiac systems. Other recognized causes of ascites include peritonitis, especially tuberculous peritonitis, rheumatic peritonitis, and tumors. The emphasis in this chapter is on ascites that develop as a result of gastrointestinal and hepatic disorders. Progressive liver diseases leading to cirrhosis and portal hypertension are usually associated with ascites.

Pathogenesis

The exact mechanism leading to ascites in liver disease is not fully understood. Certain recognized factors and pathogeneses could well contribute to the formation of ascites in gastrointestinal and hepatic disorders. The accumulation of ascites represents a breakdown of intravascular volume homeostasis. It has been recognized that the renin-aldosterone-angiotensin system, sympathetic nervous system activity, and arginine vasopressin release are the main regulators of the plasma volume.

Hypoalbuminemia

This is a well-recognized condition associated with ascites. Hypoalbuminemia can occur in gastrointestinal and hepatic disorders, as well as in renal and cardiac diseases. Fluid is accumulated in the peritoneal cavity due to reduced oncotic pressure of the plasma. Albumin may be lost through the gut due to any of the recognized conditions associated with protein-losing enteropathy or in urine as in nephrotic syndrome. In the developing countries, dietary causes associated with protein caloric malnutrition, such as in kwashiorkor, should also be considered. With the progress of liver disease, there will be reduction in albumin synthesis, which results in reduction of the intracapillary oncotic pressure with extravasations of fluid into the peritoneal cavity resulting in ascites formation.

Disturbances in Water and Electrolytes Distribution

Chronic liver disease is a recognized cause of increased production of aldosterone plasma renin, as well as antidiuretic hormone, resulting in further sodium and water retention. Capillary hydrostatic pressure and plasma colloid osmotic pressure are involved in controlling fluid movement between blood and tissue.

Increased hydrostatic pressure in hepatic sinusoids such as in hepatic vein obstruction (Budd–Chiari syndrome) results in severe ascites with respiratory distress. This mechanism in the formation of ascites constitutes the basis of the *underfilling hypothesis* in which increased sinusoidal pressure is claimed to contribute to fluid retention and ascites formation.

The underfilling hypothesis suggests that ascites due to portal hypertension and inappropriate sequestration of

fluid within the splanchnic vascular bed results in a decrease in effective circulating blood volume and renal perfusion, which in turn causes increase in plasma rennin and aldosterone, resulting in sodium and water retention. This hypothesis could not explain all points regarding the pathogenesis of ascites.

The overfill hypothesis suggests that the primary abnormality is inappropriate renal retention of sodium and water in the absence of volume depletion, leading to increased blood volume. The increased blood volume in combination with portal hypertension results in ascites. This theory was developed in accordance with the observation that patients with cirrhosis have an intravascular hypervolemia rather than hypovolemia.

The peripheral arterial vasodilation hypothesis is the most widely accepted theory of ascites formation, and suggests that portal hypertension leads to increased production of vasodilators, mainly nitric oxide, leading to arterial vasodilation, which causes decreased effective blood volume. As the disease progresses, activation of vasoconstrictor and antinaturetic factors occurs, resulting in sodium and water retention.

Spontaneous bacterial peritonitis is a potentially fatal complication of ascites in children. It should be suspected in patients with ascites, fever, abdominal pain, or neutrophilia. Occasionally, patients present only with fever. The diagnosis is achieved by abdominal paracentesis, which is characterized by a cloudy fluid with a neutrophil count of >250/mm, and a protein concentration <20 g/l. Spontaneous bacterial peritonitis is usually caused by a single species, often enteric bacteria such as *Klebsiella* spp., *E. coli*, or enterococcus. Infection with *streptoccocus pneumoniae* may also occur.

Clinical Features

The child with ascites due to gastrointestinal or hepatic disorders should be evaluated at the time of examination together with the other associated manifestations secondary to the underlying disease. The onset of ascites may be slow and insidious, or sudden with rapid increase in abdominal girth such as in cases of hemorrhage, sepsis, or acute portal vein thrombosis.

The clinical features of ascites do not differ greatly from those due to other recognized causes such as in cardiac and renal disorders. Inappropriate weight gain may be the first clinical feature of ascites formation. The abdomen is distended at variable degrees, which might result in respiratory distress. Intra-abdominal organs may be ballotable, as ascites formation continues, although in advanced cases the organs may not be palpable at all. Visible dilated veins secondary to portosystemic collaterals may also be seen. The umbilicus may be flattened or even everted. The abdomen may appear shiny with severe distention and sometimes associated with umbilical, inguinal, or femoral hernia (Fig. 212.5).

Palpation, which may be associated with some discomfort, reveals fluctuation of the fluid. Percussion over the umbilical area may be resonant, but increased tone of dullness will be noted as the percussion proceeds toward the flanks. Shifting dullness is detected with changing the position of the patient. When the fluid collection in the peritoneal cavity is massive, the examiner is able to detect transmitting thrill by placing an assistant hand firmly over the midline and tapping on one side with one hand with the other hand receiving the impulse on the other side.
